This is continued for 6 months. If the skin smear is positive at any site, the patient is given MB-MDT. If a RR develops after completion of chemotherapy, then MDT should be recommenced while on prednisone.[23]

In some countries patients with solitary leprosy skin lesions are common. A large field study in India established that the combination of rifampin (600mg), ofloxacin (400mg) and minocycline (100mg) was almost as effective as PB-MDT in the treatment of patients with single smear-negative skin lesions and no nerve involvement, although the follow-up period was only for 18 months.[26] This regimen is helpful for treating carefully selected patients in endemic countries with a high proportion of single lesion cases, but should be reserved for this setting.

Treatment for reactions

Patients who have RRs, including silent nerve function impairment, require high-dose corticosteroids for a prolonged duration to permit nerve function recovery.[16] Prednisone is started at 40mg/day and increased to 60mg/day if there is no response, and then to 120mg/day if necessary. Once there is evidence of improvement on serial voluntary muscle and sensory testing, the dose is reduced over 6 weeks to 20mg/day and this is continued for some months before gradual removal. Therapy is usually required for 4–6 months, but often for longer durations in MB leprosy.[23] It is important to maintain treatment with antimycobacterial drugs to reduce the bacillary load. Adequate analgesia is essential along with physical support during the period of active neuritis. This therapy can be successfully administered without admission if other infections and medical problems are excluded. The expected recovery rate for nerve function is 60–70%,[16] but may be up to 88% in patients with no nerve damage at diagnosis who develop acute neuropathy during MDT.[27] Recovery is less in those with pre-existing nerve function impairment or with chronic or recurrent reactions.

Mild ENL responds to aspirin or nonsteroidal anti-inflammatory drugs, increased clofazimine dosage and rest. Moderate or severe episodes and those with neuritis require prednisone, usually starting at 40–60mg/day.[16] The response is rapid, but as ENL is liable to become corticosteroid dependent the prednisone should be withdrawn over 2–3 months. Clofazimine at a higher daily dose of 300mg suppresses ENL after 4–6 weeks and can be used to prevent further episodes.

If the ENL is poorly controlled or recurs, it usually responds to thalidomide, 400mg/day for 2–3 weeks, and then 100–200mg/day as maintenance. [16] Thalidomide inhibits the release of tumor necrosis factor from macrophages and results in prompt relief. Its use, however, is severely limited by its teratogenicity and should be restricted to male and postmenopausal patients under strict supervision. Thalidomide may cause a peripheral neuropathy, but this has not been reported in leprosy patients.

Eye involvement is common and iritis requires local treatment with corticosteroid and atropine drops.[22]

Other therapies

Prevention of disability is an important component of care.[28] Regular monitoring of nerve function will reveal early reversible RRs. Patients with irreversible nerve function impairment must learn to care for insensitive hands and feet and be provided with appropriate footwear. Plantar ulceration requires prolonged rest for healing. Physiotherapy and reconstructive surgery for clawhands and clawfeet, footdrop and lagophthalmos may prevent further tissue damage and restore appearance, and facial deformity can be corrected by plastic surgery.[28] Community-based rehabilitation is proving effective in assisting patients with persistent nerve impairment to return to full participation in their own communities.[29]

Chapter 155 - Ectoparasites

Wallace Peters

EPIDEMIOLOGY

Definition and nomenclature

In the strictest sense, an ectoparasite is defined as a parasite that derives its nourishment from the skin, as distinct from an endoparasite, which lives inside the body of the host. For this chapter, the definition has been adjusted to include both parasites that derive their nourishment from the skin and parasites that live within the skin and subcutaneous tissues. Not included here are skin-invading protozoa of the genus *Leishmania* that are relatively common in returning travelers from endemic areas (see Chapter 172). Purely hematophagous parasites, such as mosquitoes and ticks (see, for example, Chapter 11 , Fig. 11.3 and Chapter 166 and Chapter 179) are of major public health importance, especially as vectors of viral and protozoal diseases, and many groups of these invertebrates are more or less cosmopolitan. However, the parasites themselves are most unlikely to be found in direct association with travelers returning to temperate climates from endemic tropical and subtropical areas. The reader is referred, therefore, to Chapter 14 , Chapter 166 and Chapter 179 & Chapter 247 and other publications for information on these parasites.[1] [2] [3] This chapter particularly considers the various species of arthropods that may invade and may become apparent in the returned traveler (Table 155.1).

Geographic distribution

The arthropods referred to below, some of which have relatively well-defined geographic distributions in warm regions (see Table 155.1), are often found in returning travelers. Current infestations with mites and ticks that have been acquired abroad are rarely seen, although their sequelae may still be apparent. However, myiasis such as that caused by *Cordylobia anthropophaga*, also called the Tumbu or mango fly, is common in parts of sub-Saharan Africa and that caused by *Dermatobia hominis*, the human botfly, is not infrequently acquired by travelers to rural areas of Central and South America. The Tumbu fly lays batches of 200–300 eggs on dry soil in shaded areas. Domestic dogs are most frequently infested by the first instar larvae, but humans are also commonly infected. *Dermatobia hominis* infests many species of domestic and wild animals and is a serious pest of cattle in some endemic areas of the New World.

The sand, chigoe or jigger flea, *Tunga penetrans*, has a wide distribution within Central and South America, west and east Africa as well as some parts of the Indian subcontinent. The larvae are found mainly in dry, sandy soil where they mature into very small adults that actively seek a mammalian or avian host. Pigs are commonly infested in or around houses, where humans are also readily attacked.

Infestation with other arthropods, such as the New World screw-worm *Cochliomyia hominivorax*, formerly a very serious, destructive pest of cattle and occasionally of humans, as well as the Congo floor maggot *Auchmeromyia senegalensis*, are now rare and unlikely to be acquired by travelers.[1] [4] Myiasis caused by other species of flies (see Table 155.1) is uncommon and not likely to be found in the returning traveler. Any suspicious object recovered from such indi-viduals should, however, be referred for specialist identification.

Mites such as *Sarcoptes scabiei* and harvest mites of various species are cosmopolitan.[5] [6] Scabies or pediculosis caused by body, head or public lice (Fig 155.1 and Fig 155.2) may of course be acquired during travel anywhere through contact with infected people and may be diagnosed only after return home. The bites of anopheline mosquitoes may result in malaria that becomes manifest only after some time, as may certain viral infections transmitted by mites, ticks, mosquitoes or other hematophagous ectoparasites[1] [3] [7] [8] (see also Chapter 166 Chapter 179 & Chapter 247 , Fig 247.1 , Fig 247.2 , Fig 247.3 , Fig 247.4 , Fig 247.5 , Fig 247.6 , Fig 247.7 , Fig 247.8 , Fig 247.9 , Fig 247.10 , Fig 247.11 , Fig 247.12).

PATHOGENESIS AND PATHOLOGY

Immunologic responses of the skin

The skin is a complex organ with complicated immune regulatory and effector functions, which involve both cellular and humoral responses to invasion by ectoparasites.[9] In order to survive within the skin and subcutaneous tissues, the parasites have evolved a number of ways in which they, in turn, modulate the host's immune response. Invading larvae of myiasis-causing flies produce proteases that facilitate their penetration of the dermal tissues as well as providing nutrition. The host response to the foreign proteins is intense and comprises a massive cellular response to both the foreign protein and the bulky, growing organism, with eosinophils and macrophages being predominant.[5] Although much research has been conducted in recent years into the parasite-host relationship of invasive arthropods, it has been directed mainly at those of veterinary importance and little detail is known about the parasites that affect humans. In areas endemic for Tumbu flies, for example, a marked level of cellular immunity, first localized but later more general, develops after prolonged and repeated exposure. [5]

Pathology

The pustular skin lesions associated with invasive larvae of myiasiscausing flies present a similar histologic picture of a fistulous track leading to a dermal cavity. This is densely infiltrated by macrophages, eosinophils and plasma cells. As the larva grows, it extends its posterior end toward the surface, through which its respiratory tubes project in the form of a pair of spiracles in a chitinous plate. The general appearance is of an acutely inflamed furuncle. As such larvae mature they push outward and are eventually extruded to the exterior, where they fall to the ground and pupate.

The pathology of *T. penetrans* is different since it is the adult female that actively burrows its way into the skin of the feet or under the toenails until her head reaches the papillary dermis. The posterior end of the insect, which bears the respiratory spiracles and sexual organs, remains at the surface. As the flea feeds and grows, its eggs develop until its abdomen becomes a pea-sized sac from which several hundred eggs are released to the exterior, a few at a time. The flea becomes encased in an inflammatory, foreign body granuloma, which may be surrounded by microhemorrhages.

TABLE 155-1 -- Classification, common names and geographic distribution of the major ectoparasites that affect humans.

CLASSIFICATION, COMMON NAMES AND GEOGRAPHIC DISTRIBUTION OF THE MAJOR ECTOPARASITES THAT AFFECT HUMANS					
Class	**Order/suborder**	**Genera and species**	**Common name**	**Geographic distribution**	**Notes**
Arachnida	Acari (mites)	*Trombicula* spp.	Scrub mites	Cosmopolitan	Include vectors of viruses, rickettsias
		Sarcoptes scabei		Cosmopolitan	Cause of scabies
	Acari (ticks)	Ixodidae and Argasidae	Hard and soft ticks	Cosmopolitan	Include many vectors of viruses, rickettsias, *Borrelia, Babesia, Ehrlichia* spp.

Insecta	Diptera	Many genera and species	Including biting and myiasis flies		
	Nematocera	Numerous genera and spp.	Mosquitoes, *Simulium*, etc.	Cosmopolitan	Major vectors of malaria, viruses, helminths
	Brachycera	*Chrysomyia bezziana*	Old World screw-worm	Widespread in tropical Africa, South East Asia and the south west Pacific	Common cause of cutaneous myiasis in South East Asia
		Cochliomyia hominivorax	New World screw-worm	Central and South America	Causes massively destructive myiasis
		Lucilia spp.	Greenbottles	Cosmopolitan	Facultative wound myiasis
		Calliphora spp.	Bluebottles	Cosmopolitan	Facultative wound myiasis
		Auchmeromyia senegalensis	Congo floor maggot	Sub-Saharan Africa	Sucks blood but no myiasis
		Cordylobia anthropophaga	Tumbu, mango fly	Sub-Saharan Africa	Causes furuncular myiasis
		Wohlfahrtia spp.	Flesh flies	Mainly in the South	Can cause tissue destruction
				Palearctic region	
		Dermatobia hominis	Human botfly	Central and South America	Causes furuncular myiasis
		Oestrus ovis	Sheep nasal botfly	Cosmopolitan	Larvae may invade nose, eye
		Hypoderma spp.	Warble, botflies	Cosmopolitan	Causes 'creeping eruption'
	Siphonaptera	Numerous genera and spp.	Fleas	Cosmopolitan	Vectors of plague, rickettsias, helminths
		Tunga penetrans	Chigger, jigger flea, chigoe	Central and South America, tropical Africa, India	Female invades dermis (especially of the foot) to develop and lay eggs
	Phthiraptera	Numerous genera and spp.	Biting and sucking lice	Cosmopolitan	
		Pediculus humanus	Body and head louse	Cosmopolitan	Vector of rickettsias, *Borrelia* spp.
		Phthirus pubis	Pubic louse	Cosmopolitan	
Parasites that derive their nourishment from the skin and parasites that live within the skin and subcutaneous tissues are included.					

Figure 155-1 Adult *Pediculus humanus corporis* (the body louse) feeding. These insects are not only a source of considerable skin irritation but also the vectors of epidemic typhus and trench fever. *Courtesy of Dr med H Lieske. With permission from Peters and Pasvol.*[7]

Figure 155-2 The 'crab louse', *Phthirus pubis.* The crab louse, which is commonly acquired during sexual intercourse, infests not only the public region but also other sites, including the eyelashes. *Courtesy of Dr med H Lieske. With permission from Peters and Pasvol.*[7]

PREVENTION

The newly hatched larvae of *C. anthropophaga* live on the ground where they are attracted to warm skin, which they can rapidly penetrate with the aid of oral hooks and backward pointing body spines (Fig. 155.3). They are also attracted to clothing, for example underwear bearing human body odors. Prevention of infection involves not lying directly on potentially contaminated ground as well as not laying washing on the ground to dry, a common practice in many tropical areas.

Dermatobia hominis (Fig. 155.4) has a more complex life cycle. The female lays its eggs individually on various species of biting flies. When these take a blood meal the eggs hatch and the emerging larvae rapidly invade the mammalian host's skin, in which they begin to develop. No rational method of prevention is therefore available. The avoidance of sites that are known to be frequented by *T. penetrans*, for example chicken houses and farm buildings, and especially the wearing of solid footwear help to prevent infection with this flea. It is also important not to disperse eggs when removing the adult females (see below).

CLINICAL FEATURES

The clinical features of furuncular myiasis are similar for all species. The infection site is inconspicuous at first but a small, reddened papule develops within about 24 hours. The papule itches intermittently but especially at night. As the larva grows within the dermal cavity over the next 2–3 weeks a dome-like swelling develops on the skin surface

Figure 155-3 Third instar larva of *Cordylobia anthropophaga*, the Tumbu fly. The powerful mouth hooks, with which the larva feeds, are seen as long, dark bars. *With permission from Peters.*[1]

Figure 155-4 Adult female *Dermatobia hominis.* The fly lays eggs on blood-sucking insects such as mosquitoes or on ticks. After about 1 week larvae hatch from the eggs to infest the skin of a human or other warm-blooded host, which is fed on by the phoretic host. *Courtesy of Dr AJ Shelley. With permission from Peters.*[1]

with a surrounding area of inflammatory edema. Itching may become intense and a throbbing pain may be present. At the center of the dome a hole develops, through which the posterior tip of the larva bearing its spiracles emerges, together with a purulent, bloody exudate. As the larva grows it moults twice; this process is often accompanied by severe pain. The clinical course runs for 14–16 days in infestation with *C. anthropophaga* but up to 1 month with *D. hominis*. Lymphangitis and regional lymphadenopathy are common from about weeks 2–4 of infestation. During this time the larva repeatedly protrudes its posterior end through the hole in the skin but rapidly withdraws if contacted (Fig. 155.5). Eventually the mature larva forces its way out of the skin, causing little pain, and drops to the ground to pupate. The skin lesion usually heals rapidly and only a pigmented scar marks the site of the lesion (Fig. 155.6).

Infection with *T. penetrans* initially causes itching and sometimes pain; multiple lesions are common. The sites most commonly attacked are the skin of the feet and under the toenails. As the insect grows it produces a firm nodule, the surface of which becomes hyperkeratotic with a central, black spot. This is the site of the projecting spiracles. Secondary infection with pyogenic bacteria is common and may be associated with lymphangitis and regional lymphadenopathy. Infection with tetanus bacilli is a particular hazard.

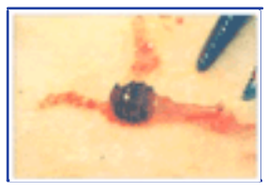

Figure 155-5 Second instar larva of *Dermatobia hominis* after surgical removal. The characteristic rows of dark spines are seen clearly. *Courtesy of Dr RP Lane. With permission from Peters and Pasvol.*[1]

DIAGNOSIS

Any pustule of several days' or weeks' duration in a returning traveler should lead to a presumptive diagnosis of myiasis, and the travel history will immediately give a clue to the possible species involved. The presence of a central dark point in the pustule containing a spiracular plate or even a protruding larval extremity confirms the diagnosis but a specialist examination of any larva removed from the lesion may be required to confirm the species involved. Similarly, the presence of tender nodules on the feet or under the toenails should give rise to a possible diagnosis of tungiasis. In this case, too, the posterior end of the flea may be observed in the center of the skin overlying the nodule.

The differential diagnosis of myiasis includes infection with pyogenic bacteria or an embedded foreign body with secondary infection. Lesions of tungiasis may resemble plantar or subungual warts or acute infective paronychia. Multiple, serpiginous, subcutaneous lesions, especially on the feet (Fig. 155.7), buttocks or hands should give rise to a suspicion of skin invasion by ground-dwelling, infective larvae of dog hookworms ('creeping eruption', see Chapter 174 and Chapter 246).

MANAGEMENT

Attempts to express the embedded larvae of flies such as *C. anthropophaga* or *D. hominis* by squeezing the pustules are likely to do more harm than good. If the surface pore through which the spiracles of *C. anthropophaga* protrude is covered with paraffin for some hours, the larva can sometimes be pulled out with forceps (Fig. 155.8) but this is rarely successful with *D. hominis*.

In endemic areas of Central and South America, it is claimed that the larva can be tempted to emerge if the lesion is covered with a piece of pork fat for 24 hours or so, but this is not a method that one would suggest for use in returning travelers! In most cases it is best to

Figure 155-7 Cutaneous larva migrans ('creeping eruption') due to invasion of infective larvae of the dog hookworm *Ancylostoma caninum.* This condition may be mistaken for infestation with the larvae of ectoparasitic arthropods. The lesions respond rapidly to treatment with albendazole or ivermectin. *With permission from Peters and Pasvol.*[7]

remove the larva surgically after infiltrating round the lesion with an appropriate local anesthetic (see Fig. 155.5). This also facilitates removal of the larva because it is anesthetized. If necessary, the cavity can be curetted and, if it is large, it can be stitched, after which it can be left to granulate. The wound usually heals in about 1 week, leaving a pigmented scar.

Gravid *T. penetrans* (Fig. 155.9) should also be removed surgically. Inhabitants of endemic areas often extract the flea with a sharp sliver of bamboo or a razor blade, frequently inadvertently breaking open the insect's abdomen in the process and releasing the eggs to continue the insect's life cycle. The residual cavity in the skin, which must be kept clean to minimize secondary bacterial contamination, usually heals rapidly but secondary infection may require appropriate antibiotic therapy.

Figure 155-8 Extracting a larva of *Cordylobia anthropophaga* after covering it with paraffin. The pair of black spiracles can just be seen in the center of the posterior tip of the larva. *Courtesy of Professor A Bryceson. With permission from Peters and Pasvol.*[7]

Figure 155-9 Surgical extraction of a gravid female *Tunga penetrans.* Care must be taken not to disrupt the abdomen and release the eggs. *Courtesy of Professor C Curtis. With permission from Peters.*[1]

Chapter 156 - Endemic Treponematoses

André Z Meheus
Om P Arya

The endemic treponematoses include yaws (also known as buba, framboesia, parangi and pian), endemic syphilis (also known as bejel, dichuchwa and sklerjevo) and pinta (also known as azul, carate and mal de pinto), all of which are chronic bacterial infections. The causative organisms (*Treponema pallidum* subsp. *pertenue, T. pallidum* subsp. *endemicum* and *Treponema carateum*, respectively) are morphologically and serologically indistinguishable from *T. pallidum* subsp. *pallidum*, which is the causative organism of venereal syphilis.

Small genetic differences, (a single base pair change) have been identified between the organisms of the venereal and nonvenereal (endemic) treponematoses. [1] [2] [3] However, none of these genetic variations identified so far can differentiate one subspecies from another and it remains unresolved whether they are all the same or different organisms. Nevertheless, there are significant clinical and epidemiologic differences.[4]

EPIDEMIOLOGY

Historic perspective

The endemic treponematoses, because of the disfigurement and disability they cause, were a major public health problem in the preantibiotic era. In 1948, the World Health Organization (WHO) and the United Nations International Children's Emergency Fund (UNICEF) sponsored a global control program. This involved 46 countries and brought these diseases under control with the help of long-acting penicillin. Unfortunately, the diseases were not eradicated and the lack of continuing vigilance allowed persistence of endemic foci in some countries, resulting in resurgence of these disease in the 1980s.

Geographic distribution

The endemic treponematoses are now largely confined to communities in remote rural areas living in poor, overcrowded and unhygienic conditions. Yaws occurs mainly in the warm, humid areas of Africa, South East Asia and the Pacific, the Caribbean and Central and South America. Endemic syphilis occurs mainly in the arid areas of sub-Saharan Africa and among the nomadic people of the Arabian peninsula. Pinta occurs mainly in Central and South America (among Indian tribes in the Amazon region and adjacent areas). Cases of imported yaws and endemic syphilis are sometimes encountered in the countries of the northern hemisphere, where clinicians may need to include them in the differential diagnosis.

INCIDENCE AND PREVALENCE

Accurate incidence and prevalence data are unavailable. The most recent estimate by WHO in 1995 yields a global prevalence of 2.5 million cases, including 460,000 infectious cases.

Age and sex

Yaws and endemic syphilis usually occur in children aged 2–14 years. For pinta the range is 10–30 years. The sexes are probably equally affected.

Mode of transmission

Yaws and pinta are transmitted by direct skin-to-skin contact with infectious lesions, transmission being facilitated by a breach in the skin of the recipient. The role of nonbiting flies in the transmission is uncertain. In the case of endemic syphilis, because the initial lesions are often in or around the mouth, the infection spreads by direct contact (e.g. older children kissing their younger siblings) and by indirect contact through infected communal eating or drinking utensils.

PATHOLOGY

Yaws and endemic syphilis affect skin and bones, whereas pinta is confined to the skin.

The basic pathology in endemic treponematoses is the same as in venereal syphilis. However, the vascular changes in the endemic treponematoses are less marked. A recent study of skin biopsies from yaws patients showed numerous plasma cells but few T and B cells; the treponemes were found mostly in the epidermis, whereas in venereal syphilis they were demonstrated mainly in the dermis and dermal-epidermal junction.[5] Because these differences are relative, they cannot be used to differentiate yaws from venereal syphilis.

In pinta, there is loss of melanin in basal cells, the presence of many melanophages in the dermis and the absence of inflammatory cells and treponemes in the achromic lesions.[6]

Contrary to occasional reports, endemic treponematoses are not believed to be associated with congenital transmission or with involvement of the cardiovascular and nervous systems.

PREVENTION

Essential in prevention of the endemic treponematoses is not only to identify and treat clinical cases but also to recognize that the presence of clinical cases in a community necessitates an immediate search for further clinical and latent cases, which also must be treated.

The preventive measures include:

- strengthening and improving accessibility of the primary health care facilities;
- training of clinicians to detect and treat patients and to examine and treat household and other obvious contacts;
- health education of the population;
- improvement in the standard of living and in personal and environmental hygiene; and
- provision of soap and water and clothing to children.

CLINICAL FEATURES

The incubation period is 9–90 days (mean 21 days).

Yaws

Early stage

The initial or primary lesion ('mother yaw') appears at the site of infection on an exposed part of the body. It may be a localized

maculopapular eruption or a papule, which may develop into a large papilloma 2–5cm in diameter. It is painless but itchy and may ulcerate as a result of scratching. It may heal in 3–6 months with or without scarring. Secondary lesions, which are the result of lymphatic and hematogenous spread of organisms, appear a few weeks to 2 years after the primary lesion. They may consist of multiple excrescences, often resembling the initial papilloma. The papillomas may ulcerate and the exudate may dry to form a yellow crust which, when removed, gives the lesion an appearance of a raspberry (hence the name 'framboesia'). The lesions may be irregular, crescentic or discoid in shape and on moist areas may mimic condylomata lata of venereal syphilis. They are rather florid and become more numerous in the rainy season (Fig. 156.1). They may last up to 6 months and heal with or without scarring. Infectious relapses may occur for 5 years and, rarely, for 10 years.

Other manifestations include:

- regional lymphadenopathy;
- palmar and plantar lesions, which may be painful, resulting in a crab-like gait; and
- osteoperiostitis of the proximal phalanges of the fingers (dactylitis) or of long bones, causing nocturnal bone pains.

The patient may at any time enter latency, with only serologic evidence of the infection.

Late stage

About 10% of patients develop late lesions after 5 years or more of untreated infection. The late stage is characterized by gummatous lesions of skin, bones and overlying tissues. The manifestations, some of which also occur in early stage but are now more destructive, include:

- ¦ hyperkeratosis of palms and soles with deep fissuring;
- ¦ juxta-articular subcutaneous nodules;
- ¦ more extensive osteoperiostitis of long bones (e.g. sabre tibia);
- ¦ hyperostosis of the nasal processes of the maxillae ('goundou'); and
- ¦ ulceration of the palate and nasopharynx (rhinopharyngitis mutilans; Fig. 156.2) with secondary infection resulting in foul-smelling discharge ('gangosa').

Figure 156-1 Mixed early yaws lesions: papillomata, ulceropapillomatous lesions and squamous macules. *Courtesy of WHO, Geneva.*

Endemic syphilis

The primary lesion is seldom seen. The early manifestations include mucous patches (i.e. shallow painless ulcers on the lips and in the oropharynx) and other mucocutaneous and bone lesions resembling those of venereal syphilis and yaws. Papilloma favor warm and moist areas and occur as split papules or angular stomatitis at the labial commissures (Fig. 156.3). Later, the patient may enter the latent phase, which may be prolonged; after this some patients develop late lesions, which are similar to those seen in yaws.

Pinta

Pinta is confined to the skin and is the mildest of all treponematoses. The primary lesion, appearing at the site of entry of *T. carateum* on an exposed part of the body, is an itchy, red, scaly

Figure 156-2 Gangosa in late stage of yaws (rhinopharyngitis mutilans; occurs also in endemic syphilis). *Courtesy of WHO, Geneva.*

Figure 156-3 Angular stomatitis (also called split papules) of endemic syphilis; these lesions are also found in early yaws. *Courtesy of Dr GM Antal.*

papule, sometimes associated with satellite lesions and regional lymphadenopathy. The secondary stage develops several months later, in other areas, with the appearance of pintids, which are similar to the initial lesions. These are also itchy. In due course, they undergo a variety of color changes from red to copper-colored, gray and bluish-black. The lesions remain infectious for many years.

The late lesions are characterized by varying degrees of hypochromia, discoloration, atrophy and achromia. Sometimes these features are seen in the same area.

Attenuated endemic treponematoses

In areas of reduced transmission, the clinical expression of endemic treponematoses can be much milder (a few or even a single papilloma) or many of the infected subjects can be asymptomatic.[4] In the Gambia, 9.3% of pregnant women were seropositive for a treponemal infection; children of seropositive mothers showed no signs of congenital syphilis and there was no increase in perinatal, neonatal or child deaths. No clinical signs of endemic treponematoses were found, indicating the asymptomatic nature of the infection.[7] [8]

HIV infection and endemic treponematoses

As yet, no information is available on any interaction between HIV infection and endemic treponematoses.

DIFFERENTIAL DIAGNOSIS

In endemic areas, an accurate clinical diagnosis can be made in the presence of classic lesions. This will, however, necessitate appropriate training of clinicians, especially in view of the rather milder forms being encountered. The difficulties arise when there are no clinical lesions (i.e. latent cases), when venereal syphilis is also locally prevalent and when the patient is an immigrant from an endemic area presenting at a clinic in a nonendemic country. Differentiation from venereal syphilis is important because of social stigma implications. A careful and detailed history (including that of mother, father and siblings when appropriate) and thorough physical examination are always essential.

Apart from venereal syphilis, the conditions to be considered for differential diagnosis include:

- ¦ skin sepsis, scabies, fungal infection, lichen planus, plantar warts, psoriasis and tungiasis in a patient who has early skin lesions;
- ¦ tropical ulcer, cutaneous leishmaniasis, mycotic lesions and leprosy in a patient who has gummatous ulceration; and
- ¦ tuberculosis and sickle cell disease in a patient who has dactylitis. Pinta may need to be differentiated from pityriasis versicolor, tinea corporis, vitiligo, leprosy and chloasma.

DIAGNOSIS

There is no test that can differentiate the treponematoses (including venereal syphilis) from one another. The diagnosis of treponemal infection is confirmed by the demonstration of treponemes (but beware of nonpathogenic commensals) in a wet preparation of the material from early lesions by dark-field microscopy or in the biopsy material stained by the silver impregnation technique.

Serologic tests (rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) nontreponemal tests; *T. pallidum* hemagglutination assay (TPHA) or

fluorescent treponemal antibody absorption (FTA-ABS) treponemal (i.e. specific) tests) should be carried out in all cases, but their interpretation requires expertise. The treponemal tests are particularly useful to confirm a reactive nontreponemal test (exclusion of false positives). A reactive treponemal test may indicate a current infection or a past infection ('serologic scar'). Radiologic evidence of osteoperiostitis may assist in the diagnosis.

If the differentiation from venereal syphilis is difficult, the patient should be managed as for venereal syphilis.

MANAGEMENT

Penicillin remains the drug of choice. Long-acting benzathine penicillin G, given intramuscularly in a single session, is preferred. The dose is 600,0000 units (0.45g) for children under the age of 6 years; 1.2 million units (0.9g) for those aged 6–15 years; and 2.4 million units (1.8g) for those over 15 years. The dose may be divided, half to be given into each buttock. While it is recognized that treponematoses have remained exquisitely sensitive to penicillin, there is a recent report of penicillin treatment failures of yaws in Papua New Guinea. [9] Three penicillin treatment failures have also been observed in Ecuador.[10] The distinction between relapse, re-infection or true resistance is difficult to make but these clinical failures are worrisome and should be further researched.

Although there is little information on the use of drugs other than penicillin to treat these conditions, oral erythromycin or tetracycline 500mg q6h for 15 days or oral doxycycline 100mg q12h for 15 days are likely to be effective for those allergic to penicillin. Children between 12 and 15 years of age should receive half that dose. Tetracyclines (including doxycycline) are not recommended for pregnant and breast-feeding women and for children under the age of 12 years.

Contacts

Arrangements should be made to examine and, if appropriate and after proper explanation, to treat the household contacts and other close contacts.

Prognosis and follow-up

The lesions become noninfectious within 24 hours after the injection of penicillin. Whereas treatment in early stages should result in cure in almost 100% of patients, it will not reverse any destructive change in late stages. Rapid plasma reagin (or VDRL) titers should decline within 6–12 months, becoming negative in about 2 years. However, in a small proportion of cases, especially if treated in late stages, the RPR (or VDRL) may remain positive, albeit in low titer (i.e. below 1:8). The specific tests (i.e. TPHA, FTA-ABS) will remain positive throughout life.

Chapter 157 - African Trypanosomiasis

David G Lalloo

EPIDEMIOLOGY

African trypanosomiasis (sleeping sickness) causes considerable mortality and morbidity across much of the African continent. Approximately 45,000 cases were reported to the World Health Organization (WHO) in 1999, but the true burden of disease is thought to be much higher, with estimates of between 300,000 and 500,000 individuals being infected.[1] [2] Intensive control activities in the 1950s and 1960s were extremely successful in reducing the incidence of disease but a lack of resources and civil conflict in many of the most heavily affected countries has led to re-emergence of the disease as a major health problem.

African trypanosomiasis occurs in two distinct clinical forms: an acute form, caused by *Trypanosoma brucei rhodesiense*, transmitted in endemic situations by savanna *Glossina morsitans* group flies and in epidemic situations by a 'riverine' species, namely *Glossina fuscipes*; and a more chronic form caused by *Trypanosoma brucei gambiense*, transmitted by the riverine species *Glossina palpalis*, *Glossina tachinoides* and *G. fuscipes* (Fig. 157.1). [3] [4] *Trypanosoma b. rhodesiense* is distributed in east and central Africa between Ethiopia and Botswana. It is a zoonosis with several game animal reservoirs; in the epidemic cycle, cattle are an important reservoir. *Trypanosoma b. gambiense* is found from Uganda west to Senegal and south through Zaire to Angola; humans are the prime reservoir of infection (Fig. 157.2 , Table 157.1). [2]

PATHOGENESIS

Members of the genus *Trypanosoma* are parasitic in the blood and tissues of vertebrates and are transmitted by blood-sucking insects. A developmental cycle occurs in the gut and sometimes in the salivary glands of the insect vectors with the production of infective metacyclic trypanosomes; mammals acquire the infection by the bite of the tsetse fly vector. Trypanosomes are microscopic, varying in length from 15µm to 35µm, and are highly active when observed under the microscope.[4]

Metacyclic trypanosomes inoculated during tsetse feeding multiply locally in extracellular spaces and induce the typical 'chancre' (Fig. 157.3), with a marked local tissue response characterized by vasculitis, perivascular mononuclear cell infiltration, edema and local tissue damage. Trypanosomes enter the lymphatics and multiply within lymph nodes, leading to parasitemia 5–12 days after infection. Antigenic variation of the surface glycoproteins causes successive waves of parasitemia as the parasite evades the host immune response.[5]

Parasites enter the central nervous system (CNS) via the choroid plexus or by transcytosis across endothelial cells to cause a lymphocytic meningoencephalitis, which particularly affects the brain stem, although cortical areas and the cerebellum are also involved.[6] Perivascular infiltration with lymphocytes, plasma cells, macrophages and characteristic morular cells occurs; microglia and astrocytes proliferate and there is neuronal destruction and demyelination. Similar lesions also occur in the heart, serous membranes and endocrine organs.

Polyclonal activation of B lymphocytes leads to elevation of IgM concentrations. Heterophile antibodies, rheumatoid factor, immune complexes and autoantibody production may occur. Some neuropsychiatric manifestations may be biochemically induced; elevated prostaglandin D_2 concentrations have been found in advanced *T. b. gambiense* infection, which may be responsible for the circadian sleep disorders.[7]

PREVENTION

There are two major components of sleeping sickness control: detection and treatment of cases, and vector control. In *T. b. rhodesiense* areas, patients who present with symptoms of early parasitemia (passive surveillance) can be treated at local rural centers: in epidemics, rapid deployment of active surveillance using blood film screening and the establishment of effective local treatment centers is important (Fig. 157.4). In *T. b. gambiense* areas, limited clinical symptoms in the early stages require active surveillance. Individuals can be screened using gland aspiration or rapid antigen tests (e.g. the card agglutination test for trypanosomes, CATT). Although prophylactic measures such as 6-monthly intramuscular injections of pentamidine have been suggested for populations most at risk, concerns about development of drug resistance and the masking of second-stage infections means that this is no longer advocated.[2]

Vector control using insecticide-impregnated traps and targets has been demonstrated to be effective in epidemics of *T. b. gambiense* in the Congo[8] and in epidemics of *T. b. rhodesiense* transmitted by *G. fuscipes* in Uganda.[9] Sterile insect release methods may also be useful in reducing vector populations.[10] Residual insecticide application to *Glossina* resting sites, insecticide spraying and the clearing of riverine habitat have been used in the past but resource and environmental considerations means that these can no longer be considered. In epidemic situations, treatment of the cattle reservoir by cattle trypanocides may also be a strategy for prevention of human sleeping sickness.[11]

CLINICAL FEATURES

A local skin lesion, the chancre, may develop at the site of inoculation (see Fig. 157.2). This is a raised, tender, edematous papule that rapidly increases in size with surrounding local edema, erythema and local lymphadenopathy. Chancres resolve after 2–3 weeks; they are common in *T. b. rhodesiense* infections, but rare in *T. b. gambiense* infections. Trypanosomes subsequently invade lymphatics and blood, leading to the hemolymphatic stage (stage I) and may invade the central nervous system and cerebrospinal fluid (CSF), leading to meningoencephalitis (stage II). *Trypanosoma b. gambiense* causes a mild but protracted illness over months or years, which is followed by the late development of meningoencephalitis. In contrast, *T. b. rhodesiense* causes a severe, acute, febrile disease, with rapid progression to meningoencephalitis and death within months.[2] [12] [13]

Figure 157-1 The causative organisms of sleeping sickness in humans. Reproduction of Dutton's original drawing of *Trypanosoma brucei gambiense* from the blood of a man. The organisms possess nucleus kinetoplast and flagella, and their relative size can be assessed from the red blood cell diameter of 7µm.

Figure 157-2 Endemic areas for trypanosomiasis.

Figure 157-3 Typical chancre of a patient infected with *Trypanosoma brucei rhodesiense.*. The chancre develops at the site of the infecting fly bite.

TABLE 157-1 -- Epidemiology and distribution of the human trypanosomiases.

EPIDEMIOLOGY AND DISTRIBUTION OF THE HUMAN TRYPANOSOMIASES		
	Trypanosoma brucei gambiense	***Trypanosoma brucei rhodesiense***
Distribution	Uganda to Senegal and Angola	Ethiopia south to Botswana and east of Rift Valley
Vector	*Glossina palpalis, tachinoides, fuscipes*; feed on any available host	*Glossina morsitans, pallidipes, swynnertoni*; host is game or cattle
Acquisition	Sites of high human-vector contact: river crossings, sacred groves, streams; end of dry season in Guinea savannas; peridomestic transmission in derived humid savanna; plantations of coffee and cocoa	Human penetration into savanna woodland; associated occupations (e.g. hunting, fishing, gathering of firewood and honey)
Epidemic characteristics	Lack of control (surveillance, diagnosis, treatment and vector control) as a result of expansion of human reservoir	Changes of habitat; intense human-fly-cattle contact for *G. fuscipes* transmission; encroachment on human habitation for *G. morsitans* transmission
Animal reservoirs	Pigs; to a lesser extent other domestic animals, rarely game animals	Game animals in endemic situation (bushbuck and hartebeest); cattle in epidemic situation

Hemolymphatic trypanosomiasis (stage I)

The characteristic clinical features of hemolymphatic trypanosomiasis comprise:

- episodes of fever, often accompanied by chills and rigors, malaise and prostration;
- headache;
- joint pains; and
- loss of weight.

In *T. b. gambiense* infections the disease slowly increases in severity as it progresses. Lymphadenopathy occurs in *T. b. gambiense* infections, and enlargement of the posterior cervical glands is characteristic

Figure 157-4 Emergency treatment center Uganda. This center was established to provide facilities for the care and treatment of patients with sleeping sickness during the epidemic in Busoga.

(Winterbottom's sign). Lymph nodes are moderately enlarged, firm and discrete. Splenomegaly occurs in around one-third of cases, and may be associated with hepatomegaly. A fleeting erythematous rash ('circinate erythema') on the trunk or upper extremities is evident in light skinned people. There are focal areas of edema, facial puffiness, dependent edema and serous effusions including ascites, pleural effusions and pericardial effusions. Myocarditis occurs especially in *T. b. rhodesiense* infections.[12] [13]

Meningoencephalitic trypanosomiasis (stage II)

In *T. b. rhodesiense* infections, cerebral involvement occurs within weeks of the onset of infection, whereas in *T. b. gambiense* infections meningoencephalitis may be delayed several years after initial infection. Headache becomes more severe and protracted. Personality changes may occur early, especially in *T. b. gambiense* infections, with apathy, lack of attention, loss of appetite, antisocial behavior and paranoid or delusional states. Abnormalities of sleep are characteristic and result from disturbance of normal circadian rhythms. Diurnal and inappropriate somnolence is often associated with nocturnal insomnia.

Neurologic features include tremors, muscle fasciculation, increased muscle tone and rigidity, choreic and athetotic movements. The gait is affected early with progressive ataxia. Speech is slow, slurred, or incoherent. Convulsions and hemiplegia can occur. Pyramidal tract and cranial nerve lesions are less common. Kerandel's sign refers to deep hyperesthesia, often with a delayed response to painful stimuli. Intractable pruritus is a feature of *T. b. gambiense*, especially in the later stages. Ocular manifestations can include iritis, chorioretinitis and papilledema.

The course of the disease is a relentless deterioration to a stuporose state, with cachexia, wasting and progressive malnutrition (Fig. 157.5). Patients become increasingly difficult to rouse and pass into deepening coma and death. This is relatively rapid in *T. b. rhodesiense* but may be protracted over months or years in *T. b. gambiense*. Intercurrent infections, especially bronchopneumonia, are common in the late stages of the disease. In *T. b. gambiense*, amenorrhea and impotence are common.[12] [13] [14]

Sleeping sickness in special groups

Although sleeping sickness is less common in children than adults, the clinical course of infection in children may be more severe and, with *T. b. rhodesiense* infection, progression to meningoencephalitis may be even more rapid than in adults.[15] Congenital infection has been described in *T. b. gambiense*.

Figure 157-5 Comatose terminal stage patient with sleeping sickness. Note the degree of cachexia.

Trypanosomiasis caused by *T. b. rhodesiense* or *T. b. gambiense* may occur in tourists and visitors to endemic areas. Severe early infections with high peripheral parasitemia are most common in travelers, characterized by a severe systemic illness with fever, anemia, biochemical abnormalities and circulating immune complexes. Thrombocytopenia is common and there may be evidence of a coagulopathy and disseminated intravascular coagulation. Most travelers do not develop CNS involvement, although delayed diagnosis may be a problem outside endemic areas, especially if no chancre is present.[16]

DIAGNOSIS

Routine laboratory tests demonstrate normal white cell counts, raised erythrocyte sedimentation rate, anemia, thrombocytopenia, low serum albumin and elevated serum IgM.

Parasitologic diagnosis

Diagnosis of sleeping sickness is dependent on finding trypanosomes in the chancre, blood, lymph gland juice or CSF — either in unfixed or unstained preparations, when moving parasites are observed, or in stained preparations. Blood films are usually positive in *T. b. rhodesiense* infection but parasitologic diagnosis may be difficult in chronic *T. b. gambiense* disease; high levels of parasites are often only found during a fever. Repeated examination and concentration techniques such as microhematocrit centrifugation may improve diagnostic sensitivity. *Trypanosoma b. gambiense* may also be diagnosed by finding parasites in aspirates from enlarged cervical lymph glands.

Diagnosis of second stage (CNS) disease requires examination of CSF. Before lumbar puncture, a single dose of suramin eliminates trypanosomes from the blood, avoiding the risk of contamination of CSF with trypanosoma.[2] [12] Parasites may be found in the centrifuged deposit, which should be examined within 15 minutes of the lumbar puncture. A raised CSF cell count (>5/mm^3) or raised CSF protein are also suggestive of CNS infection.

Immunologic diagnosis

A number of serologic tests have been developed; CATT is particularly useful for rapid preliminary screening of large populations for *T. b. gambiense* infection. A more recent approach to indirect detection of parasites is the use of an antigen detection test (CIATT) to detect *T. b. rhodesiense* in serum and CSF. This may be useful for following the response to therapy.[17]

Differential diagnosis

In endemic areas, *T. b. rhodesiense* is most common in certain occupational groups such as hunters, game wardens and fishermen, although all members of the community may be affected. Transmission of *T. b. gambiense* occurs at places of contact between humans and water, and both sexes and all age groups are affected. Outside endemic areas, trypanosomiasis caused by *T. b. rhodesiense* should be considered in travelers from eastern and southern Africa (especially those who have visited game parks) who present with an acute severe febrile illness. *Trypanosoma b. gambiense* infections may present months or years after exposure, with a febrile illness or neuropsychiatric features.

Chancres may be confused with insect bites, skin infections, an eschar or cutaneous anthrax. Early hemolymphatic disease mimics a wide range of febrile illnesses, especially malaria, relapsing fever, typhoid, brucellosis and arboviral infections. Occasionally, myocarditis may dominate the clinical picture. The differential diagnosis of meningoencephalitis includes a wide range of inflammatory cerebral infections; in particular, cryptococcal or tuberculous meningitis complicating HIV infection needs to be excluded. The neuropsychiatric presentations of trypanosomiasis may be confused with a variety of psychiatric syndromes, especially when personality change or psychotic behavior predominate. Late-stage disease may also mimic focal neurologic disorders, parkinsonism and space-occupying cerebral lesions.

MANAGEMENT

Treatment of sleeping sickness depends upon the stage of disease; a lumbar puncture is therefore crucial to determine whether there is evidence of CNS involvement. At least one dose of suramin or pentamidine should be given to clear blood parasites before a lumbar puncture is performed to prevent inoculation of parasites into CSF at the time of lumbar puncture. There have been few recent advances in the chemotherapy of trypanosomiasis and the number of available drugs is limited (Table 157.2). [18] Most treatment regimens are relatively toxic and it is therefore important to diagnose and treat nutritional deficiencies or intercurrent infections; routine anthelmintic and antimalarial treatment is often given. Hemolymphatic trypanosomiasis is treated with suramin or pentamidine; the latter is only effective in *T. b. gambiense* infection. Meningoencephalitis requires treatment with drugs that cross the blood-brain barrier in trypanocidal concentrations. The mainstays of therapy are arsenical

TABLE 157-2 -- Drugs currently used for the treatment of sleeping sickness.

DRUGS CURRENTLY USED FOR THE TREATMENT OF SLEEPING SICKNESS					
Drug	**Species**	**Indication**	**Route**	**Typical dosage regimen**	**Side-effects**
Suramin	*Trypanosoma brucei rhodesiense (Trypanosoma brucei gambiense)*	Stage 1	Slow iv infusion	Day 1: 5mg/kg test dose	Anaphylaxis
				Day 3: 10mg/kg	Cutaneous reactions
				Days 5, 11, 23, 30: 20mg/kg	
Pentamidine	*T. b. gambiense*	Stage 1	im/iv	7–10 doses of 4mg/kg daily (or alternate days)	Local reactions (im)
					Hypotension
					Hypoglycemia
Melarsoprol	*T. b. rhodesiense*	Stage 2	iv infusion	Three series of four daily doses of 1.2–3.6mg/kg, each separated by 7–10 days	Arsenical encephalopathy
	T. b. gambiense				Peripheral neuropathy
					Dermatitis
Eflornithine	*T. b. gambiense*	Stage 2	iv infusion (po)	400mg/kg daily in four divided doses for 7–14 days	Diarrhea
					Pancytopenia
					Convulsions
Nifurtimox (under evaluation)	*T. b. gambiense*	Stage 2	po	15–20mg/kg daily in three divided doses for 14 days	Anemia
	?T. b. rhodesiense				Neurologic side-effects

drugs, particularly melarsoprol, used since the beginning of the 20th century. Eflornithine and nifurtimox are also used for the treatment of late-stage *T. b. gambiense* infections. In most individuals, drugs rapidly clear parasitemia or CNS parasites, but relapses occur and 2-year cure rates are the best estimate of drug efficacy. Treatment responses vary according to the drug, severity of illness and geographic location.

Hemolymphatic trypanosomiasis

Suramin is given intravenously as a 10% solution. Fever, nausea, vomiting and urticaria are common but the most severe side-effect is an idiosyncratic anaphylactic reaction, which is infrequent (1 in 2000–4000) but may be more common in the presence of onchocerciasis. Proteinuria and renal failure may also occur. Intramuscular or intravenous pentamidine isethionate or pentamidine methanesulfonate are alternatives to suramin in *T. b. gambiense* infection and are usually well tolerated. Side-effects include a histamine-like reaction with hypotension and circulatory collapse, hypoglycemia and, after prolonged administration, hyperglycemias and diabetes; adrenaline (epinephrine) and glucose should be available when this drug is administered.

Meningoencephalitic trypanosomiasis

Melarsoprol is a trivalent arsenical compound that crosses the blood-brain barrier. A number of treatment schedules have been used, most lasting for 4–5 weeks. However, shorter 10-day treatment regimens have recently been shown to be effective in *T. b. gambiense* infection. [19] Thrombophlebitis and cellulitis following extravascular leakage are common (Fig. 157.6). The most important side-effect is reactive arsenic encephalopathy, which occurs in 2–10% of patients, usually after the third or fourth dose. Presentation is usually as an acute deterioration in conscious level often heralded by convulsions. There is an associated case fatality rate of 10–50%. Prophylactic prednisone (prednisolone) reduces the incidence of reactive arsenic encephalopathy in *T. b. gambiense* (but not *T. b. rhodesiense*) infection.[20]

Other toxicity is also common — a peripheral neuropathy occurs in up to 10% of patients and skin reactions, hepatic and renal toxicity are also seen; hemolysis may occur in glucose-6-phosphate dehydrogenase deficiency. Treatment with melarsoprol normally leads to a striking improvement in the mental and physical condition of patients with sleeping sickness. However, recent data suggest that rates of relapse following melarsoprol therapy are increasing.[18]

Figure 157-6 Treatment of a patient with an intravenous injection of melarsoprol. It is vital to adhere to the schedules of treatment and to have a scrupulous technique of injection in order to avoid destruction of local tissue as a result of leakages of the melarsoprol suspended in propylene glycol.

Eflornithine (difluoromethyl-ornithine, DFMO) is an ornithine decarboxylase inhibitor that is effective in the treatment of stage 1 and stage 2 *T. b. gambiense* infection but is poorly effective against *T. b. rhodesiense*. Most current regimens use intravenous administration, although oral preparations are being evaluated. The drug is less toxic than melarsoprol. Standard courses last 14 days; 7-day courses have been advocated but appear to be less effective in new cases of sleeping sickness. [21] Eflornithine may be particularly useful for the treatment of late-stage *T. b. gambiense* infection when the organism has become resistant to melarsoprol.

Nifurtimox is a drug that has occasionally been used in the treatment of arsenic-refractory *T. b. gambiense*, with reported response rates that vary from 50% to 80%. Its role is still being evaluated.[18]

Post-treatment follow-up

Following treatment, patients should be reviewed every 3 months for 6 months and then 6-monthly for 2 years to identify episodes of relapse, which may occur after both early and late-stage disease. In late-stage infection, the CSF abnormalities improve slowly after treatment and values usually return to normal within 1–2 years; CSF examination should be repeated before discharge and routinely at follow-up to detect parasites or a rising cell count. Relapse in *T. b. gambiense* following treatment with suramin or pentamidine is often treated with melarsoprol; eflornithine can also be used. Relapse in *T. b. rhodesiense* is usually treated with a second course of melarsoprol; nifurtimox may be effective if further relapse occurs but more data are needed.[2] Combination therapy has also been used in the treatment of relapse but there are inadequate data to determine its role at present.

Chapter 158 - Other Parasitic Infections of the Central Nervous System

Euan M Scrimgeour

This chapter reviews parasitic infections of the central nervous system (CNS), with brief reference to trypanosomiasis and cerebral malaria (see Chapter 146 , Chapter 157 , Chapter 166 and Chapter 173).

EPIDEMIOLOGY

Numerous species of protozoa and helminths parasitize man, especially in tropical and developing countries where environmental conditions promote mass transmission. Many sources of infection exist (Table 158.1). Table 158.2 lists parasites that can invade the CNS as adults, larvae or ova, depending upon the species, and gives their principal geographic distribution. It excludes parasitic Diptera, whose maggots occasionally invade the brain from the eye, nose or ear, and ticks that cause tick bite paralysis.

Many parasitic diseases are zoonoses. Examples, identifying the mammalian hosts, include:

- toxoplasmosis (cats and rodents),
- South American trypanosomiasis (domestic and wild animals),
- Rhodesian trypanosomiasis (antelopes, cattle),
- angiostrongyliasis (rodents),
- gnathostomiasis (fish-eating mammals),
- trichinosis (pigs and rats),
- toxocariasis (dogs and cats),
- schistosomiasis japonica (domestic animals and rodents), and
- echinococcosis (dogs and herbivores).

Gambian trypanosomiasis, schistosomiasis mansoni and schistosomiasis haematobium are essentially anthroponotic. In taeniasis solium (*T. solium*) humans are the definitive host but the larval cysticerci are found in pigs.

Relatively few parasites commonly involve the CNS. In some (e.g. *Plasmodium falciparum, Trypanosoma* spp., *Toxoplasma gondii, Angiostrongylus cantonensis* and *Taenia solium* (cysticercosis)), it is part of the life cycle. In others, it is accidental (e.g. eosinophilic meningoencephalitis caused by the racoon ascarid *Bayliscaris procyonis*).

Large populations are exposed to the risk of CNS parasitism. Worldwide, toxoplasmosis is probably the most prevalent neurotropic parasitosis. Schistosomiasis affects 200 million people, with prevalence rates of 10–80% in endemic areas. About 50 million individuals have African trypanosomiasis (prevalence 50–70/10,000 in endemic areas) and some 20 million — including thousands of migrants from South and Central America living in North America — have trypanosomiasis cruzi (Chagas' disease). In South East Asia and Oceania, angiostrongyliasis is common although diagnosis is infrequent.[1] Because CNS involvement is often underdiagnosed and silent, it is difficult to estimate prevalence and incidence rates. However, autopsy studies of patients with cysticercosis in Peru, Mexico, India and Zimbabwe have shown CNS infection rates of 0.5–3%, usually without clinical sequelae; in Mexico, 80% were asymptomatic.[2] Schistosomiasis japonica affects 70 million people and 2–5% of cases develop CNS complications.[3] Clinical evidence of CNS involvement is uncommon in infections with S. mansoni and S. haematobium, but autopsy studies in Zimbabwe, Nigeria, Egypt and Brazil have revealed ova in the brain in 3–28% and in the spinal cord in 0.3–2% of cases.[4] Worldwide, cerebral malaria is the most commonly diagnosed manifestation of CNS parasitism; in African children with severe falciparum malaria, 30–70% have this complication.[5]

PATHOGENESIS AND PATHOLOGY

Parasites invade the CNS as adults, larvae or ova, through the systemic circulation or retrogradely via the vertebral venous system (Fig. 158.1). Clinical sequelae depend upon the nature and number of parasites and the immune response. Immune evasion is exhibited by many parasites (e.g. *Toxoplasma gondii, Trypanosoma* spp.), with minimal tissue reaction.

In falciparum malaria, maturation of the trophozoite to the schizont requires sequestration of the parasitized erythrocyte by cytoadherence in capillaries, including those of the CNS. This is usually without clinical sequelae in immune subjects, but in cerebral malaria massive sequestration obstructs capillaries, the most plausible explanation for coma.[5] In acute African trypanosomiasis trypomastigotes rapidly invade the brain. They may become dormant but later, in stage II of the disease, especially in Gambian trypanosomiasis, they cause nonsuppurative encephalomyelitis (see Chapter 157).

Migrating larvae of the nematodes *Angiostrongylus cantonensis, Gnathostoma spinigerum, Toxocara canis* and *Toxocara cati, Trichinella spiralis*, occasionally *Loa loa, Mansonella perstans, Ascaris lumbricoides* and *Dirofilaria immitis* (the dog heartworm) produce transient focal cerebral lesions or eosinophilic meningoencephalitis.[6] [7] *Bayliscaris procyonis* and the saprophytic soil nematode *Micronema deletrix* have also been incriminated. *Angiostrongylus cantonensis*, and others that cannot complete their life cycle in humans, die after a few weeks.

Certain trematode ova and larvae can involve the CNS. In early schistosomiasis, anomalous migration of worms to the CNS is followed by a cell-mediated response to ova deposition to form a periovular granuloma.[8] When the subsequent humoral response to adult worms and egg antigens is excessive, Katayama fever occurs, especially in *Schistosoma japonicum* infection, with fever, eosinophilia and self-limiting encephalopathy or myelopathy. In chronic schistosomiasis, retrograde passage of ova and occasionally worms, through Batson's vertebral venous plexus, may result in myelopathy or cerebral lesions. This also occurs in *S. haematobium* infection with obstructive uropathy. When hepatosplenic schistosomiasis develops, ova pass through portopulmonary anastomoses to the lungs and reach the systemic circulation through arteriovenous shunts or by pulmonary veins (see Fig. 158.1). Schistosomal cor pulmonale also promotes cerebral embolization of ova. Ova in the CNS may incite little histologic reaction, but the development of a granuloma, focal vasculitis, localized infarction or rarely subarachnoid or cerebral hemorrhage can result.[4] In paragonimiasis, flukes migrate from lung to brain through the soft tissues of the neck.

TABLE 158-1 -- Sources of parasite infection and resulting disease.

SOURCES OF PARASITE INFECTION AND RESULTING DISEASE		
Source of infection		**Disease**
Food	Salads	Amebiasis, angiostrongyliasis, ascariasis, cysticercosis
	Raw aquatic plants	Fascioliasis
	Uncooked vegetables	Angiostrongyliasis, echinococcosis, cysticercosis
	Uncooked pork	Trichinosis, taeniasis solium, sparganosis
	Uncooked beef	Toxoplasmosis
	Uncooked freshwater fish	Gnathostomiasis, diphyllobothriasis, heterophyiasis, metagonimiasis
	Uncooked freshwater crayfish or crabs	Paragonimiasis, angiostrongyliasis
	Uncooked snakes, frogs*	Sparganosis
	Uncooked land molluscs (e.g. *Achatina fulica* snails)	Angiostrongyliasis
Fresh water	Skin contact	Schistosomiasis
	Nasal contact	*Naegleria fowleri* meningoencephalitis
	Consumption	Sparganosis, dracontiasis, amebiasis

Other environmental sources	Geophagy	Toxoplasmosis, toxocariasis, ascariasis, hydatidosis
	Soil	Strongyloidiasis
	Airborne	*Acanthamoeba castellani* meningoencephalitis, ascariasis
Arthropods	Mosquito (*Anopheles* spp.)	Falciparum malaria
	Mosquito (*Culex* spp.)	Bancroftian filariasis, dirofilariasis
	Midge (*Culicoides* spp.)	Mansonellosis
	Tsetse fly (*Glossina* spp.)	Rhodesian and Gambian trypanosomiasis
	Blackfly (*Simulium* spp.)	Onchocerciasis
	Chrysops flies	Loiasis
	Reduviid bugs (e.g., *Triatoma* spp.)	American trypanosomiasis (Chagas' disease)
Other sources	Blood transfusion/contaminated syringes and needles	Falciparum malaria, American trypanosomiasis (Chagas' disease) toxoplasmosis
	Cardiac, renal transplant	Toxoplasmosis
	Transplacental	American trypanosomiasis (Chagas' disease), toxoplasmosis
	Autoinfection‡	Cysticercosis, strongyloidiasis

* In South East Asia, frogs applied as a poultice may transmit sparganosis
† Patient with taeniasis solium inadvertently consumes eggs he or she has passed in feces

In cysticercosis, the larval oncospheres reach cerebral and meningeal capillaries and mature to cysticerci in the gray matter and meninges. The spinal cord is largely spared. Cysticerci survive silently for 2–10 years. Intense inflammation follows their death and antibodies appear in the cerebrospinal fluid (CSF). Healing, with fibrosis and calcification, follows. If the oncosphere enters the subarachnoid space or ventricles, then chronic meningitis with hydrocephalus may result.[2] Rarely, parasites produce large cystic lesions (e.g. in paragonimiasis, hydatidosis and coenurosis). In dracontiasis an extradural abscess containing an adult worm may compress the spinal cord, and in diphyllobothriasis an adult tapeworm competes with the host for vitamin B12 and can produce myelopathy (see Chapter 168).

Immunodeficiency and central nervous system parasitism

Immunodeficient patients are susceptible to the same parasites as the immunocompetent. Falciparum malaria is not more common in patients with HIV/AIDS but the parasite count may be increased. In toxoplasmosis, following acute infection, cysts containing the resting phase bradyzoites remain dormant in muscle, heart, brain or choroid for decades. (The risk of a nonimmune subject developing toxoplasmosis following organ transplant from a seropositive donor is 50% for cardiac and 20% for renal transplant.) In immunodeficiency states (e.g. AIDS, leukemia and lymphomas, inherited immunodeficiency syndromes, systemic lupus erythematosus, immunosuppressive drug therapy, radiotherapy, etc.), reactivation of bradyzoites produces multiplying tachyzoites, with cerebral abscess formation (see Chapter 127). Reactivation results from impaired interferon-? dependent cell-mediated and humoral immunity.[10] In AIDS, this occurs when the CD4 lymphocyte count falls below 350 cells/mm^3 . Trypanosomiasis cruzi spares the brain in the immunocompetent (except children), but in immunodeficiency (in AIDS, CD4 cell count <200/mm^3), often after symptom-free decades, reactivation produces cardiomyopathy and acute, multifocal, necrotizing meningoencephalitis or a cerebral granuloma.[10] Other opportunistic parasites that invade the CNS include free-living amoebae (eg. *Acanthomoeba culbertsoni* and *Balamuthia mandrillaris*), which produce chronic granulomatous meningoencephalitis, [11] and the intestinal microsporidium *Encephalitozoon cuniculi*, which disseminates to produce encephalopathy.[12] Some *Strongyloides stercoralis* larvae normally hatch in the jejunum, penetrate the intestinal mucosa, migrate through the lungs and return to the jejunum as adults. In immunodeficiency, especially in human T-cell lymphoma virus 1 (HTLV-1) infection, *Strongyloides* hyperinfection may develop with massive tissue invasion, encephalitis and complicating *Escherichia coli* meningitis.

PREVENTION

Control and prevention of parasite infections are based on health education for exposed populations and visitors to endemic regions (see Table 158.1) and implementation of public health measures. Vector control includes destruction of breeding habitats, spraying with insecticides and controlling freshwater snails. As a rule, it is impossible to control zoonoses effectively.

Important personal precautions include (see also Chapter 143):

TABLE 158-2 -- Parasites that cause generalized or focal or space-occupying lesions and their principal geographic distribution.

PARASITES THAT CAUSE GENERALIZED OR FOCAL OR SPACE-OCCUPYING LESIONS AND THEIR PRINCIPAL GEOGRAPHIC DISTRIBUTION			
Parasite		**CNS disease**	**Geographic distribution**
Protozoa	*Acanthamoeba castellani*[*]	Meningoencephalitis	Worldwide
	Balamuthia mandrillaris	Meningoencephalitis	Worldwide
	Encephalitozoon cuniculi	Encephalitis	Worldwide
	Entamoeba histolytica[*]	Meningoencephalitis	Tropics, subtropics
	Naegleria fowleri[*]	Meningoencephalitis	Worldwide
	Plasmodium falciparum	Cerebral malaria	Tropics, subtropics
	Toxoplasma gondii	Encephalitis, SOL brain	Worldwide
	Trypanosoma brucei gambiense	Encephalitis	West Africa eastward to Rift Valley
	Trypanosoma brucei rhodesiense	Encephalitis	Central and East Africa
	Trypanosoma cruzi	Meningoencephalitis	Central and South America
Helminths			

Nematodes	*Angiostrongylus cantonensis*	Meningoencephalitis	South East Asia, Oceania
	Ascaris lumbricoides[*]	SOL brain	Worldwide
	Bayliscaris procyonis[*]	Meningoencephalitis	North America
	Mansonella perstans[*]	Meningoencephalitis	Tropical Africa
	Dirofilaria immitis[*]	Meningitis	Worldwide
	Dracunculus medinensis[*]	SOL spinal cord	Tropical Africa, Asia and Brazil
	Loa loa[*]	Meningoencephalitis	Central and West Africa
	Gnathostoma spinigerum	Meningoencephalitis	Far East
	Micronema deletrix[*]	Meningoencephalitis	North America
	Onchocerca volvulus[*]	SOL brain	West Africa, South America, Yemen
	Strongyloides stercoralis[*]	Meningoencephalitis	Tropics, subtropics
	Trichinella spiralis	Meningoencephalitis	Worldwide
	Toxocara canis, Toxocara cati	SOL brain	Worldwide
	Wuchereria bancrofti[*]	SOL brain	Tropics, subtropics
Trematodes	*Fasciola hepatica*[*]	SOL brain	Worldwide, sheep-farming countries
	Heterophyes heterophyes[*]	SOL brain and cord	Far East, Middle East
	Metagonimus yokogawi[*]	SOL brain and cord	Far East, Europe
	Paragonimus westermani	SOL brain and cord	Far East, tropical Africa, South America
	Schistosoma japonicum	SOL brain and cord	Far East, Philippines, Indonesia (Sulawesi)
	Schistosoma mansoni	SOL brain and cord	Africa, Middle East, South America
	Schistosoma haematobium	SOL brain and cord	Africa, Middle East
	Schistosoma intercalatum	Myelopathy	Sâo Tomé e Príncipe
Cestodes	*Diphyllobothrium latum*[*]	Myelopathy	Russia, Canada and subartic Europe
	Echinococcus granulosus (hydatidosis)	SOL brain and cord	Worldwide
	Echinococcus multilocularis[*]	SOL brain and cord	Northern Europe, Canada, Japan
	Spirometra spp. (sparganosis)[*]	SOL brain and cord	South East Asia, North America
	Taenia multiceps (coenurosis)[*]	SOL brain and cord	Worldwide
	Taenia solium (cysticercosis)	SOL brain and cord	Worldwide, South America
SOL, space-occupying lesion.			
Parasites of the order Diptera, whose maggots may invade the CNS, and ticks that cause tick bite paralysis are excluded. Note that related species of some parasites listed produce similar symptomology (e.g. *Angiostrongylus mackerrasae* in Queensland, Australia, *Angiostrongylus malayensis* in Malayasia and Indonesia, and numerous *Paragonimus* spp. in different parts of the world).			

* CNS disease is infrequent or rare.

- avoidance of drinking water or eating salads or uncooked food (vegetables, meat, freshwater fish, crustaceans or terrestrial molluscs) in regions where contamination by various protozoa and helminths is probable;
- efforts to discourage children from geophagy (risk of toxoplasmosis and toxocariasis from cat and dog excreta, respectively);
- regular anthelmintic treatment of pet dogs and cats;
- prevention of skin exposure to fresh water in regions endemic for schistosomiasis;
- prevention of arthropod bites (protective clothing, use of insect repellent creams and mosquito nets);
- effective prophylaxis for falciparum malaria;
- screening patients who have been exposed to strongyloidiasis prior to immunosuppressive therapy; and
- trimethoprim-sulfamethoxazole prophylaxis for toxoplasmosis in AIDS when the CD4 count falls below 350/mm^3 .

CLINICAL FEATURES

Most parasitic CNS infections lack specific diagnostic features. Diagnosis depends on suspecting a parasitic etiology and obtaining a history of residence in an endemic area (at any time from recent to remote, depending upon the parasite suspected), when exposure to infection may have occurred. The latter often requires a searching inquiry because patients are usually ignorant of the ways in which infection is contracted. Clinicians unfamiliar with this complex field must refer to a differential diagnosis checklist, remembering that multiple parasite infections are common in the tropics.

Major neurologic syndromes

Cerebral malaria

Fever, coma, absence of meningitis or focal neurologic signs (in the early stages) and presence of falciparum trophozoites in the blood

Figure 158-1 Potential routes to the brain and spinal cord for parasitic protozoa and helminths. Collateral circulation (e.g. in hepatosplenic schistosomiasis with portal hypertension) allows ova to embolize via portopulmonary anastomoses to the lung and thence to the systemic circulation. Batson's vertebral venous plexus allows retrograde access to the spinal cord and brain by parasites and/or ova.

suggest cerebral malaria. Alternative causes in a person who coincidentally has falciparum parasitemia include encephalitides, various systemic and toxic infections, and heat stroke.[5]

Trypanosomiasis

In stage II of African trypanosomiasis (sleeping sickness), chronic encephalomyelitis develops. This presents with change of personality, apathy, extrapyramidal signs

including tremor, chorea, expressionless facies and reversal of sleep rhythm (see Chapter 157). Acute American trypanosomiasis causes meningoencephalitis in children.

Meningitis or meningoencephalitis

A specific helminthic cause is suggested by periorbital edema and generalized myositis (trichinosis) or subcutaneous migratory swellings followed by CNS complications (gnathostomiasis).[6] In angiostrongyliasis (history of eating raw *Achatina* snails), signs may fluctuate markedly; the patient may have headache, confusion, severe generalized dysesthesia, neck stiffness and various focal neurologic signs but later the same day the patient may be almost symptom free. Fever is often absent.[1] [7] Other migrating larval nematodes can produce similar variable features.

Focal or space-occupying lesions

Parasitic space-occupying lesions in the CNS are usually without diagnostic features (see Table 158.2). However, cysts in the third ventricle (e.g. cysticercus, hydatid or coenurus cysts) cause intermittent internal hydrocephalus with periodic headache and loss of consciousness.

Toxoplasmosis

Immunodeficient patients developing reactivation toxoplasmosis, with abscess formation usually in the basal ganglia, present with low-grade fever, headache, seizures, raised intracranial pressure and hemiparesis. Diffuse encephalitis is less frequent.

Cysticercosis

Acute infection presents with headache, diffuse hyperesthesia and myalgia. The first manifestation may be seizures, developing months or years after exposure to infection. Careful examination of the whole skin surface may reveal firm, painless, pea-sized, subcutaneous nodules in 50% or more of patients.[2] Differentiation from other causes of seizures is required.

Schistosomiasis

In *S. japonica* infection, and less frequently in *S. mansoni* and *S. haematobium* infections, ova in the CNS may cause seizures or present as a space-occupying lesion. There may be no other evidence of schistosomiasis.

Myelopathy

Myelopathy is uncommon in parasitic infection, except in schistosomiasis. [14] Asymptomatic deposition of ova in the spinal cord is frequent in *S. haematobium* infection but *S. mansoni* is the usual cause of myelopathy; it is uncommon in *S. japonicum* infection. *S. intercalatum* was incriminated in two cases from Sâo Tomé e Príncipe. The usual presentation is acute, flaccid, areflexic paraparesis caused by a granuloma in the conus medullaris but spasticity is present in higher lesions. Acute massive necrosis of the lower cord, presumably immunologically mediated, has been described in Brazil. The differential diagnosis includes tuberculosis, neoplasia and HTLV-1 infection. In diphyllobothriasis, megaloblastic anemia is present in association with posterior column degeneration.

Ophthalmic involvement by parasites

Reports of direct or immunologic involvement of the eye by parasites are extensive and include the following.

- Iritis: *Toxoplasma gondii, Trypanosoma gambienese* and *rhodesiense, Leishmania donovani, Onchocerca volvulus, Wuchereria bancrofti, Dirofilaria immitis, Toxocara* spp., *Gnathostoma spinigerum* and cysticerci.
- Choroidoretinitis: *T. gondii* (bilateral, congenital; unilateral, acquired), *O. volvulus, Angiostrongylus cantonensis, Toxocara* spp., *Loa loa, Schistosoma mansoni*, cysticerci and *Armillifer armillatus* (pentastomid larvae).
- Optic neuritis: *T. gondii, Trypanosoma gambiense* and *rhodesiense, O. volvulus, A. cantonensis* and *Paragonimus westermani*.
- Orbital myositis: *Trypanosoma cruzi*.
- Orbital or retro-orbital mass or lesion: *Trichinella spiralis, G. spinigerum, S. mansoni, Fasciola hepatica, P. westermani, Echinococcus granularis* cyst, cysticerci and *Taenia brauni* coenurus (in tropical Africa).

The maggots of various Diptera can invade the eye (e.g. *Oestrus ovis*), ear or nose (e.g. *Cochliomyia hominivorax*), rarely extending to the brain.

Tick bite paralysis

In Australia, Africa, America and south east Europe, various hard (ixodid) and soft (argasid) ticks possess salivary neurotoxins. Between 1 and 6 days after it starts feeding, symmetric, ascending, flaccid paralysis appears, reaching the facial and bulbar muscles. Pain, fever and sensory abnormalities are absent. Death may result from respiratory failure. Recovery follows removal of the tick.

DIAGNOSIS

Cerebral malaria

The demonstration of ring forms of *Plasmodium falciparum* in the blood and exclusion of other causes of coma (including normal CSF) are the basic diagnostic criteria.

African trypanosomiasis: sleeping sickness

Trypanosomes may be present in blood films. The enzyme-linked immunosorbent assay (ELISA) IgM is positive in 90%. Suramin is given prior to lumbar puncture (LP) to destroy blood tryptomastigotes that might otherwise enter the CSF. The CSF contains lymphocytic pleocytosis, raised protein and normal glucose levels and occasionally motile tryptomastigotes. Polymerase chain reaction (PCR) may detect *Trypanosoma* DNA in CSF. Computerized tomography (CT) and magnetic resonance imaging (MRI) scans show brain edema (see also Chapter 157).

Meningitis or meningoencephalitis

Examination of the CSF is essential. This is often deferred if papilledema or CT scan evidence of raised intracranial pressure is present, but if an early diagnosis is critical (e.g. to detect tuberculous meningitis) cisternal or LP to aspirate a small sample of CSF is justified. In protozoal infections, lymphocytosis, normal glucose and mildly raised protein levels are typical. Similar findings are present in helminthic meningoencephalitis, but eosinophilia is usually present. Nonparasitic causes of eosinophilic meningitis include Hodgkin's disease, polyarteritis nodosa and occasionally bacterial or viral meningitis. Micro-organisms observed include amebae in primary amebic meningoencephalitis, tryptomastigotes in African trypanosomiasis and in *T. cruzi* infections in children (and immunodeficient adults), and occasionally larval worms in angiostrongyliasis and in disseminated strongyloidiasis.

Other investigations may point to the diagnosis. Stool may contain larvae in strongyloidiasis and sputum ova or larval worms in many helminthic infections (see Chapter 165 and Chapter 246). In filarial diseases, microfilariae may appear in the peripheral blood at night (Bancroftian filariasis), at noon (loiasis) or at any time (mansonellosis) or in a skin snip (onchocerciasis). In trichinosis, biopsy of a tender muscle may reveal larvae.

Focal or space-occupying lesions

Basic parasitologic investigations may explain focal or space-occupying lesions. The stool may contain ova in *S. mansoni* and *S. japonicum* infections, paragonimiasis, fascioliasis, heterophyiasis, metagonimiasis and diphyllobothriasis. The terminal drops of urine may contain ova of *S. haematobium*. Multiple rectal snips may reveal

schistosome ova of all species. In paragonimiasis, and occasionally schistosomiasis, the sputum contains ova.

The CSF in toxoplasmosis and cysticercosis reveals a lymphocytic pleocytosis and raised protein and occasionally reduced glucose levels. In schistosomiasis, a modest lymphocytosis is typical and protein and glucose levels are usually normal, whereas in paragonimiasis, eosinophilia is accompanied by raised protein levels. Eosinophilia is present in only 25% of cases of cerebral hydatidosis.

Immunodiagnostic tests for protozoa and helminths (see Chapter 245 and Chapter 246).

When organisms cannot be detected, antibody or antigen detection tests in serum and/or CSF confirm exposure or support diagnosis.[14] Investigations include immunoblot, monoclonal antibody tests and PCR for DNA detection. Immunodiagnosis is especially useful in the following: toxoplasmosis (ELISA, PCR for antigens); trypanosomiasis; neurocysticercosis (ELISA is 90% specific in blood, and almost 100% in CSF; immunoblot may be negative if few cysticerci are present); echinococcosis (IHAT positive in 60% of sera); and schistosomal myelopathy (ELISA in the CSF is positive in >75% of cases). To confirm active infection with *T. cruzi*,[15] xenodiagnosis is performed utilizing laboratory-raised vector reduviid bugs to feed on the patient (see Chapter 173).

Ultrasonography of the liver or CT or MRI scans of the abdomen detect amebic and hydatid hepatic cysts (the latter calcify), *F. hepatica* flukes in bile ducts or periportal fibrosis (pathognomonic of hepatosplenic schistosomiasis). Chest radiography and CT scans may reveal pulmonary paragonimiasis, hydatid cyst (non-calcifying) or schistosomal cor pulmonale. In schistosomal myelopathy, myelography typically reveals an intramedullary lesion of the conus with a complete block between T12 and L1. Computerized tomography or MRI may identify a granuloma; occasionally diffuse cord edema is observed, as in the Katayama syndrome.

Computerized tomography and MRI scans assist diagnosis of cerebral parasitic space-occupying lesions. Toxoplasmosis presents as one or more low-density lesions, usually ring enhancing (Fig. 158.2). In early cysticercosis, small nonenhancing hypodense lesions are present. Later, a hyperdense center (the scolex) develops (Fig. 158.3), with ring enhancement when it dies (Fig. 158.4). Finally, calcification supervenes.[2] Plain radiographs may show multiple calcified cysticerci in muscle. In hydatid cyst, the CT scan is the most definitive investigation; dead cysts calcify. The CT/MRI scan in paragonimiasis reveals cystic calcified lesions containing flukes, in schistosomiasis a contrast-enhancing granuloma, and in sparganosis a granuloma containing a worm. Other investigations (e.g. gallium-67 scans and positron emission tomography) are useful but non-specific for identifying inflammatory foci.

Finally, whenever the diagnosis is in doubt, brain or spinal cord biopsy under CT guidance is required.

Immunodeficient patients

Meningitis in immunodeficiency (e.g. AIDS) is more likely to be caused by cryptococcosis or tuberculosis than parasites. In meningoencephalitis in South or Central American patients, Chagas' disease should be considered. Rarer causes include chronic granulomatous meningoencephalitis (caused by *Acanthomoeba culbertsoni* or *Balamuthia mandrillaris*) diagnosed by brain biopsy. Encephalopathy in disseminated microsporidiosis is diagnosed by identifying *Encephalitozoon cuniculi* cysts in the urine. Cerebral space-occupying lesions are most likely to be caused by toxoplasmosis (10% of cases in North America, up to 50% in Africa) or tuberculoma. In North America, 2% are due to primary CNS lymphomas; the specific investigation is thallium-201 single photon emission CT. In South America, a 'chagoma' caused by *T. cruzi* should be considered (Fig. 158.5). Many other opportunistic infections can produce space-occupying lesions (e.g. nocardiosis, cryptococcoma, aspergilloma and syphilitic gumma). Myelopathy is most likely to be caused by tuberculosis but many other causes, including toxoplasmosis and HTLV-1 infection, must be considered.

MANAGEMENT

Specific treatment of parasite infections listed in Table 158.1 is discussed in the relevant chapters. Here, the management of the major CNS parasitic disease syndromes is summarized.

Cerebral malaria

Any comatose patient who has suspected or diagnosed falciparum malaria should be treated at once with intravenous quinine (after assessing blood glucose), pending further evaluation (see Chapter 166). Corticosteroid drugs are not helpful.

African trypanosomiasis: sleeping sickness

Suramin is given to clear trypanosomes from the blood. After 1 week, melarsoporol is administered. Eflornithine is effective in Gambian trypanosomiasis only (see Chapter 157 and Chapter 209).

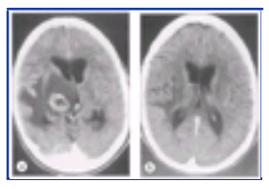

Figure 158-2 Toxoplasma abscess. (a) This CT brain scan shows a toxoplasma abscess in the left internal capsule, compressing the lateral ventricles. Contrast demonstrates a typical ring-enhancing effect. (b) Same patient after 17 days of treatment with pyrimethamine and sulfonamide showing resolving abscess.

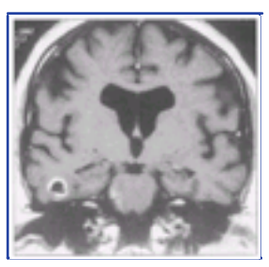

Figure 158-3 Coronal MRI of brain showing living cysticercus, with the scolex appearing as a hyperintense center ('pea in the pod' appearance). There is no visible inflammatory reaction.

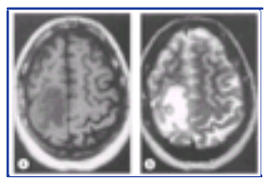

Figure 158-4 Cerebral cysticercus. (a) This MRI of brain shows a dying cysticercus surrounded by intense inflammation. (b) Post-contrast MRI T2-weighted image demonstrating the isointense wall of the cyst and surrounding hyperintense edema.

Meningitis and meningoencephalitis

When a parasitic cause is diagnosed, corticosteroid treatment (prednisolone 1–2mg/kg/day) should be considered if there is raised intracranial pressure or if the patient is seriously ill. If

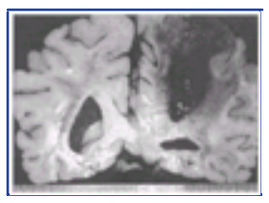

Figure 158-5 Extensive necro-hemorrhagic lesions of the right cerebral hemisphere in an AIDS patient with reactivated acute Chagas' disease. *Courtesy of Professor L Chimelli.*

specific treatment is lacking (e.g. in angiostrongyliasis, trichinosis, gnathostomiasis and toxocariasis), it may be the only option other than repeated LP to reduce pressure. Diethylcarbamazine and thiabendazole have been tried in toxocariasis and albendazole in gnathostomiasis (together with corticosteroids) with some evidence of benefit.

Focal or space-occupying lesions

In cystericercosis, when living cysticerci are present, praziquantel (without corticosteroids, which reduce its efficacy) 10–20mg/kg q8h for 21 days, sometimes increased to 25mg/kg q8h for up to 30 days,[2] is advocated. Albendazole (with preceding corticosteroid therapy) 15mg/kg/day for 1 week has replaced praziquantel in some centers. Seizures are controlled by anticonvulsants. Despite the apparent benefit of these drugs, if untreated, the majority of cysts disappear without sequelae within 1 year. Surgery should be avoided unless the cysticercus is blocking the third ventricle.

In schistosomiasis, praziquantel 40mg/kg is routinely given as a single dose; 60mg daily for 3 days may achieve more complete eradication of worms. Suspected schistosomal myelopathy should be treated conservatively with praziquantel. When this develops acutely in the Katayama syndrome, with edema of the spinal cord (Fig. 158.6), adjunctive, high-dose corticosteriod treatment is essential. Schistosomal myelopathy may improve even after several months of paraplegia. Surgery is required if there is deterioration despite treatment. If schistosomal myelopathy is encountered unexpectedly at operation, only a biopsy should be obtained.[4] It is difficult to know when schistosomiasis has been cured; antibody titers decline slowly and antigen detection may be negative although some worms persist (see Chapter 167).

Cerebral paragonimiasis is treated conservatively with praziquantel or bithionol. Hydatid cysts are completely excised, first administering praziquantel or albendazole. Surgical resection is required for a sparganum and for a coenurus (with adjunctive praziquantel).

Figure 158-6 MRI of the spinal cord of a 9-year-old Omani boy with acute schistosomiasis mansoni, who presented with transverse myelitis (vertical scale in cms). Extensive cord edema from the first thoracic vertebral level to the conus medullaris is present (arrows). He recovered and was ambulant after 2 weeks treatment with prednisone and praziquantel.

Treatment of central nervous system parasitism in immunodeficiency

Standard treatment applies for most parasitic infections. The immune status should be improved if possible (e.g. highly active antiretroviral treatment in AIDS). If brain biopsy is not possible, empiric treatment for suspected toxoplasmosis in an IgG-seropositive patient (IgM remains negative) is pyrimethamine and sulfadiazine or high-dose trimethoprim-sulfamethoxazole. A convincing response within a week to 10 days supports the diagnosis. Lifelong trimethoprim-sulfamethoxazole prophylaxis follows recovery. When *Toxoplasma* IgG is negative, an intracerebral space-occupying lesion is treated either as a tuberculoma or a primary CNS lymphoma. In South America, early treatment of Chagas' meningoencephalitis (which may coexist with toxoplasmosis) with benznidazole is imperative. No effective treatment for chronic granulomatous meningitis exists (see Chapter 173 and Chapter 244). Cerebral microsporidiosis (*Encephalitozoon cuniculi*) is almost invariably fatal, but has responded temporarily to albendazole (Chapter 209 and Chapter 243). Hyperinfection with strongyloidiasis responds to ivermectin and broad-spectrum antibiotics for the usual coexistent *E. coli* meningitis.

Chapter 159 - Epidemic Bacterial Meningitis

Montse Soriano-Gabarró
Nancy E Rosenstein
Robert Pinner
David Stephens

INTRODUCTION

Bacterial meningitis remains a major cause of morbidity and mortality throughout the world. *Neisseria meningitidis* is unique among major causes of bacterial meningitis for its ability to cause large epidemics, especially in sub-Saharan Africa. This chapter focuses on *N. meningitidis* (the meningococcus) and epidemic bacterial meningitis.

EPIDEMIOLOGY

Although acute bacterial meningitis can be caused by a variety of organisms, until recently three-quarters of all cases were caused by *Haemophilus influenzae* type b (Hib), *Streptococcus pneumoniae* and *N. meningitidis*.[1] The introduction of effective Hib conjugate vaccines in industrialized countries has led to a dramatic decline in the incidence of Hib meningitis and other invasive Hib disease.[2] The Hib conjugate vaccines are progressively being introduced into routine childhood vaccination programs in developing countries with the support of the Global Alliance for Vaccines and Immunizations (GAVI), the World Health Organization (WHO) and other partners (http://www.vaccinealliance.com). Routine use of a new 7-valent pneumococcal conjugate vaccine in infants has recently been adopted in the USA.[3] Additional vaccine and disease burden data are needed to inform decision-making for the introduction of pneumococcal conjugate vaccines in developing countries. Serogroup C meningococcal conjugate vaccines have been developed and have been introduced in the UK, other European countries and Canada.[4] Other meningococcal conjugate vaccines are under development.[5]

Haemophilus influenzae type b, pneumococci and meningococci can each cause sporadic disease and case clusters, but *N. meningitidis* is the major agent of epidemic bacterial meningitis. Endemic meningococcal disease is estimated to cause 120,000 cases per year worldwide; during epidemics, attack rates can reach 1000 times baseline rates. When epidemic meningococcal disease occurs, it commands public health attention and calls for a large-scale public health response.[6] The case-fatality rate of meningococcal disease is 5–25% and, among survivors, there is also considerable morbidity, including persistent neurologic sequelae.

Humans are the only natural host of meningococci. The organisms are spread through close contact with nasopharyngeal secretions. Only a fraction of those who are exposed to meningococci develop clinical infections; 10% of individuals carry the organism asymptomatically in the nasopharynx and can transmit it to others.

The African meningitis belt (Fig. 159.1), originally characterized by Lapeysonnie in 1963,[7] is a broad region that extends from Ethiopia in the east to Senegal in the west and includes portions of 10–15 countries.[7] [8] The following three consistent epidemiologic features characterize epidemics in the African meningitis belt:

- an increase in the rate of meningococcal disease compared with historic trends;
- a shift in age-specific incidence rates, with a higher proportion of disease in older children and young adults; and
- clonality of the organism causing epidemics.

In this region, high rates of sporadic infections (1–20 cases per 100,000 population) occur in annual cycles with large-scale epidemics (usually caused by serogroup A but occasionally by serogroup C and more recently by serogroup W-135) superimposed periodically. In the countries of the African meningitis belt, epidemics with incidence rates as high as 1000 cases per 100,000 population have occurred every 8–12 years over at least the past 50 years. In addition, major epidemics have occurred in adjacent countries not usually considered part of the African meningitis belt (e.g. Kenya, Tanzania).

In periods of endemic disease the highest attack rates occur among young children but during some epidemic situations a higher proportion of cases occur in older children and young adults.[9] Small local epidemics, often unrecognized at a national level, may precede major epidemics. Typically, once an epidemic begins to expand, it does so rapidly, reaching a peak within a few weeks and, in the absence of extensive vaccination, lasting for several months. A countrywide epidemic may consist of a series of smaller epidemics, centered at the village or province level.

Neisseria meningitidis can be classified into serogroups based on the structural and antigenic differences in the capsular polysaccharide expressed. The epidemic potential varies among the serogroups. Among the nine serogroups that cause invasive disease, serogroups A, B, C and, more recently, W-135 have been associated with epidemic disease. Less common serogroups, including Y and X, have also recently been associated with disease clusters in some parts of the world.[10]

Serogroup A

Although epidemics of serogroup A meningococcal disease were common in industrialized countries early in the 20th century, they have been rare or absent in these countries since the end of the Second World War. In the past 20 years, limited epidemics concentrated among groups of low socio-economic status have occurred in Finland and New Zealand, with attack rates below 15 cases per 100,000 people in the population. In contrast, in the developing world, attack rates can exceed 1% of the population. In the past 20 years, intense group A epidemics have occurred in Brazil, Mongolia, Nepal and various regions in sub-Saharan Africa.

Between 1996 and 1998, the largest epidemic ever reported (over 350,000 cases — probably a substantial underestimate) occurred in the African meningitis belt, with more than 10 countries recording large increases in the number of cases of serogroup A meningococcal disease. Although rapid detection and early response to epidemics can reduce illness and deaths through prompt vaccination campaigns, the region was not adequately prepared to implement comprehensive control efforts. The medical and economic impact of this epidemic was substantial. Essential services and personnel were diverted and limited health budgets strained to cope with the epidemic.

The potential for global dissemination of an epidemic-associated serogroup A strain is evident from an epidemic caused by one clonal group, identified by multilocus enzyme electrophoresis (MLEE) as

Figure 159-1 The African meningitis belt.

ET-III-1 complex. Epidemics of group A meningococcal disease caused by this clonal group occurred in Nepal in 1983 and 1984, and in Pakistan and New Delhi, India, in 1985, and may have caused earlier epidemics in China. In 1987, an epidemic of group A meningococcal disease caused by ET-III-1 strains occurred in association with the annual Moslem pilgrimage (Hajj) to Mecca.[11] The epidemic started among persons from south Asian countries, including Nepal. As the pilgrims returned to their home countries, meningococci belonging to this complex were carried throughout the world, causing secondary epidemics among pilgrims and their contacts and eventually in their immediate communities. Isolated secondary cases did occur in industrialized countries but, for reasons not entirely clear, did not spread to the general community.[12] In 1987, strains belonging to the ET-III-1 complex then caused widespread epidemics in the meningitis belt of sub-Saharan Africa, including countries traditionally considered outside the meningitis belt, such as Kenya (1989), Tanzania (1990) and Burundi (1992). During 1996, ET-III-1 strains were again responsible for the large epidemics that occurred in the African meningitis belt. Other large-scale movement or displacement of populations, such as refugees, may pose similar risks.

Serogroup B

Serogroup B meningococcal disease, a major cause of sporadic disease in industrialized countries, has been associated with epidemics with attack rates of between 10 and 50 per 100,000 population, which are generally lower than in the major serogroup A epidemics. In the late 1970s, a serogroup B strain belonging to a clonal group known as ET-5 emerged in north western Europe and caused epidemics in Norway (1974–5), the UK (1974–6), Iceland (1976) and Denmark (1981). [13] Intercontinental spread of clones from this group has been documented and was probably responsible for subsequent epidemics in Cuba (1980), Chile (1985) and Brazil (1987). Starting in 1989, an epidemic of serogroup B meningococcal disease occurred in Oregon and Washington, USA, due to the ET-5 clone, with attack rates peaking in 1996 that were seven times higher than the US national average;[14] since 2001 these rates have decreased. An ongoing serogroup B epidemic has been affecting New Zealand since 1991 with annual rates of 16.9 cases per 100,000 population; highest incidence rates are found among Maori and Pacific Island children.[15]

Serogroup C

Serogroup C meningococcus, like serogroup A, can cause endemic disease, small clusters and major epidemics, such as those that occurred in Brazil (1972) and Vietnam (1977). Although attack rates in serogroup C epidemics are usually lower than in serogroup A epidemics, they can reach high levels. During a serogroup C epidemic in Burkina Faso in 1979, attack rates exceeded 500 cases per 100,000 population. Serogroup C strains identified as a single enzyme complex, ET-37, have been found to be responsible for a number of recent epidemics and a large proportion of cases of endemic disease in the USA, Canada, Europe and Latin America.

Serogroup Y

Serogroup Y meningococcal disease has been recognized as a cause of endemic disease in some populations in the USA since the 1970s. Beginning in 1988, the proportion of meningococcal disease due to serogroup Y increased in the USA from 2% (in 1988–91) to 26% (in 1996–8). From 1999–2001, about one-third of meningococcal disease in the USA was due to serogroup Y.[16] Smaller increases have been reported in Canada, Sweden and Israel. Serogroup Y is often associated with pneumonia and disease among older age groups, as compared with serogroups B and C.

Serogroup W-135

Serogroup W-135 meningococcus has recently emerged as a cause of epidemic disease. This serogroup is responsible for only 2–5% of endemic disease worldwide. However, an epidemic of serogroup W-135 meningococcal disease occurred concurrently with a serogroup A epidemic during the 2000 Hajj in Saudi Arabia, with a serogroup W-135 attack rate of 9 cases per 100,000 population. The serogroup W-135 isolates causing the epidemic belonged to the ET-37 complex as defined by MLEE and were designated as the (W)ET-37 clone.[17] In 2000 and 2001, following this epidemic, cases of serogroup W-135 meningococcal disease were identified in Europe, North America, the Middle East, Asia and Africa, associated with returning Hajj participants or their contacts. Carriage of serogroup W-135 meningococci was observed among returning Hajj pilgrims.[18] [19]

In 2002, the first major W-135 meningococcal disease epidemic occurred in Burkina Faso. More than 13,000 suspected meningitis cases and 1,400 deaths were reported, with an overall attack rate of 104 cases per 100,000 population (Ministry of Health/WHO/Centers for Disease Control and Prevention (CDC), unpublished data).[20] Serogroup W-135 isolates found in Burkina Faso in 2002 belong to the ET-37 complex and were closely related to the Hajj 2000 isolates (Ministry of Health/WHO/CDC, unpublished data). These strains were also closely related to serogroup W-135 ET-37 complex strains found in sporadic cases or carriage in other parts of the world since the 1970s, suggesting expansion of an existing clonal group rather than introduction of a new one.[17]

The potential for dissemination of serogroup W-135 meningococcal disease epidemics in African meningitis belt countries is of great concern, given the clonal association between these two recent epidemics and the fact that historically serogroup A meningococcal disease epidemics caused by the ET-III-1 complex were first seen during the Hajj in 1987 and subsequently caused epidemics in multiple regions of sub-Saharan Africa.

RISK FACTORS

Individual host factors that predispose to invasive meningococcal infections include functional or anatomic asplenia, properdin deficiency, congenital and acquired immunoglobulin deficiencies and terminal or C3 complement deficiency. [21] In addition, genetic polymorphisms such as tumor necrosis factor (TNF) promoter region polymorphisms, mannose-binding protein abnormalities, plasminogen activator and inhibitor expression and cytokine induction have been linked with severity of meningococcal disease. People infected with HIV may be at increased risk of meningococcal disease, although the risk is probably lower than that for pneumococcal infections.

In the African meningitis belt, both sporadic and epidemic disease are characterized by seasonality, with increased rates during the dry season (December to May) and rapid decline with the onset of the annual rains. Low humidity and blowing dust may damage the mucosal membranes or inhibit mucosal defenses, leading to an increase in the proportion of those who acquire the meningococcus and develop invasive disease. Poor and crowded living conditions and smoke exposure are associated with meningococcal disease. These environmental and economic factors may result from people clustering in poorly ventilated dwellings and may facilitate the spread and risk of disease. Concurrent or preceding upper respiratory infections have also been implicated in several meningococcal disease epidemics and may contribute to their seasonality.[22] These viral or mycoplasmal 'cofactors' may increase transmission and susceptibility by damaging mucosal membranes, by causing transient immune suppression and by enhancing coughing and sneezing.

Other risk factors for meningococcal disease have been difficult to characterize because they may vary between industrialized and developing countries, between endemic and epidemic disease and among illnesses caused by the different serogroups. Differences between strains may lead to variability in exposure to the organism, in acquisition of carriage and in progression to invasive disease. Furthermore, factors that place an individual person at risk of sporadic disease may differ from risk factors for an epidemic.

Meningococcal disease epidemics are usually caused by strains that are clonal, as noted by the intercontinental spread of the serogroup A III-1 clone and serogroup W135 ET-37. In contrast, the overall population structure of meningococci is panmetric. These invasive strains appear to possess particular virulence factors that confer the capacity to be transmitted more effectively, cause increased invasive disease or have antigenic characteristics not recognized by the population, leading to enhanced susceptibility. Waxing and waning of the immunologic susceptibility of a population may contribute to the apparent periodicity of meningococcal epidemics. The striking phenomenon of meningococcal epidemics results from a complex interaction that involves strain characteristics, population characteristics and cofactors such as smoking and upper respiratory tract infections.

PATHOGENESIS AND PATHOLOGY

The human nasopharynx is the natural reservoir of *N. meningitidis* and the site from which meningococci are transmitted by aerosol or secretions to others, spread to adjacent mucosal surfaces (e.g. in the lower respiratory tract) and invade and gain access to the bloodstream to produce systemic disease. [21] Meningococci overcome clearance (e.g. mucus and ciliary activity) and other local host defenses in order to attach to and multiply on this mucosal surface (i.e. colonization). The meningococcus is carried asymptomatically in the nasopharynx by 5–10% of adults in nonepidemic periods. In closed populations (e.g. among military recruits) nasopharyngeal carriage rates can be greater than 50%. Nasopharyngeal colonization is an important immunizing process that may protect against future systemic illness.

The nasopharynx also appears to be a major site of mucosal invasion of meningococci and other meningitis pathogens. Crossing of the nasopharyngeal epithelium by meningococci allows access to subepithelial tissues and blood vessels. Meningococci may also penetrate nasopharyngeal epithelium damaged by environmental

factors such as smoking or by viral or mycoplasmal co-infections.[22] In meningococcal disease, systemic illness usually follows acquisition of the organism in the nasopharynx within 2–10 days. Successful penetration through this epithelial barrier of even a few organisms that are capable of surviving in the bloodstream may be sufficient to cause systemic disease.

Survival of meningococci after invasion into the bloodstream is determined by both organism-specific and host-specific factors. Encapsulation, outer membrane proteins, lipo-oligosaccharide, inhibition or defects in serum bactericidal activity (both bactericidal antibody and complement) and, to a lesser extent, opsonophagocytic activity are involved. Levels of bacteremia correlate with the release of inflammatory cytokines (interleukins 1 and 6 and TNF-a), which are important in the pathogenesis of meningococcemia.

The mechanism by which meningococci cross the blood-brain barrier and enter the cerebrospinal fluid is not well characterized. Endothelial cell invasion, which is important in meningococcemia, may also be involved in the invasion of the central nervous system. Meningitis results from bacterial survival and multiplication in the cerebrospinal fluid, the release of inflammatory cytokines and other host factors (e.g. nitric oxide), leukocyte infiltration across the blood-brain barrier and breakdown of the blood-brain barrier with edema, coagulation and ischemia.[23]

PREVENTION

Epidemic bacterial meningitis are primarily caused by serogroups A, C and W-135. The persistence of large serogroup A epidemics of meningococcal disease in developing countries and their virtual disappearance in industrialized countries suggests that continued improvements in the standard of living in developing countries may decrease the occurrence of epidemic meningococcal disease. For now, however, prevention of serogroup A meningococcal disease epidemics focuses on vaccination. The recent serogroup W-135 epidemics in Saudi Arabia and Burkina Faso and the possible spread of this clone to other parts of the world indicates the need for broadly based meningococcal vaccines, including the development of nonserogroup-specific vaccines.

Vaccination

Meningococcal A, C, Y and W-135 polysaccharide vaccines are composed of purified capsular polymers. In adults and in children over 2 years of age, antibodies develop rapidly after vaccination and protection is achieved within 7–10 days. These vaccines have high efficacy in adults; however, antibody levels decline over 2–3 years. Following the occurrence of epidemics in military populations, military recruits in some countries have been routinely vaccinated at the start of their military service. Because these vaccines are generally poorly immunogenic in young children and have limited duration of efficacy, meningococcal A, C, Y and W-135 polysaccharide vaccines have not widely been used in routine childhood immunization programs.

Meningococcal capsular polysaccharide vaccines are distributed in freeze-dried form, injectable by intramuscular route and available either as a bivalent A/C vaccine or as a quadrivalent A/C/Y/W-135 vaccine, containing 50µg of each antigen per dose. They are generally well tolerated, with the most common side-effects being pain and redness at the injection site.

The polysaccharide vaccines can be useful in control of epidemics of meningococcal disease. During the 1996 epidemic in northern

Ghana, vaccination campaigns reduced the number of cases by an estimated 23%.[24] Data collected during the epidemic of meningococcal disease in northern Ghana in 1996–7 was used to assess the potential effect of different vaccination strategies. A strategy of using disease incidence thresholds to trigger vaccination campaigns after the epidemic was started would have prevented 61% of cases. A similar proportion of cases (61%) could have been prevented if routine childhood and adult immunization had been used, assuming that a high vaccine coverage rate had been achieved and maintained before the epidemic.[24]

The decision about when to initiate a vaccination campaign and who to vaccinate is complicated. Vaccination campaigns are expensive and logistically difficult, involving a large commitment of resources. Vaccinating large numbers of people on the basis of only a few cases of meningococcal disease may result in wasted efforts if the epidemic fails to materialize. The WHO has published guidelines for detecting and responding to meningococcal disease epidemics; these guidelines include recommendations about approaches to surveillance, case management, and formation of epidemic response teams[25] as well as recently revised recommendations on the use of threshold incidence rates to predict epidemics and trigger early decisions to implement campaigns.[26]

Following the meningococcal disease epidemics in 1996–8 in Africa, the WHO and other international agencies created the International Coordination Group (ICG) with the objective of better assuring international co-ordination to epidemic response.[27] The ICG manages a security stock of the bivalent A/C polysaccharide vaccine, specific treatment and injection material for use in epidemic emergencies. Since 1997 a stock of approximately 7 million doses of bivalent A/C vaccine has been maintained. Every year countries experiencing epidemics have used the ICG mechanism to rapidly obtain quantities of high-quality vaccine and injection materials at preferential prices.

Meningococcal A/C/Y/W-135 polysaccharide vaccines are not assured by the ICG and are produced in limited quantities worldwide. The serogroup W-135 meningococcal disease epidemic in Burkina Faso in 2002 has represented a major challenge to the ICG and international community, given the major shortage of meningococcal A/C/Y/W-135 vaccines for use in Africa. Early in 2003, a serogroup A/C/W-135 meningococcal polysaccharide vaccine (trivalent vaccine) has been produced in limited quantities for use in African countries with the prospect of increased production in the following years.

Conjugate serogroup A and A/C/Y/W-135 vaccines are currently being developed, using methods similar to those used for Hib conjugate vaccines, in which capsular polysaccharides are covalently linked to carrier proteins to convert the T-cell-independent polysaccharide to a T-cell-dependent antigen.[28] The first clinical trials with a meningococcal serogroup A and C conjugate vaccine were conducted in the Philippines and the USA. In the late 1990s, the safety and immunogenicity of a meningococcal A/C conjugate vaccine was evaluated in infants from Niger. This and other studies have shown that meningococcal conjugate vaccines are safe, improve immune response in infants, prime immunologic memory and lead to a booster response to subsequent doses.[29] [30]

At the end of 1999, conjugate C meningococcal vaccines were introduced in the UK among children and young adults under 18 years of age. Rates of meningococcal disease in the UK were approximately 2 per 100,000 population, and 30–40% of cases were caused by serogroup C.[31] Age-specific vaccine efficacy is estimated to be 89% in children under 12 months, 89% in children aged 12–24 months and 94% in adolescents aged 15–17 years.[32] [33] Although serogroup carriage rates are low, preliminary data on the effect of a serogroup C meningococcal conjugate vaccine on carriage suggest that the conjugate vaccine may reduce carriage of serogroup C meningococci, which implies that it may decrease transmission, leading to herd inmmunity.[33] No significant increases have occurred so far in carriage of meningococci expressing other disease-associated serogroups.[33] Serogroup C conjugate vaccines have also recently been introduced in several European countries and Canada.

The newly created Meningitis Vaccine Project (funded by the Bill and Melinda Gates Foundation) seeks to promote and facilitate development of meningococcal serogroup A and serogroup A/C/Y/W-135 conjugate vaccines at a reasonable price for use in Africa.[34] Production of vaccines will be followed by introduction into some of the poorest nonindustrialized countries in the African meningitis belt. As has been demonstrated for the Hib vaccine, meningococcal conjugate vaccines could have a major impact on prevention of meningococcal disease. If these conjugate vaccines prove to be capable of providing a durable antibody response, particularly in infants and young children, then integrating them into routine childhood immunization, especially in hyperendemic areas of sub-Saharan Africa, would appear to be warranted.

Because the capsule of serogroup B meningococci is identical to human cell antigens (N-CAM) and is poorly immunogenic in humans, vaccine development has largely focused on outer membrane protein vaccines. The immunogenicity and protective efficacy of vaccines against several serogroup B outer membrane proteins have been recently evaluated; results have been encouraging, although questions remain about their effectiveness against heterologous strains and in young children.[35] [36]

Chemoprophylaxis

Most people become infected after contact with asymptomatic carriers rather than with persons who have meningococcal disease, but close contacts of patients (e.g. those living in the same home) have a 500–800 times increased risk of developing disease.[37] Antimicrobial chemoprophylaxis of close contacts of patients who have meningococcal disease remains the primary preventive measure after the occurrence of sporadic cases. Systemic antibiotics that eliminate nasopharyngeal carriage include rifampin (rifampicin), ciprofloxacin and ceftriaxone. Nasopharyngeal cultures are not useful in determining who should receive chemoprophylaxis. Mass chemoprophylaxis is not currently recommended to control meningococcal disease epidemics, given that meningococcal vaccines constitute a better epidemic control strategy.

Travelers

Since the 1987 outbreak associated with the Hajj, pilgrims to Mecca have been required to show proof of vaccination against meningococcal disease on entry to Saudi Arabia. Because of the serogroup W-135 meningococcal disease outbreak in 2000, pilgrims are now required to show proof of vaccination with quadrivalent (A/C/Y/W-135) polysaccharide vaccine when entering Saudi Arabia. For other travelers, guidelines for immunization against meningococcal disease vary. Vaccination with the quadrivalent A/C/Y/W-135 polysaccharide vaccine may benefit persons traveling to or residing in countries that are undergoing an epidemic or have hyperendemic disease, particularly if contact with the local population will be prolonged.[38]

CLINICAL FEATURES

The clinical presentation of epidemic meningococcal meningitis is similar to that of other forms of acute purulent meningitis (see Chapter 22), with sudden onset of headache, fever, nausea, vomiting, photophobia, neck stiffness and alteration in mental state. Some patients who have meningococcal meningitis, but not all, have an assotension,

Figure 159-2 Meningococcal septicemia with purpura fulminans. (a) In an infant and (b) in an adult.

purpuric or petechial rash. This may be less common in adults and is difficult to recognize in dark-skinned people. Meningococcal sepsis is characterized by abrupt onset of fever and the characteristic petechial or purpuric rash, which is often severe (purpura fulminans; Fig. 159.2) and may be associated with the rapid onset of hypotension,

TABLE 159-1 -- Antibiotic treatment, chemoprophylaxis and vaccination for epidemic meningococcal meningitis.

ANTIBIOTIC TREATMENT, CHEMOPROPHYLAXIS AND VACCINATION FOR EPIDEMIC MENINGOCOCCAL MENINGITIS	
Treatment in an outbreak setting in developing countries[22]	Long-acting chloramphenicol (e.g. tifomycin) in oil suspension, single dose: Adults, 3.0g (6ml); children 1–15 years, 100mg/kg; children <1 year, 50mg/kg
Other treatment options	Penicillin G 18–24 megaunits/day iv in divided doses q4h (250,000 units/kg/day)
	Ceftriaxone 1–2g iv q12h (100mg/kg/day)
	If penicillin-allergic: chloramphenicol 100mg/kg/day im in divided doses q6h
Vaccination (generally limited to epidemics or to travelers to endemic areas)	A/C/Y/W-135 vaccine or A/C vaccine given as single 0.5ml sc injection
	Decreased efficacy in children <2 years of age; vaccine efficacy wanes after 3–5 years
Chemoprophylaxis (recommended for close contacts of cases)	Rifampin (rifampicin): Adults, 600mg po q12h for 2 days; children >1 month, 10mg/kg po q12h for 2 days; children <1 month, 5mg/kg po q12h for 2 days
	Ciprofloxacin: Adults, 500mg po (single dose)
	Ceftriaxone: Adults, 250mg im (single dose); children <15 years, 125mg im (single dose)

acute adrenal hemorrhage (Waterhouse-Friderichsen syndrome) and multiple organ failure. In infants under 1 year of age, the presentation may be atypical with slow onset, absence of neck stiffness and the presence of bulging fontanelle.

DIAGNOSIS

Diagnosis is strongly suspected based on clinical findings of headache, fever, stiff neck and a petechial or purpuric rash. Meningococcal meningitis is confirmed by a lumbar puncture, which classically shows purulent or turbid cerebrospinal fluid, elevated white blood cell count, elevated protein level and decreased glucose, and a Gram stain showing Gram-negative diplococci (often intracellular). Meningococci can be grown on Mueller-Hinton or chocolate agar. Rapid antigen detection, by latex agglutination or countercurrent immunoelectrophoresis, can identify specific serogroup capsular antigens in cerebrospinal fluid. Blood cultures are commonly positive. If a rash is present, a skin biopsy can be examined for Gram-negative diplococci. Serogroup specific polymerase chain reaction (PCR) techniques have been used, primarily in industrialized countries, for the diagnosis of meningococcal disease; rapid PCR techniques for use in Africa are under development.

In the midst of an epidemic in a developing country, the flood of patients may overwhelm the health facilities and laboratory capacity. As soon as a meningococcal epidemic has been confirmed, rapid initiation of treatment and initiation of prevention measures take priority. Laboratory confirmation of cases throughout the epidemic is encouraged, mainly for epidemics of serogroup W-135 meningococcal disease.

MANAGEMENT

Many antimicrobial agents, including penicillin, remain active against meningococci (Table 159.1), but choice of antibiotic is increasingly threatened by drug resistance, lack of central nervous system penetration and cost. Since the emergence of sulfa-resistant meningococcal strains in the 1960s, sulfa drugs are no longer considered suitable as initial therapy. Third-generation cephalosporins, such as ceftriaxone, are excellent but currently expensive alternatives in developing countries. Recently, meningococcal isolates with increased resistance to penicillin have been recognized in the USA, Spain and Canada

and isolates with increased resistance to chloramphenicol have been recognized in Vietnam and France;[39] [40] [41] however, the clinical significance and potential impact on treatment is unclear.

The care of a large number of patients during an epidemic in a developing country makes repeated injections with crystalline penicillin or even ceftriaxone impractical. A single intramuscular dose of an oily suspension of chloramphenicol has been shown to be as effective as a 5-day course of crystalline penicillin in the treatment of meningococcal meningitis[42] and it is a useful first-line therapy during epidemic periods in developing countries. If the patient fails to improve within 48 hours, a second dose should be administered and other causes of bacterial meningitis should be considered. Management of sporadic cases consists of intravenous penicillin or ceftriaxone or, if the patient is allergic to penicillin, chloramphenicol.

Chapter 160 - Eye Infections in the Tropics

Robin Bailey

This chapter discusses the contribution of infection to the major blinding diseases of the tropics and the ocular features associated with common tropical infections. In tropical practice, visual prognosis in both major blinding infections and simple trauma is often worsened by late presentation, secondary infection and inappropriate use of traditional eye medicines.

MAJOR BLINDING INFECTIONS OF THE TROPICS

Cataract, vitamin A deficiency, trachoma and onchocerciasis are classically considered to be associated with blindness in developing countries, although community-based studies of the causes of blindness have only been conducted in a few countries.[1] [2] In two of these diseases, trachoma and onchocerciasis, and in two other important tropical infectious diseases, leprosy and measles, infection and the host response to it play prominent and contrasting roles in the pathogenesis of blindness and other ocular complications. These are discussed below.

TRACHOMA

Trachoma is a chronic follicular keratoconjunctivitis caused by infection with *Chlamydia trachomatis*, almost exclusively of serotypes A, B, Ba and C. (The 'genital' *C. trachomatis* serotypes D–K may cause disease that is indistinguishable from trachoma, but this is rare.) Trachoma is characterized by scarring sequelae of the conjunctiva after repeated infections (see Chapter 18 and Chapter 236).

Epidemiology

Trachoma is one of the most common infectious diseases; it is estimated that 500 million people are exposed to infection, and in 1995 the World Health Organization estimated that 6 million people have been blinded by trachoma. [1] As a result of demographic trends, 12 million further cases of blindness are expected within 30 years.[3] It is a disease of poverty, associated with poor personal and environmental hygiene, and it was common in much of Europe and North America during the 19th century. The map (Fig. 160.1) shows the current distribution of active trachoma based on reports reaching the WHO. 'Endemic' disease is considered to be present if there is more than 10% prevalence in school-aged children. Trachoma is found in northern and sub-Saharan Africa, the Middle East and the Indian subcontinent. There are also foci in parts of Central and South America, Australia and the Pacific.

In trachoma-endemic communities, the main reservoir of infection is the eyes of affected children; active trachoma is unusual among adults, and there is evidence that most transmission of trachoma occurs within the family[4] [5] as a result of close contact between young children and their mothers and other caregivers. Transmission is favored by poor environmental and personal hygiene, lack of water for washing, inadequate sleeping space, inadequate disposal of rubbish or sewage, and the proximity of domestic animals. It is considered to take place via fingers and fomites. Recent evidence implicates the bazaar fly *Musca sorbens*, which prefers to breed in fresh human feces on the ground, as a mechanical vector of trachoma in conditions of poor sanitation. [6] [7] The relative importance of these means of transmission probably varies from one community to another.

Pathogenesis

There is evidence that the pathologic features of trachoma are not the result of direct tissue damage but are immunologically mediated. A single infection with *C. trachomatis* usually leads to a self-limiting follicular conjunctivitis, and repeated episodes appear to be necessary for the development of intense inflammation and of scarring sequelae. The most characteristic histologic finding in active trachoma is the presence of follicles, which resemble germinal centers, in the superior tarsal conjunctiva. Subsequently subconjunctival scarring occurs and contraction of the scars causes distortion of the tarsal plate, entropion and trichiasis (inturned eyelashes).

Evidence from animal models suggests that cellular immune mechanisms are of primary importance in limiting and clearing chlamydial infection. There is evidence that scarred subjects have a reduced capacity for clearance of chlamydial infection, which occurs by way of specific T helper-1 lymphocyte responses[8] and possibly by way of cytotoxic lymphocyte activity.[9] Tumor necrosis factor-a has pro-inflammatory and antichlamydial activity and appears to participate in the process by which repeated episodes of intense disease lead to scarring.[10] Transforming growth factor-ß, a cytokine with established fibrogenic properties, is expressed to a greater extent in the conjunctivae of scarred subjects[11] and is also directly implicated in the scarring process. Antibodies to a chlamydial heat shock protein, HSP 60, are also associated with scarring in both the eye and the genital tract, but it is uncertain whether these reflect a causal role for this antigen or an epiphenomenon.

Prevention

The goal of prevention is to reduce transmission to a level at which exposure to reinfection does not occur often enough to cause blinding trachoma. Measures focused on improving personal and community hygiene, such as adequate water supplies and control of *Musca sorbens* through pit latrine provision, are likely to reduce the incidence of trachoma. A study of community education targeted at face washing showed that, with intense effort, reductions in trachoma prevalence are possible but that they were not well sustained.[12] Treatment of active cases with topical antibiotics may be effective temporarily, but such a strategy usually results in rapid reinfection either from an extraocular reservoir or from members of the household or community who are subclinically infected or incubating disease. In order to produce an effective reduction in the infectious reservoir in a community, whole families, households or communities may need systemic treatment. There is no vaccine at present.

Clinical features

In endemic communities, *C. trachomatis* infection is usually acquired early in childhood and the progressive scarring and distortion of the

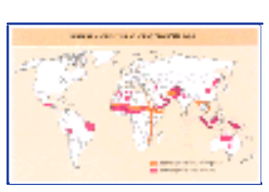

Figure 160-1 Current distribution of active trachoma (WHO).

eyelid may lead to corneal scarring and blindness, usually in late middle age. In severely affected communities signs of trachoma can be found in over 90% of children aged between 1 and 2 years, and blindness rates may approach 25% of those over 60 years. In most endemic areas, there is no sex difference in prevalence or incidence until after adolescence, but both active trachoma and its scarring sequelae are more common in women, probably reflecting their closer contact with children.

Subjects who have trachoma typically have few symptoms until the final stages, when inturned eyelashes (trichiasis) develop. Secondary bacterial infection may play a role in the mucopurulent conjunctivitis, nasal discharge and chronic otitis media seen in some patients.

The most prominent sign of active trachoma is the presence of lymphoid follicles, which are usually found on the superior tarsal conjunctiva and can be easily visualized by everting the upper eyelid, although they may also occasionally be found at the corneoscleral junction (limbal follicles). The presence of five or more of these pale yellow or white spots with a diameter <0.5mm is needed in the central area of the superior tarsal conjunctiva to meet the accepted definition of trachomatous inflammation of follicular grade (TF; Fig. 160.2). Active trachoma is also associated with capillary congestion of the conjunctiva, visible either as small red dots (papillae)

Figure 160-2 Everted eyelid showing follicular trachoma (TF). *Courtesy of the WHO Program for the Prevention of Blindness.*

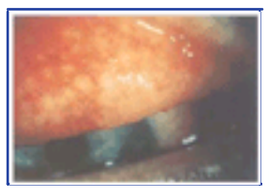

Figure 160-3 Everted eyelid showing intense inflammatory trachoma. Follicles are also present.

or as obscuration of the normally visible tarsal blood vessels. If the blood vessels are obscured in more than half of the central area over the tarsal plate, trachomatous inflammation of intense grade (TI) is said to be present (Fig. 160.3). Neovascularization of the cornea or 'pannus' is associated with active inflammatory disease and in trachoma typically involves the superior corneal margin.

Conjunctival scars (which, if clearly visible, would be graded trachomatous scarring (TS)) are initially small and stellate, but eventually become broad and confluent (Fig. 160.4). The scars contract, causing distortion of the tarsal plate and loss of its normal protective functions and resulting in inturning of the lashes (trichiasis, which is graded TT if any lash is deviated towards the eyeball), which rub on the cornea (Fig. 160.5). This can lead to corneal opacity and ultimately to blindness from abrasion of the cornea. Limbal follicles resolve to leave small depressions at the limbus known as 'Herbert's pits' (see Fig. 160.4).

Trachoma may be confused with other conditions producing a follicular conjunctivitis (Table 160.1). With the exception of viral conjunctivitis, which is acute and self-limiting, the other conditions in Table 160.1 are never endemic in a community; however, limbal follicles or Herbert's pits (Fig. 160.4) are the only clinical sign unique to trachoma[13] and these do not occur even in a majority of cases.

Figure 160-4 Everted eyelid showing trachomatous scarring (TS). There are also Herbert's pits visible at the corneoscleral junction. *Courtesy of the WHO Program for the Prevention of Blindness.*

TABLE 160-1 -- Causes of follicular conjunctivitis.

CAUSES OF FOLLICULAR CONJUNCTIVITIS	
Cause	**Comments**
Folliculosis	Follicles are few and occur in the inferior fornix without inflammation or hyperemia; a common finding
Viral infections	Acute, self-limiting with signs of resolution in 2 weeks
Trachoma	
'Inclusion conjunctivitis' and other ocular chlamydial infections	Also caused by ocular chlamydial infection, often with genital serotypes; frequently unilateral
'Toxic' follicular conjunctivitis:	
Molluscum contagiosum	Caused by spillage of contents of molluscum lesions on eyelids
Drug induced	Follows use of eye medications for months or years
Eye cosmetics	Granules of cosmetic seen in follicles
Bacterial infections: *Moraxella* spp. and others	Angular blepharitis with *Moraxella lacunata*; seen in adolescent girls who share eye make-up
Axenfeld's chronic follicular conjunctivitis	Reported in institutionalized children and native Americans; probably a mild form of trachoma[11]
Chronic follicular conjunctivitis of Thygeson	Outbreak in a Californian high school that contained trachoma cases; features compatible with mild active trachoma[11]
Parinaud's oculoglandular syndrome	Associated with pathogens invading through the conjunctivae; associated with systemic malaise and gross pre-auricular lymphadenopathy; some cases associated with exposure to cats and may be due to feline strains of *Chlamydia psittaci*; many other causes (e.g. syphilis, lymphogranuloma venereum, tuberculosis, tularemia)
Vernal catarrh	Occurs in atopic subjects; characteristic appearance with giant 'cobblestone' papillae

Diagnosis

Trachoma is usually diagnosed on clinical grounds. The simplified grading scheme including TF, TI, TS and TT has been developed by the World Health Organization for public health purposes.[14] Several laboratory tests can be used to confirm a diagnosis of trachoma, but these are rarely available in endemic areas. Chlamydial infection is characterized by blue intracytoplasmic inclusions in Giemsa-stained epithelial cell scrapings. The organism can be cultured in cell monolayers, visualized in smears using direct fluorescent antibody methods, or detected by enzyme immunoassay. Deoxyribose nucleic acid amplification by polymerase chain reaction and ligase chain reaction based on target sequences in the common plasmid

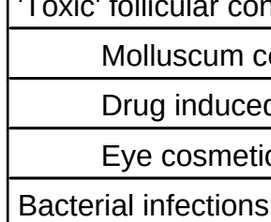

Figure 160-5 Trachomatous trichiasis (TT) and secondary corneal opacity. *Courtesy of the WHO Program for the Prevention of Blindness.*

pCT1 of *C. trachomatis* are the most sensitive methods described for demonstrating ocular chlamydial infection.[15]

Management

Individual sporadic cases are normally treated with 1% tetracycline ointment topically q12h for 6 weeks. A single oral dose of azithromycin (20mg/kg) is also effective.[16] Treatment of patients in endemic areas is usually compromised by rapid reinfection, as discussed above, and mass treatment or systemic treatment may need to be considered. Trichiasis can be treated by epilation, but this normally provides only temporary relief and lid surgery is usually needed to prevent blindness. Tarsal rotation[17] is the operation of choice. The

International Trachoma Initiative currently supports azithromycin donation to trachoma control programs as a component of the SAFE (Surgery Antibiotic treatment

Facial cleanliness and Environmental improvement) strategy endorsed by the WHO.

ONCHOCERCIASIS

Pathogenesis

In the eye, as in the rest of the body, pathology is due to an inflammatory reaction to dead microfilariae of *Onchocerca volvulus*. As these can be found in the cornea, the anterior chamber, the iris, the lens, the retina and the choroid, onchocercal lesions may involve all these sites. In the conjunctiva and iris, an immunohistochemical study has found that chronic ocular onchocerciasis is associated with predominant infiltration by $CD8^+$ lymphocytes and is associated with major histocompatibility complex class II antigen expression in resident cell populations, suggesting activation (see Chapter 18 and Chapter 246). [18]

Clinical features

Eye involvement in onchocerciasis is usually bilateral and affects men more commonly than women.

Punctate or 'snowflake' keratitis occurs as inflammatory cells accumulate around dead microfilariae, and it may respond to topical corticosteroids. Sclerosing keratitis, in which neovascularization and scarring develop nasally and temporally in the cornea and then extend inwards from the inferior limbal margin to involve the whole surface to produce a total corneal scar, has been a common cause of blindness, particularly in savannah regions. Microfilariae may be visible in the anterior chamber with a slit lamp, often as movement that is closely associated with the posterior corneal surface. Inflammatory reactions may produce iritis, and cataract may also contribute to reduced vision. In the posterior segment of the eye, choroidoretinal atrophy, with clumping and breaking up of the retinal pigment epithelium, and associated optic atrophy may follow onchocercal chorioretinitis (leading to the 'Hissette-Ridley' fundus). These changes in the posterior segment contribute further to visual loss and there is no specific treatment.

MEASLES

Pathogenesis

Measles virus infection and its consequences are a major risk to sight in tropical practice. In Africa they cause about 50% of childhood blindness, usually from corneal scarring.[19] Although measles virus infects the corneal epithelium and the conjunctiva, its devastating effects on the cornea are the result of secondary processes, which include infection, acute vitamin A deficiency, exposure and the effects of traditional eye medicines. Measles virus-associated immunosuppression appears to be responsible for reactivation of herpes simplex virus, which has been found in corneal ulcers after measles,[20] and gut involvement appears to precipitate acute vitamin A deficiency in those with marginal reserves.

Clinical features

The direct effects of measles on the eye are a punctate keratitis and sometimes conjunctival lesions that are analogous to Koplik's spots, which normally resolve without sequelae. Corneal ulceration and keratomalacia with liquefaction of the cornea and the whole eye may supervene in acute vitamin A deficiency. Secondary ulceration due to herpes simplex virus may be typically dendritic or modified by other factors as discussed below. If subjects are too sick or dehydrated to close their eyes, corneal dryness and exposure ulceration may result, and in tropical practice, traditional medicines are frequently applied and may contribute to secondary infection and a worse prognosis. Subjects who have ocular complications of measles should be treated with vitamin A, topical antibiotics and measures to avoid corneal exposure.

LEPROSY

Pathogenesis

In leprosy three main mechanisms operate in the eye to cause pathology. Overwhelming bacterial infection in lepromatous leprosy may lead to atrophy of the involved tissues. The eye may be involved in type I reactions (reversal reactions), in which motor and sensory nerve loss is prominent, and in type II reactions, in which inflammation within the eye is prominent. As elsewhere in the body, it is the reactions that cause most damage, manifesting as visual loss and blindness in the case of the eye.

Clinical features

Lepromatous leprosy may be characterized by limbal lepromata, painless yellow or pink nodules at the corneoscleral junction. Chalky deposits may be associated with corneal invasion by *Mycobacterium leprae*. The iris may become thin and atrophic, and pathognomonic 'iris pearls', which are calcified foci of dead leprosy bacilli, appear as white nodules on the surface of the iris.[20] Type I reactions involving the fifth cranial nerve can result in corneal anesthesia and lagophthalmos (inability to close the eyes) may occur if the seventh cranial nerve is involved. Together these produce a cornea that is both anesthetic and exposed, and therefore requires protection. Eye health education, blinking exercises, protective spectacles and surgical procedures such as tarsorrhaphy may all be needed.[20] Type II reactions may cause acute or chronic iritis, which requires treatment with topical corticosteroids and mydriatics, or scleritis, which may require systemic treatment with corticosteroids and clofazimine (see Chapter 154).

CLINICAL ASPECTS OF EYE INVOLVEMENT IN COMMON TROPICAL INFECTIONS

BACTERIAL INFECTIONS

Tuberculosis

Primary tuberculosis may affect the conjunctiva with nodular lesions and associated chronic conjunctivitis that is not responsive to standard topical treatment. In miliary disease, tubercles may be found in the conjunctiva, the iris or the choroid. Phlyctenular conjunctivitis and granulomatous uveitis may be associated with tuberculosis but are not specific for it. Optic neuritis may complicate tuberculous basal meningitis.

Sexually transmitted diseases

Ocular gonococcal infection, usually as a result of autoinoculation from the genital tract, causes an acute purulent conjunctivitis that may progress rapidly to corneal ulceration and perforation in the absence of appropriate treatment.

Gonococcal ophthalmia neonatorum, acquired by an infant passing through an infected birth canal, is similarly threatening to sight and usually presents in the first week of life as a bilateral purulent conjunctivitis.[21]

Ocular autoinoculation from genital *C. trachomatis* infection causes a clinical picture identical to trachoma, except that it is commonly unilateral. Among infants born to infected mothers, 30% develop chlamydial ophthalmia neonatorum, which is usually

a self-limiting bilateral mucopurulent conjunctivitis presenting within 2 weeks of delivery. In a small proportion of cases, pneumonia and permanent lung sequelae follow. Thus chlamydial and gonococcal ophthalmia neonatorum both require systemic and topical therapy.

Iritis, retinal vasculitis, optic neuritis and disseminated chorioretinitis may be features of secondary acquired syphilis (see Chapter 75).

Other bacterial infections

Petechiae may be seen at the conjunctiva in meningococcal meningitis; conjunctivitis, anterior uveitis and even panophthalmitis may complicate meningococcemia. Diphtheria may present with a membranous conjunctivitis, lid edema and local effects of exotoxin. Cholera with rapid dehydration has been associated with the acute development of cataracts. Rose spots in typhoid fever may involve the conjunctiva. The clinical picture of Parinaud's syndrome (follicular or granulomatous conjunctivitis, pre-auricular lymphadenopathy, often with systemic malaise) is associated with pathogen invasion via the conjunctiva and may be seen with tuberculosis, syphilis, tularemia and lymphogranuloma venereum. Brucellosis has been associated with chronic granulomatous uveitis. Dilatation of the conjunctival vessels and subconjunctival hemorrhages may be presenting features of leptospirosis or typhus.

PARASITIC INFECTIONS

Retinal hemorrhages may be seen in malaria and may be the earliest sign of cerebral involvement. Unilateral edema of the eyelid (Romaña's sign) may be seen in American trypanosomiasis if the inoculation site is in the region of the eye. Chorioretinitis is the most common ocular manifestation of toxoplasmosis. An ocular larva migrans syndrome (larvae migrating within the eye) may be seen with *Toxocara* spp. and *Gnathostoma* spp., and *Loa loa* typically migrates under the conjunctiva. Egg granulomas may occur in the conjunctiva or choroid in schistosomiasis. Cysticerci of *Taenia solium* may occur within the eye, often subretinally.

VIRAL INFECTIONS

Herpes simplex virus, which has a worldwide distribution, can have devastating effects on the eye. In many tropical environments this is the most common cause of corneal ulceration, often occurring as a complication of measles or causes of high fever such as malaria. A narrow, branching, dendritic ulcer that is best seen with fluorescein staining is typical (Fig. 160.6), but in tropical practice the time to presentation and inappropriate use of traditional eye medicines often modify this, leading to larger ameboid ulcers. If available, idoxuridine

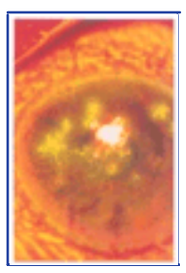

Figure 160-6 Typical dendritic ulcer caused by herpes simplex virus, visualized with fluorescein staining.

or aciclovir drops should be given very frequently until epithelial healing takes place.

Infection with HIV may itself cause a retinopathy with cotton wool spots, indicating ischemic damage to the retina. Cytomegalovirus retinopathy does not seem to be common in tropical practice, but syphilis, tuberculosis and herpes simplex virus infections and their associated ocular manifestations are more common among HIV patients. Kaposi's sarcoma may involve the eyelid or conjunctiva.

FUNGAL INFECTION AND SUPPURATIVE KERATITIS

Corneal ulceration, usually arising from mismanaged traumatic corneal abrasion, is prone to secondary colonization and infection with both bacteria and filamentous fungi. This results in a suppurative keratitis: an infected corneal ulcer with or without pus in the anterior chamber (hypopyon). The management of this condition depends on demonstrating a causative pathogen on culture or corneal scraping or on a local knowledge of the patterns of infection commonly encountered. A recent study in Ghana and India found that infected ulcers were commonly colonized with bacteria, *Streptococcus* spp. (India) or *Pseudomonas* spp. (Ghana), or fungi, *Fusarium* or *Aspergillus* spp.[22]

Chapter 161 - Secretory Diarrheas: Cholera and Enterotoxigenic *Escherichia coli*

Richard A Cash
Davidson H Hamer

INTRODUCTION

Cholera, the most severe of the secretory diarrheas, can cause dehydration and death within hours of onset in a severely purging individual. Although less likely to lead to dehydration than cholera, a more common cause of secretory diarrhea is enterotoxigenic *Escherichia coli* (ETEC); see Chapter 144). Although morbidity and mortality from cholera tend to be greatest in epidemic settings, ETEC infections occur more commonly as sporadic cases, especially in travelers to or children living in developing regions of the world.

Treatment programs that emphasize oral rehydration therapy have greatly reduced mortality from cholera and other watery dehydrating diarrheas worldwide, although diarrhea still remains the second most important cause of death in children in developing countries. Diarrheal disease is also a major cause of morbidity in the USA, where physicians are consulted for more than eight million episodes annually [1] and there is a yearly reported average of approximately 300 diarrheal deaths for children under 5 years of age, with most deaths related to dehydration.[2]

EPIDEMIOLOGY

Vibrio cholerae

Although the Bangladesh region has been the traditional home of cholera, the current pandemic — the seventh recorded in modern times — began in Indonesia in 1961 before traveling to the Indian subcontinent, the Middle East, the Soviet Union, Sub-Saharan Africa and finally to South America in 1991. The organism associated with the current pandemic is an El Tor biotype. The South American epidemic that began in Peru in January 1991 caused over a million cases in the first 3 years. The disease occurred in all age strata since the population had no protective antibody. Unboiled drinking water, unwashed fruits or vegetables and food or water from street vendors were implicated in this explosive outbreak. [3]

A newly described toxigenic non-01 strain, now designated *Vibrio cholerae* 0139 Bengal, was first identified in 1992 in southern India and Bangladesh.[4]

Cholera occurs sporadically along the Gulf Coast of the USA, mainly in Texas and Louisiana.[5] Among the millions of American travelers to endemic areas in foreign countries, only 42 imported cases of cholera were reported in the USA in the period 1965–1991.[6]

Humans are the only host for *V. cholerae* and carriers (about 5% following exposure) are seen only with the El Tor biotype. Contaminated water is the primary vehicle for spread, but certain foods have been implicated in some epidemics, especially if washed with contaminated water or, in the case of seafood (especially crustaceans and bivalves), harvested from water containing *V. cholerae*.[3] Person-to-person transmission is uncommon and health personnel rarely acquire cholera. Reduced gastric acidity, whether idiopathic or caused by drugs (e.g. H_2 -blockers, proton pump inhibitors), or previous gastrectomy increases susceptibility to infection. The inoculum of *V. cholerae* leading to natural infection is not known, but samples of water sources epidemiologically linked to outbreaks rarely contain more than 10^3 organisms/ml. *Vibrio cholerae* 01 can enter into a viable nonculturable state but still retain its pathogenicity. The bacterium can also survive on aquatic vegetation (i.e. water hyacinth) and in the hindgut mucosa of zooplankton. Both of these factors might account for the low vibrio counts in contaminated water and explain where *V. cholerae* resides in the noncholera season.[7]

Enterotoxigenic *Escherichia coli*

These infections are also acquired from other humans as animal strains of ETEC are host specific. Like cholera, the major vehicles of infection are contaminated food and beverages.

Infection occurs primarily in children, with the highest incidence in the tropics, where the reported annual incidence of ETEC-related diarrhea in children varies from 15% to 50%.[8] Reports of ETEC infection in the USA have generally demonstrated a low incidence in most cities. However, ETEC is the most common cause of diarrhea in those traveling from North America or northern Europe to areas of the developing world where diarrheal disease is prevalent.

PATHOGENESIS AND PATHOLOGY

Acute bacterial diarrhea can be classified into:

- toxigenic types, in which an enterotoxin is the major if not exclusive pathogenic mechanism; and
- invasive types, in which the organism penetrates the mucosal surface as the primary event, but enterotoxin may be produced as well.

Diarrheal toxins can be grouped broadly into two categories:

- cytotonic, producing fluid secretion by activation of intracellular enzymes such as adenylate cyclase without causing any damage to the epithelial surface; and
- cytotoxic, causing injury to the mucosal cell as well as inducing fluid secretion but not primarily by activation of cyclic nucleotides.

Both *V. cholerae* and ETEC produce cytotonic enterotoxins.

There have been several exciting developments in the area of pathogenesis during recent years, including the finding that the structural genes for the cholera toxin are encoded by a filamentous bacteriophage.[9]

Vibrio cholerae

Vibrio cholerae is an aerobic, motile, Gram-negative rod that is shaped like a comma. Toxigenic *V. cholerae* that agglutinate in 01 antiserum are the main cause of epidemic cholera. The two major biotypes of *V. cholerae* 01, classic and El Tor, can both produce identical severe watery diarrhea. Although the percentage of mild and moderate cases is higher with El Tor infections, there are more cases of El Tor and thus more severe illness is caused by this biotype. The major serotypes associated with clinical disease are Inaba and Ogawa. The clinical features of illness caused by different sero- and biotypes of *V. cholerae* 01 are virtually indistinguishable.

All wild strains of *V. cholerae*, including 0139, elaborate the same enterotoxin: a protein molecule composed of two subunits, A and B.

The B subunit is responsible for binding to the receptor on the mucosa, whereas the A subunit is responsible for binding and activation of adenylate cyclase located on

the inner cellular membrane. *Vibrio cholerae* requires both the cholera enterotoxin and toxin-coregulated pili (required for intestinal colonization) for full virulence.

The secretory diarrhea seen in cholera is caused by the action of the toxin on the epithelial cells of the small intestine. There appears to be a differential action on the mucosal cells characterized by:

- a direct secretory effect on the crypt cells; and
- an antiabsorptive effect on the villous cells.

Fluid loss originates in the duodenum and upper jejunum; the ileum is less affected. The colon is usually in a state of absorption because it is relatively insensitive to the toxin. The large volume of fluid produced in the upper intestine overwhelms the capacity of the lower bowel to absorb it.

The electrolyte composition of the stool is isotonic with plasma and the effluent has a low protein concentration. No inflammatory cells are visible on microscopic examination. Stool of heavily purging patients has very little odor except for a slightly 'fishy' smell.

Enterotoxigenic *Escherichia coli*

Inspired by the discoveries in cholera, investigators focused on *E. coli* as a possible cause of acute toxigenic diarrheal disease and found that some strains of *E. coli* elaborated an enterotoxin similar to the toxin of *V. cholerae*. There are two types of enterotoxins produced by ETEC with some species producing both or one:[10]

- the heat-labile toxin (LT) is a protein that is destroyed by heat and acid, acts like cholera toxin by activating adenylate cyclase, thereby causing secretion of fluid and electrolytes into the intestinal lumen, and shares antigenic components with cholera toxin; and
- the heat-stable toxin (ST) has no biochemical similarity to cholera toxin, is able to withstand heating to 212°F (100°C) and activates guanylate cyclase.

As is the case with *V. cholerae*, ETEC must elaborate both adherence factors and enterotoxin in order to be pathogenic.

PREVENTION

The four possible approaches to preventing cholera and ETEC infection are:

- avoidance of potentially contaminated water and food;
- prophylactic antibiotics;
- other prophylactic medications; and
- immunization.

Food and water precautions

These are necessary to prevent diarrhea and other diseases transmitted by the fecal-oral route. In endemic areas, if the quality of water is in doubt, bottled or boiled water should be used. Carbonated beverages are safer than noncarbonated ones as the organisms are very sensitive to the lower pH (4.0–5.0). Tea and coffee prepared with boiling water are generally safe. Food should be well cooked and eaten hot if possible. Snacks prepared by street vendors carry a higher risk, especially if the food is not well cooked. In coastal areas of Louisiana and Texas, seafood, especially crustaceans, should be well cooked.[6]

Prophylactic antibiotics and other prophylactic medications

Prophylactic antibiotics should not be used for cholera, especially on a mass scale, as resistance may develop. Antimicrobials have been extensively studied for the prevention of diarrhea in travelers.[10] Studies employing trimethoprim-sulfamethoxazole have shown protection rates of 71–95%. Similar rates have been observed with norfloxacin and ciprofloxacin. The prophylactic use of antibiotics should generally be discouraged, however, as it increases the risk of adverse reactions to the agent used and may enhance antimicrobial resistance.

Bismuth subsalicylate has been used for prevention, based on its antimicrobial and antisecretory properties, but provides only modest protection and must be taken daily at high doses, creating side-effects (black tongue and stool, tinnitus) that many find unacceptable.

Immunization

People infected with ETEC develop antibodies against the enterotoxin and colonization factors. Those living in high-risk areas appear to develop immunity as the attack rate for symptomatic infections for resident adults is much less than for visitors. At present there are no commercial vaccines for ETEC. An experimental ETEC oral killed vaccine has proven to be safe and immunogenic and field tests are now under way.[11]

Exposure to vibrios, whether by actual infection or asymptomatic carriage, causes an elevation of vibriocidal antibody. Protection is related to, but not guaranteed by, the presence of vibriocidal antibody titer. In endemic areas, vibriocidal activity increases with age, as acute cholera in endemic areas is a disease of young children. Antitoxin titers rise slowly after acute infection and remain elevated for months. Natural immunity is short term (3–6 months), biotype and serotype specific, and primarily vibriocidal, with some antitoxin component. The susceptibility of adults in cholera-endemic areas to *V. cholerae* 0139 Bengal strain indicated that these populations were immunologically naive and that previous exposure to *V. cholerae* 01 and its toxin provided incomplete cross-protection.

The current commercially available cholera vaccine is a parenteral killed whole-cell preparation that provides approximately 50% protection from disease for 3–6 months. Cholera vaccine has no protective value in epidemics as it requires two doses and takes weeks to be effective. As the risk of contacting cholera is small and the vaccine has limited effectiveness, the World Health Organization (WHO) recommends that a vaccine not be required for routine international travel and most countries no longer require a cholera vaccination for entry.

Limited immunity to the toxin can be achieved by injecting the B subunit of cholera toxin. By combining the B subunit with a killed *V. cholerae* vaccine, an oral vaccine with a protective efficacy of about 85% has been evaluated in field trials.[12] [13] Several genetically engineered vaccines for both *V. cholerae* O1 and O139 have been developed and have provided some promising results.[14]

CLINICAL FEATURES

For cholera and ETEC, like many other infectious diseases, there is a spectrum of clinical manifestations, from an asymptomatic carrier state to the person with one loose stool to a desperately ill patient with severe dehydration.

Cholera

After an incubation period of 16–72 hours, the initial stage of cholera is characterized by a feeling of fullness. This is soon followed by diarrhea, which accelerates over the next few hours to frequent purging. There may be nausea and vomiting. As the purging increases in frequency and volume, the stool becomes liquid and the color changes from brown to green to yellow and finally to 'rice water' (so named because it looks like water left over after boiling a pot of rice).

All of the clinical signs and symptoms of cholera can be ascribed to fluid and electrolyte losses. The stool is isotonic with plasma,

TABLE 161-1 -- Electrolyte composition of infectious diarrhea and fluid therapies.

ELECTROLYTE COMPOSITION OF INFECTIOUS DIARRHEA AND FLUID THERAPIES	
	Electrolyte concentrations (mmol/l)

	Sodium	Potassium	Chloride	Bicarbonate
Stool

Pedialyte	45	20	35	30†
Ceralyte	70	20	60	30†

* Equivalent from lactate conversion
† Equivalent base in the form of citrate

although there is an inordinate loss of potassium and bicarbonate (Table 161.1). With increasing fluid loss the external signs of dehydration are:

- the pulse progresses from rapid to thready;
- skin turgor decreases (often difficult to assess in infants and the elderly);
- the patient may develop 'washerwoman's hands';
- urine specific gravity increases; and
- urine volume decreases.

Breathing becomes deep and rapid as factors leading to respiratory alkalosis attempt to compensate for the metabolic acidosis brought on by the profound loss of bicarbonate in the stool. Metabolic acidosis may mask hypokalemia, which occurs in severely malnourished children or patients on diuretics. Severely dehydrated patients may present in hypovolemic shock which, if not immediately treated, can lead to cardiovascular collapse and, uncommonly, to renal failure. Mild fever may be a feature, but there are no signs of sepsis. Diarrhea can persist for up to 5 days in the untreated patient.

Enterotoxigenic *Escherichia coli* infection

There is nothing distinctive about the clinical presentation of ETEC infection. Following an incubation period of 24–48 hours, the patient develops a sense of intestinal distress (cramping is uncommon), followed shortly thereafter by watery diarrhea. As in cholera, the illness ranges from mild to quite severe, although it rarely leads to the profound dehydration seen in cholera. Although most people have 3–5 loose stools/day, about 20% of cases have 6–15 watery bowel movements/day. The average duration of illness is 3–5 days. Strains that produce only ST cause a milder attack of diarrhea than LT-producing strains, but cause more vomiting and constitutional symptoms.[15]

DIAGNOSIS

Cholera

Cholera should be suspected in patients with watery diarrhea that has little odor (especially during the periods of heavy purging), and which on microscopic examination fails to reveal formed cellular elements such as erythrocytes and leukocytes. If fresh unstained cholera stool is examined under a dark-field microscope, spiral shaped organisms will be seen to have a 'shooting star' pattern of motility; they are immobilized by antisera. If cholera is suspected, fresh stool should be cultured on thiosulfate citrate bile salts (TCBS) sucrose medium. A colorimetric test that uses monoclonal antibodies can be used to identify *V. cholerae* rapidly in clinical specimens with a high degree of sensitivity and specificity. [16]

Enterotoxigenic *Escherichia coli* infection

Diagnosis of ETEC in a routine bacteriologic laboratory is difficult and generally impractical; ETEC cannot be differentiated from nonpathogenic strains of *E. coli* on routine culture on MacConkey agar and special tests such as enzyme immunoassays, DNA probes or polymerase chain reaction are required to determine virulence factors at either the genotypic or phenotypic level.

MANAGEMENT

The major goal of treatment is replacement of fluid and electrolytes lost in the diarrheal stool. The traditional route of fluid administration has been intravenous, but oral rehydration solutions (ORSs) have proved equally effective and safe for all but the most severely dehydrated, heavily purging patients.[17] The mortality from even severe cholera should be less than 1% with proper fluid therapy (in contrast to as much as 50% if untreated). The composition of intravenous solutions and ORS is directly related to the electrolyte composition of secretory diarrhea (see Table 161.1).

Oral rehydration therapy is based on the physiologic principle that glucose enhances sodium absorption in the small intestine, even in the presence of secretory losses caused by bacterial toxins. From practical, economic and logistic perspectives, ORS is the preferred treatment in developing countries. It is also the treatment of choice for mild-to-moderate diarrhea in both children and adults in the USA and it can be used for maintenance therapy in patients with severe diarrhea after initial parenteral fluid replacement.[18]

The volume and rate of fluid replacement are based on the patient's degree of dehydration (Table 161.2). [18] The patient is thirsty when mildly dehydrated and begins to show the physical signs of dehydration without vascular collapse when fluid loss is moderate. Clinical signs of dehydration become evident after 4–5% of body weight has been lost. The level of dehydration may be difficult to determine in the elderly and often goes unrecognized. A changing

TABLE 161-2 -- **Assessment of dehydration.** Physical findings highlighted in bold type are important signs in the assessment of dehydration.*

ASSESSMENT OF DEHYDRATION			
Physical finding or symptom	**No signs of dehydration (loss of <2.5% body weight)**	**Some dehydration (loss of 2.5–10% body weight)**	**Severe dehydration (loss of >10% body weight)**
Mental status	Alert, appears well	**Irritable, restless**	**Lethargic or unconscious, floppy infant**
Eyes	Normal	Sunken	Very sunken and dry
Tears	Present	Absent	Absent
Oral mucosa, tongue	Moist	Dry	Dry
Thirst	Absent, drinks normally	**Thirsty, drinks eagerly**	**Drinks poorly or is unable to drink**
Fontanelle	Normal	Sunken	Very sunken
Skin pinch	Goes back rapidly	**Goes back slowly**	**Goes back very slowly**

* *Adapted from Tacket et al.*[14]

mental status may be an early sign. After rehydration has been completed, the amount given should be at least equal to that lost in the stool. The most common reason for treatment failure with either intravenous fluids or ORS is that insufficient amounts are given. Vomiting is not a contraindication to the use of ORS; rather, ORS should be given in smaller, more frequent sips until emesis stops, which is usually within the first 4 hours of therapy. Figure 161.1 Figure 161.2 Figure 161.3 illustrate the dramatic effect that ORS fluid replacement has on the rehydration of an adult cholera patient.

The ORS formula recommended by the WHO has been used effectively in hundreds of millions of cases. Recent studies have suggested that an ORS formula that has a lower content of sodium chloride and glucose may be better absorbed in children, therefore resulting in a need for less ORS.[18] Others have suggested, however, that the change in formula provided only marginal improvement in stool output that is more than offset by a negative net salt balance and its consequences, especially in the adult cholera patient.[19] An inexpensive alternative to glucose-based ORS is a solution in which starch derived from rice or other cereals is substituted for glucose. The taste of cereal-based solutions is more appealing to some, but additional preparation time is required and heating (and fuel use) may be necessary.

Eating during an acute episode of watery diarrhea is an important aspect of effective treatment. The traditional approach of dietary abstinence, which restricts the intake of necessary calories, has no place in the treatment. Diarrhea may be prolonged if a child is starved during the illness, and so it is particularly important to

Figure 161-1 Severe dehydration from cholera. Decreased skin turgor in a severely dehydrated cholera patient. *Courtesy of the International Centre for Diarrhoeal Diseases Research, Bangladesh.*

Figure 161-2 Oral rehydration. The patient is immediately given ORS to correct her dehydration. *Courtesy of the International Centre for Diarrhoeal Diseases Research, Bangladesh.*

Figure 161-3 Complete recovery from cholera after rehydration. The patient 24 hours later is completely rehydrated on ORS alone. *Courtesy of the International Centre for Diarrhoeal Diseases Research, Bangladesh.*

restart feeding as soon as the child is able to accept food. Breast-feeding should not be discontinued. Full-strength dairy products may increase diarrhea in some individuals as a result of lactose intolerance, and so should be avoided during the episode of acute diarrhea in those not dependent upon milk as the principal source of caloric intake. Alcohol and beverages that contain caffeine or methylxanthine such as coffee or tea may increase intestinal motility, so they should be avoided.

Antimicrobial agents can be useful in the treatment of cholera as the duration of an episode, volume of stool output and period of *V. cholerae* excretion can be reduced with effective therapy (Table 161.3).[20] A 3-day course of tetracycline is effective; there is no proven value in lengthening the duration of therapy to 4 or more days. A single-dose ciprofloxacin (1g in adults) is also effective in the treatment of *V. cholerae* O1 or O139.[21]

Antimotility drugs such as loperamide have little place in the treatment of watery diarrhea in children in developing countries. The same can be said for various absorbing agents such as kaolin or pectin. Literally hundreds of antidiarrheal remedies can be found in pharmacies and assorted medical establishments throughout the world. Many products contain a combination of drugs, most of them therapeutically ineffective and others potentially dangerous.

Although few studies have evaluated the treatment of ETEC infections (as a distinct group) with antibiotics, short courses of therapy with trimethoprim-sulfamethoxazole or fluoroquinolones such as ciprofloxacin will reduce the mean duration of diarrhea in travelers who frequently have ETEC as the underlying enteropathogen.[10] Results with single-dose therapy of acute traveler's diarrhea with fluoroquinolones are also encouraging.

Travelers to areas with high rates of diarrhea would be advised to take two or more 1-liter ORS packets and, if possible, a collapsible 1-liter container for accurate measurement of water.

TABLE 161-3 -- Antimicrobial therapy of cholera.

ANTIMICROBIAL THERAPY OF CHOLERA		
	First-line therapy	**Alternatives***
Adults	Tetracycline 500mg po q6h for 3 days	Single dose of ciprofloxacin 1000mg po
	Single dose of doxycycline 300mg po	Erythromycin 250mg po q6h for 3 days
		Trimethoprim-sulfamethoxazole 160mg/800mg po q12h for 3 days
		Furazolidone 100mg po q6h for 3 days
Children	Tetracycline 12.5mg/kg po q6h for 3 days	Erythromycin 10mg/kg po q8h for 3 days
	Single dose of doxycycline 6mg/kg po†	Trimethoprim-sulfamethoxazole (5mg/kg trimethoprim plus 25mg/kg sulfamethoxazole) po q12h for 3 days
		Furazolidone 1.25mg/kg po q6h for 3 days

* For use when resistant organisms are suspected or documented present or if the patient has a history of an allergic reaction to the first-line therapy
† Not recommended for use in children under 8 years of age as it may lead to permanent discoloration of teeth

Chapter 162 - Tropical Malabsorption and Sprue

Gerald T Keusch

INTRODUCTION

Tropical malabsorption and sprue are clinical syndromes of still uncertain pathogenesis, although many possibilities have been proposed over the years. These syndromes are expressed as a continuous spectrum of manifestations from asymptomatic malabsorption with mild histologic changes of the small bowel (tropical enteropathy) to persistent diarrhea with laboratory evidence of malabsorption (tropical malabsorption), extending to an overt clinical malabsorptive disease, tropical sprue, in which severe villous atrophy is associated with steatorrhea, chronic diarrhea and a wasting syndrome. Some of these episodes can be proven to be infectious in nature, and household or community outbreaks have been described. The term 'post-infectious tropical malabsorption' is used by a number of authorities for such illnesses.[1] In other patients, the onset of malabsorption is insidious, and no specific intestinal infection is ever documented. However, there is no evidence that tropical enteropathy is a precursor lesion for overt tropical malabsorption or sprue. As a result, tropical malabsorption and sprue have become paradigms of illnesses acquired in the tropics by native and long-term expatriate residents alike, in which infection, malabsorption and malnutrition interact to a varying extent in individual patients to cause an illness with similar overlapping manifestations.

EPIDEMIOLOGY

Definition and nomenclature

Because there is no specific diagnostic test or universally agreed definitions for this syndrome, tropical malabsorption and sprue are defined by a constellation of clinical and laboratory findings, often including the response to therapy.

Tropical enteropathy is a biochemical and histologic process occurring in residents or visitors to the tropics, in which D-xylose malabsorption[2] is associated with alteration of the small bowel villus architecture from the normal finger-like villus to a shorter, broader, tongue-like structure, with lymphocyte infiltration of the mucosa. There may be no symptoms or mild diarrhea and minimal weight loss. Tropical malabsorption is defined as clinical malabsorption associated with an identified infection, whereas in tropical sprue no etiology is found. Both are more severe than tropical enteropathy; that is, they are associated with more profound malabsorption of two or more unrelated nutrients (including carbohydrate, fat or vitamin B12), more severe villus atrophy and more intense clinical symptoms, which if not treated last for months. The associated clinical conditions include megaloblastic anemia and, on occasion, neurologic complications of vitamin B12 deficiency.

Typically, tropical enteropathy and malabsorption or sprue develop during a period of residence of months to years in the tropics, especially in the Caribbean and the Indian subcontinent, although cases are also reported from Africa [3] and other areas of Asia[4] (Fig. 162.1). Neither condition is commonly contracted by short-term visitors to the tropics.

In southern India, epidemic waves of tropical malabsorption were documented over years, typically associated with fever, leading to the speculation that a specific infectious agent was responsible.[5] In some cases, a 'corona virus-like' structure was observed in biopsy specimens of small bowel, although a specific enteric virus was not isolated.[6] Preparations for a prospective field study to isolate and identify the agent were made, but epidemic sprue subsequently disappeared and the investigators have been unable to do the study since.

PATHOGENESIS AND PATHOLOGY

Asymptomatic tropical enteropathy

With the development of safe and simple instruments for biopsy of the small bowel approximately 40 years ago, a new entity, tropical enteropathy, was defined. Studies in Bangladesh[7] and Thailand [8] in the mid-1960s reported that apparently healthy residents of these countries had shortened villi, deepened crypts and lymphocyte infiltration of the lamina propria of the jejunum compared with apparently healthy residents of industrialized nations. When simple intestinal function studies were carried out, these subjects were generally lactase deficient and malabsorbed xylose but not fat or vitamin B12. Studies of Peace Corps volunteers living in the community in Thailand demonstrated that they acquired the same histopathologic lesion and intestinal functional abnormalities during the first year in the country, and some progressed to overt tropical sprue, whereas US military personnel in the same country living in more sanitary conditions and generally eating on a military base retained a more normal mucosa and normal function.[8] Studies of Bangladeshi subjects and former American residents of Pakistan living in the USA demonstrated that the lesions of tropical enteropathy regress after a few years. [9] [10] These studies suggest that living in a fecally contaminated environment with poor sanitation in which water and food commonly contain large numbers of enteric micro-organisms is the basis for the structural and functional intestinal lesions of tropical enteropathy.

Pathologic and pathophysiologic changes

The essential features of tropical enteropathy develop in early childhood, when the finger-like villi of the small bowel of neonates become shorter and broader, with increased crypt thickness, reduced ratio of villus length to crypt length, more frequent mitotic figures and increased cellularity of the lamina propria with lymphocytes and plasma cells.[11] The enterocyte turnover rate is increased, suggesting enterocyte injury with compensatory increase in cell generation in the crypts. Studies in acute epidemic tropical sprue in India have shown focal degeneration of crypt cells at a time when villus cells are intact, which argues for a primary insult to the crypt cells. With the reduced mature villus absorptive surface, carbohydrate absorption, commonly measured by the xylose tolerance test, is diminished as well. This is associated with the failure to absorb as much as 5% of the energy content of the diet in some studies. Abnormal gut permeability as measured by the lactulose-mannitol test has been shown in such subjects.

Figure 162-1 Global distribution of tropical malabsorption and sprue. Tropical malabsorption and sprue in central equatorial Africa remains largely unexplored or unreported.

With the development of tropical sprue, greater damage of villus cells is noted, including disturbed brush border, dilated rough endoplasmic reticulum, loss of mitochondrial cristae and an increase in lysosomes. This is associated with extrusion of damaged villus cells, and an increase in cells with pyknotic nuclei, surrounded by lymphocytes and plasma cells. Fat droplets are present in the cytoplasm, in the thickened basement membrane and in the lamina propria. These changes reverse with prolonged residence in industrialized countries.[10]

It is difficult to document the sequence of physiologic changes that occur in tropical malabsorption and sprue. However, delayed small intestinal transit time may be an early and common event. Cook[1] postulates that the process is initiated by epithelial cell injury, probably postinfectious, leading to the release of enteroglucagon, which in turn results in intestinal stasis, secondary bacterial overgrowth and malabsorption. Cultures of small bowel fluid obtained by aspiration in sprue patients reveals high numbers of bacteria, including a variety of Gram-negative rods (*Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter cloacae*, *Citrobacter freundii*, *Serratia*

marcescens and others). Enterocyte injury is reflected in the increased permeability of the intestine as measured by increased urinary lactulose excretion following an oral dose of lactulose. Colonic function is often abnormal, with increased losses of water and electrolytes; this correlates with the level of free unsaturated fatty acids in stool.

If the diagnosis is restricted to adults without HIV infection who have persistent diarrhea, clinical malabsorption and wasting, the number of patients meeting the case definition of tropical malabsorption and sprue has diminished remarkably over the past 20 years throughout the world. The reasons for this remain speculative, although some authorities believe the increased use of antibiotics for acute diarrhea, prompt attention to dehydration and nutritional status during and after acute diarrhea, and improved environmental hygiene in many developing countries may account for the observations. With more aggressive nutritional and antimicrobial therapy, mortality rates have dropped dramatically in the non-HIV-infected population.

PREVENTION AND RISK FACTORS

Other than residence in the tropics and acute or recurrent diarrhea, no specific risk factors have been identified. Although genetic factors have been suspected for a long time, and some HLA associations are reported,[12] no specific genes mediating susceptibility have been found. Presumably eating foods that are prepared in a sanitary environment and, therefore, are likely to be less contaminated may be useful in preventing the illness.

CLINICAL FEATURES

There are generally no clinical manifestations of tropical enteropathy in indigenous populations of the tropics; expatriates may experience a moderate increase in stool number, with softer stools and modest weight loss. Acquired lactase deficiency can result in clinical lactose intolerance, presenting as the acute onset of cramps and diarrhea after ingestion of lactose-containing dairy products. With the progression to tropical malabsorption and sprue, stool bulk usually increases and the classic manifestations of steatorrhea develop, including foul-smelling, greasy stools that float. This may be accompanied by bloating, belching, borborygmi and flatus. Continuing malabsorption is manifested by anorexia and progressive weight loss, which can be profound. Progressive vitamin deficiency (e.g. of vitamin B12 and folate) leads to megaloblastic anemia, with fatigue and limited exercise tolerance and, rarely, severe neurologic complications of vitamin B12 deficiency (subacute combined degeneration of the spinal cord).

DIAGNOSIS

The requirement for a diagnosis of tropical malabsorption and sprue is the intestinal lesion, for which small bowel biopsy is necessary. Biopsy has become much simpler than it used to be with the advent of endoscopy, which can also be used to diagnose giardiasis and strongyloidiasis and to obtain small bowel fluid for culture. There is, however, no reason to biopsy patients for suspected tropical enteropathy if they have no clinical manifestations. Malabsorption of multiple nutrients should be documented; the classic tests are carbohydrate tolerance tests (xylose or lactose), 3-day fecal fat excretion and the Schilling test for vitamin B12 absorption. Breath tests for carbohydrate absorption, small bowel overgrowth, bile salt deconjugation and intestinal transit time, as well as intestinal permeability as evaluated by the lactulose-mannitol test, are useful adjuncts to help to characterize the pathophysiologic lesion more fully. A simple full blood count and examination of the cells can document megaloblastic anemia, which suggests the value of measuring vitamin B12 and folate levels. Small bowel overgrowth is a common finding in tropical sprue, but culture of the small bowel contents is not necessary. It is, however, mandatory to look for specific treatable causes of the

TABLE 162-1 -- Differential diagnosis of tropical malabsorption and sprue.

DIFFERENTIAL DIAGNOSIS OF TROPICAL MALABSORPTION AND SPRUE	
Category	**Cause**
Malabsorption syndromes	Tropical malabsorption or sprue
	Celiac sprue
	Short bowel syndromes (trauma, surgery)
	Blind loop syndromes
	Venous or lymphatic obstruction (constrictive pericarditis, idiopathic tropical cardiomyopathy, filariasis)
Digestive conditions	Chronic calcific pancreatitis
	Bite salt deficiency (chronic liver disease, ileal tuberculosis)
Infectious diseases	Parasitic infections (*Giardia lamblia*, *Cryptosporidium parvum*, *isospora belli*, *Strongyloides stercoralis*, *Capillaria philippinensis*, leishmaniasis and others)
	Viral infections (HIV, possibly Burkitt's lymphoma)
	Bacterial infections (enteroaggregative *Escherichia coli*, possibly others)

malabsorption syndrome by culture and examination of stool for enteric bacteria and parasites, often supplemented by a string test for *Giardia* spp. and *Strongyloides* spp. In endemic areas such as the Indian subcontinent, a dye contrast study or endoscopy may be indicated to rule out intestinal tuberculosis.

Differential diagnosis

Giardia lamblia, once cause of acute travelers' diarrhea, may progress to a malabsorption syndrome with steatorrhea that mimics tropical sprue. It seems likely that one of the earliest described cases of tropical sprue in Barbados was, in reality, giardiasis.[13] Persistent diarrhea (symptoms continuing for a minimum of 2 weeks) is a hallmark of tropical sprue; however, most patients who have this complaint do not have this syndrome. Many are infected with a limited list of infectious agents, including *G. lamblia*, *Cyclospora cayetanensis* and *Cryptosporidium parvum*, and on occasion a bacterium such as enteroaggregative *Escherichia coli*, *Campylobacter jejuni* or *Aeromonas hydrophila*. Such patients respond to specific treatment for the infection (see Chapter 144).

Other illnesses overlap the clinical manifestations of tropical malabsorption and sprue (Table 162.1). [14] Since the mid 1980s, persistent diarrhea and malabsorption have been common manifestations of AIDS, especially in the tropics. These episodes are often due to opportunistic infections with *Cryptosporidium parvum*, *Isospora belli* or a *Microsporidium* spp. Other causes of persistent diarrhea and malabsorption in the tropics include parasitic hyperinfection syndromes with *Strongyloides stercoralis* or *Capillaria philippinensis*, or persistent enteritis with *Salmonella typhimurium*, *Shigella* spp. or *Campylobacter jejuni*. HIV itself appears to be capable of infecting enterocytes, resulting in a chronic diarrhea-malabsorption syndrome known as AIDS enteropathy.[15] By convention, such specific infections and AIDS enteropathy in patients with HIV infection are not classified as tropical malabsorption or sprue, even though the pathophysiology may be similar if not identical.

Several other specific causes of malabsorption may present in the tropics and are distinct from tropical malabsorption and sprue. These include gluten-induced enteropathy, intestinal tuberculosis, Burkitt's lymphoma, kala-azar and even pellagra in maize-eating cultures. Gluten sensitivity can appear for the first time during residence in the tropics, and this can be readily confused with tropical sprue, as can the less common Whipple's disease.

Persistent diarrhea in infants in the tropics, whether or not the infant is HIV seropositive, is usually accompanied by carbohydrate malabsorption and failure to thrive; this is not classified as tropical malabsorption or sprue. This is considered to be a postinfectious malabsorption syndrome, whether or not the etiology is identified.

MANAGEMENT

Treatment for specific causes of infectious malabsorption syndromes in the tropics does not differ from treatment in industrialized countries. Thus, the drugs of choice are now:

- metronidazole (2g/day for 3 days) or tinidazole (a single dose of 2g) for *G. lamblia*;
- albendazole (400mg q12h for 7 days) or thiabendazole (25mg/kg q12h for 3 days) for *S. stercoralis*; and

¦ albendazole (400mg q12h for 7 days) for *C. philippinensis*.

Patients who have AIDS and have *C. parvum* infections and malabsorption are optimally managed when combination antiretroviral therapy is given, but this is not possible in many tropical countries because of the cost of the drugs. *Isospora belli* responds to trimethoprim-sulfamethoxazole (co-trimoxazole) 160mg/800mg q6h for 10–14 days, even without antiretroviral therapy, but relapse is common when therapy stops; therefore chronic suppressive therapy is recommended (160mg/800mg three times weekly). When no specific etiology is discovered, therapy is directed toward the elimination of small bowel overgrowth with an antibiotic. Tetracycline is commonly used for this, and doses as low as 250mg q8h for 4 weeks are usually successful. Metronidazole is an alternative (500mg/day) because the anaerobic flora may be the primary culprits. The antibiotic regimen is usually supplemented with oral folic acid (5mg q12h) for 3 months; however, folic acid alone may be sufficient to reverse all manifestations of the illness.

Chapter 163 - Typhoid Fever

John Richens

EPIDEMIOLOGY

Typhoid fever is a special form of salmonellosis that is confined to humans and characterized by prominent systemic symptoms. It is often lumped with the closely related paratyphoid illnesses under the term 'enteric fever'. Typhoid has been virtually eliminated from more affluent countries, but high levels of transmission occur notably in the Indian subcontinent, in Indonesia, in much of sub-Saharan Africa and in parts of South and Central America. Point-source outbreaks of typhoid occasionally occur in industrialized countries when contaminated foods are imported or when measures to protect the community from excreting carriers break down. Apart from this, the majority of cases of typhoid seen in industrialized countries occur in travelers returning from endemic areas.

Typhoid has been estimated to cause 33 million infections per year.[1] Community-based studies of typhoid transmission in areas of high endemicity have shown annual incidences reaching 1200 per 100,000 of the population. Transmission rates can be high both in dry weather, when access to water is poor and personal hygiene declines, and with the onset of rains, when contaminated matter is washed into water catchment areas.

PATHOGENESIS AND PATHOLOGY

At the macroscopic level, the main effects of typhoid infection are to be seen in the lymphoid tissue of the ileum known as Peyer's patches, which display an initial hypertrophy and subsequent ischemia and necrosis (Fig. 163.1). At the microscopic level, systemic *Salmonella* infections such as typhoid are characterized by the location of organisms predominantly within macrophages, where their virulence is closely linked to an ability to survive within 'spacious' phagosomes[2] and to trigger an acute inflammatory response capable of producing harmful local ischemia and necrosis. At the moleculer level, recently identified triggers of the acute inflamatory response include a caspase-1 dependent necrosis,[3] the release of interleukin (IL)-1ß and IL-18, and the release of bacterial lipopolysaccharide.

Following ingestion, typhoid bacilli multiply within the bowel lumen. They then pass through epithelial cells to reach the lamina propria and are conveyed from there to the mesenteric lymph nodes. From these nodes, organisms reach the bloodstream via the thoracic duct and, in the course of a transient primary bacteremia, the infection seeds to other reticuloendothelial sites. During the incubation period of 1–2 weeks, organisms multiply silently within sites to which they have been seeded by the primary bacteremia. The onset of symptoms correlates with the spill-over into the blood of large numbers of organisms from primarily infected sites. Infection now disseminates widely throughout the liver, spleen and bone marrow. The gallbladder is an important reservoir of infection that constantly delivers more bacilli to the intestine and Peyer's patches via the bile. It has recently been suggested this re-exposure of Peyer's patches to antigen produces a reaction analagous to the Schwartzman reaction and Koch phenomenon resulting in necrosis (Fig. 163.2).[4]

As the infection progresses, non-specific changes associated with systemic sepsis appear in many organs, such as the heart, brain and kidneys, culminating in circulatory collapse in the most severely affected patients. The local effects of ischemia and necrosis of typhoid nodules in Peyer's patches may lead to perforating intestinal ulcers. The mortality of untreated typhoid used to be about 10%. The majority of patients mount an effective immune response involving a mix of cell-mediated, humoral and mucosal elements.

PREVENTION

There are three broad strategies that can be used to interrupt the transmission of typhoid. The first is to identify and eradicate *Salmonella typhi* from infected people (patients or carriers), primarily through the use of antibiotic therapy. This will include both the management of typhoid patients and measures to detect and treat asymptomatic carriers.

The second strategy is to take measures to prevent ongoing transmission by people who are known to be infected but in whom treatment measures have failed or have not yet produced results. This includes such measures as safe disposal of infected urine and feces from patients, prevention of nosocomial transmission and legislation to exclude chronic carriers in whom eradication measures have failed from food-handling professions.

The third strategy involves protective measures that can be taken by people who may be exposed to risk of infection. These measures include avoidance of unsafe water and food in areas of typhoid transmission and typhoid vaccination.

The identification and treatment of carriers are dealt with in the section on Management, below. In areas of typhoid endemicity, tap water is unsafe when water supplies are contaminated by raw effluent, and foodstuffs (such as fresh vegetables) are unsafe when washed with such water. *Salmonella typhi* thrives in a wide range of foods. Notable outbreaks have occurred in association with dairy products, including ice cream, processed meats and shellfish, which efficiently concentrate *Salmonella* spp. from sea water that has been contaminated by untreated effluent.[5]

A range of vaccines have been developed for typhoid.[1] None of them is wholly effective and protection may be overcome by heavy inocula of bacteria. Because efficacy data on typhoid vaccines come principally from studies that have been conducted in endemic areas, where higher levels of naturally acquired immunity are present, the degree of protection for previously unexposed people tends to be overestimated.

Vaccines that are currently available do not offer concomitant protection against paratyphoid strains. A recent meta-analysis of published studies of vaccines against typhoid reported 3-year cumulative efficiencies of 73% for two doses of the parenteral whole-cell vaccine, 55% for a single dose of the parenteral Vi vaccine and 51% for three doses of the oral Ty21a vaccine.[6] Local and systemic reactions are common with whole-cell vaccines and abdominal symptoms may occur with the oral vaccine.

Figure 163-1 Perforating typhoid ulcer of the terminal ileum. This large, necrotic ulcer covered in dark brown slough is on the antimesenteric side of the distal ileum. A gloved fingertip is seen within the large perforating ulcer that caused the patient's death. *Reproduced with permission.*[22]

CLINICAL FEATURES

Typhoid affects the sexes equally. In endemic areas it shows a predilection for children and young adults.

The majority of patients with typhoid seen in affluent countries present with the triad of persistent fever, headache and abdominal symptoms (mainly abdominal pain

and diarrhea or constipation). Their symptoms rarely progress beyond this stage. In developing countries, patients tend to present later and are more likely to be seen with the vast array of less common symptoms and complications that are associated with typhoid.

The fever of typhoid has special characteristics that help to differentiate it from other fevers. The onset is typically gradual and in the early part of the infection a persistent high fever with relatively little

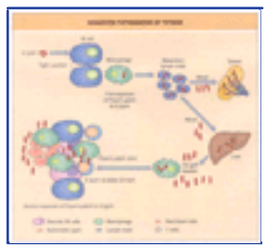

Figure 163-2 Suggested pathogenesis of typhoid. A Schwartzman-type reaction occurs when Peyer's patches are re-exposed to Salmonella typhi following initial uptake, hematogenous dissemination and return to small intestine via gallbladder.[4]

diurnal variation is common. Rigors are not typical of early typhoid but they may be observed in the second and third weeks of untreated infection. Prominent temperature-pulse dissociation is a well-known feature of typhoid but it is not invariably present, nor is it unique to typhoid.

Headache is a prominent feature of typhoid and its absence should cast considerable doubt on the diagnosis.

The primary focus of typhoid within the small bowel gives rise to a variety of abdominal symptoms. Gastroenteritic symptoms (diarrhea, abdominal pain, nausea, vomiting) are prominent in some patients (more so in children), but constipation is equally well known. Severe diarrhea has been described in AIDS patients who have typhoid. The absence of abdominal symptoms does not exclude typhoid and in some patients the systemic symptoms very much dominate the clinical picture. A dry cough is a common feature of typhoid and scattered wheezes may be audible on auscultation.

As the infection progresses, typhoid patients may display a variety of neuropsychiatric manifestations.[7] A depressed, apathetic appearance may occur first and progress later to an agitated, twitching delirium before the onset of coma. Typhoid presenting with psychotic symptoms is well known in Africa and India. Such neuropsychiatric manifestations carry important prognostic significance, the mortality in a study from Indonesia being 50% in patients with marked confusion.[8]

Findings on examination

When examining patients with suspected typhoid, a search should be made for the classic rose spots that develop in 60% of Caucasian patients at about the 10th day. Lesions are less common and also less easy to discern on dark skins. Rose spots tend to be quite few in number, are most likely to be found on the skin of the abdomen (Fig. 163.3) and can extend to the chest, back and upper arms.

Figure 163-3 Typhoid rose spots. The abdomen is the best place to look for these lesions, which appear at the end of the first week and are usually quite sparse. They usually take the form of pink macules that blanch when the skin is stretched, but they may take on a more purpuric, nonblanching character, as in this patient. *Reproduced with permission.*[22]

Typically, they appear as small pink macules that blanch with pressure. Purpuric lesions may also be found. More florid versions of the same rash are associated with paratyphoid.

Abdominal examination may reveal enlargement of the liver and spleen in some cases and a diffuse abdominal tenderness is often present. In more serious cases gaseous abdominal distention occurs and this may herald the onset of the acute abdomen that accompanies ileal perforation.

Clinical assessment of patients should also include an assessment of the mental state and hemodynamic status, because hypotension and mental abnormalities carry important prognostic significance.

Complications

The important complications of typhoid are:

- bleeding and perforation of ileal ulcers,
- circulatory collapse in severely ill patients,
- relapse following treatment, and
- long-term carriage of infection.

A comprehensive list of the complications of typhoid, most of which are rare and seen mainly in patients in whom there has been a delay in diagnosis and treatment, is presented in Table 163.1 .

DIAGNOSIS

The clinical features of typhoid are often non-specific and many other causes of fever may have to be entertained. The most dangerous condition that requires exclusion is usually falciparum malaria. Vasculitic conditions, notably temporal arteritis, can masquerade as typhoid. Complicated cases of typhoid may present with pneumonia, nephritis, meningitis or psychosis.

The definitive diagnosis of typhoid requires isolation of *S. typhi*. Less definitive but sometimes more rapid evidence of infection can be obtained by demonstrating the presence of *S. typhi* antigens in body fluids or of antibodies to those antigens.

Culture

Salmonella typhi can be grown from feces, urine, blood, bone marrow, bile or rose spots. The highest yield is obtained from bone marrow, which can continue to yield positive cultures in patients who have been exposed to effective antibiotic therapy before culture attempts. Fine-needle aspiration methods can be used to minimize patient discomfort.

TABLE 163-1 -- Complications of typhoid.

COMPLICATIONS OF TYPHOID.
Abdominal complications
Intestinal perforation
Intestinal hemorrhage
Hepatitis
Cholecystitis

Spontaneous splenic rupture
Rupture and hemorrhage of mesenteric nodes
Pancreatitis
Genitourinary complications
Urinary retention
Glomerulonephritis
Pyelonephritis
Cystitis
Orchitis
Cardiovascular complications
Myocarditis
Pericarditis
Endocarditis
Electrocardiographic abnormalities
Phlebitis and arteritis
Deep venous thrombosis
Gangrene
Shock
Sudden death
Respiratory complications
Bronchitis
Pneumonia
Laryngeal ulceration
Glottal edema
Neuropsychiatric complications
Delirium
Psychosis
Depression
Deafness
Meningitis
Encephalomyelitis
Transverse myelitis
Upper motor neuron signs
Extrapyramidal disorders
Impairment of co-ordination
Optic neuritis
Peripheral and cranial neuropathy
Guillain-Barré syndrome
Pseudotumor cerebri
Hematologic complications
Anemia
Disseminated intravascular coagulation
Hemoloysis
Hemolytic-uremic syndrome
Focal infections
Abscesses of brain, liver, spleen, breast, thyroid, muscle, lymph nodes
Parotitis
Pharyngitis
Osteitis
Arthritis
Other complications
Myopathy
Hypercalcemia
Decubitus ulceration
Abortion
Development of chronic carrier state
Relapse
Most of these complications occur rarely and are seen mainly in patients in whom there has been a delay in diagnosis and treatment.

Serology and antigen detection

The tube agglutination tests originally developed by Widal and others to demonstrate a serologic response to *S. typhi* continue to enjoy widespread use, but the interpretation of such test has many pitfalls. Preferably, they should be used in conjunction with more reliable methods. A 4-fold rise of antibodies to *S. typhi* O, H or Vi antigens provides support for a diagnosis of typhoid in culture-negative patients. High levels of antibody are found in some healthy people in endemic areas and after vaccination. Some patients fail to mount a response to specific antigens. A modification of the Widal test carried out as a slide agglutination using commercially

available antigens offers a useful way of obtaining rapid support for a diagnosis of typhoid. Detection of *S. typhi* antigens in urine can also be used for rapid diagnosis of typhoid.[9]

Hematologic and biochemical findings

Patients with typhoid commonly have leukopenia. Hemoglobin and platelet counts may show a modest reduction.

Biochemical findings commonly include a modest degree of hyponatremia and hypokalemia and modest elevation of transaminase levels. Occasionally, a typhoid hepatitis develops with more pronounced derangements of liver function tests.

Imaging

Chest radiography may be prompted in typhoid patients by the presence of cough and abnormal auscultatory findings. Usually, the appearance of the chest radiograph is normal, but occasionally typhoid presents with, or is complicated by, a secondary pneumonia. Abdominal sonography may demonstrate enlargement of the liver and spleen, prominent mesenteric lymph nodes and, in the event of perforation, abdominal fluid collections.

MANAGEMENT

A decision about initiating therapy must be made according to the patient's condition and the likelihood of typhoid. Initiation of fluorinated quinolone therapy will bring rapid relief of symptoms to typhoid patients but delay in initiating therapy carries few hazards for

TABLE 163-2 -- Treatment options for patients with typhoid.

TREATMENT OPTIONS FOR PATIENTS WITH TYPHOID						
Drug	**Daily dose**	**Route**	**Doses/day**	**Duration**	**Comments**	**Key trials**
Fluorinated quinolones						
Ciprofloxacin	0.5–1g	po/iv	2	7–14 days	Rapid fever clearance and low relapse rates. Short courses (as little as 3 days) work well for those living in endemic areas. Longer duration may be required for nonimmune travelers	Arnold *et al.*[16]
Fleroxacin	400mg	po/iv	1			
Ofloxacin	800mg	po/iv	2			
Pefloxacin	800mg	po/iv	2			
Extended-spectrum cephalosporins						
Cefixime	20mg/kg	po	1	7–14 days	Slower response rates and higher treatment failure than with quinolones. Short course therapy more likely to fail. Less concern about toxicity in pregnancy and children	Cao *et al.*[17]
Ceftriaxone	50–60mg/kg	im/iv	2			
Azalides						
Azithromycin	500mg	po	1	7 days	Compares favorably with quinolone therapy. Useful in areas with quinolone resistance. Not validated in severe typhoid	Chinh *et al.*[18]
These treatments are suitable for most patients infected with multiple-resistant strains of *Salmonella typhi*.						

mild cases. At least one trial has reported no difference in outcome for children with uncomplicated typhoid treated with and without antibiotics[10] and management without antibiotics is well validated for other forms of uncomplicated salmonella diarrhea.[11]

Antibiotics for typhoid

Chloramphenicol was shown to be effective in the treatment of typhoid in 1950 and for many years it was considered the treatment of choice. Later studies showed equally good results from treatment with amoxicillin and trimethoprim-sulfamethoxazole.

The management of typhoid has been complicated over the past 30 years by the emergence all over the world of strains that are multiply resistant to these antibiotics. In the search for newer antibiotics with good activity against multiple-resistant strains of *S. typhi*, most of the attention has been on fluorinated quinolones, extended-spectrum cephalosporins and, more recently, azithromycin. Randomized comparisons of quinolones and cephalosporins suggest that the quinolones tend to give higher cure rates and more rapid defervescence, [12] whilst azithromycin is proving useful in areas with emerging quinolone resistance.

The incidence of long-term carriage and relapse after treatment with quinolones also appears to compare favorably with other antibiotics. An important concern about quinolone use has been its suitability for pregnant women and children, but there is now an increasing amount of evidence that quinolones are superior to alternative agents and that children can be treated safely with these drugs.[13] Many different fluorinated quinolones have been tried in the treatment of typhoid and most appear to be effective. Fleroxacin[14] [15] has the advantage of once-daily oral treatment and recent trials have indicated that as little as 3 days treatment are sufficient for children with uncomplicated typhoid in Vietnam. To summarize, most authorities would prefer quinolones over cephalosporins for the treatment of multiple-resistant typhoid in all age groups.[12] The optimal duration of treatment for typhoid is not clearly established. Short courses of quinolone therapy often work well for those resident in endemic areas but may be less adequate for travelers. Treatment recommendations for typhoid are listed in Table 163.2 . Quinolone resistance is being reported increasingly from Asian countries. A UK reference

laboratory has reported quinolone resistance in 23% of 179 infections investigated in 1999.[19] Such cases may respond to prolonged maximum dose quinolone therapy, a cephalosporin or azithromycin.

Management of severe typhoid

Trials of quinolones in typhoid have mostly been conducted in patients with mild disease. So far there are few data on the impact of quinolones and the optimal duration of therapy in patients with severe typhoid. Work conducted in Indonesia in the 1980s defined a group of patients, on the basis of circulatory and mental findings, who were at greatly increased risk of a fatal outcome.[8] The criteria for 'severe' typhoid were mental confusion (or more profound alterations of conscious level) or shock, defined as systolic blood pressure of below 12kPa (90mmHg) in adults and 10.67kPa (80mmHg) in children under 12 years, associated with evidence of decreased organ perfusion — peripheral shutdown, oliguria after rehydration (<0.3ml/kg urine output per hour) or an abnormal state of consciousness. In a randomized controlled trial involving patients who met these criteria, the administration of high-dose dexamethasone (3mg/kg infused intravenously over 30 minutes, followed by eight further doses of 1mg/kg q6h) resulted in a case fatality rate of 10.0% compared with one of 55.6% in controls not treated with corticosteroids.[8]

Ileal perforation and hemorrhage

In a small number of patients, one or more of the ileal Peyer's patch ulcers progresses to full perforation, resulting in an acute abdomen. The onset of symptoms can be gradual with perforation occurring against a steadily increasing background level of abdominal pain. Gas under the diaphragm may be demonstrable radiographically and ultrasound can be used to locate feculent fluid collections. The outcome of patients with perforation is greatly improved by prompt diagnosis, full preoperative resuscitation, early surgery and the addition of metronidazole to the antibiotic regimen. Conservative management of perforation, although once in vogue, is no longer advocated[20] because available data suggest poorer outcomes, but no controlled trials have ever been undertaken. Hemorrhage from ileal ulcers may accompany perforation or it may occur in isolation. A minority of bleeds require transfusion; life-threatening hemorrhage is rare.

Relapse

Typhoid shows a natural tendency to relapse in about 10% of patients. Relapse occurs about 2 weeks after recovery from the initial episode and usually takes the pattern of the initial episode in milder and shorter form. *Salmonella typhi* isolates from relapsing patients show the same antibiotic susceptibilities as isolates from the

initial episode and thus treatment with the same drugs is feasible. Lower relapse rates have been reported since the introduction of fluorinated quinolones in typhoid management.

Typhoid carriers

Typhoid carriers play a central role in typhoid transmission and the detection and management of carriers are central to the control of epidemics. Excretion of organisms may occur during acute illness, during the convalescent phase and, in a small proportion of those infected, it continues for life. After treatment of typhoid, a series of stool and urine specimens should be cultured for *S. typhi*. In the first 3 months following infection, most carriers identified excrete on a temporary basis only and the only intervention called for its strict personal hygiene and safe disposal of excreta. Anyone still excreting *S. typhi* at 3 months is likely to become a long-term carrier. Detection of persistently high Vi antibody offers an additional way of screening for long-term carriers. Successful eradication of long-term carriage can be achieved using ciprofloxacin 750mg q12h or norfloxacin 400mg q12h orally for 4 weeks.[21]

Chronic typhoid carriage is more likely in the presence of chronic diseases of the liver (opisthorchiasis), gallbladder (cholelithiasis) or urinary tract (nephrolithiasis or schistosomiasis), and treatment of these associated conditions facilitates antibiotic eradication of *S. typhi*.

Chapter 164 - Amebiasis and Other Protozoan Infections

Adolfo Martínez-Palomo
Martha Espinosa-Cantellano

INTRODUCTION

In terms of its morbidity and mortality, invasive amebiasis is the most important protozoan infection of the gastrointestinal tract. Most of this chapter is therefore devoted to this disease. Giardiasis and cryptosporidiosis are also frequently encountered in geographic and travel medicine and are briefly discussed.

Amebiasis is the infection of the human gastrointestinal tract by the protozoan parasite *Entamoeba histolytica*. The motile form of the parasite, the trophozoite, lives in the lumen of the large intestine, where it multiplies and differentiates into the cyst, the resistant form responsible for transmitting the infection. Trophozoites can invade the colonic mucosa and produce dysentery and through blood-borne spread give rise to extraintestinal lesions, mainly liver abscesses. The course of dysentery is usually self-limiting, but amebic liver abscess is potentially fatal unless diagnosed promptly and treated appropriately.

During the past 20 years there has been growing evidence in the fields of biochemistry, immunology, molecular biology, clinical medicine and epidemiology that many asymptomatic intestinal infections formerly attributed to 'nonpathogenic' strains of *E. histolytica* are caused by a different species of ameba, namely *E. dispar*. This species is morphologically identical to *E. histolytica*, but has a non-invasive nature, as suggested by Brumpt in 1925 (see Chapter 242).[1]

AMEBIASIS

EPIDEMIOLOGY

Invasive amebiasis is a major health and social problem in certain areas of Africa, Asia and Latin America. In most industrialized countries, however, severe amebiasis is much less common, but knowledge of the disease is still important in these areas because failure to identify an amebic infection can result in a lethal outcome (e.g. intestinal amebiasis may be treated as chronic ulcerative colitis). In addition, high infection rates can exist among certain immigrant groups and epidemic outbreaks can occur in institutions such as schools or psychiatric hospitals. A major increase in intestinal amebic infections has been detected in male homosexual populations in several large cities of the USA, Canada and England with point prevalence rates varying from 20% to 31%. In these populations most reported cases are asymptomatic, probably because many of the infections are caused by *E. dispar*. In Japan, however, invasive amebiasis due to *E. histolytica* is not uncommon among sexually active male homosexuals.

In areas of high prevalence invasive amebiasis is characteristically endemic. In 1984 it was estimated that 40 million people worldwide developed disabling colitis or liver abscesses. At least 40,000 deaths that year were attributable to amebiasis, mostly as a consequence of liver abscesses.[2] Therefore, on a global scale, amebiasis is the third most common parasitic cause of death, behind only malaria and schistosomiasis. More recent data on the morbidity and mortality of amebiasis are lacking.

Symptomatic intestinal amebiasis occurs in all age groups, whereas liver abscesses are mostly seen in adult males. The people who pose the greatest risk of transmitting the infection are those who pass cysts of *E. histolytica*, especially if they are involved in food preparation and handling. In endemic areas a variety of conditions, including poor education, poverty, overcrowding, inadequate and contaminated water supplies and poor sanitation, favor fecal-oral transmission from one person to another.

PATHOGENESIS AND PATHOLOGY

The lytic and invasive characteristics of *E. histolytica* are related to multifactorial mechanisms that include:

- striking trophozoite motility and phagocytic capacity; and
- release of membrane pore-forming peptides and proteases that produce contact-dependent lysis of target cells and degradation of extracellular matrix components.[3]

Invasion of the colonic and cecal mucosa by *E. histolytica* begins in the interglandular epithelium. Cell infiltration around invading amebae leads to rapid lysis of inflammatory cells and tissue necrosis. Acute inflammatory cells are therefore seldom found in biopsy samples or in scrapings of rectal mucosal lesions. The ulcerations may deepen and progress under the mucosa to form typical 'flask ulcers', which extend into the submucosa, producing abundant microhemorrhages (Fig. 164.1). This explains the finding of hematophagous amebae in stool specimens and rectal scrapings, which are the best indication of the amebic nature of a case of dysentery or bloody diarrhea. Macroscopically, the ulcers are initially superficial, with hyperemic borders, a necrotic base and normal mucosa between the sites of invasion. Progression of the lesions may result in a loss of the mucosa and submucosa covering the muscle layers and eventually lead to rupture of the serosa. Recent advances in the study of amebic pathogenicity have started to unravel the molecular basis of the pathologic findings in invasive amebiasis.[4]

Complications of intestinal amebiasis include perforation, direct extension to the skin and dissemination, mainly to the liver. Amebae probably spread from the intestine to the liver through the portal circulation. The extent of liver involvement bears no relationship to the degree of intestinal amebiasis, and the two conditions do not necessarily coincide. The early stages of hepatic amebic invasion have not been studied in humans. In experimental animals, inoculation of *E. histolytica* trophozoites into the portal vein produces multiple foci of neutrophil accumulation around the parasites, followed by focal necrosis and granulomatous infiltration (Fig. 164.2). As the lesions increase in size, the granulomas are gradually replaced by necrosis until the lesions coalesce and necrotic tissue progressively occupies an increasing proportion of the liver. Hepatocytes close to the early lesions show degenerative changes, which lead to necrosis, but direct contact between liver cells and amebae is very rarely observed.[5] Human liver abscesses consist of areas in which the parenchyma has been completely replaced by a semisolid or liquid

material (Fig. 164.3) composed of necrotic material and a few cells. Neutrophils are generally absent and amebae tend to be located at the periphery of the abscess. Liver abscesses may heal, rupture or disseminate.

If appropriately treated, invasive amebic lesions almost invariably heal without the formation of scar tissue whether localized in the large intestine, liver or skin. The absence of fibrotic tissue following regeneration is particularly striking in the liver.

PREVENTION

The main reservoir of *E. histolytica* is humans. The infection has a prepatent period ranging from 2 days to 4 months. The transmissibility period of untreated intestinal infections is variable as cysts have been demonstrated in feces for as long as 2 years. The cysts may remain viable and infective for a few days in feces. Because they are killed by desiccation, cyst-laden dust is not infective. Cysts are also killed by temperatures higher than 154.4°F (68°C), and so boiled water is safe to use. The amount of chlorine usually used to purify water is insufficient to kill cysts; higher concentrations of chlorine are effective, but the water must be dechlorinated before use.[6]

Invasive amebiasis could be controlled through improvements in living standards and the establishment of adequate sanitary conditions

Figure 164-1 Pathology specimen from a fatal case of human amebic colitis. Deep ulcerations into the submucosa have produced abundant hemorrhages. *Courtesy of Dr Jesús Aguirre García, Hospital General de México, Secretaria de Salud.*

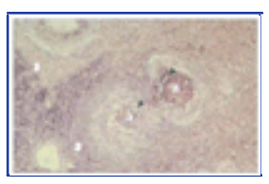

Figure 164-2 Experimental amebic liver abscess. Two characteristic granulomas can be observed with several trophozoites (arrowheads) around its necrotic center (N) and epithelioid cells limiting the lesion, surrounded by an area of fibrosis (F).

in countries where the disease is prevalent. Strategies should be aimed at:

- the community, through the improvement of environmental sanitation including water supply, food safety and health education to prevent fecal-oral transmission; and
- the individual, through early detection and treatment of cases of infection and/or disease.[7]

Cases of invasive amebiasis require prompt chemotherapy and asymptomatic carriers should be treated if infected with *E. histolytica*. Mass chemotherapy of high-risk populations has been attempted with only partially successful results. Individual or collective chemoprophylaxis is not indicated. [8]

CLINICAL FEATURES

Intestinal amebiasis

The clinical spectrum of intestinal *E. histolytica* infection ranges from the asymptomatic carrier state and acute colitis to fulminant colitis with perforation, depending upon the host's nutritional status and susceptibility, including age and, probably, differences in the virulence of amebic strains.

Invasive intestinal amebiasis usually manifests as an acute rectocolitis. Most patients present with a nontoxic dysenteric syndrome and constitutional symptoms are not as prominent as in *Shigella* dysentery. The onset of acute rectocolitis is gradual and 85% of patients have intense abdominal pain. Initially there are loose watery stools, but these rapidly become blood-stained and contain mucus. Tenesmus occurs in 50% of patients and is always associated with rectosigmoidal involvement. Watery diarrhea or loose stools without blood may be present for a few days, particularly if the distal colon is involved.[9]

Amebic liver abscess

This is the most common extraintestinal form of invasive amebiasis. Amebic abscesses occur in all age groups, but are 10 times more frequent in adults than in children and are more common in males than in females. Although liver abscess develops after intestinal infection, patients rarely have associated amebic rectocolitis, but the large intestine is colonized with *E. histolytica* in more than 70% of cases. Lesions are usually single and localized to the right lobe of the liver in the posterior, external and superior portions.

Figure 164-3 Human amebic liver abscess. Multiple abscesses, one cavitated, can be observed occupying virtually all lobes of the liver parenchyma, which is replaced by a semisolid material. *Courtesy of Dr Jesús Aguirre García, Hospital General de México, Secretaría de Salud.*

In most patients, mainly those under 30 years of age and children, the clinical presentation and course of the disease are typical (Table 164.1). The onset is abrupt, with pain in the upper abdomen and high fever. The pain is intense and constant, radiating to the scapular region and right shoulder; it increases with coughing, deep breathing or when the patient rests on the right side. When the abscess is located in the left lobe, the pain tends to be felt in the epigastrium and may radiate to the left shoulder. Fever is present in most cases; it varies between 100.4°F (38°C) and 104°F (40°C), frequently in spikes, but is sometimes constant over several days, with rigors and profuse sweating. There is anorexia and rapid weight loss and approximately one-third of patients have nonproductive cough. Nausea and vomiting may occur and in some cases there may be diarrhea or dysentery. Physical examination reveals a pale wasted patient who has an enlarged tender liver. Digital pressure in the right lower intercostal spaces produces intense pain and there is often marked tenderness on percussion over the right lower ribs in the posterior region. Movement of the right side of the chest and diaphragm is greatly restricted, as is the intensity of respiratory sounds. Older patients may present with a chronic and milder nonspecific febrile illness, hepatomegaly, anemia and abnormal liver function tests.[9]

Complications

Amebic liver abscesses commonly produce thoracic complications, particularly pleurisy with a nonpurulent pleural effusion, rupture into the bronchial tree and, less commonly, rupture into the pleural cavity or amebic pericarditis. Rupture into the abdomen occurs in approximately 8% of patients who have amebic liver abscess; only rarely do abscesses rupture into the gallbladder, stomach, duodenum, colon or inferior vena cava. Occasionally, an abscess may erode through the abdominal wall and reach the skin. Secondary infection of amebic liver abscesses is an uncommon complication, which can be suspected when the patient presents with a severe toxic state and there is lack of response to antiamebic chemotherapy.[10]

TABLE 164-1 -- Clinical features of amebic liver abscess.*

CLINICAL FEATURES OF AMEBIC LIVER ABSCESS	
Clinical feature	**Proportion of cases (%)**
Symptoms for <2 weeks	37–66
Symptoms for 2–4 weeks	20–40
Symptoms for 4–12 weeks	16–42
Symptoms for >12 weeks	5–11
Fever	71–98
Abdominal pain	62–98
Diarrhea	14–66
Cough	10–32
Weight loss	33–53
Tender liver	80–95
Hepatomegaly	43–93
Epigastric tenderness	22
Rales, rhonchi	8–47
Jaundice	10–25
White cell count >10,000/mm^3 (10×10^9 /1)	63–94
Hemoglobin <2g/dl (20g/l)	25–90
Elevated transaminases	26–50
Elevated alkaline phosphatase	38–84
Elevated bilirubin	10–25
Increased erythrocyte sedimentation rate	81

* *Data from Martínez-Palomo and Ruiz-Palacios.*[3]

DIAGNOSIS

Intestinal amebiasis

Rectosigmoidoscopy and colonoscopy of benign cases show small ulcerations with linear or oval contours, 3–5mm in diameter and covered by a yellowish exudate containing many trophozoites. In the great majority of cases rectosigmoidoscopy and immediate microscopic examination of rectal smears for the presence of motile

hematophagous trophozoites of *E. histolytica* are the most important diagnostic procedures. The microscopic examination of amebae has several drawbacks, including the requirement for a skilled technician and the need to perform the examination on fresh clinical specimens. Cyst detection usually requires concentration methods including flotation or sedimentation procedures. In cases of colonic invasive amebiasis serologic detection of antiamebic antibodies is positive in approximately 75% of cases. Reliable and sensitive assays such as immunoassay or hybridization using gene probes to distinguish *E. histolytica* from *E. dispar* infections are already in the market, but still unavailable to clinical laboratories in developing countries due to high costs. However, initial pilot studies have produced excellent results using specific diagnostic reagents.[11]

Amebic liver abscess

This condition should be suspected, particularly in endemic areas or if there is a history of travel to those countries, in patients who present with a spiking fever, weight loss and abdominal pain in the upper right quadrant or epigastrium and tenderness in the liver area. Other signs include leukocytosis, an elevated alkaline phosphatase and an elevated right diaphragm in chest radiographs. Liver imaging with sonography or computerized tomography will demonstrate a space-occupying lesion in 75–95% of cases depending upon the procedure used and course of the illness. This should be followed by testing for antiamebic antibodies, which are elevated in more than 90% of cases. The tests currently used are indirect hemagglutination, counterimmunoelectrophoresis and enzyme immunoassays. The antibody response is directly related to the duration of the illness. It may be negative during the first week after onset and titers reach a peak by the second or third month, decreasing to lower but still detectable levels by 9 months.[3]

Differential diagnosis

The differential diagnosis of amebic liver abscess should include pyogenic abscess and neoplasm (see also Chapter 49). Pyogenic abscess is more common in older patients who have a previous history of hepatobiliary diseases, abdominal sepsis, appendicitis, diverticulitis or abdominal surgery. These patients are more likely to present with jaundice, pruritus and septic shock. Hepatomegaly and an elevated diaphragm in the chest radiographs are uncommon and amebic serology is negative. Aspiration is indicated for microscopy and culture if there is a space-occupying lesion and negative serology.

Liver neoplasm is a differential diagnosis when the patient is febrile and wasted and has vague abdominal discomfort. Neoplasms produce distinct images, particularly on CT scanning, and testing for tumor markers such as alpha fetoprotein or carcinoembryonic antigen is useful.

Stool microscopy for the identification of trophozoites or cysts of *E. histolytica* is of value for the diagnosis of amebic liver abscess because, as mentioned above, many patients have associated asymptomatic intestinal amebiasis.

MANAGEMENT

Metronidazole and related nitroimidazole compounds have contributed greatly to decreasing the morbidity and mortality rate of

amebiasis. They are reasonably well tolerated and despite their reported carcinogenic effect in rodents and their mutagenic potential in bacteria, no such effects have been reported in humans. Emetine hydrochloride, dehydroemetine and chloroquine, which have activity against the organism, are seldom used now.

Amebic liver abscess should be treated with chemotherapy; surgery is rarely indicated. The recommended oral dosage for metronidazole is 1g q12h for 5–10 days for an adult and 30–50mg/kg/day in three divided doses for 10 days for children. The intravenous route is highly effective for patients who have a complicated hepatic abscess; the recommended dosage in those cases is 500mg q6h for 5–10 days. In many cases of amebic hepatic abscess, a favorable response is obtained following the third day of treatment, but administration of the drug for 10 days increases the rate of cure to nearly 95%. Other nitroimidazole derivatives may be effective within 1–3 days but in view of the serious nature of amebic liver abscess as a disease, there is little reason to shorten the duration of therapy. Despite some isolated reports of failure in the treatment of amebic liver abscess with metronidazole, in-vitro studies and experiments with animal models of liver abscess have not demonstrated the existence of metronidazole-resistant strains of ameba. In 85% of cases liver imaging reveals resolution of amebic abscesses within 6 months of treatment; the remaining 15% of cases still show imaging defects 3 years after treatment.[3]

Oral administration of metronidazole is occasionally accompanied by symptoms of gastrointestinal upset such as abdominal pain, nausea and vomiting. Additionally, patients often report a metallic taste and a brownish discoloration of the urine. Undesirable reactions are observed on ingesting alcoholic beverages, probably due to inhibition of alcohol dehydrogenase. Metronidazole and its derivatives should not be administered during the first trimester of pregnancy and should only be prescribed under strict supervision during the second and third trimesters because of their ability to cross the placental barrier and rapidly enter the fetal circulation. The effect of these drugs on fetal development is unknown. Similarly, because of their elimination in breast milk, they are not recommended for nursing mothers; breast-feeding should be suspended if metronidazole is prescribed. To prevent recurrences and transmission, patients who have amebic liver abscess treated with metronidazole should also be treated with a luminal amebicide because up to two-thirds of them have asymptomatic intestinal colonization with *E. histolytica*. The most frequently used amebicides with luminal action are diloxanide furoate, di-iodohydroxyquin and paromomycin.

Current indications for percutaneous drainage of an amebic liver abscess are:

- imminent rupture of a large abscess;
- as a complementary therapy to shorten the course of the disease when the response to chemotherapy has been slow; and
- when pyogenic or mixed infection is suspected.

Drainage should be carried out under ultrasound or CT guidance. Catheters should not be left in for drainage and should be rapidly removed to avoid contaminating the track and skin.

Indications for surgical drainage include:

- imminent rupture of an inaccessible liver abscess, especially of the left lobe;
- a risk of peritoneal leakage of necrotic fluid after aspiration; and
- rupture of a liver abscess.

Monitoring the patient's condition

A prompt diagnosis and adequate chemotherapy will control most cases of liver abscess produced by *E. histolytica*. In general, a full clinical recovery and disappearance of the liver lesions (as confirmed by CT scanning) can be expected for uncomplicated cases. The prognosis is favorable in the absence of severe malnutrition or alcoholism, age over 50 years, multiple lesions, signs of peritonitis, evidence of toxemia or a history of operative treatment for amebiasis. A poor prognosis is associated with ascites or coma, especially if in a patient over 50 years or if the patient has severe jaundice, signs of peritonitis or toxemia.

GIARDIASIS

Giardiasis is a common infection of the human small intestine by the protozoan parasite *Giardia lamblia*. Most patients are asymptomatic, but an unspecified percentage of those infected develop acute or chronic symptoms. Acute manifestations include a sudden onset of explosive, watery, foul diarrhea with flatulence, cramps and abdominal distention and absence of blood, mucus or cellular exudate in the stools. Subacute or chronic infections may be accompanied by flatulence, mushy foul stools, cramps and abdominal distention. Spontaneous resolution of the infection seems to be common. Diagnosis is carried out by finding trophozoites or cysts on microscopic examination of the stools. Treatment is usually effective with metronidazole, tinidazole or furazolidone. Metronidazole is the drug of choice.

Extraintestinal complications of giardiasis are rare and include chronic cholecystitis with pain in the right upper quadrant of the abdomen, perhaps as a consequence of the presence of trophozoites in the gallbladder. In addition, granulomatous hepatitis and cholangitis have been reported in association with chronic diarrhea, weight loss, fever, hypoalbuminemia and anemia. In all of these reports, eradication of the parasite with specific chemotherapy has produced a rapid improvement of symptoms and a resolution of the histologic changes when liver biopsy has been performed. For a fuller description of the clinical and laboratory aspects of giardiasis see Chapter 46 and Chapter 242 .

CRYPTOSPORIDIOSIS

Cryptosporidium are intestinal protozoan parasites of domestic and wild animals and have recently been found to be an uncommon cause of debilitating diarrhea in humans. In immunocompetent patients the infection is usually self-limiting and the symptoms include diarrhea, abdominal pain, nausea, vomiting and anorexia. In contrast, in immunocompromised patients, particularly those who have AIDS, the symptoms may last for several months and produce profound weight loss. The diagnosis is based on the microscopic finding of *Cryptosporidium* in stool samples using acid-fast stains to differentiate the parasite from yeasts (see also Chapter 46 , Chapter 127 and Chapter 243).

An effective treatment for cryptosporidiosis in humans is not yet available. Paromomycin may have modest activity, but has not proved to be efficacious in controlled trials.

Cryptosporidium infection of the gallbladder and biliary tract has been found in 10–26% of patients who have AIDS and results in acalculous cholecystitis, extrahepatic bile duct stenosis and sclerosing cholangitis. Sonographic or CT imaging show an enlarged gallbladder with a thickened wall, dilated or irregular intra- and extrahepatic biliary ducts and a normal or stenotic distal common bile duct. Diagnosis is made histologically after cholecystectomy or ampullary biopsy or by examination of the bile for oocysts. Among patients who have HIV infection who are exposed to *Cryptosporidium*, those who have a $CD4^+$ T cell count less than 50 cells/mm^3 have an increased risk of developing biliary symptoms and of death within 1 year after the infection. Paromomycin treatment decreases stool frequency and oocyst excretion, but biliary disease progresses despite long-term therapy. Operative treatment includes cholecystectomy and sphincterotomy, with variable therapeutic success.[12]

Chapter 165 - Ova, Cysts and Parasites in the Stool

Peter L Chiodini

INTRODUCTION

The objective in the diagnosis of parasitic disease is to find the parasite and, for most infections, microscopy remains the 'gold standard'. If the specimen is examined by a competent microscopist, then a rapid, highly specific diagnosis can be obtained. However, the very need for experienced laboratory staff is also the weakness of microscopy as a diagnostic method, because well-trained pathologists and laboratory technologists are in short supply, especially in those areas of the world where parasitic disease is most prevalent. New methods for detection of parasite antigens by enzyme-linked immunosorbent assay (ELISA), 'dipstick' technology or detection of parasite DNA are coming into routine use. Optimum diagnosis requires:

- an understanding of the life cycles of the parasites and of their geographic distribution;
- examination of freshly collected samples, preserved where appropriate; and
- the use of the correct parasite isolation method and stain for those parasites potentially present in a given specimen.

When helminth eggs or larvae are found in the stool, the adult worms are usually situated in the bowel. Exceptions to this rule are:

- *Fasciola* spp., *Clonorchis* spp. (Fig. 165.1) and *Opisthorchis* spp., the adults of which live in the bile ducts;
- *Schistosoma* spp., paired adult worms of which live in the mesenteric or perivesical veins; and
- *Paragonimus* spp., the adults of which reside in the lungs.

The protozoa whose cysts or trophozoites are detected in stool samples are all primarily parasites of the gastrointestinal tract, although extraintestinal spread occurs in *Entamoeba histolytica* infection and in *Cryptosporidium parvum* or microsporidial infections in immunocompromised hosts (see Chapter 46).

Geographic distribution

The geographic distribution of the common parasites that can be diagnosed by stool examination is shown in Table 165.1 .[1]

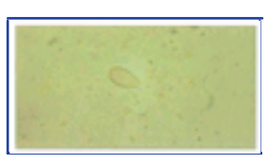

Figure 165-1 Ovum of *Clonorchis.* Large, operculated ova in fecal specimen.

INVESTIGATIONS TO CONFIRM THE DIAGNOSIS

Relevant information

The test request form should state the patient's clinical symptoms and signs, where the patient is normally resident and whether there has been any recent overseas travel, stating the particular location visited if so. If the patient is immunocompromised, this should also be stated because it should prompt the diagnostic laboratory to perform tests for parasites such as microsporidia, which might otherwise be omitted.

Sample collection

Unless the fecal sample is properly collected and taken care of, it will be of no value for diagnosis. A clean, dry container is essential; urine and water destroy protozoal trophozoites and dirt renders identification more difficult. Approximately 100g of feces is required. Ideally, the sample should be brought to the laboratory as soon as it is passed, to avoid deterioration of protozoal trophozoites. Diarrheal specimens and specimens containing blood or mucus should be examined promptly after receipt in the laboratory because such samples may contain motile amebic or flagellate trophozoites, which may become rounded and non-motile and be missed if examination is delayed. Where amebic dysentery is suspected, the laboratory should be advised that a 'hot' stool is being submitted, to permit its examination within 20 minutes of being passed. (It should be noted that the term 'hot stool' refers to the urgency of the request. The stool should not be heated but merely prevented from cooling significantly by prompt delivery to the laboratory.) With the exception of 'hot' stools, samples that cannot be examined on receipt should be stored at 39°F (4°C).

Rectal scrapes for amebae should be placed directly on to a microscope slide by the clinician performing the proctoscopy. A drop of 0.9% sodium chloride solution kept at 98.6°F (37°C) is added and a coverslip is applied. The scrapes are then taken directly to the laboratory, which should be informed in advance so that the specimen can be examined on receipt.

Rectal snips for schistosome eggs should be placed directly onto a microscope slide by the clinician taking them, a drop of 0.9% sodium chloride added and then a coverslip applied. The snips need to be examined promptly in the laboratory in order to prevent them from drying up.

Many laboratories routinely advise preservation of fecal samples as soon as possible, either immediately after collection or on receipt by the laboratory. Examples of preservation fluids include formalin, merthiolate-iodine-formalin and sodium acetate-acetic acid-formalin. The choice of preserving fluid is influenced by the subsequent technique to be used. For example, formalin is not a suitable fixative if permanently stained fecal smears are to be prepared.

Visual observation of the fecal sample

The macroscopic appearance of the fecal sample can sometimes give a clue to the underlying pathology; for example, the pale fatty

TABLE 165-1 -- Geographic distribution of the common parasites that can be diagnosed by stool examination.*

GEOGRAPHIC DISTRIBUTION OF THE COMMON PARASITES THAT CAN BE DIAGNOSED BY STOOL EXAMINATION	
Widespread, especially in areas of poor sanitation	**Organism**

Protozoa		*Giardia intestinalis (lamblia)*
		Entamoeba histolytica and
		Entamoeba dispar
		Cryptosporidium parvum
		Isospora belli
		Cyclospora cayetanensis
		Dientamoeba fragilis
		Blastocystis hominis
		Microsporidia (various species)
Helminths	Nematodes	*Strongyloides stercoralis*
		Hookworm
		Ascaris lumbricoides
		Trichuris trichiura
		Enterobius vermicularis
	Cestodes	*Hymenolepis nana*
		Hymenolepis diminuta
		Taenia saginata

Focal distribution		Geographic areas
Helminths		
Nematodes	*Capillaria philippinensis*	Philippines, Thailand, Egypt, Indonesia
Cestodes	*Taenia solium*	Central and South America, southern Asia, China, parts of Africa
	Diphyllobothrium latum	Russia, parts of North and South America, potential for transmission in eastern Scandinavia and eastern Europe
Trematodes	*Schistosoma haematobium* (ova occasionally seen in stool rather than urine)	Africa, eastern Mediterranean, Indian Ocean Islands, western Asia
	Schistosoma mansoni	Arabian peninsula, Africa, parts of South America, some Caribbean islands
	Schistosoma japonicum	China, Indonesia, Philippines, Thailand
	Paragonimus spp.	Asia, Africa, Central and South America (including China, Taiwan, Thailand, Cambodia, Nigeria, Peru, Ecuador)
	Clonorchis spp. and *Opisthorchis* spp.	Far East, eastern Europe, former Soviet Union
	Fasciola gigantica	Southern and South East Asia, Africa
	Fasciola hepatica	Parts of Europe, the Middle East, Africa, Central and South America.
	Fasciolopsis buski	Asia
	Heterophyids (including *Heterophyes* spp. and *Metagonimus*)	Asia, Siberia, Turkey, the Balkans

** Data from the World Health Organization.*[1]

stool of malabsorption may suggest giardiasis. The presence or absence of blood, mucus and exudate are noted. Adult nematodes (e.g. *Ascaris*, *Enterobius*) or tapeworm proglottids may also be seen in the specimen.

Preparation for microscopic examination

A formalin-ether or formalin-ethyl acetate concentration method should be performed on all fecal samples examined for parasites. This increases the numbers of ova, cysts and larvae per given volume by approximately 20-fold but does not improve the yield of trophozoites, which are usually destroyed by this method. Direct microscopy should be done on all unformed and liquid samples. This permits detection of amebic or flagellate trophozoites and provides information on the presence of any exudate in the stool (e.g. fecal leukocytes). All fecal specimens should be examined for the presence of *Cryptosporidium*. If laboratories are unable to do this, a minimum requirement is that all specimens from children up to and including 15-year-olds be tested.[2] Ideally, a permanently stained direct fecal smear should be prepared from all stool samples. Where resources are limited, its application may be restricted to bloody, liquid or semiformed stools. Permanently stained smears can reveal the presence of intestinal parasites that are either destroyed or missed by the formalin-ether or ethyl acetate concentration method. A plan for testing stool specimens is given in Figure 165.2 .

Reporting criteria

Ideally, the presence of all parasites should be reported, especially in the case of protozoan cysts, whether or not they are considered to be pathogens. If the practice of the laboratory is to report all parasites, the report should then state whether they are regarded as pathogens. The stage of the parasite should also be stated:

- for protozoa, whether cysts or trophozoites were seen; and
- for helminths, whether adult worms or their eggs were detected and the developmental stage of any larva found.

Morphology

The microscopic appearances of common protozoan cysts and trophozoites are summarized in Table 165.2 and Table 165.3 .

Particular care must be taken to distinguish oocysts of *Cyclospora* spp. from those of *Cryptosporidium* spp. because both are acid-fast in fecal smears stained with modified Ziehl-Neelsen stain (see Table 165.3).[3] [4]

It is important to note that cysts of *E. histolytica* and *Entamoeba dispar* cannot be distinguished from each other morphologically but, if amebic trophozoites are evident in a fresh stool preparation, the presence of ingested erythrocytes within them is diagnostic of *E. histolytica*. However, macrophages can also ingest erythrocytes, which can lead to confusion with amebae. Permanently stained preparations may be required to resolve the diagnosis.

Microsporidial spores can be visualized in a thin fecal smear by non-specific fluorescence[5] using calcofluor or uvitex 2B stains, but the presence of microsporidial spores must be confirmed using a modified trichrome stain[6] as small fungi and some artefacts may also fluoresce.[7] With the modified trichrome stain, the spores are seen as oval, pinkish structures with a polar vacuole, often with a diagonal line across the spore. Size varies according to species, with an approximate range of 1.5–3µm for the microsporidia found in human feces.

A key to identifying eggs of the common intestinal helminths is given in Figure 165.3 .[1]

Nematode larvae in fresh fecal specimens are usually the result of *Strongyloides* spp. infection. However, if an unfixed stool sample more than 12–24 hours old is received, hookworm eggs (Fig. 165.4) may hatch to release larvae, which then need to be distinguished from those of *Strongyloides*. When seen in fecal concentrates, rhabditiform larvae of hookworm are 100–150µm × 15–17µm in size, with a long (15µm) buccal cavity. The esophagus occupies one-third of the body

length and has two swellings. The hookworm larva has a small (7µm) genital primordium and the anal pore is 80µm from the

Figure 165-2 Laboratory examination of fecal specimens.

TABLE 165-2 -- Morphology of common protozoal cysts and trophozoites in fecal samples.

MORPHOLOGY OF COMMON PROTOZOAL CYSTS AND TROPHOZOITES IN FECAL SAMPLES					
Species	**Cyst**				**Trophozoite**
	Size (µm)	**Number of nuclei**	**Chromidial bar**	**Glycogen inclusion**	
Entamoeba hartmanni	7–9	1–4	Blunt, round end-young cyst	Diffuse	Clear pseudopodia
Entamoeba histolytica/dispar	9–14.5	1–4	Blunt, round end-young cyst	Diffuse	Ingested RBC (*E. histolytica* only), clear pseudopodia
Entamoeba coli	14–30	1–8	Seldom seen, sharp, splintered	Diffuse	Blunt pseudopodia, sluggish movement
Iodamoeba butschlii	9–15	1	-	One compact mass	Rarely seen
Endolimax nana	6–9	4 (pin-point)	-	-	-
Dientamoeba fragilis	No cyst stage				Small, angular, two nuclei
Refractile inclusion					
Giardia intestinalis (lamblia)	8–12	4 (not obvious)	Clear axostyle	-	Pear shaped, two nuclei, undulating flagella, little motility
Chilomastix mesnili	5–6	1	Axostyle	-	Size similar to *Giardia*, pointed tail, rapid motility
Trichomonas hominis	5–6	1	-	-	Undulating membrane
Enteromonas hominis	No cyst stage				Small, three flagellae

TABLE 165-3 -- Comparison of microscopic appearances of *Cyclospora*, *Isospora* and *Cryptosporidium*.

COMPARISON OF MICROSCOPIC APPEARANCES OF *CYCLOSPORA, ISOSPORA* AND *CRYPTOSPORIDIUM*			
	Cyclospora	***Isospora***	***Cryptosporidium***
Size range (µm)	8–10	20–33 × 10–19	4–6
Appearance in formalin-ether concentrate	Spherical refractile, greenish central morula. Unsporulated when passed in feces	Oval. Usually unsporulated when passed in feces	Not usually seen
Sporulated occyst	Two oval sporocysts, each containing two sporozoites	Two spherical sporocysts, each containing four sporozoites	Spherical or slightly ovoid; four sporozoites
Appearance in modified Ziehl-Neelsen stain	Irregular staining	Stains well, often cyst wall only	Stains well with pale center
Appearance under ultraviolet light	Bright blue autofluorescence	No effect	No effect
Fluorescence with auramine	Poor	Variable	Good; bright yellow discs, often with erythrocyte-shaped pattern
Fluorescence with monoclonal antibody to *Cryptosporidium*	Absent	Absent	Good; often shows line on surface of oocyst

posterior end. Rhabditiform larvae of *Strongyloides* (Fig. 165.5) are 200–300µm × 15–18µm in size, with a short (4µm) buccal cavity. The esophagus occupies one-third of the body length and has two swellings. The genital primordium is large (22µm) and the anal pore is 50µm from the posterior end.

Incubation of fecal samples in a charcoal-based culture system to yield filariform larvae is more sensitive than concentration methods for the diagnosis of *Strongyloides*. Again, any larvae isolated must be distinguished from those of hookworm. Filariform larvae of *Strongyloides* are 500µm × 14–20µm in size, unsheathed and have a forked tail. The esophagus occupies half the body length. Filariform larvae of hookworm are 500µm × 14–20µm in size, with a sheath and a tapered tail. The esophagus occupies one-third of the body length.

Serodiagnosis by ELISA provides a useful screening method for the diagnosis of *Strongyloides* but it exhibits some cross-reactivity with other nematode infections, which can render interpretation difficult.

Alternative methods to classical microscopy for the diagnosis of cysts, ova and larvae in the stool

In recent years there has been increasing interest in the development of new methods to detect parasites in fecal samples.

Cryptosporidium parvum

Cryptosporidial infection in humans is most commonly due to *C. parvum*, but *Cryptosporidium felis*, *Cryptosporidium muris* and *Cryptosporidium meleagridis* have been identified in immunocompromised individuals. *Cryptosporidium parvum* has two genotypes, type 1 (human-derived) and type 2 (animal- and human-derived), and it has been suggested that they may represent two distinct species. [8]

Oocysts of *C. parvum* can be detected with improved specificity by fluorescence microscopy using *Cryptosporidium*-specific monoclonal antibody. It is often possible to demonstrate a 'suture' line on the oocyst surface using this method. Cryptosporidial infection can also be diagnosed by an antigen-capture ELISA[9] for the detection of oocyst antigen in stool supernatant. The test has a reported sensitivity of 94% and specificity of 99% compared with microscopy. Using fluorescence-labeled probes for real-time detection of *Cryptosporidium* and melting curve analysis of the polymerase chain reaction (PCR) products to differentiate species and genotypes, the genetic polymorphism in the small subunit ribosomal RNA of *Cryptosporidium* can be exploited to detect and speciate cryptosporidia infecting humans. This provides a rapid tool for the investigation of water-borne outbreaks.[10] Detection of *Cryptosporidium* in water supplies also provides a powerful tool for outbreak investigation. Filtration and purification techniques such as immuno-magnetic separation and flow cytometry with fluorescent activated cell sorting provide efficient oocyst capture and

separation from noncryptosporidial debris. Polymerase chain reaction or reverse transcription (RT)-PCR methods permit speciation and genotyping of the parasite.[11]

Giardia intestinalis (Giardia lamblia)

Monoclonal antibody-based immunofluorescence can be used to detect *Giardia* sp. in a fecal smear. An ELISA is available for the detection of *Giardia*-specific antigen (GSA)-65, a glycoprotein of molecular weight 65kDa, in aqueous extracts of feces.[12] The assay has a reported sensitivity of 98–100% compared with conventional fecal microscopy and has the substantial advantage of analyzing many samples simultaneously without the subjectivity of microscopy.

Entamoeba histolytica and Entamoeba dispar

Understanding of human amebiasis has been transformed by the demonstration that the organism formerly known as *E. histolytica* is, in fact, two separate species, *Entamoeba histolytica* and *E. dispar*, the cysts of which are morphologically identical.[13] *Entamoeba histolytica* is pathogenic to humans; *E. dispar* is not. If cysts of *E. histolytica* or *E. dispar* are found in a fecal sample, further evaluation is required in order to determine whether *E. histolytica* is present. Amebic serology, if positive, supports the diagnosis of *E. histolytica* but, especially in areas where amebiasis is common, seropositivity may be related to past infection rather than to current infection. Furthermore, sensitivity of serology is low in asymptomatic amebic cyst passage.

Entamoeba histolytica infection can be diagnosed by an ELISA that detects antigen by using antibodies to the galactose adhesin of *E. histolytica*.[14] Reported sensitivity and specificity for identification of *E. histolytica* antigen are 92.6% and 96.7% respectively, compared with positive specimens in which *E. histolytica* could be identified by zymodeme analysis. Correlation between zymodeme analysis and the antigen detection ELISA is 94.7%.

Detection of *E. histolytica* and *E. dispar* in fecal samples can be undertaken by PCR-solution hybridization enzyme-linked immunoassay (PCR-SHELA).[15] [16] The PCR assay is based on primers specific for a 145bp DNA sequence in *E. histolytica* and a 133bp DNA sequence in *E. dispar*. These are based on highly repeated sequences in

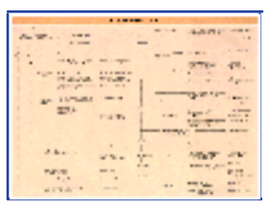

Figure 165-3 Key to the identification of helminth eggs. *Adapted from the World Health Organization.*[1]

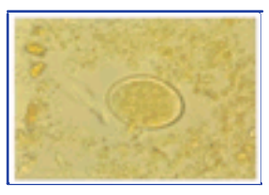

Figure 165-4 Ovum of *Diphyllobothrium latum* in a fecal specimen.

ribosomal DNA episomes, several hundred of which are present in each amebic trophozoite. Hybridization of PCR product to probes labeled with 5' digoxigenin (for *E. histolytica*) and 5' fluorescein (for *E. dispar*) is followed by colorimetric detection using peroxidase-labeled antidigoxigenin and peroxidase-labeled antifluorescein. The method is reported to identify 10^{-1} *E. histolytica* and 1–10 *E. dispar* trophozoites per gram of feces when they are present separately, and 10 *E. histolytica* and 100 *E. dispar* trophozoites per gram of feces in the presence of 10^6 trophozoites per gram of feces of the other species. When this assay was applied to 18 clinical specimens from which *E. histolytica* or *E. dispar* had been cultured and identified by isoenzyme analysis, the PCR-SHELA gave the correct result in each case.

Microsporidia

Microscopy for these organisms requires a high level of expertise and is time-consuming. Diagnosis can be aided by use of species-specific

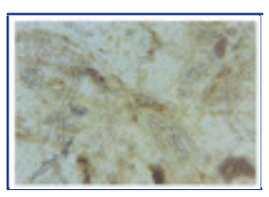

Figure 165-5 Numerous rhabditiform larvae of *Strongyloides* in a duodenal juice specimen.

immunofluorescence of microsporidial spores,[17] when sensitivity comparable to that achieved by PCR has been reported,[18] and by PCR.[19] One study comparing light microscopy and PCR for the detection of microsporidia in fecal specimens[20] recorded 89% sensitivity and 98% specificity for PCR, compared with 80% sensitivity and 95% specificity for light microscopy. Neither species-specific immunofluorescence nor PCR for these emerging pathogens is widely available at present.

TREATMENT AND COMPLICATIONS

Provided samples have been examined by a competent microscopist, identification of named parasitic ova, cysts or parasites in a fecal sample is diagnostic, and so specific treatment can be given. Empiric treatment is, therefore, rarely required.

The treatment and complications of these infections are discussed in Chapter 46 and Chapter 209 .

Chapter 166 - Malaria

Geoffrey Pasvol

INTRODUCTION

Malaria is an infection caused by the coccidian protozoan parasite of the genus *Plasmodium* carried by female *Anopheles* spp. mosquitoes. The clinical disease in humans may vary widely according to the species of parasite — *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale* or *Plasmodium malariae* — and the genetics, immune status and age of the host. These variables have a major influence on all aspects of the disease, including epidemiology, pathogenesis, clinical features and management.

EPIDEMIOLOGY

Geographic distribution

Wherever temperatures are favorable and humans and mosquitoes co-exist, there is the potential for malarial transmission. Malaria certainly existed until the mid-20th century in Europe, especially in Italy, as well as in northern parts of Asia adjoining the former USSR. Almost 2 billion people are at risk of malaria in endemic areas and each year it is estimated that up to 250 million clinical cases occur and over 1 million die, largely among infants and young children in Africa. [1] [2]

Malaria occurs throughout the tropics and subtropics, especially where the temperature exceeds the 60.8°F (16°C) isotherm (see Chapter 245 and Fig. 166.1). The four species of malaria parasites that affect humans differ in their geographic distributions:

- *P. falciparum* is most common in sub-Saharan Africa and Melanesia (Papua New Guinea and the Solomon Islands);
- *P. vivax* is found mainly in Central and South America, North Africa, the Middle East and within the Indian subcontinent;
- *P. ovale* is found predominantly in West Africa but also in Asia; and
- *P. malariae* occurs worldwide, although most cases occur in Africa.

With modern air travel, individuals with malaria can be rapidly transported within hours to any part of the world and malaria is the single most common imported infection occurring in travelers.

There have been occasional reports of 'airport malaria' where infected mosquitoes have been imported on board aircraft into a nonendemic area of the world where they infect local inhabitants who have not traveled.

A few outbreaks have also been documented in nonendemic areas where environmental conditions have become optimal for the transmission of disease by local susceptible mosquitoes becoming infected after biting individuals who have obtained their infection elsewhere (e.g. as occurred in New York in the summer of 1993). In addition, there is now the threat of a global climate change. If the predictions of a 3.6°F (2°C) rise by the year 2100 become a reality, this might lead to the spread of malaria back into areas previously affected by malaria.

Malaria can also be transmitted by blood and blood products.

The epidemiology of malaria depends upon a complex interplay between the:

- host (humans),
- vector (mosquito), and
- malarial parasite.

Population density and prevalence of infection among children are important factors because children tend to have both high parasitemias and rates of carriage of the sexual forms of the parasite (gametocytes), which are necessary for transmission of the infection. Paradoxically, in the 2 weeks after effective treatment of *P. falciparum* malaria, the numbers of gametocytes in the blood rises, so that while the patient improves clinically, mosquitoes biting the patient during this time are more likely to transmit infection.

The longevity of the mosquito is also crucial because it needs to be of sufficient duration to allow for full development of the parasite. Ambient temperatures have a major impact, because higher temperatures significantly shorten this period of maturation in the mosquito (the extrinsic incubation period) and increase transmission. Seasonal rainfall dramatically increases the breeding of mosquitoes.

Where malaria prospers, human societies prosper the least and there is a striking correlation between malaria and poverty. The effects of malaria are felt on diverse areas including fertility, population growth, savings and investment, worker productivity, absenteeism, premature mortality and medical costs.

PATHOGENESIS AND PATHOLOGY

Malaria is one of the few infective agents of humans that invades red cells. [3] [4] All four species of malarial parasites that infect humans have a similar life cycle that alternates between human and mosquito (see Chapter 245). The clinical symptoms and signs are produced by the asexual forms of the parasite, which invade and destroy red cells, localize in critical organs and tissues in the body, and induce the release of many proinflammatory cytokines (see Fig. 166.2), of which tumor necrosis factor (TNF)-a is thought to be the most important. The sporozoites injected by the bite of the infected mosquito, the exoerythrocytic parasites, which subsequently develop in the liver, and the sexual forms of the parasite (macro- and microgametocytes), which arise from the asexual forms do not cause clinical disease.

Invasion of red cells

Merozoites in the peripheral blood invade red cells (and occasionally platelets) and the rate and degree to which the parasite multiplies appear to relate to disease severity in nonimmune individuals. Invasion is a highly specific, ordered and sequential process in which the invasive form, the merozoite, attaches to a susceptible red cell, reorients itself so that its apical end is apposed to the red cell membrane, and then slowly moves into a localized invagination. [5] The entire process of invasion is completed within 30 seconds. In falciparum malaria the erythrocyte binding antigen (EBA 175) and/or merozoite surface proteins (MSP-1 and MSP-2) appear to interact with the red cell sialoglycoproteins (glycophorins), whereas in *P. vivax* infection, the red cell Duffy antigen on the uninfected red cell is involved (see Table 166.1). There is surprising redundancy in the

Figure 166-1 Distribution map of malaria. Despite intensive control measures over the past 50 years, malaria is still widely distributed in the tropics and subtropics. The breakdown of large-scale vector control operations and the emergence of multidrug-resistant parasites have even led to an increase in the incidence of malaria in some regions. O, areas where malaria has disappeared, been eradicated or never existed; +, areas with limited risk; + +, areas where malaria transmission occurs. *(Adapted from WHO 1999, Map No. WHO 99419 EF.) Courtesy of Dr C Lavaissiere.*

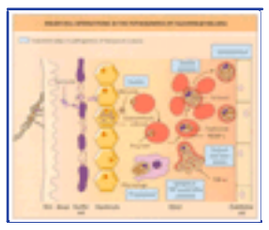

Figure 166-2 Major cell interactions in the pathogenesis of falciparum malaria. The injected sporozoites invade hepatocytes. Merozoites released from rupturing liver schizonts invade red cells. The parasite matures via the ring to the trophozoite to the erythrocytic schizont stage. Such schizonts can bind to uninfected red cells (rosette formation) or to the endothelial cells lining the postcapillary venules (cytoadherence). When the mature schizont ruptures, 'toxin'-like molecules are released which induce the release of proinflammatory cytokines such as TNF-a.

invasion pathways of *P. falciparum* and a number of sialoglycoprotein and nonsialoglycoprotein pathways have been identified.

Attachment and orientation is followed by interiorization accompanied by deformation of the red cell membrane. Although each merozoite of *P. falciparum* can theoretically produce from 16 to 32 new merozoites every 48 hours, a more realistic figure *in vivo* is between three and 10. It is only recently (largely because of technical difficulties) that parasite multiplicative ability within red cells (i.e. the ability to invade) has been shown to relate to disease severity.

TABLE 166-1 -- Major interactions of red cell invasion, rosetting, cytoadherence and TNF induction and some of the molecules involved in the pathogenesis of falciparum malaria.

MAJOR INTERACTIONS OF RED CELL INVASION, ROSETTING, CYTOADHERENCE AND TNF INDUCTION AND SOME OF THE MOLECULES INVOLVED IN THE PATHOGENESIS OF FALCIPARUM MALARIA				
	Invasion	**Rosetting**	**Cytoadherence**	**TNF Induction**
Parasite-induced molecules	Erythrocyte-binding antigen (EBA-175)	*Plasmodium falciparum* erythrocyte membrane-1 (PfEMP-1)	PfEMP-1	Glycosylphosphatidylinositol (GPI)-anchored molecules
	Merozoite surface protein-1 (MSP-1)	Rosettins	PfEMP-3	Phospholipid
	MSP-2/4/5		Histidine-rich protein-1 (HRP-1)	Hemazoin
	Apical membrane antigen (AMA)		Ring surface protein-1 + 2 (RSP1/2)	
	Rhoptry-associated protein (RAP-1)		Modified band-3 (Pfalhesin)	
	RAP-2		Cytoadherence-linked asexual gene protein (CLAG)	
	RAP-3			
Molecules of host cell origin	Glycophorin A (Gp-A)	CD36	CD36	CD 36 on monocyte/macrophages
	Gp-B	Rosettins	Thrombospondin	Red cell membrane
	Gp-C	Blood group A	Intercellular adhesion molecule (ICAM-1) (ICAM-2)	
	Sialic acid a2–3 linkage	Complement receptor-1 (CR1)	Vascular cellular adhesion molecule (VCAM-1)	
	Sialic acid independent pathways-as yet unspecified		Platelet endothelial cellular adhesion molecule (PECAM-1)	
			E-selectin	
			P-selectin	
			Chondroitin sulfate A (CSA)	
			Hyaluronic acid (HA)	
			Heparan sulfate-like glycosaminoglycans (GAG)	
			a_v ß$_3$ integrin	
Molecules in the host serum/plasma	Immunoglobulin	Nonimmune IgM	Immune immunoglobulin	Unknown
		Immune immunoglobulin		
		Other undefined factors		

Cytoadherence

Cytoadherence, the process whereby mature infected cells specifically bind to endothelial cells in postcapillary venules, appears to play a central role in the pathogenesis of falciparum malaria, possibly by localizing mature forms of the parasite in critical organs such as the brain.[6] In addition, cytoadherence of mature parasites:

- prevents their passage through the spleen, a major site of parasite destruction;
- localizes maturing parasites at sites of reduced oxygen tension, which favors parasite growth; and
- may facilitate the invasion of uninfected red cells.

However, despite these effects many studies have failed to find an association between cytoadherence and severe disease.[7] Cytoadherent parasites presumably lead to microvascular obstruction, although the role and extent of this obstruction remain unclear. Cytoadherence may also serve to localize the effect of parasite toxins, which lead to endothelial cell activation and damage as a result of cytokine release.

The molecular interactions that occur in cytoadherence have been studied in some detail. During parasite maturation a number of regular, symmetrically arranged 'knobs' appear on the surface of the infected cell. These knobs are thought to be the sites at which the parasitized red cell attaches to the endothelial cell. A number of high-molecular weight parasite proteins protrude from these knobs, of which the best known is the *P. falciparum* erythrocyte membrane protein (PfEMP)-1 coded for by the *var* (variant) genes. A single parasite may be capable of expressing up to 50 variants of PfEMP-1. Other possible adhesive parasite antigens on the infected red

cell surface include a molecule called sequestrin and a modified form of band 3 (the main anion transporter of the red cell) called pfalhesin.

In turn PfEMP-1 may bind to a number of potential receptors on the surface of endothelial cell. These include:

- the adhesion molecule CD36;
- the bridging molecule thrombospondin (a major component of the platelet a granule);
- two members of the immunoglobulin superfamily — intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule;
- E-selectin; and

- the recently described glycosaminoglycan, chondroitin sulfate A (see Table 166.1).

Whether PfEMP-1 is the molecule that binds to all of the above molecules has yet to be established. It appears that ICAM-1 and CD36 are the major ligands;[8] ICAM-1 acts as a rolling receptor, whereas CD36 and thrombospondin seem to be involved in more stable interactions. Cytokines, especially TNF-a, can upregulate the expression of ICAM-1. How cytoadherence leads to severe pathology remains an unresolved issue.

Rosetting

In rosetting, red cells containing the more mature stages of parasite bind uninfected red cells to their surface. The mechanisms by which rosetting leads to disease remain obscure, but may involve microcirculatory obstruction. Rosetting falciparum parasites have been associated with severe disease,[9] but both *P. vivax* and *P. ovale* are capable of rosetting without causing severe disease. The specific molecules involved in rosetting on the infected and uninfected red cell have not been fully characterized, although PfEMP-1 and small (between 20 and 40kDa) molecular weight 'rosettins' on the parasitized cell and CD36 and the ABO blood group molecules on the uninfected cell have been implicated (see Table 166.1). Most recently the complement receptor CR1, which is present at low levels (approximately 250 copies per cell) on uninfected cells, has been implicated as binding to PfEMP-1 and playing a role in rosetting.[10]

Parasite toxins and cytokines

The paroxysmal increase of many cytokines, notably TNF-a and interferon-?, during a febrile episode and coinciding with rupture of schizont-infected red cells suggests the release of a toxin. Attempts to identify a definitive malarial 'toxin' remain unproductive. Parasite molecules anchored in the red cell membrane by a glycosyl phosphotidylinositol (GPI) structure are favored candidates, but other molecules have been proposed, including an as yet undefined phospholipoprotein molecule and protease-sensitive components associated with malarial pigment (hemozoin). Antibodies to GPI anchors are associated with a lack of disease in adults. However, even products from lysed uninfected red cells are capable of inducing cytokine release from macrophages.

Different falciparum parasite lines vary in their capacity to stimulate TNF-a from macrophages. It is not known whether this observation is due to a quantitative or qualitative attribute of the toxin or why infection by *P. vivax*, sometimes leading to TNF levels comparable with falciparum malaria, results in relatively benign disease. This may be because *P. vivax* does not exhibit cytoadherence which would localize effects of the parasite in critical organs such as the brain.

It is proposed that such a malarial toxin or toxins lead to the release of the cytokines TNF-a interferon-? and interleukin (IL)-1 among others. There is a good correlation between high levels of TNF-a and the outcome of falciparum malaria. Production and release of TNF-a could account for the fever, leukocytosis, enhanced sequestration, hypoglycemia, acidosis and dyserythropoiesis, and possibly even the impaired consciousness observed in malaria. In addition, TNF-a may upregulate the expression of adhesion molecules such as ICAM-1 and other receptors that bind the parasitized red cell. Other cytokines may be synergistic.

Pathophysiologic events leading to cerebral malaria

There is a debate as to whether the major mechanism in the pathogenesis of malaria is:

- ischemia due to obstruction of the microcirculation by sequestering parasites; or
- release of mediators induced by the parasite toxin(s).

A model of the pathogenesis of cerebral malaria due to *P. falciparum* needs to take into account the delicate interplay between both factors, which may prove to be equally relevant. For example, sequestration, the result of rosetting and cytoadherence of infected cells, would not only lead to microvascular obstruction, but could also localize the effect of parasite toxins when released by rupturing schizonts.

In cerebral malaria there appears to be no reduction in total cerebral blood flow, although blood flow is low relative to the cerebral arterial oxygen content.[11] Cerebral malaria can occur in the absence of a localized inflammatory cell response, direct tissue invasion, a breakdown in the blood-brain barrier, cerebral edema, disseminated intravascular coagulation and hypoglycemia. The cerebrospinal fluid in cerebral malaria shows no increase in cell number or protein concentration and may only show a raised lactate concentration, and in some cases, especially in children, a raised opening pressure. [12] A raised cell count or protein concentration should cause one to think of an alternative or additional diagnosis.

Raised intracranial pressure has been invoked in the pathogenesis of cerebral malaria in children in Africa, but its role in adult disease has yet to be determined, although the volume of the brain is increased, probably as a result of sequestration and compensatory vasodilation of the cerebral vasculature.[13]

Tissue infarction is not a major feature of cerebral malaria. In addition, the majority of patients who recover from coma due to malaria appear to have few, if any, neurologic sequelae, in contrast to those resulting from other neurologic infections of equal severity.

Small microhemorrhages may occur around capillaries and venules, but there are few platelets or microthrombi.

The syndrome of cerebral malaria appears to be related to the tight packing of schizonts in the small capillaries of the brain.[14] This process is brought about by sequestration, which in turn results from cytoadherence, rosetting or the decreased deformability of infected cells or a combination of these factors.

PREVENTION

There are a number of points in the malaria parasite's life cycle where the infection can be interrupted. This mainly involves reduced mosquito contact and the use of antimalarial chemoprophylaxis. Vaccination against malaria is currently not a reality.

Antimosquito measures

In endemic areas those at risk should:

- sleep in properly screened rooms;
- use mosquito nets without holes and impregnated with permethrin and tucked in carefully under the mattress before nightfall;
- wear long-sleeved clothing and long trousers when outdoors after sunset; and
- use other adjuncts — insect spray (usually containing permethrin) and mosquito coils or repellents such as diethyltoluamide, DEET or citronella.

For those living in highly endemic areas, the use of permethrin-impregnated bednets has been found to reduce both malarial morbidity and mortality. However, problems remain regarding cost, state of repair of the net, regular impregnation and how the bednets might change the rate of acquisition of immunity and consequently the pattern of disease, especially relating to severity. By protecting the very young against the severe manifestations of malaria, it is argued that severe complications may be deferred until they are older, but this remains a theoretic possibility only.

Malarial chemoprophylaxis

The spread of drug-resistant *P. falciparum* malaria and awareness that some of the more effective combination drugs, such as pyrime-thamine with sulfadoxine

(Fansidar) and pyrimethamine with dapsone

TABLE 166-2 -- **Brief guidelines for the chemoprophylaxis of malaria.**

BRIEF GUIDELINES FOR THE CHEMOPROPHYLAXIS OF MALARIA		
Chemoprophylaxis	**Area to be visited**	**Dose/comments**
None	North Africa (Morocco, Algeria, Tunisia, Libya, tourist areas of Egypt)	Antimosquito measures should still be applied. Risk of other vector-borne diseases still possible
	Tourist areas of South East Asia (Thailand, Philippines, Hong Kong, Singapore, Bali, China)	
Chloroquine	Middle East (including summer months in rural Egypt and Turkey)	300mg base (2 tablets) once per week
or	Central America	
proguanil (Paludrine)	Rural Mauritius	200mg (2 tablets) once per day
Chloroquine and proguanil	Indian subcontinent	Doses as above. Also indicated:
	Afghanistan and Iran	• in pregnancy (safe)
	South America	• in children (liquid formulations)
		• when other antimalarials cannot be tolerated
Mefloquine (Lariam), doxycycline or Malarone (each tablet contains atovaquone 250mg and proguanil 100mg)	Sub-Saharan Africa, e.g.	*Mefloquine*: 250mg (1 tablet) per week.
	Cameroon, Kenya, Malawi, Tanzania, Uganda, Zaire, Zambia	Use especially in areas of high risk. Use up to 1 year
	All rural areas of SE Asia, Papua New Guinea, Solomon Islands and Vanuatu	Contraindicated in epilepsy and psychiatric disorders
		Doxycycline: 100mg per day. Beware light sensitization
		Malarone: Start 1 day before entry, during and 1 week after exit from a malarious area
Doxycycline	As above and mefloquine-resistant parts of South East Asia	100mg daily
		Can be used as an alternative to mefloquine, Malarone or chloroquine and proguanil where these are not tolerated
Specialist advice should be sought for details.		

(Maloprim) and amodiaquine (Camoquin), may rarely have severe and sometimes fatal side-effects[15] have complicated malarial chemoprophylaxis. The risk of contracting malaria in any given country or situation needs to be weighed constantly against the risk of a serious adverse reaction to any drug used. In the absence of adequate data, this becomes difficult. Compliance is of extreme importance because, although those who comply poorly have a similar attack rate, their risk of death is much greater than that of individuals on no prophylaxis.

A brief guide to antimalarial chemoprophylaxis is shown in Table 166.2 . If there is any doubt, specialist advice should be sought (see also Chapter 143). Chemoprophylaxis should start 1 week before entering an endemic area (to ensure adequate blood levels and to evaluate any potential side-effects), and continue while within such an area and for 4 weeks after return except in the use of Malarone which can be commenced on the day before entry into a malarious area and continue for a week after leaving. Chloroquine, two tablets (300mg base) once a week, together with proguanil, two tablets (200mg) daily, is one of the safest and most inexpensive regimens, but is of diminishing efficacy. These drugs have only minor side-effects, the commonest being difficulty in visual accommodation in the case of chloroquine and mouth ulcers with proguanil. There is increasing use of mefloquine one tablet (250mg) weekly, doxycycline one tablet (100mg) daily and Malarone one tablet daily, by travelers to sub-Saharan Africa, Papua New Guinea and the Solomon Islands because of chloroquine resistance.[15] The main side effects of mefloquine are neuropsychiatric and are of varying severity. Doxycycline can lead to light sensitization and Malarone can cause gastroenterological upset.

More detailed and specialist advice should be sought in specialized circumstances, including for:

- long-term visitors,
- children under 12 years of age,
- individuals who have drug allergies, immunosuppression because of disease or therapy, or epilepsy, and
- women who are pregnant.

In individuals born and living in an endemic area chemoprophylaxis should be made available for those with sickle cell disease and pregnant women.

Vaccination

An effective and safe malarial vaccine is still not available. A live attenuated whole sporozoite vaccine has been shown to work, but only on a very small scale and is impractical for widespread use. Results with the SPf66 vaccine, a synthetic peptide, have proved disappointing. Most recently a vaccine using part of the circumsporozoite protein linked to hepatitis B surface antigen and administered in a formulation with a novel adjuvant has shown preliminary promise but protection appears short-lived. A DNA-based vaccine has also been tested.[16]

CLINICAL FEATURES

The most frequent presentation of malaria is that of a pronounced febrile illness with rigors. However, the clinical features of malaria can be extremely diverse because the parasitized red cell circulates to every organ and tissue within the body and therefore has the

TABLE 166-3 -- Manifestations of severe malaria requiring special management.

MANIFESTATIONS OF SEVERE MALARIA REQUIRING SPECIAL MANAGEMENT	
Manifestation	**Comment**
Cerebral malaria	Coma with peripheral parasitemia and other causes of encephalopathy excluded
Severe anemia	Normocytic anemia with hemoglobin <50g/l (5gm/dl) (<15% hematocrit) in presence of parasitemia >10,000/µl
Respiratory distress	Pulmonary edema or adult respiratory distress syndrome
Renal failure	Urine output of less than 400ml/24h (or less than 12ml/kg in children) and a serum creatinine >3.0mg/dl (265µmol/l)

Hypoglycemia	Whole blood glucose <40mg/dl (2.2mmol/l)
Circulatory collapse (shock)	Systolic blood pressure less than 70mmHg or core skin temperature difference >18°F (10°C)
Coagulation failure	Spontaneous bleeding or laboratory evidence of disseminated intravascular coagulation
Impaired consciousness of any degree, prostration, jaundice, intractable vomiting, parasitemia =2%	In nonimmune individuals should be managed as severe malaria (i.e. with parenteral antimalarials)

potential for producing a wide variety of pathology. In endemic areas the manifestations of severe disease in children are mainly those of cerebral malaria, often with convulsions, respiratory distress and severe anemia (Table 166.3), whereas adults are more likely to develop multiorgan failure (e.g. renal failure) and are less likely to have convulsions or severe anemia. Complications of prolonged malarial infection such as hyperactive malarial splenomegaly (HMS) and nephrotic syndrome due to *P. malariae* infection are rare in travelers.

Mild malaria

The incubation period for malaria is variable, but under optimal conditions may be as short as 7 days and in exceptional cases up to 20 years, as in the case of *P. malariae* infections. The majority (>90%) of *P. falciparum* infections in travelers occur within 6 weeks of leaving an endemic area.

The clinical presentation of mild malaria with rigors is well known. There is usually a history of travel to or residence within an endemic area. A history of even the best compliance with the most effective antimalarial chemoprophylaxis cannot exclude the diagnosis. There may be a prodromal period of tiredness and aching. The features of a classic paroxysm are:

- an abrupt onset of an initial 'cold stage' associated with dramatic rigors in which the patient visibly shakes;
- an ensuing 'hot stage' during which the patient may have a temperature of well over 104°F (40°C), may be restless and excitable, and may vomit or convulse; and
- finally, the sweating stage, during which the patient defervesces and may fall asleep.

Such a paroxysm may last 6–10 hours and a prolonged asymptomatic period may follow and last 38–42 hours in the case of *P. vivax* and *P. ovale* infections and 62–66 hours in *P. malariae* infections. In *P. falciparum* infections the periodicity of fever tends to be less predictable and the fever may be continuous. There may be an accompanying headache, cough, myalgia (flu-like symptoms), diarrhea and mild jaundice.

Malaria is rarely, if ever, the cause of lymphadenopathy, pharyngitis or a rash, and alternative explanations need to be considered for these specific symptoms.

Severe malaria

Definitions of the clinical manifestations of severe falciparum malaria are included in Table 166.3 . [17] However, many of these definitions are for study purposes in order to compare data from different parts of the world, especially for the standardization of clinical trials, and must be taken in context. For example, any degree of impairment of consciousness, prostration, jaundice or evidence of renal impairment, especially in a nonimmune individual, should be taken seriously. Furthermore, parenteral therapy is regarded by many as necessary for a parasitemia of 2% or above in a nonimmune patient and in the presence of vomiting.

Cerebral malaria

Cerebral malaria in which the patient passes from drowsiness into coma may develop insidiously over a few days or abruptly within 1–2 hours and is often heralded by a convulsion. The majority of patients have no focal neurologic signs, but there may be a wide variety of neurologic manifestations such as a cranial nerve palsy, monoplegia or hemiplegia, extensor posturing, decerebrate or decorticate rigidity, conjugate or even dysconjugate eye movements, grinding of the teeth (bruxism) or hiccoughs. Some patients have retinal hemorrhages (Fig. 166.3), sometimes with extramacular whitening of

Figure 166-3 Retinal hemorrhage in severe *falciparum* malaria. Examination of the fundus is important in the physical examination of a patient with severe *falciparum* malaria as it can give some indication as to prognosis. In this case the hemorrhage is near the macula. Such hemorrhages have been found in as many as 18–30% of patients with cerebral malaria. In children, additional changes of extramacular whitening and changes in which the vessels turn white in isolated segments, often at branch points, occur.

Figure 166-4 Massive hepatosplenomegaly in a patient with severe malarial anemia due to *P. falciparum.* This CT scan of the abdomen was taken in a traveler from West Africa who, after a prolonged history of fevers, presented with a hemoglobin concentration of less than 50g/l. The scan shows a massively enlarged liver, the left lobe of which is encircling an equally enlarged spleen.

the fundus and retinal vessel changes where they turn white in isolated segments, particularly at branch points. Coma in malaria may not only be due to primary neurologic involvement, but may also be part of a prolonged postictal state, status epilepticus or a severe metabolic disorder such as acidosis or hypoglycemia. Thus drowsiness and coma may be the result of a number of different pathological processes.

Anemia

The anemia of falciparum malaria is both complex and multifactorial. [18] [19] The fall in hemoglobin is often far in excess of what can be accounted for by the loss of infected red blood cells alone. The major mechanisms in the pathogenesis of anemia are those of:

- red cell destruction because of rupture of infected cells, removal of uninfected cells due to antibody sensitization or other physicochemical changes, and increased reticuloendothelial activity, particularly in organs such as the spleen; and
- decreased red cell production due to marrow hypoplasia as seen in acute infections and dyserythropoiesis, a morphologic appearance that in functional terms results in ineffective erythropoiesis.

Two clinical presentations of anemia predominate which represent the ends of a clinical spectrum.

- Severe acute malaria in which anemia supervenes but only after a few days of severe illness such as cerebral malaria. There may be respiratory distress with acidosis, cardiac failure (often difficult to diagnose in children), poor tissue perfusion and death. There is shortened red cell survival (hemolysis) and evidence of bone marrow suppression despite the progressive fall in hematocrit.
- Severe anemia in patients in whom the illness has developed insidiously over a period of days or sometimes weeks (Fig. 166.4). These patients are often very young children living in endemic areas and are anemic when first seen. They have splenomegaly of varying degree and the peripheral blood film may show only scant asexual parasitemia. The bone marrow often shows a picture of dyserythropoiesis, although in this setting erythropoietin levels may be raised but not necessarily appropriate for the degree of anemia. In many cases gametocytes and malarial pigment are seen in phagocytic cells. Because the development of this

type of anemia is slow, there is adaptation to the low hematocrit and the clinical condition may often conceal the severity of the underlying anemia.

Figure 166-5 Chest radiograph of a patient with acute respiratory distress sydrome (ARDS) due to *falciparum* malaria. This X-ray shows new, bilateral, diffuse, homogeneous pulmonary infiltrates without cardiac failure, fluid overload, chest infection or chronic lung disease in an adult with severe *falciparum* malaria. The prognosis is poor. This condition is rare in children.

Respiratory distress

Respiratory distress is manifest by rapid labored breathing and sometimes abnormal rhythms of respiration.[20] In children there may be intercostal recession, use of the accessory muscles of respiration and flaring of the alar nasae, making it difficult to differentiate from an acute respiratory infection.

Respiratory distress in patients with malaria may be the result of a number of pathologies:

- ¦ respiratory compensation for a profound metabolic acidosis in the majority of cases;
- ¦ a direct effect of the parasite or raised intracranial pressure on the respiratory center in the brainstem;
- ¦ secondary lung infection as a consequence of immunosuppression;
- ¦ air hunger as a result of severe anemia; and
- ¦ pulmonary edema as a consequence of hypoalbuminemia, iatrogenic fluid overload or direct alveolar capillary damage by parasites and neutrophils leading to the acute respiratory distress syndrome (Fig. 166.5);
- ¦ overuse of anticonvulsants, particularly phenobarbitone which depresses the respiratory center drive.

Identification of these different causes of respiratory distress is important as they each require different modalities of management.

Acidosis

Acidosis (base excess =12) or acidemia (pH <7.3) in malaria indicates a poor prognosis and can be due to a number of causes:[21]

- ¦ poor tissue perfusion, in some cases due to hypovolemia, leading to reduced oxygen delivery;
- ¦ lactate production by the parasite;
- ¦ lactate generation as a result of cytokine activity, especially TNF, in the acute phase response;

- ¦ reduced hepatic blood flow and therefore lactate clearance;
- ¦ impaired renal function and therefore acid excretion; and
- ¦ exogenous acids due to aspirin (salicylate) administration.[22]

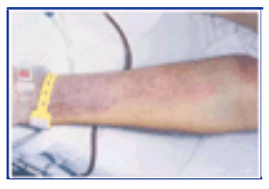

Figure 166-6 Disseminated intravascular coagulation in *falciparum* malaria. Bleeding into the skin seen in a patient with a thrombocytopenia, a prolonged prothrombin time, increased fibrinogen degradation products and hypofibrinogenemia. The patient had no signs of cerebral malaria.

Hypoglycemia

The characteristic clinical manifestations of hypoglycemia may not be evident in malaria, often because the patient is already unconscious. Suspicion of this important complication is often circumstantial: on admission in children and during quinine therapy in adults. The cause of hypoglycemia is multifactorial: [23]

- ¦ depletion of glucose stores because of starvation or malnutrition;
- ¦ malabsorption of glucose due to decreased splanchnic blood flow;
- ¦ increased tissue metabolism of glucose;
- ¦ parasite utilization of glucose;
- ¦ cytokine-induced impairment of gluconeogenesis; and
- ¦ hyperinsulinemia due to quinine therapy.

Anaerobic metabolism of glucose leads to acidemia and the production of lactate. Acidemia (blood pH <7.3) and hyperlactatemia are important prognostic factors in severe malaria. Acidemia is associated with respiratory rhythm abnormalities (especially a slow respiratory rhythm) and death.

Shock

Unlike the sepsis syndrome, shock is relatively rare in severe malaria. In most cases the blood pressure of patients with malaria is at the lower end of the normal range, probably due to vasodilatation. Marked hypotension in a few cases may be the result of dehydration, but is more commonly due to concomitant sepsis. Care should be taken to look for signs of sepsis, especially septicaemia and respiratory and urinary tract infection.

Bleeding

Bleeding due to the commonly occurring thrombocytopenia in malaria is rare. Bleeding is more likely to occur in the setting of disseminated intravascular coagulation (Fig. 166.6). However, more often there is only subtle activation of the coagulation cascade with a reduction in antithrombin III concentration, an increase in

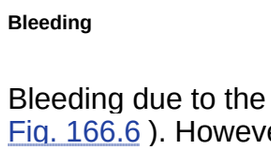

Figure 166-7 Blackwater fever. Urine specimen on admission (left) and days 2, 3 and 4 in a cross-Africa traveler with *falciparum* malaria on quinine treatment, showing the characteristic dark urine of blackwater fever, which showed gradual clearing. The same patient presented with a fever 1 week later and when treated presumptively for malaria with quinine, developed dark urine once again. Renal function was only mildly impaired.

thrombin-antithrombin III complexes and a reduction in factor XII and prekallikrein activities, which do not appear to be clinically significant.[24]

Renal involvement and blackwater fever

A degree of renal impairment, often due to hypovolemia but not always clinically evident, almost always occurs in severe malaria. Acute renal failure, which is less common, may occur in malaria both during the acute parasitemic phase, but also after parasite clearance.[25] In addition, the acute renal failure of malaria may be nonoliguric. Although the urinary manifestation of blackwater fever may be dramatic (Fig. 166.7), occurring in the setting of glucose-6-phosphate dehydrogenase (G6PD) deficiency or a semi-immune patient given quinine, it does not invariably lead to renal failure and appears to be considerably more benign than the classically

described syndrome.[26]

Differential diagnosis

Malaria may have little to distinguish it from other febrile illnesses. In the absence of a travel history, malaria can be transmitted in

'airport malaria' where infected mosquitoes are brought from endemic areas on planes or due to autochthonous spread during a hot summer in a nonendemic area where infected individuals pass the infection on to the local mosquito population. Malaria must also be considered in patients with a fever after blood transfusion, organ transplantation or needlestick injury. A critical step in the diagnosis of malaria, especially outside endemic areas, is consideration of the possibility of this diagnosis. A travel history should now be a routine part of any clinical consultation, especially in patients with a fever. Malaria needs to be excluded in any febrile patient in or returning from an endemic country whether or not they have been taking antimalarials. No antimalarial at present can guarantee absolute protection.

Malaria is a great mimic and must enter the differential diagnosis of a number of clinical presentations.

- In the acute presentation fever due to malaria needs to be differentiated from typhoid, viral illnesses such as dengue fever and influenza, brucellosis and respiratory and urinary tract infections. Less common causes of tropical fevers include leishmaniasis, trypanosomiasis, rickettsial infections and relapsing fevers.
- The coma of cerebral malaria need to be differentiated from meningitis (including tuberculous meningitis), encephalitis, enteric fevers, trypanosomiasis, brain abscess and other causes of coma (see Chapter 153).
- The anemia of malaria can be confused with other common causes of hemolytic anemia in the tropics such as that due to the hemoglobinopathies (e.g. sickle-cell disease, thalassemia), G6PD deficiency, and the South East Asian form of ovalocytosis. The anemia of malaria must be differentiated from that of iron, folate or vitamin B12 deficiency.
- The renal failure of malaria must be distinguished from renal impairment due to massive intravascular hemolysis seen in G6PD deficiency, sickle-cell disease, leptospirosis, snake envenomation, use of traditional herbal medicines and chronic renal disease resulting from glomerulonephritis and hypertension.
- The jaundice and hepatomegaly of malaria must be distinguished from that of viral hepatitis (A, B and E, cytomegalovirus and Epstein-Barr virus infections), leptospirosis, yellow fever, biliary disease and drug-induced disease, including alcohol.

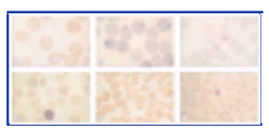

Figure 166-8 Thin blood films from patients with malaria. (a) Delicate small ring forms of *Plasmodium falciparum* showing multiply infected red cells and a characteristic 'appliqué' form in the uppermost parasite in the central red cell where the parasite appears as if it is applied to the surface, rather than within the red cell. (b) Ring forms of *P. falciparum* in a heavy infection and where the pH of the stain is 7.2 rather than 6.7 showing the irregular, basophilic Maurer's clefts in the cytoplasm of infected cells characteristic of *P. falciparum.* (c) Very early trophozoites of *P. falciparum* in the peripheral blood film of a patient with severe disease. The relative size and presence of pigment indicate the greater maturity of the parasite and may indicate a poorer prognosis. (d) Peripheral blood film from a patient with *vivax* malaria showing mixed ring and schizont forms. The ring forms are far more fleshy and ameboid and the cytoplasm of the infected cell shows the characteristic regular and eosinophilic Schüffner's dots, which help in diagnosis. (e) Peripheral blood film from a patient with *ovale* malaria showing a small ring form on the left, which could quite easily be mistaken for *P. falciparum*. The larger central parasite has enlarged the cell into an oval shape and has also formed a fimbriated fringe at the upper pole of the cell. (f) Peripheral blood film from a patient with *malariae* malaria showing the characteristic rosette schizont with daughter merozoites (usually eight) around a central piece of pigment (*hemazoin*). The ring forms of this species characteristically form a band stretching across the width of the red cell.

Clinical diagnosis on its own is notoriously inaccurate and may be incorrect in up to 50% of cases.

DIAGNOSIS

The definitive diagnosis of malaria is made by prompt microscopic examination of thick and thin blood films. There is no need to wait for a fever peak before carrying out a blood film as parasites are often present throughout the red cell cycle. Malarial chemoprophylaxis should be withheld during investigation for malaria as antimalarials can suppress peripheral parasitemia.

The most common abnormality on full blood count is thrombocytopenia, especially in the nonimmune. This is thought to be largely splenic pooling of platelets but also platelet activation.[34] The total white count is usually in the normal range but often there is a lymphopenia on presentation due to lymphocyte redistribution and more recently, apoptosis of lymphocytes has been identified in falciparum malaria.[35]

Thick blood films

One or two drops of blood from a fingerprick are stirred in a circle on a glass slide, allowed to air dry and then stained with Giemsa or Field's

stain. With this method, the red cells lyse whereas the white cells and parasites remain intact. Parasites are identified by recognizing both the eosinophilic nucleus and the basophilic cytoplasm of the malarial parasite. Parasite density can be related to the number of white cells present. This method has far greater sensitivity than the thin blood film.

Thin blood films

A thin film is produced by spreading a small drop of blood across a slide using the edge of a second slide, thereby producing a monolayer of red cells. Fixation is usually with methanol and the staining technique is as for the thick blood film (optimally at pH 7.2). The red cells remain intact. The thin blood film allows accurate speciation of the parasite and quantitation, in which the number of parasites is related to the number of red cells present. It is important that parasites are accurately recognized, as platelets or debris can often be mistaken for parasites. The size, shape and stippling of the red cell cytoplasm help in the speciation of the parasite. Examples of the four species are shown in Figure 166.8 .

Other valuable information can be obtained from the blood film, especially in severe disease. Careful staging of the parasites in the peripheral blood can indicate disease severity as the presence of more mature parasites may reflect a greater proportion of sequestered parasites and indicate more severe disease (Fig. 166.8).[27] The presence of malarial pigment in more than 5% of neutrophils provides some indication of the total parasite load and is associated with a poor prognosis.[28]

Other methods

Malaria can be diagnosed using other methods, but each has its own drawbacks with regard to time, cost or being nonquantitative or nonspecific.

- The polymerase chain reaction is useful for making an accurate species diagnosis and detecting low level parasitemias, but its expense, the time taken and requirement for specialized equipment make it impractical. This methodology is currently more frequently used in epidemiological and pharmacological studies.
- The QBC (quantitative buffy coat) method involves taking blood into a small capillary tube containing a float and an acridine orange stain, which stains the nuclear material of parasites and increases the sensitivity of detection, but its expense and inability to speciate or quantitate parasites accurately are limiting factors. Rapid dipstick methods have in many cases replaced this methodology.
- The ParaSight F and the Malaria PF antigen capture tests use a monoclonal antibody to the histidine-rich protein 2 of *P. falciparum* and are very useful tests in those who have not had malaria before, requiring minimal expertise. However, these tests are expensive, not quantitative and can only detect the presence of *P. falciparum*.
- The OptiMAL test detects parasite lactate dehydrogenase (pLDH) which can be distinguished from human LDH. This test can also distinguish *falciparum* from *vivax* infections.
- Autopsy diagnosis.

MANAGEMENT

Once a definitive diagnosis of malaria has been made treatment with specific antimalarial drugs can be initiated.[29]

Non-falciparum malaria

Malaria due to *P. vivax*, *P. ovale* or *P. malariae* requires a standard course of treatment with chloroquine, which usually leads to defervescence (Table 166.4). Chloroquine-resistant asexual forms of *P. vivax* have recently been documented and may require quinine treatment. In the case of *P. vivax* and *P. ovale* malaria treatment with an 8-aminoquinoline (primaquine) is given to eradicate the exoerythrocytic forms, especially the hypnozoites responsible for relapses. Levels of G6PD should be measured in all patients before they are given primaquine, an oxidant drug which can lead to major hemolysis in G6PD-deficient individuals. Treatment with primaquine should be delayed until after delivery and/or breastfeeding in pregnant women. Primaquine-resistant *vivax* hypnozoites have been identified which require more prolonged (often 3 weeks) and higher dose (22.5mg/day) therapy.

Falciparum malaria

Mild falciparum malaria

In endemic areas the treatment of malaria in children involves the use of drugs that are locally affordable and appropriate. For this reason mild *falciparum* malaria in many parts of Africa is still treated with chloroquine as for non-*falciparum* malaria and recrudescences are treated with pyrimethamine/sulfadoxine (Fansidar). For travelers and in areas where there is resistance to chloroquine and pyrimethamine/sulfadoxine, the mainstay of treatment is oral quinine sulfate used as shown in Table 166.4 , followed by the use of pyrimethamine/sulfadoxine or doxycycline to eradicate remaining asexual forms of the parasite. Mefloquine may be used and more recently drug combinations such as atovaquone with proguanil (Malarone) and artemether/lumefantrine (Coartemether) have been successfully used. Whichever drug is used, parasitemia may paradoxically rise in the first 24–36 hours and is not generally indicative of treatment failure.

Severe falciparum malaria

The management of severe *falciparum* malaria constitutes a medical emergency.[29] The diagnosis needs to be confirmed microscopically and intravenous access obtained as soon as possible. Depending upon the clinical manifestations, the investigations detailed in Table 166.5 should be carried out.

Patients with severe malaria should be transferred to the highest possible level of clinical care (e.g. a high-dependency or intensive therapy unit). Measurement of glucose and where possible lactate and arterial blood gases should be performed in the initial assessment. An effective antimalarial, at present quinine in most cases, should be given intravenously by slow infusion. Meticulous care must be given to fluid balance as both dehydration and overhydration can occur as a result of the disease or treatment. Convulsions should be treated with intravenous diazepam and attention paid to hypoglycemia and hyponatremia. The routine use of prophylactic anticonvulsants is unwarranted.

Blood should be taken for cross-matching and coagulation studies. A baseline electrocardiogram should be obtained with careful observation of the rhythm and QT interval in elderly patients, particularly those with underlying heart disease, and where possible a cardiac monitor should be set up.

In endemic areas a loading dose of quinine (20mg/kg) should be given to young children and fit young adults. Care is necessary in the administration of quinine to the elderly, especially where there is underlying cardiovascular disease because of the risks of arrhythmias. Quinidine can be safely and effectively substituted for intravenous quinine (intravenous quinine is not available in the USA). Cardiac dysrhythmias and hypotension may occur and therefore quinidine should be administered in an ICU setting.

Recent evidence in childhood malaria has shown that blood transfusion may be of benefit in patients who have respiratory distress and metabolic acidosis. [30] In units with appropriate facilities complicated hyperparasitemia may be treated with exchange transfusion. The use of exchange transfusion is controversial,[31] but should be considered where safe blood is available for all patients in whom the parasitemia exceeds an arbitrary 30% and for those in whom parasitemia is lower, but who:

TABLE 166-4 -- Summary of the drug treatment of malaria.

SUMMARY OF THE DRUG TREATMENT OF MALARIA			
Type of malaria	**Drug**	**Dose**	**Comments**
Non-*falciparum* malaria	Chloroquine phosphate or sulfate (each tablet contains 150mg base)	Loading dose 600mg, 300mg 6 hours later, then 300mg daily for 2 days (i.e. 10 tablets)	Chloroquine and primaquine resistance now documented for *vivax* malaria
	Followed in *vivax* and *ovale* malaria by primaquine	15mg daily for 14 days	Not given in G6PD deficiency or 45mg weekly for 6 weeks with monitoring for hemolysis. Not given in pregnancy
***Falciparum* malaria**			
Mild			
(A range of treatments can be used depending on availability of drugs and choice of local practice)	Quinine sulfate	10mg (salt)/kg (usually 600mg) q8h po for 3–7 days (at a practical level when parasite clearance has been achieved for 24 hours)	Almost all patients develop cinchonism (ringing in the ears, deafness, nausea, vomiting, etc.) and especially if they have liver or renal impairment. Reduce dose to q12h if the parasite count is falling
	Followed by: doxycycline or pyrimethamine/sulfadoxine (Fansidar)	200mg loading dose, then 100mg daily for 6 days Single dose of three tablets (each tablet contains 500mg sulfadoxine and 25mg pyrimethamine)	Not for children or in pregnancy Mainly for malaria from West Africa; doxycycline is preferred with increasing resistance to Fansidar in Africa
	Atovaquone and proguanil (Malarone)	Four tablets daily for 3 days (each tablet contains atovaquone 250mg and proguanil 100mg)	Fewer side-effects than quinine — mainly gastrointestinal. Caution as newly approved drug
	Artemether and lumefantrine (Riamet)	Four tablets q12h for six doses (each tablet contains artemether 20mg and lumefantrine 120mg)	Relatively few side-effects. Caution as newly approved drug
	Mefloquine	750mg as a single dose, repeated after 6 hours	Contraindicated in early pregnancy and in patients who have a neuropsychiatric history
Severe	Quinine dihydrochloride	10mg (salt) per kg, q8h until parasites cleared, then doxycycline or Fansidar as above when the patient can take medication orally	Can induce hypoglycemia and cardiac arrhythmias; a loading dose 20mg/kg can be given to young otherwise healthy patients when hyperparasitemia cannot be treated by exchange transfusion

Severe — newer regimens	Artemether (a qinghaosu (artemesinin) derivative)	3.2mg/kg iv followed by 1.6mg/kg daily (usual adult dose 160mg followed by doses of 80mg)	An alternative to quinine given im. Doxycycline usually required as recrudescences are common
	Artesunate	2.4mg/kg iv followed by 1.2mg/kg at 12 and 24h; then 1.2mg/kg daily (usual adult dose 120mg followed by doses of 60mg)	Can be given intravenously as it is water soluble Also requires doxycycline as recrudescences are common
	Quinidine gluconate	7.5mg/kg q8h over 4h until patient can swallow	For emergencies and in the USA where intravenous quinine is not available. Requires ECG monitoring
G6PD, glucose-6-phosphate dehydrogenase.			

- have manifestations of severe complicated malaria;
- have underlying medical complaints, such as diabetes mellitus and ischemic heart disease;
- are elderly; or
- are pregnant.

During the course of treatment useful parameters for monitoring progress should include twice-daily parasite counts, regular pH and blood gas measurements and, where appropriate, measurement of glucose and lactate concentrations and renal function.

Each patient needs to be assessed individually. During an infusion of quinine it is essential to monitor blood glucose carefully.

Elective ventilation needs to be considered where facilities are available, especially if there is severe acidosis, clear evidence of raised intracranial pressure or respiratory failure of any cause. Further details of investigations and management are given in Table 166.5 .

Cerebral malaria

Antimalarials form the mainstay of treatment for cerebral malaria. A number of adjuvant therapies such as corticosteroids and heparin have been tried, but have not been shown to be effective. Some children and a few adults show evidence of raised intracranial pressure,

TABLE 166-5 -- Investigations in the management of malaria.

INVESTIGATIONS IN THE MANAGEMENT OF MALARIA		
Investigation	**Relevance**	**Management**
Full blood count		
Hemoglobin	Often not anemic on presentation; an indicator of duration of infection	Generally threshold for transfusion is high (e.g. <7.5g/dl (75g/l) in adults, <5g/dl (50g/l) with respiratory distress in children in an endemic area); self-recovery is generally rapid once the parasites have been removed
White blood cells	Normal in uncomplicated cases; often lymphopenic; in severe malaria a neutrophil leukocytosis is common	Generally none; secondary bacterial infection is common in severe cases and will require antibiotics
Platelets	Often low	Bleeding in the absence of DIC is uncommon
Blood film and parasite count	Essential for diagnosis and continuing management if high; more mature forms or pigment in =5% neutrophils indicates a poor prognosis (see text)	Depending upon setting and severity (see text) exchange transfusion might be required
Electrolytes		
Sodium	Often low; some cases are due to the syndrome of inappropriate antidiuretic hormone secretion, others due to an inability to secrete free water	Self-correcting with treatment
Potassium	Normal unless high due to acute renal failure	Dialysis may be necessary
Creatinine	Normal or high	Dialysis may be necessary
Calcium	Often low in severe cases	May need replacement especially if the QT interval is prolonged on the electrocardiogram
Magnesium	Can be low	May need replacement especially if the QT interval is prolonged on the electrocardiogram
Glucose and lactate		
Glucose	Often low in severe cases in children and also during quinine administration in adults; often there is an absence of classical symptoms and signs of hypoglycemia	Regular monitoring of glucose in severe cases; immediate administration of 50ml 50% glucose (0.5–1.0gm/kg in children)
Lactate	Raised in severe cases; good prognostic and progress marker from hour to hour; important to measure in spinal fluid if lumbar puncture performed	Important to ensure good tissue perfusion, especially by correction of any hypovolemia
Coagulation		
Including prothrombin time, thrombin time, D-dimers (or fibrinogen degradation products) and platelets	Activated in almost all cases of malaria to some degree	Fresh frozen plasma and platelets might be required if there is clinical evidence of bleeding
Liver function tests		
Albumin	Often low in acute infection	Does not require correction unless clinically relevant; danger of fluid overload and pulmonary edema
Transaminases	Can be moderately raised; if very high consider other concomitant infections (e.g. hepatitis)	Quinine dosage may need modification (e.g. reduction to q12h regimen)
Alkaline phosphatase	Not raised in malaria	If raised think of other causes
C-reactive protein	Raised in acute attack	Useful for daily monitoring in severe cases
Blood gases		
pH	Acidosis important in the prognosis of severe cases	Requires adequate fluid replacement, possible blood transfusion in anemic cases and avoidance (if possible) of epinephrine if inotropes are required [33]

Partial pressure of oxygen	Hypoxia uncommon unless there is pulmonary edema or infection	Oxygen
Partial pressure of carbon dioxide	Can be low in acidosis	
Bicarbonate	Low in acidosis	Replacement unlikely to help in acidemia
Other investigations		
Quinine levels	Free rather than total quinine levels are relevant to efficacy and toxicity. (a_1 -acid glycoprotein (a_1 -AGP) is the main quinine binding plasma protein)	Not generally helpful in management; maintain at 10–15mg/l according to parasite sensitivity and for quinidine 4–6mg/l
Electrocardiograph monitoring (corrected QT (QTc) interval)	Interval can be prolonged in nonimmune patients, especially if there is an underlying cardiac disorder	Quinine dosage may be need to be reduced
Blood and urine culture	Patients often acquire a secondary infection (most commonly respiratory, renal tract or sepsis) due to immunosuppression	May require systemic antibiotics
Lumbar puncture (only when patient is stable)	Relevant in very young and elderly and when other causes of encephalopathy, especially meningitis, must be excluded	Appropriate antimicrobial chemotherapy
The feasibility of these investigations and their management will depend upon the severity of disease and availability of facilities. DIC, disseminated intravascular coagulation.		

in which case a therapeutic trial of an osmotic agent such as mannitol may be attempted.

Acute renal failure

Dialysis or hemofiltration may be required. The indications are similar to those for any other form of renal failure. Nonoliguric renal failure may be managed conservatively.

Acidosis

Adequate fluid replacement avoiding fluid overload is essential. Sodium bicarbonate has not been shown to be of any benefit and may worsen acidosis. Transfusion of anemic patients has been shown to improve severe acidosis and reduce lactate concentration in young children.[30] Early hemodifiltration and ventilation may be used according to availability. The inotrope epinephrine (adrenaline) should be avoided unless absolutely necessary as it may worsen the acidosis, unlike dopamine, dobutamine and norepinephrine (noradrenaline). [32] Aspirin can also exacerbate metabolic acidosis.

Bacterial superinfection

Bacterial superinfection is common in malaria and must be suspected, particularly if the fever remains high despite antimalarial treatment or if there is evidence of septicemia or focal sepsis (e.g. pneumonia or urinary tract infection).

Adjunctive therapies

Many adjunctive therapies have been tried in malaria but few, if any, have been shown to be of benefit. The use of anti-TNF antibodies has been disappointing, leading only to a decrease in fever but no difference in clinical outcome. Corticosteroids are clearly not indicated in the treatment of acute cerebral malaria. The role of iron chelators and heparin remains unresolved, as does the use of an anti-TNF agent, pentoxifylline.

The role of mannitol in patients who have evidence of raised intracranial pressure, dichloroacetate in patients who have hyperlactatemia and the free radical scavenger, desferrioxamine, remain unclear.

Chapter 167 - Schistosomiasis

Adel AF Mahmoud

INTRODUCTION

Schistosomiasis is the most significant helminthic infection in humans because of its global prevalence, the protean nature of its associated disease manifestations and the remarkable difficulties encountered in attempts to control its spread.[1] Humans may be infected with one of five species: *Schistosoma haematobium, Schistosoma mansoni, Schistosoma japonicum, Schistosoma mekongi* and *Schistosoma intercalatum*.

EPIDEMIOLOGY

The geographic distribution of schistosomiasis in endemic areas is dependent on the availability of a considerable reservoir of infection in humans or, in the case of *S. japonicum*, in domestic animals and specific snail intermediate hosts. Transmission necessitates a set of cultural, social and health habits that facilitate the spread of infection. In addition, this infection is extending its geographic distribution to new areas because of irrigation projects[2] or massive population movement. The main areas of endemicity of the five schistosome species responsible for the bulk of human infection are given in Table 167.1 .[3] Attention should always be given to the nonuniform distribution of infection in any specific locality; endemicity, therefore, must be precisely mapped out. Detailed information on geographic distribution is unfortunately missing in most circumstances.

The schistosomes, similar to most other helminthic infections of humans, have a unique biologic characteristic in that they do not replicate within their definitive host. With the availability of procedures to quantify infection, it is therefore possible to appreciate several unique epidemiologic features of schistosomiasis. In endemic countries children encounter infection in their early years of life (4–6 years). Prevalence of infection increases with age and peaks in the age group 15–20 years. This age-dependent prevalence of infection is a constant finding in all endemic areas, irrespective of the peak percentage of infected individuals.[4] Intensity of infection, which is a measure of the number of eggs excreted in urine or feces and consequently is an estimate of worm load, follows a similar pattern to prevalence in the age group 5–20 years. Infection intensity increases with age to peak at age 15–20 years; thereafter the curves of prevalence and intensity diverge. Although prevalence remains stable, intensity of infection decreases remarkably, so that by age 30 years or older the number of eggs quantified in urine or stools is significantly lower than peaks achieved in persons a decade younger. The age-specific dependence of intensity of infection may be explained by acquisition of immunity or change in water exposure patterns of individuals living in endemic areas.[5] [6]

Another of the remarkable epidemiologic features of schistosomiasis in the populations of endemic areas is its overdispersed distribution.[7] This means that among infected individuals most harbor low worm burden and only a minority (5–15%) are heavily infected. What determines the susceptibility to heavy infection is not known, but age (the young acquire heavier infection) and/or genetic susceptibility[8] are among the better recognized factors.

Expression of disease manifestations caused by schistosome infection is a multifactorial process. It depends on the species of the parasite and where ova are trapped in host tissues. Within the different species and perhaps geographic strains, a heterogeneity of disease manifestations is appreciated. For example, a considerable percentage of children infected with *S. haematobium* will complain of dysuria and hematuria, and objective evaluation of blood in urine demonstrates positive results in up to 80% of examined populations. In contrast, in children and young adults infected with any of the intestinal schistosomes, no more than 10–20% will complain of gastrointestinal symptoms or show signs of hepatosplenomegaly. Although the high prevalence of symptoms in *S. haematobium*-infected individuals may be related to the anatomic localization of worms and ova, the paucity of specific clinical features in intestinal schistosomiasis raises the possibility of additional pathogenetic factors such as age, genetic make-up and degree of immune responsiveness.[9]

PATHOGENESIS AND PATHOLOGY

Disease manifestations caused by schistosome infection are multiple, not only because of the several species that infect humans but also because of the multiple stages of the pathogen within the human host and the myriad responses it elicits. A summary of the main pathogenetic mechanisms in acute and chronic schistosomiasis is given in Table 167.2 . Acute schistosomiasis is seen more commonly in infections with either *S. mansoni* or *S. japonicum*. It may manifest either as cercarial dermatitis, which is caused by the development of humoral and cellular immune responses to invading cercariae or as Katayama fever, which is probably a serum sickness-like illness caused by antigen-antibody complex deposition and proinflammatory cytokines in response to the maturing worms and the shower of egg antigens that follow. [10]

In contrast to the general immunologic nature of pathogenesis in acute schistosomiasis, the causes of disease in the chronic stages are mainly localized in specific sites within infected individuals. Central to the pathology of chronic infection is egg deposition and the subsequent host granulomatous response. Mature worms begin oviposition 6–9 weeks after cercarial invasion. Egg deposition occurs intravascularly in the small venous tributaries of the measenteric or vesical plexuses. Through the secretion of enzymes, and perhaps aided by urinary tract or intestinal movement, the parasite eggs find their way to the lumen of these viscera where they are carried to the outside via urine or stools. A proportion of parasite eggs, however, fail to traverse from the venous lumen to visceral cavities and are either retained locally in host tissues or carried via venous blood to distant organs such as liver, lung, etc. At these sites, the effector arms of the host immune system mount a granulomatous response to enclose the parasite ova (Fig. 167.1). The response is initiated by cell-mediated mechanisms and is regulated by multiple humoral and cytokine cascades. The result is a space-occupying lesion that may obstruct portal blood flow through the liver, leading to portal hypertension, or may obstruct urine flow through the ureters, leading to

TABLE 167-1 -- Geographic distribution of human schistosomes.

GEOGRAPHIC DISTRIBUTION OF HUMAN SCHISTOSOMES					
Species	**Africa**	**Middle East**	**Asia**	**Americas**	**Caribbean**
S. haematobium	+	+	+	+	+

TABLE 167-2 -- Pathogenetic mechanisms in human schistosomiasis.

PATHOGENETIC MECHANISMS IN HUMAN SCHISTOSOMIASIS			
Syndrome	**Parasite stage**	**Immunologic mechanisms**	
		Induction	**Regulation**

Swimmer's itch	Cercarial	Humoral and cellular	Undefined
Acute stage	Adults and eggs	Antigen-antibody complexes	Undefined
Chronic stage			
Granuloma	Eggs	Cell mediated	Antigens, cells, cytokines
Fibrosis	Egg antigens	Cell mediated	Cytokines

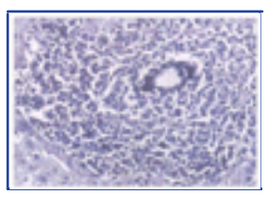

Figure 167-1 The basic pathologic lesions of intestinal schistosomiasis. A liver biopsy is depicted with egg deposition, granuloma formation and fibrosis in the periportal areas. *Courtesy of Professor MA Madwar.*

hydroureters and hydronephrosis. The nidus for these granulomatous lesions is the parasite eggs with their multiple antigens that are recognized by the host. The miracidia within the eggs, however, survive for only 6–8 weeks and then die, thus eliminating the continuous antigenic stimulation. The result is a decrease in granuloma size, but more significant is tissue healing through fibrosis. Such mechanisms lead to the permanence of schistosomal tissue injury and hemodynamic effects.

PREVENTION

For individuals traveling to areas endemic for schistosomiasis, prevention simply means no contact with infected bodies of fresh water. Because the distribution of infection in most endemic areas is not clearly demarcated, avoidance of all fresh-water sources is most prudent. Of particular importance is the unreliability of equating fast-running water with less chance of infection. Anticercarial preparations may be applied under special circumstances, but their widespread use has not been tested. In contrast, prevention in people living in endemic areas is complex and multifaceted. It reflects the degree of education, economic growth and cultural and recreational practices. Four strategies have been used and are still in use: mollusciciding; provision of sanitary water and sewage disposal; chemotherapy delivered to infected individuals as mass chemotherapy or targeting treatment to specific segments of infected populations; and economic and social development in general. Each of these strategies has its limitations and none has achieved widespread and sustained control of infection or disease in endemic areas. Significant effort is given to discovery of antischistosome vaccines. Although such a goal is important, understanding of the complexity of the organisms and the host immune responses has not resulted to date in a practical vaccination strategy.[11]

CLINICAL FEATURES

The clinical manifestations of disease caused by schistosomiasis are related not only to the species of the parasite but also to intensity of infection, genetic make-up of the host and other interactions with infectious and nutritional conditions. It is, therefore, essential to use the clinical descriptions that follow with a full understanding that the phenotypic expression of disease caused by schistosomiasis is multifactorial in nature.

The first major set of clinical manifestations of schistosomal infection occurs during its acute phase and results in varying degrees of morbidity in association with the five species responsible for the bulk of human infection. Swimmer's itch or cercarial dermatitis is a maculopapular itchy rash that usually occurs 1–2 days after exposure. The rash is related to cercarial invasion and, therefore, it usually occurs in areas of the skin that are exposed to infected waters. Cercarial dermatitis has been reported more often in newly exposed persons in endemic areas. The lesions are usually self-limited and require little medical attention. A more severe form of cercarial dermatitis occurs after human exposure to avian schistosomes. These helminths are endemic in many parts of the world, including North America. Exposure usually occurs in spring when transmission of the parasites in their natural habitat begins. The maculopapular eruptions are more severe and recur with each exposure.

A few weeks after schistosome infection occurs (4–8 weeks) some individuals exhibit systemic manifestations of acute schistosomiasis.[12] This is the more common manifestation seen in travelers who return after exposure to infection in endemic areas. The symptoms include fever, malaise, general aches and, upon examination, lymphadenopathy and hepatomegaly may be detected. Most of these individuals will show moderate peripheral blood eosinophilia, positive serology for schistosomiasis and schistosome eggs may be demonstrated in their excreta. Acute schistosomiasis is more prevalent in individuals newly exposed to the helminth, particularly those experiencing heavy exposure. The condition has resulted in a few reported fatalities, but the majority survive.

Chronic schistosomiasis and its sequalae and interactions with other clinical conditions occur within several months to several years after infection. Symptoms, signs and pathologic lesions are

species specific. Clinical features are described according to the parasite species below.

Urinary schistosomiasis

Symptoms and signs related to *S. haematobium* infection are seen in a considerable proportion of infected individuals, significantly more often than in those infected with any of the other species of schistosome. Furthermore, these features are seen earlier in the course of infection. In endemic areas children infected with *S. haemotobium* will complain of hematuria, which may be terminal, dysuria and frequency. Urine examination may show evidence of hematuria, proteinuria and cellular markers of inflammation. [13] The prevalence of these symptoms varies from 40% to 80% of infected individuals. Ultrasonographic examination of the urinary tract, which is the current suggested investigative modality, demonstrates thickening of urinary bladder wall, granulomas, hydronephrosis and sometimes evidence of bladder and ureteric calcification. At this stage of disease, the functional abnormality in the urinary tract is bladder neck obstruction. Later the course of disease may be complicated by frequent urinary tract bacterial infection, bladder or ureteric stone formation, renal functional abnormalities and ultimately kidney failure. In several endemic areas there is a strong epidemiologic association with squamous cell carcinoma of the bladder, which occurs characteristically in the age group 30–50 years.[14]

Intestinal/hepatic schistosomiasis

Clinical features that are specifically linked to any of the four intestinal species of schistosomes (*S. mansoni, S. japonicum, S. mekongi* and *S. intercalatum*) are seen in a relatively small proportion of infected individuals. Most of the clinical descriptions available report on either *S. mansoni* or *S. japonicum* infection. Established infection with either of these two species results in intestinal and/or hepatic disease.[15] The intestinal presentations are characterized by vague abdominal pains and bloody diarrhea; the latter feature is usually mild, not dysenteric in nature and variable in course. Liver disease manifests originally as hepatomegaly that is subsequently associated with evidence of portal hypertension, including splenomegaly and development of portosystemic collaterals, particularly at the esophagogastric junction and anterior abdominal wall (Fig. 167.2). Liver function tests at this stage are preserved because of the slow rate of development of the portal hypertension, because of the fibrotic and not cirrhotic pathologic changes in the liver, and because of arterialization of the hepatic blood supply that preserves parenchymal cell perfusion and oxygenation. The late stages of liver disease are associated with fibrosis and shrinking of organ size (Fig. 167.3),

Figure 167-2 Late manifestations of disease caused by *Schistosoma mansoni* infection. Note marked ascites and collateral circulation on anterior abdominal wall. *Courtesy of Professor MA Madwar.*

Figure 167-3 Advanced liver fibrosis in portal tracts (clay pipe-stem). *Courtesy of Professor MA Madwar.*

extensive splenomegaly, ascites, repeated episodes of hematemesis and finally hepatic failure. The phenotypic expression of hepatic disease in schistosomiasis may not only relate to intensity of infection but also to intercurrent infections, such as viral hepatidites,[16] [17] and the genetic constitution of the host.

Schistosomal disease may affect other organs in the body;[1] examples include cor pulmonale, cerebral or transverse myelitis, and cutaneous and genital manifestations. In general, these are less frequent than the previously described features and are usually seen in populations of endemic areas.

DIAGNOSIS

Infection with any of the schistosome species should be suspected in a variety of clinical presentations, as indicated above. A high index of suspicion, obtaining accurate geographic history and enquiry about possible exposure to infected water bodies are, therefore, elementary but essential steps in approaching the individual who possibly has schistosomal infection. Epidemiologic evaluation of infection in travelers necessitates similar examination of others who were exposed. Diagnosis is based on demonstrating the presence of parasite eggs or on serologic evidence (see Chapter 246).[18] Schistosome eggs may be detected in urine samples (for *S. haematobium*). Urine should preferably be collected between 1100h and 1300h, when egg passage is maximal. Sedimentation or filtration allows more sensitive diagnosis and quantification. The usefulness of detecting hematuria with reagent strip and correlating its presence with *S. haematobium* infection has been demonstrated in several studies in endemic areas. This practice, however, is not recommended for the returning occasional traveler in the developed world because of the multiple etiologies of hematuria. For intestinal schistosomes stool examination is performed by any of several concentration techniques, the Kato being the easiest and providing quantitative data. Assessing the parasite burden is important in appreciating the degree of tissue damage and in following up success of therapy. Diagnostic methods that are based on egg identification in urine or stool samples may also be combined with ova hatching to determine their viability. Serologic testing gives evidence for current or past infection by demonstrating antigen-specific antibodies; in the USA these tests are available in some state laboratories or at the Centers for Disease Control and Prevention. Serology for schistosomiasis detects antibodies against several stages of the parasite. It usually converts within 1–2 weeks after exposure and remains positive for a long period, even after chemotherapeutic cure. The test as performed has no useful quantitative value and does not differentiate present from past infection. Antigen detection techniques are also available that allow examination of serum or urine and may be helpful in determining the viability of the worms and their numbers.[19] The decision to work up a person with positive history depends on specific exposure and on the symptoms and signs related to schistosomiasis.

Other diagnostic tests include tissue examination for parasite eggs. Samples may be obtained from rectal mucosa, bladder and liver

biopsies, or from other tissues. Care should be taken when examining tissue for schistosome eggs to identify the parasite species, the viability of the miracidia contained within the egg shells and any evidence of calcification. Clinical diagnosis of schistosomiasis based on symptoms or signs without laboratory or serologic evidence should not be used, except in rare circumstances. These include peripheral blood eosinophilia in those suspected of having acute schistosomiasis, the characteristic liver or urinary tract pathology seen upon ultrasonographic examination or the rare central nervous system and other ectopic disease manifestations.

MANAGEMENT

Praziquantel is the current drug of choice for treating active infection with any of the five schistosome species.[20] The drug is administered orally 40mg/kg body weight in one dose for *S. haematobium, S. mansoni* or *S. intercalatum* infection, and 60mg/kg body weight in three divided doses over 1 day for *S. japonicum* or *S. mekongi* infection. Praziquantel administration is usually not associated with significant side-effects; however, in those with heavy burdens, abdominal pain, nausea and vomiting may occur. The drug is effective in producing parasitologic cure in approximately 80% of treated individuals and achieves over 90% reduction of egg counts in the remaining individuals. Follow-up urine or stool examination within 3 months is advised to assess efficacy of therapy. Praziquantel therapy in early infection also will result in reversal of pathologies such as hepatomegaly, bladder wall thickening or hydroureters. In established pathologic conditions, such as portal hypertension or extensive hydronephrosis, no reversal of pathology may be accomplished.

Treatment of the chronic sequelae of schistosomiasis may necessitate measures other than specific chemotherapy. For example, management of individuals with end-stage liver or kidney disease should be handled along general medical practices. Corrective surgical procedures for portal hypertension or urinary tract anatomic alterations also may be necessary in some cases.

Chapter 168 - Cestode and Trematode Infections

Guy Baily

INTRODUCTION

Cestode and trematode worms are highly specialized, ubiquitous flatworm parasites infecting both vertebrate and invertebrate animals. Typically, they have a complex life cycle that involves more than one host species harboring stages of the parasite that differ markedly in morphology. Most of these parasites are restricted in their range of host species, particularly in the definitive host of the adult reproductive worms. From among the enormous number of known parasitic flatworms, humans are the preferred host of only a handful, with rather more being capable of incidental or paratenic human infection.

Despite this variety, the life cycles of the parasites that infect humans have certain features in common. The strategy of the trematode parasites is to use aquatic snails as an amplification host. Snails are infected by a first larval stage hatched from eggs that have entered the aquatic environment in the waste products (most often feces) of a definitive host. For the blood flukes that cause schistosomiasis, the larvae (known as cercaria) released by the snails invade directly through skin or mucous membranes in contact with infected water. Other human trematode parasites cause infection through ingestion and rely on their cercaria 'hitching a lift' by encysting on an item of human diet present in the aquatic environment. Adult cestodes are tapeworms that live in the gut of their definitive hosts. Intermediate hosts are infected by ingesting ova, which develop into a sessile larval form, often with a cystic structure, in their tissues. The life cycle is completed when these infected tissues are eaten by a suitable definitive host. The larval forms of cestode parasites often have serious consequences for the function of the intermediate host and are among the most grave human helminthic infections. (Schistosomiasis is discussed in Chapter 167 and hydatid disease in Chapter 169 .)

CYSTICERCOSIS

Epidemiology and prevention

Cysticercosis is infection with the larval or metacestode stage of the pork tapeworm *Taenia solium*. It is acquired as a feco-oral infection from human tapeworm carriers and is therefore a disease of poor sanitation. Historically it occurred worldwide but it has now been largely eliminated from affluent countries through sanitation and meat inspection. The prevalence is strongly influenced by local customs in both diet and animal husbandry. It remains common in Central and South America, south Asia and China, and locally in Africa. A postmortem prevalence of nearly 2% has been reported from Mexico City. Individuals can protect themselves through the ordinary hygienic precautions employed against other feco-oral infections. Mass treatment campaigns with praziquantel can reduce cysticercosis by eliminating tapeworm infections; this may be a useful additional benefit of praziquantel use in schistosomiasis control in Africa.

Pathogenesis and pathology

Ingested *T. solium* ova are activated by exposure to the gastric and duodenal environments into invasive larval forms, termed onco-spheres. These migrate into the tissues, where they develop into a sessile cyst about 1cm across and surrounded by a host-derived capsule. Almost any tissue may be infected but skeletal muscle and the central nervous system, where cysts may be a little larger, are the preferred sites. Significant clinical sequelae are related to neurologic involvement (Fig. 168.1). Unless they are degenerating, cysts elicit very little immune response.

Clinical features

Most people who have cysticerci in their brain have no attributable symptoms. Much the commonest consequence is epilepsy, which is often focal. Where cysticercosis is prevalent, it may account for more than one-third of cases of adult-onset epilepsy.[1] Other neurologic manifestations are very varied. Focal neurologic syndromes may occur, including paralysis, extrapyramidal movement disorders and spinal cord syndromes. When there are many cysts, raised intracranial pressure may be the dominant problem. If untreated, this may lead to permanent loss of cerebral function with dementia and cortical blindness.

In children, who tend to mount a more substantial local immune response, a subacute encephalitis syndrome, with fitting and global changes in cerebral function, may occur.[2]

A minor abnormality of cerebrospinal fluid, mild pleocytosis or slightly elevated protein, can be found in around half of cases of neurocysticercosis; this is a reflection of how commonly cysts have some contact with the meninges. Much less commonly, cysticerci in the larger subarachnoid spaces, especially the cisterna magna, give rise to a clinical presentation of chronic meningitis with headache and global deterioration in cerebral function associated with markedly abnormal cerebrospinal fluid.[3] This may progress to hydrocephalus through obstruction of the ventricular foramina.

Cysticerci in the eye are not uncommon. Usually they are sited in the vitreous or under the retina, where they give rise to visual scotomata. Any significant inflammatory response is likely to result in loss of vision. Serious clinical consequences from cysts at other extraneurologic sites are very rare.

Diagnosis

A clinical diagnosis of neurocysticercosis is seldom possible because the neurologic presentation is never specific and could reflect a number of disease processes. For this reason it may be consierably underdiagnosed in the resource-poor regions where it is most prevalent. Occasionally, evidence of extracranial cysticercosis provides a clue to the origin of neurologic disease (e.g. palpable subcutaneous cysticerci or spindle-shaped calcification of muscle cysts seen on radiography). Eosinophilia is seldom present in established infection. Serology for cysticercosis is available in a number of centers and, although it is not completely sensitive and despite some cross-reactivity among other cestode infections, it provides a very valuable

Figure 168-1 Cysticerci in the brain.

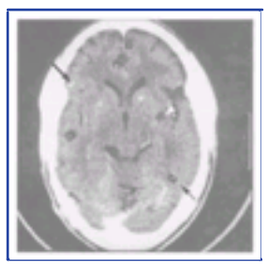

Figure 168-2 Computerized tomography appearances in neurocysticercosis. Viable cysts appear as radiolucent defects (arrowhead). The central protoscolex appears as a radiodense spot in about 50% (small arrow). Cysts that show ring enhancement are probably degenerating. Calcified cysts (large arrow) are dead and will not benefit from specific therapy.

screening tool for neurology patients in endemic countries.[4] Cysticerci can usually be visualized with intracranial imaging (Fig. 168.2). Magnetic resonance imaging is superior to computerized tomography (CT) for intraventricular cysticerci, cysticerci in the posterior fossa and spinal disease.

Management

Anthelmintic drug therapy is now widely used for neurocysticercosis, although its exact role remains controversial. Much of this controversy results from the complexity of the natural history of the disease. Cysts that enhance on CT are inflamed and likely to be degenerating. Prospective studies have shown that they will almost always disappear within a year without specific treatment.[5] This is the usual sequence of events in children unless they are heavily infected. Nonenhancing cysts, often seen in adults, are likely to persist. Praziquantel in large doses (40mg/kg daily orally for 15 days) has been shown to reduce the size and number of nonenhancing parenchymal brain lesions and to lessen fitting.[6] Albendazole (15mg/kg daily orally for 1 month) appears to be at least as effective. [7]

The value of anthelmintics for other clinical presentations is not well documented. On balance, children who have enhancing lesions can reasonably be managed with corticosteroids, symptomatic treatment such as fit control and close follow-up. Nonenhancing parenchymal cysts should be treated with anthelmintics.

The principal complication of both praziquantel and albendazole treatment is acute raised intracranial pressure, which may occasionally be life-threatening. It can be largely prevented with corticosteroids, although this may reduce the efficacy of praziquantel. Practice varies, but a favored opinion is that anthelmintic treatment for cysticercosis should always be accompanied by corticosteroids (e.g. dexamethasone 2mg q12h for 3 days).

Shorter courses of both albendazole and praziquantel may improve CT appearances but are not yet sufficiently established to be generally recommended. [8] Finally, surgery retains a place, particularly in the management of ventricular cysts and hydrocephalus.

OTHER LARVAL CESTODE INFECTIONS

Coenurosis

Humans are occasionally infected by the metacestode larvae of *Taenia multiceps*, which is normally maintained between dogs and sheep. The metacestode is a coenurus; it is a large cyst, more than 2cm in diameter, with multiple invaginated protoscolices, most often localizing in the brain. It is a rare illness but one with a wide geographic distribution.[9] Biopsy is necessary for diagnosis once a large cyst has been identified by imaging. Surgical excision has been advocated; the value of anthelmintics is unknown.

Sparganosis

Sparganosis is infection with the migratory plerocercoid larvae of cestodes of the genus *Spirometra*. These have an aquatic life cycle, similar to *Diphyllobothrium* spp. The larvae ascend the aquatic food chain from invertebrates such as *Cyclops* to reptiles and amphibians. Humans may become infected from drinking water that contains infected *Cyclops* spp., from eating inadequately cooked frog or snake meat, or from using the skin of these animals to dress wounds and sore eyes, as is the custom in some parts of eastern Asia. It is an uncommon but widespread disease in warm climates.

Clinically, there is a localized subcutaneous inflammatory swelling, which migrates rather slowly and contains a single worm-like sparganum (Fig. 168.3). The eye may be damaged by adjacent lesions; entry of the worm into the brain is rare but may be devastating. Excision of the worm is the only reliably effective treatment.

TAPEWORM INFECTIONS

Taeniasis

Humans are the only definitive host for two *Taenia* spp: *T. saginata*, the beef tapeworm; and *T. solium*, the pork tapeworm (Fig. 168.4). Infection is acquired by eating undercooked infected beef or pork, respectively. The clinical consequences of taeniasis are generally trivial and are limited to minor abdominal symptoms, such as occur in irritable bowel syndrome. *Taenia saginata* generates highly motile proglottids (pale, rectangular tapeworm segments) that may cause distress by emerging spontaneously from the anus. *Taenia* spp. do not appear to have any significant nutritional effect on their host. The principal concern in taeniasis is that *T. solium* may give rise to cysticercosis in the same host through feco-oral autoinfection.[10]

Figure 168-3 A sparganum worm dissected from an inguinal mass.

Figure 168-4 *Taenia saginata.* A mature worm may be over 33 feet (10m) long.

Diphyllobothriasis

Diphyllobothrium spp. are a large group of tapeworms that include a complex aquatic phase in their life cycle, ascending the food chain in fish. The species adapted to humans is *Diphyllobothrium latum*. Most human infection now occurs in Russia. Humans acquire infection by eating inadequately cooked or preserved fish. A large tapeworm, up to 33 feet (10m) long, develops in the small bowel; multiple infections are common. Clinical consequences, as with other tapeworm infections, are minor. Tapeworm anemia, described principally from Finland, was an association between diphyllobothriasis and deficiency of vitamin B12. It has not been recorded for several decades and is of historic interest only.[11] A variety of other *Diphyllobothrium* spp. may infect humans, principally in the sub-Arctic and the northern Pacific areas. Prevalences of up to 30% have been recorded in Canadian Inuit communities for *Diphyllobothrium dendriticum*. Clinical consequences of these infections are not well documented, but they are also thought to be minor.

Hymenolepis

The dwarf tapeworm, *Hymenolepis nana*, has the unique distinction among cestodes of being able to complete its life cycle within a single human host. Ova ingested from the environment encyst within a villus of the small bowel epithelium and, after a few days, evaginate a protoscolex. This develops into a new tapeworm only 1.6 inches (4cm) long in the gut lumen. The worm is thus transmitted directly between humans as a feco-oral infection. It is strongly associated with poor sanitation and is common in warm countries, especially among children, in whom prevalences may exceed 10%. In addition to abdominal symptoms, some systemic features such as headache and irritability occur, and eosinophilia is common. There is evidence that heavy infections may contribute to growth retardation. [12]

Zoonotic tapeworms

Various tapeworms that are not primarily adapted to humans may nevertheless occasionally cause human infection. *Hymenolepis diminuta* is a parasite of rats and mice, using their fleas as an intermediate host. Similarly, *Dipylidium caninum* passes between dogs and their fleas. Both are occasional sources of human infection worldwide, principally in children, through the accidental ingestion of fleas. There are no known serious clinical consequences.

Diagnosis and management of tapeworm infections

The diagnosis of tapeworm infection is by direct microscopy of feces for the detection of ova which, within the genera *Taenia* and *Diphyllobothrium*, cannot be readily speciated. Entire proglottids or larger worm portions may sometimes be seen. Treatment with a single dose of praziquantel at 10mg/kg is effective for all the human tapeworms except *H. nana*, for which at least 20mg/kg should be given.

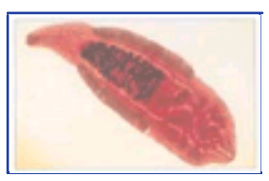

Figure 168-5 An adult liver fluke (*Clonorchis sinensis*). The worm is typically about 0.75 inches (2cm) in length.

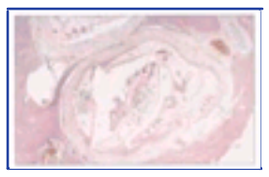

Figure 168-6 Low-power section of a human bile duct containing adult *Clonorchis sinensis* flukes.

LIVER FLUKE INFECTIONS

Epidemiology and prevention

There are three closely related trematodes, *Clonorchis sinensis, Opisthorchis viverrini* and *Opisthorchis felineus*, which for clinical purposes can be considered as one entity; the human liver flukes (Fig. 168.5). Aquatic snails are infected when human feces containing ova contaminate their environment. Cercaria released from the snails encyst under the scales of freshwater fish and will infect a new human host if eaten raw. Thus, either the sanitary disposal of feces or the thorough cooking of fish will interrupt transmission. The liver flukes are almost entirely restricted to eastern Asia and some foci in Siberia. Local prevalences may reach 35%.[13]

Pathogenesis and pathology

Ingested larvae migrate from the duodenum through the ampulla into the biliary tract, developing into adult flukes within small bile ducts in the liver, where they may live for many years. Pathologic consequences arise from the constant abrasion and inflammation of the bile duct in contact with the rough tegument of the flukes (Fig. 168.6). With time the bile duct walls become fibrotic and thickened and the liver becomes enlarged. The gallbladder is frequently abnormal, with distension, irregular thickening, or stones.

Clinical features

Light infections are likely to be asymptomatic. Heavier infection may be associated with right hypochondrial pain and other abdominal symptoms.[14] Significant complications include biliary obstruction and acute cholangitis. There is a strong association between liver fluke infections, especially with *O. viverrini*, and cholangiocarcinoma, which may be among the leading causes of mortality in highly endemic areas.[15]

Diagnosis and management

Liver fluke infection can be sensitively detected by stool microscopy with appropriate concentration technique — the fecal egg burden is a guide to the worm burden, which is in turn proportional to the severity of the pathology. A single dose of praziquantel 40mg/kg is usually effective, although more prolonged treatment may be preferable in heavier infections.

FASCIOLIASIS

Humans are also occasionally infected with liver flukes that are primarily adapted to animals. Principal among these are two species of *Fasciola*: the sheep liver fluke, *F. hepatica*; and the cattle fluke, *F. gigantica*. The cercaria of *Fasciola* spp. encyst on the leaves of aquatic plants, hoping to be eaten by their herbivorous definitive host. Humans are most often infected through wild watercress. Fascioliasis is uncommon but widely distributed. There is typically an acute illness as larvae migrate to the liver; this stage is characterized by fever, eosinophilia and painful hepatomegaly. Even in established infection, ova are difficult to find in the stool, so the diagnosis depends on serology. This is the only human flatworm infection that is unresponsive to praziquantel. Corticosteroids will alleviate much of the immune-mediated acute illness. Bithionol is the established specific treatment, but few physicians have much experience with this drug.[16]

LUNG FLUKE INFECTIONS

Epidemiology

Several trematodes in the genus *Paragonimus* cause human infection. Cases have been reported from most tropical areas but the principal foci are in eastern Asia and central and western Africa. *Paragonimus* cercaria encyst in the gills and other organs of fresh water crustaceans such as crabs and crayfish. Where these are customarily eaten raw or lightly cooked, human paragonimiasis is likely to occur.

Pathogenesis and pathology

Ingested larvae migrate through the intestinal wall and cross the diaphragm to enter the lungs, where they mature, inhabiting a host-derived fibrous capsule typically in the upper zones of the lungs. Pathologic consequences may result from the inflammatory response to larval migration or from the local effects of established adult worms. Occasionally worms develop in ectopic sites, most significantly in the brain, where the inflammatory response is likely to be very destructive.

Clinical features

The pattern of disease differs between *Paragonimus* spp. Mature flukes give rise to a chronic, low-grade, cavitating pulmonary disease. There is chronic sputum production and often hemoptysis. In the African disease, extrapulmonary manifestations are not a feature, but Asian parasites may give rise to migratory subcutaneous inflammatory

Figure 168-7 Shadowing in the right upper zone with cavitation in a 6-year-old-boy with an African lung fluke infection (*Paragonimus uterobilateralis*).

swellings and more seriously to an eosinophilic meningitis with a variety of focal or global neurologic features.[17]

Diagnosis and management

Diagnosis is by the detection of characteristic ova in the sputum or stool (which they reach via the larynx and esophagus). Serologic tests are also available. The chest radiograph is often abnormal but not diagnostic. Typical appearances are of a cavitating disease in the upper zones; this is easily confused with tuberculosis (Fig. 168.7). Eosinophilia is common. Praziquantel at a dose 25mg/kg q8h for 3 days is very effective.[18]

INTESTINAL FLUKE INFECTIONS

There are a variety of trematodes in eastern Asia that can inhabit the human intestine, most notably *Fasciolopsis buski*, which is principally a parasite of pigs. Symptoms are generally absent or mild but heavy *Fasciolopsis* infections can result in significant malabsorption. Intestinal flukes are almost always eliminated by a single dose of praziquantel at 15mg/kg.

Chapter 169 - Hydatid Disease

Bruno Gottstein

Echinococcus spp. are cestode parasites commonly known as small tapeworms of carnivorous animals. Their medical importance lies in the infection of humans by the larval stage of the parasites, predominantly including two species:

- *Echinococcus granulosus*, which is the causative agent of cystic hydatid disease (or cystic echinococcosis, CE); and
- *Echinococcus multilocularis*, which causes alveolar echinococcosis (AE).[1] [2]

Two other species, namely *Echinococcus vogeli* and *Echinococcus oligarthrus*, are extremely rarely found in humans and are therefore not covered in this chapter.

EPIDEMIOLOGY

Echinococcus granulosus

Echinococcus granulosus lives as a small intestinal tapeworm of dogs and occasionally other carnivores. The shedding of gravid proglottids or eggs in the feces occurs within 4–6 weeks after infection of the definitive host (Fig. 169.1). Ingestion of eggs by intermediate host animals or humans results in the release of an oncosphere into the gastrointestinal tract, which then migrates to primary target organs such as liver and lungs, and less frequently to other organs (Fig. 169.2). Usually, the fully mature metacestode (i.e. hydatid cyst) develops within several months or years.

Infections with *E. granulosus* occur worldwide, predominantly in countries of South and Central America, the European and African part of the Mediterranean area, the Middle East and some sub-Saharan countries, Russia and China. The annual incidence rates of diagnosed human cases/100,000 inhabitants vary widely, for example 13 in Greece, 143 in some provinces of Argentina, 197 in the Hinjang province of China and 220 in the Turkana district of Kenya. Most cases observed in Europe and the USA are associated with immigrants from highly endemic areas. Various strains of *E. granulosus* have been described, and differ especially in their infectivity for intermediate hosts such as humans. The most important strains for human infection include sheep and cattle as intermediate hosts.

Echinococcus multilocularis

The natural life cycle of *E. multilocularis* involves predominantly red and arctic foxes as definitive hosts (Fig. 169.3), but domestic dogs or house cats can also become infected and represent an important infection source for humans in highly endemic areas.[3] In the definitive host, egg production starts as early as 28 days after infection. After egg ingestion by a rodent or a human, larval maturation will occur within the liver tissue in more than 98% of the cases (see Fig. 169.2); subsequent metastases may occur in adjacent or distant tissues. Proliferation occurs by exogenous budding of metacestode tissue with a progressive tumor-like growth.

The geographic distribution of *E. multilocularis* is restricted to the northern hemisphere. In North America, the cestode is present in the subarctic regions of Alaska and Canada. The parasite has been discovered in its wildlife cycle in several other states, therefore indicating an apparent expansion of distribution within the North-Central American continent.

In Europe, relatively frequent reports of AE in humans occur in central and eastern France, Switzerland, Austria and Germany. The Asian areas where *E. multilocularis* occurs include the whole zone of tundra, from the White Sea eastward to the Bering Strait, covering large parts of the Soviet Union, China and northern Japan.

Worldwide there are scant data on the overall prevalence of human AE. Some well-documented studies demonstrate a generally low prevalence among affected human populations. The annual mean incidence of new cases in different areas including Switzerland, France, Germany and Japan has therefore been reported to vary between 0.1 and 1.2/100,000 inhabitants.[1] [2]

PATHOGENESIS AND PATHOLOGY

Echinococcus granulosus

Cystic echinococcosis (cystic hydatid disease) is clinically related to the presence of one or more well-delineated spherical primary cysts, most frequently formed in the liver, and then in the lungs and other organs such as kidney, spleen, brain, heart and bone (see Fig. 169.2). Tissue damage and organ dysfunction result mainly from this gradual process of space-occupying displacement of vital host tissue, vessels or parts of organs. Consequently, clinical manifestations are primarily determined by the site, size and number of the cysts, and are therefore highly variable. Accidental rupture of the cysts can be followed by a massive release of cyst fluid and hematogenous or other dissemination of protoscolices. Occasionally, this results in anaphylactic reactions and multiple secondary cystic echinococcosis (as protoscolices can develop into secondary cysts within the intermediate host).

The histology of a typical hydatid cyst exhibits the germinal layer as the primary site of parasite development (see Fig. 169.1). It is surrounded by a parasite-derived thick laminated layer, which is rich in aminocarbohydrates, as shown by periodic acid-Schiff positivity. The germinal layer forms protoscolices and brood capsules within the cyst lumen. Granulae, calcareous corpuscules and occasionally free daughter cysts are often observed. The parasite evokes an immune response, which is involved in the formation of a host-derived adventitious capsule. This often calcifies uniquely in the periphery of the cyst, one of the typical features found in imaging procedures. In the liver there may be cholestasis. Commonly, there is pressure atrophy of the surrounding parenchyma. Immunologically, the coexistence of elevated quantities of interferon (IFN)-?, interleukin (IL)-4, IL-5, IL-6 and IL-10 observed in most of hydatid patients supports Th1 and Th2 cell activation in CE. In particular, Th1 cell activation seemed to be more related to protective immunity, whereas Th2 cell activation was related to susceptibility to disease.[4]

Echinococcus multilocularis

In infected humans the *E. multilocularis* metacestode (larva) develops primarily in the liver (see Fig. 169.2). Occasionally, secondary lesions form metastases in the lungs, brain and other organs. The

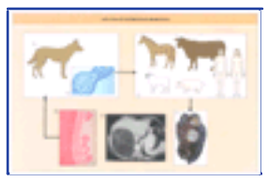

Figure 169-1 Life cycle of *Echinococcus granulosus.* Adult tapeworms parasitize the small intestine of definitive hosts, mainly dogs (1). Parasite proglottids and eggs are shed with the feces (2), such eggs being infectious for intermediate hosts including humans (3). Hydatid cyst formation occurs predominantly in the liver (4), but also in lungs and other organs. Imaging techniques such as CT (5) demonstrate well-delineated, fluid-filled, usually unilocular bladder-like lesions. Internal daughter cysts may be visible in larger cysts as septated segments within the primary cyst. Histologically, the cyst by itself consists of a very thin inner germinal and nucleated layer with a predominantly syncytial structure (6). The germinal layer is externally protected by an acellular laminated layer of variable thickness. The endogenous formation of brood capsules and protoscolices is a prerequisite for completion of the life cycle (6), which occurs when definitive hosts ingest protoscolex-containing hydatid cysts.

typical lesion appears macroscopically as a dispersed mass of fibrous tissue with a conglomerate of scattered cavities with diameters ranging from a few millimeters to centimeters in size. In advanced chronic cases, a central necrotic cavity containing a viscous fluid may form, and rarely there is a bacterial superinfection. The lesion often contains focal zones of calcification, typically within the metacestode tissue.

Histologically, the hepatic lesion is characterized by a conglomerate of small vesicles and cysts demarcated by a thin laminated layer with or without an inner germinative layer (see Fig. 169.3). Parasite proliferation is usually accompanied by a granulomatous host reaction, including vigorous synthesis of fibrous and germinative tissue in the periphery of the metacestode, but also necrotic changes centrally. In contrast to lesions in susceptible rodent hosts, lesions from infected human patients rarely show protoscolex formation within vesicles and cysts.

Genetic and immunologic host factors are responsible for the resistance shown by some patients in whom there is an early 'dying out' or 'abortion' of the metacestode.[5] Therefore, not everyone infected with *E. multilocularis* is susceptible to unlimited metacestode proliferation and develops symptoms 5–15 years after infection. [2] [3] The host mechanisms modulating the course of infection are most likely of an immunologic nature, including primarily T cell interactions. Thus, the periparasitic granuloma, mainly composed of macrophages, myofibroblasts and T cells, contains a large number of $CD4^+$ T cells in patients with abortive or died-out lesions, whereas in patients with active metacestodes the number of $CD8^+$ T cells is increased. An immunosuppressive process is assumed to downregulate the lymphoid macrophage system. Conversely, the status of cured AE is generally reflected by a high in-vitro lymphoproliferative response. The cytokine mRNA levels following *E. multilocularis* antigen stimulation of lymphocytes show an enhanced production of Th2-cell cytokine transcripts IL-3, IL-4 and IL-10 in patients, including a significant IL-5 mRNA expression in patients and not in healthy control donors.[6] The phenomenon of immunologic or constitutional resistance may be dependent upon

a potential immunogenetic predisposition associated with HLA-DR.[7] [8] Conversely, lack of Th cell activity such as in advanced AIDS is associated with a rapid and unlimited growth and dissemination of the parasite in AE.[9]

PREVENTION

Prevention of both CE and AE focuses primarily on veterinary interventions to control the extent and intensity of infection in definitive host populations, which may indirectly be approached by controlling the prevalence in animal intermediate hosts also. The first includes

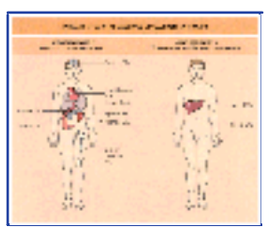

Figure 169-2 Primary sites of metacestode development in humans. Organ distribution of the primary sites of metacestode development for *Echinococcus granulosus* (cystic echinococcosis) and *Echinococcus multilocularis* (alveolar echinococcosis) in human disease.

regular pharmacologic treatment and taking sanitary precautions for handling pets or meat to prevent infection and egg excretion, respectively.[10] For the second, a vaccine for ruminant intermediate hosts is in evaluation.[11] Prevention of human infection is strategically very difficult.

CLINICAL FEATURES

The initial phase of primary infection is always asymptomatic. The infection may then remain asymptomatic for years or even decades depending upon the size and site of the developing cyst or metacestode mass. After a highly variable incubation period, the infection may become symptomatic due to a range of different events.

Cystic echinococcosis

Depending on the size and the site of the developing hydatid cyst, the infection can remain asymptomatic for months, years or even longer. After a highly variable incubation period, the infestation may become symptomatic due to a range of different events.

¦ The growing cyst exerts pressure on or induces dysformation of adjacent tissues, thus inducing dysfunction of the affected organ or vascular compromise. In the case of hepatic CE, signs and symptoms may include hepatomegaly with or without a palpable mass in the right upper quadrant, right epigastric pain, nausea, vomiting and occasionally cholestatic jaundice. In inoperable cases, hepatic compromise may lead to biliary cirrhosis and the Budd-Chiari syndrome.
Infestation of the lungs may present with chronic cough, hemoptysis, bilioptysis, pneumothorax, pleuritis, lung abscess and parasitic lung embolism.
Rare but often catastrophic infestations can affect the heart or the brain. In the heart this can present as tumor, pericardial effusion up to tamponade, complete heart block and sudden death. In the spine and brain presentation is as a tumor with neurologic symptoms. Hydatid disease should be considered as a cause of stroke in young patients.
¦ A cyst may rupture and spill its content into the adjacent site. Rupture into the biliary tree will mimic biliary colic or result in cholestatic jaundice and cholangitis or pancreatitis. This is the presenting symptom in 5–25% of patients. Ruptures in the liver but also in the lungs and other organs may result in acute anaphylactic shock reactions which usually represent the initial and life-threatening manifestation.
¦ The cyst can become superinfected; in hepatic hydatid disease this occurs in about 9% of patients and is an indication for rapid surgical intervention.[12]

The majority of patients with CE have single organ involvement with solitary cysts. Simultaneous involvement of two or more organs is observed in 10–15% of patients, depending on the geographic origin of the patient and the strain of the parasite. In hepatic CE, the right lobe is more frequently affected than the left lobe. Cyst size varies usually between 1 and 15cm in diameter. Cyst growth ranges between a size increase of a few millimeters (1/3 of the patients) to approximately 10mm (most of the patients); 1/10 of the patients exhibit a rapid increase with an annual average of 30mm. In Europe, the average age of patients at diagnosis is 36 years. Approximately 10% of the CE cases occur in children, and the rate of lung involvement is significantly increased among this group of young patients. Pulmonary cysts occasionally become superinfected and this is best detected by computerized tomography (CT) scanning. The ratio of males to females may vary dependent on the geographic area but is statistically not significant overall.

Hepatic alveolar echinococcosis

In patients with hepatic AE, the size of the liver lesion will range between a few millimeters up to 50cm or more when patients present for diagnosis and initial treatment.[2] Typical calcifications occur in 70% of cases and central or peripheral necrotic cavities are also found in approximately 70% of cases. Clinical signs at diagnosis

Figure 169-3 Life cycle of *Echinococcus multilocularis.* This involves predominantly foxes as definitive hosts (1) and occasionally other carnivores such as domestic dogs or house cats. Egg production by the tapeworm starts as early as 28 days after infection (2). Eggs must be ingested by a suitable intermediate host (3), including humans and various rodent species (4). As a result, the parasite metacestode primarily becomes established in the liver. Macroscopically, the typical lesion is characterized by a dispersed mass of fibrous tissue with a multitude of interconnected vesicles ranging from a few millimeters to centimeters in size (5). The lesion often contains focal necrotic zones with scattered calcifications, as demonstrated by CT (6). Histologically, the hepatic lesion consists of a conglomerate of small vesicles and cysts demarcated by a thin laminated layer with or without an inner germinal layer and, predominantly in the rodent intermediate host, protoscolex formation (7). Oral ingestion of protoscolex-containing metacestodes by definitive hosts completes the life cycle.

include hepatomegaly-cholestasis-jaundice, secondary biliary cirrhosis, liver abscess, portal hypertension and Budd-Chiari syndrome. The disease starts frequently with non-specific symptoms such as epigastric pain or cholestatic jaundice. In complicated cases, evidence of secondary biliary cirrhosis and/or cholangitis will be found. Evidence of cholestasis is frequently present, while transaminases are only rarely and moderately elevated, in particular when there is central necrosis. One of the most feared complications is infection of a necrotic cavity and/or obstructed bile ducts, which are associated with very high mortality due to development of septic shock. Distant metastases can occur late in the disease; these have been described in brain, spine, lung and bone. Metastatic disease occurs in approximately 10–20% of patients.

The growth rate of the metacestode tissue is usually slow in immunocompetent patients. Analysis by CT scans indicated an average volume increase of 15ml/year for progressive forms of AE. In Europe, the average age of AE patients at diagnosis is 55 years.[2] Young children rarely develop AE, unless the cellular immune system is compromised.[9] The ratio of males to females varies geographically, but any variation is not statistically significant.

DIAGNOSIS

Echinococcus granulosus

In most cases, imaging procedures together with serology will yield the diagnosis. Sonography is the primary diagnostic procedure of choice for hepatic cases, although false positives occur in up to 10% of cases due to the presence of nonechinococcal serous cysts, abscesses or tumors.[2] The main diagnostic features of hydatid disease include:

¦ separation of the membrane from the wall,

¦ daughter cysts, and
¦ ruptured cysts.

Computerized tomography is the best investigation for detecting extrahepatic disease and volumetric follow-up assessment; magnetic resonance imaging (MRI) assists in the diagnosis by identifying changes in the intra- and extrahepatic venous systems. Ultrasonography is also helpful in following up treated patients as successfully treated cysts become hyperechogenic. Calcification of variable degree occurs in about 10% of the cysts.

Aspiration cytology appears to be particularly helpful in the detection of pulmonary, renal and other nonhepatic lesions for which

imaging techniques and serology do not provide appropriate diagnostic support. The viability of aspirated protoscolices can be determined by microscopic demonstration of flame cell activity and trypan blue dye exclusion. Anti-Ag5 monoclonal antibody has been used for the detection of the respective antigen in diagnostic fine-needle aspiration biopsies (FNABs) from patients with suspected CE.[13] Immunodiagnostic tests to detect serum antibodies or circulating antigens are used to support the clinical diagnosis of CE.[14] The indirect hemagglutination tests and the enzyme-linked immunosorbent assay using *E. granulosus* hydatid fluid antigen are diagnostically relatively sensitive for hepatic cases (85–98%). For pulmonary cysts the diagnostic sensitivity is markedly lower (50–60%) and for multiple organ involvement it is very high (90–100%). These tests are usually used for primary serologic screening. Specificity is low for other cestode infections. To increase specificity, primary seropositive sera are retested using a confirmation test such as immunoblotting for a relatively specific 8kDa/12kDa hydatid fluid polypeptide antigen.[14]

Serologic studies to follow-up patients with CE postoperatively have emphasized the detection of circulating immune complexes or antigens. The detection of circulating parasite antigens proved useful for monitoring the course of disease and for assessing the extent of surgical removal of parasite lesions.[14]

Besides skin tests and basophil degranulation tests, diagnostic cellular immunodiagnosis has focused on in-vitro lymphoproliferative responses to *E. granulosus* antigens. The diagnostic sensitivity of cell-mediated immunodiagnosis is 75%, including the finding of seronegative patients with a positive proliferation test.[14]

Echinococcus multilocularis

Among the imaging procedures, ultrasonography, CT and MRI are of greatest diagnostic value, none of those being uniquely superior.[15] Irregularly dispersed clusters of calcifications on plain abdominal radiographs may give the first clue as to the etiology of the disease; the percentage of calcifications within the lesions increases from 30% to nearly 100% as the disease progresses. Hyperechogenic and hypoechogenic zones characterize the lesions. The cystic appearance may reflect central necrotic cavities. Similar findings can be found on CT and the lesions are typically not enhanced with contrast medium. The lesions are heterogeneous hypodense masses with irregular contours and lacking well-delineated walls. Hilar involvement can lead to liver atrophy, which is easily visualized by CT. Ultrasonography is the preferred imaging procedure for mass screening programs. Magnetic resonance imaging adds to diagnosis, in particular in cases with appropriate organ localization such as brain and bone, and to visualize pathologically altered microstructures in certain affected organs. Thus, MRI can give a precise analysis of the different components of the parasitic lesions such as necrosis and fibrosis.[15] However, in contrast to CT microcalcifications are not visualized by MRI. Assessing the parasite viability in vitro following therapeutic interventions may be of tremendous advantage when compared with the invasive analysis of resected or biopsied samples. Such alternatives may be offered by magnetic resonance spectrometry or positron emission tomography. The latter technique has recently been used for assessing the efficacy of chemotherapy in AE.[16]

Immunodiagnosis represents a valuable secondary diagnostic tool complementary to imaging procedures and is useful for confirming the nature of the etiologic agent.[14] Serologic tests are more reliable in the diagnosis of AE than CE. The use of purified *E. multilocularis* antigens such as the Em2 antigen or recombinant antigens II/3–10 (identical to EM10 and Em18) exhibits diagnostic sensitivities ranging between 91% and 100%, with overall specificities of 98–100%.[14] These antigens allow discrimination between the alveolar and the cystic forms of disease with a reliability of 95%. Seroepidemiologic studies reveal asymptomatic preclinical cases of human AE as well as cases in which the metacestode has died at an apparently early stage of infection (see above).[3] Serologic tests are, however, of limited value for assessing the efficacy of treatment and chemotherapy. The best respective information is provided by the detection of anti-II/3–10 (and Em18) antibodies, a status reflecting the presence of viable metacestode lesions. Cellular immune tests show that the in-vitro lymphoproliferative response to *E. multilocularis* antigen stimulation is high in cured patients who have had radical surgery and in patients with dead lesions, and is significantly lower in patients who have had partial or no surgical resection.

Histopathologic and immunohistochemic procedures to analyze surgically resected samples or biopsies obtained by FNAB include the use of species-specific MAbs such as MAbG11[17] or molecular techniques such as polymerase chain reaction.[18]

MANAGEMENT

The management of CE and AE follows the strategy recommended in the manual on echinococcosis published in 2001 by the Office International des Epizooties and the World Health Organisation.[10]

Echinococcus granulosus

Surgery remains the mainstay in the treatment of hepatic hydatid disease. Cystectomy and pericystectomy offer a good chance for cure and should be undertaken wherever possible. Occasionally, formal hepatic resection will be required. Radical surgery — either pericystectomy or resection — is possible in 50–85% of cases. In the absence of complications this can be achieved with little mortality and an acceptable morbidity. Recently, laparoscopic pericystectomy has been demonstrated to be as safe and effective as open laparotomy in selected cases with hepatic and/or splenic involvement.[19]

If surgical removal of the cyst is contraindicated, treatment of CE has several alternatives such as PAIR (Puncture, Aspiration, Injection of an heminthicide and Reaspiration), chemotherapy or 'wait and observe' approach.

Basically, indications for hepatic surgery include large liver cysts with putatively multiple daughter cysts; single liver cysts, situated superficially, which may rupture spontaneously or as a result of trauma; bacterially superinfected cysts; cysts communicating with biliary tree and/or exerting pressure on adjacent vital organs; brain, heart and kidney cysts; and spinal and bone cysts. Relative contraindications are inoperable cases as defined for surgical procedures in general; patients with cysts difficult to access; and abortive cysts either partly or totally calcified.

A direct communication between the hydatid cyst and the biliary tree may contraindicate the use of protoscolicidal solutions, which can cause chemical cholangitis leading to sclerosing cholangitis. Formalin should not be used for this reason. Effective protoscolicides with a relatively low risk of toxicity are 70–95% ethanol or 15–20% hypertonic saline solution.

Preoperative chemotherapy with albendazole or mebendazole is indicated for reducing the risk of secondary echinococcosis after operation and should begin at least 4 days before surgery and be continued for at least 1 or preferably more months. Diagnostic puncture of hydatid cysts harbors the risk of cyst rupture and dissemination of protoscolices and is therefore not recommended.

PAIR has become well justified in selected cases but it still needs to be practiced by experienced specialists.[20] Indications for PAIR are patients refusing surgery; infected cysts not communicating with the biliary vessel system; inoperable patients (see contraindications for surgery, above); pregnant patients; children >3 years; anechoic lesion =5cm in diameter; cysts with a regular double laminated

layer; cysts with more than five septal divisions; multiple cysts (=5cm in diameter) in different liver segments; relapse after surgery; and failure to respond to chemotherapy. Relative contraindications for PAIR are inaccessible or risky location of the cyst in the liver; multiple septal divisions; cysts with echogenic lesions; inactive cysts or calcified lesions; communicating cysts; cysts located in the lung and bones; and some others. It should not be performed when exophytic cysts or dilated bile ducts are observed on preoperative imaging.

Treatment with benzimidazoles (preferably albendazole) is highly recommended for 4 days prior to intervention. After successful instillation of protoscolicides and re-aspiration, benzimidazoles should be given for 3 months.

Treatment of nonresected cysts with benzimidazoles (albendazole or mebendazole) results in cyst disappearance in 30% of cases; in 30–50% of patients there is cyst degeneration or a significant reduction in cyst size and in 20–40% of patients the cysts show no morphologic change.[10] Indications for chemotherapy include inoperable patients as listed above.

The formerly conventional dosage of albendazole (10–15mg/kg/day in several 1-monthly courses with 14-day intervals) included three courses at minimum, and more than six courses were usually not necessary. This strategy is more commonly replaced by continuous treatment, which demonstrated equal or improved efficacy without increased adverse effects when compared with cyclic treatment.[21] For mebendazole, the usual dosage is 40–50mg/kg/day for at least 3–6 months. Praziquantel has been proposed as an additional antiprotoscolicidal drug to be given once a week in a dose of 40mg/kg along with benzimidazoles. It is also recommended before and after surgery/PAIR when there is a risk of cyst rupture and release of protoscolices.

Echinococcus multilocularis

The following strategies are commonly accepted for treatment of AE:

- the first choice of treatment is radical surgical resection of the entire parasitic lesion from the liver and other affected organs in all operable cases, with excision of the parasitic lesion following the rules of radical tumor surgery;
- concomitant chemotherapy for all cases after radical surgery or after nonsurgical interventional procedures;[21] and
- long-term chemotherapy for inoperable or only partially resectable cases and all patients after liver transplantation.[10]

Presurgical chemotherapy is not indicated for AE. The daily dosage for albendazole and mebendazole treatment is the same as for CE. For albendazole, continuous treatment is well tolerated for a duration up to 6 years, and is replaced by the former discontinuous scheme (see above) only in cases with side-effects related to medication. For mebendazole, plasma drug levels should be over 74ng/ml (250nmol/l). Generally, the duration of treatment is at least 2 years after radical surgery or continuously for many years for inoperable cases or if resection is incomplete.

As an ultimate goal liver transplantation has been proposed for a selected group of patients who have inoperable AE and chronic liver failure. However, the indications are limited and focus on cases with extensive lesions restricted to the liver and secondary liver disease leading to chronic liver failure;[22] relapse is frequent and caused by extrahepatic metacestodes, which rapidly proliferate under immunosuppressed conditions.

Chapter 170 - Filariasis

Eric A Ottesen

INTRODUCTION

Lymphatic filariasis, onchocerciasis and loiasis are the three most important filarial infections of humans (Table 170.1) and for two of these three diseases (lymphatic filariasis and onchocerciasis) there are now major public health initiatives to control or eliminate them completely. [1] [2] [3] [4] All of these infections are caused by parasites transmitted by biting arthropods (mosquitoes or flies). Each goes through a complex life cycle that includes a slow maturation (often 3–12 months) from the infective larval stage, carried by the insects, to the adult worm that resides either in the lymph nodes and adjacent lymphatics or in the subcutaneous tissue. The offspring of the adults, the microfilariae, are 200–350µm in length and either circulate in the blood (lymphatic filariasis and loiasis) or migrate through the skin (onchocerciasis), awaiting ingestion by the insect vectors in which they develop infectivity for humans to continue this complex life cycle (see Chapter 246).

EPIDEMIOLOGY

Lymphatic filariasis

There are 120 million people in at least 80 countries of the world who are infected with lymphatic filarial parasites, and it is estimated that 1000 million people (20% of the world's population) are at risk of acquiring infection. [1] [3] Of these infections, 90% are caused by *Wuchereria bancrofti*, whose only host is humans, and most of the remainder are caused by *Brugia malayi*. The major vectors for *W. bancrofti* are culicine mosquitoes in most urban and semiurban areas, anopheline mosquitoes in the more rural areas of Africa and elsewhere, and *Aedes* spp. in many of the endemic Pacific islands. For the *Brugia* parasites, *Mansonia* spp. serve as the major vector, but in some areas anopheline mosquitoes are responsible for transmitting the infection. *Brugia* parasites are confined to areas of eastern and southern Asia, especially India, Malaysia, Indonesia, the Philippines and China.

Onchocerciasis

There are 17 million people in 35 endemic countries who are infected with *Onchocerca volvulus*; 95% of these people live in sub-Saharan Africa.[2] [4] Humans are the exclusive host for *O. volvulus*; there is no nonhuman reservoir of infection. Blackflies of several *Simulium* spp. are the vectors of infection, and because the larvae of these flies require fast-flowing water for their development, transmission is limited to those areas within the flight range of the flies that breed in such rivers. Thus, the distribution of onchocerciasis ('river blindness') is very much determined by the river systems and tributaries in Africa, Yemen and the Americas, where the infection is endemic.

Loiasis

Loa loa infects approximately 12 million people in the rainforest belt of western and central Africa and equatorial Sudan, where the *Chrysops* vector flies can easily find breeding spots. Although *L. loa* can be found in a number of nonhuman African primates, there is little or no cross-infection between the cycles of *L. loa* in humans and in nonhuman primates.

PATHOGENESIS AND PATHOLOGY

The pathology associated with filariases results from a complex interplay of the pathogenic potential of the parasite, the immune response of the host and external ('complicating') bacterial and fungal infections.[5] [6]

Lymphatic filariasis

Although genital abnormalities (especially hydrocele) and lymphedema or elephantiasis are the most recognizable clinical entities associated with lymphatic filarial infections (Fig. 170.1), earlier changes can be detected when lymphoscintigraphy[4] or ultrasound techniques are used,[5] including lymphatic dilatation with abnormal lymphatic function. These can occur with and without an inflammatory response. Secondary host inflammatory responses, including responses to bacterial and fungal superinfections of tissues with compromised lymphatic function, cause most of the progression and physical destruction associated with elephantiasis.

The pathology in lymphatic filariasis that is immune mediated most commonly derives from the lymphatic obstructive consequences of the responses to dead or dying worms in the lymphatics, but in the syndrome of tropical pulmonary eosinophilia, the pathogenesis is distinctly different[7] and results from immunologic hyperresponsiveness to the microfilaria-stage parasites.

Onchocerciasis

Most of the significant pathology in onchocerciasis affects the skin (Fig. 170.2) or the eyes. There are both noninflammatory and inflammatory routes to tissue damage.[6] In 'steady-state', chronic *O. volvulus* infections, between 10,000 and 500,000 microfilariae are produced each day. These microfilariae migrate through the skin, inducing little inflammatory response; however, the elaboration of collagenases, elastases and other enzymatic molecules leads to hyperpigmentation, atrophy and thinning of the skin (see Fig. 170.2). Superimposed inflammatory reactions to dying microfilariae result in episodic papular dermatitis. In the eyes, these inflammatory responses result either in a characteristic punctate keratitis and, ultimately, anterior segment blindness or in uveitis and retinal lesions that can lead to posterior segment blindness. The possibility that a bacterium (*Wolbachia* spp.) that is an endosymbiont living within *O. volvulus* has a role in the pathogenesis of onchocerciasis has recently been advanced.[8]

Loiasis

'Calabar' swellings, the angio-edematous lesions characteristic of loiasis, have been less well studied. Presumably, these are immune-mediated inflammatory responses to migrating subcutaneous adult worms (Fig. 170.3) and are more common in the immunologically

TABLE 170-1 -- Principal filarial diseases.

PRINCIPAL FILARIAL DISEASES							
Disease	**Number of people infected worldwide**	**Parasite**	**Vector**	**Principal clinical manifestations**	**Distribution**	**Location of microfilariae within the body**	**Periodicity**

Lymphatic filariasis	120 million	*Wuchereria bancrofti*	Mosquitoes	Lymphedema, elephantiasis, genital pathology (hydrocele)	Tropics worldwide	Blood	Nocturnal (95%), 'subperiodic' (5%)
		Brugia malayi	Mosquitoes	Lymphedema, elephantiasis	Asia, India, Philippines	Blood	Nocturnal (75%), 'subperiodic' (25%)
Onchocerciasis	17 million	*Onchocerca volvulus*	Blackflies	Dermatitis, blindness	Africa (95%), Americas, Yemen	Skin	Minimal
Loiasis	12 million	*Loa loa*	Deer flies	Angio-edema, 'eyeworm'	Africa	Blood	Diumal

Figure 170-1 Elephantiasis. (a) Already advanced elephantiasis in a 14-year-old Indian girl who has bancroftian filariasis. Although such clinical expression of filarial disease is more commonly seen in adults, infection in endemic areas is usually established in early childhood. (b) Scrotal elephantiasis in an adult man who has bancroftian filariasis.

naive. Not common in untreated patients, but increasingly problematic in populations receiving ivermectin for co-endemic onchocerciasis, is a central nervous system (CNS) depression syndrome leading to coma or even death.[9] Its pathogenesis is suspected to involve inflammatory responses to dying microfilariae in cerebral vessels, but many details remain uncertain.

Figure 170-2 Onchocerciasis. Evidence of excoriation caused by the patient's trying to relieve the maddening pruritus caused by onchocerciasis. Note also the marked dermal atrophy associated with chronic infection.

PREVENTION

Filarial infections can be acquired only from vector-borne infective larvae. Therefore, prevention of infection can be achieved either by decreasing contact between humans and vectors, generally through vector control efforts, or by decreasing the amount of infection the vector can acquire, through treating the human host.

Lymphatic filariasis

Population-based prevention

Efforts to decrease filariasis in populations through mosquito-vector control have usually proved ineffective owing to high cost and the long lifespan of the parasite (4–8 years). More recently, especially with the advent of extremely effective single-dose, once-yearly, two-drug regimens (albendazole 400mg plus either ivermectin 200µg/kg or diethylcarbamazine (DEC) 6mg/kg), the alternative approach of decreasing microfilariae in the population has been preferred.[10]

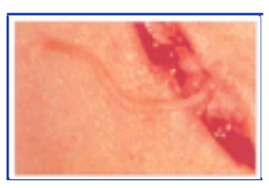

Figure 170-3 *Loa loa* adult worm. The worm has been teased from the subcutaneous tissue after incision was made through a small pruritic papule (0.5cm in diameter) in an expatriate patient who had loiasis. Such papules can occur spontaneously or after treatment with DEC.

Indeed, it is this strategy that forms the basis of the new Global Program to Eliminate Lymphatic Filariasis undertaken by the World Health Organization (WHO) and a global alliance of public and private sector partners.[3]

Individual-based prevention

Contact with infected mosquitoes can be decreased through the use of personal insect repellents, bednets or insecticide-impregnated materials. Alternatively, suggestive evidence from animal models and some limited experience in human populations indicate that a prophylactic regimen of DEC (6mg/kg/day for 2 days each month) could provide effective protection against infection.

Onchocerciasis

Population-based prevention

A program to prevent onchocerciasis in 11 West African countries has been undertaken by the WHO, the United Nations Development Programme and the World Bank. It was initially based on eliminating the blackfly vectors of the infection for a period that needed to exceed the lifespan of all adult *O. volvulus* worms (12–15 years) in that area. This 'Onchocerciasis Control Program' has now run for more than 25 years and been extraordinarily successful in 'reclaiming' both land and lives of people otherwise severely compromised by onchocercal disease.[4] However, because this approach is both expensive and difficult, a new strategy for treatment and consequent prevention of infection through the use of once-yearly ivermectin in affected populations has been undertaken in all of the remaining African countries where onchocerciasis is endemic. [4]

Individual-based prevention

Decreased contact with infected blackflies through protective clothing and repellents is helpful in preventing infection. Although no prophylactic treatment regimen has yet been defined, recent studies employing monthly doses of ivermectin in cattle exposed to the related parasite *Onchocerca ochengi* show a dramatic prophylactic effect of ivermectin, but studies have not yet been undertaken to see whether similar prophylactic efficacy can be shown for ivermectin in humans as well.

Loiasis

Population-based prevention

No specific prevention efforts in populations have been undertaken.

Individual-based prevention

There are good data that repeated use of DEC (300mg weekly or 6mg/kg/day for 2 days each month in adults) is effective prophylaxis against acquisition of *L. loa* infection.[11]

CLINICAL FEATURES

Lymphatic filariasis

Chronic manifestations

Hydrocele, even though it is found only with *W. bancrofti* infections (and not *Brugia* infection), is the most common clinical manifestation of lymphatic filariasis. Uncommon in childhood, it is seen more frequently after puberty and there is a progressive increase in prevalence with age.[12] In many endemic communities, 40–60% of all adult males have hydrocele. It often develops in the absence of overt inflammatory reactions and, indeed, many patients who have hydrocele also have microfilariae circulating in the blood. The localization of adult worms in the lymphatics of the spermatic cord leads to a thickening of the cord so that the cord is palpable on physical examination of most patients. Hydroceles can become massive but still occur without the development of lymphedema or elephantiasis in the penis and scrotum[13] (see Fig. 170.1).

Although lymphedema can also develop in the absence of overt inflammatory reactions and in the early stages be associated with microfilaremia, the development of elephantiasis (either of the limbs or the genitals) is most frequently associated with a history of recurrent inflammatory episodes. Patients who have chronic lymphedema or elephantiasis are rarely microfilaremic. Very important in the progression of these lesions is the fact that the redundant skin folds, cracks and fissures of the skin provide havens for bacteria and fungi to thrive and intermittently penetrate the epidermis, leading to either local or systemic infections.

Chyluria, another of the chronic filarial syndromes, is caused by the intermittent flow of intestinal lymph (chyle) through ruptured lymphatics into the renal pelvis and subsequently into the urine. The mechanisms underlying this have not been well defined and the clinical course is known to be intermittent. Nutritional compromise can, however, be severe in patients who have chronic chyluria; special diets (low-fat and high-protein, supplemented with fluids) can often be helpful. [13]

Acute manifestations

There are four distinct acute manifestations of lymphatic filariasis, each with a different set of causative mechanisms and pathogenic implications.

The first and most important is acute inflammation of the limbs or scrotum that is related to bacterial or fungal superinfection of tissues with already compromised lymphatic function.[7]

Another type of 'filarial fever' was confused with this picture in the past. In this second type, the inflammation is initiated in the lymph node (commonly the inguinal node) with 'retrograde' extension down the lymphatic tract and an accompanying 'cold' edema. Here the inflammation appears to be immune mediated and less frequent (10–20% of cases) than the episodes of inflammation initiated by dermal infection.[13]

A third acute filarial syndrome is tropical pulmonary eosinophilia, a distinctly different syndrome caused by an immunologic hyperresponsiveness to filarial infection.[7] It is characterized by:

- extremely high levels of peripheral blood eosinophilia;
- asthma-like symptoms;
- restrictive (and often obstructive) lung disease;
- very high levels of specific antifilarial antibodies; and
- an excellent therapeutic response to appropriate antifilarial treatment with DEC.

It occurs with a frequency of less than 1% of all filariasis cases, but it is a severe condition that can lead to chronic interstitial fibrosis and pulmonary failure.

The fourth (and least commonly recognized) form of acute inflammatory reaction is that seen early after infection, particularly in expatriates who are exposed to and acquire filarial infection for the first time. Lymphangitis occurs around developing larval and early adult stages in these patients, associated with acute eosinophilic inflammation.[7]

Asymptomatic presentations

Of all the patients who have lymphatic filariasis, at least half appear clinically asymptomatic, although they have microfilariae circulating in their blood and essentially all have hidden damage to their lymphatic or renal systems. [14]

A second asymptomatic 'presentation' exists in people who do not have demonstrable microfilaremia but who do have parasite antigen in the blood (which will disappear after appropriate treatment). The clinical features and long-term sequelae of infection in this group remain to be defined.

A variety of other syndromes co-existing with filariasis are found in filarial-endemic regions and because they show some evidence of therapeutic response to DEC they have been regarded as possible manifestations of lymphatic filariasis. These include arthritis (typically monoarticular), endomyocardial fibrosis, tenosynovitis, thrombophlebitis, lateral popliteal nerve palsy and others. Although future studies may strengthen an etiologic relationship with filariasis, such presentations cannot now be confidently attributed to filarial infection.

Onchocerciasis

Chronic presentations

Most damage from onchocerciasis occurs in the skin and eye. Subcutaneous nodules (generally 1–6cm in diameter) can be palpated superficially. However, most of the skin activity is a waxing and waning of maculopapular rashes, which are essentially always accompanied by itching (see Fig. 170.1),[2] presumably because of allergic responses to dying microfilariae. During the long course of infection, the skin becomes extensively damaged, losing much of its elasticity and even pigmentation. Indeed, when the skin over the inguinal nodes (which often are enlarged owing to their continual stimulation by dying microfilariae) becomes so atrophic that it cannot support the underlying lymph nodes, the clinical presentation of 'hanging groin' occurs.

In the eye, acute changes are those associated with dying microfilariae and the local inflammatory reactions that they induce.[2] In the cornea, 'fluffy opacities' (inflammatory cells associated with the dying microfilariae) can lead to punctate keratitis, but in prolonged and heavy infection, inflammation in the cornea results in sclerosing keratitis, whereas inflammatory responses located elsewhere in the eye lead to iridocyclitis, choroidoretinitis or optic atrophy. Complications of these inflammatory eye processes also include glaucoma and cataract.

Loiasis

The two most characteristic clinical features of loiasis are the passage of an adult filarial worm across the eye ('eye worm'), often in an otherwise asymptomatic person, and Calabar swellings. Calabar swellings are localized areas of erythema and angio-edema that may be 5–10cm or more in size. Often they occur in the extremities and last for several days before regressing spontaneously. If the inflammatory reaction extends to nearby joints or peripheral nerves, corresponding symptoms may develop. Routine radiographs of people in endemic areas may reveal calcified dead worms lying between the metacarpals.

Expatriate syndrome

Recently, this 'new' filarial syndrome has been recognized as one of clinical and immunologic hyperresponsiveness that is found in expatriate visitors to regions endemic for loiasis *and other filariases*. These people manifest prominent signs and symptoms of inflammatory reactions (including allergic reactions) to the mature or maturing parasites. In loiasis, these manifestations have included primarily Calabar swellings, hives, rashes and occasionally asthma. In bancroftian filariasis (when military personnel or other migrants to endemic areas have acquired these infections), the manifestations have usually been lymphangitis, lymphadenitis and genital pain (from inflammation of the associated lymphatics), with hives, rashes and other 'allergic-like' manifestations, including blood eosinophilia. [7]

DIAGNOSIS

Except for *W. bancrofti* infections, diagnosis of filarial infections depends on the direct demonstration of the parasite (almost always microfilariae) in blood or skin specimens using relatively cumbersome techniques and having to take into account the periodicity (nocturnal or diurnal) of microfilariae in blood (see Table 170.1). Most alternative methods based on detection of antibodies by immunodiagnostic tests have not proved to be satisfactory because of their failure to distinguish between active and past infections and their problems with specificity. There is good evidence, however, that recombinant antigens will greatly improve the value of such antibody-based immunodiagnostics in the future.

Lymphatic filariasis

Antigen detection

Circulating filarial antigen detection with almost complete specificity and high sensitivity should now be regarded as the 'gold standard' for diagnosing *W. bancrofti* infections.[15] Two commercial forms of this assay are available. One is based on the methodology of an enzyme-linked immunosorbent assay and yields semiquantitative results; the other is based on a simple card (immunochromatographic) test and yields only qualitative (positive or negative) answers. No such test is currently available for brugian filariasis.

Microfilaria detection

Before the development of the circulating filarial antigen assay, detection of microfilariae in blood was the standard approach to diagnosing lymphatic filarial infection, and it is the one still required today for both brugian filariasis and those situations where the antigen detection test is not available for bancroftian filariasis. Such assessments must take into account the possible nocturnal periodicity of the parasites when the the optimal time for drawing blood is chosen; this is between 10.00pm and 2.00am for most brugian filariasis and bancroftian infections.[1] [13] The simplest technique for examining blood or other fluids (e.g. hydrocele fluid or articular effusions) is to spread 20µl evenly over a clean slide that is dried and then stained with Giemsa or a similar stain. A wet smear may also be made by diluting 20–40µl of anticoagulated blood with water or 2% saponin, which will lyse the red blood cells but allow the microfilariae to remain motile and thus more readily identifiable. The larger the blood volumes examined, the greater will be the likelihood of detecting low levels of parasitemia. Other concentration techniques are also available.[13]

Clinical diagnosis

Many lymphatic filariasis patients are amicrofilaremic and therefore the diagnosis of these infections must be made 'clinically'.[16] For amicrofilaremic syndromes other than tropical eosinophilia syndrome (see Chapter 150), serologic findings based on detecting IgG_4 antibodies have proved helpful, because this subclass of IgG has

greater diagnostic specificity and is stimulated by the presence of active infection. Such antibody analyses also are particularly helpful in diagnosing the 'expatriate syndrome', in which background (i.e. pre-exposure) levels of IgG and especially of IgG_4 antibodies to filarial antigens are very low, so that elevated levels have significant diagnostic implications in association with the clinical presentation. [16]

Eosinophilia is a frequent concomitant of all filarial syndromes but is diagnostically helpful only when the eosinophil levels are extremely high (as in tropical eosinophilia or the expatriate syndrome).

Onchocerciasis

Parasitologic techniques are most commonly used to diagnose onchocerciasis. [2] Microfilariae can be visualized directly in the anterior chamber fluid of the eye by slit-lamp examination of patients who have been 'prepared' by remaining for 2 minutes in a head-down position to allow microfilariae to drift forward into the anterior chamber. Skin microfilariae can be visualized after a skin snip has removed the most superficial layers of skin with either a corneoscleral punch or a small needle and disposable razor blade to obtain approximately 1mg of a bloodless piece of skin. This sample is then placed in saline or water for examination for the emergence of microfilariae after 30 minutes to 24 hours. Alternative tests include a polymerase chain reaction on skin-snip specimens or a patch test, in which DEC is incorporated into a cream that is placed on the skin, covered by gauze and the area later observed for development of papular dermatitis resulting from the death of the microfilarial parasites. Also, subcutaneous or deep nodules (generally 1–6cm in size) can be detected by palpation or ultrasound, and the adult worms they contain can be identified histologically in specimens that have been removed surgically.

Loiasis

Diagnosis of loiasis remains dependent on direct parasitologic identification (most frequently microfilariae in the blood) or indirect serologic approaches in association with a compatible clinical presentation and exposure history. [16] *Loa loa* microfilarial periodicity in the blood means that blood sampling must be done near midday (usually between 12.00pm and 2.00pm). Treatment with DEC of some amicrofilaremic patients who have suspected loiasis can induce an inflammatory nodule which, on biopsy, frequently discloses an adult worm surrounded by acute inflammatory cells. Eosinophilia and antifilarial antibodies are important diagnostic tools in expatriates with extensive exposure to infection.[16] Radiographic assessment is of little diagnostic value in these patients, but because hyper-eosinophilia resulting from loiasis has been associated with endomyocardial disease, echocardiography is of value in establishing whether cardiac damage has occurred.

MANAGEMENT

Lymphatic filariasis

Treatment of the infection

Remarkable advances in treating lymphatic filarial infection have recently been achieved, but most of these have focused not on individual patients but on the community. Community reduction of microfilaremia through once-yearly treatment of parasites has been described already. Few clinical trials, however, have focused on optimizing treatment of the individual patient, so there is still insufficient data to permit recommendation for a change from the older treatment regimens (DEC 6mg/kg/day for 12 days in bancroftian filariasis and for 6 days in brugian filariasis).[1] These regimens can be repeated at intervals of 1–6 months if necessary but, interestingly, essentially the entire effectiveness of a 'course' of DEC results from the first dose.[17] Ivermectin, although very effective in decreasing levels of microfilaremia, appears not to kill adult worms and thus it cannot be expected to cure infection completely. Albendazole, on the other hand, appears to kill the adult worms after prolonged courses (2–3 weeks) and to inhibit production of microfilariae after single doses (400mg)[18] but optimization of its usage is just now beginning.

Therefore, for treating infection in individual patients, single or repeated courses of DEC are still recommended. However, because the use of DEC in patients who have either onchocerciasis or loiasis can be unsafe (see below), it is important that individual patients who have bancroftian filariasis who live in areas endemic for these other infections should be examined for co-infection with these parasites before being treated with DEC.

Both diethylcarbamazine and, ivermectin, given separately at the doses necessary to treat microfilaremic patients, have minimal or no-side-effects per se. However, their rapid killing of the microfilariae releases enough antigen to overwhelm the modulating effects of the host's immune system and to induce a variety of side reactions.[19] These occur in proportion to the microfilarial levels before treatment and include headaches, fever, myalgia, lymphadenopathy and occasionally rash, itching and other symptoms. Although the most severely affected patients can also experience postural hypotension, generally these reactions are well managed through the use of antipyretics, antihistamines or, in the most severe instances, corticosteroids. In the tropical eosinophilia syndrome, as there are no microfilariae in

the blood, there is no exacerbation of symptoms, but rather a steady improvement over the 2–4 weeks during which DEC is administered.

Treating the disease

Although it is important to try to cure the infection itself, management of the consequences of that infection (particularly the lymphedema, elephantiasis and genital pathology) is what is often of greatest concern to the patient. For early disease manifestations, it has been shown repeatedly that community treatment of infection with either intermittent (monthly, 6-monthly or yearly) drug administration or the steady use of DEC-fortified table or cooking salt leads to clinical improvement, with decreases in hydrocele size and prevalence and in regression of early lymphedema.

In more chronic states, patients with hydroceles or related urogenital pathology must be subjected to surgical procedures in order to obtain relief.[20]

The most dramatic change in managing patients with lymphatic filariasis has come from the recent recognition that bacterial and fungal superinfections of tissues with compromised lymphatic function play a prominent and progressively exacerbating role in disease development, so that careful attention to these infections can dramatically improve the outcome.[13] Rigorous hygiene in the affected limbs removes much of the excess stress on the lymphatic system and allows it (although still functionally compromised) to handle much more of the extracellular fluid. Management regimens should include the following:

- twice-daily washing of the affected parts with soap and water;
- raising the affected limb at night;
- regular exercise of the affected limb to promote lymph flow;
- keeping the nails clean;
- wearing shoes; and
- the use of antiseptic or antibiotic creams to treat small wounds or abrasions.

The addition of elastic bandages and other adjunctive measures can further improve results.

These same intensive local hygiene efforts and antibiotic ointments can also decrease the frequency of recurrent infection episodes in patients who have elephantiasis of the penis or scrotum but, unfortunately, specific guidelines for management have not yet

been developed for successfully reversing such anatomic distortions caused by the infection.

Noninvasive management of chyluria relies on nutritional support, especially replacement of fat-rich diets with high-protein, high-fluid diets supplemented where possible with medium-chain triglycerides.[13] Surgery, the sclerosing effects of lymphangiography or, often, time alone can also lead to the cessation of the lymphatic leakage into the renal pelvis, collecting system and urine.

Onchocerciasis

Complete cure of *O. volvulus* infections is difficult to achieve because the only drug available that kills the adult worms is intravenous suramin, which is highly toxic, difficult to administer and probably not even indicated.[2]

Rather, for most patients, because the pathology is generally associated with the microfilarial stage of the parasite, treating to kill the microfilariae both rids the patients of existing symptoms and protects them from development of further eye lesions. The safest, most effective microfilaricide is ivermectin at the recommended dosage of 150–200µg/kg; in various settings it has been repeated at 12-, 6- or even 3-monthly intervals. For individual patients, the frequency of treatment can best be determined by the rate at which symptoms (primarily itching and rash) recur. For individual patients, optimal management requires a thorough eye examination before initial treatment to ensure that no microfilariae are present, since it is the inflammatory complications of treatment with microfilaricides that must be avoided, especially in the eye. If there are microfilariae in the eye, the most conservative approach to treatment would include administration of prednisone 1 day before the dose of ivermectin is given and for 2 days after it. Short courses of corticosteroids have little negative effect on the microfilaricidal activity of ivermectin, and they are clearly effective in diminishing the side reactions caused by killing the microfilariae.

The side reactions that follow treatment of onchocerciasis with ivermectin (or, earlier, with DEC) have been termed the Mazzotti reaction. They consist primarily of headache, fever, pruritus, adenopathy, rash and, occasionally, postural hypotension.[21] Although pronounced after DEC, they are much milder after ivermectin and are self-limiting (beginning within hours of treatment and persist-ing as long as 4–5 days); they can be managed satisfactorily with antipyretics, analgesics, antihistamines and, if necessary, systemic corticosteroids.

Because adult worms, which are not killed by either ivermectin or DEC, continue to shed microfilariae for up to 12–15 years, symptoms may recur and require additional treatment over an extended period of time.

Loiasis

The approach to treatment of loiasis depends on the clinical presentation. In patients who do not have microfilaremia, DEC 6–8mg/kg/day for 3 weeks is the optimal treatment and results in cure of approximately half of the patients. Repeated courses of the drug are indicated when patients become symptomatic again and each repeated treatment results in additional patient cures.[22]

For microfilaremic patients, the approach to treatment is more difficult because the side reactions induced by the dying microfilariae can include CNS effects and even death. Such severe reactions rarely, if ever, occur in patients who have blood microfilaria counts of less than 2000/ml of blood (drawn at the time of day for peak parasitemia). However, even in a very controlled, hospital setting, when highly microfilaremic loiasis patients were treated with DEC (initially at very low dosages — 0.25mg/kg — and then increased progressively), there were still some patients in whom there was development of a post-treatment encephalopathy and death. This was not prevented, even when corticosteroids were co-administered. [23] When ivermectin is used instead of DEC, the clearance of microfilaremia from the blood is very much slower and not so complete. While it is very much safer than DEC, both in terms of the systemic side reactions that it elicits (which are similar to those of the Mazzotti reaction) and in terms of avoiding the catastrophic neurologic complications in patients with extremely high levels of microfilaremia (15,000–100,000/ml), ivermectin has still led to instances of CNS deterioration, coma and death. With optimal clinical care, the transient CNS compromise of such ivermectin-treated patients can be managed successfully and catastrophic results minimized. However, the treatment of loa-endemic populations with ivermectin (usually as part of national programs linked to the African Program for Onchocerciasis Control[4] or the Global Program to Eliminate Lymphatic Filariasis[3]) often is rendered in remote areas without access to optimal medical management. Therefore, this potential complication of treatment provides a major challenge that must be overcome before these massive public health initiatives can be successful in the loa-endemic regions of Africa.

If patients experience an adult *L. loa* crossing the eye below the conjunctiva, such worms can be removed through simple surgical incision of the conjunctiva, but because usually there are multiple parasites within the patient, a single procedure may not be curative.[24]

Chapter 171 - Infections in Sickle Cell Disease

Graham R Serjeant

DEFINITION

Sickle cell disease is a 'generic' term that embraces a group of genotypes characterized by pathology associated with the presence of sickle hemoglobin (HbS). This abnormal hemoglobin (Hb) results from a single amino acid substitution of valine for glutamic acid at position 6 in the ß-chain. Inheritance of this abnormal gene from one parent and a normal gene for HbA from the other results in the harmless carrier state, the sickle cell trait. Sickle cell trait (AS genotype) is excluded from the definition of sickle cell disease because it causes no clinical problems in the great majority of subjects unless they are exposed to hypoxic environments such as high altitude or respiratory depression. The principal genotypes of sickle cell disease include:

- homozygous sickle cell (SS) disease, in which the abnormal HbS gene is inherited from both parents;
- sickle cell HbC (SC) disease, in which the gene for HbS is inherited from one parent and the gene for HbC from the other. HbC is the second most common abnormal Hb among people of West African origin; and
- inheritance of the sickle cell gene with one of the genes for ß-thalassemia.

The ß-thalassemia genes reduce the synthesis of ß-chains; the degree of ß-chains produced determines the amount of HbA. This inhibits sickling, and influences the hematology and clinical course. Several molecular mutations causing ß-thalassemia have been described in association with HbS. In sickle cell $ß^{O}$ -thalassemia there is no HbA and a generally severe course, whereas a variety of sickle cell $ß^{+}$ -thalassemia syndromes result in variable amounts of HbA and variable clinical courses. The most common form of sickle cell $ß^{+}$ -thalassemia among peoples of African origin results in 20–30% of HbA and a very mild clinical course.

DISTRIBUTION AND PREVALENCE

In equatorial Africa, the prevalence of the sickle cell trait commonly reaches 20–30%. Contrary to the common belief that the sickle cell gene is confined to peoples of African ancestry, the gene is widespread in populations around the Mediterranean (Sicily, northern Greece, southern Turkey, the Levant and northern Africa), eastern Saudi Arabia and central India. HbC is a marker of west African ancestry, reaching prevalences of 20% in parts of Ghana and Burkina Faso, falling to 3–5% in Nigeria, and not occurring in central or east Africa, Saudi Arabia, Greece or central India.

In Nigeria, where approximately 25% have the sickle cell trait, it is estimated that SS disease occurs once in every 50 births, or in 100,000 births annually. The prevalence of SS disease at later ages is determined by the mortality of this genotype, which in Africa is often very high with infrequent survival to adult life. In Jamaica, the relative frequencies of the four major genotypes at birth (Table 171.1) are also influenced at later ages by their relative mortality, which is greater in SS disease and $Sß^{O}$ -thalassemia. The prevalence of these four major genotypes among African-Americans and among the UK population of Afro-Caribbean origin are similar to those in Jamaica (because of similar gene frequencies), although the increasing population of direct African origin has markedly increased trait and disease frequencies in the UK. In all populations, the prevalence of sickle cell disease at birth is determined by the gene frequency but at later ages is influenced by the relative survival of affected patients; in hospital-based populations frequency is influenced by the relative severity, which determines presentation.

PATHOGENESIS AND PATHOLOGY

On deoxygenation, HbS molecules form rigid linear structures (polymers), which increase the intracellular viscosity and deform red cells into an abnormal 'sickled' shape. This can be reversed on oxygenation but after several sickle-unsickle cycles, these cells may become permanently deformed. These less deformable red cells have difficulty negotiating the capillary beds where normal red cells with an average diameter of 7µm must bend and fold to traverse a capillary measuring 3µm. As a result, these abnormal red cells become prematurely destroyed (hemolysis) and may also block blood flow (vaso-occlusion).

Accelerated hemolysis results in anemia, jaundice, an increased prevalence of pigment gallstones and marked bone marrow expansion with high metabolic demands. The consequences of vaso-occlusion are determined by the site of the occlusion, but may include strokes, retinal ischemia, acute chest syndrome, a variety of splenic pathologies and chronic leg ulcers. Some manifestations, such as bone marrow necrosis, are influenced by both the hemolytic and vaso-occlusive components giving rise to dactylitis, the painful crisis, and avascular necrosis of long bones and femoral head. In these conditions, the pathology is confined to areas of active bone marrow activity, where the metabolic demands are believed to exceed the supply, which has been diminished either by vaso-occlusion or, more likely, by shunting of blood away from the active marrow.

The pathologies of particular relevance to infections in sickle cell disease are the accelerated bone marrow activity, the prevalence of leg ulcers, acute chest syndrome and — most important of all — the early loss of splenic function. These processes are most marked in SS disease and sickle cell $ß^{O}$ -thalassemia, and less marked in the generally mild conditions of SC disease and sickle cell $ß^{+}$ -thalassemia.

The spleen in sickle cell disease

The spleen acts like a filter in the circulation, removing damaged red cells and bacteria from the bloodstream. It achieves this function by requiring red cells to squeeze between endothelial cells (Fig. 171.1) as the blood traverses from the cordal tissue to the splenic sinuses before returning to the circulation. In addition to the filtering mechanism, the spleen also represents a large mass of reticuloendothelial tissue that is in intimate contact with the circulation and is important in the production of specific antibodies. These are particularly important if the liver is to participate actively in the removal of blood-borne antigens. Splenectomy removes these protective mechanisms and, in patients

TABLE 171-1 -- Relative frequency of principal genotypes of sickle cell disease in Jamaica.

RELATIVE FREQUENCY OF PRINCIPAL GENOTYPES OF SICKLE CELL DISEASE IN JAMAICA	
Genotype	**Frequency at birth**
Homozygous sickle cell (SS) disease	1 in 300
Sickle cell-hemoglobin C (SC) disease	1 in 500
Sickle cell $ß^{+}$ -thalassemia	1 in 3000
Sickle cell $ß^{0}$ -thalassemia	1 in 7000
In these data, sickle cell $ß^{+}$ -thalassemia refers to the common Jamaican form with 20–25% HbA.	

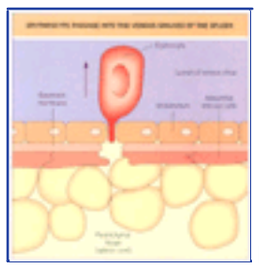

Figure 171-1 Erythrocyte passage into the venous sinuses of the spleen. A red cell passing between endothelial cells (arrow shows direction of movement) from the cordal tissue to the vascular sinus. Sickle cells do not have this deformability, so they accumulate in the spleen. Modified from Weiss.[1]

without sickle cell disease, splenectomy has been calculated to increase the risk of sepsis 50- to 60-fold (see Chapter 109).

In sickle cell disease, the abnormal red cells damage splenic function early in life. Even when the spleen is clinically enlarged, splenic uptake of ^{99m} technetium sulfur colloid is abnormal;[2] and elevated pitted red cell counts, which suggest abnormal splenic function, may occur as early as 6 months of age, and are seen in 20% of SS children by 1 year of age and in 40% by 2 years of age.[3] This loss of splenic function appears to be directly related to the susceptibility to infection [4] and may be reversed by chronic transfusion in young children (Fig. 171.2). [5] It is also delayed in SS patients with high levels of fetal Hb (HbF), which inhibit sickling and allow persistence of splenic function in SS patients in eastern Saudi Arabia.[6]

CLINICAL FEATURES

Bacterial infection Streptococcus pneumoniae

The susceptibility to pneumococcal sepsis in SS disease is well substantiated and was first reported in 1928. The relative risk has been

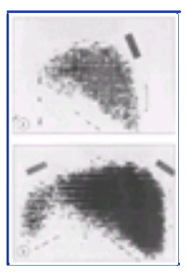

Figure 171-2 ^{99m} Technetium sulfur colloid scans (posterior view) in a 2-year old child with SS disease and splenomegaly. (a) The scan shows hepatic uptake but no splenic uptake. (b) A repeat scan 6 days after a blood transfusion shows restoration of splenic uptake of colloid. From Pearson *et al.*[5]

calculated to be at least 20 times that in the general population, and age-specific incidence rates are highest before the age of 2 years and fall sharply after 5 years. [7] Infection is closely linked to the appearance of clinical splenomegaly before 6 months of age.[8]

Prophylactic penicillin markedly reduces this risk, whether given orally[9] or by depot monthly intramuscular injection, [10] and has now become routine for children with severe genotypes (SS disease, Sß^{O} -thalassemia). Although there is some evidence of an increased risk in SC disease, the risk is not generally considered of sufficient magnitude to justify routine prophylaxis in the milder genotypes (SC disease, Sß$^{+}$ -thalassemia). The maximum risk from pneumococcal sepsis in Jamaica is in the first 3 years of life (Fig. 171.3), and depot injections of penicillin during that period prevent infection. It is unclear when to stop but the current Jamaican protocol provides intramuscular penicillin monthly from 4 months to 4 years with a single dose of 23-valent pneumococcal vaccine at the time of the last penicillin injection. Intramuscular injections are preferred in Jamaica to avoid the problems of compliance, which may compromise the twice-daily oral penicillin generally favored in the USA. Twice-daily erythromycin may be used in children who are allergic to penicillin. The nonconjugated capsular polysaccharide pneumococcal vaccine does not confer adequate protection in young children, but its immunogenicity improves with the age of the patient, and preliminary data suggest that protective levels against many of the serotypes are achieved by the vaccine given at 4 years of age.

Two recent factors may cause these policies to be reassessed: the increasing prevalence of penicillin-resistant pneumococci, which may account for 20–50% of isolations in children with SS disease in the USA; and the development of a conjugate pneumococcal vaccine, which may be effective given at 2, 4 and 6 months, and is currently under assessment. Preliminary data suggest this vaccine may generate what are believed to be protective levels of antibody but potential disadvantages are the high cost and the less comprehensive coverage (7- or 9-valent) compared with the standard 23-valent nonconjugate vaccine.

This susceptibility to the pneumococcus has not been shown in all sickle cell populations, and several studies on the bacteriology of

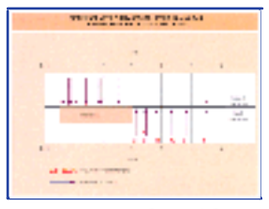

Figure 171-3 Experience with pneumococcal sepsis in Jamaican children from birth to 6 years of age. Pre-trial experience shows that sepsis episodes commenced at 6 months and 9 or 10 episodes occurred before 3 years. During penicillin prophylaxis from 6 months to 3 years, no episodes occurred but seven episcodes occurred after cessation of penicillin. The numbers by the arrows refer to pneumococcal serotypes.

septic children with SS disease in Nigeria[11] and Uganda revealed the most common agents to be *Klebsiella* spp., staphylococci, *Salmonella* spp. and *Escherichia coli*, with a paucity of *S. pneumoniae*. Possible interpretations of this infrequency of pneumococci include the early use of over-the-counter penicillin, the rapid demise of septicemic patients so that they do not reach hospital, the environmental dominance of Gram-negative organisms, or the intriguing postulate that malaria-induced splenomegaly may allow persistence of splenic function.[11] The role of the pneumococcus in SS disease in equatorial Africa must be clarified if governments are to be advised to spend limited resources on pneumococcal prophylaxis programs in sickle cell disease.

Haemophilus influenzae *type b*

It seems likely that children with SS disease are also more prone to *Haemophilus influenzae* type b (Hib) infection, which has been increasing in importance with the advent of effective pneumococcal prophylaxis.[12] Extensive data from the US Cooperative Study of Sickle Cell Disease showed an incidence rate of 0.45 per 100 patient-years under 6 years of age, not significantly different from the incidence in the normal black population;[6] however, a susceptibility of 20–160 times that in the normal population has been proposed from other studies. [13] Although the risks of Hib infection in SS disease are unclear, prophylaxis appears justified and may be effected by conjugated Hib vaccines given between 2 and 6 months of age.[14]

Salmonella

There is a long-standing and well-recognized susceptibility to *Salmonella* osteomyelitis in SS disease, and a less well-recognized association with *Salmonella* sepsis. In a Jamaican study, half of the *Salmonella* isolations from blood occurred without obvious bone involvement and were associated with a 22% mortality because the potential significance of *Salmonella* spp. in a septic patient often went unrecognized.[15] On the other hand, none of the patients with *Salmonella* isolations associated with bone involvement died because the increased awareness of the association led to the early use of specific therapy against *Salmonella* spp.

Salmonella osteomyelitis is believed to be a secondary infection of avascular bone marrow, and its distribution reflects that of the underlying bone marrow necrosis. The complication may become superimposed upon dactylitis in young children and should be suspected if the swelling is marked or there is high fever, in which case a surgical opinion should be sought regarding drainage; infection may be followed by a premature epiphysial fusion and a permanent shortening of affected small bones. At later ages, osteomyelitis may follow bone marrow necrosis in the shafts of the long bones, ribs or sternum, pelvis and vertebrae. Infection of the avascular femoral head may be particularly difficult to diagnose, but this can lead to very rapid dissolution and extensive bone damage. Diagnosis depends on positive blood culture, and the diagnostic yield may be increased by invasive procedures such as bone marrow aspirate or trephine biopsies. The differential diagnosis of sterile avascular necrosis and osteomyelitis is a difficult clinical challenge and even bone scanning techniques have generally been unhelpful, the diagnosis resting on clinical judgment.

Treatment is by specific antibiotics against *Salmonella* spp., such as chloramphenicol, ampicillin, trimethoprim-sulphamethoxazole (co-trimoxazole), or third-generation cephalosporins. Surgical drainage and the removal of sequestra may be necessary for complete healing and, even after apparent recovery, patients are prone to recurrence, sometimes years later, suggesting that the organisms remain dormant or loculated.

The source of *Salmonella* organisms in SS disease remains unknown, but common speculations include microinfarction of the gut wall in patients carrying *Salmonella*, or gallbladder colonization associated with gallstones and an abnormal gallbladder wall. However, a recent study showed no association with gallstones or with indices of vaso-occlusion, and *Salmonella* isolation from stools is only occasionally reported in patients with *Salmonella* osteomyelitis. The high prevalence of *Salmonella enteritidis*, which accounted for one-third of all isolations in the Jamaican series, suggests a dietary source; an intriguing possibility is carriage of *Salmonella* spp. by white cells, which would have the ironic effect of introducing the organism to the site of initially sterile avascular necrosis. More work is needed on the method of acquisition of *Salmonella* spp. in SS disease.

Escherichia coli

The extent of the increased risk of *Escherichia coli* infections in SS disease is unknown, but a significant excess of the SS genotype has been noted among black children admitted to hospital with serious infection and diagnosed as having *E. coli* sepsis. [16] *Escherichia coli* sepsis has also been associated with osteomyelitis and stroke. Urinary tract infections appear more common in SS disease and are a likely origin of *E. coli* sepsis.

Splenectomy and infection

Splenectomy, which may avoid morbidity and potential deaths in acute or chronic red cell sequestration, may be deferred because of concerns over loss of the splenic contribution to immune competence. However, the spleen in such patients is already immune compromised and no increase in severe infections or deaths occurred in 130 splenectomized SS patients when compared with 130 age-and sex-matched SS controls over the same period.[17] If indicated, splenectomy in SS disease should not be deferred for fear of losing persistent splenic immune function.

Malaria

There is a special relationship between malaria and the HbS gene, which was initially noted because malaria endemicity tended to coincide with high frequencies of the sickle cell trait in Africa. This has been the basis of many studies, which have reached general agreement that during a critical period in early childhood (between the loss of passively acquired maternal immunity and the development of active immunity), the presence of the sickle cell trait confers some protection against malaria. The mechanism remains controversial and may be multifactorial, but increased sickling of parasitized red cells has been demonstrated and may serve to identify the host cell to the spleen and brings about its more effective removal. The maintenance of high frequencies of the sickle cell gene in areas of falciparum malaria led to the hypothesis of balanced polymorphism, proposing that a survival advantage in the sickle cell trait was balanced by the disadvantage and presumed loss of two genes in the early deaths occurring in SS disease. For patients with SS disease, malaria is believed to be a major cause of morbidity and mortality; further hemolysis being superimposed upon that already present. Some African workers suggest that such patients do not die of malaria but succumb to symptoms that are related to sickle cell disease but are precipitated by malaria.

Viral infection

Patients with SS disease are not intrinsically more prone to viral infections. Antibody responses to viral vaccines appear normal and infection rates by human parvovirus are similar in SS disease and AA controls. The greater exposure to blood transfusion may render patients more prone to transfusion-acquired viral infections such as hepatitis C virus and HIV.

Human parvovirus infection appears to be the cause of aplastic crisis in SS disease, but this reflects a difference in response rather than an increased susceptibility. Human parvovirus infection colonizes and destroys red cell precursors in the bone marrow, but the virus becomes neutralized by specific antibody, and bone marrow function returns after 7–10 days. In SS disease, the red cell survival may be as short as 7–10 days and, unless oxygen delivery is maintained by transfusion, the aplastic crisis may result in death. Human parvovirus displays the general characteristics of a viral infection — most affected patients are under 15 years of age, epidemics occur at 3- to 4-year intervals, and there is high infectivity between siblings. The risk of aplasia among susceptible siblings of an affected patient is 50% within 3 weeks. A human parvovirus vaccine has been developed but it is still awaiting clinical trial.

Infection with atypical organisms

Mycoplasma pneumoniae and *Chlamydia pneumoniae* have been associated with the acute chest syndrome in patients with SS disease, especially in the autumn. The clinical course of these infections may be severe but it is unknown whether SS patients are more prone to develop these infection. The increased rate of hospital admission among SS patients also exposes them to an increased chance of hospital-acquired infections.

Other mechanisms of infection

Gallstones

The rapid hemolysis and consequent high excretion of bilirubin leads to increased gallstone formation, which occurs in 50% of unselected SS patients by the age of 25 years. Jamaican experience[18] suggests that most are asymptomatic, but acute or chronic cholecystitis may occur. The organism involved is usually *E. coli*, although anaerobes may also occur.

Leg ulceration

Chronic leg ulceration, a feature of SS disease, affects approximately 70% of Jamaican SS patients; they occur most commonly for the first time between 15 and 20 years of age and run a healing-relapsing course. The ulcer surface is commonly colonized by *Staphylococcus aureus, Pseudomonas aeruginosa* and ß-hemolytic streptococci, but these ulcers are rarely associated with evidence of systemic infection. A possible association between ulcer-borne ß-hemolytic streptococci and glomerular disease with proteinuria has been suggested, similar to the association between skin carriage of this organism and acute glomerulonephritis described from Trinidad, but subsequent analysis has indicated that, although both leg ulceration and proteinuria increased with age, there was no relationship between the two after correction for age. Leg ulcers occasionally act as a portal of entry for tetanus.

The lack of evidence for systemic infection in leg ulceration suggests a limited role for antibiotic therapy, although infection with *P. aeruginosa* may occasionally be associated with ulcer deterioration and poor healing.

Acute chest syndrome

The acute chest syndrome is a pneumonia-like pathology with elements of infection, infarction, pulmonary sequestration and fat embolism. It is a major cause of morbidity and the most common single cause of mortality at all ages after 2 years. The contribution of primary infection is controversial, and, although early studies reported pathogens in approximately half the cases in children aged under 3 years, recent studies have found evidence of bacterial infection in only 4–14% of episodes. Furthermore, the poor response to antibiotics and the striking improvement in many cases following transfusion has favored a vascular pathology rather than an infective one. Infections with the atypical agents *M. pneumoniae* and *C. pneumoniae* have been mentioned above.

CONCLUSION

Patients with sickle cell disease are susceptible to some but not all infections. However, any infective illness coinciding with sickle cell disease may precipitate sickle-related complications, such as painful crisis, by inducing fever and possibly dehydration from vomiting and diarrhea.

Chapter 172 - Leishmaniasis

Robert N Davidson

EPIDEMIOLOGY

Protozoa of the genus *Leishmania* can cause cutaneous (CL), mucocutaneous (MCL) and visceral (VL, kala-azar) leishmaniasis. The distribution of the leishmaniases is shown in Figure 172.1 and Figure 172.2 . About 10 million cases of CL and 400,000 cases of VL occur annually.[1] A country by country review has been published by the World Health Organization (WHO).[2] Phlebotomine sandflies transmit leishmaniasis, either to humans from a wide range of infected animals as a zoonosis, or from human to human. Transmission varies geographically depending upon climate, habitat, season and opportunities for sandfly contact. However, the numbers of all forms of leishmaniasis are increasing in many areas. For example, in Brazil, the increase in VL and CL is due to deforestation, which brings humans into close contact with animal reservoirs and forest vectors of *Leishmania braziliensis* and other species. In north Africa and the Middle East, irrigation projects have resulted in increased numbers of gerbils and construction of new townships in these areas has led to marked increases in endemic CL caused by *Leishmania major*. Breakdown of the infrastructure in Afghanistan has caused outbreaks of urban CL due to *Leishmania tropica*.

Visceral leishmaniasis

This is caused by *Leishmania donovani*, *Leishmania infantum* and *Leishmania chagasi* (see Fig. 172.1); the latter two species are indistinguishable. A reduction of dichlorodiphenyltrichloroethane (DDT) spraying against malaria vectors in India and Bangladesh has been blamed for the present epidemic of VL (due to *L. donovani*), which affects hundreds of thousands annually. From 1984 to 1999 there was a major epidemic of VL (*L. donovani*) in southern and then eastern Sudan brought on by population movement, famine, civil war and ecologic change. [3] [4] In Europe prior to widespread use of effective antiretrovirals, 20–70% of cases of VL (due to *L. infantum*) were co-infected with HIV, and 1.5–9% of AIDS patients had VL.[5] Co-infections of HIV and *Leishmania* are increasingly reported from Africa, India and South America.

Serologic and leishmanin skin test surveys suggest that subclinical self-healing infection occurs more frequently than clinical VL, particularly where *L. infantum* or *L. chagasi* is involved.[6] In epidemics involving *L. donovani*, however, most infections are symptomatic, and the mortality rate is high.[7]

Cutaneous leishmaniasis

In the Old World, *L. tropica* causes anthroponotic CL in villages, towns and cities; *L. major* causes zoonotic CL in those living or working near gerbil burrows. Smaller numbers of CL cases are caused by *L. infantum* in Europe and *Leishmania aethiopica* in Ethiopia and parts of Kenya. In the New World CL is mainly caused by members of the *Leishmania mexicana* complex (*L. mexicana mexicana*, *L. m. amazonensis*, *L. m. venezuelensis*) and the *Leishmania braziliensis* complex (*L. braziliensis braziliensis*, *L. b. panamensis*, *L. b. guyanensis*, *L. b. peruviana*; see Fig. 172.2).[8] [9]

PATHOGENESIS AND PATHOLOGY

Infected macrophages rely mainly on nitric oxide production as an innate mechanism for killing *Leishmania* spp.; this is specifically inhibited by the parasite, which is able to multiply in the parasitophorous vacuole. Eventually infected macrophages rupture and amastigotes are taken up by new phagocytic cells. Macrophages and dendritic cells present *Leishmania* antigens to T cells and this results in either:

- an effective cellular immune response — a T-helper (Th)1 pattern; or
- an ineffective humoral response — a Th2 pattern).

In the Th1 response, T cells activate macrophages by releasing the cytokines interferon (IFN)-? and interleukin (IL)-2. In the Th2 response, T cells release cytokines IL-4, IL-5, IL-10 and transforming growth factor (TGF)-ß which inhibit macrophages from killing *Leishmania* spp. (see Chapter 2). Although each *Leishmania* sp. produces a typical pattern of disease, host cellular immunity will determine whether:

- a clinical or subclinical infection results;
- the disease is visceral, cutaneous or mucocutaneous;
- lesions are few or diffuse; and
- response to treatment is complete or partial.[10]

PREVENTION

Helpful measures for individual protection are wearing long sleeves and trousers, using insect repellents and impregnating mosquito nets and clothing with permethrin.[11]

In the community, known animal reservoirs can be controlled, for example by bulldozing gerbil burrows, destroying infected dogs, or providing the dog population with deltamethrin-impregnated collars. Active case finding and treatment of patients who have VL and post-kala-azar dermal leishmaniasis (PKDL) caused by *L. donovani* and CL caused by *L. tropica* should reduce human-to-human transmission. Early case finding has been helped by the use of serologic tests that are suitable for field use, mainly the direct agglutination (DAT) test and rapid test strips using a recombinant antigen, rK39.[12] [13] Sandflies remain susceptible to residual insecticides and spraying of homes or fogging of streets will reduce the density of peridomestic sandflies.

Two doses of a vaccine, combining killed *Leishmania* promastigotes and live bacillus Calmette-Guérin (BCG), were more than 70% protective against CL in Ecuador;[14] in Iran one dose of a similar vaccine was ineffective[15] and in Sudan a similar vaccine did not prove effective against VL.[16]

CLINICAL FEATURES

Visceral leishmaniasis

In VL, amastigotes disseminate throughout the reticuloendothelial system. After an incubation period of 2–8 months (range 10 days to

Figure 172-1 Global distribution of visceral leishmaniasis. More than 90% of VL cases occur in India/Nepal/Bangladesh, Sudan/Ethiopia and Brazil.

Figure 172-2 Global distribution of cutaneous leishmaniasis. More than 90% of CL cases occur in the regions of Brazil/Peru, Algeria, Saudi Arabia and Syria/Iraq/Iran/Afghanistan.

over 2 years), the patient develops pyrexia, wasting and hepatosplenomegaly, which may become massive (Fig. 172.3). Males and females are equally affected in Sudan but outdoor activities make males more frequently affected in Kenya, Uganda, India and some other areas. Most cases in Europe are seen in children.

The onset can be ill-defined, and months elapse before the patient presents with fever, discomfort from an enlarged spleen, abdominal swelling, weight loss, cough or diarrhea. In some patients, such as those who are infected during an epidemic, the disease has an abrupt onset with high fever and rapid progression resulting in prostration, weakness, dyspnea and acute anemia.

The physical signs (Table 172.1) depend upon the duration of the disease, the nutritional state of the patient and the presence of complications. Patients who present late are thin, with wasted muscles. Hair changes and pedal edema may accompany hypoalbuminemia, but ascites is rare. Hyperpigmentation of the face, hands, feet and abdomen is characteristic of VL in India (kala-azar means 'black sickness'). The

Figure 172-3 Visceral leishmaniasis. (a) Hepatosplenomegaly and pallor in a 29-year old Italian man. (b) Splenomegaly and pallor in a 23-year old Angolan. Both complained of weight loss, fatigue and fever of several weeks' duration.

TABLE 172-1 -- Features of visceral leishmaniasis *(Leishmania donovani)*.

FEATURES OF VISCERAL LEISHMANIASIS *(LEISHMANIA DONOVANI)*	
Clinical feature	**Proportion affected (%)**
Age <9 years	22 (*L. infantum* and *L. chagasi* more commonly affect children and infants)
Age <15 years	44
Fever	83–100
Wasting	70–100
Loss of appetite	62–74
Uncomfortable spleen	81–88
Cough	72–83
Epistaxis	44–55
Diarrhea	25–55
Vomiting	2–37
Splenomegaly	93 (adults), 98 (children)
Hepatomegaly	55–65
Lymphadenopathy	55–86 (uncommon outside Africa)
Jaundice	2–7
Edema	2–7
Laboratory findings	**Proportion (%)**
Globulin >30g/l	98
Albumin <30g/l	88
Anemia	61–92
Leukopenia	84
Thrombocytopenia	73
Elevated bilirubin	17
Elevated liver transaminases	22
Elevated alkaline phosphatase	40
Positive *Leishmania* serology	95
Parasitologically proven	96
The duration of symptoms is 2–4 months but is shorter in children.	

spleen is massively enlarged, often reaching the left or even right iliac fossa. It is smooth and nontender unless there has been a recent infarct. The liver is moderately enlarged in one-third of cases. Lymphadenopathy is common only in African patients, in whom unimpressive, peanut-sized lymph nodes are often palpable in the groins. Jaundice, mucosal and retinal hemorrhage, and episcleritis

are occasional features. After several weeks to months of illness, approximately 90% of patients who have VL will die, often as a result of uncontrolled bleeding, secondary bacterial pneumonia, tuberculosis or dysentery, or other infections such as cancrum oris.

Leishmaniasis in patients who are immunosuppressed or have HIV infection

Visceral leishmaniasis caused by *L. infantum* occurs as an opportunistic infection among patients co-infected with HIV (typically $CD4^+$ lymphocytes <200 cells/mm^3),[6] patients on corticosteroid treatment and patients who have undergone organ transplantation or thymectomy. Travel to an endemic area may have been years previously. The clinical features are often atypical; the symptoms may be vague, the laboratory abnormalities may be less severe and hepatosplenomegaly may be

absent or unimpressive. Amastigotes may be found unexpectedly in bone marrow aspirates or skin biopsies of febrile HIV-positive patients. Amastigotes may be found in unusual cells (e.g. circulating neutrophils). Gastrointestinal symptoms may predominate and amastigotes of *Leishmania* spp. found in rectal or duodenal biopsies. *Leishmania* serology is negative in one-third of immunosuppressed patients. Such patients may respond well to antileishmanial treatment only to relapse 2–12 months later. Alternatively, the response to treatment may be incomplete or the patient may be completely nonresponsive or experience exaggerated drug toxicity. In Ethiopia, *L. donovani* infection in HIV-infected patients is clinically indistinguishable from VL in HIV-negative patients. However, those who have HIV co-infection have around 30% mortality during treatment, rising to about 50% by 6 months, and have higher rates of relapse and PKDL.[17]

Cutaneous leishmaniasis has been reported in patients who have HIV infection in Africa and South America. The lesions often resemble those of diffuse cutaneous leishmaniasis (DCL, see below).

Viscerotropic Leishmania tropica

Nine US soldiers who served in the Persian Gulf area in 1990–1 were found to have systemic infection caused by viscerotropic *L. tropica*.[18] They experienced a non-specific febrile illness with fatigue, arthralgia and diarrhea. Some soldiers recovered spontaneously, whereas others progressed and developed a chronic condition with adenopathy or splenomegaly. Most responded to treatment with sodium stibogluconate.

Post-kala-azar dermal leishmaniasis

After successful treatment for VL due to *L. donovani* (but not *L. chagasi* or *L. infantum*), patients may develop a rash called PKDL.

In Africa, PKDL occurs toward the end of apparently successful treatment or within a few weeks or months later. In Sudan, PKDL occurs in approximately 55% of patients who have VL, including those who have had subclinical VL.[19] In India, PKDL is less common, and occurs months to years after VL. Occasionally, PKDL is acute and severe, resulting in desquamation of skin and mucosae. More commonly, it is characterized by the development of hypopigmented patches, nodules and plaques. Parasites are infrequent or absent from the biopsies. People who have PKDL may act as a reservoir of *L. donovani* between outbreaks.

Cutaneous leishmaniasis

In CL (Fig. 172.4) amastigotes multiply in dermal macrophages near the site of inoculation, typically on the arms, legs, face or ears. The lesions may be:

- nodular or ulcerative; and
- single or with multiple satellite nodules or lymphangitic spread.

The most typical lesion of CL is a chronic ulcer with a diameter of 2–5cm and indurated margins. The ulcer may be covered by a

Figure 172-4 Cutaneous leishmaniasis. *Leishmania tropica* recidivans leishmaniasis lesions on the face and forearm of a Syrian girl. These had been present for 4 years with slow healing in the center and multiple recurrences despite courses of intralesional meglumine antimonate.

Figure 172-5 Mucocutaneous leishmaniasis. A young man from Peru who had a 2-year history of slow enlargement of the lips and ulceration of the nostrils. *Courtesy of Professor Luis Valda Rodriguez.*

fibrinous crust or there may be an exudate. It is painful if large or secondarily infected.

The histologic picture is of an intense lymphoid and monocytic infiltrate with granulomas. A 'tissue-paper' scar remains after healing. The spontaneous healing rate differs for each species and is typically:

- less than 5 months for *L. major*;
- less than 8 months for *L mexicana*; and
- approximately 1 year for *L. tropica* and *L. braziliensis*.[8]

There are two chronic forms of CL. Difuse cutaneous leishmaniasis is rare but disfiguring. Widespread plaques containing huge numbers of amastigotes persist for decades. People who have DCL are anergic to leishmanin, but do not have visceral dissemination or systemic symptoms. It is caused mainly by *L. aethiopica* in Africa and *L. amazonensis* in South and Central America. Leishmaniasis recidivans is a chronic, nonhealing or relapsing cutaneous infection, seen mainly with *L. tropica* infection in the Middle East. These patients are hypersensitive to leishmanin and organisms are rarely identified (see Fig. 172.4).

Mucocutaneous leishmaniasis

Mucocutaneous leishmaniasis (MCL; Fig. 172.5) occurs in approximately 3–10% of cases of CL due to *L. b. braziliensis*; it is commonest in Peru and Bolivia. The mucosal lesions usually manifest months to years after the cutaneous sores have healed, but cases of simultaneous CL and MCL occur, as do cases that have no history of CL. Usually the tip of the nose, nasal cartilage or upper lip are involved first with a painless induration or ulceration. The condition may remain static or there may be extension over months to years into the nasopharynx, palate, uvula, larynx and upper airways. The nose may be destroyed.

Biopsies show a chronic inflammatory and granulomatous infiltrate with very few amastigotes. Cultures of biopsies are usually positive for *L. braziliensis* but this may require repeated attempts. Less

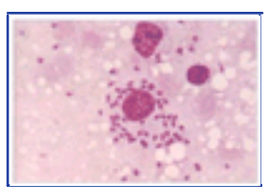

Figure 172-6 Amastigotes (Leishman-Donovan bodies) in bone marrow aspirate from a patient who had *Leishmania infantum* visceral leishmaniasis and AIDS. The nucleus and kinetoplast stain deeply with Giemsa and give the organism its characteristic appearance. *Histoplasma* spp. are the main source of mistaken identification in bone marrow smears, but lack these structures. Amastigotes measure 2–3μm in length and are found within macrophages in tissue sections, but usually lie free in smears because infected macrophages burst as they are smeared.

severe oral or nasal mucosal involvement rarely occurs with other species, such as *L. infantum*, and this often indicates an underlying immune defect.

DIAGNOSIS

Parasitologic diagnosis

Leishmaniasis is suggested by clinical features and supported by serologic or skin tests but should be confirmed by finding or culturing the parasite. *Leishmania* spp. may be isolated from material taken from reticuloendothelial tissue or from biopsies of skin or mucosal lesions. Some of the sample is smeared onto glass slides stained with Giemsa stain, and examined for amastigotes (Fig. 172.6). The rest of the sample is inoculated into suitable media and cultured at 78.8–82.4°F (26–28°C)

and a positive culture will produce microscopically visible motile promastigotes within 2 weeks.

In VL, positive yields from smears of aspirates are of the following order: spleen, more than 95%; bone marrow or liver, 70–85%; lymph node (Africa), 58–65%; and buffy coat of blood up to 70%.[12] Cultures yield about another 10% in good hands. The technique of splenic aspirate is shown in Figure 172.7 .

In CL, DCL, PKDL and MCL, slit skin smears are taken from the raised edge of the CL ulcer or center of the nodule (Fig. 172.8 ; see Chapter 154). Amastigotes are most abundant in fresh CL lesions and are very numerous in DCL. Conversely, they are infrequent in old CL lesions, in MCL and in PKDL.

Immunologic diagnosis

In VL, 95% of cases have positive serology for *Leishmania* with high titers using DAT, the immunofluorescent antibody test (IFAT) or enzyme-linked immunosorbent assay.[12] The leishmanin skin test is invariably negative, indicat-ing antigen-specific anergy and an absence of Th1 cell-mediated immunity.

In CL, *Leishmania* serology may be weakly positive and the leishmanin skin test is usually positive. In MCL and PKDL, both serology and the leishmanin skin test are usually positive. In DCL, there is anergy and both serology and the leishmanin skin test are negative.

Figure 172-7 Splenic aspiration. The picture shows a splenic aspirate being performed under field conditions on a child suffering from *Leishmania donovani* kala-azar in south Sudan. The procedure is simple, painless and safe if the prothrombin time is normal and the platelet count is above 40×10^9 /l. Palpate the spleen and mark its outline. Using a 1.25 inch (30mm) long 21-gauge needle attached to a 5ml syringe, penetrate the skin over the spleen. Withdraw the plunger 1 ml and plunge the needle into the spleen upwards at an angle of 45° and withdraw immediately, maintaining suction. The tiny amount of material obtained is sufficient for culture and smear. *Courtesy of Drs Robert Wilkinson and Jill Seaman.*

Figure 172-8 Slit skin smear. The picture shows a slit skin smear being taken from the edge of a chronic *Leishmania infantum* ulcer obtained in Malta. Smears are taken from the raised edge of the ulcer or center of the nodule, where amastigotes are most abundant. The skin is cleaned and then firmly pinched throughout the procedure to squeeze away blood. A 5mm-long and 3mm-deep incision is made and then the scalpel is turned through 90° and the blade is used to scrape the edge of the slit. A line of tissue scrapings is gently streaked on to a slide and the process is repeated until two or three lines of scrapings are present on at least two slides. Further scrapings and fluid oozing from the pinched slit are put into culture medium.

MANAGEMENT

First-line agents

Pentavalent antimonials

Pentavalent antimonials (Sb^V) have been used for millions of cases since the 1940s.[8] [9] [20] Sodium stibogluconate contains Sb^V 100mg/ml; meglumine antimonate contains 85mg/ml. In the systemic treatment of VL, CL and MCL, a single daily dose of Sb^V of 20mg/kg is used for 28 days. Intravenous injections are less painful than intramuscular injections. Courses of up to 3 months are used for PKDL. Primary resistance to Sb^V is seen in approximately 1% of cases in Africa and

up to 60% in parts of India. Relapse rates should be less than 5%, but secondary Sb^v resistance is likely to develop in patients who relapse unless they are retreated very thoroughly.

Toxicity

This relates to the daily and cumulative dose of Sb^v , as well as to unknown factors; for example, toxicity is almost never seen in patients treated for PKDL, whereas patients who have VL regularly have symptoms suggestive of toxicity and occasional sudden deaths occur in VL patients that might be due to arrhythmias. Children tolerate Sb^v better than adults and may be given higher doses per unit of body surface area. Before starting treatment, ideally a full blood count, biochemistry profile and electrocardiograph should be obtained. Patients should be hospitalized during systemic Sb^v therapy and, where possible, blood tests and electrocardiographs should be repeated twice weekly. Hospital-based Sb^v treatment is usually impossible in endemic countries, where Sb^v is administered by a nurse to outpatients without the facilities for monitoring toxicity. Nonetheless, serious adverse events are rare and deaths due to Sb^v very rare, even in severely debilitated VL patients.[9] [20]

The toxicity is reversible and includes an elevation of serum amylase and liver enzymes, arthralgia and myalgia, thrombocytopenia, leukopenia, anorexia and thrombophlebitis. Patients may complain of lethargy, headache, nausea, vomiting, a metallic taste or pruritus. The most common electrocardiograph changes are ST-segment and T-wave changes; prolongation of the corrected QT interval to more than 0.5s is an indication to temporarily discontinue therapy.[21] Toxicity can usually be managed by stopping Sb^v treatment for 1–2 days. If toxicity recurs the daily dose should be reduced. Acute renal failure, thrombocytopenia, arthritis, tremors and exfoliative dermatitis occur occasionally.

Pancreatic toxicity is a common complication; asymptomatic hyperamylasemia is very common, and symptomatic[22] and even fatal [23] Sb^v -associated pancreatitis have been reported.

Intralesional administration

When used intralesionally, approximately 1ml of undiluted Sb^v is infiltrated into the base and edges of a CL lesion. The injections are repeated every 2–3 days for up to 2–3 weeks. There are no systemic side-effects, but the injections are painful.

Amphotericin B

Amphotericin B deoxycholate is a very powerful antileishmanial and is a first-line drug in India. Amphotericin B is remarkably nontoxic in the regimens used for Indian VL. The optimal regimen is 20 doses of 1mg/kg on alternate days.[24]

Amphotericin B is the drug of choice for advanced MCL, for which Sb^v treatment is often ineffective, and total doses of 30mg/kg are used.

Amphotericin B has not been systematically assessed for CL or PKDL.

Lipid-associated amphotericin B

These compounds are all taken up by macrophages and therefore target amphotericin B to the site of infection, achieving very high levels in liver and spleen. All have lower toxicity than amphotericin B but are more expensive.

Liposomal amphotericin B (AmBisome®) is rapidly effective and nontoxic for VL in Europe[25] and is of value for VL in Sudan[26] and India.[27] The usual regimen is a total dose of 20–30mg/kg, given as at least five daily doses of 3–4mg/kg over a period of 10–21 days. Very short courses of liposomal amphotericin B 1mg/kg daily for 5 days, or 5mg/kg as a single dose, have a high cure rate in India[27] but are unlikely to be effective in Sudan.[26] A few complicated cases of CL have been successfully

treated with long courses of liposomal amphotericin B.

Amphotericin B cholesterol dispersion (Amphocil®) has been used for Brazilian VL at a dosage of 2mg/kg/day for 7 or 10 days.[28] Amphotericin B lipid complex (Abelcet®) has been used successfully for Indian VL in a regimen of 3mg/kg on consecutive or alternate days for five doses.[29]

Second-line drugs

Miltefosine

Miltefosine is the first oral drug with demonstrated efficacy against kala-azar, the dose in adults who have VL being 50mg twice daily for 28 days. [30] It is teratogenic, so cannot be given to pregnant women or women who could become pregnant within 6 months after treatment. Experience thus far is limited to India, where it has been licensed.

Paromomycin (aminosidine)

Paromomycin may be synergistic with Sb^v , a suitable regimen in VL being paromomycin 15–17mg/kg/day plus Sb^v 20mg/kg/day, given together for 17 days.[31] Paromomycin as a single agent is safe and effective at doses of up to 16–20mg/kg/day for 30 days, the optimal regimen being 15mg/kg/day for 21 days.[32]

Pentamidine

Pentamidine is too weak to be routinely used for VL, although short courses — seven doses of 2mg/kg on alternate days or four doses of 3mg/kg on alternate days — are effective for New World CL.[33]

Immunotherapy

Interferon-? added to Sb^v improves the cure rates for relapsed or Sb^v -unresponsive VL and MCL[34] but toxicity and expense exclude it from routine use.

Granulocyte-macrophage colony-stimulating factor combined with Sb^v in the treatment of VL induces a more rapid increase in leukocyte count and fewer secondary infections[35] but cannot be recommended for routine use.

Second-line oral agents

Ketoconazole is effective for CL caused by *L. major* and *L. mexicana*, but less effective against *L. tropica, L. aethiopica* and *L. braziliensis*. Fluconazole[36] or itraconazole have similar efficacy and are better tolerated. Imidazoles cannot reliably cure VL or PKDL and there are no studies of their use in the treatment of MCL.

Allopurinol has been assessed in the treatment of all forms of leishmaniasis but has not shown consistent benefit.

Topical treatment

Topical aminosidine 15% in methylbenzethonium chloride applied twice daily for 10–30 days is effective in the treatment of *L. major* CL.[37] Preparations without methylbenzethonium chloride are of little value.

Monitoring response to treatment

Visceral leishmaniasis

Intercurrent infections such as malaria, tuberculosis and dysentery must be treated, and good hydration and nutritional supplements should be provided.

If responding, the patient will be afebrile within 1 week and clinical and laboratory abnormalities will improve within 2 weeks.

After successful treatment, amastigotes will be absent from aspirates and culture will be negative, and these should be confirmed before treatment is stopped. The patient should be reviewed during 6–12 months after treatment. Slight splenomegaly may persist for several months. Most relapses occur within 6 months. Body weight, spleen size, full blood count, serum albumin concentration and

erythrocyte sedimentation rate are all sensitive markers of recurrent VL. A relapse rate of less than 5% is expected for immunocompetent patients but more than 80% for patients who also have HIV infection. Maintenance with intravenous pentamidine every 2–4 weeks or amphotericin B once or twice weekly may be useful to prevent or delay relapse for patients who have HIV infection but its efficacy is unproven.

A second course of Sb^v may be used successfully to treat a relapse of VL but a different drug such as amphotericin B is probably more effective.

For patients who have HIV co-infection, relapses may be less severe than the first attack and accompanied by vague, minor or atypical clinical features. For such patients, the benefit to be gained from any treatment must be weighed against the adverse effects of prolonged or repeated courses of toxic drugs.

Cutaneous leishmaniasis

Treatment is necessary if the lesions are large, multiple, disfiguring or overlie a joint. Intralesional Sb^v is cheap and usually effective but CL due to *L. braziliensis* should be treated systemically to reduce the risk of subsequent MCL. Most relapses of CL will occur within 12 months.

Mucocutaneous leishmaniasis

Untreated MCL will slowly progress to produce extensive mutilating lesions. Early lesions respond better to treatment[38] but the response is slow and relapses are common. Corticosteroids should be added if the larynx or airways are involved, to prevent edema complicating the start of treatment. Relapse may occur up to several years after treatment, so prolonged clinical follow-up is necessary.

Chapter 173 - Chagas' Disease (American Trypanosomiasis)

Michael A Miles

EPIDEMIOLOGY

Chagas' disease was first described by the Brazilian scientist Carlos Chagas in 1907.[1] The causative agent, *Trypanosoma cruzi*, is a kinetoplastid protozoan parasite. It is transmitted to mammals by blood-sucking triatomine bugs (order Hemiptera, family Reduviidae, subfamily Triatominae) not by their bite but by contamination of the host with *T. cruzi*-infected bug feces. Secondary routes of transmission include:

- blood transfusion;
- organ transplant;
- transplacental transmission; and
- orally by consumption of food contaminated with triatomine bug feces or of uncooked meat from infected mammals.

Infective forms (metacyclic trypomastigotes) of *T. cruzi* gain entry to the mammalian host from triatomine feces by penetrating mucous membranes or abraded skin. Trypomastigotes can then enter nonphagocytic or phagocytic cells, in which they transform to amastigotes and divide by binary fission to produce a pseudocyst. Before rupture of the pseudocyst amastigotes transform to trypomastigotes, which upon release re-enter cells or circulate in the blood (Fig. 173.1) from where they are picked up when the host is again attacked by bugs.

Multiplication within the insect vector occurs by binary fission as the epimastigote stage in the intestinal tract. Triatomines acquire *T. cruzi* infection only by feeding on an infected host and not by transovarial transmission. They are highly susceptible to infection and once infected usually remain infective for life.

The trypomastigote, amastigote and epimastigote life cycle stages are distinguished by the position of a discrete organelle, the kinetoplast, in relation to the nucleus and by the presence or absence of a free flagellum (see Diagnosis, below). Organisms at all stages of the life cycle can be grown in culture.[2]

The majority of triatomine bug species[3] are found in the New World and *T. cruzi* is restricted to the Americas. A few bug species cause widespread and abundant household infestation, principally:

- *Triatoma infestans* (Argentina, Bolivia, Brazil, Chile, Paraguay, Peru and Uruguay);
- *Rhodnius prolixus* and *Triatoma dimidiata* (northern South America and Central America);
- *Panstrongylus megistus* (central and eastern Brazil); and
- *Triatoma brasiliensis* (north eastern Brazil).

The natural habitats of triatomines are trees, burrows and rocks, where they feed on mammals, birds and reptiles. All mammals, but not birds or reptiles, are considered to be susceptible to *T. cruzi* infection and the organism has been reported in more than 150 mammal species of 24 families. Domestic dogs, guinea pigs, cats, rats and mice living in houses may therefore be important domestic reservoir hosts. In addition, chickens, although not infected, are a significant factor because they can sustain large bug infestations. The most common sylvatic reservoir host of *T. cruzi* is the opossum, *Didelphis*. Sylvatic cycles of *T. cruzi* transmission are found from southern Argentina and Chile (latitude 46° south) to northern California (latitude 42° north), although human infection is rare in the USA and sporadic in the Amazon basin because local vectors have not adapted to colonize houses.[4]

Serologic surveys indicate that more than 10 million people carry *T. cruzi* in the Americas, with prevalence rates of more than 70% in some communities. In some endemic localities seropositivity rates among blood donors may reach 20%. Transmission cycles have been described as:

- enzootic, with rare human infections but sympatric sylvatic transmission (as in USA; Amazon basin);
- discontinuous, with separate domestic and sylvatic transmission cycles involving different triatomine vector species (as in Southern Cone countries, see below); and
- continuous, with overlapping domestic and sylvatic transmission cycles involving the same triatomine vector species (as in parts of Venezuela).[5]

The initial, acute phase of *T. cruzi* infection may be asymptomatic (see Clinical features, below) and is not commonly reported. Although 10% of acute phase infections in children may be fatal, the epidemiologic importance of Chagas' disease also arises from chronic infection. Once *T. cruzi* infection has been acquired, in the absence of treatment it is usually retained for life.

Trypanosoma cruzi frequently invades heart muscle and smooth muscle of the alimentary tract. Up to 30% of chronic infections have been reported to lead to chagasic cardiomyopathy, electrocardiograph (ECG) abnormalities and sudden death or progressive heart disease. Associated chronic phase syndromes are mega-esophagus and megacolon (see below).

Biochemical studies and genotyping have demonstrated that *T. cruzi* is genetically diverse. Two principal subspecific groups have been identified and named *T. cruzi* I and *T. cruzi* II, the latter with five subgroups (a–e). *Trypanosoma cruzi* I predominates in the Amazon basin and in endemic countries north of the Amazon; *T. cruzi* II is the predominant cause of Chagas' disease throughout the Southern Cone countries of South America.[6] The disparate distribution of *T. cruzi* strain groups has been circumstantially linked to regional differences in the severity of chronic Chagas' disease.[6] *Trypanosoma cruzi* I hybrids have been generated in the laboratory from clonal parental genotypes.[7] Phylogenetic evidence indicates that genetic exchange may have contributed significantly to the evolution of *T. cruzi*.[7] [8] Genetic exchange may facilitate the spread of virulent and drug-resistant strains, or the extension of host range.[7]

PATHOGENESIS AND PATHOLOGY

The pathogenesis of Chagas' disease is still somewhat enigmatic. Many infected individuals who survive the acute phase show no progression to chronic disease. Pathogenesis has been described as involving an inflammatory response, focal neurologic damage and, in some cases, resurgence of a chronic inflammatory response that may be triggered by autoimmunity. An immunocompromised state may lead to reactivation of infection, producing symptoms typical of the acute phase.

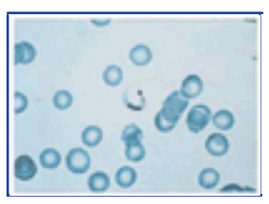

Figure 173-1 *Trypanosoma cruzi* C-shaped trypomastigote in Giemsa-stained thin blood film.

TABLE 173-1 -- Phases of Chagas' disease.

PHASES OF CHAGAS' DISEASE		
Acute phase		
Inflammatory response to ruptured pseudocysts		
Mononuclear infiltrate (macrophages, lymphocytes)		
Trypanosoma cruzi antigen, immunoglobin and complement in situ		
Spreading lymphocytic infiltration, some destruction of nonparasitized tissue		
Focal destruction of conducting tissue (cardiac failure)		
Inflammatory and degenerative changes subside		
Chronic phase		
Indeterminate	'Asymptomatic' chronic infection	
	Refined techniques may detect some abnormalities (electrocardiograms, septal endomyocardial biopsy)	
Chronic disease	Neurogenic	Minimal active inflammatory lesions
		Focal fibrosis
		Pronounced neuron loss (heart, esophagus, colon)
		Apical aneurysm
		No progressive congestive heart failure
		Sudden death
	Myogenic	Moderate to intense diffuse active progressive myocarditis (macrophages, lymphoid cells, fibrosis) in the absence of parasites
		Progressive congestive heart failure

Local multiplication at the portal of entry of *T. cruzi* may lead to a skin lesion or conjunctivitis (see Clinical features, below) with a local inflammatory response. Pseudocyst rupture in the heart or other organs generates an inflammatory response with infiltration of lymphocytes, monocytes and/or polymorphonuclear cells (Table 173.1). In those surviving acute phase infection, intracellular multiplication and parasitemia in the blood subside, although trypomastigotes may still be detectable by sensitive methods (see Diagnosis, below).

Focal lesions in the conducting system of the heart are associated, both clinically and experimentally, with corresponding ECG abnormalities. The

Figure 173-2 Apical aneurysm of the left ventricle in chronic Chagas' disease. *Courtesy of Dr JS Oliveira.*

Figure 173-3 Mega-esophagus on radiograph. *Courtesy of Dr JS Oliveira.*

pathogenesis of this 'neurogenic' form of chronic Chagas' disease is thought to depend upon irreversible neuron loss in the acute phase, exacerbated by further loss with age, such that a threshold is reached beyond which organ function is perturbed. Electrocardiogram abnormalities or aperistalsis of the alimentary tract then ensue, with organ enlargement, or mega syndromes. Gross pathology of the heart consists of megacardia and focal thinning of the myocardium, especially at the apex of the left ventricle, which may lead to apical aneurysm formation, which is considered to be pathognomonic of chronic chagasic cardiomyopathy (Fig. 173.2). Apical aneurysm can be produced experimentally without *T. cruzi* infection by inoculating catecholamines, suggesting that it may be associated with sympathetic dominance. Chagasic mega-esophagus (Fig. 173.3) is more common than chagasic megacolon (Fig. 173.4) and either or both may be associated with chagasic cardiomyopathy. [9]

Figure 173-4 Megacolon. *Courtesy of Dr JS Oliveira.*

Some patients who have chronic 'myogenic' Chagas' disease present with a renewed inflammatory response and a progressive diffuse myocarditis associated with a slow decline in cardiac function. It has been proposed that this pathology can be explained by an autoimmune pathogenesis. It is known that antigens released from ruptured pseudocysts may spread from the immediate site of infection, and be adsorbed to uninfected cells. This may lead to an extension of focal damage and the release of normally sequestered host antigens, which could precipitate autoimmunity. Candidate cross-reactive epitopes between *T. cruzi* and mammalian tissues have also been described, including the C-terminus of the *T. cruzi* ribosomal P protein, and myosin epitopes. It is not clear whether autoantibodies are markers of pathology or have a causal role.[10]

A tentative overall explanation of the pathogenesis of Chagas' disease is that:

- direct and indirect focal neuronal damage in the acute phase may with time culminate in ECG abnormalities and sudden death or mega syndromes; and
- in a proportion of patients there is autoimmune reactivation of the inflammatory response and progressive myocarditis.

The Pan American Health Organization has produced a review of Chagas' disease and the nervous system.[11]

PREVENTION

There is no vaccine for Chagas' disease. Crude or fractionated antigens can protect experimental animals against a normally fatal challenge infection. Prospects for vaccine development are remote because of the alleged involvement of autoimmunity in the pathogenesis of Chagas' disease and the impracticality of vaccine trials.

Immunotherapy has been proposed but not devised, and is likely to be of limited use and not cost-effective.

Chagas' disease is maintained by poverty and poor housing, which prevent families and communities from controlling domestic triatomine populations. Prevention of new cases of vector-borne *T. cruzi* infection relies on insecticide spraying, health education and improved housing. Screening or treatment of donor blood, and of organ donors and recipients are also essential measures.

Pyrethroids, which have low toxicity and high residual activity, are the insecticides of choice for killing triatomines. Control campaigns are organized and run in three phases — preparatory, attack and vigilance:

- during the preparatory phase the distribution of dwellings is mapped, the number of infested houses assessed and the second and third phases are costed and planned;
- in the attack phase all houses and peridomestic buildings are sprayed, irrespective of the known presence of bug infestation; and
- in the vigilance phase a community surveillance system reports residual or new triatomine bug infestations, eliciting a rapid respraying response for those houses affected.[12]

Blood for transfusion and organ donors or recipients can be screened by one of several serologic methods. In highly endemic areas, if serology cannot be performed, blood may be treated with crystal violet (at 250mg/l) and stored at 39.2°F (4°C) for a minimum of 24 hours, which will kill *T. cruzi* trypomastigotes.

Serology is also crucial for monitoring the success of control programs. Children born after control campaigns are initiated should be serologically negative, except for some of those under 9 months of age who will retain transplacentally transferred IgG from seropositive mothers (see Diagnosis, below). Seropositivity in the relevant age group will pinpoint residual triatomine bug infestation and vector-borne transmission or sporadic cases of congenital transmission of infection from mother to child (see Diagnosis and Clinical features, below). To monitor control campaigns serology can be used economically to screen:

- entire populations of countries or endemic regions; and
- selected populations in areas of high seroprevalence or on the edges of endemic areas where new epidemic outbreaks might occur.

These well-established control principles have lead to a Southern Cone initiative to eliminate *Triatoma infestans* from the southern countries of South America (Argentina, Bolivia, Brazil, Chile, Paraguay, Peru and Uruguay).[13] The cost of prevention in this way is a small proportion of the economic burden of the diagnosis, management and treatment of acute and chronic Chagas' disease. The Southern Cone program has stimulated ministries of health to invest in triatomine control and has led to a dramatic reduction in domestic infestation over wide areas. The success of the program is assisted by the fact that *T. infestans* is thought to be restricted to domestic habitats throughout its range, except in Bolivia where it is also found in feral guinea pig colonies. Surveillance programs are being planned to protect the Amazon basin from immigration by domestic triatomine species and to report adaptation of local sylvatic bugs to colonization of houses.[4] [14]

The prospects for vector control in northern South America and Central America are less straightforward, as in some regions domestic bugs may be continuously replenished from nearby sylvatic foci. Morphologic similarities between *Rhodnius* spp.[15] may, however, have led to an overestimation of the degree of movement between sylvatic and domestic bug populations. Andean and Central American initiatives to control Chagas' disease have been launched in an effort to mimic the success of the Southern Cone program.[16]

CLINICAL FEATURES

Acute phase *T. cruzi* infections are most common in children. If bug feces contaminate the eye, metacyclic trypomastigotes may penetrate the conjunctiva, leading to unilateral conjunctivitis and periophthalmic edema known as Romaña's sign (Fig. 173.5). If the portal of entry is the skin, a cutaneous lesion (chagoma) may result. Occasionally multiple chagomas may be seen in acute phase infections in infants. With both sites there may be regional lymphadenopathy and local infiltration of lymphocytes and monocytes. Further clinical signs during the acute phase may include fever, hepatosplenomegaly, generalized lymphadenopathy, facial or generalized edema, rash, vomiting, diarrhea and anorexia. There may be early ECG abnormalities, including sinus tachycardia, increased PR interval, T-wave changes and low QRS voltage. The incubation period between exposure to infection and the appearance of symptoms may be as short as 2 weeks but can be as long as several months if infection results from blood transfusion. Shorter incubation times in vector-borne infections may be due to the adaptation of metacyclic organisms to rapid invasion of cells, whereas trypomastigotes in contaminated transfusion blood may less efficiently invade the heart or other organs.

Figure 173-5 Romaña's sign.

General lymphadenopathy and splenomegaly are common in patients who have acquired infection by blood transfusion.[17]

Signs of congenital infection may include fever, edema, metastatic chagomas and neurologic signs such as convulsions, tremors and weak reflexes, and apnea. Hepatosplenomegaly is also common in congenital infections. The ECG picture in congenital cases is usually normal but there may be low-voltage complexes, decreased T-wave height and increased atrioventricular (AV) conduction time.[17]

Meningoencephalitis is infrequent in adults but more common in infants and carries a poor prognosis. Meningoencephalitis is also common in those immunocompromised by AIDS, as the organism frequently traverses the blood-brain barrier in these patients.[18]

Individuals who recover from the acute phase may lead entirely normal lives without any further signs. Indeed, one of the first cases described by Carlos Chagas, a young girl called Berenice, lived into her eighth decade with no associated illness, even though *T. cruzi* was isolated from her on several occasions and late into life. After a symptom-free indeterminate phase of unpredictable duration, ECG abnormalities typical of chronic Chagas' disease arise in up to 30% of patients who recover from the acute phase. Cardiac signs include dysrhythmias, palpitations, chest pain, edema, dizziness, syncope and dyspnea. The most typical reported ECG changes are right bundle branch block and left anterior hemiblock, but there may also be AV conduction abnormalities, including complete AV block. Many different types of dysrhythmia may occur, including sinus bradycardia, sinoatrial block, ventricular tachycardia, primary T-wave changes and abnormal Q waves. The severity of heart disease is graded according to the extent of the disturbance. Radiography of the thorax is a useful aid for detecting cardiac enlargement (megacardia). [17]

Signs of mega-esophagus include loss of peristalsis, regurgitation and dysphagia. Megacolon may be associated with failure of defecation and severe constipation. In both cases there may be progressive dilatation of the organs, which is clinically graded to describe severity.[9] [19]

Differential diagnosis includes distinction from all other types of heart disease and ECG abnormalities, but changes such as right bundle branch block and left anterior hemiblock associated with a history of exposure to *T. cruzi* infection (see Diagnosis, below) are indicative.[20] Megacolon due to Hirschsprung's disease is usually recognizable, in part because of its rarity in adults.[9]

DIAGNOSIS

During the acute phase of infection circulating trypomastigotes may be detectable by direct microscopy of unstained wet-blood preparations. Several methods can be attempted to improve the sensitivity of parasitologic diagnosis. These include microscopy of:

- Giemsa-stained thick blood films;
- the buffy coat layer after centrifugation of hematocrit capillaries (with care to avoid exposure to infection);
- centrifugation sediment from recently separated serum (Strout's method); and
- centrifugation sediment after lysis of red blood cells with 0.87% ammonium chloride.

All these methods may fail, even in the acute phase of infection, if the parasitemia is low. A more sensitive method of parasitologic diagnosis is the process known as xenodiagnosis, in which triatomine bugs from laboratory colonies maintained on birds are fed on the suspect patient. The fed bugs are then dissected about 20–25

days later and the hind gut contents are examined for the presence of *T. cruzi* epimastigotes. The hind gut and rectum are drawn out into a drop of sterile physiologic saline, mixed with a blunt instrument such as a microspatula, and examined for the typical motile epimastigotes and trypomastigotes. Care must be taken to avoid infection during this procedure and bugs are usually dissected behind a small Perspex screen or, if available, in a microbiologic safety cabinet. It is also necessary to ensure that colony bugs are not infected with the monoxenous flagellate *Blastocrithidia triatomae*, which may be found in *T. infestans*.

Culture of venous blood on to a blood agar base medium may be used as an alternative to xenodiagnosis[21] but demands better laboratory facilities, is difficult to perform under field conditions and seldom achieves the sensitivity of xenodiagnosis.

In the chronic phase of Chagas' disease xenodiagnosis is still the parasitologic method of choice throughout most of Latin America.

Detection of DNA by the polymerase chain reaction (PCR) may be an adjunct to parasitologic diagnosis for research purposes but is not a routine clinical procedure.[22] In areas where *Rhodnius prolixus* is a vector of *T. cruzi*, xenodiagnosis may yield the nonpathogenic human trypanosome *Trypanosoma rangeli*. Frequently, *T. rangeli* infections in *Rhodnius* spp. can be identified by the presence of long, slender (up to 80µm) epimastigotes, by the smaller kinetoplast and the capacity to invade the bug salivary glands (*T. rangeli* is transmitted by inoculation not by contamination).

Serum antibody is usually detectable within a few days of *T. cruzi* infection and usually persists for life unless the infection is elim-inated by chemotherapy. Rarely, serologic reversion may occur without treatment. There is an initial IgM response and a sustained IgG response, which is detectable by a variety of assays. Commonly used tests are the indirect fluorescent antibody test (IFAT), the enzyme-linked immunosorbent assay (ELISA) and the indirect hemagglutination test. Washed organisms (IFAT) or lysates of epimastigotes grown in vitro (ELISA) are used as antigens. Around 50% of seropositive cases may yield a positive parasitologic result by careful xenodiagnosis.

No universal specific, highly sensitive, recombinant antigen is yet available.[23] [24] Diagnostic assays must be standardized adequately to determine cut-off titers, with positive and negative control sera, and it is advisable to establish reference laboratories for checking assay reproducibility. Cross-reactions may occur, especially with visceral and cutaneous leishmaniasis, which may be sympatric (co-exist in the same geographic area) with Chagas' disease. Infants born of seropositive mothers may be seropositive until up to 9 months of age due to transplacental transfer of IgG. Seropositivity in such infants using an IgM-specific conjugate suggests congenital infection.

Short-term visitors to endemic areas are extremely unlikely to acquire Chagas' disease and, if infection is suspected through exposure to triatomine bug bites or blood transfusion, serologic status may be used to exclude more likely causes of heart disease (Fig. 173.6).

Strain groups of *T. cruzi* may be identified using enzyme electrophoresis or DNA amplification of kinetoplast minicircle DNA, or ribosomal and mini-exon gene targets, but the identification of infecting strain is not yet a proven prognostic indicator. Antibody recognition of the *T. cruzi* II specific epitope of a mucin-like protein is reported to be associated with confirmed Chagas' disease in patients from Argentina, Brazil and Chile.[25] This is not surprising, because *T. cruzi* II predominates in human populations in this region, whereas *T. cruzi* I predominates in endemic countries north of the Amazon

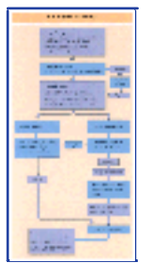

Figure 173-6 Diagnosis of Chagas' disease. ELISA, enzyme-linked immunosorbent assay; IFAT, indirect fluorescent antibody test; IHAT, indirect hemagglutination test.

basin. Chagasic myocardiopathy occurs in *T. cruzi* I endemic regions of northern South America and Central America, even though chagasic megacolon and mega-esophagus appear to be rare or absent.

MANAGEMENT

The oral synthetic nitrofuran nifurtimox has been used for treatment of Chagas' disease but is no longer readily available. The sole drug to treat *T. cruzi* infection is now benznidazole, which is an orally delivered nitroimidazole. The drug is given at 5–7mg/kg/day orally for

Figure 173-7 Modified Duhamel-Haddad procedure for surgical correction of megacolon.[9] [19] [27]

adults, in two divided doses, for 60 days using 100mg tablets. Children tolerate higher doses of 10mg/kg/day given in two divided doses. Side-effects include rashes, fever, nausea, peripheral polyneuritis and leukopenia, and rarely agranulocytosis. Adverse effects may lead to interruption of treatment.

Chemotherapy is recommended during the acute phase of infection as it suppresses the parasitemia and may be life-saving, and for chronic cases in children, who are less susceptible to side-effects.[26] Elimination of infection is not guaranteed. Chemotherapy for chronic Chagas' disease in adults is more controversial as the pathogenesis might be largely attributable to acute phase damage. Adult chronic cases are thus not always treated because:

- the contribution of continued low-level infection to pathogenesis is uncertain [10] ;
- side-effects may cause interruption of treatment;
- treatment often fails to eliminate the organism; and
- cure is difficult to prove (negative parasitology is not sufficiently sensitive to prove absence of infection and reversion of serology may take decades).

Immunocompromised patients must be treated, and double or even higher dose rates, if tolerated, may be recommended to treat meningoencephalitis. Similarly, congenital cases also demand treatment (10mg/kg/day for up to 60 days).

Supportive chemotherapy is often required (e.g. for fever, vomiting, diarrhea and convulsions).[17] Sodium intake is restricted if there is acute-phase heart failure and diuretics and digitalis may be indicated. Management of acute meningoencephalitis may require anticonvulsants, sedatives and intravenous mannitol. Vasodilatation (angiotensin-converting enzyme inhibitors) and maintenance of normal serum potassium may be required initially for chronic chagasic heart disease; digitalis is advisable only as a last resort because it may aggravate dysrhythmias.

Bradycardia that does not respond to atropine, atrial fibrillation with a slow ventricular response, or complete AV block may necessitate a pacemaker.

Amiodarone has been suggested as the most useful drug to treat dysrhythmias, but may produce cutaneous side-effects, such as photosensitivity. Lidocaine (lignocaine), mexiletine, propafenone, flecainide and ß-adrenoreceptor antagonists are effective treatment for ventricular extrasystoles.

Management of chronic chagasic heart disease may therefore be a balancing act between patient management, drug administration and use of a pacemaker. In emergencies lidocaine may be used intravenously. Surgical resection of dysrhythmic endocardial regions and of ventricular aneurysms has been suggested. Detailed expert reports, such as that by the World Health Organization (WHO),[17] and physicians experienced in the management of chagasic cardiomyopathy should be consulted directly to assist in prolonging patient life expectancy and optimizing prognosis.

Surgical treatments have been developed in Brazil for megaesophagus and megacolon. The modified Duhamel-Haddad operation is recommended for surgical correction of megacolon.[9] [19] [27] This procedure involves resection of the sigmoid loop, closure of the rectal stump and bringing the descending colon through the rear wall of the rectum as an initial perineal colostomy (Fig. 173.7). The stump of the colon is subsequently sectioned into anterior and posterior halves, with peridural anesthesia, and the anterior wall of the colon and posterior wall of the rectum sutured in an inverted V to widen the junction. Sigmoidostomy as a separate operation and recovery before Duhamel-Haddad surgery may allow more of the colon to be retained.

Mega-esophagus may improve with dietary control, or respond to dilatation of the cardiac sphincter using probes, air or hydrostatic pressure. The Heller-Vasconcelos surgical procedure for alleviating megaesophagus involves selective removal of a portion of muscle at the junction between the esophagus and stomach. [27] More severe mega-esophagus may demand replacement of the distal esophagus with another part of the alimentary tract such as the jejunum.

Chapter 174 - Migrating Worms

Stephen H Gillespie

INTRODUCTION

Somatic migration of larvae is a normal part of the life cycle of many nematode pathogens, for example *Ascaris lumbricoides*. However, some nematodes are able to invade the human host but are unable to complete their development into adults. In this circumstance the somatic migration stage is prolonged and gives rise to the condition of visceral larva migrans. The most common cause of this syndrome is the canine ascarid *Toxocara canis*, although more rarely *Gnathostoma* larvae and *Angiostrongylus* spp. and the dog hookworms are implicated.

TOXOCARA CANIS

LIFE CYCLE

Toxocara canis is a pathogen of canids, including the domestic dog and feral fox. Ingested eggs hatch in the intestine and the larvae invade the wall and migrate through the liver and lungs. Passing through four larval moults, mature larvae are coughed up and adults develop in the small intestine. This classic ascarid migration occurs mainly in dogs less than 6 months old. In older dogs larval maturation is halted at the second larval stage (L_2), and the larvae migrate and persist in the tissues. Larvae reactivate in pregnant bitches during week 6 of gestation, cross the placenta and are excreted in milk to infect puppies. This mechanism of transmission is very efficient, so that almost all dogs are infected. In dogs, adult worms continue to lay eggs until they are expelled, usually when the dog is about 6 months old. The fertilized eggs must mature in the soil for 2–4 weeks before they are infectious (Fig 174.1 and Fig 174.2). In humans, *T. canis* eggs hatch and larvae invade in the same way but are unable to develop beyond the L_2 stage and continue to migrate through the body for a prolonged period.[1] Humans, along with many other animals, are paratenic hosts. Infection can follow ingestion of fertilized embryonated eggs or uncooked tissue of another paratenic host.

EPIDEMIOLOGY

Serologic studies among adults show that between 2% and 8% of the population has evidence of previous infection. Seroprevalence in children is higher, up to 35% in warm, moist tropical areas with poor sanitary conditions. Symptomatic disease typically occurs in children, with a male predominance. The peak incidence of visceral larva migrans occurs between 3 and 7 years of age and the peak incidence of ocular disease occurs between 7 and 10 years of age. Infection is commonly associated with dog ownership and pica. Several occupational groups that have an excess contact with dogs (e.g. kennel workers) have increased risk of infection, but symptomatic disease is rare in adults. Fecal-oral transmission of infection by ingestion of fertilized mature eggs is the main route of acquisition of *T. canis*. Public parks are thought to be an important source of infection. There have been a few reports of outbreaks of *T. canis* infection associated with the ingestion of raw meat containing L_2 larvae. Examples include undercooked chicken and a Lebanese dish that includes raw sheep liver.[2]

PATHOGENESIS

The L_2 larvae of *T. canis* excrete a complex mixture of glycoproteins, the excretory antigens (*Toxocara* excretory secretory antigens, TES or TEX) from the larval surface. These antigens activate complement, stimulate cytokine production and have potent elastase, acetylcholinesterase and superoxide dismutase activities.[3] As larvae migrate through the tissue there is an intense inflammatory response to TES. The symptoms and signs of toxocariasis are a consequence of this immune response. When the larval load is high there is an intense systemic response, leading to the syndrome of visceral larva migrans (see below). If a larva is trapped in the retina, the inflammatory response is localized, leading to ocular complications such as endophthalmitis or uveitis. Healing of the lesion may be followed by fibrosis with the potential for retinal traction and detachment.[4]

CLINICAL FEATURES

Visceral larva migrans

This syndrome was clearly described in Paul Beaver's initial report as consisting of prolonged fever, cough, wheeze, hepatosplenomegaly and eosinophilia. [5] Since then, more subtle clinical symptoms and signs have been associated with infection, including failure to thrive, urticaria and abdominal pain, and clinicians may include toxocariasis in the differential diagnosis of children with asthmatic symptoms, chronic non-specific abdominal pain, failure to thrive and anemia in addition to the classic visceral larva migrans syndrome (Table 174.1 and Table 174.2). [6] [7] [8] [9] Rarely, heavy infections are associated with myocarditis and a fatal outcome. Associations between toxocariasis and asthma and between toxocariasis and seizures have been made, but a clear etiologic role for *T. canis* has not been identified.

Ocular infection

The pattern and severity of ocular disease depend on the age of the child, the location of the lesion and the immune response. In younger children early lesions may go unrecognized and untreated, so that they present only in routine medical examinations, by which time treatment may not be effective. Ocular toxocariasis may present with endophthalmitis or uveitis. Vision may be reduced by the presence of inflammatory cells in the ocular medium or damage may be caused by a retinal granuloma. Macular lesions can cause a complete loss of vision. Ocular toxocariasis is usually unilateral, but bilateral disease has been reported in up to 3% of series.[4]

Diagnosis

As *T. canis* does not complete its life cycle in humans, adult worms do not develop and eggs cannot be found in the stool. The diagnosis

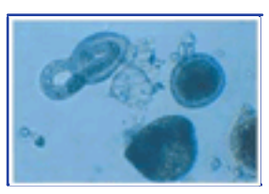

Figure 174-1 Fully embryonated egg of *Toxocara canis* hatching. To the right are two unfertilized eggs.

Figure 174-2 Life cycle of *Toxocara canis.* This demonstrates the importance of transplacental transmission in maintaining canine infection, and the role of young dogs in transmitting infection to humans.

of toxocariasis depends on serologic methods and hematologic parameters. An antibody capture enzyme immunoassay, based on TES antigens, is used worldwide. This test has proved sensitive and specific, with few cross-reactions with other helminth parasites. [10] Alternative diagnostic approaches have included IgE-specific antibody testing and detection of TES antigens, but none of these techniques has proved sufficiently robust for routine clinical diagnosis.[11] There is evidence that IgE detection, although less sensitive, does make the diagnosis of cases of eosinophilia where the serum IgG test is negative. Also serum IgE becomes negative after treatment and has been proposed as a method of following patients who have been given anthelmintic agents.[12]

TREATMENT

The natural history of visceral larva migrans tends toward resolution over a period of weeks or months. Treatment should be considered when the severity or prolonged nature of the symptoms makes it necessary. A single comparative trial showed no enhanced clinical benefit for albendazole over thiabendazole.[13] Albendazole 400mg for 7 days is probably the treatment of choice, although diethyl carbamazine and thiabendazole are alternatives.

In ocular disease therapy is directed toward reducing the severity of the inflammatory response. There is no controlled trial evidence to suggest whether specific anthelmintic therapy is beneficial. There are several reports that support the value of therapy with both albendazole and corticosteroids.[14] [15] Vitrectomy and surgical correction of retinal detachment is beneficial in approximately half of patients with retinal traction. [16] Laser treatment of retinal granuloma has been described but its benefit has not been systematically assessed in comparison with other therapy.

PREVENTION AND CONTROL

Control measures are directed toward reducing contact between children and infective eggs. Because eggs require a period of embryonation in soil, contamination of soil in public parks is an important target for control measures. Dog owners should be encouraged to worm their dogs regularly and to clean up after their pets have defecated. This may be supported by local legislation punishing promiscuous canine defecation in public areas with fines. It is especially important that children's play areas should be made dog proof and children should be encouraged to wash their hands thoroughly after playing in a park.

ANGIOSTRONGYLUS CANTONENSIS

Angiostrongylus cantonensis is a nematode parasite closely related to hookworm. The life cycle involves two hosts, a vertebrate and a snail in which the infective larvae develop. Humans become infected

when they eat slugs or snails or fruits and vegetables on which larvae have been shed in slime. Humans are abnormal hosts for *A. cantonensis* and severe symptoms may result: eosinophilic meningitis, eosinophilic meningoencephalitis and eosinophilic radiculomyeloencephalitis.

A closely related species, *Angiostronglus costaricensis*, causes abdominal symptoms that may mimic acute appendicitis or ileitis and is found in Central America.[17] Treatment with benzimidazoles may be beneficial.

Infection with *A. cantonensis* principally occurs in South East Asia, Oceania, India, Madagascar, Côte d'Ivoire and Egypt, but a new focus of infection has been described in the Caribbean.[18] Treatment may exacerbate symptoms by releasing parasite antigens, and management with corticosteroids may be beneficial, although experience is limited.

GNATHOSTOMIASIS

Gnathostomia spinigerum is the commonest species associated with human gnathostomiasis. The organism has a complex life cycle involving an adult in the intestinal wall of the cat and eggs in the feces, which are ingested by a water-dwelling cyclops and are subsequently ingested by fish, snakes and amphibians. Human infection arises by eating raw or undercooked fish by handling ducks or chickens that have eaten intermediate hosts. The larvae are unable to complete their life cycle in humans and migrate through the tissues for prolonged periods. The disease principally presents as migratory cutaneous swellings but, more seriously, invasion of the central nervous system or ocular disease may develop, causing eosinophilic meningitis, which may involve the spinal cord. Meningitis in gnathostomiasis is frequently fatal. In the eye, the parasite can produce severe inflammation and hemorrhagic lesions. Treatment is unsatisfactory although some have recommended the use of benzimidazoles for treatment.

ANCYLOSTOMA CANINUM AND *ANCYLOSTOMA BRAZILIENSE* INFECTIONS

Dog hookworms cannot complete their life cycle in noncanine hosts and may cause cutaneous larva migrans.[19] Cutaneous larva migrans does not occur after the first exposure to *Ancylostoma caninum* and *A. braziliense* larva, suggesting that the disease is due to hypersensitivity to larval secretions. The lower extremities are more often affected, with eruptions on the feet making up almost two-thirds of all cases. Infection is commonly reported in patients returning from tropical travel. Lesions may be found in the upper legs, urogenital region and on the arms and trunk. Lesions on the head are extremely rare but have been described.[19] The lesions are intensely itchy, red and edematous and show a worm-like migratory pathway under the skin. However, recent studies indicate that *A. caninum* can achieve a wider migration and is implicated in the condition of eosinophilic enteritis.[20] Eosinophilic enteritis is characterized by abdominal pain that is often colicky moving to the periumbilical region or right of the iliac fossa. It usually lasts up to 1 month. It is associated with anorexia, nausea and diarrhea, and some patients can be sufficiently ill to present with an acute abdominal condition that may mimic acute appendicitis or intestinal obstruction.[21]

The diagnosis of cutaneous larva migrans is made on the basis of the characteristic clinical features. The laboratory has no role to play in diagnosis. Eosinophilia is only a feature of a minority of cases. The total serum IgE is usually normal and other serologic tests for helminth infections are unhelpful. In eosinophilic enteritis the patient has significant eosinophilia and a high total IgE level but these laboratory features may be absent in some patients. The diagnosis is made histologically using tissue biopsies obtained during colonoscopy.[20] Aphthous ulcers can be seen in the cecum and terminal ileum on colonoscopy. Laparotomy, when performed for a suspected diagnosis of appendicitis, often reveals an inflamed ileum with intense serositis and enlarged mesenteric lymph nodes. Antibodies to the excretory-secretory antigens of adult *A. caninum* patients can be found in more than 85% of patients with eosinophilic enteritis by antibody capture enzyme-linked immunosorbent assay.

Cutaneous larva migrans is readily treated by application of 10% thiabendazole paste and an occlusive dressing for 24 hours. In severe cases systemic treatment with albendazole or ivermectin may also be used. Eosinophilic enteritis is readily treated with 200mg mebendazole. Failure to respond within 24 hours would suggest an alternative diagnosis.

Chapter 175 - Melioidosis

David AB Dance

INTRODUCTION

The term 'melioidosis' refers to infections caused by the Gramnegative bacillus *Burkholderia* (formerly *Pseudomonas*) *pseudomallei*, which is recognized increasingly as a public health problem in some tropical regions.[1] The considerable recent progress in our understanding of the pathogenesis of this infection and the sequencing of the bacterial genome contrast starkly with our poor knowledge of the epidemiology and distribution of the disease worldwide.[2]

EPIDEMIOLOGY

The distribution of melioidosis is shown in Figure 175.1 . Most cases are diagnosed in South East Asia and northern Australia. The disease is probably under-recognized elsewhere (e.g. half the recent cases diagnosed in the UK originated from the Indian subcontinent). Imported infection is seen mainly in immigrants or soldiers serving in endemic areas, but occasionally occurs in tourists.

Burkholderia pseudomallei is a saprophyte found in soil and surface water, particularly rice paddies, in endemic areas. A closely related, arabinose-assimilating, avirulent organism, *Burkholderia thailandensis*, is similarly distributed, and may give rise to confusion, particularly in serologic tests. Humans and a wide range of other animals acquire infection from contact with soil (e.g. through rice farming), probably by inoculation or inhalation.[3] Recent clusters of infection in Australia have also been associated with contamination of potable water supplies. [2] Most cases present during the rainy season, when people are maximally exposed to the organisms in the environment.[3] [4] Animal-to-human and person-to-person spread, iatrogenic infection and laboratory-acquired infection have all been reported occasionally. All ages may be affected, with a peak from 40–60 years. Males are more often affected than females.[3] [4]

PATHOGENESIS AND PATHOLOGY

The outcome of infection with *B. pseudomallei* depends on a balance between the virulence of the organism, the size of inoculum and the resistance of the host. Between 50% and 70% of patients who have melioidosis have predisposing underlying diseases, especially diabetes mellitus but also chronic renal disease, malignancy, immunosuppressive treatment (e.g. corticosteroids), liver disease, alcohol or drug abuse, pregnancy and cystic fibrosis.[3] [4] Interferon (IFN)-? appears to play a key role in controlling the infection in experimental animals. Recent studies have shown that capsular polysaccharide is a major virulence determinant in *B. pseudomallei*, possibly by reducing intracellular killing.[5] Other potential virulence factors include lipopolysaccharide, a lethal exotoxin, various enzymes (lecithinase, lipase, proteases and acid phosphatase), type III secretion systems and a siderophore. Several of these appear to be encoded on 'pathogenicity islands', possibly acquired by horizontal transfer.[2] Intracellular survival of *B. pseudomallei* probably contributes to the recalcitrant nature of melioidosis.

Burkholderia pseudomallei causes localized abscesses or granulomas at the site of primary infection, depending on the duration of the lesion. Invasion of the bloodstream leads to sepsis, which may in turn result in metastatic foci of infection in other tissues. The host response may also contribute to pathogenesis, because serum levels of several cytokines, including IFN-?, tumor necrosis factor, interleukin (IL)-6 and IL-8, are also correlated with mortality.

PREVENTION

Because *B. pseudomallei* is ubiquitous in the environment in endemic areas, avoidance of the organism is virtually impossible. No *B. pseudomallei* vaccine has been developed for human use, although several experimental vaccines are under development and some have been used on animals. The organism should be handled in containment level 3 facilities in the laboratory. Patients should ideally be cared for in standard isolation, although person-to-person spread is very rare.

CLINICAL FEATURES

None of the clinical classifications of melioidosis is entirely satisfactory. Infections may be acute or chronic and localized or disseminated, but one form of the disease may progress to another and individual patients are often difficult to categorize. Several reviews of the clinical features of melioidosis have been published.[4] [6] The manifestations of the disease in Australia are similar to those in Thailand, although prostatic abscesses and neurologic involvement are more frequently described and parotid abscesses less often.[4]

Mild and subclinical infections

Antibodies to *B. pseudomallei* are very common yet disease is rare, so the majority of infections are presumably mild or asymptomatic. A flu-like illness associated with seroconversion has been reported.

Latent infections

Unusually for a bacterial infection, long periods of latency (up to 29 years) may occur before the disease becomes apparent, which usually happens during intercurrent stress (hence the name 'the Vietnamese time bomb').

Septic melioidosis

Positive blood cultures are found in 46–60% of cases of culture-positive melioidosis.[4] [6] Most of these cases present with a picture of fulminant sepsis syndrome with a short history of high fever and rigors, although some patients have a less acute, typhoidal picture with a remittent fever. Only half have evidence of a primary focus of infection, usually in the lung or skin and subcutaneous tissues. Confusion and stupor, jaundice and diarrhea may also be prominent features. Initial investigations usually reveal:

- anemia;
- a neutrophil leukocytosis;
- coagulopathy; and
- evidence of renal and hepatic impairment.

Figure 175-1 World distribution of *Burkholderia pseudomallei* and *Burkholderia pseudomallei*-like organisms. The boundaries are political and are not intended to define

the true limits of distribution. *With permission from Dance.*[1]

Figure 175-2 Chest radiograph of patient who has septic melioidosis. Note the multiple areas of consolidation scattered throughout both lung fields (blood-borne pneumonia). *With permission from Prof N J White.*

Patients often deteriorate rapidly, developing widespread metastatic foci, metabolic acidosis with Kussmaul's breathing, and shock, and many die within 48 hours of hospital admission. Poor prognostic features include absence of fever, leukopenia, azotemia and abnormal liver function tests.[6]

If the patient survives the acute phase, the manifestations of metastatic septic foci become prominent. An abnormal chest radiograph is found in 60–80% of patients, the most common pattern being widespread, nodular shadowing (Fig. 175.2). Multiple liver and splenic abscesses are common.[7] Cutaneous pustules or subcutaneous abscesses occur in 10–20% of cases.[6] Other common sites for secondary lesions include the urinary tract (kidneys and prostate gland), bones and joints. Involvement of the central nervous system may comprise cerebral abscesses or a syndrome of peripheral motor weakness, brain stem encephalitis, aseptic meningitis and respiratory failure.[4]

Localized melioidosis

Localized melioidosis is most common in the lung, where it usually causes a subacute cavitating pneumonia accompanied by profound weight loss. This may be confused with tuberculosis, although relative sparing of the apices and the infrequency of hilar adenopathy may help to distinguish the two. Any lung zone may be affected, although there is a predilection for the upper lobes. Complications include pneumothorax, empyema, purulent pericarditis and ultimately progression to sepsis. Acute suppurative parotitis (Fig. 175.3) is a characteristic manifestation of melioidosis in children in Thailand, although it is rarely reported elsewhere. Localized *B. pseudomallei* infection may affect any other tissue or organ (e.g. cutaneous and subcutaneous abscesses, lymphadenitis, osteomyelitis and septic arthritis, liver or splenic abscesses, cystitis, pyelonephritis, prostatic abscesses, epididymo-orchitis, keratitis, brain abscesses and mycotic aneurysms).

DIAGNOSIS

Melioidosis should be considered in any patient who has sepsis or abscesses who has ever visited an endemic area, particularly if the patient has an underlying disease such as diabetes mellitus. Microscopy of a Gram-stained smear of pus or sputum is neither specific nor sensitive but immunofluorescent microscopy, which is only available in a few centers, offers the best opportunity of making a rapid diagnosis. Definitive diagnosis depends on isolation and identification of *B. pseudomallei* from cultures of blood or clinically affected sites (e.g. pus, sputum). It is important to alert the laboratory to the suspicion of melioidosis. Preliminary culture results should be available within 48 hours, although identification may be delayed in nonendemic areas because microbiologists are not familiar with the organism. Several rapid diagnostic techniques for the detection of *B. pseudomallei* antigens or nucleic acids have been developed, but these are not yet sufficiently sensitive or specific to be widely used.[9]

The serologic test most widely used in endemic areas is an indirect hemagglutination (IHA) test, although other assays that detect IgG antibodies give similar results. There is a need for internationally standardized serologic tests. High background seropositivity means that false-positive reactions are common in people from endemic areas,[6] but a single high IHA titer (>1:40) in someone

Figure 175-3 Acute suppurative parotitis. This form of melioidosis accounts for around one third of pediatric cases in north east Thailand, but has rarely been reported elsewhere. *With permission from Dance et al.*[6]

from a nonendemic area, or a rising titer, may be diagnostically useful. Tests for specific IgM (e.g. indirect immunofluorescence, enzyme-linked immunosorbent assay) correlate better with disease activity and, along with measurement of C-reactive protein, they may be useful during follow-up of patients on treatment. Imaging, including the use of labeled white cell scans, is also useful in determining the initial extent of dissemination and monitoring the response to treatment.

MANAGEMENT

Supportive treatment

Patients who have septic melioidosis usually require aggressive supportive treatment, including correction of volume depletion and septic shock, respiratory and renal failure, and hyperglycemia or ketoacidosis. Abscesses should be drained whenever possible.

Specific treatment

Burkholderia pseudomallei is intrinsically resistant to many antibiotics, including aminoglycosides and early ß-lactams, and a failure to respond to these agents is characteristic of melioidosis.[6] Several recent studies have shown that the mortality of acute severe melioidosis can be substantially reduced by newer ß-lactam agents such as ceftazidime, imipenem, amoxicillin-clavulanic acid and cefoperazone-sulbactam, with or without trimethoprim-sulfamethoxazole.[10] Very encouraging results have also been reported from Australia using meropenem plus trimethoprim-sulfamethoxazole.[4] The role of granulocyte colony-stimulating factor, which has also been used as adjunctive treatment in Australia, remains to be determined. Ceftazidime or a carbapenem are currently the treatments of choice and should be given in full doses (ceftazidime 120mg/kg/day, imipenem and meropenem 60mg/kg/day, or a dose appropriately adjusted for renal function) for 2–4 weeks according to the clinical response.

Following parenteral treatment, prolonged oral antibiotics are needed to prevent relapse, which occurs in up to 23% of patients and is more common in patients who have more severe disease. The proportion of patients who relapse can be reduced to less than 10% if antibiotics are given for 20 weeks.[10] The combination of chloramphenicol (40mg/kg/day), doxycycline (4mg/kg/day) and trimethoprim-sulfamethoxazole (10mg/kg trimethoprim plus 50mg/kg sulfamethoxazole per day) has been associated with a lower relapse rate than amoxicillin-clavulanic acid (60mg/kg amoxicillin plus 15mg/kg clavulanic acid per day). Lately the chloramphenicol has been omitted from this regimen without apparent detriment[11] and trimethoprim-sulfamethoxazole alone has been used in Australia,[4] although doxycycline alone and fluoroquinolones are inadequate. Amoxicillin-clavulanic acid is preferable in children and pregnant or lactating women. In patients who have mild localized disease, any of the oral regimens described above may be used.

OUTCOME AND FOLLOW-UP

Even with optimal treatment, the mortality from acute severe melioidosis is high (30–47% in Thailand, 19% in Australia).[4] [9] In patients who survive, there is often chronic morbidity resulting both from the disease itself and from the underlying conditions. Patients require long-term follow-up to detect relapse. Susceptibility tests should be carried out on isolates obtained during or after treatment, because resistance may emerge in 5–10% of cases.

Chapter 176 - Plague

David T Dennis
Kenneth L Gage

Plague is an acute, life-threatening zoonosis caused by the bacterium *Yersinia pestis*. The disease is best known for three devastating pandemics, including the Black Death of the Middle Ages. Plague is primarily a disease of rodents, and humans typically acquire the disease as a result of being bitten by rodent fleas, less commonly by handling infected animals, and rarely by inhaling infectious respiratory particles. Urban, rat-borne plague outbreaks have historically been responsible for most human plague cases; in recent decades, however, plague has occurred typically in remote, rural populations. The three principal clinical forms of plague are bubonic plague, septic plague and pneumonic plague. The most common of these is bubonic plague, an acute illness characterized by fever and one or more enlarged tender lymph nodes (buboes) that usually appear in the groin or the axillary or cervical regions proximal to the site of an infective inoculation. Bacteremia and sepsis occur when lymphatic defenses have been breached, and plague pneumonia can arise secondarily as a result of blood-borne seeding of the lungs. Occasionally, pneumonic plague spreads from person to person, most often in crowded, substandard living conditions.

Plague is often fatal when not diagnosed and treated with appropriate antibiotics early in the course of infection. The aminoglycosides, tetracyclines and chloramphenicol are the antibiotics most commonly used to treat plague. Pneumonic plague patients should be isolated under respiratory droplet precautions until no longer infectious, and it is recommended that persons who have been in close contact with pneumonic plague patients be placed on antimicrobial prophylaxis and monitored for fever. Prevention and control of plague relies on environmental sanitation, human and animal disease surveillance, flea and rodent control, and early detection, treatment and isolation of cases, as indicated. Plague is considered to be an important potential weapon of bioterrorism.

EPIDEMIOLOGY

Agent

Yersinia pestis is a Gram-negative, microaerophilic coccobacillus belonging to the family Enterobacteriacae (see Chapter 228). The entire genome of *Y. pestis* has been decoded, showing that the organism recently evolved from *Yersinia pseudotuberculosis*, a gut pathogen.[1] It is nonmotile and nonsporulating, does not ferment lactose and exhibits bipolar staining with Wayson's, Giemsa's or Wright's stains. Growth occurs in a variety of media at a wide range of temperatures (39–104°F (4–44°C); optimal 82–86°F (28–30°C)) and pH values (5.0–9.6; optimal 7.2–7.6). It is a facultative intracellular pathogen that normally grows in extracellular environments; importantly, it invades, multiplies within and is transported by phagocytes during the initial phases of infection.[2]

Genetic factors that enable *Y. pestis* to survive in its mammalian hosts and flea vectors and be transmitted between them are outlined in Table 176.1 .[2] [3] [4] [5] [6] Some factors are expressed selectively at temperatures and environments encountered in fleas or mammals. For example, hemin storage locus (*hms*) products are expressed in the low temperature environment of the flea, apparently enabling the bacteria to form the gut blockages necessary for their survival and efficient transmission.[2] [6]

Three biotypes of *Y. pestis*, which are classified according to their ability to ferment glycerol and reduce nitrate, have been correlated with the three principal plague pandemics. The biotype that spread around the world during the third pandemic beginning in the late 19th century is termed the orientalis biotype; it occurs alone in South East Asia, portions of Africa, Madagascar and in the Western Hemisphere. The antiqua biotype occurs in parts of Africa, southeastern Russia and in Central Asia. The mediaevalis biotype, thought to have been responsible for the Black Death, occurs in natural foci around the Caspian Sea. Results of typing by restriction fragment length polymorphism analysis of rRNA genes (ribotyping) supports these distinctions and has shown chromosomal rearrangements in the orientalis biotype after its spread around the world about 100 years ago.[7]

Life cycle

Understanding the epidemiology of plague requires a working knowledge of the ecology of *Y. pestis* and its transmission cycles. In general, *Y. pestis* is maintained in both enzootic and epizootic cycles involving various sylvatic and commensal rodent species and their fleas (Fig. 176.1).[8] Historically, the commensal black or roof rat, *Rattus rattus*, the sewer rat, *Rattus norvegicus*, and their fleas (especially the oriental rat flea, *Xenopsylla cheopis*) have been the principal sources of epidemics of plague and its pandemic spread.

During interepizootic periods the plague bacterium is maintained in 'silent' enzootic cycles involving populations of wild rodents that exhibit variable responses to *Y. pestis* infection. The most susceptible members of an enzootic host population are likely to develop high bacteremias and serve as suitable sources for infecting feeding fleas. Other members of the same population of rodents develop little or no bacteremia and infect few fleas. These more resistant animals will, however, survive to reproduce and are likely to have offspring that vary in their susceptibility to plague, a factor that promotes the survival of enzootic host populations and yet allows the transmission cycle to be maintained. Most enzootic host species also have relatively high reproductive rates, which further promotes the ongoing introduction of susceptible, nonimmune animals into the population.[9] Under certain conditions, plague is likely to spread from enzootic hosts to more susceptible rodent species (epizootic hosts), causing explosive epizootics and massive die-offs. Commensal rats and certain burrowing rodents, such as prairie dogs, marmots and various ground squirrels, are among the most important epizootic hosts.

Humans and other incidental hosts of *Y. pestis* are not directly involved in maintaining its natural cycle. *Yersinia pestis* can, however,

TABLE 176-1 -- Proposed virulence and transmission factors for *Yersinia pestis*.

PROPOSED VIRULENCE AND TRANSMISSION FACTORS FOR *YERSINIA PESTIS*		
Genomic element	**Virulence or transmission factor**	**Proposed role in virulence or transmission**
9.5kb plasmid (pesticin plasmid; a 19kb dimer of this plasmid also exists)	Pesticin sensitivity (*pst*)	Loss of sensitivity to pesticin (a bacteriocin) is associated with reduced siderophore binding capability (affects iron uptake)
	Plasminogen activator (*pla*)	Fibrinolytic activity (important for dissemination)
70–75kb plasmid (low calcium response plasmid)	*Yersinia* outer proteins (Yops — genes found in the Yop virulon, a type III secretion system; includes *lcrV* or V antigen)	Proposed functions vary among Yops and include: translocation of other Yops (effectors) across cell membranes; disturbance of phagocyte cytoskeleton dynamics (interferes with phagocytosis); blocking production of proinflammatory cytokines and interfering with ability of B and T cells to be activated by means of antigen receptors (immunosuppression); or binding thrombin (interferes with thrombin-platelet aggregation)
100–110kb plasmid	Murine toxin (*ymt*)	Required for survival in fleas; also has ß-adrenergic antagonist activity in rats and mice but not guinea pigs, rabbits, dogs or nonhuman primates
	F1 'capsular' antigen (*caf1*)	Resistance to phagocytosis by monocytes
Chromosomal	Pigmentation (*pgm* locus, includes genes of *hms* locus, high pathogenicity island and *ybt* operon)	Pigment-positive strains bind hemin and appear pigmented on culture media containing Congo Red; *pgm* locus contains genes of the high pathogenicity island (HPI), which is found in other Yersiniae and certain related enteric bacteria; the HPI contains the *ybt* (yersiniabactin) operon, which encodes genes of a siderophore-based iron uptake system; the *pgm* locus also contains the *hms* locus, which must be functional for 'blocking' to occur in the flea vector (blocking is required for efficient transmission of plague by fleas)
	Endotoxin (lipopolysaccharide)	Lipopolysaccharide release responsible for major pathogenic effects of plague sepsis, systemic inflammatory response syndrome and associated adult respiratory distress syndrome, cytokine activation, complement cascade, DIC, bleeding, unresponsive shock and organ failure
	Serum resistance (lipopolysaccharide in part)	Resistance to complement-mediated lysis; proposed to be related in part to lipopolysaccharide structure
	pH 6 antigen (*psa*)	Entry into naive macrophages; assists in delivery of Yops into phagocytic cells

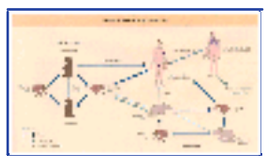

Figure 176-1 Transmission cycles of *Yersinia pestis*.

Figure 176-2 Global distribution of plague. Compiled from sources of the WHO, the Centers for Disease Control and Prevention, and the individual countries.

be directly transmitted from one person to another by respiratory secretions, causing primary plague pneumonia in the recipient (see Fig. 176.1).

Geographic distribution

Plague foci are widely distributed throughout the world, and human cases are typically reported from 10 or so countries each year.[10] Countries reporting human or animal plague at some time in the past 15 years are shown in Figure 176.2 .

Populations affected

Plague is mostly a public health problem of impoverished populations living under substandard conditions. It typically affects inhabitants of rural villages in the developing world that are heavily infested with susceptible rodent hosts and their fleas. Urban rat-borne plague is now unusual around the world, occurring most recently in Madagascar in the 1990s. In the USA, most persons acquire plague from exposures to infection around rural residential properties, which often have poorly maintained woodpiles, abandoned vehicles, dilapidated buildings and other debris that provide favorable harbor for rodents. Cases also occasionally arise among campers, hikers, hunters and others exposed to plague in natural settings.

In the absence of control measures, plague has the potential to spread from rural areas to population centers, including major cities and ports, either through unintended transport of infected rats and fleas or through direct exchange of infection between contiguous rodent populations.[8] Occasionally, persons incubate plague while traveling (peripatetic plague), develop plague pneumonia and transmit plague to others along the way or at their destination. The risk of plague to persons visiting endemic areas for business or tourism is, in general, extremely low.

Disease incidence

The International Health Regulations of the World Health Organization (WHO) require prompt reporting of human plague cases to the WHO.[11] Twenty-four countries reported to the WHO a total of 33,948 cases (mean of 2263 cases per year) and 2653 (8% fatality rate) deaths during the years 1985–99 (Table 176.2).[10] Countries in eastern and southern Africa, and the adjacent island of Madagascar, reported 77% of these cases, with the remaining cases occurring in Asia (17%) and the Americas (6%). Madagascar alone reported 28% of the cases reported to WHO from 1985 to 1999 and

World totals		**33,948**	**2653**

Tanzania accounted for almost another 20% of cases. The recent reemergence of plague, both urban and rural, in southeastern Africa

and Madagascar has been striking.[12] [13] The rise in the proportion of cases reported from Africa and Madagascar was particularly pronounced in the 1990s, and the number of cases occurring in these countries has remained high. During 1985–99, Vietnam (11% of world total) and Peru (4% of world total) reported the most cases from Asia and the Americas, respectively.

Plague was introduced into the USA in 1900 and is considered an emerging disease there.[13] More than 400 cases of plague have been reported in the USA since 1950. Although enzootic and epizootic plague occurs in rural areas of 17 of the contiguous western states of the USA, extending from the Pacific coastal states to the Great Plains states and eastern Texas, 80% of human cases occur in the southwestern states of New Mexico, Arizona and Colorado, and approximately 10% in California.[13] [14]

Sources of infection and risks for humans

Flea bites are the most common source of *Y. pestis* infection. The risk of plague for humans increases greatly during rodent epizootics when large numbers of *Y. pestis*-infected fleas seek new hosts to replace those killed by plague. Human plague can also be a direct result of handling tissues or body fluids of infected animals. This is an important source of plague among persons who hunt and skin marmots (*Marmota* spp.) in Central Asia and northern China, and occasionally this is the source of plague in the USA in persons who handle the carcasses of infected prairie dogs, rabbits and carnivores.[8] Pet owners and veterinary staff may become infected with *Y. pestis* while caring for domestic cats that develop oropharyngeal or pneumonic plague from having ingested infected rodents.[15] Outbreaks of plague have occurred in Saudi Arabia, Libya and Jordan as a result of persons handling and consuming infected camel and goat meat.[16]

Primary pneumonic plague occurs when persons inhale infectious respiratory secretions. This usually arises in the setting of an outbreak of bubonic plague in which some persons who develop secondary pulmonary infection spread infection to others through infectious respiratory droplets, starting a chain of respiratory transmission. Persons living in the same quarters as a pneumonic plague patient and persons attending the sick, such as family members and health care personnel, are especially at risk. *Yersinia pestis* is classified as a category A agent of potential danger as a weapon of bioterrorism because it could be aerosolized and cause outbreaks of severe or fatal illness, create panic, and requires special actions for medical and public health preparedness (see Chapter 6).[17] [18] The release of an aerosol of *Y. pestis* in a biologic terrorism event would be expected to result in an outbreak of respiratory plague with potential for person to person spread. Under natural conditions, primary pneumonic plague usually comprises only a small fraction of the total number of cases in any plague-endemic region (less than 2% in the USA); nevertheless, this form of plague is extremely dangerous because of a high case fatality rate and the risk of epidemic spread.[19]

Seasonality

Flea-borne cases of human plague in the temperate Northern Hemisphere are most likely to occur between late spring and the end of summer when epizootic transmission peaks.[8] In tropical and semitropical plague foci, transmission may vary between a wet, relatively cool season and another season of hotter, drier weather, with the numbers of cases being lowest during the latter period.[20] Although flea-borne cases of human plague are occasionally reported during 'off-season' months in various plague foci, particularly those in tropical or semitropical regions, they are rare in other areas such as the USA. Most 'off-season' (winter) cases in the temperature Northern Hemisphere occur among hunters or trappers handling infected animals. In the USA, these animals include rabbits, hares and carnivores, such as coyotes and wild and domesticated cats.

PATHOGENESIS AND PATHOLOGY

Yersinia pestis is among the most pathogenic bacteria known. Both chromosomal and plasmid-encoded gene products are associated with adaptability to its various hosts and to virulence (Table 176.1).[2] [3] [4] [5] [6] The virulence of the organisms is expressed in a wide range of severe disease.[21] [22] [23] [24] [25]

Yersinia pestis organisms inoculated through the skin or mucous membranes travel to and multiply within regional lymph nodes. In the early stages of infection, affected nodes are found to be edematous and congested and to have minimal inflammatory infiltrates and vascular injury. Fully developed buboes, however, contain large numbers of infectious plague organisms and show vascular damage, hemorrhagic necrosis and infiltration of neutrophilic leukocytes. The affected nodes are usually surrounded by a collection of serous fluid. When several adjacent lymph nodes are involved, a boggy edematous mass can result. In later stages, abscess formation and spontaneous rupture of lymph glands may infrequently occur.

Plague sepsis in the absence of signs of localized infection, such as a bubo, is termed primary septic plague. It can result from direct entry of *Y. pestis* through broken skin or mucous membranes or from the bite of an infective flea. Secondary septic plague can occur in the course of bubonic or pneumonic plague when lymphatic or pulmonary defenses are breached and the plague bacillus enters and multiplies within the bloodstream. Bacteremia is common in all forms of plague; septicemia is less common and immediately life-threatening.

Yersinia pestis can invade and cause disease in almost any organ, and untreated infection usually results in widespread and massive tissue destruction. Diffuse interstitial myocarditis with cardiac dilatation, multifocal necrosis of the liver, diffuse hemorrhagic splenic necrosis and fibrin thrombi in renal glomeruli, are commonly found in fatal cases.[19] [21] [22] [24] If disseminated intravascular coagulation (DIC) occurs, it results in thrombosis within the microvasculature, necrosis and bleeding, with widespread cutaneous, mucosal and serosal petechiae and ecchymoses. Gangrene of acral parts, such as fingers and toes, may occur in the late stages of this process (Fig. 176.4).

Primary plague pneumonia, which results from inhalation of infective respiratory particles, usually begins as a lobular process and then extends by confluence, becoming lobar and then multilobar. Typically, plague organisms are numerous in the alveoli and in pulmonary secretions. Secondary plague pneumonia arising from hematogenous seeding of the lungs typically begins more diffusely as an interstitial process, with plague bacilli most numerous in the interstitial spaces. In untreated cases of both primary and secondary plague pneumonia, the usual pathologic findings are diffuse pulmonary congestion, edema, hemorrhagic necrosis and scant neutrophilic infiltration.[19] [24]

PREVENTION AND CONTROL

Plague prevention and control is best accomplished by a combination of:

- environmental sanitation;
- awareness campaigns to promote avoidance of potential infective exposures; and
- early detection of human and animal plague to focus remedial environmental actions and to institute early treatment of cases, infection control procedures and prophylaxis of exposed persons, as indicated.

In endemic areas, public health services must provide a continuing system of human and animal plague surveillance, epidemiologic investigations and control actions.

The principal environmental remediation measures during outbreaks of human plague or dangerous epizootics are insecticidal flea control, rodent control and sanitation. Flea control should be carried out before or in conjunction with the killing of rodents to reduce the chances that infected fleas will feed on humans. [8] [26]

A killed, whole-cell plague vaccine has limited availability and usefulness. It was available in the USA until the late 1990s, but is no longer being manufactured there. Use of this vaccine was limited primarily to certain groups that were thought to be at high risk, including research laboratory workers, biologists working with susceptible animal populations and some military personnel. The efficacy of this vaccine was never evaluated in clinical trials, and evidence for vaccine protection was based on animal experiments, immunogenicity studies in humans and observations on its use in USA servicemen during the Vietnam conflict. It was thought to be protective against flea-borne exposures but to be only partially protective, if at all, against respiratory exposures. Primary immunization consisted of a series of three injections followed by boosters at intervals of 6 months or more.[27] Research is underway to develop improved plague vaccines that are likely to be protective against airborne routes of exposure, but it is unknown when these vaccines will be approved and commercially available. At present, the most promising candidates are recombinant subunit vaccines that express both the F1 and V antigens of *Y. pestis*.[28] Interest in developing an effective plague vaccine has increased greatly in recent years because of concerns about bioterrorism and biowarfare.

In the event of an outbreak of plague, measures should be taken to rapidly control spread, as described in international regulations and manuals of plague control.[11] [26] These measures include:

- determining the source;
- defining the geographic limits of activity;
- establishing active surveillance;
- laboratory confirmation of cases, and isolation of pneumonic cases;
- rapid treatment of cases and others at risk of infection, including close contacts of symptomatic pneumonic plague cases; and
- control of fleas and rodents in plague-infected areas, in port facilities and on ships and other conveyances.

CLINICAL FEATURES

Bubonic plague

Bubonic plague has a usual incubation period of 2–6 days, occasionally longer. Typically, the patient experiences the acute onset of chills, fever that rises within hours to 100.4°F (38°C) or higher, myalgias, arthralgias, headache and a profound lethargy. Soon, usually within

Figure 176-3 Left inguinal and femoral buboes, demonstrating surrounding edema and overlying desquamation.

24 hours, tenderness and pain occur in one or more regional lymph nodes proximal to the site of inoculation of the plague bacillus. The femoral and inguinal groups of nodes are most commonly involved, axillary and cervical nodes less so, varying with the site of inoculation. The enlarging bubo or buboes become progressively swollen, painful and tender, sometimes exquisitely so. Typically, the patient guards against palpation and limits movement, pressure and stretching around the bubo. The surrounding tissue often becomes edematous, sometimes markedly, and the overlying skin may be reddened, warm and tense (Fig. 176.3). Inspection of the skin surrounding the bubo or distal to it may reveal the site of a flea bite marked by a small papule, pustule, scab or ulcer (phlyctenule). Larger furuncular lesions, sometimes with eschars that are similar to those caused by tularemia, occur rarely. The bubo of plague differs from lymphadenitis of most other causes by its rapid onset, extreme tenderness, surrounding edema, accompanying signs of toxemia and absence of cellulitis or obvious ascending lymphangitis.

If treated in the uncomplicated state with an appropriate antimicrobial agent, bubonic plague usually responds quickly, with defervescence and resolution of other systemic manifestations over a 2- to 5-day period. Buboes often remain enlarged and tender for a week or more after treatment has begun and infrequently become fluctuant. Without effective antimicrobial treatment, typical bubonic plague patients manifest an increasingly toxic state of fever, tachycardia, lethargy leading to prostration, agitation and confusion and, occasionally, convulsions and delirium. Mild forms of bubonic plague, called pestis minor, have been described in South America and elsewhere; in these cases, the patients are ambulatory and only mildly febrile and have subacute buboes.

Differential diagnostic possibilities for bubonic plague include streptococcal or staphylococcal adenitis, tularemia, cat-scratch disease, mycobacterial infection, acute filarial lyphadenitis, chancroid and strangulated inguinal hernia.

Septic plague

Septic plague is manifest as a rapidly progressive, overwhelming endotoxemia.[21] [22] [23] [24] [25] Primary sepsis occurs in the absence of regional lymphadenitis, and the diagnosis of plague is often not suspected until results of blood culture are reported by the laboratory. Furthermore, patients who have septic plague often present with gastrointestinal symptoms such as nausea, vomiting, diarrhea and abdominal pain, making misdiagnosis even more likely. If it is not treated early with appropriate antibiotics and aggressive supportive care, septic plague is usually fulminant and fatal. Petechiae, ecchymoses, bleeding from puncture wounds and orifices, and ischemia of acral parts are manifestations of DIC (Fig. 176.4). Refractory hypotension, renal shutdown, obtundation and other signs of shock are pre-terminal events. Acute respiratory distress syndrome, which

Figure 176-4 Septic plague patient who demonstrated disseminated intravascular coagulation, bleeding into the skin and acral gangrene as a late manifestation.

Figure 176-5 Chest radiograph of a patient who has primary plague pneumonia, showing extensive infiltrates in the right middle and lower lung fields.

can occur at any stage of septic plague, may be confused with other conditions such as hantavirus pulmonary syndrome.

Differential diagnostic possibilities include septicemia caused by other bacterial infections, including other Gram-negative bacteria, meningococcemia, bacterial endocarditis and tularemia.

Pneumonic plague

Pneumonic plague is the most rapidly developing and fatal form of plague.[19] [21] [22] [24] The incubation period for primary pneumonic plague is usually 3–5 days (range 1–6 days). The onset is most often sudden, with chills, fever, headache, body pains, weakness, dizziness and chest discomfort. Cough, sputum production, increasing chest pain, tachypnea and dyspnea typically predominate on day 2 of the illness, and these features may be accompanied by hemoptysis, increasing respiratory distress, cardiopulmonary insufficiency and circulatory collapse. In primary plague pneumonia, the sputum is most often watery or mucoid, frothy and blood-tinged, but it may become frankly bloody. Chest signs in primary plague pneumonia may indicate localized pulmonary involvement in the early stage; a rapidly developing segmental consolidation may be seen before bronchopneumonia occurs in other segments and lobes of the same and opposite lung (Fig. 176.5). Liquefaction necrosis and cavitation may develop at sites of consolidation and leave significant residual scarring.

Plague pneumonia arising from metastatic spread (secondary pneumonic plague) typically manifests first as a diffuse interstitial pneumonitis in which sputum production is scant, and is more likely to be inspissated and tenacious in character than the sputum found in primary pneumonic plague.

Differential diagnostic possibilities include other bacterial conditions such as tularemia, community-acquired bacterial pneumonias such as mycoplasma pneumonia, Legionnaires' disease and staphylococcal or streptococcal pneumonia. Viral pneumonias to be differentiated include influenzal pneumonitis, hantaviral pulmonary syndrome and pneumonia caused by respiratory syncitial virus or cytomegalovirus infection. Q fever may need to be considered.

Other manifestations

Meningitis is an unusual manifestation of plague. In the USA there were 12 (3%) cases of meningitis among the total 390 cases of plague reported in the period from 1947 to 1996.[14] All these cases were complications of treated bubonic plague and all the patients survived. Plague occasionally presents as pharyngitis accompanied by fever, sore throat and cervical lymphadenitis. In its early stages, this may be clinically indistinguishable from more common infectious causes of pharyngitis. Plague pharyngitis can arise in primary form from respiratory exposures or from ingestion of undercooked tissues of infected animals, and it is usually associated with marked cervical glandular enlargement. Inoculation of *Y. pestis* through the conjunctiva can result in oculoglandular plague.

DIAGNOSIS

Except in outbreak situations, a high index of clinical suspicion and a careful clinical and epidemiologic history and physical examination are required to make a timely diagnosis of plague. A delayed or missed diagnosis is associated with a high case fatality rate,[14] and infected travelers who seek medical care after they have left

endemic areas are especially at risk. Laboratory tests for plague are highly reliable when conducted by persons experienced with *Y. pestis*, but such expertise is usually limited to selected reference laboratories.

When plague is suspected, clinical specimens should be obtained promptly for microbiologic studies, chest radiographs taken and specific antimicrobial therapy initiated pending confirmation of diagnosis. Blood and other clinical materials such as bubo aspirates, sputum, tracheal washes, swabs of skin lesions or pharyngeal mucosa and cerebrospinal fluid, as indicated, should be inoculated onto suitable media (e.g. brain-heart infusion broth, sheep blood agar, chocolate agar or MacConkey agar).[29] Bubo aspirates typically yield only small amounts of serosanguinous fluid and 1–2ml of saline may need to be injected first to obtain adequate material for diagnosis. Smears of each specimen should be stained with Gram's, Wayson's or Giemsa's stain. Direct fluorescent antibody testing is a useful presumptive diagnostic procedure available at some reference laboratories. An acute-phase serum specimen should be collected for *Y. pestis* antibody testing, followed by a convalescent-phase specimen collected 3–4 weeks later. For diagnosis in fatal cases, tissues, including buboes and samples of liver, spleen, lungs and bone marrow, should be collected at autopsy for culture, fluorescent antibody testing and histologic studies, including possible immunohistochemical staining. Cary Blair medium or a similar holding medium can be used to transport *Y. pestis*-infected tissues. Presumptive identification of *Y. pestis* can be made by polymerase chain reaction or antigen capture enzyme-linked immunosorbent assay. A recently developed rapid immunogold dipstick assay designed to detect *Y. pestis* antigens in patient samples also appears highly promising.[30]

Laboratory confirmation of plague depends on isolation of *Y. pestis* from body fluids or tissues. When the patient's condition allows, several blood cultures taken over a 45-minute period before treatment will usually result in successful isolation of the bacterium. *Yersinia pestis* strains are readily distinguished from other Gram-negative bacteria by polychromatic and immunofluorescence staining properties, characteristics of growth on microbiologic media, biochemical profiles and confirmatory lysis by the *Y. pestis*-specific bacteriophage. Laboratory mice and hamsters are susceptible to *Y. pestis* and are used in specialized laboratories to make isolations from contaminated materials and for virulence testing.

In the absence of a cultural isolation, a diagnosis of plague can be made by the demonstration of a 4-fold or greater change in serum antibodies to *Y. pestis* antigen using passive hemagglutination testing. A serum antibody titer of 128 or greater in a single serum sample from a patient who has a compatible illness and who has not received plague vaccine is also diagnostic. A few plague patients will develop detectable antibodies as soon as 5 days after the onset of illness, most seroconvert 1–2 weeks after onset, a few seroconvert 3 or more weeks after onset and a few (<5%) fail to seroconvert. Early specific antibiotic treatment may delay seroconversion by several weeks. After seroconversion, positive serologic titers diminish gradually over months to years. Enzyme-linked immunosorbent assays for detecting IgM and IgG antibodies to *Y. pestis* have been found to be useful in identifying antibodies in early infection and in differentiating them from antibodies developed in response to previous vaccination.

TABLE 176-3 -- Treatment guidelines for plague.

TREATMENT GUIDELINES FOR PLAGUE			
Drug		**Dosage**	**Route of administration**
Streptomycin	Adults	1g q12h	im
	Children	15mg/kg q12h*	im
Gentamicin	Adults	1–1.5mg/kg q8h†	im or iv
	Children	2.0–2.5mg/kg q8h	im or iv
	Infants/neonates	2.5mg/kg q8h	im or iv
Tetracycline	Adults	0.5g q6h	po
	Children >8 years old	6.25–12.5mg/kg q6h	po
Doxycycline	Adults	100mg q12h	po or iv
	Children >8 years old and >45kg	100mg q12h	po or iv
	Children >8 years old and <45kg	2.2mg/kg q12h	po or iv
Chloramphenicol	Adults	12.5mg/kg q6h‡	po or iv
	Children >1 year old	12.5mg/kg q6h‡	po or iv
Hematologic values should be monitored closely			

* Not to exceed 2g/day
† Daily dose should be reduced to 3mg/kg as soon as clinically indicated
‡ Up to 100mg/kg per day initially. Dosage should be adjusted to maintain plasma concentrations at 5–20µg/ml.

Plague patients typically have white blood cell counts of 10,000–25,000/mm^3 with a predominance of early stage polymorphonuclear leukocytes. Leukemoid reactions with white cell counts as high as 50,000/mm^3 or more can occur.

MANAGEMENT

Untreated, plague is fatal in over 50% of patients who have bubonic disease and in nearly all patients who have septic or pneumonic plague. The overall mortality rate in plague cases in the USA in the past 25 years has been approximately 15%.[14] Fatalities are almost always due to delays in seeking treatment, misdiagnosis and delayed or incorrect treatment. Rapid diagnosis and appropriate antimicrobial therapy (Table 176.3) are essential.[31]

Streptomycin has long been considered the drug of choice for treating plague, but gentamicin is increasingly being used in its place because of its wider availability and ease of administration, and it is currently recommended for use in managing patients in a bioterrorism attack.[18] Tetracyclines or chloramphenicol are effective alternatives to the aminoglycosides. Chloramphenicol is indicated for conditions in which high tissue penetration is important, such as plague meningitis, pleuritis, endophthalmitis or myocarditis. It may be used separately or in combination with an aminoglycoside. Although doxycycline has, because of its ease of administration and rapid action, become the tetracycline of choice for treating plague, clinical trials of its efficacy have not been performed. Trimethoprim-sulfamethoxazole (co-trimoxazole) has been used successfully to treat bubonic plague, but it is not considered a first-line choice. *Yersinia pestis* is highly sensitive to several fluoroquinolones, and ciprofloxacin has been recommended as an alternative antimicrobial for treating plague cases in the event of a bioterrorism attack.[18] Penicillins, cephalosporins and macrolides have a suboptimal effect and should not be used to treat plague. In general, antimicrobial treatment should be continued for 7–10 days or for at least 3 days after the patient has become afebrile and has made a clinical recovery. Patients begun on intravenous antibiotics may be switched to oral regimens as indicated by clinical response. Improvement is usually evident 2–3 days from the start of treatment, even though fever may continue for several more days.

Complications of delayed treatment of plague include DIC, adult respiratory distress syndrome and other consequences of bacterial sepsis. Patients who have these disorders require intensive monitoring and close physiologic support. Buboes may require surgical drainage if they threaten to rupture spontaneously. Abscessed nodes can be a cause of recurrent fever in patients who have otherwise made satisfactory recovery; the cause may be occult if intrathoracic or intra-abdominal nodes are involved. Viable *Y. pestis* organisms have been isolated from affected nodes 1–2 weeks after clinical recovery from acute disease. Strains of *Y. pestis* that are resistant to antimicrobials have only rarely been isolated from humans. Such resistant strains have usually involved partial resistance to a single agent only and have not been associated with treatment failure. Recently, however, a multidrug-resistant strain of *Y. pestis* was isolated from a bubonic plague patient in Madagascar.[32] This isolate was resistant at high levels to all first-line antibiotics recommended for treating plague (including tetracycline, streptomycin and chloramphenicol). Resistance was plasmid-mediated and transferable to other strains of *Y. pestis* and to *Escherichia coli*. Fortunately, surveillance for multidrug-resistant *Y. pestis* in Madagascar and elsewhere has not disclosed any other such resistant strains. Isolated instances of strains resistant to streptomycin or tetracycline are occasionally reported.

Antimicrobials are recommended in some situations as prophylaxis against plague.[27] [31] Postexposure treatment for 7 days with a tetracycline, chloramphenicol or

trimethoprim-sulfamethoxazole is recommended for persons who have been in close contact with a pneumonic plague patient in the previous 7 days. Prophylaxis with doxycycline or ciprofloxacin has been recommended in the event of a bioterrorism attack.[18] Short courses of antimicrobial prophylaxis are sometimes recommended for household members of bubonic plague patients because of possible rodent flea exposures. Prophylaxis is only rarely warranted for people who visit or reside in an area where plague is occurring. Isolation and respiratory droplet precautions are recommended for managing patients with pneumonic plague, including the use of masks for persons caring for these patients while they are infectious. The use of masks may be an important measure for interrupting person to person transmission in the event of a pneumonic plague outbreak. Respiratory plague patients are generally considered to be non-contagious following 48 hours of antibiotic treatment.

Chapter 177 - Tularemia

David T Dennis

Tularemia is an uncommon, potentially severe bacterial zoonosis caused by *Francisella tularensis*. The natural cycle of the causative organism involves maintenance of infection in a wide diversity of animal hosts and in certain hard ticks. Transmission of *F. tularensis* to humans, which are incidental hosts, occurs by several modes, including bites by infective ticks and other arthropods, direct inoculation of *F. tularensis* through skin or mucous membranes from handling infectious materials, ingestion of contaminated water or food, or by inhalation of contaminated aerosols or dusts. The agent of tularemia is widely distributed in temperate and subarctic regions of North America and Eurasia. Human infection results in various clinical presentations of varying severity depending on the route of inoculation, the dose and virulence of the infecting strain, and the host defenses. The most common clinical form, ulceroglandular tularemia, presents as an illness with fever, an ulcer at the site of inoculation and regional lymphadenitis. Several other forms occur involving various organ systems. Tularemia is considered to be an important potential weapon of bioterrorism (see Chapter 6).

EPIDEMIOLOGY

Agent

Francisella tularensis (formerly *Pasteurella tularensis*) is a small, facultatively intracellular, Gram-negative coccobacillus. The organism has a lipidated envelope and is able to survive under favorable conditions for several weeks in water, moist soil and decaying animal carcasses. *Francisella tularensis* strains may be divided into two main groups by virulence testing, biochemical reactions and epidemiologic features. Formerly, it was thought that strains of the more virulent type, termed Jellison type A (*F. tularensis* subsp. *tularensis*), were restricted to North America. Recent molecular studies have shown that some *F. tularensis* strains found in Central Asia and in Japan share significant genetic homology with *F. tularensis* subsp. *tularensis*. [1] The less virulent Jellison type B strains (*F. tularensis* subsp. *holarctica*) are found throughout Eurasia, and they are also found widely in North America. A closely related subspecies, *Francisella tularensis* subsp. *novicida*, has been associated with febrile illness in a small number of patients in North America. *Francisella tularensis* is considered to be a potential agent of bioterrorism because it can be weaponized as an aerosol, could result in large numbers of casualties, and because it requires special actions for medical and public health preparedness.[2]

Life cycle

Francisella tularensis is widespread in nature and has been recovered from more than 100 species of wild mammals, at least nine species of domestic animals (including cats, dogs and cattle), numerous species of birds, some amphibians and fish, and more than 50 species of arthropods.[3] [4] The principal natural cycles of the agent involve maintenance of infection in wild mammalian hosts, such as lagomorphs (wild hares and rabbits), terrestrial rodents (especially voles and meadow mice) and aquatic rodents (water rats, muskrats, beaver). Certain species of hard ticks are able to maintain infection from one developmental stage to another. Transmission among animals is accomplished by the bites of blood feeding arthropods or by direct exposures to contaminated materials in the environment (Fig. 177.1).[3] [4] Predation and cannibalism may also contribute to the natural cycle.

Humans become infected:

- when they intrude into the arthropod-borne cycle and are bitten by ticks, which are true biologic vectors, or by blood-feeding flies or mosquitoes that have contaminated mouthparts;
- by handling or ingesting infectious animal tissues or fluids;
- by ingestion of contaminated water or food; or
- by inhalation of infective aerosols or dusts.

Occasional cases occur following infective bites or scratches by cats,[5] or other carnivores or predators with contaminated mouths or claws. Although the agent is highly infectious, requiring only 10–50 organisms to regularly cause experimental infections of humans, person-person transmission has not been documented.

Geographic distribution

Tularemia is endemic throughout much of the Nearctic and Palaearctic regions between latitudes 30°N and 71°N. This includes all of North America from the Arctic Circle to northern Mexico, much of Eurasia and some states of northern Africa along the Mediterranean coast.[3] [4] In North America, the highest incidence of tularemia in humans occurs in south-central, south-eastern, Great Plains and Rocky Mountain regions of the USA (Fig. 177.2),[6] but cases have been reported throughout the continental USA, across Canada, and in Mexico as far south as Guadalajara. In Eurasia, the disease occurs most frequently in Scandinavia and in states of the former Soviet Union. Tularemia also occurs sporadically throughout most of Europe, in some areas of the Near East and Middle East, in Central Asia and in Mongolia. It has not been documented in Central or South America, Australia or Africa outside the Mediterranean littoral.

Populations affected

Tularemia is a rural disease. It affects persons of all ages and both sexes. Groups at highest risk include:

- hunters and trappers, wildlife specialists, animal skinners and dressers, butchers and others who handle potentially infective animal carcasses;
- rural residents, especially farmers, who are exposed to water, soils and dusts contaminated by infected wild animals, such as meadow voles, lagomorphs and aquatic mammals; and
- persons exposed in enzootic areas to bites by certain hard ticks, tabanid flies or mosquitoes.[7] [8] [9] [10]

Disease incidence

Global incidence figures are not available. In Eurasia, recent outbreaks involving hundreds of cases each have been reported from Scandinavia,[10] Kosovo[11] and Spain,[12] and outbreaks involving

Figure 177-1 Life cycles of *Francisella tularensis.* The two major life cycles in nature are shown. In cycle (a), which is dominant in North America, *F. tularensis* is maintained predominantly among lagomorphs and hard ticks. In cycle (b), which is dominant in Eurasia, *F. tularensis* is principally maintained among cricetine rodents, especially field voles and mice, water voles and other aquatic rodents. Humans are incidental hosts that are infected by tick vectors and by the bites of flies or mosquitoes that have contaminated mouthparts, by direct contact with infected animal carcasses or other contaminated materials, by ingestion of contaminated matter or by inhalation of infectious aerosols or dusts.

Figure 177-2 Reported cases of tularemia per 100,000 population in the USA, 1990–2000.

thousands of persons have been reported in the past from the former Soviet Union. Tularemia incidence is relatively stable in the USA, where the disease has been in steady decline since 1945.[6] In the period 1990–2000, a total of 1368 cases were reported from 44 states, averaging 124 cases (range 86–193) per year. Four states accounted for 56% of all reported cases: Arkansas (315 cases), Missouri (265 cases), South Dakota (96 cases) and Oklahoma (90 cases). The age distribution was bimodal, with highest incidence rates in the age groups 5–9 years and 75 years of age and older. Males predominated in all age groups. Disease onsets peaked in the period May–August (70% of all cases), although cases were reported from all months of the year.[6]

Sources of human infection

Eurasia

Cricetine rodents (especially, meadow voles, lemmings, water voles and muskrats), water and soil contaminated by these animals, hares (*Lepus* spp.) and bites by contaminated mosquitoes (especially *Aedes cinereus* and *Aedes excruscians*) are the principal sources of human tularemia in Eurasia.[3] [4] Mosquito-borne infection occurs in forested and marshy Scandinavian and Baltic regions. Sporadic cases also result in Eurasia from bites by infected ticks and by blood-feeding flies. Outbreaks of tularemia among farmers have been described in Europe following respiratory exposure to dusts from contaminated stored and fresh mown hay,[13] [14] and among workers in agricultural processing plants exposed to contaminated water sprays. Ingestion of water and food contaminated by infected rodents or hares has also resulted in outbreaks in the region, such as recently reported from Kosovo and Turkey.[11] [15] In Japan, the disease has historically been associated with the trapping, handling and eating of wild hares.

North America

The principal animal sources of infection in North America are the cottontail rabbit (*Sylvilagus* spp.), wild hares and rodents (muskrats, beaver, voles, ground squirrels).[3] [4] [7] The agent is vectored by certain species of hard ticks, especially the dog tick, *Dermacentor variabilis*, the lone star tick, *Amblyomma americanum*, and the Rocky Mountain wood tick, *Dermacentor andersoni*. [3] [4] Biting tabanid flies, especially deer flies (*Chrysops* spp.), mechanically transmit the infection.[9] The epidemiology of tularemia in North America has changed significantly since the 1930s and 1940s, when the disease most commonly called 'rabbit fever' had a much higher incidence and when cases were more likely to be linked to the hunting, dressing and butchering of wild rabbits and hares than to arthropod bites.[16] [17]

Seasonality

Mosquito-borne transmission in Eurasia peaks in the summer months. In North America, a peak of tularemia cases in the spring and summer months is associated mostly with bites by ticks and blood-feeding flies, and a second peak in the late autumn and winter is associated with handling infected animals, especially among hunters and trappers.[17]

PATHOGENESIS AND PATHOLOGY

The principal pathologic changes in localized disease occur at the cutaneous site of inoculation and in the regional lymph nodes draining the site; when the disease is disseminated, the lungs, spleen, lymph nodes, liver and skin are most often involved.[18] [19] [20] The primary skin lesion begins as a papule several days following inoculation. The papule rapidly progresses to a vesicle that erodes and develops into an ulcer, which is typically 2–3cm in diameter with an irregular slightly raised and erythematous border. The base is necrotic, and frequently covered with a thick dark scab that can mimic the eschar of cutaneous anthrax (Fig 177.3). Affected lymph nodes show hemorrhagic necrosis and may suppurate. Secondary skin lesions have also been described in tularemia, including papular and papulovesicular lesions, erythema nodosum and erythema multiforme.

Francisella tularensis is a facultative intracellular organism, and the response to infection has a prominent component of cell-mediated immunopathology.[21] Histologically, the early disease is characterized by focal suppurative necrosis. The central area of necrosis is at first composed primarily of polymorphonuclear leukocytes and macrophages, which may be replaced by epithelioid cells in more advanced lesions. A wall of fibroblasts may surround the acute inflammatory reaction. Later, smaller lesions may be indistinguishable from miliary tubercles. A frequent finding on pathologic examination of affected lungs is small (3–12mm), yellowish, necrotic subpleural nodules. Patchy interstitial infiltrates are common in pneumonic tularemia; bronchopneumonia is found in about 30% of cases, and lobar pneumonia with consolidation of an entire lobe in about 15% of pneumonic cases. Lung abscesses occasionally occur. Hilar lymph nodes may be inflamed and enlarged.

Prevention

Persons exposed in endemic areas to ticks, biting flies or mosquitoes should, when feasible, wear protective clothing, tuck their trouser legs into their socks and apply repellents containing diethyltoluamide (DEET) to skin and clothing as directed by the manufacturer. Permethrin-based products can be applied to clothing to kill ticks and biting flies on contact. Frequent examinations should be made to identify and remove ticks on clothing and skin. Persons should always avoid direct contact with sick or dead animals, and hunters, trappers, dressers and butchers should wear impervious gloves when skinning and handling wild animal carcasses. Recently, an outbreak of pneumonic tularemia occurred in Massachusetts, USA, among landscapers using power tools that typically raise environmental dusts,[22] and the use of fine particle masks while engaged in these activities has been suggested as a possible means of reducing infective inhalation exposures.

Live attenuated vaccines have been used to protect laboratory personnel who routinely work with *F. tularensis*. Vaccines have also been used in an attempt to reduce the incidence of disease among rural residents of highly endemic areas of the former Soviet Union. A live attenuated tularemia vaccine was until recently available in the USA under investigational new drug (IND) protocol; its manufacture is currently under Food and Drug Administration review. Persons exposed to a laboratory accident possibly resulting in aerosolization or inoculation of *F. tularensis* should be considered for prophylactic antibiotic administration or placed on fever watch and closely monitored for early signs of illness.

CLINICAL FEATURES

The primary forms of tularemia include:[18] [19] [20]

- ulceroglandular tularemia (45–85% of cases),
- glandular tularemia (10–25% of cases),
- oculoglandular tularemia (<5% of cases),
- typhoidal (septic) tularemia (<5% of cases),
- oropharyngeal tularemia (<5% of cases), and
- pneumonic (inhalation) tularemia (<5% of cases).

The incubation period is usually 2–5 days (range 1–14 days). Onset is sudden; typically, the patient has fever of 100–104°F (38–40°C) and a constellation of non-specific manifestations including chills, headache, generalized body aches (often prominent in the lumbosacral region), nausea, weakness, cough and chest pain.[18] [19] [20] Without treatment, nonspecific symptoms usually persist for several weeks. Sweats, chills, progressive weakness and weight loss characterize the continuing illness. Any of the principal forms of tularemia may be complicated by bacteremic spread that may lead to secondary sepsis, tularemic pneumonia, meningitis or other metastatic infection.

Figure 177-3 Tularemic ulcer with eschar formation after percutaneous inoculation of *Francisella tularensis*.

Before antibiotics became available, the overall mortality rate from infections with the more severe type A strains was in the range of 5–10%; however, a considerably higher fatality rate was reported for typhoidal and pneumonic forms of disease. Untreated, infections with type B strain have been associated with a fatality rate of only 1–3%. In the USA, the fatality rate for all forms in recent years has been less than 2%.[23]

Ulceroglandular tularemia

A local papule appears at the site of inoculation at the time of, or shortly after, the onset of fever and other generalized symptoms. This becomes vesiculated and pustular, and then ulcerates within a few days of its first appearance. Typically, the ulcer is tender, has an indolent character and may be covered by a scab (Fig. 177.3). By the time of ulceration, painful lymphadenitis occurs in one or more adjacent nodes in the afferent pathway. In persons infected by handling contaminated materials, the epitrochlear nodes (8%) and the axillary nodes (65%) are the most commonly affected. In persons infected by arthropod bites, the femoral-inguinal nodes (64%), the axillary nodes (24%) and the cervical nodes (6%) are commonly involved.[20] In some cases, an abscessed node may suppurate, create a sinus tract and

discharge purulent material to the outside.

Oculoglandular tularemia

Oculoglandular tularemia (Parinaud's syndrome) follows contamination of the conjunctival sac. Ulceration may occur on the conjunctiva, which becomes severely inflamed, with marked edema and vasculitis. Characteristically, there is painful swelling of nodes draining the periorbital tissues, such as the preauricular, submandibular and cervical chain nodes.

Glandular tularemia

Glandular tularemia differs from the ulceroglandular type only in not having the local cutaneous ulceration. It is more likely to follow arthropod-borne inoculation than direct percutaneous inoculation of the hands and fingers of persons handling infected animal tissues.

Typhoidal tularemia

Typhoidal tularemia presents as an acute illness without localizing signs.[20] The diagnosis is most often made by the identification of *F. tularensis* in cultures of the blood. Abdominal pain, diarrhea and vomiting may be prominent in the early illness. Sepsis may occur and the systemic inflammatory response syndrome may ensue, rarely

accompanied by complications such as disseminated intravascular coagulation and bleeding, acute respiratory distress syndrome, shock and organ failure. Typhoidal tularemia may result from inapparent inhalation exposures, that then progresses to pneumonia in more than 50% of cases; infection of the kidneys and the meninges may also occur. In some cases, the upper gastrointestinal tract may be the principal target organ in typhoidal tularemia.

Oropharyngeal tularemia

Oropharyngeal tularemia is acquired by ingesting inadequately cooked game, or contaminated water or food. The patient may develop a painful exudative pharyngitis or tonsillitis, or a stomatitis, sometimes with ulceration, and tender cervical lymphadenopathy. Suppuration, fistula formation and drainage of cervical nodes may occur.[11]

Pneumonic tularemia

Pneumonic tularemia is a common secondary complication of other forms of tularemia. Infrequently, primary pneumonia arises from inhalation of an infective aerosol or dust. In addition to fever, chills, fatigue and other generalized symptoms of infection, pulmonic manifestations include cough (usually with minimal sputum production), chest discomfort, sometimes with pleuritic pain, dyspnea, tachypnea and occasionally mild hemoptysis. *Francisella tularensis* was weaponized for aerosol delivery by biowarfare programs during and after the Second World War, and it is assumed that this would be the most likely mode of delivery in a potential terrorism attack. The expected result would be an outbreak of pneumonic tularemia and non-specific febrile illness (typhoidal tularemia) beginning 3–5 days after exposure; this might at first be difficult to distinguish from the many usual causes of community-acquired infection. It is possible that an aerosol exposure could also result in cases of oropharyngeal and oculoglandular tularemia. Since naturally acquired tularemia is almost entirely a rural disease, bioterrorism should quickly be suspected should a cluster of cases occur in an urban population. The recognition, and medical and public health management of tularemia as a weapon of bioterrorism has recently been outlined.[2]

DIAGNOSIS

The presumptive diagnosis of tularemia is made by clinical examination combined with information on potentially infective exposures. Differential diagnostic possibilities are many, as follows:

- in persons who have glandular or ulceroglandular disease they include plague, sporotrichosis, cat-scratch fever, lymphogranuloma venereum, streptococcal or staphylococcal lymphadenitis, toxoplasmosis, mycobacterial infection, chancre and chancroid;
- in persons who have oropharyngeal tularemia, other bacterial and viral causes of stomatitis, pharyngitis and cervical adenitis must be considered, such as streptococcal infection, infectious mononucleosis, mycobacterial infection, adenoviral infection and diphtheria;
- in persons who have pneumonia, they include mycoplasmal pneumonia, chlamydial pneumonia, Legionnaires' disease, staphylococcal or streptococcal pneumonitis, *Haemophilus influenzae* pneumonia, plague, histoplasmosis and tuberculosis; and
- in persons who have typhoidal tularemia, they include bacterial endocarditis, disseminated mycobacterial or fungal infection, typhoid fever, brucellosis, listeriosis, leptospirosis, Q fever, plague and other causes of sepsis.

The clinical diagnosis of tularemia is confirmed by cultural isolation of *F. tularensis* or diagnostic rises in serologic titers.[24] The organism can be grown in routine culture systems; however, clinical suspicion of tularemia is critical in directing selection of the correct (cysteineenriched) culture media that favors growth of *Francisella* spp. In addition to culture, materials other than blood should be streaked on glass slides for presumptive diagnosis by direct fluorescent antibody testing. The agglutination reaction for combined IgM and IgG immunoglobulins is the routine serological procedure in use in most laboratories. Reference laboratories use microagglutination methods that are more sensitive than tube agglutination procedures. Antibody titers usually do not rise before 10 days or more of illness onset. A 4-fold rise in titer between acute and convalescent serum specimens, or a single titer of 1:160 or greater is considered diagnostic for *F. tularensis* infection. Potentially useful diagnostic procedures include enzyme-linked immunoassay, immunoblotting for IgM antibodies, polymerase chain reaction assays immunochromatographic handheld assays, and DNA probes, but these are still in the experimental stages of development. [25] Many routine diagnostic laboratories have policies that exclude work on *F. tularensis* because it readily aerosolizes from culture and is notorious as a cause of laboratoryacquired infections. [26] Biosafety level 2 precautions are essential for routine procedures, and biosafety level 3 precautions are required for safe manipulation of cultures and for animal studies.[27]

MANAGEMENT

Patients are best managed under hospital care until a full diagnostic evaluation and satisfactory treatment response has occurred. Streptomycin, which is bactericidal, is the drug of choice based on experience and efficacy. It is given to adults intramuscularly in a dosage of 0.5–1.0g q12h for 10 days. Gentamicin, an acceptable alternative, is given parenterally in an adult dosage of 3–5mg/kg per day, once daily or in equal divided doses at 8-hour intervals[28] for 10 days. A tetracycline (most commonly, doxycycline) or chloramphenicol may be used in place of an aminoglycoside, especially in less severely ill patients, but use of these bacteriostatic agents occasionally results in primary treatment failures, and dosage schedules of at least 14 days are recommended to prevent relapses. Oral or parenterally administered ciprofloxacin has been used to treat adults and children with good success in standard doses for 10 days.[29] Patients begun on parenterally administered antimicrobials can switch to oral administration when clinically indicated. *Francisella tularensis* organisms routinely produce ß-lactamase and are resistant to ß-lactam antibiotics and azithromycin, but they are generally highly susceptible to aminoglycosides, tetracyclines, chloramphenicol and quinolones.[30] [31] Penicillins and cephalosporins are not effective and should not be used. Typically, fever and general symptoms of acute infection begin to regress within 24–48 hours of initiation of appropriate antibiotic administration. Factors associated with a poor outcome include delays in seeking medical care, or delays in diagnosis and treatment, and underlying medical disorders, such as diabetes or alcoholism. [32] Standard (universal) precautions only are required for purposes of hospital infection control.[2] Postexposure prophylactic antibiotic treatment of close contacts is not recommended because human to human transmission is not known to occur.

Chapter 178 - Diphtheria

Androulla Efstratiou

EPIDEMIOLOGY

Mass immunization with diphtheria toxoid during the 1940s and 1950s resulted in the virtual elimination of diphtheria in many countries by the 1970s as a result of the introduction of the Expanded Program on Immunization by the World Health Organization (WHO). However, an all-time low of 623 reported cases in the WHO European Region was reached in 1980, which is in contrast to the total global figure of 97,811. Since 1989, major resurgence was observed in Europe, centered mostly in the newly independent states (NIS) of the former Soviet Union. The epidemic within the NIS commenced in 1990 and affected all 15 countries of the NIS by the end of 1994. In 1990, the number of reported cases was 1481 and peaked at 50,449 in 1995. In 1995, cases in the NIS accounted for 88% of reported cases globally (56,966). As a result of vigorous action taken in the NIS and collaboration between the epidemic countries and various international agencies, the incidence began to decline in 1996 (Fig. 178.1). The decreasing trend has continued; the number of cases reported in 1999 and 2000 was approximately 1500.[1] There is therefore evidence of progress toward control of the epidemic in the NIS since 1996. Diphtheria control is still urgently required in Georgia, Kyrghyzstan, Latvia, the Russian Federation and Tajikistan. During 2001–2, Latvia had the highest rate of diphtheria in Europe and the reasons for the resurgence in Latvia are unclear.[2] The overall situation within the European Region is still considered to be of high priority by the WHO.

A major contribution toward the control of these epidemics has been the formation of a specific microbiologic and epidemiologic global network for diphtheria. Initially, the European Laboratory Working Group on Diphtheria (ELWGD) was formed in 1993 at the request of WHO, with participation from primarily European countries.[3] During the past 7 years the network has expanded significantly and now comprises participants from 40 countries worldwide. The Diphtheria Surveillance Network (DIPNET) continues its collaborative and co-ordinated approach to support countries to improve diphtheria surveillance for early detection of cases and contacts by accurate microbiologic surveillance and the establishment of a network of national and international laboratories (http://www.phls.org.uk/inter/diphtheria/menu.htm).

Small epidemics are also occurring in other parts of the world, including South East Asia, India, Pakistan, Bangladesh and South America.[4] All these outbreaks and epidemics strongly emphasize the need for maintaining full immunization coverage and clearly demonstrate that, when immunization programs are disrupted by social, political or other changes, the disease may return. Vaccine-induced immunity does not last for life and various serologic studies in developed countries have shown that many adults are potentially susceptible, particularly when immunization courses are incomplete.

Increasing international travel and migration from areas where the disease is prevalent clearly indicate the need for maintaining clinical awareness of the disease, particularly among travelers from these areas and their contacts. All these epidemics have been classically associated with the causative agent of diphtheria, namely toxin-producing *Corynebacterium diphtheriae*. However, more recently within Europe, there have also been increasing reports of diphtheria caused by toxigenic *Corynebacterium ulcerans*. The latter is a known veterinary pathogen and causes mastitis in cattle and other domestic and wild animals. Toxigenic strains of *C. ulcerans* have been associated with classical diphtheria as well as milder symptoms. At least one death in the UK has recently been attributed to such an infection.[5]

PATHOGENESIS AND PATHOLOGY

The pathogenesis of the disease is complex. Virulence is thought to be associated with the production of an exotoxin by the causative organisms, potentially toxigenic corynebacteria, *C. diphtheriae* or *C. ulcerans*. The *C. diphtheriae* genome has now been sequenced and the complete genome is finished and is currently undergoing annotation and analysis. The annotation has revealed a number of interesting features that should provide an insight into the life and pathogenicity of the organism (sequence data: http://www.sanger.ac.uk/Projects/C_diphtheriae/).

Humans are the only known reservoir for *C. diphtheriae*. The mode of transmission is usually by direct contact with a patient or a carrier by aerosol transmission. More rarely, contact with articles contaminated with discharges from lesions or infected material can also occur.

Corynebacterium ulcerans, however, has always been regarded as a zoonosis and has always traditionally been associated with the ingestion of unpasteurized dairy products. In the UK, there has been recent documentation of toxigenic *C. ulcerans* in domestic cats with chronic rhinitis.[6] There had previously been no reports in the literature of infection among small domestic animals with *C. ulcerans*, so the implications are unclear. The risk to humans is greatest in household contacts of the cats and other very close human contacts who may examine them, such as veterinary surgeons. Overall, the bacteria do not actively invade deep tissues or the blood but tend to multiply locally and produce diphtheria toxin. Despite the proven role of the toxin, toxigenicity does not appear to be synonymous with pathogenicity because strains that do not produce toxin can survive for long periods in the upper respiratory tract and are also able to cause disease, ranging from relatively mild pharyngitis to severe tonsillitis and, in rare instances, systemic disease such as endocarditis.

PREVENTION

Diphtheria is notifiable in all countries of Europe and North America. It is imperative that all cases be rapidly identified and properly investigated according the WHO guidelines.[7] Cases are usually classified as suspected, probable or confirmed and are definitively described in the WHO manual. Local European guidelines are also available, in particular within the UK, where clinical recommendations have also been established for the management of toxigenic *C. ulcerans* cases. The advice is similar to that given for

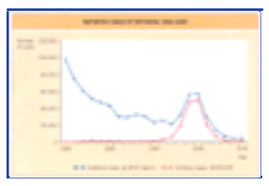

Figure 178-1 Reported cases of diphtheria 1980–2000. Cases reported to the WHO worldwide and within the WHO European Region.

Figure 178-2 Characteristic diphtheria pseudomembrane in a child. *Courtesy of Dr Norman Begg.*

toxigenic *C. diphtheriae* with management of close contacts as well as index cases.[5] The main aim of prevention and control of diphtheria is to eradicate toxigenic corynebacteria from the community and to maintain adequate levels of protective immunity by active immunization. Published data have indicated that, for example, approximately 38% of adult UK blood donors are susceptible to diphtheria. A significant trend of decreasing immunity with increasing age is apparent from many recent serologic studies.[8] [9] The recommendations and guidelines for immunization strategies are given by many health authorities and consist of primary immunization (e.g. within the UK three doses for children aged 2–4 months with an interval of 1 month between each dose) and reinforcing immunization (preschool booster dose and

another booster just before leaving school for all teenagers). However, in any country where an epidemic situation exists or is imminent, aggressive mass immunization of high-risk groups must be implemented. Low levels of immunity in adults and a gradual increase in the percentage of children not immunized with at least three doses of adsorbed diphtheria—tetanus—pertussis vaccine pose a danger for recurrence of diphtheria, as seen in eastern Europe.[10] [11]

CLINICAL FEATURES

Diphtheria is usually classified according to its site of manifestation; there are two major 'forms' of disease the classic respiratory condition and nonrespiratory (cutaneous) diphtheria. The clinical manifestations vary from place to place and from time to time depending

Figure 178-3 Characteristic diphtheria lesion of the lower limb, showing the classic rolled, 'crater-like' edge and eschar.

on a range of host and environmental factors that are not fully understood. The most important factor is individual immunity to the toxin, which is mediated either by neutralizing antibody induced by toxoid or by natural immunity.

The incubation period for the disease is 2–5 days, occasionally longer. The first symptoms are malaise, low-grade fever, sore throat and loss of appetite. A pseudomembrane forms in the throat and may extend into the lungs (Fig. 178.2). The disease is usually subdivided into three stages: early, late and severe. Each stage is associated with the isolation of the causative organism and the presence of the pseudomembrane. The pseudomembrane adheres to underlying tissue and the tissue bleeds when attempts are made to remove it. This feature is useful for diagnosing diphtheria because pseudomembranes caused by other infectious agents are not adherent.

In the early stage of disease, manifestations are localized in the upper respiratory tract or in skin lesions, leading to the severe stage resulting in toxic circulatory collapse, severe edema of the neck, submucosal or skin petechial hemorrhages and acute renal insufficiency. The late stage is associated with neurologic and cardiologic features owing to the dissemination of the toxin to the major organs. This results in extensive cardiac and neurologic damage: myocarditis, blurred vision and paralysis of the soft palate, diaphragm and limbs. Between 10% and 25% of patients who have

clinical respiratory diphtheria develop some form of myocardial damage and up to 75% develop a neuropathy. Symptoms may range from pharyngitis with low-grade fever in faucial diphtheria to partial or even complete respiratory obstruction due to the formation of the pseudomembrane in laryngeal or tracheobraonchial diphtheria.

Cutaneous diphtheria is a chronic condition associated with the tropics; it is prevalent within South East Asia. The characteristic lesions are difficult to treat and they often take months even years to heal. They are quite marked in their appearance with a characteristic rolled, 'crater-like' edge (Fig. 178.3). The lesions are covered with an eschar, a hard bluish-gray membranous scar that is slightly raised. The lesion, therefore, acts as a potential reservoir for transmission and spread of the pharyngeal form of the disease. Cutaneous diphtheria lesions proved to be the 'vehicles' of transmission of the organism in the outbreak that occurred in the USA in the late 1970s among the Skid Row alcoholics.[12]

DIAGNOSIS

The presumptive clinical diagnosis of respiratory diphtheria is based on the presence of the pseudomembrane. However, in many instances, particularly in countries where the disease is uncommon, diagnosis is often difficult and diphtheria may be misdiagnosed or confused with other diseases such as severe streptococcal sore throat, glandular fever or even Vincent's angina. This thus highlights the importance of the microbiologic diagnosis of the disease, and isolation and confirmation of the causative organism, toxigenic *C. diphtheriae* or *C. ulcerans* (see Chapter 226). However, bacteriologic diagnosis should be complementary to the clinical diagnosis and should not delay immediate and specific treatment of the patient. A throat swab and, if possible, samples of the membrane should be collected and cultured. The most important test is, of course, the test to detect diphtheria toxin. Guidelines for the microbiologic diagnosis of diphtheria are described in the WHO manual for the laboratory diagnosis of the disease.[13] Guidelines that incorporate the laboratory and clinical diagnosis of *C. ulcerans* are described further in the UK guidelines.[14] Current approaches to laboratory diagnosis in Europe and beyond have recently been updated.[15]

Close (household and kissing) contacts may be asymptomatic carriers or at risk of developing the disease and they should also be sampled by taking throat swabs. Local public health authorities must be alerted if a suspected case has been identified; the appropriate measures for swabbing, contact tracing and management (including immunization and antibiotic prophylaxis) should be initiated. Guidelines for the control, treatment and management of the disease, cases and contacts have been outlined by the WHO.[7] A travel, medical and immunization history of the suspected case and close contacts should be ascertained.

MANAGEMENT

Because patients who have suspected respiratory diphtheria may deteriorate rapidly, treatment should not be delayed and should not depend solely upon the result from the microbiology laboratory. In suspected cases, treatment should commence with diphtheria antitoxin, antibiotics and strict isolation. The three main areas of therapy are essentially:

- administration of diphtheria antitoxin;
- administration of antibiotics; and
- strict isolation procedures.

Diphtheria antitoxin

Administration of diphtheria antitoxin (hyperimmune horse serum) aims at neutralizing circulating toxin that has not yet bound to tissue. The dose of antitoxin depends on the severity of the disease and the site and extent of the pseudomembrane. Before administration of antitoxin the patient must be tested for sensitivity to horse serum and, if necessary, desensitized. Usually, in cases of tonsillar or pharyngeal diphtheria, the dose is 15,000–40,000 units of antitoxin by intramuscular or intravenous injection; in severe forms, doses as high as 80,000–100,000 units are given.[7]

Antibiotics

Antibiotics are essential for eradicating the organism and eliminating its spread but they are not a substitute for antitoxin treatment. Penicillin (0.5–1.0g q6h orally) or erythromycin (500mg q6h) is recommended. Antibiotic therapy should be continued for 14 days. Antibiotics are also important for eradicating colonization in contacts and for postexposure prophylaxis.[7] At present, there is no significant, relevant antimicrobial resistance among *C. diphtheriae*; however, erythromycin resistance has been reported from South East Asia.[16] [17]

Isolation procedures

Patients should be cared for in strict isolation and attended by staff whose immunization history is documented. Before patients are discharged they should be confirmed as 'culture-negative' for *C. diphtheriae* or *C. ulcerans* by collection of three swabs at 24-hour intervals and also given a booster dose of diphtheria toxoid, because natural infection does not necessarily confer immunity. It is important also to monitor the cardiac status closely with early intervention if appropriate (e.g. pacing for cardiac conduction disturbances and therapy for arrhythmias).

Cutaneous diphtheria

For cutaneous diphtheria, vigorous cleaning of the wound with soap and water is recommended in addition to antibiotic therapy. It is also advisable to take respiratory

tract swabs from both the index case and close household contacts. Some authorities also advocate the use of antitoxin therapy because toxic sequelae have been documented among patients who have cutaneous disease.[7]

SUMMARY

In summary, it is important to consider the following practical points:

- the diagnosis of diphtheria should be considered in travelers returning from endemic and epidemic areas or from areas where recent cases have occurred;
- a history of the immunization status of the patient does not necessarily exclude the diagnosis of diphtheria;
- microbiologic confirmation is essential for the definitive diagnosis but treatment must not be delayed pending confirmation; and
- expert opinion should be sought early and contacts must be actively followed up.

Chapter 179 - Scrub Typhus and Other Tropical Rickettsioses

Philippe Parola
Didier Raoult

INTRODUCTION

Rickettsioses (also called typhus) are infectious diseases caused by obligate intracellular bacteria formerly grouped in the order Rickettsiales. These organisms were first described as short, Gram-negative rods that retained basic fuchsin when stained by the method of Gimenez.[1] Recent developments in molecular taxonomic methods have resulted in the reclassification within the Rickettsiales.[1] However, four groups of diseases are still usually called rickettsioses. These include:

- scrub typhus due to *Orientia tsutsugamushi*;
- diseases due to bacteria of the genus *Rickettsia* (including the spotted fever group and the typhus group);
- ehrlichioses due to bacteria within the family Anaplasmataceae (ehrlichioses have not, however, been properly demonstrated to occur in the tropics); and
- Q-fever, which is due to *Coxiella burnetii*.

DIFFERENTIAL DIAGNOSIS BASED ON REGION

The agents of rickettsioses are associated with arthropods including ticks, mites, fleas and lice, which may act as vectors, reservoirs and/or amplifiers of the organisms. Most of these vectors favor specific optimal environmental conditions, biotopes and hosts. These factors determine the geographic distribution of the vector and consequently the risk area for the rickettsioses. This is particularly true when vectors are also reservoirs of pathogens, as seen in the case of ticks for most spotted fever group rickettsioses.[1] [2] Thus, although some rickettsioses are distributed worldwide (i.e. Q-fever, murine typhus), a specific area is usually associated with specific diseases. Therefore, most rickettsioses are geographic diseases. Table 179.1 presents the rickettsioses occurring in tropical areas of Africa, Asia, America and Australia.[1] [2]

EXPOSURE

Most rickettsioses are transmitted to humans by arthropods. Thus, exposure to the disease is closely linked to exposure to the arthropod vectors. Furthermore, although *C. burnetii*, the agent of Q-fever, has been found to infect more than 40 species of ticks throughout the world, the role of ticks in human infections is not confirmed. In fact, Q-fever is usually acquired by the ingestion or inhalation of virulent organisms from infected mammals, mostly goats, sheep and cats, and their products.[2]

Chiggers

'Chiggers' is the commonly used name of several species of larval-stage, trombiculid mites, which are the vectors (and reservoirs) of scrub typhus due to *Orientia tsutsugamushi*. Risk areas range from typical tropical secondary growth (scrub) vegetation in the Asia-Pacific region to temperate zones and even the Himalayas. Although scrub typhus is essentially an occupational disease among rural residents engaged in agricultural or gathering activities, travelers or soldiers in the field may be infected when entering the biotope of the vectors. [3]

Ticks

Ticks are obligate hematophagous acarins that parasitize every class of vertebrate throughout the world and may bite people. Ticks are not only vectors but also reservoirs of most of the currently known spotted fever group rickettsiae. Ecologic characteristics of the tick are keys for the epidemiology of tick-borne diseases. For example, the brown dog tick *Rhipicephalus sanguineus*, which is the vector of *Rickettsia conorii*, lives in dog environments (kennels and human houses) and has a low affinity for people. Cases of Mediterranean spotted fever are sporadic in endemic areas and most cases are encountered in urban areas. In contrast, *Amblyomma hebraeum*, which are vectors of *Rickettsia africae* in southern Africa, emerge from their habitats and actively attack animals, particularly nearby ruminants. They also feed readily on people that enter their biotopes. Furthermore, numerous ticks can attack a host at the same time. These ticks are highly infected by rickettsiae. Thus, cases of African tick-bite fever often occur as grouped cases among subjects entering the bush (e.g. during a safari) and people can suffer several tick bites simultaneously.[2] [4]

House mouse mite

The house mouse mite (*Liponyssoides sanguineus*) has been described as a vector of *R. akari*, the agent of rickettsialpox. These hematophagous arthropods maintain *R. akari* among house mice (*Mus musculus*) and may transmit the disease when biting people. Exposure to the mite is linked to contact with house mice. However, *Rickettsia akari* has been also identified in Korean voles (*Microtus fortis pelliceus*).

Fleas

Fleas are hematophagous insects. The rat flea *Xenopsylla cheopis* is the main vector of murine typhus due to *Rickettsia typhi*, whereas rodents, mainly *Rattus norvegicus* and *Rattus rattus*, act as reservoirs. It is generally accepted that most people become infected when flea feces containing *R. typhi* contaminate disrupted skin or are inhaled into the respiratory tract. [1] Infections may result from flea bites as well. Exposure to rat fleas is linked to exposure to rats. The diseases are urban as well as rural. Fleas are also suspected to be the vectors of the emerging infection due to *Rickettsia felis*. Cat fleas (*Ctenocephalides felis*), dog fleas (*C. canis*) and human fleas (*Pulex irritans*) are all possible vectors, but the disease cycle has not yet been described.

Lice

Human body lice (*Pediculus humanus corporis*) are insects that live in human clothing. They thrive during periods of cold weather, particularly in conditions or areas of reduced hygiene maintenance, poverty and wars. The body louse is the vector of *Bartonella quintana* (the agent of trench fever), *Borrelia recurrentis* (agent of relapsing fever) and *Rickettsia prowazekii* (the agent of epidemic typhus). Until recently, epidemic typhus was considered to be endemic only in Ethiopia. However, an outbreak of typhus in approximately

*Suspected by detection of the pathogen in the relevant arthropod
†Although not included in tropical areas, Japan and China are mentioned regarding the aspects of travel medicine
‡Isolated from voles (*Microtus fortis pelliceus*)

100,000 people was reported during the civil war in Burundi in 1997, in addition to cases that were reported in Peru, Russia, the USA, Algeria and France in the 1990s.[5] Epidemic typhus, then, must still be considered a potential major health risk in tropical countries; this is thought to be particularly true of refugee camps in the cooler mountainous areas. Infected body lice always die within 1–2 weeks (red louse disease). People, therefore, are considered to be the major reservoirs of this disease. *Rickettsia prowazekii* is transmitted to people by infected louse feces (in which *R. prowazekii* survives for weeks), through aerosols (thought to be the main route of infection for health workers attending patients) or by skin autoinoculation, following scratching.

CLINICAL FEATURES

Scrub typhus

Symptoms occur usually 7–10 days after the chigger's bite. A papule at the bite site that later ulcerates, forming a black crust of eschar (Fig 179.1 and Fig 179.2), is typically associated with fever, regional lymphadenopathy, a macular or maculopapular rash, headache and myalgia. However, eschar and rash may be absent or unnoticed.[3]

Spotted fevers

These diseases include tick-borne rickettsioses, rickettsialpox due to *R. akari*, and the emerging flea-borne infection due to *R. felis*. Generally, the clinical symptoms of spotted fever group rickettsioses begin 6–10 days after the arthropod bite and typically include fever, headache, muscle pain, rash, local lymphadenopathy and a characteristic inoculation eschar ('tache noire') at the bite site.[1] However, the main clinical signs vary depending on the rickettsial species involved and therefore may allow us to distinguish between the diseases. For example, African tick-bite fever is characterized by the occurrence of multiple inoculation eschars and grouped cases, due to the fact that numerous highly infected *Amblyomma* may attack and bite many people in several places at the same time.[4] In contrast, in cases of Mediterranean spotted fever due to *R. conorii*, a single eschar is usual because of the low likelihood of the tick biting people and a low rate of infection of the ticks. Details of each pathogen and clinical pictures are presented elsewhere (see Chapter 14).

Murine typhus

Murine typhus is a mild disease with non-specific signs. The incubation period is 7–14 days and at presentation the classic triad of fever,

Figure 179-1 Macular rash in a patient with scrub typhus.

headache and skin rash is observed in less than 15% of cases. Later in the disease progression, fever and headache occur more frequently than rash. Rash is present in less than 50% of patients and is often transient or difficult to observe. Nausea, vomiting, abdominal pain, diarrhea, jaundice, confusion and seizures have also been reported.[1]

Epidemic typhus

The incubation period is about 10–14 days. Patients develop malaise and vague symptoms before the abrupt onset of signs including fever (100%), headache (100%) and myalgia (70–100%). Other common

Figure 179-2 Eschar at the bite site, a hallmark of rickettsial diseases.

signs include nausea or vomiting, coughing and neurologic involvement ranging from confusion to stupor and coma. Diarrhea, pulmonary involvement, myocarditis, splenomegaly and conjunctivitis may also occur. Most patients (20–80%) develop a skin rash that classically begins on the trunk of the body and spreads to the limbs. It may be macular, maculopapular or petechial and may be difficult to detect on darker skin tones. Epidemic typhus may be confused with typhoid. Recrudescence of epidemic typhus, also called Brill-Zinsser disease, can appear many years after the acute disease and has milder symptoms.[5]

Acute Q-fever

This disease is usually mild, with up to half of the infected people being asymptomatic. A self-limited febrile syndrome or 'pseudo-flu' occurs most frequently in symptomatic patients, but in more serious cases there might be hepatitis, pneumonitis and prolonged fever[2] (see Chapter 235).

INVESTIGATIONS

Routine laboratory investigation

Common non-specific laboratory abnormalities in rickettsioses include leukocyte count abnormalities, anemia and thrombocytopenia. Hyponatremia, hypoalbuminemia and hepatic and renal abnormalities may also occur.[3]

Serology

Serological tests are the most valuable tools in the diagnosis of rickettsioses.[1] The Weil-Felix test, the oldest serologic assay for rickettsioses, is based on the detection of antibodies to various *Proteus* antigens that cross-react with rickettsiae (*P. vulgaris* OX2 with spotted fever rickettsiae, *P. vulgaris* OX19 with typhus-group rickettsiae and *P. mirabilis* OXK with *O. tsutsugamushi*). Although it lacks both specificity and sensitivity, it is still used in many tropical countries. However, immunofluorescence is currently considered the reference method for the diagnosis of spotted fever group and typhus group. Cross-absorption of sera and Western blotting can be used to differentiate infections within rickettsial antigens when cross-reactions occur. For scrub typhus, the major surface protein antigen is the 56kDa protein including group-specific and strain-specific epitopes. However, several major serotypes (Karp, Kato, Gilliam, Kawasaki and Boryon) have been shown to present sufficient cross-reactivity with antigen from other strains to be used for serologic diagnosis. Immunofluorescence and immunoperoxidase assays are the most reliable serologic tools, but dot blot immunoassay and enzyme-linked immunosorbent assay tests have been developed and are commercially available. For Q-fever, the antigenic variation of *C. burnetii* is extremely useful to differentiate between the acute and chronic forms of the disease. Indeed, when isolated from animals or humans, *C. burnetii* expresses phase I antigen and is highly infectious. After subculture in the laboratory, there is an antigenic variation of *C. burnetii* to phase II form, which is less infectious. In acute Q-fever, antibodies to phase II antigens predominate and their titer is higher than the phase I antibody titer. On the other hand, in chronic forms of the disease, elevated antiphase I antibodies are uniformly detected.

Culture

The growth of rickettsiae in reference laboratories requires living host cells (animal mouse models, embryonated eggs) or cell cultures (VERO, L929, HEL or MRC5 cells), as well as a P3 safety level laboratory. The centrifugation shell-vial technique using HEL fibroblasts is the reference method. Rickettsiae can be seen in tissue by Giemsa or Gimenez staining or by immunodetection methods. [1]

Molecular tools

Polymerase chain reaction and sequencing methods are useful, sensitive and rapid tools to detect and identify rickettsiae in blood and skin biopsies (the inoculation eschar being the most useful specimen).[1] [2] [4] Primers amplifying sequences of several genes can be used for typhus group and spotted fever group rickettsiae, including *OmpA, OmpB, gltA* and gene D. Polymerase chain reaction amplification and sequencing of the 56kDa protein gene of *O. tsutsugamushi* have also been developed. Q-fever can also be diagnosed by molecular tools. Arthropods may also be used as epidemiologic tools. For example, *R. prowazekii* was detected in lice collected from refugees in Burundi after having been sent to our laboratory in Marseille to confirm the presence of epidemic typhus.

COMPLICATIONS

Spotted fever group rickettsioses range from mild to severe and fatal diseases. For example, to date no mortalities or severe complications have been reported in patients with African tick-bite fever, whereas the mortality rate may be as high as 2.5% for Mediterranean spotted fever.[1] [2] [4]

Murine typhus is usually a mild disease, although severe forms requiring hospitalization have been reported. Signs in untreated patients last for 7–14 days after which there is usually a rapid return to health.

Epidemic typhus is a potentially fatal disease. Without treatment, mortality rates are 10–30% depending on the presence of other underlying conditions and the patient's nutritional state.[1]

Scrub typhus is a public health problem in Asia; about 1 million cases occur each year and 1 billion people may be exposed. The severity of the disease varies from asymptomatic to fatal (up to 30%), depending on the susceptibility of the host and/or the virulence of the strain.[3]

Chronic Q-fever represents the development of the acute disease in predisposed hosts. It may present as endocarditis in patients with underlying heart valve lesions or, more rarely, as vascular aneurysms, graft infections, chronic bone infections or pseudotumors of the lung.

MANAGEMENT

Empiric treatment of rickettsioses is started before laboratory confirmation of the diagnosis.

Unless contraindicated, doxycycline is the preferred treatment of scrub typhus and the usual adult oral dose is 100mg twice daily for 7 days. Tetracycline 500mg q6h for 7 days may also be used. Chloramphenicol is the common alternative to the tetracyclines. The usual adult dosage is 500mg q6h for 7 days or 50–75mg/kg/day in children. Based on preliminary studies, rifampin (1-week 600–900mg/day oral treatment) and azithromycin (500mg on the first day followed by 250mg daily for 2–4 more days) may be proposed as alternatives to doxycycline and chloramphenicol.

The treatment of choice for spotted fever rickettsioses is 200mg doxycycline/day for 1–7 days depending on the severity of the

disease. In children and pregnant women, macrolides including josamycin (50mg/kg/day in children or 3g/day in adults) and roxythromycin, but not erythromycin, can be used for 8 days.

The treatment of choice for murine and epidemic typhus is a single 200mg dose of oral doxycycline usually leading to defervescence within 48–72 hours.

PREVENTION

There are no vaccines currently available for travelers against scrub typhus and other tropical rickettsioses. Thus prevention is mainly based on avoiding the arthropod bite.

Currently, the best method to avoid tick, flea and chigger bites comprises two components: topical DEET (N,N-diethyl-m-toluamide) repellent applied to exposed skin and treatment of clothing with permethrin, which kills arthropods on contact. These products are commercially available in a wide variety of formulas. Bites may also be limited by wearing long trousers that are tucked into boots. People staying in infested area should be advised to check their bodies routinely for the presence of arthropods. Any tick found attached should be removed immediately using blunt, rounded forceps.

In the case of epidemic typhus, louse eradication (e.g. in refugee camps) is the most important preventive measure and is essential in the control of outbreaks. Since body lice live only in clothing, the simplest method of delousing is to remove and then destroy or wash and boil all clothing. Dusting of all clothing with 10% DDT, 1% malathion or 1% permethrin is also a rapid and effective method of killing body lice and reduces the risk of re-infestation.

Chapter 180 - Brucellosis

Finn T Black

EPIDEMIOLOGY

Brucellosis, also known as undulant fever or Malta fever, is a zoonosis caused by bacteria of the genus *Brucella*. The disease exists worldwide, with the highest prevalence in the Mediterranean countries, Asia, Africa and Central and South America. Around 500,000 new cases are reported annually worldwide, of which fewer than 100 are in the USA,[1] but brucellosis is probably underreported.

Brucellosis is transmitted to humans by direct contact with infected animals, by ingestion of unpasteurized milk or milk products, through cuts and abrasions or by inhalation of aerosols. In many European countries and in the USA it is mainly an occupational disease occuring in abattoir workers, butchers and farmers. Veterinary surgeons may become infected by accidental inoculation of live attenuated *Brucella* vaccine. Person-person transmission is extremely rare.

Four *Brucella* spp. can cause infection in humans:

- *Brucella melitensis*, which is found in goats, sheep and camels, is the most widespread and is the most virulent;
- *Brucella abortus*, which is found in cattle and camels, is less virulent;
- *Brucella suis*, which is found in pigs, is also less virulent; and
- *Brucella canis*, which is found in dogs, is the least common.

Other animals, including wildlife, may provide a reservoir for brucellae.[2]

PATHOGENESIS

Brucellae are facultative intracellular bacteria that are able to survive and multiply within mononuclear phagocytes. The mechanism is poorly understood but seems to include the suppression of degranulation of myeloperoxidase-containing granules, suppression of phagosome-lysosome fusion and production of protective enzymes.

The host reaction to brucellae is the formation of granulomas. *Brucella melitensis* and *B. suis* cause the most severe disease with caseating granulomas. Granulomas eventually heal with fibrosis and calcification.

Humoral antibodies seem to play some role in protection against reinfection. The control of the infection, however, depends on cell-mediated immunity. [2]

PREVENTION

The prevention of human brucellosis is dependent on the elimination of brucellosis in domestic animals. The use of veterinary vaccines for *B. abortus* and *B. melitensis* together with pasteurization of milk has resulted in a dramatic decrease in the incidence of human brucellosis. There is no effective vaccine available for *B. suis*. People at high risk of infection, such as veterinary surgeons and abattoir workers, should wear protective clothing. Laboratory-acquired brucellosis can be prevented by adherence to biosafety level 3 precautions. No effective vaccine is available for human use. Travelers to high endemic areas should be advised not to drink unpasteurized milk.

CLINICAL FEATURES

Brucellosis is a systemic infection that can involve any organ or organ system. The incubation period is normally between 2 and 4 weeks, but it may be months. The onset of clinical disease can be acute or insidious. Subclinical infection has been observed. Brucellosis is characterized by numerous somatic complaints in contrast to the few abnormal physical findings. Hepatosplenomegaly is present in 20–60%, depending on the species of *Brucella*, and mild lymphadenopathy is present in 10–20%. The non-specific symptoms (e.g. fever, sweats, anorexia, fatigue, myalgia, malaise, headache and depression) are common and may mimic diseases such as tuberculosis, toxoplasmosis, mononucleosis, hepatitis, systemic lupus erythematosus, typhoid and many others.

When symptoms related to a single organ or organ system are dominant it is often referred to as localized disease. The most common complications are listed in Table 180.1 . The term 'chronic brucellosis' should be reserved for patients who have complaints of ill health for more than 12 months.[2] This includes patients who have relapsing illness or persisting focal infection and patients complaining of weakness, fatigue and depression, but with no objective signs of infection and no elevation of IgG antibody titer. This last group is believed to suffer from a psychoneurosis or a syndrome akin to chronic fatigue syndrome (see Chapter 94).

Complications

Osteoarticular complications

Osteoarticular complications affect 20–40% of patients. Sacroiliitis is the most common reported complication, especially when *B. melitensis* predominates.[3] The characteristic radiographic findings are blurring of articular margins and widening of the sacroiliac space. The clinical presentation is systemic symptoms and pain.

Spondylitis is most often seen in the lumbosacral region in elderly men, probably reflecting pre-existing anomalies in the spine, and it may be complicated by paraspinal abscesses (Fig. 180.1). The main symptoms are fever and vertebral pain. The typical radiographic findings are epiphysitis of vertebrae and narrowing of the intervertebral disc (Fig. 180.2). Bone scans and computerized tomography scans may detect infection earlier than radiography.[4]

Differential diagnosis includes tuberculosis, fungal and pyogenic osteomyelitis, multiple myeloma and metastatic carcinoma.

Arthritis especially involves the hips, knees and ankles.

Gastrointestinal complications

Up to 70% of patients have intestinal complaints such as anorexia, nausea, vomiting, abdominal pain, diarrhea or constipation. The liver is probably always involved, but liver function tests are usually only mildly abnormal. Cirrhosis does not seem to follow *Brucella* infection.

Pulmonary complications

Respiratory symptoms are reported in 15–25% of patients. They range from flu-like symptoms to bronchitis, interstitial pneumonitis, lung abscesses, hilar lympadenopathy and lung effusions.

TABLE 180-1 -- Common complications of brucellosis

COMMON COMPLICATIONS OF BRUCELLOSIS	
Organ system	**Patients (%)**
Cardiovascular	1–2
Endocarditis	0–2
Cutaneous	5–10
Gastrointestinal	50–70
Genitourinary	1–5
Orchitis	1–4
Neurologic	2–4
Osteoarticular	20–40
Sacroiliitis	10–15
Spondylitis	8–10
Pulmonary	15–25

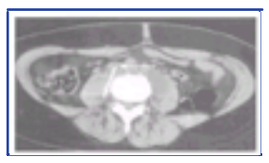

Figure 180-1 CT scan of fine needle aspiration of paraspinal abscess (arrow) in a patient with brucellosis.

Figure 180-2 Radiograph of the lumbar spine in a patient who has discitis and spondylitis of $L_{3–4}$ caused by brucellosis. Note the reduced disc space and the destruction of the upper articular margins of L_4 (arrows).

Genitourinary complications

Complications from the genitourinary tract are rare. Acute orchitis or epididymo-orchitis with signs of systemic infection do occur and interstitial nephritis, glomerulonephritis and pyelonephritis resembling tuberculosis have been described. Brucellosis during pregnancy is rare but it can result in abortion like any other systemic infection.

Neurologic complications

Depression is a common complaint, but invasion of the central nervous system occurs in only 2–4% of cases. It usually presents as acute or chronic meningitis. Encephalitis, polyradiculopathy, psychosis and meningovascular complications have also been described.[5] Analysis of cerebrospinal fluid reveals elevated protein, lymphocytic pleocytosis, low to normal glucose and most often intraspinally produced specific antibodies. Brucellae are isolated from cerebrospinal fluid in less than 30% of patients.

Cardiovascular complications

Endocarditis, although rare, is the main cause of death related to brucellosis.[6] The aortic valve is involved more often than the mitral valve. Other complications include mycotic aneurysms, myocarditis and pericarditis.

Cutaneous involvement

Cutaneous manifestations of brucellosis consist mainly of transient non-specific lesions including erythema nodosum, petechiae, vasculitis, papules and rashes.

DIAGNOSIS

Because the symptoms of brucellosis are non-specific, it is crucial that the attending physician anticipate the probability of the disease. A certain diagnosis of brucellosis is made when brucellae are isolated from blood, bone marrow or other body fluids or tissues. Most laboratories employ rapid isolation methods for blood cultures. However, these cultures need to be maintained for up to 30–40 days to successfully isolate *Brucella* spp. Bone marrow cultures are more sensitive than blood cultures in acute brucellosis and tend to remain positive later in the course of the infection, even during antimicrobial treatment.

The serum agglutination test is the simplest, best standardized and most widely used test.[8] It measures both IgG and IgM antibodies; IgM antibodies are removed by pretreating the serum with 2-mercaptoethanol. Antibodies to *Vibrio cholerae*, *Francisella tularensis* and *Yersinia enterocolitica* can give false-positive reactions. False-negative reactions due to blocking antibodies are seen and dilutions of 1:640 should be made. A titer >1:160 is normally considered positive, as is a 4-fold or greater rise in titer.

Most patients who have acute infection develop IgM and IgG antibodies. The IgG antibodies persist as long as the infection is active and they increase with relapse and decrease with cure. The enzyme-linked immunosorbent assay appears to be more sensitive than and as specific as the serum agglutination test. It is rapid, easy to perform and can be automated.[9] The polymerase chain reaction has also been shown to be a very sensitive and specific rapid diagnostic test.[7]

MANAGEMENT

Doxycycline is the most effective single drug for treatment of brucellosis because of its excellent activity against brucellae, its penetration into cells and its passage over the blood-brain barrier.[10] Because of the high relapse rate (5–40%) with single drug therapy, a combination of two or three drugs is usually recommended. Uncomplicated brucellosis is treated with oral doxycycline 200mg q24h plus oral rifampin (rifampicin) 600–900mg q24h for 3–6 weeks. An alterna-tive is oral doxycycline for 3–6 weeks plus an intramuscular amino-glycoside (e.g. streptomycin 1g q12h or gentamicin 240mg q24h) for 2–3 weeks. Children less than 8 years of age and pregnant women should not be treated with doxycycline.

Instead, oral trimethoprim-sulfamethoxazole can be used (20mg/kg sulfamethoxazole and 4mg/kg trimethoprim q12h in children for 3–6 weeks, 800mg sulfamethoxazole and 160mg trimethoprim q12h in adults for 3–6 weeks) plus intramuscular gentamicin (5mg/kg q24h in children for 1 week and 240mg q24h in adults for 1 week). Gentamicin can be replaced by oral rifampin (10–20mg/kg q24h in children for 3–6 weeks, 600mg q24h in adults for 3–6 weeks).

Complications

Complications of brucellosis such as meningitis and endocarditis require longer courses of therapy, directed by the response.[2] In severe cases, a combination of three agents is often recommended (e.g. doxycycline and aminoglycoside plus rifampin or trimethoprim-sulfamethoxazole and aminoglycoside plus rifampin). Endocarditis often requires additional surgical intervention.[6]

Many other antimicrobial agents have shown in-vitro activity against *Brucella* spp., including fluoroquinolones, third-generation cephalosporins and azithromycin. However, when these drugs are administered alone the relapse rates are unacceptable and they should be kept as second-line drugs until further studies have been carried out.

With chemotherapy the overall mortality rate is less than 2%.

Chapter 181 - Leptospirosis

Charles N Edwards

EPIDEMIOLOGY

Leptospirosis is caused by pathogenic serovars of *Leptospira*, of which 17 species are now recognized, defined by DNA-DNA hybridization. The disease is maintained in nature by chronic renal infection of mammals and is probably the most widespread zoonosis.[1] Human infection follows exposure to infected animals, either directly or indirectly through contaminated soil and water. Leptospires survive for days or weeks in warm, damp, slightly alkaline conditions, especially in still or slowly moving fresh water in the temperate summer and in damp soil and water in the tropics, especially in the rainy season.

Over 230 serovars of leptospires are recognized — the most ubiquitous serovars and their reservoir are *icterohaemorrhagiae*, usually derived from rats (*Rattus norvegicus*), and a number of serovars associated with domestic livestock animals, such as *hardjo* (cattle) and *pomona* (pigs). Other serovars are more restricted in their distribution, such as *lai*, which causes most cases of human infection in China and the Korean peninsula.

In temperate climates, leptospirosis is acquired mainly through recreational or occupational exposure, but in tropical regions exposure through avocational activities is more widespread.[2] Leptospirosis is an important cause of febrile illness in tourists returning from the tropics, particularly those involved in adventure tourism.[3] The reported incidence of leptospirosis in developed countries is declining and the disease is no longer reportable in the USA. The burden of disease is greatly underestimated in the tropical developing world.

PATHOGENESIS AND PATHOLOGY

Leptospires gain access to the circulation through penetration of abraded skin or intact mucous membranes, disseminate and ultimately penetrate various tissues. This action results in a systemic illness with a wide spectrum of clinical features. A systemic vasculitis with endothelial injury is the basic microscopic finding in the disease. Damaged endothelial cells usually show varying degrees of swelling, denudation and necrosis. Leptospires have been documented in large- and medium-sized blood vessels and capillaries in various organs. The major affected organs are:

- the kidneys, with a diffuse tubulointerstitial inflammation and tubular necrosis;
- the lungs, usually congested, with focal or massive intra-alveolar hemorrhage; and
- the liver, which shows cholestasis associated with mild degenerative changes in hepatocytes.

Whether a direct toxic effect of the leptospires or immune complex deposition causes the vascular injury is unclear. Production of humoral antibodies (IgM in the second and third weeks, IgG later) produces inflammatory responses such as meningoencephalitis and anterior uveitis. During recovery leptospires continue to be excreted in the urine for some days.

PREVENTION

Prevention measures are based upon an awareness of the epidemiology of disease occurring in a region.

Rodent control should be attempted where appropriate and feasible. Occupational protective clothing is effective in groups at risk. In some high-risk groups (e.g. soldiers on jungle maneuvers), oral chemoprophylaxis with doxycycline 200mg weekly is effective,[4] but there have been few attempts to use this approach on a large scale, such as after massive flooding.

Vaccines for human use are licensed in France, China, Japan and Cuba.[5] The large number of serovars makes general protection of human populations by immunization almost impossible. Vaccines for use in dogs and livestock animals historically have been unable to prevent renal infection and thus the reservoir state, and generally have not generated lasting immunity to acute infection. A new generation of vaccines for use in cattle appears to stimulate a cell-mediated immune response and overcomes the limitations of earlier vaccines.[6]

CLINICAL FEATURES

Humans become ill 7–12 days after exposure to leptospires. The majority of patients (90%) experience a mild febrile illness while a minority (10%) have a severe illness called Weil's syndrome. A biphasic course of illness can be seen in all patients. The first or septicemic phase is characterized by a sudden onset of fever, retro-orbital headache, chills, myalgias classically involving the paraspinal, calf and abdominal muscles, conjunctival suffusion (Fig. 181.1), vomiting, prostration and a skin rash, which may be maculopapular or purpuric. Defervescence of fever occurs after 5–7 days in this phase.

The second or immune phase is characterized by the appearance of IgM antibodies. Symptoms recur and signs of meningitis may develop in up to 50% of cases. In severe cases, fever may persist and be associated with renal insufficiency or failure, pulmonary hemorrhage, varying levels of jaundice and myocarditis. Death, occurring in 10–15% of these severe cases, is thought to be due to pulmonary hemorrhage or cardiac failure and arrhythmias secondary to myocarditis. Chest radiographs may reveal numerous abnormalities including segmental opacities or a diffuse pneumonitis.

Clinical laboratory investigations reveal red and white cells in the urine with albuminuria. An elevated white cell count, thrombocytopenia and a high creatinine phosphokinase are commonly observed. When the bilirubin is elevated, the transaminases are only mildly elevated.

The differential diagnosis of leptospirosis includes dengue fever, malaria, influenza and several other acute febrile illnesses depending on the geographic location.

DIAGNOSIS

Because of the broad spectrum of symptoms and the wide differential diagnosis, a high index of clinical suspicion is required if appropriate diagnostic tests are to be made.[7] During the first week of

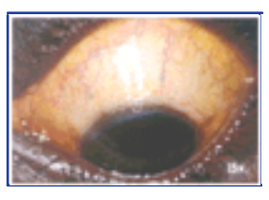

Figure 181-1 Conjunctival suffusion and jaundice.

illness leptospiremia occurs, while in the second week leptospires are excreted in urine and are found in the cerebrospinal fluid of patients with meningitis. Isolation of

the organism requires special media and may take several weeks of incubation, and thus does not contribute to individual patient diagnosis. Detection of leptospiral DNA by polymerase chain reaction is more sensitive than culture, but has yet to be optimized.

A strong IgM antibody response, which appears about 5–7 days after onset of symptoms, may be detected using several commercial assays. The microscopic agglutination test is a complex assay that detects antibodies against live antigen suspensions and is performed only in reference laboratories. Diagnosis using this assay requires paired acute and convalescent sera. This test yields information about the presumptive infecting serogroup and thus has epidemiologic value. In endemic areas, single elevated titers must be interpreted with caution because antibodies persist for years after acute infection.

Direct microscopic examination of clinical samples is of little value, but immunohistochemical staining of autopsy specimens is a valuable diagnostic tool.[8]

MANAGEMENT

Patients with mild or anicteric disease usually get better without treatment. Doxycyline 100mg daily has been shown to shorten the duration of the illness.[9] Hospitalization is recommended for severe cases. Excellent supportive care with particular attention to fluid and electrolyte balance and pulmonary and cardiac function is critical. Renal failure should be treated by peritoneal or hemodialysis. Until the efficacy of antibiotics in this severe illness is resolved, patients should be treated with intravenous penicillin G (benzylpenicillin)[10] or cefotaxime.

Chapter 182 - Relapsing Fever

David A Warrell
Eldryd HO Parry

INTRODUCTION

Repeated abrupt episodes of fever, separated by afebrile periods, give relapsing fever its name. There are two forms:

- tick-borne relapsing fever, caused by various *Borrelia* spp.; and
- louse-borne relapsing fever, caused by *Borrelia recurrentis*.

The two diseases differ in their epidemiology, clinical features and management (see Chapter 230).

EPIDEMIOLOGY

The epidemiology of the relapsing fevers has been considered in a number of studies.[1]

Tick-borne relapsing fever

Borrelia—*tick complex*

Different species of soft ticks of the genus *Ornithodoros* (Argasidae) and of *Borrelia* spirochetes are involved in different parts of the world:

- in central and western USA and Mexico, *Ornithodoros hermsi*, *Ornithodoros parkeri* and *Ornithodoros turicata* with *Borrelia hermsi, Borrelia parkeri* and *Borrelia turicatae*;
- in Central and South America (chiefly in Colombia and Venezuela, with a focus around northern Argentina, Bolivia and Paraguay), *Ornithodoros rudis* (*O. venezuelensis*) with *Borrelia venezuelensis*;
- in east, central and southern Africa, *Borrelia duttonii* with the *Ornithodoros moubata* complex;
- in Senegal and some other parts of north and east Africa and the Middle East, *Borrelia crocidurae* with *Ornithodoros sonrae* (*O. erraticus* small form);
- in the Middle East, Iran and a belt stretching eastward through Uzbekistan and other countries of the former Soviet Union to western China, *Borrelia persica* with *Ornithodoros tholozani* (*O. pappilipes*); and
- in north Africa and the Iberian peninsula, *Borrelia hispanica* with *Ornithodoros erraticus*.

The soft tick vectors are found in dry savanna areas and scrub, particularly rodent burrows, caves, piles of timber and dead trees, or in the roof spaces and beneath the floors of log cabins — anywhere that small rodents can establish their nests. Unlike louse-borne relapsing fever, tick-borne relapsing fever is a zoonosis, except for *B. duttonii* infection, which is transmitted only between humans. The vertebrate reservoir, which varies with the ecology of the area, may be various species of rodent (rats, gerbils, mice, squirrels, chipmunks) or even dogs and some birds. Ticks become infected when they feed on an infected animal (or human) and in turn they infect the next host either by a bite, when infected saliva is injected, or perhaps when infected coxal fluid contaminates mucosal membranes.

Humans are accidentally infected when they are in contact with infected ticks. In eastern Africa, humans have displaced rodents and have become the reservoir for the *O. moubata - B. duttonii* complex. This also occurs in Senegal.[2] A tick remains infected for life and can survive prolonged starvation. The female can transmit the spirochete transovarially to its offspring, so that the infection is enzootic among ticks and awaits the reservoir animal or human to infect. Borrelias are not found in tick feces.

Tick-borne relapsing fever is endemic in most continents except Australasia and the Pacific region. In western Senegal, a recent survey revealed a prevalence of 1% among children.[2] At one health center in Rwanda, 1650 proven cases are treated each year (6% of all patients) and the disease is prevalent in the Dodoma region of Tanzania.

Louse-borne relapsing fever

This classic epidemic disease of armies, refugees and immigrants remains endemic in the highlands of Ethiopia and adjacent countries, hilly areas of Yemen and some parts of the Peruvian and Bolivian Andes.[3] The human body louse, *Pediculus humanus*,[4] and head louse, *Pediculus capitis*, are obligate blood-sucking ectoparasites that ingest borrelias when they feed on humans and then transmit the organism when they are crushed against broken skin or rubbed on a mucous membrane such as the conjunctiva, so that spirochetes in their celomic fluid enter the person's blood. Unlike ticks, lice cannot infect their progeny. Humans are the only reservoirs of this infection.

Louse-borne relapsing fever thrives where people are crowded and poor, where a cold, wet climate (as in the highlands of Ethiopia) encourages them to wear clothes that harbor lice, where water for washing may be scarce and where agents to kill lice are unavailable. The clothes of an infected person teem with lice, particularly around the waist and the buttocks, and lice move from person to person. In the highlands of Ethiopia, the disease flares up in the rainy season because people are crowded and cold. The prevalence of lice is higher during the rainy season but the prevalence of lice in the communities where louse-borne relapsing fever is endemic is high and constant, and it is linearly related to the intensity of infection in an individual person. Rarely, relapsing fevers are diagnosed in travelers who have returned from endemic areas, in intravenous drug users and in recipients of blood transfusions.

PATHOGENESIS

Relapses are due to fresh antigenic variants of borrelias. Extra chromosomal DNA in linear plasmids recombines to activate the genes that control variable major protein synthesis.[5] Experimentally, spirochetes persist in the brain or eye in immunodeficient animals even though they are apparently cleared from the peripheral blood.[6]

PREVENTION

Tick-borne relapsing fever can be prevented if ticks are suppressed, if rodents are controlled and if travelers avoid sleeping in places where ticks or their rodent reservoir could be abundant, such as poorly maintained log cabins. Rodent-proofing of such cabins is feasible in some places, such as the North Rim of the Grand Canyon.[7] There are sporadic cases in travelers in the Middle East, Africa and Europe, and small outbreaks in the USA (e.g. Browne Mountain, the Grand

Canyon) during the vacation season or among those who have worked or stayed in caves, but the risk of transmission of borrelias from an infected tick to humans is not high. Ticks can be eliminated with pyrethroids, benzene hexachloride, malathion or dichlorodiphenyltrichloroethane (DDT).

Prevention of louse-borne relapsing fever depends on breaking transmission from louse to the susceptible population, and this can only be achieved by eradicating the body louse. Infected clothing should be washed and treated with chlorine bleach and an insecticide. The lice are abundant in hair, which must be shaved off or washed and treated too. This is better than giving tetracycline to people at risk of relapsing fever.[8]

CLINICAL FEATURES

Tick-borne relapsing fever

The bite of the tick is painless and produces no eschar. Therefore, it may not be noticed. An incubation period of 3–18 days follows, long enough that potential exposure may be forgotten.

The first symptoms are explosive: fever, headache, muscle and joint pains, extreme fatigue with prostration and drenching episodes of sweating. [9] Epistaxis, abdominal pain, diarrhea and cough may follow. In 5–10% of patients neurologic symptoms and signs, which are the most important clinical problem, manifest as a wide range of focal deficits and are typically transient. They include paresthesias, cranial nerve palsies (especially VII) and visual symptoms, and hemiparesis or paraparesis. Meningeal symptoms, which are usually accompanied by a lymphocytic pleocytosis, are rare. Various erythematous rashes and petechiae may also be seen. The density of spirochetemia governs the clinical severity. Symptoms abate after a few days — the duration depends on the severity of the initial episode — only to recur about 7–15 days later. As many as eight relapses may occur, but they become steadily less severe. Few cases remain undiagnosed for so long. Pregnancy is interrupted in up to a third of cases.

Louse-borne relapsing fever

There is a very wide range of clinical features, from a mild and insignificant fever to a disease that affects many systems in a critically ill person. [1] Typically, after an incubation period of 4–17 (average 7) days, the first symptoms are fever, chills, headache, muscle and body aches, fatigue, dizziness, anorexia and nightmares. Then, in at least 50% of patients, there is evidence of bleeding, commonly manifest as epistaxis, subconjunctival hemorrhage (Fig. 182.1) and petechial hemorrhages, especially on the trunk. An enlarged and tender liver, often with an enlarged spleen, is palpable in as many as 50% of cases in some outbreaks, and about half of these are jaundiced. The respiratory system is affected in about 15% of cases. Cough may indicate pneumonia but it may also precede clinical pulmonary edema. Rarely, there are manifestations of adult respiratory distress syndrome.

Transient myocardial damage may lead to pulmonary edema, which is an additional hazard during treatment. Neurologic and

Figure 182-1 Ethiopian patient who has louse-borne relapsing fever 4 days after the start of febrile symptoms, showing subconjunctival hemorrhages and jaundice.

meningeal signs, transient focal deficits and, ominously, a confusional state and coma are less common than in tick-borne relapsing fever. Fetal loss is very common in pregnant women.

Spontaneous crisis and Jarisch-Herxheimer reaction

The clinical course of relapsing fever, especially louse-borne relapsing fever, is usually terminated either by a mild 'spontaneous crisis' on about day 5 of the untreated illness or by a Jarisch-Herxheimer reaction. This much more severe reaction is induced by, and follows 1–3 hours after, antimicrobial treatment. [1] [10] The patient becomes restless 1–3 hours after treatment. Frank rigors may develop and the temperature, respiratory rate, pulse rate and blood pressure increase rapidly. There may be associated vomiting, diarrhea, coughing, musculoskeletal pains and delirium, and some patients die of hyperpyrexia at the height of the fever. During the ensuing flush phase of this endotoxin-like reaction, there is profuse sweating, intense vasodilatation with a fall in mean arterial pressure and a slow decline in temperature over the next 6–12 hours. Fatalities during this phase are due to hypovolemic shock or acute pulmonary edema resulting from myocarditis. The incidence of Jarisch-Herxheimer reactions varies from 30% to almost 100% in different published reports.

A borrelial pyrogen, an outer membrane variable major lipoprotein [11] [12] released by the action of antimicrobial agents, stimulates an explosive release of cytokines from macrophages through NF-?B,[13] principally tumor necrosis factor (TNF)-a, interleukin (IL)-6, IL-8 and IL-1ß, just before the start of the clinical manifestations of the Jarisch-Herxheimer reaction (Fig. 182.2).[14] The reaction is unaffected by corticosteroids, is delayed by meptazinol (an opiate agonist-antagonist) and can be prevented by a polyclonal antibody against TNF if this is given just before antimicrobial treatment.[15]

LABORATORY FINDINGS

Spirochete density in peripheral blood may exceed 500,000/mm^3 . There is a peripheral neutrophil leukocytosis but, during the

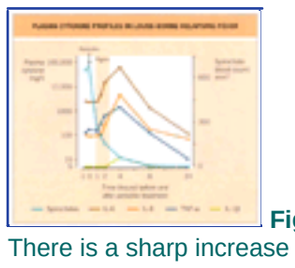

Figure 182-2 Plasma cytokine profiles in louse-borne relapsing fever. These profiles are from an Ethiopian patient treated with penicillin (at time 0 on the horizontal axis). There is a sharp increase in (TNF)-a, IL-6 and IL-8 concentrations at the start of the phase of violent rigors.

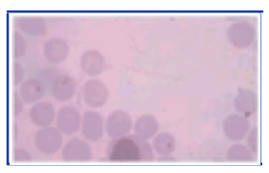

Figure 182-3 Thin blood smear from an Ethiopian patient who has louse-borne relapsing fever (Giemsa stain), showing numerous spirochetes.

Jarisch-Herxheimer reaction or spontaneous crisis, there is a transient profound fall in leukocyte count. Thrombocytopenia is common and there is a coagulopathy attributable partly to hepatic dysfunction and partly to disseminated intravascular coagulation with increased fibrinolytic activity. Biochemical evidence of hepatocellular damage is found in most patients.[1] A few patients show transient, mild renal impairment. A mild neutrophil-lymphocyte pleocytosis has been described.

DIAGNOSIS

If the patient has an acute fever and has traveled in the tropics, it is essential to do a blood film to look for malarial parasites. This may also reveal the spirochetes of tick-borne relapsing fever, which will be recognized in a thin or thick blood film (Fig. 182.3). In suspected tick-borne relapsing fever, the spirochetes must be searched for repeatedly; in louse-borne relapsing fever the higher and more persistent spirochetemia is more easily detected. In suspected cases of tick-borne relapsing fever, blood must be taken at the height of a relapse because it is unlikely to reveal borrelias between relapses.

The serologic response in tick-borne relapsing fever may be helpful but *Borrelia burgdorferi*, the organism responsible for Lyme disease, leads to production of antibodies, mainly to 41kDa and 60kDa antigens, which cross-react with the antiborrelial immunoglobulins of tick-borne relapsing fever. This is due to conserved antigenic epitopes expressed by borrelias.[16] [17] Both *B. duttonii* and *B. recurrentis* have been cultivated in vitro. [18]

In the clinical diagnosis of a traveler at risk, two less common causes of episodic recurrent fever are possible: trench fever (caused by *Bartonella quintana*) if the traveler might have been in contact with the body louse, or rat-bite fever (caused by *Spirillum minus*).

The differential diagnosis of a febrile patient with jaundice, petechial rash, spontaneous systemic bleeding and hepatosplenomegaly includes, apart from relapsing fevers, falciparum malaria, yellow fever and other viral hemorrhagic fevers (such as Rift Valley fever in the Horn of Africa), viral hepatitis, rickettsial infections, especially louse-borne typhus, which has the same epidemiologic predispositions as louse-borne relapsing fever, and leptospirosis. Secondary infections, known to complicate louse-borne relapsing fever, include bacillary dysentery, salmonellosis, typhoid, typhus, malaria and tuberculosis.

PROGNOSIS

Reported case fatalities during epidemics have exceeded 40% but this can be reduced to less than 5% with antimicrobial treatment, provided that appropriate ancillary treatment is given during the life-threatening Jarisch-Herxheimer reaction. Deaths during relapses are most unusual and occur only in tick-borne relapsing fever.

MANAGEMENT

The principles of treatment are:

- to eliminate spirochetemia and prevent relapses, using antibiotics;
- to monitor the patient very carefully through the Jarisch-Herxheimer reaction; and
- to restore and maintain circulating volume during the 24 hours after starting antibiotic treatment.

Antibiotic agents

The choice of agents is based on clinical experience.[19]

Tick-borne relapsing fever

Doxycycline 100mg per day for 10 days is recommended for adults. For pregnant women and young children, erythromycin can be used.

Louse-borne relapsing fever

A single 500mg oral dose of tetracycline or erythromycin stearate is effective. In severely ill patients who are likely to vomit, effective parenteral treatment consists of either a single intravenous dose of tetracycline hydrochloride (250mg)[20] or, for pregnant women and children, a single intravenous dose of erythromycin lactobionate (300mg for adults, 10mg/kg for children). In mixed epidemics of louse-borne relapsing fever and louse-borne typhus, a single oral dose of doxycycline 100mg has proved effective. Penicillins and chloramphenicol are also effective.[20]

Supportive treatment

Postural hypotension and cardiac arrhythmias are prevented by nursing the patient flat in bed for 24 hours after antibiotic treatment. Hyperpyrexia and hypovolemia must be prevented. Acute heart failure with pulmonary edema responds to intravenous furosemide (frusemide) and digoxin. Bleeding and clotting problems are treated with vitamin K, platelets and clotting factor concentrates. Complicating infections, notably typhoid, salmonellosis, bacillary dysentery, tuberculosis, malaria and typhus in some endemic situations, must be treated appropriately.

Chapter 183 - Viral Hemorrhagic Fevers

Joseph B McCormick

INTRODUCTION

Viral hemorrhagic fevers (VHFs) are endemic in every continent with the possible exception of Australia. The diseases are characterized by an acute onset and high fever, and in some cases, a high mortality rate. The bleeding by which they are known is a complication of severe disease, but the underlying pathology is a leaky capillary syndrome with prominent pulmonary edema. Death, when it occurs, is usually due to hypovolemic shock with or without adult respiratory distress syndrome (ARDS).

VIROLOGY AND NATURAL HISTORY

These diseases, almost all zoonoses, are caused by a range of enveloped RNA viruses. Humans are not part of the natural history of these viruses, and therefore infection of humans is an accident, usually the consequence of intrusion into the ecologic niche of the virus. The viruses belong to four major families — Bunyaviridae, Arenaviridae, Filoviridae and Flaviviridae (Table 183.1).

The bunyaviruses Crimean-Congo hemorrhagic fever virus (CCHFV), hantaviruses and Rift Valley fever virus (RVFV) cause VHF in humans. Crimean-Congo hemorrhagic fever virus is spread by ticks and occurs widely across Africa, south-eastern Europe, the Middle East and Asia. Hantaviruses are found throughout the world as natural silent infections in many rodents. A hantavirus in the USA, a pathogen of deer mice, causes the hantavirus pulmonary syndrome (HPS). Rift Valley Fever virus is mosquito borne and causes an acute illness in livestock and wild animals as well as humans.

Arenaviruses also infect rodents, the most important being Lassa virus, which is confined to West Africa, and the South American hemorrhagic fever viruses, of which four are known and cause VHF. The filoviruses, Ebola and Marburg viruses, are a unique family of filamentous viruses known as Filoviridae, from Africa. African filovirus infections have a high mortality rate, but recently described Asian filoviruses have not, so far, been seen to be pathogenic for humans.

The Flaviviridae include yellow fever virus (see Chapter 222) and dengue virus (see Chapter 184), which are both spread by mosquitoes.

Other viruses can cause hemorrhagic fever, such as those causing Kyasanur Forest disease and Omsk hemorrhagic fever, but these are confined to very local areas and are not discussed in detail here. Neither are viruses such as West Nile virus, which, although common and causing increasing numbers of cases in a widening geographic area, rarely cause hemorrhagic disease (and is covered in Chapter 222).

EPIDEMIOLOGY

These infections are primarily rural diseases in developing communities occurring in areas where there is substantial contact with rodents, ticks or mosquitoes and usually with poor facilities for medical care. They are often undiagnosed, particularly single sporadic cases. Much of our knowledge of these diseases is the result of outbreak investigation, and rarely based on experience with endemic sporadic infections. Most of these infections are predominant in the poor. Some of these infections are also transmissible from person to person, such as Lassa virus, Ebola virus and CCHFV. These are particularly notorious for causing nosocomial outbreaks. Only dengue and occasionally yellow fever are seen in the cities where large populations of humans form effective reservoirs along with the abundant mosquitoes that act as both reservoirs and transmitters of the viruses. However, as a result of the increasing mobility of populations everywhere, infected patients can and do appear almost anywhere in the world. Missionaries and medical staff working in remote areas are at risk, but often more likely to reach tertiary care facilities than locals. Large epidemics of VHF can kill thousands of people, such as with yellow fever. Some viruses, particularly filoviruses, have only ever emerged in small epidemics, but their very high mortality rates have given them a notoriety perhaps disproportionate to the number of people actually infected. Monkeys and chimps appear to be as sensitive (or even more so) to the filoviruses as are humans. As a result, there have been many cases of monkey infection now documented, including their onward transmission to humans. There is no evidence, however, that chimps or monkeys are the natural reservoir.

DIAGNOSIS AND CLINICAL FEATURES

The most critical element in the clinical diagnosis in nonendemic areas is to take a thorough history covering the incubation period (3 to a maximum of 4 weeks before the onset of fever). The element that alerts the physician to VHF (and usually indicates which one it is likely to be) is the contact the patient has had with known ecologic niches (see Table 183.1). The history must include:

- a thorough travel history, particularly in Africa, and contact with known severely ill febrile individuals;
- any possible contact with ticks, fresh animal blood, rodent urine or blood, wild animals or mosquitoes and other insects;
- any recent camping in exotic and potentially endemic areas;
- any entry into bat caves; and
- attendance at ceremonial funerals.

Usually these risks occur in rural and remote areas. A medical care provider or other worker who might have had contact with blood from a primary case should also alert the physician to possible VHF.

The essential clinical features (Table 183.2) are a short history of fever, which is usually high and of sudden or rapid onset. Severe body pains and headache are prominent and may be excruciating. Other features may include severe pharyngitis, nausea and vomiting, petechiae, oozing from the gums and bradycardia. Proteinuria is common. Peripheral white blood cell counts are often low very early in disease, but may go up dramatically later, and therefore the presence of neutrophilia may falsely indicate a bacterial disease and be misleading. Thrombocytopenia is common and platelet function is often impaired, even in the presence of low normal platelet counts. Partial thromboplastin times may be prolonged, but prothrombin times are relatively unaffected. Disseminated intravascular coagulation

TABLE 183-1 -- Epidemiologic characteristics of the most important viral hemorrhagic fevers.

EPIDEMIOLOGIC CHARACTERISTICS OF THE MOST IMPORTANT VHFs								
	Arenaviruses*		**Filoviruses**		**Bunyaviruses**			**Flaviviruses**
	Lassa virus	**Junin, Machupo, Guanarito, Sabia**	**Ebola**	**Marburg**	**Hantavirus**	**Crimean-Congo**	**Rift Valley fever**	**Yellow fever**
Geography	West Africa	South America, North America	Central and West Africa	East and Central Africa	Worldwide	Europe, Asia, Africa	Africa	South America and Africa

Primary source of infection	Rodent (*Mastomys natalensis*)	Rodent (*Calomys, Zygodontomys* sp.)	Unknown; possibly bats		Rodents; species depends on location	Tick-borne, (>27 species)	Mosquito	Mosquito-borne (*Aedes* and *Hemogogus* spp.)
Transmission	Nosocomial Rodent to human/person to person	Rodent to human	Nosocomial; possibly reservoir to human; person to person; also infected chimps and possibly monkeys can transmit to humans		Rodent to human	Nosocomial tick to human; possibly animal to human; possibly person to person	Mosquito to human; possibly animal to human via blood	Mosquito to human (human reservoir in outbreaks)
Risk factors	Close contact *Mastomys* rural West Africa; close contact infected persons	Contact rodents in circumscribed agricultural areas South America, possibly North America	Close contact infected blood or secretions from infected persons; environmental risk unknown (possibly caves for Marburg)		Contact with rodent or rodent urine in dust; laboratory	Tick bites; contact with infected livestock; contact with blood or secretions from infected persons	Mosquito bites rural Africa	Mosquito bites rural West Africa and South American rainforests
Treatment	Responds to ribavirin when treated early	Junin responds to immune plasma given early; all may respond to ribavirin	No present treatment; does not respond to ribavirin		Ribavirin may be beneficial early; trial and current use in China; open-label trial in USA for acute pulmonary disease was inconclusive	Sensitive to ribavirin; several published reports of successful case treatment	Sensitive to ribavirin; limited data in monkeys; no human data	No therapy; does not respond to ribavirin
Vaccine	Vaccinia vectored glycoprotein vaccine protects primates Development of human vaccine possible	Attenuated vaccine to Junin virus has greatly reduced cases in Argentina; no vaccine available for others	Protection in small animal studies. Protection of primates not clear	Nothing available	M gene DNA vaccine expressing glycoproteins 1 and 2 protects small animals from challenge and elicits neutralizing antibody in Rhesus monkeys; also formalin-inactivated vaccine but no trial data	Killed vaccine available in Eastern Europe and China, but no published trials	Attenuated vaccine for animals, none for humans	Live attenuated vaccine since 1940s; one of the most effective vaccines ever

* Arenaviruses have been isolated from wood rats in the south-western USA — their capacity to cause human infection is uncertain

* Reston is not a human pathogen

is not a feature of VHF except as a complication of the general deterioration of patients in the terminal phase.

As the disease progresses hypovolemic shock, pulmonary edema and frank bleeding ensue. Aspartate aminotransferase (AST) is usually raised and virtually all VHFs distinguish themselves from viral hepatitis because the AST is disproportionately high compared with alanine aminotransferase (ALT). Ratios of AST to ALT may be as

high as 11 to 1, and the level of AST also reflects prognosis. Patients are rarely jaundiced (except in yellow fever) and the bilirubin is usually normal.

The viruses are pantropic, primarily targeting the reticuloendothelial system. There are usually high titers of virus in the blood and tissues. The central nervous system is relatively spared, but encephalopathy and neurologic sequelae such as ataxia and deafness can occur, particularly in the early convalescent phase. Viruses are rarely recovered from the cerebrospinal fluid.

Care must be taken in collecting, handling and transporting specimens, and consultation with the laboratory is essential. Gloves must be worn at all times and the specimens clearly labeled as hazardous. Blood samples should preferably be drawn into a vacuum tube system. Specimens for transport should be transferred to a leakproof plastic container and double-wrapped in leakproof containers in which they can be transported to a suitable reference laboratory (see Chapter 222).

Laboratory diagnosis may be provided by several methods, depending on the virus in question by:

- presence of virus-specific IgM in the serum;
- presence of viral RNA, usually in serum or white cells, demonstrated by a reverse transcriptase polymerase chain reaction (PCR);
- presence of viral antigen through enzyme-linked immunosorbent assay (ELISA) for specific viral antigens in serum or blood;
- isolating the virus from serum; or
- demonstrating a 4-fold rise in antibody titer;

Sera may be inactivated for serology by gamma irradiation or, if this is unavailable, heating at 140°F (60°C) for 30 minutes. Immunofluorescence assays and ELISAs detect both virus antibody and antigen. More recently, molecular techniques such as PCR performed directly on serum or tissues to detect viral RNA have been found to be rapid, reliable and safe, and while they are more widely available, they are not always available in the areas endemic for VHFs. No truly successful diagnostic system has yet been developed that can be easily and uniformly applied in the remote areas where these diseases occur. New advances in PCR offer the most likely method.

MANAGEMENT

Viral hemorrhagic fevers are self-limiting diseases, and if the patient can be brought through the acute crisis recovery is rapid and complete, although fatigue and general weakness may persist well after the acute disease. The main challenge of acute disease is careful management of fluid balance. Patients often present with a high hematocrit due to dehydration. Despite this, pulmonary edema is a real risk and patients should be infused with caution. Blood and platelet replacement may be necessary. Full intensive care support may be required including mechanical ventilation, monitoring of central venous pressure and dialysis. Seizures and arrhythmias will need to be controlled. Any necessary operation (e.g. obstetric intervention) should be carried out. Pregnant patients are a major challenge. They often present with absent fetal movements and the survival of the mother in Lassa fever has been shown to depend upon the presence of aggressive obstetric intervention to remove the dead fetus.

Lassa virus and CCHFV are highly treatable using the antiviral agent ribavirin, provided therapy is instituted as early as possible in the course of the disease (see Table 183.1). Therapy with immune plasma has also been advocated, but efficacy has never been demonstrated except for Argentine hemorrhagic fever. Disseminated intravascular coagulation is not an underlying feature and heparin is contraindicated. Early accurate diagnosis and good intensive care support are the most important underlying principles for the physician.

Patients who have VHF do not travel well because their cardiovascular system is often unstable and trauma is likely to induce bleeding. It is therefore advised that moving a suspected patient is avoided wherever possible. Moving the patient also exposes a greater number of people to secondary infection. Patients may be managed quite successfully in standard hospital isolation rooms with rigorous barrier nursing because these diseases do not transmit from person to person by aerosol.

PREVENTION

The fearsome reputation of some of these viruses comes from their ability to spread to medical staff and patients in facilities where poor training and inadequate materials for barrier nursing lead to blood-to-blood contact with the virus, for example as a result of a needlestick injury, blood spill on unprotected damaged skin or mouth- to-mouth resuscitation. In some countries, the re-use of needles and syringes has produced devastating nosocomial outbreaks. There are also reports of outbreaks among surgical teams who have unwisely performed laparotomies on infected patients. In these circumstances, the mortality rate has been high.

The key to the prevention of nosocomial transmission in both endemic and nonendemic areas has consistently been good hospital and laboratory practice, with strict isolation of febrile patients and rigorous use of gloves and disinfection.

A small number of named personnel should undertake direct care and be kept fully informed about the nature of the virus and the precautions to be taken. Intensive care, operative interventions and air evacuation in the absence of any local hospital facility should not be denied because they do not pose substantial threats to a well-trained staff accustomed to simple barrier nursing techniques. Aerosol spread in hospitals has not been documented; indeed, there is much published evidence showing that this is not a major hazard. Past recommendations for strict isolation of patients in a plastic isolator have been abandoned in favor of simple strict barrier nursing. This practice presents no excess risk to hospital personnel and allows substantially better care of the patient.

The major factor in nosocomial transmission is the combination of unawareness of the possibility of the disease by a worker who is also inattentive to the requirements of effective barrier nursing. Contacts should be carefully assessed and monitored. Postexposure prophylaxis may be offered where appropriate. Once the diagnosis has been considered and appropriate precautions instituted, the risk of nosocomial transmission is very small (<1%).

A high risk of infection is associated with direct percutaneous or mucosal contact with blood or body fluids and prophylaxis with ribavirin should be offered after exposure to CCHFV and arenaviruses. Other contacts (includes most unprotected contact with blood or body fluids) may safely be observed daily for the development of a persistent high fever for 3 weeks from the last date of contact. The practice of following up airline passengers who do not have any direct physical contact and other low-risk contacts with Lassa fever virus has been discontinued (see Practice Point 186a).

The 1988 USA Centers for Disease Control and Prevention Guidelines for the Management of Patients with VHFs therefore recommend routine patient isolation in a single room, preferably but not necessarily with a negative air pressure gradient from the hallway through an anteroom to the patient room. Staff education, use of gloves, gowns and masks, and rigorous disinfection with fresh liquids are mandatory. The recommendations issued for patient management

and handling of clinical specimens from patients who have AIDS are adequate for the containment of VHFs. The major event to be avoided is direct contact with the blood or other fluid or excretions from an acutely infected patient.

Lassa and Ebola viruses in particular are robust and even withstand some drying. Blood from severely ill patients may contain as much as 10^9 infectious units/ml. However, all the viruses can be inactivated by heat, detergents, chlorine, formalin and ultraviolet radiation (including sunshine). Disinfection can be accomplished by washing with 0.5% phenol in detergent, 0.5% hypochlorite solution, formaldehyde, glutaraldehyde or paracetic acid. Care should be taken to ensure solutions are freshly and correctly made up and time allowed for disinfectant to work on spills.

Finally, a major hazard of VHFs, particularly viruses such as Ebola virus, is the fear and press attention they receive. A single case can be quite traumatic for an institution unless the situation is carefully handled. A measured and informed approach from a collaborative team of doctors, nurses, administrators and others is needed. Careful education of all medical staff, emphasizing the real risks and the ways to avoid them and allaying unnecessary fears, and avoiding panic will result in appropriate management of the patient, and avoid secondary infections. Press attention can be quite disruptive and is best managed by the sharing of accurate and regular information.

Details of appropriate management and containment facilities, contact handling, surveillance, laboratory procedures and resource laboratories have been published.

Chapter 184 - Dengue Fever/ Dengue Hemorrhagic Fever

Scott B Halstead

The dengue viruses (types 1, 2, 3 and 4) are enveloped ssRNA viruses of the Flaviviridae family. Transmission from human to human is by the mosquito *Aedes aegypti*, which bites in the daytime, is adapted to human habitats and has a strong preference for human blood meals. It breeds in relatively clean water stored for drinking or washing purposes in a variety of containers, and in rainwater that collects in manmade containers (e.g. tires, plastic containers, bottles, pails, tanks, cisterns, shallow wells).

The population explosion since World War II and subsequent migration from rural to urban areas have resulted in large cities, deteriorating urban environments and the spread of *A. aegypti* to almost all tropical countries.[1] [2] All four dengue virus types are now endemic around the globe. Of the 2.5 billion inhabitants of these areas, it is estimated that about 50–100 million individuals become infected by dengue viruses each year. Since the end of World War II, a syndrome first recognized in South East Asia — dengue hemorrhagic fever/dengue shock syndrome (DHF/DSS) — has spread globally (see Fig. 184.1), resulting in hundreds of thousands of hospitalizations and thousands of deaths each year.[2] Travelers to most tropical areas are at risk of dengue infection. In 2001, Hawaii experienced a 6-month epidemic of dengue type 1 transmitted by *Aedes albopictus*.

PATHOGENESIS

Dengue hemorrhagic fever/DSS is an immunopathologic syndrome that occurs in:

- infants infected for the first time who have acquired maternal dengue antibody in utero;[3] and
- children and, less commonly, adults during a second dengue virus infection. [4] [5]

Enhancing antibodies appear to be responsible for DHF/DSS. From protective levels at birth, maternal dengue antibodies degrade from neutralizing to enhancing concentrations over a period of 2–10 months.[3] Non-neutralizing antibodies, even in very small numbers, form infectious immune complexes with dengue viruses.[6] These attach efficiently to the Fc receptors of mononuclear phagocytes (macrophages, monocytes, Kupffer cells). The virus then attaches to receptors and fuses through adjacent plasma membrane, extruding viral RNA into the cytosol. The net effect is enhanced infection — more cells infected more rapidly than without enhancing antibody, a phenomenon now documented in humans.[7] Sequential infection in children over 1 year of age accounts for 85% of cases of DHF/DSS. In this setting, enhanced infections occur when antibody from a first infection fails to cross-neutralize a second dengue virus type.[8]

Only viruses of South East Asian origin appear to produce DHF/DSS. [9] [10] In the American genotype dengue 2 virus, the occurrence of dengue 1-like epitopes results in significant cross-reaction and some level of protection in persons immune to dengue 1 virus.[11]

The mediator of DSS has not yet been identified. Recent data suggest that IL-2, interferon-? and tumor necrosis factor released as a result of interactions between activated T cells and infected macrophages may damage postcapillary endothelial junctions. Dengue hemorrhagic fever/DSS is more severe in:

- whites and Asians (versus black people);[12] [13]
- females (versus males); and
- well-nourished (versus malnourished) children.[2]

PREVENTION

Aedes aegypti is a furtive black-and-white striped mosquito that often bites shadowed areas of the skin on the back of the neck, arms and legs. Most dengue infections are acquired at home. Prevention consists of scrupulous destruction and control of breeding sites. All unwanted containers should be discarded, buried or filled with sand.[2] Salt prevents eggs from hatching in water-filled ant traps and water coolers. Standing water that needs to be conserved can be treated with a 1% sand granule formulation of Abate, 1ppm [0,0'-(thiodi-*p*-phenylene) 0,0,0,0'-tetramethylphosphorothioate].

Larvivorous small fish can provide reliable control of mosquito larvae. Adult mosquitoes can be destroyed by pyrethrin knock-down sprays or organophosphate sprays delivered in microdroplets. However, source reduction is always the best method of preventing dengue infections.

For travelers to tropical countries, the only practical method of prevention is to avoid mosquito bites. Topical repellents are effective, but prevention comprises avoiding daytime visits to high-risk areas.

A tetravalent live-attenuated dengue vaccine is in the final stages of development.

CLINICAL FEATURES

Most primary dengue infections in children and many in adults are silent. Dengue infection presents clinically as three overlapping syndromes: undifferentiated fever, dengue fever syndrome and DHF/DSS.[2] The early signs and symptoms of overt dengue infections are common to many acute viral, bacterial and parasitic infections. The pathophysiologic presentation of classic DSS (history of recent high fever, thrombocytopenia, elevated hematocrit and hypotension or narrow pulse pressure) is unique in infectious diseases. Presumptive diagnosis of dengue fever or DHF requires a careful travel history to establish possible exposure to dengue infection. The differential diagnoses for the dengue fever and viral hemorrhagic fever syndromes are shown in Table 184.1 .

Undifferentiated fever

This occurs in young children and is a mild febrile illness lasting 1–3 days, often with upper respiratory signs.

Dengue fever syndrome

This occurs in adolescents and adults. After an infective mosquito bite, there is an incubation period of 3–8 days, followed by a sudden onset of fever with severe headache, pain behind the eyes, backache, chills, lack of appetite, gastrointestinal disturbances and generalized

Figure 184-1 Geographic distribution of dengue.

TABLE 184-1 -- Differential diagnosis of dengue fever and dengue hemorrhagic fever.

DIFFERENTIAL DIAGNOSIS OF DENGUE FEVER AND DENGUE HEMORRHAGIC FEVER
Dengue fever syndrome
• *Mosquito-transmitted febrile exanthems*
- chikungunya (Africa, Asia)
- o'nyong nyong (Africa)
- West Nile (US, Europe, Africa, Asia)
• *Insect transmitted — no rash*
- sandfly fever (Europe, Middle East)
- Rift Valley fever (Africa, Egypt)
- Ross River fever (Australia, Pacific Islands)
- Oropouche (Amazon basin)
• *Febrile diseases in dengue-endemic areas*
- most acute viral and bacterial infections

- malaria
- yellow fever
- leptospirosis
- scrub typhus
- viral hepatitis
Hemorrhagic fevers
• *Ubiquitous*
- meningococcemia
• *Viral hemorrhagic fevers*
- mosquito-borne: Rift Valley fever, yellow fever
- tick-borne: Crimean-Congo HF, Omsk HF, Kyasanur Forest disease
- infectious secretions/tissues: Argentine HF, Bolivian HF, Venezuelan HF, Lassa fever, Marburg disease, Ebola HF, hemorrhagic fever with renal syndrome

pains in the muscles and bones ('breakbone fever'). A maculopapular rash usually appears on the trunk between the third and fifth day of the illness, spreading to the face and extremities. Fever is accompanied by leukopenia, relative lymphocytosis and moderate thrombocytopenia. Dengue fever may be complicated by bleeding, particularly in menstruating women or adults who have peptic ulcer disease.[14] The illness usually lasts for about 4–10 days. Convalescence may be accompanied by prostration and depression.

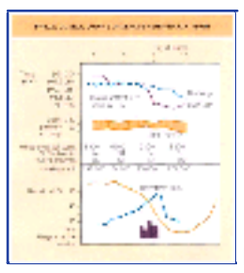

Figure 184-2 Typical clinical course of dengue hemorrhagic fever.

DENGUE HEMORRHAGIC FEVER/DENGUE SHOCK SYNDROME

This is an acute vascular permeability syndrome accompanied by abnormal hemostasis. Although both adults and children develop the syndrome, children are inherently more susceptible due to greater capillary fragility,[5] [15] [16] with a characteristic illness progression (Fig. 184.2). A relatively mild first phase with abrupt onset of fever, malaise, vomiting, headache, anorexia and cough may be followed after 2–5 days by a rapid deterioration and physical collapse due to hypovolemia secondary to increased vascular permeability.[17]

In this second phase, as the temperature becomes normal the patient may have cold clammy extremities, a warm trunk, flushed face, circumoral cyanosis, diaphoresis, restlessness, irritability and midepigastric pain. Respirations and pulse are rapid. Blood pressure may exhibit narrow pulse pressure (20mmHg) or low systolic and diastolic pressures. Scattered petechiae may be seen on the forehead and extremities along with spontaneous ecchymoses, easy bruising and bleeding at venepuncture sites.

As the disease progresses, the liver is usually palpable two or three fingerbreadths below the costal margin, firm and nontender. Chest radiography shows unilateral (right) or bilateral pleural effusions. Sonograms show ascites and perivesicular edema. Approximately 10% of patients have gross ecchymoses or gastrointestinal bleeding. Laboratory abnormalities include thrombocytopenia, elevated hematocrit and abnormal levels of liver enzymes. Convalescence is fairly rapid for children who recover after a 24–36-hour period of crisis.

In addition to classic DSS, adults may have a stormy, often fatal course characterized by elevated liver enzymes, hemostatic abnormalities and gastrointestinal bleeding.

MANAGEMENT

Dengue fever

Dengue fever should be treated supportively. Aspirin is avoided because it may exacerbate the bleeding tendency. Patients who go into shock with normal or falling hematocrit levels should be investigated for gastrointestinal bleeding. [14]

Dengue hemorrhagic fever/dengue shock syndrome

Dengue hemorrhagic fever/dengue shock syndrome is life-threatening and requires immediate evaluation of vital signs, hemoconcentration, dehydration, urine output and electrolyte imbalance (Fig. 184.3). Close monitoring for at least 48 hours is essential because shock may occur or recur precipitously early in the disease. Patients who are cyanotic or have labored breathing should be given oxygen.

Rapid intravenous replacement of fluid and electrolytes using normal saline can often sustain patients until they have a spontaneous recovery. [2] [17] Colloid preparations, such as dextran 70, should be given if the pulse pressure is 10mmHg or less or the hematocrit remains elevated after fluid replacement.[18] Care should be taken to

Figure 184-3 Dengue hemorrhagic fever/dengue shock syndrome. Case definition, clinical staging and treatment strategies for DHF/DSS.

avoid overhydration, which is heralded by a fall in hematocrit and a wide pulse pressure. Diuretics may be necessary. Fresh frozen plasma, whole blood, platelets or heparin (if there is laboratory evidence of severe consumptive coagulopathy), together with rigorous replacement of fluid and protein with colloids, may be required if bleeding complicating DHF/DSS is sufficiently severe. Bleeding is thought to be due to one or more platelet abnormalities.[19]

Chloral hydrate or diazepam may be necessary to manage agitated children.

Corticosteroids, vasopressors, a-adrenergic blocking agents and aldosterone have no role in treatment. Salicylates are contraindicated.

The etiology can be established by recovering the virus from the acute-phase serum, usually on or before the fifth day after the onset of fever. An IgM antibody-capture enzyme-linked immunosorbent assay on serum obtained between 7 days and 2 months after the onset of the fever enables identification of a recent dengue infection. Increases in antibody titer can be detected by hemagglutination inhibition or neutralization tests on paired sera (optimally separated by 2 weeks). [20]

Chapter 185 - Anthrax

Mehmet Doganay

INTRODUCTION

Anthrax is an ancient disease that was rarely seen outside certain well-defined geographic areas, except as an occasional occupational hazard, but which has recently assumed greater importance as a result of its potential use as an agent of bioterrorism.

EPIDEMIOLOGY

Anthrax is usually a disease of herbivores and only incidentally infects humans. This infection still persists in arid and semiarid regions of the Middle East, in Africa, Asia, South America and Haiti. Humans almost invariably acquire anthrax directly or indirectly from infected animals. The main route of transmission is contact with or inhalation of *Bacillus anthracis* spores.[1] [2] Human cases may occur in an agricultural or an industrial environment.[1] [3]

Agricultural cases have occurred in individuals who came into contact with sick or dead animals in rural areas. In certain impoverished communities, livestock owners are forced to slaughter animals at the first sign of infection in order to salvage the meat, hair and hides because of economic problems. Farmers, butchers, knackers, shepherds and veterinarians are therefore the most frequently infected. Anthrax is also reported in women spinning wool with hand spindles and in carpet weavers.[1] [3] [4] Another route of infection is by ingestion of raw or undercooked meat from an infected carcass.[5] Travelers should be aware that, in certain societies, some traditional meals are made of raw meat and are consumed without any cooking or preservation methods. In our series of 113 cases of anthrax, 89 patients gave a history of handling of, or contact with infected dead animals or their products. In four cases, there was a history of consumption of meat from the carcass of a diseased cow or sheep. The source of infection in the remaining 20 cases could not be determined but they were clearly agricultural in origin.[6]

There is also an infection risk after contact with a commercial product prepared from inadequately treated wool or leather. For example, a human case of cutaneous anthrax was acquired from contact with imported souvenir drums with drumheads made of goatskin and another case was most probably acquired from a purchased wool coat. A fatal case of inhalation anthrax was also recorded in a home weaver as a result of contact with imported yarn from Pakistan that contained animal fibers.[1] [3]

Insect vectors, such as horseflies, have been reported to transmit *B. anthracis* from an infected animal to a second animal. They could also theoretically infect humans by mechanical transfer but this has not been well documented.[1] [3]

Industrial anthrax occurs as a result of the inhalation of spore-laden dust or other aerosols or contact with spores. In the industrial environment, spores in dust clouds created from the handling of dry hides, skins, sheep wool, goat hair, bone meal and the like are inhaled or spread through contact with the skin of workers. Most cases in industrialized countries are associated with exposure to animal products, particularly goat hair, imported from countries in which anthrax is endemic.[1] [3] [7]

Records of person-to-person spread are very rare; an unqualified nursing orderly in Zimbabwe acquired an anthrax lesion on his finger as a result of removing dressings from a patient who had cutaneous anthrax, and communal loofahs were found to be responsible for, spreading infection from person to person in the Gambia. Laboratory-acquired infections occur occasionally.[1] [3] In 2001 there was an outbreak of anthrax in the USA that apparently resulted from the deliberate distribution of spores in the postal system, resulting in a number of cases of both cutaneous and inhalational anthrax.[2]

CLINICAL FEATURES

The disease occurs primarily in three forms: cutaneous, respiratory and gastrointestinal. Sepsis and meningitis can rarely develop after the lymphohematogenous spread of *B. anthracis* from a primary lesion (cutaneous, gastrointestinal or pulmonary).

Cutaneous anthrax

Cutaneous anthrax accounts for 95% of human cases. The spore is introduced to the skin via a cut, abrasion or insect bite. The incubation period ranges from 1 to 19 days, usually 2–7 days. The lesion begins as a pruritic papule. The papule enlarges and a ring of vesicles develops around the papule at day 2–4 of the disease. Vesicular fluid may be a hemorrhagic exudate (Fig. 185.1). This area is surrounded by a small ring of erythema and marked edema develops. Unless there is secondary infection, there is no pus and the lesion is not painful, although painful lymphadenitis may occur in the regional lymph nodes. Eventually, the vesicle or vesicular ring ruptures, discharging a clear fluid, and a central depressed black necrotic lesion known as an eschar is formed (Fig. 185.2). Edema extends some distance from the lesion. The eschar begins to resolve about 10 days after the appearance of the initial papule. Resolution is slow (2–6 weeks), regardless of treatment (Fig. 185.3).[1] [7] [8] [9]

The lesion is usually 1–3cm diameter and remains round and regular. Rarely, a lesion may be larger and irregularly shaped. Systemic symptoms, including low-grade fever, malaise and headache, may be present. The cutaneous reaction may be severe in some patients and is characterized by significant local and spreading edema associated with blebs, bullae, induration, chills and fever (see Fig. 185.2b). Clinical symptoms may be more severe if the lesion is located in the face, neck or chest. In these more severe forms, clinical findings are high fever, toxemia, regional painful adenomegaly and extensive edema; shock and death may ensure (Fig. 185.4). [6] [7] [8] [9] [10] [11]

More than 90% of the lesions occur in exposed areas such as the face, neck, arms or hand. The site of infection often reflects the occupation of the patient. Workers who carry hides or carcasses on their shoulders are prone to infection on the back of the neck. Handlers of contaminated animal products tend to be infected on the arms, wrists and hands. The patients generally have a single cutaneous lesion but sometimes they have two or more. For example, if the

Figure 185-1 A cutaneous anthrax lesion with extensive erythema and hemorrhagic bullae on the wrist.

infection has been acquired by skinning an infected dead animal with hands and arms, multiple lesions can be seen on hands, wrists and arms. Atypical localization can also be seen.[1] [3] [4] [6] [7] The distribution of lesions in 114 cases of anthrax treated in our clinic is shown in Table 185.1 . A skin lesion was seen on the hand and fingers in the majority of cases. Lesions localized to other anatomic sites were less frequently observed.

Gastrointestinal anthrax

Ingestion of *B. anthracis* in contaminated food or drink can cause gastrointestinal anthrax. The incubation period is commonly 3–7 days. There are two clinical forms of gastrointestinal anthrax: intestinal and oropharyngeal.[1] [5] [7] [8]

Figure 185-2 Cutaneous anthrax. (a) A well developed lesion on the right forearm (third day of disease). (b) The extension of the skin lesion in the same patient on the sixth day. Extensive edema, induration and bullous changes have occurred over the last 3 days despite antibiotic therapy. Antibiotic therapy does not prevent inflammatory reactions.

The symptoms of intestinal anthrax are initially non-specific and include nausea, vomiting, anorexia and fever. With progression of the illness, abdominal pain, hematemesis, bloody diarrhea and massive ascites occur, and signs suggestive of acute abdomen appear. Then toxemia and shock develop, followed by death. The lesions occur most commonly on the wall of the terminal ileum or cecum. The stomach, duodenum, upper ileum and large bowel are occasionally affected.[1] [7]

Oropharyngeal anthrax is less common than the gastrointestinal form. The lesion is generally localized in the oral cavity, especially on the buccal mucosa or tongue, or the tonsils, and the posterior wall of the pharynx. In some cases, the lesion may be present in two or more places in the gastrointestinal system, oropharynx and intestine. The oral lesion is generally 2–3cm in diameter and covered with a gray pseudomembrane surrounded by extensive edema. When infection is localized on the tonsils, the affected tonsil is also intensely edematous and covered with pseudomembrane. The main clinical features are sore throat, dysphagia, fever and painful regional lymphadenopathy in the neck. The illness progresses rapidly and edema develops around the lymph node and may extend to the upper anterior chest wall. Bacteremia may develop. The infection leads to toxemia and acute respiratory distress syndrome. Shock and coma ensue. In some cases, toxemia leads to sudden death. Despite intensive medical therapy, the mortality is about 50%.[5]

Inhalation anthrax

This natural form of anthrax was previously almost always caused by industrial exposure to spores; however, the most serious outbreaks of anthrax in 1979 in Sverdlovsk and in October 2001 in America are new and notable exceptions. [2] [12]

Inhalation anthrax shows a biphasic clinic pattern with a mild initial phase followed by an acute and severe second phase. After an incubation period of 1–6 days (up to 43 days in the event at Sverdlovsk), the illness begins with mild fever, fatigue, malaise, myalgia, nonproductive cough and some chest or abdominal pain.

Figure 185-3 A dried black anthrax eschar on the eyelids on the 15th day of therapy (third week of the disease). The lesion healed leaving a deep scar. *Courtesy of Professor O Ural, Konya, Turkey.*

TABLE 185-1 -- Distribution of lesions in 114 cases of anthrax.

DISTRIBUTION OF LESIONS IN 114 CASES OF ANTHRAX		
Site of lesion	**No. of cases**	**No. of deaths**
Cutaneous	**107**	**0**
Hands and fingers	79	
Wrist and arms	10	
Eyelid and face	11	
Neck	2	
Foot and leg	5	
Oropharyngeal	**6**	**3**
Tonsil	5	
Tongue	1	
Meningitis	**1**	1

The disease progresses to the second phase within 2–3 days. The second phase is characterized by high fever, toxemia, dyspnea and cyanosis. Hypothermia and shock develop, resulting in death. In up to half of patients, meningitis develops as a complication.[7] [13]

Anthrax meningitis

The meningeal form of anthrax is very rare. The world's literature contains approximately 100 cases of anthrax meningitis, with a mortality rate of over 90%.[8] [14]

Meningitis may be a complication of the three forms of primary anthrax. The most common portal of entry is skin (52%) and then the lungs (22.9%). Anthrax meningitis also occurs in cases of gastrointestinal anthrax. The organisms can spread to the central nervous system by hematogenous or lymphatic routes. The primary focus of infection can not be determined in about 10% of cases and it is called primary anthrax meningitis. Blood cultures are positive for *B. anthracis* in 70% of patients who have meningitis.[14]

The clinical presentation includes sudden onset of fever, fatigue, myalgia, headache, nausea, vomiting, agitation, seizures, delirium and meningeal symptoms. The initial signs are followed by rapid neurologic deterioration and death. The cerebrospinal fluid is often bloody and contains many Gram-positive bacilli. [7] [8] [14]

Figure 185-4 An anthrax lesion of the eyelids surrounded by erythema and massive edema extending from the left eye to the right and down to and beyond the neck. Such extensive edema is characteristic of anthrax. This lesion healed with therapy and left a deep scar.

Anthrax sepsis

Sepsis may occur by spreading of *B. anthracis* via lymphohematogenous route from a primary lesion. Sepsis is rarely seen in patients who have cutaneous anthrax; it is more commonly seen in patients who have inhalation and gastrointestinal anthrax. Clinical features include fever, respiratory distress and changing mental status. Severe toxemia and shock may lead to death in a short time.[5] [8]

COMPLICATIONS

Some 10–20% of untreated cases of cutaneous anthrax might be expected to result in death. With treatment, the mortality rate is less than 1%. Toxemic shock due to massive edema, airway obstruction by compression on the trachea from edematous swelling around the neck, deep scar tissue, deep tissue necrosis and secondary infection are all recorded as complications in cases of cutaneous anthrax. [1] [7] [8] In our 107 cases of cutaneous anthrax, toxemic shock occurred in two cases, airway obstruction in two, eyelid deformity in two, temporal artery inflammation in one, and secondary infection and deep tissue necrosis in two.[6] [10] [11]

Serious complications such as sepsis and meningitis can be seen in inhalation anthrax and gastrointestinal anthrax. These complications are less frequently seen in cutaneous anthrax. The mortality rate in industrial-related inhalation anthrax is over 80%, despite treatment. Gastrointestinal anthrax is also a potentially fatal disease. Mortality is greater than 50%. If an early diagnosis is made and an appropriate treatment is given, the disease can be cured.[1] [5] [7] [8] [13]

DIFFERENTIAL DIAGNOSIS

A history of exposure to contaminated animal materials, occupational exposure and living in an endemic area are all important clues for the suspicion of anthrax.[3] [8]

Cutaneous anthrax should be suspected when the patient describes a painless, pruritic papule, surrounding vesicles and edema, usually on an exposed part of the body. The ulcerative eschar of cutaneous anthrax must be differentiated from other papular and ulcerative lesions that present with regional lymphadenopathy. If regional lymphadenopathy together with a purulent lesion is present, a cutaneous anthrax lesion may be superinfected with pyogenic bacteria such as staphylococci. The differential diagnosis should include ecthyma gangrenosum, rat-bite fever, ulceroglandular tularemia, plague, glanders, orf, rickettsialpox, erysipelas, staphylococcal skin and lymph node infection, syphilitic chancre and cutaneous tuberculosis.[7] [8] [9] [13] Occasionally, the cutaneous reaction may be severe. A severe

cutaneous anthrax lesion involving the face, neck and anterior chest wall must be differentiated from orbital cellulitis, dacryocystitis and deep tissue infection of the neck. Necrotizing soft tissue infections — particularly group A streptococcal infections and gas gangrene — and severe cellulitis due to staphylococci should also be considered in the differential diagnosis of severe forms of cutaneous anthrax. Gas and abscess formation are not observed in patients who have cutaneous anthrax. [7] [8] [9]

Intestinal anthrax mimics food poisoning (in the early stages), acute abdomen of other causes and hemorrhagic gastroenteritis, particularly necrotizing enteritis due to *Clostridium perfringens*.[7] [8] In the differential diagnosis of oropharyngeal anthrax, streptococcal pharyngitis, Vincent's angina, Ludwig's angina, parapharyngeal abscess and deep tissue infection of the neck should be considered.[5]

The clinical picture of anthrax meningitis is acute hemorrhagic meningitis. Differential diagnosis should include acute meningitis of other bacterial etiology and subarachnoid hemorrhage. In the differential diagnosis of anthrax sepsis, sepsis due to other bacteria should be considered.[7] [8]

The initial symptoms of inhalation anthrax are non-specific and clinical presentation is similar to those of atypical pneumonia from other causes and cardiovascular collapse with noninfectious causes.[7] [13] More details on inhalation anthrax are given in Chapter 231 .

INVESTIGATIONS

The investigation of a potential exposure to the infectious agent is very important for suspicion of anthrax. However, the source of infection cannot be determined in some cases.

The well-developed lesion of cutaneous anthrax is readily recognized by its central eschar, ring of vesicles and accompanying edema. Swabs are appropriate for collecting vesicular exudates for microscopy and bacterial culture. In a well formed eschar, in which vesicular exudate is absent, the edge of the eschar can be lifted up with forceps and fluid obtained by a capillary tube. A smear is made from the material and is stained with polychrome methylene blue and examined microscopically for the presence of the pink-staining encapsulated bacilli (McFadyean reaction). The samples are also inoculated on blood agar.[1] [8]

For the isolation of *B. anthracis* in patients who have suspected gastrointestinal anthrax, swabs from oropharyngeal lesion, vomit, fecal specimens, blood and ascites samples are obtained. Specimens likely to be contaminated with commensal flora should be cultured on polymyxin-lysozyme-EDTA-thallous acetate (PLET) agar as a selective medium for *B. anthracis*. [1] [8]

Radiographic examination of the chest usually reveals widening of the mediastinum in inhalation anthrax. Parenchymal infiltration and pleural effusion can also be seen. Direct examination of a smear of pleural fluid or blood, stained with polychrome methylene blue or Gram stain, may show encapsulated bacilli. *Bacillus anthracis* can be isolated from the cultures of these specimens. Culture of nasal swabs has been used for the determination of inhalation exposure to *B. anthracis*.[2] [7] [13]

Blood or cerebrospinal fluid smear stained with polychrome methylene blue should be examined for the encapsulated bacilli and blood or/and cerebrospinal fluid cultures are taken for the isolation of *B. anthracis* in cases of sepsis or meningitis.[7] [8] [14]

Serologic tests are also useful for diagnosis of anthrax. For routine confirmation of anthrax infection or in monitoring the response to the anthrax vaccine, a determination of antibodies against protective antigen alone appears to be satisfactory. Diagnosis may be confirmed serologically by demonstrating an increase in antibody titers; two or more serum samples taken 2–4 weeks apart will give greater diagnostic reliability. If only one serum sample is collected, it will be of greater diagnostic value if collected more than a week after the onset of symptoms. [15]

New diagnostic techniques include immunohistochemical testing of clinical specimens by using *B. anthracis* capsule and cell wall antibody and, most recently, by *B. anthracis*-specific polymerase chain reaction. These new rapid methods may become useful in early diagnosis and in culture-negative patients.[2] [7]

MANAGEMENT

Viable *B. anthracis* organisms disappear from the lesions of cutaneous anthrax within a few hours of the initiation of treatment with parenteral penicillin G. Given the severity of disease, however, patients who have suspected anthrax should receive immediate empiric therapy pending definitive diagnosis. Penicillin G has been the drug of choice, an alternate being doxycycline (although recently ciprofloxacin has been added as a first line agent — see below). Treatment is usually continued for 7–10 days. Naturally occurring strains have also been sensitive to erythromycin, cefazolin, tetracycline, chloramphenicol, gentamicin and ciprofloxacin (see also Chapter 226).

The recommendations for antibiotic use in the setting of a bioterrorism attack are based upon a small series of cases in humans, studies in experimental animals and the knowledge that strains may have been engineered for antibiotic resistance. [16] Because of the rapid course of bioterrorism-related symptomatic inhalation anthrax, early antibiotic administration is essential. Limited early information from the 2001 anthrax attacks suggest that those treated with two or more intravenous antibiotics active for *B. anthracis* had a greater chance of survival.[2] Although small numbers make these observations statistically inconclusive, given the severity of the illness, this seems prudent. The treatment of choice has been ciprofloxacin, with doxycycline as an alternative. An aminoglycoside is often added. Once clinically stable, patients are switched to oral regimens but, because of the risk of delayed germination of spores, it has been suggested that antibiotic therapy should be continued for at least 60 days.

PREVENTION

The mainstay of prevention of anthrax is the avoidance of contaminated animals or animal products. An inactivated acellular vaccine exists and is used mostly in

occupational and military settings. This vaccine is not recommended for normal travelers unless there is likely to be occupational exposure. A live attenuated vaccine has been produced and used in the former Soviet Union. Accelerated development is underway to produce safer and more effective vaccines.

Chapter 186 - Practice Points

186.a Management of a patient who has suspected viral hemorrhagic fever

Steven M Opal

Introduction

Continued expansion of human populations into tropical rain forests, economic pressures and changing ecologic conditions around equatorial regions of the world have increased the risk of exposure to a variety of tropical viral diseases. Global markets and expanded international trade in combination with improved access to remote areas by expanded international airline transportation makes it feasible that these viral illnesses could spread worldwide. Physicians in endemic areas must be aware of the potential threat of viral hemorrhagic illnesses. Moreover, physicians in nonendemic regions must recognize the potential risk of hemorrhagic viral illness in international travelers from tropical regions. Animal handlers in primate research laboratories throughout the world are also at risk. Regrettably, these viral agents are potentially exploitable as a bioterrorist weapon as well. It is essential that health care facilities develop a plan to manage viral hemorrhagic fever (VHF) even if the chances of seeing such patients seem remote.

It is important that physicians are aware of the potential risk of tropical VHFs for several reasons:

- to ensure appropriate diagnosis and management of index cases;
- to provide advice, counseling and possible prophylaxis to close contacts;
- to minimize the risk of nosocomial transmission among health care workers (HCWs) caring for such patients; and
- to contact public health authorities immediately in the event of a possible outbreak of VHF.

Strict adherence to basic infection control techniques and some advance planning will minimize the risk to HCWs and allow rapid, compassionate and safe care of affected patients.

Microbiology and pathogenesis

Hemorrhagic viruses in which person-to-person transmission has been documented include representatives of the arenavirus, bunyavirus and the filovirus groups. The most important examples are Lassa fever, Ebola virus and Marburg virus, and Crimean-Congo hemorrhagic fever, caused by a tick-transmitted bunyavirus (see Chapter 222). Lassa, Ebola, Marburg and Crimean-Congo hemorrhagic fever viruses are particularly important to recognize because nosocomial transmission to HCWs is a real possibility. Although the animal reservoir and mode of transmission to humans is reasonably well understood for Lassa and Crimean-Congo hemorrhagic fevers, the method of transmission of Ebola virus and Marburg virus remain an unsolved mystery.

These viral syndromes share many overlapping clinical features in humans. After an incubation period of between 3 and 21 days, patients develop the abrupt onset of fever, headache, myalgia, sore throat, respiratory symptoms, abdominal pain, nausea, vomiting, diarrhea and conjunctivitis with associated pharyngitis and cervical lymphadenitis. A macular skin eruption may occur in infections with Ebola and Marburg virus; this is less common in Lassa and Crimean-Congo hemorrhagic fever. Various degrees of mucosal and cutaneous hemorrhage occur associated with thrombocytopenia and disseminated intravascular coagulation. The geographic location or travel history of the patient is most useful in distinguishing between the different types of VHFs before virologic confirmation.

The viruses share rapid growth potential and the ability to invade a variety of cell types, resulting in high-grade viremia. The patient's blood and body fluids become potentially contagious to others who come in direct contact with them. Transmission may also occur through handling of bodies during burial rituals, as demonstrated in recent Ebola outbreaks in central Africa. Although many other febrile illnesses, such as malaria, typhoid fever, meningococcemia, arboviral infections and leptospirosis, may present in a similar fashion, infection control measures must be instituted to guard against potential transmission of VHFs until the diagnosis is established.

Diagnosis and management

Recent improvements in the serologic diagnosis of VHFs now make it possible to make a specific diagnosis in the majority of acutely ill patients. An antigen-capture enzyme-linked immunosorbent assay (ELISA) has been developed for Ebola virus and may allow rapid diagnosis in acutely ill patients. Specific IgM and IgG capture ELISA antibody studies are available for serologic diagnosis in convalescent samples. Unfortunately, diseases such as Ebola virus infection, in

TABLE 186.a-1 -- Infection control methods for suspected viral hemorrhagic fevers.

INFECTION CONTROL METHODS FOR SUSPECTED VHFs	
Isolation method	**Comments**
Isolation room	In the past, the negative pressure room was the ideal and still may be used where available. However, the patient can be managed through strict contact isolation, universal blood and body substance precautions and enhanced prevention measures in the handling of blood and body fluids
Personnel and visitors	Traffic flow into the patient's room should be restricted. A daily record of those who enter and leave the patient's room should be kept. Only essential personnel should be exposed to the patient and the patient's body fluids
Personal protection	Fluid-impervious gowns, gloves, face shields or surgical masks with eye protection (goggles); if cough, vomiting or extensive hemorrhage, respirators with filters (high-efficiency particulate air respirators) and leg and shoe coverings should be worn
Clinical samples	Clinical samples should be placed in plastic sealed bags and transported in a leak proof container without contaminating the external surfaces. Samples should be handled in a biologic safety cabinet (biosafety level III). Serum should be pretreated with a polyethylene glycol phenolic for 1 hour before handling. Automated analyzers should be disinfected with 1:100 dilution of bleach after use. Fixation of blood smears and tissue samples will inactivate the virus and can be handled in a routine manner
Decontamination of the environment and of linen	Contaminated environmental surfaces should be disinfected using a registered hospital disinfectant or 1:100 dilution of bleach. Soiled linens can either be decontaminated by use of an autoclave or incineration. Hot cycle laundering with bleach may be acceptable.
Human excrement and blood and body fluids	As an added precaution, human excreta, blood and body fluids should be decontaminated by 1:100 dilution of bleach for at least 5 minutes before disposal
Surgical procedures and autopsy	If a surgical procedure or autopsy is essential, extreme precautions must be used to avoid blood contamination. Double gloves, full face shields with high-efficiency particulate air filtration, water-impervious gowns and shoe covers should be worn. Every effort should be taken to avoid generation of an aerosol. Deceased persons should not be embalmed. The body should be placed in leakproof, sealed material and cremated or buried in a sealed casket

which mortality rates exceed 75%, do not often allow the opportunity to study convalescent samples. Virus isolation from the blood and body secretions of acutely ill patients is the definitive diagnostic method. This is, of course, a severe biohazard and it should only be attempted in biosafety level IV facilities. Reverse transcription and polymerase chain reaction for specific viral RNA is also a useful diagnostic method in patients who have viral hemorrhagic illnesses. Many of these methodologies

are unavailable in regions of the world where these diseases are endemic. For this reason, the recent development of an immunochemical staining method for skin biopsy samples is particularly valuable. This method allows for fixation of tissues at the site of diagnosis and eliminates the biohazard of transportation of infected human tissues.

Routine diagnostic methods to evaluate other common febrile illnesses should not be delayed because of suspected VHF. In particular, care must be taken to exclude falciparum malaria, which may be fatal if unrecognized and left untreated. In practice, most cases of suspected VHF turn out to be malaria. Universal precautions when handling blood and body secretions should suffice to protect HCWs from hemorrhagic viruses (see Chapter 183).

Infection control methods

The viruses are transmitted through direct contact with the patient or the patient's secretions. There is a remote risk of airborne transmission based upon studies with nonhuman primates, and one potential transmission by respiratory aerosol in a patient who had Lassa fever with extensive pulmonary involvement has been reported. Therefore, the primary infection control strategy is strict contact isolation, universal blood and body substance precautions, and enhanced preventive measures in the handling of blood and body fluids. Body substances are contagious during the acute febrile illness, but there is no evidence of transmission during the incubation phase of the illness. The guidelines listed in Table 186a.1 should be instituted in patients who have suspected VHF.

Postexposure prophylaxis

The arenavirus that causes Lassa fever is susceptible to ribavirin, and this antiviral agent may be of some value to HCWs exposed to blood or body fluids (e.g. by percutaneous needlestick accident). Passive immunotherapy with plasma from surviving patients with high-titer antibody has been shown to be of limited benefit in the prevention of VHF.

Reporting

It is essential that patients who have suspected VHF are reported to public health authorities as soon as possible. This allows a coordinated response to a potential epidemic situation and ensures that diagnostic and therapeutic efforts will be handled appropriately. Expert international assistance may be necessary should a VHF occur in an international traveler.

186.b Follow-up of the traveler who has swum in Lake Malawi

Nick J Beeching

Introduction

Lake Malawi is a huge freshwater resource 630km long and 50km wide in Central Africa, providing essential food and income for a large proportion of Malawians and people of the other nations that border its shores (Fig. 186b.1). Over the past two decades it has become a major attraction for both 'local' tourists and for backpackers and overlanders from outside Africa, with the associated development of hotels and facilities for watersports such as scuba diving and windsurfing. These are especially found in the south around Cape Maclear and Monkey Bay, where the shores are relatively shallow and the snail vectors for *Schistosoma haematobium* have become established. Further north and centrally, the ecology of the lake differs, with deep water close to the land. Bilharzia was recognized by early European visitors to Malawi and was noted in 50% of lakeshore inhabitants in the early 1900s. It has become more widely

Figure 186.b-1 Lake Malawi.

established since then, particularly with the development of irrigation schemes. The predominant species is *Schistosoma haematobium*, but small pockets of *Schistosoma mansoni* also exist.

Schistosomiasis has become a common diagnosis in expatriates and short-term tourists in Malawi. Similar risks are already well-recognized for visitors to the Dogon area of Mali or to the waters of the Kariba Dam and the Zambesi, but Lake Malawi has overtaken these sites as the main source of the many cases of schistosomiasis imported annually from Africa to the UK and elsewhere. A large case-control study showed that 33% of foreigners in Malawi had serologic evidence of exposure to infection, the highest risk being associated with repeated exposure to the lake, especially around Cape Maclear. Our own experience of screening groups of returned travelers is that 75% of those who spend a week scuba diving at Cape Maclear will have clinical or asymptomatic laboratory evidence of infection. People are at risk from showers and swimming pools that are fed directly with unchlorinated lake water as well as from paddling and swimming. Brief exposure is sufficient; we recently screened students from the same school who had spent 48 hours only at two locations around the lake. Of those camping near Cape Maclear 90% (19/21) had been infected, compared with none of 17 students camping on Likoma Island, another popular tourist spot.

General approach to the traveler who has swum in Lake Malawi

The general approach to the traveler who has swum in Lake Malawi is the same as that for any other traveler, including the need to exclude malaria in febrile patients. A detailed travel and exposure history must be taken, including the precise timing, frequency, type and locations of any freshwater contact. Previous travel and possible schistosomal risk activity should be checked along with pre-existing illnesses including atopy and urologic or gastrointestinal problems. Enquiries should routinely review adherence to antimalarial chemoprophylaxis and mosquito avoidance measures, and the use of measures that might reduce schistosomal load such as vigorous rubbing of the skin immediately after immersion, or pre-exposure use of antischistosomal soaps or permethrin on the skin.

Only a minority of people will remember experiencing 'swimmer's itch', lasting from a few to 48 hours after swimming, caused by penetration of the skin by cercariae. This does not reliably predict later symptoms, which first appear in a substantial minority of patients 3–8 weeks after exposure, as the 'Katayama syndrome,' which is related to an immunologic reaction to final migration of schistosomules around the body and the onset of oviposition by the maturing flukes (see Chapter 167). Typical symptoms include fever, headache, malaise, wheezing, dry cough and dyspnea. Transient urticarial rashes are common (Fig. 186b.2), and lymphadenopathy and hepatosplenomegaly may be found on examination. Usually this is a diagnosis of exclusion and the supportive laboratory finding of eosinophilia exceeding 2×19^9 /l is not always present. We have seen cases misdiagnosed as glandular fever due to coincident lymphocytosis, false-positive slide tests for infectious mononucleosis and mild disturbance of liver function tests. Transient shadows may be seen on chest radiographs.

Whether or not patients have experienced earlier symptoms, continued oviposition from 3 to 6 months after exposure may then cause symptoms related to the organs involved. *Schistosoma haematobium* principally affects bladder, prostate and seminal vesicles and typical complaints are of terminal hematuria, perineal discomfort and, in males, alteration in the consistency (thin or lumpy) or color (yellow

Figure 186.b-2 Giant urticaria associated with Katayama syndrome after swimming in Lake Malawi. *Courtesy of Dr ME Jones, Edinburgh.*

or frank blood) of semen. Women occasionally notice a wart-like genital granuloma. *Schistosoma mansoni* primarily affects the large bowel, leading to blood in feces and alteration in bowel habit, but the anatomic location of both species has considerable overlap. Symptoms are more common with *S. haematobium* infections and may be associated with non-specific fatigue.

The long-term outcome of untreated, relatively light infections of visitors is unknown, but is likely to be benign and not to lead to the complications caused by chronic and repeated infections of inhabitants of endemic areas, such as bladder cancer and portal or pulmonary hypertension (see Chapter 167). However, a small minority of travelers develop central nervous system complications such as epilepsy or spinal cord damage due to ectopic deposition of ova, and the general expert consensus is that all exposed travelers should be screened and treated.

Screening

The minimum investigations, whether or not symptoms are present, should include an absolute eosinophil count, testing of urine for blood, and microscopy for ova in feces and on a filter of a 4-hour mid-day urine specimen. 'Routine' urine microscopy is insufficiently sensitive. Semen microscopy may become positive earlier than urine or feces, and males can be asked to provide a sample for microscopy, particularly if being screened in the first few months after water exposure (Fig. 186b.3). If the index of clinical suspicion remains high and other tests are negative, a squash preparation of a fresh rectal biopsy can be examined for ova. Viability of ova, hence current infection, can be inferred from the observation of active flame cells within the miracidium developing in the ovum. Eosinophilia is only found in about 50% of patients in the chronic phase of infection.

The rather crude serologic tests available from European reference centers include an enzyme-linked immunosorbent assay (ELISA) using circumoval protein as antigen to detect circulating antischistosomal antibodies. These become positive from about the time of oviposition, but seroconversion may take up to 6 months and late follow-up screening is essential for those who are asymptomatic and who have negative tests before this time. The serologic tests available from the US Centers

for Disease Control and Prevention become positive soon after exposure to infection, and discriminate between *S. haematobium* and other species. Once positive, serology remains positive for years and titers may even increase during the first year after treatment. Follow-up serologic tests after treatment are not, therefore, useful as a test of cure or even for distinguishing reinfection

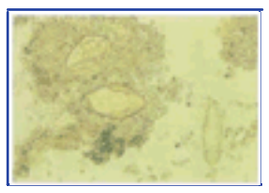

Figure 186.b-3 Empty ovum case and hatched miracidium of *Schistosoma haematobium* in semen. Note oligospermia, which usually resolves after treatment.

after subsequent re-exposure of the patient to infected water. The disappearance of any symptoms or other positive tests, including eosinophilia, is more reliable for follow-up after treatment.

Treatment

Treatment is now relatively easy and harmless, using oral praziquantel in a dose of 40mg/kg, sometimes split into two doses 6 hours apart to reduce any associated nausea. Many scuba divers and other visitors treat themselves with locally purchased praziquantel immediately after diving, but this is useless as postexposure prophylaxis. Praziquantel has little effect on migrating schistosomules, and so patients treated at the stage of Katayama syndrome symptomatology need to be re-treated 3 months later. Patients with moderate-to-severe Katayama syndrome probably also benefit from a short course of prednisone (e.g. 40mg daily for several days), preferably started a few hours before anthelmintic treatment. However, this anecdotal recommendation merits a prospective randomized trial to establish both short-term benefit and longer term benefit in reducing chronic fatigue, which is quite common after Katayama symptomatology. Coticosteroids reduce the efficacy of praziquantel, so increased dosing of praziquantel is therefore recommended by some.

Patients who present later, with symptoms such as hematuria or positive laboratory tests, should also be treated and should be followed up 6 months later to establish disappearance of any previous positive findings. Asymptomatic travelers with negative screening tests 6 months or more after lake exposure do not require treatment or further follow-up. It is debatable whether every patient who presents with hematuria and ova in the urine should have further investigations such as ultrasonography or cystoscopy to exclude coincident tumors or other problems. We have a low threshold for urologic referral, which is essential if local symptoms do not resolve after antischistosomal drugs.

Summary

Overall, the risk of acquiring schistosomiasis from swimming in the south of Lake Malawi is so high that screening of returned expatriates, travelers and immigrants is essential and is unlikely to yield false-positive results. Many expatriates regard the risk as so common that they bypass the screening process and treat themselves and their families as a routine every 6 months. We suggest that this approach is inappropriate for the occasional traveler who has swum in Lake Malawi (or similar freshwater bodies), who should be fully assessed

before possible treatment with an anthelmintic that is only available on a named-patient basis outside the tropics.

186.c Indications for exchange transfusion in severe malaria

Robin Bailey

Introduction

Patients with high proportions of their red cells parasitized by *P. falciparum* are at increased risk of developing all the complications of severe malaria. It has been suggested that this risk is proportional to the parasitemia and thus that exchange transfusion might benefit some patients with very high parasite counts. The rationale for exchange transfusion is that physical removal of infected red blood cells from the circulation and their replacement by healthy and unparasitized red cells will:

- lower the parasite burden more quickly than chemotherapy alone;
- reduce the antigenic load and its concomitant burdens of parasite-derived toxins and metabolites and the host responses to them;
- correct anemia and improve the oxygen-carrying capacity and microcirculatory properties of the blood.

With these theoretical benefits come dangers of the procedure, including hypocalcemia, hemodynamic disturbance, transfusion reactions and infection.

The use of exchange transfusion has been reported in over 200 patients since 1974. A recent meta-analysis of eight studies involving 279 subjects with severe malaria found no evidence for a survival benefit and concluded that the evidence base supporting its use was inadequate, with publication bias and a tendency for more severely ill patients to receive exchange transfusion being particular difficulties in the interpretation of published studies. No adequately powered randomized controlled trial has been conducted and it is doubtful whether such a trial could be conducted given the logistic difficulties and the number of centers that would need to be involved. However, the balance of expert opinion favors its use as an adjunct to optimal chemotherapy in extreme situations.

When should exchange transfusion be considered?

Exchange transfusion only becomes an option if large amounts of adequately screened, pathogen-free and properly cross-matched blood are available, there are adequate monitoring facilities in a high-care environment, and the exchange itself can be carried out safely. The benefits may be greatest where nonimmune patients have high parasitemias and have not responded to optimal chemotherapy.

The WHO suggests the following indications for exchange transfusion in patients receiving optimal chemotherapy.

- Parasitemia of greater than 30%.
- Parasitemia of greater than 10% in the presence of severe or complicated disease, especially cerebral malaria, acute renal failure, adult respiratory distress syndrome or jaundice, or severe anemia.
- Parasitemia of greater than 10% not responding to optimal chemotherapy after 12–24 hours.
- Parasitemia of greater than 10% and poor prognostic features (for example, elderly patients or late-stage schizonts in the peripheral blood).

There are some problems in basing decisions on the parasitemia. Although high parasite densities imply severity, the reverse is not always true, particularly in nonimmune persons where there may be wide differences between the proportions of the burden of parasitized cells circulating in the peripheral blood as opposed to sequestered in the microvasculature. Serial blood films at 6–12 hour intervals may reveal rapid changes in parasitemia, especially in synchronous infections, even with optimal treatment. In particular, the relation between the peripheral blood and total body parasite burden depends on the stage of the parasite development. If early *P. falciparum* trophozoites are predominant the peripheral parasitemia is likely to be more representative of the parasitized cell burden in the body and, presumably, more easily removed by exchanging. The later pre-schizont and schizont stages sequester in the microvasculature, a phenomenon believed to be responsible for the cerebral and renal manifestations of severe malaria. Thus although the presence of late-stage schizonts on the peripheral blood film may indicate that another cycle of replication is imminent, a greater proportion of the parasitized red cells are sequestered and thus not accessible to removal during exchange transfusion.

Methods of exchange transfusion

Traditionally double-lumen catheters or venesection/transfusion through separate lines have been used to perform manual exchanges, usually of six units of blood, one unit at a time. This is time consuming and inevitably causes some hemodynamic disturbance. The

use of cell separator hardware and software to remove only the red cell fraction and replace it with donor red cells in a single automated isovolemic procedure of 'erythrocytapheresis' is preferable as the method of choice where the expertise and facilities are available, for example in hematology departments in developed country settings.

Conclusion

Exchange transfusion as an adjunct to optimal chemotherapy in severe malaria is recommended by many centers, especially for high parasitemias in nonimmune patients. This cannot be considered an evidence-based recommendation, but it is supported by expert opinion for the indications listed above. A definitive randomized controlled trial is needed, but would be difficult to carry out.

186.d What are the treatment options for a pregnant patient with malaria?

Edgar Dorman
Caroline Shulman

Definition of the problem

Falciparum malaria is responsible for massive maternal and perinatal morbidity and mortality globally. The clinical features in pregnancy depend to a large extent on the immune status of the woman, which in turn is determined by her previous exposure and continued exposure to malaria.

In pregnant women with little or no pre-existing immunity, such as travelers or women from nonendemic areas, infection is associated with extremely high risks of both maternal and perinatal mortality. Women of all parities are affected and are at 2–3 times greater risk of developing severe disease than nonpregnant women. They are also at approximately three times greater risk of dying if they do develop severe disease. Severe disease in pregnant women has been associated with 20–30% maternal mortality and at least a 60% risk of miscarriage, premature delivery or neonatal death. Particular dangers are hyperpyrexia, hypoglycemia, severe hemolytic anemia, cerebral malaria and pulmonary edema. The hyperpyrexia can precipitate miscarriage or premature labor. Hypoglycemia may be severe and refractory and may be associated with fetal heart rate abnormalities. It may be present prior to commencement of treatment but is particularly common in patients treated with quinine, due to quinine-induced hyperinsulinism. Although hypoglycemia usually presents as an alteration in the woman's conscious level or as abnormal behavior, often with sweating and an increased respiratory rate or dyspnea, it may be asymptomatic. Pulmonary edema associated with malaria in pregnancy is usually due to abnormal capillary permeability and can occur without positive fluid balance, as acute respiratory distress syndrome.

In areas of moderate or high transmission (holo- or hyperendemic), including large parts of sub-Saharan Africa, adults usually have a high level of immunity to malaria, maintained by continued exposure to infection. During pregnancy, this immunity is altered and pregnant women are at greater risk of infection than nonpregnant women. Primigravidae are affected most, with the risk decreasing in each successive pregnancy. In women with substantial pre-existing immunity, severe disease is uncommon and infection is frequently asymptomatic. However, even when asymptomatic, placental parasitization is common, whereby infected red cells sequester in the placenta in the intervillous space and malaria in pregnancy is associated with the development of severe maternal anemia and low birth-weight delivery. The low birth weight is mediated through a combination of intrauterine growth restriction (IUGR) and prematurity. Because it is asymptomatic, malaria may go unsuspected and undetected, particularly as the peripheral film may be negative despite placental infection (Fig. 186d.1).

The other species of malaria are not associated with severe disease and usually present with fever, although infection with *Plasmodium vivax* during pregnancy is associated with mild anemia and low birth-weight delivery.

Clinical cases

Case 1 — nonimmune

A 37-year-old West African woman presented to a London maternity department at 29 weeks' gestation in her first pregnancy, with a 5-day history of fever. She had recently returned to London, her home for the past 2 years. On admission her temperature was 103.1°F (39.5°C), pulse 130 beats/min (bpm) and, blood pressure 108/56mmHg. She was conscious and responsive. Her urine contained protein ++ on ward testing and was sent for culture (subsequently negative). Her uterus was soft and fetal size was appropriate for 29 weeks. There was a fetal tachycardia (180 bpm) with a suspicious pattern: a flat trace with reduced short-term variability (<5 bpm). Her initial investigation results were as follows: hemoglobin (Hb) 8.2g/dl, white blood cell (WBC) count 18 × 10^9 /1 and platelets 66 × 10^9 /1. Apart from her thrombocytopenia, her coagulation screen was normal. Two hours after admission her malaria film was reported to be positive with a 10% *Plasmodium falciparum* parasitemia. Her blood sugar was subsequently found to be 2.6mmol/l.

The patient was transferred to the intensive care unit and commenced on an infusion of 10% dextrose after a bolus of 50%. She received a loading dose of intravenous quinine 20mg/kg over 4 hours. In view of the hyperparasitemia, she was transferred to a tertiary referral unit for consideration of exchange transfusion. She required two top-up transfusions over the subsequent 3 days but her parasitemia

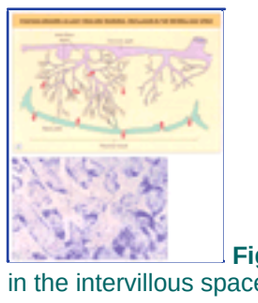

Figure 186.d-1 Heavy placental sequestration of malaria parasites is a common feature of malaria in pregnancy. (a) Placenta showing villous trees and maternal circulation in the intervillous spaces (broad arrows). (b) Photomicrograph showing trophozoites in maternal red blood cells in the intervillous spaces.

decreased and was negative after day 5. The patient remained well thereafter.

Ultrasound assessment on day 2 revealed an appropriately grown fetus with normal amniotic fluid volume. There was bilateral notching of the uterine artery Doppler waveforms with raised resistance indices, suggesting a degree of placental dysfunction. The umbilical artery and fetal arterial Doppler studies were normal. Over the subsequent 5 days the uterine artery Doppler waveforms normalized and remained normal throughout the rest of the pregnancy. However, subsequent serial scans for growth demonstrated IUGR, despite normal Dopplers.

HIV testing was undertaken during antenatal follow-up and the patient was found to be HIV positive. For this reason and because of the IUGR, she was delivered by cesarian section at 37 weeks' gestation.

Case 2 — semi-immune

A 26-year-old woman from East Africa presented at 24 weeks' gestation for antenatal booking. She was an asylum seeker who had arrived in the UK 2 weeks previously. She reported no specific symptoms other than tiredness and lethargy. Routine booking investigations were carried out. All results were unremarkable apart from the hemoglobin (6.2g/dl with iron-deficient indices). The patient was recalled to clinic and was subsequently admitted for transfusion of four units of packed cells. She was followed up in the clinic and 4 weeks later was severely anemic again (Hb 6.5g/dl). On this occasion stool was sent for microscopy and a malaria film was requested. Further transfusion of packed cells was arranged. The stool microscopy and malaria film were reported to be negative. However, the patient complained of flu-like symptoms over the ensuing days and a further malaria film was positive (*P. falciparum* <1% parasites seen). After treatment with oral quinine for 5 days followed by sulfadoxine-pyrimethamine (SP), the patient recovered. She had no further episodes of anemia during the antenatal period.

Diagnosis

The investigation of a patient with suspected falciparum malaria in pregnancy should be treated with great urgency.

Thick and thin blood films, stained with Giemsa, should be examined by an experienced microscopist. If the film is negative, it should be repeated if the patient remains symptomatic. Rapid dipstick tests (such as the ICT card test or OPTIMAL) are available as an aid to diagnosis in addition to microscopy. However, they are not as

sensitive as microscopy in the hands of an experienced microscopist.

Blood and urine should be cultured to exclude other infections and in the comatose patient, lumbar puncture should be considered to exclude meningitis, providing there is no evidence of raised intracranial pressure.

TABLE 186.d-1 -- Drugs that can be used for treatment of clinical malaria in pregnancy.

DRUGS THAT CAN BE USED FOR TREATMENT OF CLINICAL MALARIA IN PREGNANCY	
In any trimester	• Quinine
	• Chloroquine: though widespread drug resistance has now made this redundant for the majority of cases of falciparum malaria.
	• Sulfadoxine-pyrimethamine: theoretical risk of teratogenicity when used early in the first trimester and of kernicterus when used late in the third trimester. However, evidence suggests these risks are very low, so provided there is not likely to be drug-resistant disease, it can be used at any gestation for symptomatic disease, as the risks will be outweighed by benefits.
In the second and third trimesters only	• Artemisin derivatives
	• Amodiaquine
	• Mefloquine: to be used only if no other effective drugs are available
Drugs that are contraindicated in pregnancy	• Halofantrine
	• Primaquine
	• Doxycycline
NB: No drug is safe enough for treating malaria in pregnancy if there is a high level of resistance to the drug in the population. The most effective drug available should be used	

In a woman from an endemic country with severe anemia and suspected asymptomatic disease, presumptive treatment should be given even if a blood slide is negative, as illustrated by the second case history.

Management

Nonimmune pregnant women with malaria are more ill, more hypoglycemic and deteriorate more rapidly than nonpregnant patients and should be managed jointly by a physician and an obstetrician with an interest in materno-fetal medicine. As well as monitoring the parasitemia, regular hemoglobin, platelet counts and blood sugar measurements should continue during the course of the infection. The priority is to treat the mother. Delivery should not be contemplated until her condition is stabilized. Evidence of fetal compromise may resolve during the course of treatment, as in the first case history.

Unless there is multidrug resistance, quinine is the first-line drug for all symptomatic falciparum malaria infections in pregnancy. It is safe for use at any gestation, although it may have some weak oxytocic activity. In clinical practice, quinine use is not associated with premature labor and the greatest risk factor for premature labor is fever in the inadequately treated patient. If there is doubt about the malaria species, treatment with quinine should be commenced, pending confirmation from a reference laboratory.

In nonsevere disease, oral therapy with quinine should be given at a dose of 10mg salt/kg (maximum 600mg) q8h. If severe tinnitus or deafness occurs, dosage should be reduced to q12h. After 5 days or after clearance of parasitemia, whichever is the longer, a single treatment dose of SP may be given and quinine discontinued. Where possible, SP should be avoided both in the first trimester, due to the theoretical risk of teratogenicity, and near to term, due to the theoretical risk of kernicterus in the newborn. Both of these risks appear extremely low, however, and it can be used if alternatives are not available.

In severe disease, intravenous therapy should be instituted, converting to oral treatment as above as soon as the patient can swallow. A loading dose of quinine dihydrochloride 20mg/kg (maximum 1400mg) should be infused over 4 hours. Eight hours after the start of treatment, maintenance therapy with 10mg/kg over 4 hours should be started and repeated every 8 hours.

Malaria imported from parts of Thailand, Papua New Guinea and elsewhere in South East Asia may be resistant to quinine, SP and other drugs. Mefloquine may remain effective for these infections but it should be used with caution in pregnancy. The other effective alternative for treatment failures, alone or in combination with quinine, are the Qinghausu derivatives (artemether or artesunate), which appear safe in pregnancy and which the World Health Organization recommends for treatment of quinine-resistant severe malaria.

Careful attention should be paid to fluid balance in any patient with falciparum malaria, specifically avoiding the use of fluid challenges in response to oliguria, as this may precipitate pulmonary edema.

Transfusion with packed cells should be given slowly in any severely anemic patient. Patients with high parasitemia should be transfused earlier, as their hemoglobin will continue to fall due to hemolysis, despite treatment. In patients with parasitemia >10%, exchange transfusion allows physical clearance of parasites from the circulation. Exchange transfusion may also be considered at lower parasitemia levels in the presence of pre-rupture schizonts in the peripheral film, as this indicates an escalating parasitemia.

Conclusion

In nonimmune women, malaria in pregnancy is a dangerous condition associated with a high risk of maternal and perinatal mortality. Particular dangers are hyperpyrexia, hypoglycemia, severe hemolytic anemia, cerebral malaria and pulmonary edema. Even in immune women, falciparum malaria in pregnancy is associated with severe maternal anemia and low birth-weight delivery.

Malaria should be considered likely in any febrile patient with a travel history in the past year and treatment commenced for falciparum malaria if there is any doubt about the diagnosis. Severe or complicated malaria should be managed in an ITU setting and should involve early liaison between obstetricians and experts in tropical medicine.

Pregnant women should be advised against travel to malaria-endemic areas and if travel is unavoidable, advice on personal protection and chemoprophylaxis must be given.

186.e Treatment of dysentery in a pregnant woman

Lucia Larson

Introduction

Encountering dysentery or debilitating diarrhea in a pregnant woman sets the physician on a challenging path. Fetal health is inextricable from maternal health, making concerns about morbidity doubly important. Physiologic stresses of severe diarrhea may be well tolerated by a young woman but they may not be when she is pregnant. Furthermore, her unborn child relies for its survival on maternal volume status by way of placental blood flow. The dysenteric pregnant woman should be hospitalized immediately if at all possible. The clinician must work quickly to ensure hydration, to establish a diagnosis and to select a rational management plan.

Pathogenesis

Etiologic considerations are the same for pregnant and nonpregnant patients but there are a few specific organisms to which a pregnant woman may be particularly predisposed. Noninfectious causes of dysentery should also be considered, particularly inflammatory bowel disease.

For example, physiologic changes of pregnancy may place the patient at risk for contracting or manifesting certain conditions. Cellular immunity is suppressed, predisposing the woman to intracellular pathogens, such as *Listeria* spp. The decreased gastrointestinal motility of pregnancy may allow for higher concentrations of enteric pathogens to accumulate in the bowel lumen, leading to more severe enteric illness. This, in combination with increased mucosal vascularity, may increase systemic access of enteric pathogens.

The normal physiology of pregnancy can obscure diagnosis in the dysenteric patient. Leukocytosis is common. Uterine enlargement complicates the abdominal examination. Common symptoms of pregnancy can delay recognition of disease or lead to interventions that place the patient at risk of more significant dysenteric disease. For example, decreased bowel motility and laxity of the gastroesophageal sphincter, both caused by elevated estrogen levels, can cause severe gastroesophageal reflux and intestinal bloating and cramping. These symptoms may obscure the early recognition of enteric infections in pregnant women.

Microbiology

The classic bacterial organisms associated with dysenteric disease are *Salmonella* spp. and *Shigella* spp., with the former more commonly associated with bacteremia and a carrier state. Enterohemorrhagic strains of *Escherichia coli* are an increasingly recognized cause of bloody diarrhea and may cause severe dysentery in pregnant women (Chapter 43). In addition, a number of cases of postpartum hemolytic uremic syndrome have had evidence of Shiga toxin-producing *Escherichia coli* infection.

Listeria monocytogenes infection typically causes a febrile diarrheal illness in pregnancy. Pregnancy is the most common independent risk factor for infection with *Listeria* spp., which are invasive, intracellular bacterial pathogens. Most reported cases of listeriosis in otherwise immunocompetent hosts are in pregnant women, particularly in the third trimester. Transplacental infection of the fetus and amnion, with severe outcomes, is well described even with mild maternal illness, making aggressive detection and treatment essential. The patient who has listeriosis may have additional signs and symptoms, including myalgia, pharyngitis or meningitis. She may, unfortunately, present only with a mild febrile diarrheal illness and intrauterine fetal death, which should focus the clinician immediately on *Listeria* spp. (Chapter 63).

Campylobacter spp. are increasingly common agents of diarrheal illness that can afflict patients by multiple pathogenic mechanisms (Chapter 43). Symptoms are often suggestive of appendicitis, bowel perforation or inflammatory bowel disease. *Campylobacter* spp. have been described as a cause of abortion, chorioamnionitis and perinatal sepsis. *Salmonella* spp. have also been documented to cause transplacental infection causing fetal loss, neonatal sepsis and even episiotomy site infection. These pathogens should be vigorously pursued in pregnant women who have diarrheal illness.

Parasitic infections deserve consideration in the pregnant patient who has diarrhea. *Entamoeba histolytica* may cause severe amebic colitis without typical symptoms of amebic dysentery in pregnant women. *Giardia lamblia*, although not a classic cause of dysentery, is problematic in pregnancy. Achlorhydria and any form of immunodeficiency each enhance risk of infection. Although pregnancy has never been identified as an independent risk factor for giardiasis, the disease may easily be missed in the pregnant patient who has intermittent bouts of gastrointestinal distress. Misdiagnosis can range from psychosomatic illness to hyperemesis gravidarum (Chapter 242). Giardia has not been known to cause intrauterine or fetal infection.

Clinical features

What is most striking about pregnant women with any major illness is how quickly they can become severely ill, making early diagnosis and treatment essential. Pregnant women have at least a 20% greater plasma volume than nonpregnant women, with corresponding requirements for fluid intake. They and their fetuses tolerate fluid losses poorly, whether from diarrhea, fever or the decreased fluid intake that often accompanies enteric illness. Decreased peripheral vascular tone with vasodilatation contributes to a tendency for

postural hypotension or presyncopal symptoms that may develop rapidly.

In the course of any significant infectious illness, particularly one with tissue invasion or associated Gram-negative bacteremia, the previously healthy pregnant woman is at substantial risk of developing pulmonary edema owing to the lowered colloid oncotic pressure of the gravid state. This is true even before rigorous hydration. A high index of suspicion for pulmonary edema is warranted in assessing and managing the pregnant patient with any infection. Her fetus will not tolerate hypoxemia as well as she does.

Many features of dysentery in pregnancy are no different from those in the nonpregnant patient; these include fever, abdominal cramping and bloody diarrhea. In *Shigella*, *Salmonella* and *Campylobacter* enteritis, the abdomen may be so tender that peritonitis is suspected. Peritoneal signs may be difficult to distinguish from chorioamnionitis in pregnancy. Vigilance and serial clinical examinations are essential to ensure prompt and proper diagnosis.

As with any infectious illness in a pregnant patient, infectious diarrhea or dysentery may present as preterm labor. In addition, the fetus may show signs of distress because of decreased uterine blood flow resulting from maternal volume depletion, hypoxemia or other physiologic alterations.

Investigations

When evaluating the pregnant woman who has a dysentery-like illness, it is important to account for normal physiologic changes of pregnancy (Table 186e.1).

Blood cultures may provide the definitive diagnosis in diarrhea caused by *Salmonella* spp. or *Listeria* spp. If the patient is febrile, it is appropriate to culture all potentially infected body fluids, such as urine, stool and even amniotic fluid. Where there is a question of peritonitis

TABLE 186.e-1 -- Normal laboratory findings in pregnancy.

NORMAL LABORATORY FINDINGS IN PREGNANCY				
Test	**Increased**	**Unchanged**	**Decreased**	**Comment**
Hemoglobin and hematocrit			?	Red cell indices unchanged

Leukocyte count	?			
Platelet count		?

Albumin			?	
Creatinine clearance	?			1.5–2 times baseline

or chorioamnionitis as well, amniocentesis is appropriate and is best performed by a qualified obstetrician.

A Gram stain of a stool specimen to look for evidence of mononuclear or polymorphonuclear white blood cells can quickly focus further investigations. Most importantly, bacterial isolates of enteric pathogens should undergo antibiotic susceptibility testing to avoid repeated trials of ineffective multiple antibiotics that lead to unnecessary and potentially injurious drug exposures in pregnant patients.

Ulcerative colitis or colonic Crohn's disease is often diagnosed by a flexible sigmoidoscope examination and biopsy, strategies with no excess risk in pregnancy. Occasionally, radiographic imaging of the abdomen is warranted. Fetal risks of radiation exposure must be weighed carefully against the risk of delayed or inaccurate diagnosis. However, fetal well-being depends on maternal well-being. A pregnant woman should not be denied a potentially life-saving diagnostic intervention, nor should it be delayed on account of her pregnancy.

Management

After an appropriate diagnostic evaluation (Table 186e.2) empiric antimicrobial agents need to be considered. Further, if there is any suspicion of an infection that may be life threatening to the mother or fetus, such as listeriosis, then empiric therapy should be instituted. Precautions should be taken to prevent neonatal infection should a delivery occur at the time of an active maternal infection.

Numerous sources of information are available on the safety of antibiotics in pregnant women. Most readily available is the manufacturer's package insert, which usually includes a 'pregnancy category'. These categories are not always consistently applied. It is therefore wise to seek more detailed information from other sources, such as the online resources that are widely available in medical libraries and hospital pharmacies.

The number of commonly recommended antibiotics for diarrheal diseases is small. None of them are known teratogens. Ampicillin and other ß-lactam antibiotics (with the potential exception of ticarcillin) have a strong record of safety in pregnancy and are best administered in doses at the upper end of the therapeutic range for women in the second and third trimesters owing to altered pharmacokinetics.

Metronidazole is teratogenic in experimental animals and its use in pregnancy is controversial in some settings. Its use is probably warranted when the patient has a severe illness, such as symptomatic amebiasis. Fluoroquinolones are more controversial. As human data are scant, this class of agents is best avoided in pregnant women owing to the risk of arthropathy in the developing fetus, which has been well characterized in animal models. For all potential causes of dysenteric illness where fluoroquinolones are considered first-line therapy, alternative agents exist that have better characterized safety risk profiles in pregnancy. Tetracyclines (which carry the risk of hepatotoxicity and staining of permanent teeth), chloramphenicol (which suppresses bone marrow), and prolonged courses of aminoglycosides (which are ototoxic) are best avoided in pregnancy if possible. Macrolides are generally safe, but even

TABLE 186.e-2 -- Management of the pregnant woman who has dysentery.

2. Fluid and electrolyte replacement
3. Oxygen monitoring
4. Fetal evaluation by an obstetrician
5. Begin diagnostic evaluation
6. Empiric therapy if indicated

erythromycin has been occasionally associated with hypertrophic pyloric stenosis in infancy. Sulfa drugs should be avoided in the third trimester because of the potential increased risk of kernicterus. Trimethoprim-sulfamethoxazole (co-trimoxazole) has been associated in some studies with cleft palate when administered to rats at high doses, and it has the potential for interference with folate metabolism, raising concern about potential neural tube defects in the developing fetus. However, these have not been shown to be significant risks for humans.

The clinician unaccustomed to the uncertainties of prescribing in pregnancy may find little reassurance in such data. Absolute risk from a given agent in a given situation may be minimal, but the anxiety created by the unknown can be substantial. It must be remembered that delay of needed therapy may offer far more risk to the fetus than the therapy itself. Thus, as in the early stages of patient evaluation, the clinician must resist being paralyzed by indecision and the unknown regarding therapies. Rather, it is appropriate and wise to seek additional information. Most important, open and honest discussion of uncertainties with the patient and her obstetrician will serve all parties well.

Chapter 187 - Principles of Anti-infective Therapy

Vito R Iacoviello
Stephen H Zinner

The science of antimicrobial chemotherapy began in the last century, during which time we have witnessed a dramatic reduction in morbidity and mortality due to infections caused by common bacterial agents, only to be presently threatened by the worldwide emergence of antibiotic-resistant bacteria. Antimicrobial resistance limits the usefulness of antimicrobial agents, and careful attention to appropriate antimicrobial use might mitigate the extinction of these life-saving drugs. The past century also saw the introduction of effective chemotherapy directed against fungi and viruses as well as protozoa and parasitic organisms. This chapter focuses on the principles that guide appropriate use as well as an understanding of the mechanisms of action, pharmacokinetics and pharmacodynamics, indications and clinical selection of antimicrobial agents.

ANTIBIOTICS

General principles of antibiotic selection

The selection of appropriate antibiotic therapy depends on a number of important factors. First, antibiotics are useful only for the treatment of bacterial infections, and so general confirmation of the presence of such an infection is critical. The clinical presentation of an obvious pyogenic infection with such features as fever, purulent cough or exudate, shaking chills, tachycardia, diaphoresis and a localized inflammatory site in the chest, abdomen, urinary tract, joint or meninges, or on the skin should prompt appropriate diagnostic tests. These usually include blood cultures and smears and cultures from the clinically obvious infected site. Samples of pus, purulent exudate, cerebrospinal fluid, synovial fluid, urine or other likely infected material should be examined microscopically with a Gram-stained smear. If a predominating pathogen is strongly suggested on this examination, then the choice of antimicrobial agent is facilitated. Appropriate use of bacteriologic cultures and new molecular techniques such as DNA probes and polymerase chain reaction will help in selecting the most appropriate antibiotic and limit antibiotic resistance resulting from the selective pressure of unbridled antibiotic use.

Often, the presence of a bacterial infection is suspected simply on clinical grounds and there is no direct source of pus or other material for culture. In office practice of medicine, many patient encounters are via the telephone and antibiotic selection is often made in the absence of a physical or laboratory examination. Although the majority of these encounters are for viral infections, in those cases where bacterial infection is more probable, a reasonable choice of antimicrobial can be made based on the usual pathogens responsible for the symptoms in question. For example, purulent tonsillitis with fever and tender adenopathy is likely to be caused by *Streptococcus pyogenes*, as is uncomplicated cellulitis on an extremity. A carbuncle or furuncle is often caused by *Staphylococcus aureus* and uncomplicated cystitis with fever or pyelonephritis is usually due to infection with *Escherichia coli* or other enteric Gram-negative bacteria. Other clinical presentations may suggest the presence of *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Mycoplasma pneumoniae* or *Streptococcus pneumoniae*, among others. In these situations it might be possible to select appropriate antibiotics directed against these specific pathogens (Table 187.1). [1] When empiric therapy is prescribed in these situations, the provider must be aware of local susceptibility patterns. Antibiotics that might have sufficed a decade or more ago now may be less effective as a result of increasing antibiotic resistance.

As a general rule, whenever possible appropriate clinical specimens should be obtained to attempt a culture-proven diagnosis so that the most effective antibiotic can be selected for targeted therapy and for the correct duration. Cultures are also important to isolate the infecting organism and determine the presence of antibiotic resistance. Unnecessary use of antibiotics for prophylaxis and for probable nonbacterial infections, as well as excessively prolonged courses for uncomplicated bacterial infections, should be avoided.

Bacteriostasis and bactericidal effects

Antibiotics exert an antibacterial effect that results either in inhibition of bacterial growth (bacteriostasis) or in bacterial killing (bactericidal effect). While not always specific for a given antibiotic and a particular bacterial pathogen, bacteriostatic antibiotics include tetracyclines, sulfonamides, clindamycin and chloramphenicol as examples. However, chloramphenicol is bactericidal against pneumococci, meningococci and *Haemophilus influenzae*. Aminoglycosides, ß-lactams and fluoroquinolones are bactericidal against most susceptible bacterial pathogens. Macrolide and azalide antibiotics may be inhibitory or bactericidal depending on drug concentrations, bacterial inocula and growth rates. [2] Some organisms, notably *Enterococcus* spp., require two agents to effect bacterial killing — a cell-wall-active agent such as a penicillin or glycopeptide plus an aminoglycoside are required for bactericidal activity, although either drug alone might induce an inhibitory or bacteriostatic effect.[3]

Some infections, such as uncomplicated bacterial cystitis, may be adequately treated with antibiotics that inhibit bacterial growth, such as sulfonamides. If bacterial multiplication is arrested, then normal host defenses including micturition and dilution with uninfected urine from the upper urinary tract will help to eradicate the infection. More invasive bacterial infections such as meningitis, bacterial endocarditis, peritonitis and bacteremia are best treated with bactericidal agents. Similarly, host factors might determine the choice of bactericidal versus bacteriostatic agents. In general, in neutropenic patients or patients who have other immune defects, bacterial infections are best treated with bactericidal drugs.[4]

Bactericidal antibiotics differ in the time course of bacterial killing. Some agents, such as cephalosporins, penicillins and penems, show time-dependent killing and produce maximal effect approximately 6–8 hours after exposure. Higher concentrations of antibiotic do not produce a greater bactericidal effect. The percentage of time during a given dosing interval that antibiotic concentration is above the minimal inhibitory concentration for a given organism (time above MIC) is the pharmacodynamic parameter that predicts the effect of time-dependent antibiotics (see below). Other antibiotics such as aminoglycosides and fluoroquinolones produce concentration-dependent killing. With these antibiotics

TABLE 187-1 -- Common clinical sites for bacterial infections in adults, frequently encountered organisms and appropriate antibiotics.

COMMON CLINICAL SITES FOR BACTERIAL INFECTIONS IN ADULTS, FREQUENTLY ENCOUNTERED ORGANISMS AND APPROPRIATE ANTIBIOTICS		
Infection site	**Common bacterial etiology**	**Appropriate antibiotics***
Oropharynx, tonsil	*Streptococcus pyogenes*	Penicillin V ×10 days, azithromycin, second-generation cephalosporin, clindamycin, erythromycin, clarithromycin
Acute sinusitis	*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis,* group A streptococcus	Amoxicillin, ampicillin-clavulanate, cefpodoxime, cefuroxime axetil, cefdinir, fluoroquinolone
Acute exacerbation of chronic bronchitis	*S. pneumoniae*, *H. influenzae*, *M. catarrhalis*	Mild: amoxicillin, doxycycline, trimethoprim-sulfamethoxazole, oral cephalosporin
		Severe: ampicillin-clavulanate, azithromycin, oral cephalosporin, levofloxacin, gatifloxacin, moxifloxacin
Pneumonia, community-acquired, smoker	*S. pneumoniae*, *H. influenzae*, *M. catarrhalis*	Outpatient: azithromycin, fluoroquinolone, second-generation cephalosporin
Pneumonia, community-acquired, non-smoker	*M. pneumoniae*, *Chlamydia pneumoniae*, *S. pneumoniae*	As above
Pneumonia, community-acquired	As above	Inpatient: third-generation cephalosporin, plus erythromycin or azithromycin, fluoroquinolone
Urinary tract infection, uncomplicated cystitis	Enterobacteriaceae	Trimethoprim-sulfamethoxazole, trimethoprim, fluoroquinolone
Pyelonephritis	Enterobacteriaceae, *Enterococcus* sp.	Fluoroquinolone, ampicillin plus gentamicin, third-generation cephalosporin, ticarcillin-clavulanate, ampicillin-sulbactam, piperacillin-tazobactam
Urethritis, gonococcal	*Neisseria gonorrhoeae*	Ceftriaxone, cefixime, ciprofloxacin, ofloxacin
Urethritis, non-gonococcal	*Chlamydia* sp., *Mycoplasma hominis*, *Ureaplasma* sp.	Doxycycline, azithromycin
Pelvic inflammatory disease	*N. gonorrhoeae*, *Chlamydia* sp., *Bacteroides* sp., Enterobacteriaceae, *Streptococcus* sp.	Ofloxacin or levofloxacin plus metronidazole, ceftriaxone plus doxycycline, cefotetan or cefoxitin plus doxycycline, ampicillin-sulbactam plus doxycycline

Prostatitis, <35 years old	*N. gonorrhoeae*, *Chlamydia* sp.	Ofloxacin, ceftriaxone plus doxycycline
Prostatitis, >35 years old	Enterobacteriaceae	Fluoroquinolone, trimethoprim-sulfamethoxazole
Gastroenteritis	*Shigella* sp. *Salmonella* sp., *Campylobacter* sp., *Escherichia coli* 0157H7	Fluoroquinolone
Cholecystitis	Enterobacteriaceae, enterococci, anaerobes	Ampicillin-sulbactam, piperacillin-tazobactam, imipenem, meropenem
Diverticulitis	Enterobacteriaceae, anaerobes, enterococci	Ampicillin-sulbactam, piperacillin-tazobactam, imipenem, meropenem, metronidazole plus fluoroquinolone
Spontaneous bacterial peritonitis	Enterobacteriaceae, *S. pneumoniae*	Cefotaxime, ceftriaxone, ticarcillin-clavulanate, piperacillin-tazobactam, ampicillin-sulbactam
Cellulitis	Group A streptococcus, *Staphylococcus aureus*	Nafcillin, oxacillin, first-generation cephalosporin, erythromycin, ampicillin-clavulanate
Septic arthritis, monoarticular, sexually active	*N. gonorrhoeae*	Ceftriaxone, cefotaxime, ceftizoxime
Septic arthritis, monoarticular, not sexually active	*S. aureus*, *Streptococcus* sp., Gram-negative rod	Nafcillin or oxacillin plus third-generation cephalosporin or ciprofloxacin
Septic arthritis, prosthetic	*Staphylococcus epidermidis*, *S. aureus*, Enterobacteriaceae, *Pseudomonas* sp.	Vancomycin plus ciprofloxacin or aztreonam, or ceftazidime or cefepime
Osteomyelitis	*S. aureus*	Nafcillin, oxacillin, first-generation cephalosporin, vancomycin
Meningitis	*S. pneumoniae*, *N. meningitidis*	Ceftriaxone ± vancomycin
Endocarditis, native valve	*Viridans* streptococcus, other streptococcal species, enterococci, staphylococci	Penicillin or ampicillin, plus nafcillin-oxacillin, plus gentamicin; vancomycin plus gentamicin
Endocarditis, prosthetic valve	*S. epidermidis*, *S. aureus*	Vancomycin plus gentamicin ± rifampin
This table is not intended to be all-inclusive. Specific infections are considered in detail in other chapters.		

* This is a general overview, the choice of antibiotics must consider the resistance pattern in any given geographic area (e.g., penicillin and macrolide resistance in *S. pneumoniae*; ampicillin and trimethoprim-sulfamethoxazole resistance among *E. coli*), as well as adjustments based on the identified etiologic agent and susceptibility testing.

higher concentrations produce more rapid and more complete bacterial killing. The ratio of maximal drug concentration to MIC (C_{max} /MIC) and the ratio of the area under the concentration-time curve (AUC) to MIC (AUC/MIC) are pharmacodynamic predictors of the effect of concentration-dependent antibiotics. The clinical significance of these differences is not clear, primarily because clinical trials are usually designed to test different doses rather than different dosing intervals.[5]

Postantibiotic effects

Bacterial growth may be inhibited following exposure to an antibiotic even after the drug concentration has fallen far below the MIC. This is

known as the postantibiotic effect (PAE) and is determined in vitro by observing bacterial growth after the drug has been removed. Animal models have been described to measure PAE in vivo.[6] Postantibiotic effects vary with different drugs and micro-organisms. For example, prolonged PAEs have been reported after aminoglycoside or fluoroquinolone exposure to Gram-negative rods, whereas most ß-lactam antibiotics exhibit shorter PAEs. It has been reported that PAEs in animal models may be longer than those measured in vitro.[6] Postantibiotic leukocyte enhancement (PALE) considers enhanced white blood cell killing of organisms that have just been exposed to antibiotic. It can add to the inherent PAE of a given drug-organism pair. Both PAE and PALE contribute to the dosing interval; drugs exhibiting prolonged PAEs may be dosed less frequently.

Antibiotic resistance

Bacteria have evolved complex mechanisms to resist the action of antibiotics. The mechanisms are discussed in detail in Chapter 189 . Although some organisms (e.g. *Enterococcus gallinarum*) are inherently resistant to some antibiotics, much of the impetus for bacterial resistance is believed to relate to excessive antibiotic use. It is remarkable that such mechanisms exist because widespread antibiotic use has been available for only 60 years. Bacteria may exhibit antibiotic resistance based on the elaboration of an enzyme that renders the antibiotic ineffective. There are a large number of ß-lactamases produced by many different bacteria that hydrolyze the ß-lactam ring of penicillins, cephalosporins and penems.[7] Examples of common ß-lactamases include a penicillinase of *S. aureus*, which is responsible for penicillin-resistant staphylococci, and TEM-1 ß-lactamase in *E. coli*, which mediates ampicillin resistance. Some of these enzymes are responsible for inactivation of broad-spectrum cephalosporins (extended spectrum ß-lactamases (ESBLs) such as OXA-11, OXA-14 in *Pseudomonas aeruginosa*, SHV-2 in *Klebsiella pneumoniae* and TEM 3–29, also in *K. pneumoniae* and other Enterobacteriaceae). ß-Lactamase genes may be found on plasmids and transposons or may be chromosomally mediated. Aminoglycoside antibiotics may be inactivated by bacterial enzymes, which result in phosphorylation, acetylation or nucleotidylation. Transposons or plasmids may transfer these modifying enzymes.

Bacteria can increase the elimination of antibiotics by upregulating efflux mechanisms, as is seen with macrolide antibiotics and Grampositive cocci carrying the *mef* gene.[8] Other bacteria resist antibiotics by altering their cell wall structure to reduce permeability through outer or internal membranes. Alterations in the shape or number of porin channels make it difficult for antibiotics to transfer from the external milieu to the ribosomal targets within the organism. These mechanisms have been found in imipenem resistant *P. aeruginosa* and other Gram-negative rods.[9]

Still other bacteria can modify the target site of antibiotic action rendering the usual binding impossible. Mutations in *gyrA* or *gyrB* genes responsible for DNA gyrase production alter the binding sites for fluoroquinolone antibiotics. Vancomycin resistance in enterococci is mediated by *vanA* or *vanB* genes that encode cell-wall proteins that have altered affinity for the antibiotic. [10] Ribosomal binding sites might be modified by methylation in macrolide-resistant bacteria and mutations in the DNA-dependent RNA polymerase mediate resistance to rifampin (rifampicin). Rifampin resistance may develop rapidly during therapy as a result of one-step bacterial mutations. For this reason, rifampin is rarely used alone except in the four-dose regimen used for meningococcal prophylaxis.

There is growing evidence to suggest that increasing antibiotic use results in increased rates of antibiotic resistance.[11] [12] Global travel, worldwide food distribution, antibiotics in animal feed and other products, as well as poor adherence to infection control techniques enhance the spread of antibiotic resistance.[13] Within hospitals or hospital units, it has been possible to show decreased resistance associated with decreased use of a given antibiotic. However, it has been more difficult to show clearly a reduction in resistance in the community associated with such usage changes.[14] Since antibiotics are found in foods, animal feeds, battleship paints, household products and other sources, this difficulty is not surprising. Common sense dictates that limited and appropriate use of these resources will limit the emergence of resistance. Patients who exhibit no evidence of bacterial infections should be encouraged to accept other therapeutic agents for symptom relief and to decrease their demand for unnecessary antibiotics. Several novel population interventions are in progress to test new approaches to the control of antibiotic resistance in the community.[15] Maximizing infection control efforts within the hospital and global education of physicians and patients will help to reduce the emergence of resistance. Optimizing dosing using pharmacokinetic/pharmacodynamic principles also might be successful. [5]

Although the classic teaching has been to select appropriate older antibiotics to which organisms are susceptible and use the lowest successful dose, in order to minimize the selection of resistant organisms perhaps the use of the most active or most potent antibiotics might be preferred. In the early part of the last century Ehrlich wrote, '*frapper fort et frapper vite*' ('hit hard and hit fast').[16] This might translate today into the use of rapidly bactericidal drugs that achieve concentrations at the infection site high enough to eradicate all the infecting organisms and thus minimize the opportunity for the development of resistance. Whether this approach will result in less antibiotic resistance remains to be tested clinically.

Determinants of the antimicrobial effect

In-vitro and in-vivo techniques

The activity of an antibiotic against an isolated pathogenic bacterium may be expressed using a number of techniques. The most frequently used of these methods are disc diffusion tests (such as the Kirby-Bauer method in North America, or Stokes or the BSAC method in Europe), and the determination of the MIC of the antibiotic. Disc susceptibility testing involves the agar inoculation of an approximated number of bacteria as a 'lawn', with the overlaying of antibiotic-impregnated discs. After overnight incubation, zones of inhibition appear around the discs impregnated with antibiotics to which the organism is susceptible (Fig 187.1a). MIC testing used to be done by agar or broth dilution, but now most laboratories use an ingenious antibiotic-impregnated strip, the E-test (Fig. 187.1b) or other automated techniques. In the USA, the National Committee for Clinical Laboratory Standards (NCCLS) sets 'breakpoints' for the MIC based on the integration of MICs with achievable antibiotic levels in serum and tissues, clinical pharmacology and data from in-vitro and animal models.[17] Typically these results are presented to the clinician as a report of 'sensitive', 'intermediate' or 'resistant'. Determinations of MIC are rough guides to the susceptibility of an isolated pathogen and these values form the usual basis for antibiotic selection. In clinical situations, bacterial concentrations might be larger than those used in the in-vitro determination. Pharmacokinetic considerations are not included in the MIC determination, and pharmacokinetic and pharmacodynamic parameters are important in predicting outcome (see below).

Determinations of MIC might not provide the most complete assessment or optimal prediction of the likely outcome of antibiotic therapy. Minimal inhibitory concentration values correlate with the ability of an antibiotic to inhibit a given bacterium under specified laboratory conditions. In some clinical situations, such as bacterial endocarditis, it is useful to know the ability of an antibiotic to kill the infecting organism. The minimal bactericidal concentration (MBC) can be determined using microtiter plate well or tube dilutions of antibiotic inoculated with a known concentration of the isolated infecting organism. After overnight incubation and subsequent quantitative subculture of the non-turbid wells or tubes, the concentration of drug that produces a

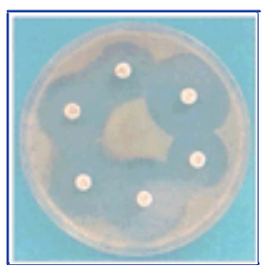

Figure 187-1a A disc diffusion sensitivity plate showing a fully sensitive coliform tested against a typical range of first-line antibiotics. *Courtesy of Dr M Cubbon, Brighton, UK.*

Figure 187-1b An E-test showing a methicillin-sensitive S. *aureus*. The MIC of oxacillin for this strain is 0.25 mg/L, and is obtained by noting the point at which the zone of inhibition intersects with the test strip. *Courtesy of Dr M Cubbon, Brighton, UK.*

99% or 99.9% reduction in the starting inoculum determines the MBC. For research purposes bacterial killing curves are studied using known bacterial inocula and antibiotic concentrations that approximate achievable serum levels. The time course of bacterial killing is determined by sampling and bacterial quantitation. In some clinical situations it is useful to determine the ability of various dilutions of serum sampled after an antibiotic dose to kill a standardized inoculum of the patient's infecting organism. The serum bactericidal assay is performed infrequently today but it has been used to estimate the adequacy of an antibiotic regimen in patients who have bacterial endocarditis or in bacteremic neutropenic patients.[18] [19]

The effects of antibiotic combinations also can be studied in vitro. Various techniques have been introduced to apply increasing concentrations of two antibiotics to known concentrations of bacteria. These include antibiotic-impregnated disc approximations, tube dilution tests, microtiter well methods, replicator plating techniques and bacterial killing concentrations. Experimental animal models have also been used to study the effects of antibiotic combinations.

Antibiotic combinations may be judged as additive when their activities can be summed, synergistic when the effect is greater than the

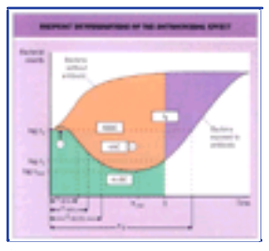

Figure 187-2 End-point determinations of the antimicrobial effect. See text for details. *Redrawn with permission of the American Society for Microbiology from Firsov et al.*[22]

sum of each drug's activity (i.e. the MIC of each drug in the presence of the other is reduced significantly) or antagonistic when the effect of the drugs in combination is less than the sum of each alone. Although several techniques have been described, [20] the study of antibiotic combinations is not routinely performed in clinical microbiology laboratories and this information is rarely available to the clinician.

In-vitro pharmacodynamic models have been introduced in the past two decades to incorporate pharmacokinetic and pharmacodynamic parameters into in-vitro predictions of the antimicrobial effect.[21] These models mimic human antibiotic dosing and can be used to study the relationship of pharmacodynamics to the antimicrobial effect (see below). These models have been used to describe additional end-point determinations of the antimicrobial effect. In the presence of changing concentrations of antibiotic following a simulated dose, several bacterial end points can be used[22] (Fig. 187.2). These include the time to reduction of the starting inoculum by 90%, 99% or 99.9% (t_{90} , t_{99} , $t_{99.9}$); the difference between the starting inoculum and the number of bacteria at the nadir of the killing and regrowth curve (n_0 -n_{min}); the time to the nadir of the kill curve (t_{min}), n_{min} itself; the viable count at the end of the usual dosing interval, t (n_t); and several integral end points that reflect areas above or below the bacterial time curve. The integral end points may be related to the dosing interval, t, such as the area under the bacterial curve (AUBC), the area above the curve (AAC) or the area between the curves in the presence and absence of antibiotic (ABBC); or the area may extend beyond the dosing interval and reflect the area between the control growth curve and the curve in the presence of a simulated antibiotic dose (intensity of the effect, I_E).[23] Of these, I_E has been shown most comprehensively to reflect the antimicrobial effect in in-vitro dynamic models.

Animal models

A variety of animal models have been developed and used to study optimal dosing and scheduling of antibiotics as well as antimicrobial pharmacodynamics. Animal and human pharmacokinetics differ significantly, especially in small animals. Although these models are rarely used clinically, they are quite important in the preclinical evaluation of antimicrobials. Specific models might be particularly useful in developing appropriate therapeutic regimens for bacterial endocarditis or meningitis, for example. In the endocarditis model, New Zealand rabbits are used and an intravascular catheter is inserted to cross the heart valve.[24] The catheter remains in place and organisms are introduced intravenously to establish typical bacterial vegetations similar to those that occur in clinical endocarditis. Meningitis models have been described in many animal systems and usually involve a stereotactic injection of bacteria directly into the

cerebrospinal fluid.[25] Other models have been developed for peritonitis and intra-abdominal abscess, pyelonephritis, pneumonia and osteomyelitis. The neutropenic

mouse thigh infection model of Craig and colleagues has been particularly helpful in correlating pharmacodynamic parameters with outcome. [26]

Antibiotic pharmacology

As with all drugs, pharmacologic considerations aid in the appropriate selection of antibiotics. Antibiotics may be administered orally or intravenously (and less often via the intramuscular route). Oral antibiotics must be absorbed via the gastrointestinal tract. Bioavailability, *F*, refers to 'the fraction of the administered dose that is absorbed intact'. [27] The bioavailability of intravenously administered antibiotics is 100%. The bioavailability of orally administered antibiotics is dependent on absorption across the gastrointestinal tract and ranges from 20% for sulfasalazine to up to 100% for sulfadiazine, ciprofloxacin, nitrofurantoin and cefaclor, for example. To be effective at the site of infection, antibiotics must be well distributed in the tissues. In general, lipophilic agents (e.g. chloramphenicol) and uncharged or nonpolar drugs (e.g. fluoroquinolones) are able to cross biologic membranes and achieve effective concentrations in tissues. The apparent volume of distribution of an antibiotic, V_d, is calculated by dose/plasma concentration and may reflect the ability of the drug to enter inflammatory cells and tissues. Distribution is affected by the protein binding of the drug in plasma and, in general, very highly bound drugs (e.g. >95%) may not cross biologic membranes as well as less highly bound drugs. However, as most of this binding to albumin and other plasma proteins is in reversible equilibrium, the clinical significance of protein binding remains confusing. In general, very highly protein bound antibiotics can be expected to penetrate into cerebrospinal fluid and abscesses less than drugs with lower degrees of protein binding. [28]

TABLE 187-2 -- Pharmacokinetic and pharmacodynamic parameters that affect antibiotic therapy.

PHARMACOKINETIC AND PHARMACODYNAMIC PARAMETERS THAT AFFECT ANTIBIOTIC THERAPY		
Parameters		**Details**
Pharmacokinetic	*F*	Bioavailability, fraction of the administered dose absorbed intact; intravenous drugs have 100% bioavailability; oral drugs vary with absorption and are usually less bioavailable than intravenous forms
	C_{max}	Maximal serum concentration after single or multiple doses
	t_{max}	Time after drug administration to reach C_{max}
	$t_{½\ elim}$	Elimination half-life; time to reduce peak serum concentration by 50%
	AUC	Area under the concentration-time curve (relates to total drug exposure following a dose)
Pharmacodynamic	C_{max} /MIC, Peak/MIC	Ratio of the maximum serum concentration to the MIC (predicts activity of concentration dependent bactericidal antibiotics)
	AUC/MIC	Ratio of the area under the concentration-time curve to the MIC (also predicts activity of concentration dependent bactericidal antibiotics)
	t>MIC, t_{eff}	Time above the MIC; the duration of time during a dosing interval that serum concentration remains above the MIC (predicts activity of time-dependent bactericidal antibiotics)

Metabolism is another important consideration in the selection of antibiotics. A rapidly metabolized drug that is excreted by the kidney in an inactive form would not be an appropriate choice for the treatment of urinary tract infections, for example. Some drugs are metabolized in the liver by the cytochrome P450 system and as such may interact with other drugs metabolized via this system. Metabolism is a critical determinant of drug interactions and these must be understood and appreciated when patients receive multiple pharmaceutical interventions.

A clear understanding of the elimination half-life and excretion of antibiotics also influences selection. Drugs with a short half-life are rapidly eliminated and need more frequent administration to produce high levels of the antibiotic at the site of infection. Drugs with a longer half-life are often more convenient because single daily dosing is usually effective. Drugs that are primarily excreted via the kidney often need dose adjustment in the face of renal insufficiency; drugs primarily excreted via the hepatic and biliary system might accumulate inappropriately in patients who have hepatic insufficiency. Although antibiotics are not usually thought to be highly toxic drugs, some concentration-related adverse effects are likely to be more prevalent in the face of dysfunctional organs of excretion.

The pharmacokinetic variables that are most useful in antibiotic chemotherapy include bioavailability (*F*), maximal serum concentration (C_{max}), time to reach C_{max} (t_{max}), elimination half-life ($t_{½}$) and area under the drug concentration curve following a dose (AUC; Table 187.2).

Recently, pharmacodynamics has been popularized in the antibiotic field. Antibiotic pharmacodynamics can be described as the interrelations between pharmacokinetics (drug concentrations) and the antibacterial effects that result from these concentrations in, for instance, serum, tissues and body fluids. The most useful pharmacodynamic variables (see Table 187.2) include the ratio of the area under the 24-hour concentration-time curve to the MIC (AUC_{24} /MIC), the ratio of C_{max} to MIC (Peak/MIC) and the time during a given dosing interval that the serum concentration remains above the MIC (time above MIC, *t*>MIC, t_{eff}).

Pharmacokinetic/pharmacodynamic (PK/PD) variables are of increasing interest as possible predictors of the antimicrobial effect. Such parameters may be exploited to develop optimal dosing regimens, although there are relatively few clinical studies to test the ability of these parameters to predict outcome. One such clinical study suggested that C_{max} /MIC was useful in predicting outcome of levofloxacin treatment for several different infections. [29]

Other in-vitro and clinical studies suggest that PK/PD parameters might be exploited to minimize the emergence of resistant organisms during exposure or therapy. It remains to be determined whether PK/PD-based antibiotic prescribing and dosing can reduce adverse effects and costs while providing an optimal antibacterial effect.

Antibiotics in general are very safe drugs. However, adverse effects of antibiotics do occur and include gastrointestinal events (nausea, vomiting, diarrhea, antibiotic-associated colitis, pseudomembranous colitis), cutaneous reactions (rash, urticaria, Stevens-Johnson Syndrome), neurologic symptoms (agitation, insomnia, seizures), hepatic dysfunction, renal insufficiency, anemia, agranulocytosis and thrombocytopenia, among others. Some adverse events associated with antibiotics are idiosyncratic or hypersensitivity reactions and some are related to their concentration in serum and tissues. For example, prolongation of the QT_c interval with macrolide and other antibiotics might increase at higher drug concentrations as a result of either increased dose or decreased elimination. [30] Some hepatic toxicities are also related to dose and duration, and toxicity in general is dose-limiting for many antibiotics. Careful attention to appropriate use and dosing should reduce antibiotic-associated toxicity.

Choice of antibiotics for empiric therapy

Combinations: monotherapy versus multiple antibiotics

A single antibiotic is usually sufficient for the treatment of most bacterial infections. In some situations more than one antibiotic is prescribed. Most commonly two or more antibiotics are administered because the diagnosis is not obvious or not clearly established. Antibiotics are often combined in presumed mixed bacterial infections such as intra-abdominal abscesses or peritonitis, where antibiotics with activity against facultative Gram-negative rods, such as ampicillin plus gentamicin or a quinolone or third-generation cephalosporin, are combined with an antianaerobic agent such as metronidazole or clindamycin. For some specified infections such as pelvic inflammatory disease, multiple organisms, including *C. trachomatis*, *N. gonorrhoeae* and facultative and strict anaerobic Gram-negative rods, are assumed to be present and in fact might not be cultured. Antibiotic combinations are often prescribed for this infection.

Early studies of carbenicillin plus aminoglycosides in severe *Pseudomonas aeruginosa* infections suggested that these two antibiotics were more effective than either alone; this has led to the routine use of two antibiotics for infections caused by this organism. This concept has recently been challenged, but the importance of high concentrations of bactericidal antibiotics remains cogent. [31] Optimal results for pseudomonal infections might require two active agents. Even more clearly, bacteremic infections caused by *Enterococcus faecalis* are best treated with a combination of a cell-wall-active penicillin or glycopeptide plus an aminoglycoside (assuming that high-level resistance to one or both agents is not present). [32] Some studies of bacterial endocarditis caused by viridans streptococci and bacteremia caused by *Staphylococcus aureus* suggest better outcomes with combination therapy.

Antibiotics also might be combined to minimize or prevent the selection of resistant organisms. This is most clearly demonstrated with *Mycobacterium tuberculosis*, where use of two or more anti-mycobacterial agents (depending on the likely inoculum size) reduces the likelihood of selecting for resistant bacteria. Whether this also applies to pyogenic bacteria is not definitively proven.

Antibiotic combinations (e.g. an aminoglycoside and an anti-pseudomonal ß-lactam) were initially recommended for the treatment of presumed bacterial infections in febrile, neutropenic patients. Prolonged and profound granulocytopenia places these immunocompromised patients at particular risk for Gram-negative rod bacteremia. Although combination therapy is still considered acceptable for these patients, several potent antibiotics (such as imipenem, meropenem, cefepime and ceftazidime) are currently acceptable for single-agent empiric therapy.[4]

Duration of therapy

For most acute bacterial infections in the respiratory or urinary tracts, the duration of therapy can be short (e.g. from 3 to 7 or 10 days). In the early antibiotic era, patients who had pneumococcal pneumonia were successfully treated with courses of antibiotics that lasted for 3–5 days after the patient became afebrile. Modern therapy duration may be inappropriately based on standardized clinical trials needed for drug registration purposes. There is a trend now for shorter courses of treatment for some respiratory infections such as acute bacterial exacerbations of chronic bronchitis. Rigid adherence to 10- to 14-day treatment regimens for many acute infections is probably not necessary and may contribute to excess antibiotic use, increased adverse effects and complications of therapy, as well as the emergence of resistant organisms.

Subacute and more chronic infections such as endocarditis and osteomyelitis are treated for prescribed lengths of time. Six weeks of intravenous therapy is often required for bacterial osteomyelitis and 4 weeks is usually prescribed for patients who have bacterial endocarditis (although 2-week treatment courses are clearly effective for certain organisms, e.g. viridans streptococci; see Chapter 52 & Chapter 59).

Route of administration

The intravenous administration of antibiotics is preferred for patients who are critically ill or bacteremic, or in whom gastrointestinal absorption cannot be guaranteed. For most acute bacterial infections (e.g. pneumonia, pyelonephritis) it is possible to switch to oral therapy with the same or comparable agents when the patient has stabilized and vital signs are returning toward normal.[33] Fluoroquinolone antibiotics are particularly useful in these situations, assuming that the infecting organism is susceptible. Home administration of intravenous antibiotics is now entirely possible and preferable for long-term treatment with these drugs for infections such as endocarditis and osteomyelitis, where high concentrations at the site of infection are desired.

Topical use of antibiotics is limited to specific infections. [34] Although minor cutaneous infections might respond to topical therapy, some evidence suggests that sensitization via this route is frequent for some agents. Excessive use of topical antibiotics may lead to increased bacterial resistance. Topical administration may be employed to treat bacterial conjunctivitis with ciprofloxacin, trachoma with tetracycline, and acne with clindamycin, tetracycline or erythromycin, for example. Topical aminoglycosides have been useful in the prophylaxis and treatment of burns and burn wound infection (see Chapter 85). Topical mupirocin (its only formulation) is used to treat impetigo and nasal carriage of *S. aureus*. Polymyxin and neomycin are used in topical therapy of minor wound infections. Adverse effects seen with intravenous or oral administration of the same drug can certainly occur following topical therapy.

Cost, restricted use policy and formulary constraints

Antibiotics comprise a significant portion of the pharmacy budget for most hospitals and managed care plans. The appropriate use of first-line agents for proven or strongly suggested bacterial infections should help to control these costs. The cost to pharmaceutical companies to develop a new antibiotic may be as high as US$800,000,000. Increasing regulatory requirements and safety concerns clearly contribute to these costs. Incentives for continued development of antibiotics in the face of rising rates of bacterial resistance are clear societal needs, and these factors also contribute to the high cost of these drugs.

Some hospitals adopt policies to restrict use of certain antibiotics to infectious disease clinicians or other designated experts. Although these schemes have been shown to reduce costs and improve appropriate antibiotic use, their success is tied to continual monitoring and control of antibiotic prescribing.[35] Most successful programs include physician education to sustain their impact. Many managed care organizations limit their formularies to less expensive and older drugs. The impact of these policies on clinical outcome and resistance development is under study.[15]

Antibiotic use in special populations

Special considerations modify the use of antibiotics at the extremes of age, in the presence of renal or hepatic insufficiency, in pregnancy and in the presence of foreign bodies. In neonates and infants less than 1 year of age, dosing is often based on the body mass index. In elderly patients the fever and leukocytosis associated with bacterial infections may be blunted or absent, making diagnosis more problematic. Antibiotic dosing must consider the aging-related slight decline in gastrointestinal absorption and decreases in renal function associated with nephron loss. Drug interactions are particularly worrisome in the elderly because of the large number of drugs that such patients may be taking. QT_c prolongation might be enhanced when some antibiotics are combined with other classes of drugs known to increase the QT_c interval. Metronidazole may interact with warfarin,

resulting in increased effect of the anticoagulant. Loop diuretics may increase aminoglycoside-related ototoxicity. Adherence to drug regimens should be stressed as elderly patients may find the addition of any new agent confusing, even for a short course of therapy. Side effects are also more common in elderly patients. [36]

The dosing of some antibiotics, notably those primarily excreted by the kidney, must be reduced in the presence of renal insufficiency. The more severe the renal failure the more the dose or its interval must be altered. Patients on hemodialysis or peritoneal dialysis need special dosing modifications to supplement antibiotics (usually those of low molecular weight) that are removed during the procedures. For some drugs, such as aminoglycosides, the dosing interval can be extended and/or the dose itself reduced according to the estimated creatinine clearance. Some adverse effects of frequently used antibiotics are increased in patients who have renal insufficiency. For example, seizures may be seen with usual dosing of imipenem or quinolones, and hearing loss may occur with erythromycin. Several tables have been published to guide the appropriate dosing of antibiotics in patients who have renal insufficiency. [1] [37]

In the face of hepatic failure additional considerations affect the choice or dose of antibiotic. Drugs excreted by the liver such as metronidazole, tetracycline and clindamycin often need dose adjustment in hepatic failure. In the presence of large-volume ascites, some antibiotics might need to be administered in a larger dose to ensure appropriate concentrations at the site of infection.

Antibiotic selection in pregnancy is determined by the specific infections under treatment. Penicillins and cephalosporins are generally considered safe in pregnant women, and aminoglycosides also can be used if needed. Trimethoprim-sulfamethoxazole and other sulfonamides may be used in pregnancy but not in the last few months because of their effect on bilirubin conjugation and the risk of kernicterus in neonates. Fluoroquinolones, tetracyclines and chloramphenicol should not be used in pregnancy.

The treatment of infections in the presence of foreign bodies such as intravascular or bladder catheters and orthopedic prostheses is covered elsewhere (see Chapters 53). As foreign bodies may be coated with a microbiologic biofilm, agents that reduce bacterial mucus, slime or biofilm production, even if they are not bacteriostatic or bactericidal for the infecting organisms, might be useful in conjunction with other antibacterial agents. Macrolides and fluoroquinolones have been shown to reduce bacterial mucoid production.[38] In most cases, infected foreign bodies need to be removed to resolve the infection completely.

Prophylaxis

Surgical prophylaxis is discussed in Chapter 190 . Medical prophylaxis against bacterial infections is limited to specific indications, such as the prevention of *S. pyogenes* infection in patients who have known rheumatic fever or to reduce the possibility of bacterial endocarditis in patients who have known valvular cardiac disease and are undergoing dental, gastrointestinal or genitourinary procedures. Prophylaxis against traveler's diarrhea is not usually recommended (but empiric therapy is preferred, see Chapter 143). Inappropriate or excessive use of prophylactic antibiotics is likely to contribute to the increased incidence of antibiotic resistance.

New targets for antibiotics

With increasing antibiotic resistance and few new antibiotics in the pharmaceutical pipeline, it is urgent to begin to identify new bacterial targets and novel approaches to antimicrobial chemotherapy. Several lines of work have begun to find new inhibitors of bacterial efflux pumps, biofilm production, essential bacterial protein secretion, membrane proteins, signaling systems, DNA replication and bacterial cell division. Identification of bacterial genomes also has revealed important potential targets and functional genomics should allow opportunities for new drug development. [39] Recent work on quorum sensing by bacteria also might provide new chemotherapy targets.[40]

ANTIFUNGAL THERAPY

Health care providers are faced with increasing numbers of patients who are susceptible to severe, invasive fungal infections. Multiple factors play a role, including chemotherapy-induced neutropenia, immunosuppression secondary to chronic infections such as HIV, and immunosuppression related to organ transplantation, as well as exposure to lengthy courses of broad-spectrum antibiotics. These agents are used to treat documented infections and increasingly for prophylaxis of invasive fungal infection in these at-risk patients. Prior to the late 1970s only amphotericin B and flucytosine were available for the treatment of serious fungal infections. In the past two decades many new agents have been developed and approved, and new classes of antifungals are now entering clinical trials. Treatment of specific fungal infections is covered in detail in Chapter 111 , Chapter 126 and Chapter 237 Chapter 238 Chapter 239 Chapter 240 Chapter 241 ; here the classes of antifungal agents, mechanisms of action and the emerging topics of antifungal pharmacodynamics and resistance are outlined briefly.

Amphotericin B, a polyene, and its newer formulations remain the mainstay of antifungal therapy for severe infection. The mechanisms of action primarily include binding to ergosterol, the principal sterol in the fungal cell membrane, leading to permeability changes and cell death. Secondary actions include the generation of oxidative metabolites and free radicals, as well as stimulation of host macrophages. The newer formulations (lipid complex, colloidal dispersion, cholesteryl complex and liposomal amphotericin B) offer some reduced toxicity and the ability to deliver higher drug concentrations. Amphotericin B is active against a wide variety of fungi; it is fungicidal against many of these but fungistatic against others. Some fungi (*Pseudallescheria boydii*, *Fusarium* spp., *Trichosporon* spp. and some *Candida* spp.) demonstrate reduced amphotericin B susceptibility, while others have developed frank resistance.[41]

Nystatin, a tetraene-diene, was the first antifungal polyene. It has broad antifungal activity similar to that of amphotericin B. Nontopical formulations are presently being investigated and may prove to be efficacious, given this agent's fungicidal properties.

Flucytosine, a low-molecular-weight, synthetic pyrimidine analogue, is taken up by the fungal cell wall and, after enzymatic modification, causes RNA miscoding and inhibition of DNA synthesis. Flucytosine has activity against *Candida* spp., *Cryptococcus neoformans*, *Saccharomyces cerevisiae* and some dematiaceous models. At clinically achievable doses it is fungistatic. When flucytosine is used as monotherapy, resistance emerges rapidly and thus it is usually used in combination with amphotericin B or fluconazole. Resistance can emerge from mutations that affect production of uridine monophosphate pyrophosphorylase, cytosine permease or cytosine deaminase, or increased pyrimidine production. Toxicity includes bone marrow suppression, which is most evident when used in combination with amphotericin B. This occurs as a consequence of the high rate of renal impairment with amphotericin B and subsequent high flucytosine levels. Recent pharmacokinetic studies have suggested that flucytosine may be safer and more effective at lower and less frequent dosing.[42]

As a class the azoles act by inhibiting fungal cytochrome-P450-dependent conversion of lanosterol to ergosterol, ultimately leading to altered cell membrane properties and inhibition of cell growth. The imidazoles clotrimazole, ketoconazole and miconazole have two nitrogens in the five-member ring whereas the triazoles have three. For many years ketoconazole was the only available oral agent for the treatment of systemic fungal infections. Because of difficulty with absorption, substantial toxicity and disappointing treatment

TABLE 187-3 -- Antiviral drugs: non-HIV.

ANTIVIRAL DRUGS: NON-HIV				
Agent	**Mechanism of action**	**Antiviral activity**	**Mechanism of resistance**	**Toxicity/side effects**
Aciclovir	Inhibits DNA polymerase, chain terminator. Requires viral thymidine kinase and cellular enzymes	HSV-1, HSV-2, VZV, CMV (much less activity), EBV (in vitro)	Mutations in thymidine kinase (more common) and mutations in DNA polymerase	Intravenous: phlebitis, crystalline nephropathy. Confusion, delirium, lethargy, tremors, nausea, vomiting, lightheadedness, diaphoresis, rash
Adefovir	Nucleotide analogue	HBV	As of 2000, no mutations	Renal impairment at >30mg q24h
Amantadine	Inhibits transmembrane protein M2, reduced uncoating of viral genome	Influenza A	Point mutation in gene encoding transmembrane domain M2 protein	Nervousness, anxiety, lightheadedness, confusion, insomnia
Cidofovir	Acyclic nucleoside phosphonate (does not require a virus-specific thymidine kinase)	HSV-1, HSV-2, VZV, EBV, CMV	Mutations in DNA polymerase	Severe nephrotoxicity, neutropenia, ocular hypotony, metabolic acidosis. Carcinogenic, teratogenic
Famciclovir	Prodrug to penciclovir	See penciclovir	See penciclovir	Headache, nausea, diarrhea, vomiting, pruritus, LFT abnormalities
Fomivirsen (intravitreal)	Antisense oligonucleotide	CMV	In-vivo resistance not seen	Iritis, vitreitis, increased ocular pressures, visual changes
Foscarnet	Noncompetitive inhibitor of viral DNA polymerase (does not require thymidine kinase)	HSV-1, HSV-2, VZV, CMV, EBV, influenza A, influenza B, HBV, HIV	In CMV, single mutation in conserved region of DNA polymerase	Renal impairment, electrolyte disturbances, seizures, anemia, neutropenia, fever, nausea, vomiting, diarrhea, headache
Ganciclovir	Inhibitor of DNA polymerase, also competitive inhibitor of deoxyguanosine triphosphate (monophosphorylation by infection-induced kinases in HSV and VZV, and viral-encoded phosphotransferase in CMV-infected cells)	HSV-1, HSV-2, VZV, CMV, EBV, HHV-6	One or more point mutations in UL97, mutations in CMV DNA polymerase	Bone marrow suppression, fever, rash, increased LFTs, nausea, vomiting, eosinophilia, seizures, confusion, encephalopathy

Interferon-a	Induces changes in infected/exposed cells to promote resistance to infecting virus. Produces proteins that inhibit RNA synthesis, cleaves cellular and viral DNA, inhibits messenger RNA, alters cell membranes, inhibits release of replicated virions	Papillomavirus, HCV, HBV, HDV, HIV	Fever, headache, chills, arthralgias, myalgias, fatigue, dizziness, neutropenia, thrombocytopenia, somnolence, depression, cognitive changes, suicidal ideation, increased LFTs, altered thyroid function, nausea, vomiting, diarrhea	
Lamivudine	Competitively inhibits viral reverse transcriptase, terminates proviral DNA chain extension	HBV, HIV	Mutations at YMDD locus (conserved domain reverse transcriptase)	Low-dose equivalent to placebo. High dose: headache, fatigue, insomnia, myalgias, arthralgias, diarrhea, rash, lactic acidosis, hepatomegaly
Lobucavir	Guanosine analogue	HBV	Mild anorexia, dizziness, abdominal pain. Clinical testing halted with concerns for carcinogenesis	
Oseltamivir	Neuraminidase inhibitor	Influenza A, influenza B	Mutation in viral neuraminidase and viral hemagglutinin	Nausea, vomiting
Penciclovir (topical)	Incorporated into DNA molecule	HSV-1, HSV-2, VZV, EBV (less so), CMV (less so), HBV (in vitro)	Mutations in thymidine kinase and mutations in DNA polymerase	Topical same as placebo
Pleconaril	Capsid binding compound prevents viral attachment to cells and/or release of viral RNA from the capsid	Picornaviruses (enterovirus, rhinovirus)	Observed in vitro but clinical significance not clear	Crystalluria
Ribavirin	Guanosine analogue, three possible mechanisms: competitive inhibition of host enzymes, inhibition of viral RNA polymerase complex, inhibition of messenger RNA formation	RSV, HCV (clinically); but also influenza A, influenza B, mumps, measles, parainfluenza, herpesviruses, togavirus, bunyavirus, adenovirus, Coxsackie virus, hemorrhagic fever virus, HAV, HBC, Lassa fever virus, Hantaan virus, ?Hantavirus	Anemia, hyperbilirubinemia, elevated uric acid, nausea, headache, lethargy. Teratogenic, mutagenic, embryotoxic, gonadotoxic	
Rimantadine	Inhibits transmembrane protein M2, reduced uncoating of viral genome	Influenza A	Point mutation in gene encoding transmembrane domain M2 protein	Nervousness, anxiety, lightheadedness, confusion, insomnia (much less so than amantadine)
Trifluridine (topical)	Pyrimidine nucleoside	HSV-1, HSV-2, CMV, vaccinia, some adenoviruses		
Valganciclovir	Metabolized to ganciclovir	See ganciclovir	See ganciclovir	Bone marrow suppression, fever, nausea, headache, vomiting, insomnia, abdominal pain, peripheral neuropathy, paresthesias, potential carcinogen
Zanamivir (aerosolized/intranasal)	Neuraminidase inhibitor	Influenza A, influenza B	Mutations in viral neuraminidase and viral hemagglutinin	Nasal, throat discomfort, bronchospasm in asthmatics
CMV, cytomegalovirus; EBV, Epstein-Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HHV, human herpesvirus; HSV, herpes simplex virus; LFT, liver function test; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.				

results in immunocompromised patients, it has largely been replaced by the triazoles.

The triazoles are less susceptible to degradation and have greater target specificity, increased potency and an expanded activity spectrum. The first generation triazoles fluconazole and itraconazole are active against dermatophytes, *Candida albicans* and some non-*albicans* candidal species; in addition, itraconazole has activity against *Aspergillus* spp. and some dematiaceous molds. Fluconazole is generally fungistatic and itraconazole is both fungicidal and fungistatic depending on the fungal strain. Second-generation triazoles include posaconazole, ravuconazole and the FDA-approved voriconazole. These drugs have enhanced target activity especially against *Aspergillus* spp., specificity and a wide spectrum of activity. Available data show that voriconazole is well tolerated, with rash, fever and visual disturbances reported most frequently. Like the triazoles, these agents also appear to be both fungicidal and fungistatic depending on the specific organism. As a group they have potential for substantial drug-drug interactions with agents metabolized by the cytochrome system.[43]

The echinocandins inhibit the synthesis of 1,3-ß-D-glucan, a polysaccharide in the cell wall of many pathogenic fungi. Glucan fibrils are involved in the maintenance of osmotic integrity of the cell wall as well as playing a role in cell division and growth. Caspofungin, micafungin and anidulafungin all possess potent, broad antifungal activity against *Candida* and *Aspergillus* spp. They are not metabolized through the cytochrome P450 system. In-vitro models have demonstrated both fungicidal and fungistatic properties. Caspofungin has recently been approved by the US Food and Drug Administration (FDA) for the treatment of candidemia and invasive aspergillosis in patients refractory to or intolerant of other therapies.

Sordarins exert their antifungal effect by selective inhibition of fungal protein synthesis by interacting with translocation elongation factor 2 and the large ribosomal subunit stalk rpP0. In vitro, they have shown fungicidal activity against *C. albicans*, some non-*albicans* species, *C. neoformans*, as well as some other yeast-like fungi and endemic molds.

There is little doubt that severe invasive fungal infections will continue to be clinically challenging, especially in immunocompromised patients. In addition to minimizing the use of broad-spectrum antibiotics, limiting immunosuppression to the lowest safe doses and protecting HIV-infected patients by judicious use of antiretrovirals, there will still be a need for newer and safer antifungal agents. In addition we need more studies investigating the pharmacodynamics and pharmacokinetics of already available agents in order to offer patients safer and equally, if not more, efficacious treatment options. Readily available and clinically relevant resistance testing would be a major advance in the therapy of these infections.

ANTIVIRAL THERAPY

Specific therapy for viral infections has become possible only recently. The discovery of many potent and effective antiviral drugs as well as marked improvements in diagnostic techniques that allow more rapid identification of viral infections have made effective therapy possible. Although most viral infections are usually self-limiting, others are overwhelming and devastating, with significant morbidity and mortality. Antiviral therapy is now available for herpesviruses, hepatitis C virus (HCV) and hepatitis B virus (HBV), papillomavirus, influenza and HIV, among others. Antiviral drugs share the common principle of being virustatic; they are only active against replicating viruses and do not affect latent virus. Therapeutic approaches to viral infections share very little other common ground. Some infections require monotherapy for very brief periods of time (aciclovir for herpes simplex virus), others require dual therapy for prolonged periods of time (a-interferon/ribavirin for HCV), while others require multiple drug therapy for indefinite periods of time (HIV).[44] Table 187.3 briefly summarizes the antiviral activity, resistance mechanisms and more

common toxicities of the non-HIV antivirals.[44] [45] Chapter 205 to Chapter 207 address specific antiviral agents.

The approaches to treatment of HIV infection are in constant flux. Like other infections, cure is the goal; however, like other viral infections, cure is not possible at this time, although suppression of viral replication and preservation of the immune system are short-term goals of therapy. In less than two decades antiretroviral therapy has emerged as a great success but it remains an enormous challenge.

TABLE 187-4 -- Antiviral drugs: HIV.

ANTIVIRAL DRUGS: HIV		
Agent	**Mechanism of action**	**Toxicity/side effects**
Abacavir	Nucleoside reverse transcriptase inhibitor	Hypersensitivity syndrome, rash, fever, nausea, vomiting, diarrhea, abdominal pain, elevated LFTs
Amprenavir	Protease inhibitor	Nausea, vomiting, diarrhea, rash, oral paresthesias, dysgeusia, mood disorder
Atazanavir	Protease inhibitor	Increased unconjugated bilirubin, gastrointestinal symptoms
DAPD	Nucleoside reverse transcriptase inhibitor	Nausea, vomiting, diarrhea, abdominal pain, hepatitis
Delavirdine	Non-nucleoside reverse transcriptase inhibitor	Rash, headache, Stevens-Johnson syndrome
Didanosine	Nucleoside reverse transcriptase inhibitor	Nausea, vomiting, diarrhea, abdominal pain, peripheral neuropathy, pancreatitis
Efavirenz	Non-nucleoside reverse transcriptase inhibitor	Dizziness, difficulty concentrating, nausea, vomiting, diarrhea, rash, flu-like symptoms
Emtricitabine	Nucleoside reverse transcriptase inhibitor	Nausea, diarrhea, headache
Enfurvirtide	Fusion inhibitor	Injection site inflammation
Hydroxyurea	Potentiates didanosine, may facilitate immune reconstitution	Myelosuppression, stomatitis, leg ulcers
Indinavir	Protease inhibitor	Nephrolithiasis, nausea, dysgeusia, benign hyperbilirubinemia
Interleukin-2	Peripheral expansion of existing $CD4^+$ lymphocytes	Nausea, vomiting, diarrhea, fever, asthenia, pruritus
Lamivudine	Nucleoside reverse transcriptase inhibitor	No significant toxicity, peripheral neuropathy, pancreatitis
Lopinavir	Protease inhibitor	Nausea, asthenia, diarrhea
Nelfinavir	Protease inhibitor	Diarrhea
Nevirapine	Non-nucleoside reverse transcriptase inhibitor	Dizziness, rash, difficulty concentrating, nausea, vomiting, diarrhea, flu-like symptoms
Ritonavir	Protease inhibitor	Dysgeusia, nausea, vomiting, diarrhea, circumoral paresthesias, increased triglycerides, LFTs, CPK and uric acid
Saquinavir	Protease inhibitor	Nausea, vomiting, diarrhea, headache
Stavudine	Nucleoside reverse transcriptase inhibitor	Peripheral neuropathy
Tenofovir	Nucleoside reverse transcriptase inhibitor	Nausea, vomiting, diarrhea, headache, elevated LFTs and CPK
Tipranovir	Protease inhibitor	Nausea, vomiting, diarrhea
Zalcitabine	Nucleoside reverse transcriptase inhibitor	Oral ulcers, peripheral neuropathy, pancreatitis
Zidovudine	Nucleoside reverse transcriptase inhibitor	Anemia, neutropenia, nausea, vomiting, myositis, neuropathy
CPK, creatine phosphokinase; LFT, liver function test		

There is no doubt that antiretroviral therapy has saved lives; however, this has occurred at considerable expense, including morbidity due to immediate side effects and long-term metabolic toxicities, as well as recognition of serious drug-drug interactions and the emergence of highly resistant virus. Much attention has been focused on combination studies, including older work that revealed potential antagonistic antiretroviral combinations. More recent pharmacokinetic and pharmacodynamic studies have revealed drug-drug combinations with reduced toxicity and improved efficacy. Newer agents and new formulations have allowed for simpler therapeutic regimens, which hopefully will add the benefit of improved adherence and consequently decreased resistance. These agents are no longer used only for the treatment of chronically infected patients but also to treat acutely infected patients, to prevent maternal-child transmission and as prophylaxis against infection following sexual exposure or exposure in a health care setting. Table 187.4 briefly outlines the agents used in the treatment of HIV infection. Chapter 139 and Chapter 204 address antiretroviral agents and the therapy of HIV infection in detail.

The list of available agents to combat both HIV and non-HIV viral infections is expanding rapidly. In addition to new agents, the agents already available are being manipulated by using them in combination at lower, less toxic doses against viruses for which they were not initially investigated and stretching their pharmacology to optimize efficacy and minimize toxicity. As with antibiotics, increased use of antiviral agents will lead to resistance, a major impediment that warrants constant attention.

ANTIPARASITIC THERAPY

Parasitic infections are major causes of significant morbidity and mortality worldwide. In developing countries, lack of resources for many basic services has allowed vector-borne illnesses to persist and propagate. In developed countries health care providers are more frequently encountering parasitic infections as a consequence of increased international travel and a growing number of patients immunocompromised by HIV, antineoplastic therapies and chronic medication-induced immunosuppression.

Although new agents have been introduced in recent years, advances in antiparasitic therapy have lagged behind antibacterials, antivirals and antifungals. The reasons for this are multifactorial and include lack of in-depth knowledge of the life cycle and potential targets for many of these organisms, lack of financial incentives for pharmaceutical companies to invest in drug development for infections not frequently encountered in the developed world, and hesitancy to invest the monies needed to pursue FDA approval for drugs already developed.

Antiparasitic drugs can loosely be characterized as antiprotozoal or anthelmintic, although some agents do have activity against both. They are used in the treatment of acute infections and also in chronic infections. Prophylactic use is increasing in international travelers. For many agents the mechanisms of action are incompletely understood, and this is especially true for many antimalarials. Anthelmintic agents can be characterized as inhibitors of metabolic

---

pathways, inhibitors of neuromuscular function or drugs that disrupt reproduction and larval development.[46] [47]

Resistance to antiparasitic therapy is most clearly recognized in the antimalarials. Recent studies have suggested potential resistance mechanisms (p-glycoprotein involved in efflux of the antimalarial) but these explanations are just beginning.[48] Antiparasitic agents are discussed in detail in Chapter 209 , and parasites and the treatment of parasitic infections are covered throughout the text under organ-specific infections, Infections in the Immunocompromised Host, HIV and AIDS, Geographic and Travel Medicine, and Clinical Microbiology.

SUMMARY

Antimicrobial therapy is one of the great advances of the last century. Currently, there are many classes of antimicrobials with activity against most agents of infection, including bacteria and mycobacteria, rickettsiae, fungi, viruses and parasites. Appropriate use of these drugs should include applications of their pharmacology to specifically diagnosed or suspected infections. Doses should be adequate to ensure eradication of the pathogens when possible and the duration of treatment should follow standard regimens based on carefully performed clinical trials. Physicians should be encouraged to use these agents sparingly and only for their proven indications. Excessively long courses, inappropriate prophylactic use, unnecessary combinations and failure to consider the impact of each prescription on the bacterial ecology will ultimately limit the lifespan and usefulness of these life-saving drugs. Careful and thoughtful diagnosis should precede the use of antimicrobial agents and knowledge of their adverse event profiles and potential for drug interactions are prerequisites for their appropriate use. Appropriate antimicrobial use will not only reduce selection of resistant organisms but is likely to improve patient care by reducing adverse effects, toxicities, drug-drug interactions and cost.

Chapter 188 - Mechanisms of Action

Francoise Van Bambeke
Didier M Lambert
Marie-Paule Mingeot-Leclercq
Paul M Tulkens

ANTIBIOTICS THAT ACT ON THE CELL WALL

The basis of the bacterial cell wall is peptidoglycan, a polymer that contains alternating residues of glucosamine and muramic acid in ß-1?4 linkage. The carboxyl groups of muramyl residues are substituted by short peptides (usually pentapeptides such as L-Ala-D-Glu-D-Asp-D-Ala-D-Ala, L-Ser-D-Glu-D-Asp-D-Ala-D-Ala or Gly-D-Glu-D-Asp-D-Ala-D-Ala). Cell-wall-active antibiotics act by inhibiting the activity of enzymes involved in the synthesis of the precursors or in the reticulation of peptidoglycan.

ß-lactams

The ß-lactam nucleus is the basic building block of an exceptionally large class of antibiotics, all of which share a common mode of action but have quite distinct properties in terms of spectrum, pharmacokinetics and activity against resistant strains (see Chapter 193).

Chemical structure

All antibiotics in this class contain a cyclic amide called ß-lactam, but different classes have been described according to the nature of the cycle or of the heteroatom included in the cycle. The main classes are (Fig. 188.1):

- penams — ß-lactams with a five-membered ring containing a sulfur atom (penicillins);
- clavams — ß-lactamase inhibitors that contain a five-membered ring with an oxygen as heteroatom (e.g. clavulanic acid; some sulfur analogs have also been reported);
- carbapenems — five-membered rings with a double bond (e.g. thienamycin, imipenem);
- penems — five-membered unsaturated ring with a sulfur atom (faropenem);
- cephems — six-membered unsaturated rings with a sulfur atom (cephalosporins);
- oxacephems — the oxygen analogs of cephems (latamoxef); and
- monobactams — cyclic amides in a four-membered ring (azetidine) with a methylcarboxylate function in the case of nocardicins and a sulfonate in the case of the other monobactams (e.g. aztreonam).

Other representatives members of the ß-lactams are thiacephems, dethiacephems, dethiacephams, heterocephems and cephams, as well as diverse bicyclic systems.

Some non-ß-lactam analogs have been also reported but seem to be of little interest.

Mode of action

ß-lactams act primarily as inhibitors of the synthesis of the cell wall, by blocking the action of transpeptidases (Fig. 188.2).[1]

Specialized acyl serine transferases or transpeptidases are involved in the assembly of the bacterial cell wall. The structural properties of ß-lactams mimic the D-Ala-D-Ala sequence in that the distance between the carboxylate and the cyclic amide is similar. Thus, these antibiotics act as a false substrate for D-alanyl-D-alanyl transpeptidases. The carboxylate or the sulfonate of the ß-lactams react with a serine residue of the transpeptidases [also called penicillin-binding proteins (PBPs)] to give an acyl enzyme, with the formation of a covalent bond (Fig. 188.3).[2] The acylated enzyme is inactive. Such a mechanism is called suicide inhibition or mechanism-based enzyme inactivation. Transpeptidases are located in the perisplamic space, which is directly accessible in Gram-positive bacteria. In Gram-negative bacteria, ß-lactams have to cross the outer membrane of the bacteria either through the membrane (by passive diffusion) or via porin channels.

The perturbations induced by the ß-lactams in cell wall formation explain the inhibition of the growth of the bacteria, but the bactericidal effect results from indirect mechanisms (mostly the activation of autolytic enzymes). ß-lactams are active only against rapidly dividing bacteria.

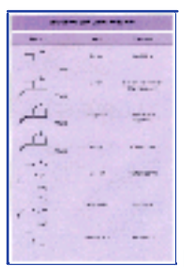

Figure 188-1 Diversity of ß-lactam antibiotics: main ring structures, names and representative antibiotics.

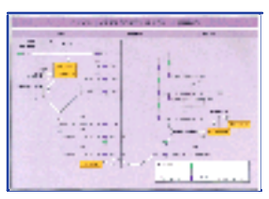

Figure 188-2 Site of action of antibiotics that perturb the synthesis of peptidoglycan. The peptidoglycan unit is formed in the cytosol of bacteria by the binding to uridine diphosphate (UDP)-*N*-acetylmuramic acid of a short peptide (the nature of which differs between bacteria). This precursor is then attached to a lipidic carrier and added to *N*-acetylglucosamine before crossing the bacterial membrane. At the cell surface peptidoglycan units are reticulated by the action of transglycosylases (catalyzing the polymerization between sugars) and of transpeptidases (catalyzing the polymerization between peptidic chains). The antibiotics act as follows: fosfomycin is an analog of phosphoenolpyruvate, the substrate of the *N*-acetylglucosamine-3-*o*-enolpyruvyl transferase synthesizing *N*-acetylmuramic acid from *N*-acetylglucosamine and phosphoenolpyruvate; cycloserine is an analog of D-Ala and blocks the action of D-Ala racemase and D-Ala:D-Ala ligase; bacitracin inhibits the transmembrane transport of the precursor; vancomycin binds to D-Ala-D-Ala termini and thus inhibits the action of transglycosylases and transpeptidases; and ß-lactams are analogs of D-Ala-D-Ala and suicide substrates for transpeptidases.

Resistance

Resistance of ß-lactams may occur at four different levels (see Chapter 189):

¦ first, access to the PBPs in Gram-negative bacteria might be abolished by an alteration of porin channels — this phenomenon predominantly affects highly water-soluble ß-lactams;
¦ second, the antibiotic concentration in the periplasmic space of Gram-negative organisms such as *Pseudomonas aeruginosa* or *Escherichia coli* can be reduced by active efflux mechanisms[3] — the corresponding pumps are characterized by a large substrate specificity, conferring cross-resistance to antibiotics from unrelated classes and by an ill-explained selectivity for some ß-lactams (e.g. meropenem is a better substrate than imipenem);
¦ modification of PBPs can also be observed, in particular, for the PBP2, which is indeed an essential protein involved in the 'shaping' of the bacteria — resistant strains (methicillin-resistant staphylococci), produce a PBP2 protein with a very low affinity for ß-lactams and other PBPs can also show the same decreased affinity;
¦ the fourth and most abundant mechanism is the production of hydrolyzing enzymes called ß-lactamases[2] [4] [5] [6] [7] — these enzymes are serine proteases enzymes that cleave the ß-lactam ring by opening the amide bond and the corresponding genes may either be carried on chromosomes (and their expression may be constitutive or inducible) or on plasmids — this system of resistance is very efficient because these enzymes are secreted out of the cell wall in Gram-positive bacteria and in the perisplamic space in Gram-negative bacteria, and the affinity for ß-lactams is greater than that for PBPs.

Most ß-lactamases open the ß-lactam ring in exactly the same way as transpeptidases, but the major difference is that the hydrolysis rate is far quicker in the case of ß-lactamase than in the case of PBP (see Fig. 188.3). In other words, the speed of hydrolysis of the acyl enzyme is higher and explains the high efficiency of ß-lactamases. The turnover of PBPs and ß-lactamases is indeed very different (1 ß-lactam per hour and 1000 ß-lactams per second respectively). Analytic data and genetic studies of ß-lactamases show a high level of structural homology, which suggests that both derive from a common ancestor. A number of ß-lactams have been

Figure 188-3 ß-Lactam antibiotics as substrates for transpeptidases and ß-lactamases. The left part of the illustration shows how a ß-lactam covalently binds to the transpeptidases. Hydrolysis of this acylated enzyme is very slow (one ß-lactam per hour), making the enzyme inactive. The right part of the illustration shows that the same reaction occurs in the case of a ß-lactamase. Hydrolysis of the acylated enzyme is, however, very rapid (1000 ß-lactams per second), making the antibiotic inactive and regenerating the enzyme for a new cycle of hydrolysis.

made resistant to ß-lactamases by appropriate steric hindrance or change in conformation (Fig. 188.4), giving rise to the large number of successive generations of penicillins and cephalosporins. ß-lactamases, however, have an extraordinary plasticity and inevitably develop activity against all new derivatives at a fast pace (Table 188.1).

Thanks to their specific structure, clavams are poor antibiotics but bind tightly to ß-lactamases. Given in combination with ß-lactams, they provide protection unless the bacteria produces ß-lactamases. Some ß-lactamases can also hydrolyze the clavams.

Pharmacodynamics

ß-lactams are relatively slow-acting antibiotics and show only limited post-antibiotic effects. They must therefore be present at a concentration above the minimum inhibitory concentration (MIC) as long as possible (from 40% in moderately severe infections to probably much more and perhaps up to 100% in severe, life-threatening infections). Conversely,

Figure 188-4 Structural modifications of ß-lactam antibiotics that overcome ß-lactamase degradation. A first strategy, applied in penicillins, cephalosporins, oxacephems and monobactams consists of the introduction of a large side chain on the nucleus, possibly containing a substituted imine or alkene. A second strategy, applied in oxacephems and cefoxitin consists of the introduction of a methoxy group on the ß-lactam ring.

concentrations higher than 4–5 times the MIC provides little gain in activity so frequent dosing is more appropriate than infrequent administration of large doses (administration by continuous infusion is being developed, but may encounter difficulties due to the intrinsically fragile character of the ß-lactam ring, making the molecules potentially unstable in aqueous media).[8]

Glycopeptides

Chemical structure

Glycopeptide antibiotics (vancomycin, teicoplanin) contain two sugars and an aglycone moiety made of a relatively highly conserved heptapeptide core, in which two amino acids bear a chloride substituent. The aglycone fraction is responsible for the pharmacologic activity of the molecule, whereas the sugars are thought to modulate its hydrophilicity and its propensity to form dimers (see below). As a result of their large size, glycopeptides are not only unable to cross the outer membrane of Gram-negative bacteria (which explains their inactivity against these organisms), but are also unable to penetrate inside bateria, which limits them to an extracellular target.

Mode of action

Glycopeptide antibiotics inhibit the late stages of cell wall peptidoglycan synthesis (see Fig. 188.2). Glycopeptides bind to D-Ala-D-Ala terminals of the pentapeptide-ending precursors localized at the outer surface of the cytoplasmic membrane. At the molecular level, glycopeptides form a high affinity complex with D-Ala-D-Ala by establishing hydrogen bounds via their aglycone moiety.[9] The strength of this binding is, however, greatly enhanced either by:

¦ dimerization of the glycopeptide molecules (mediated by their sugars and the chloride atoms substituents on the aglycone — as observed in vancomycin); or
¦ anchoring of glycopeptide molecules in the membrane by a fatty acyl chain substituent (as observed in teicoplanin).[10]

The subsequent steric hindrance around the pentapeptide terminals blocks the reticulation of peptidoglycan by inhibiting the activity of transglycosylases (responsible for the new dissacharide-pentapeptide subunit on the nascent peptidoglycan) and of transpeptidases (catalyzing the formation of interpeptide bridges).[9]

Resistance

Resistance to glycopeptides results from substituting a D-lactic acid in place of terminal D-Ala of the pentapeptide. Although this does not prevent the action of the transpeptidase, it prevents the binding of the glycopeptides because of the loss of one crucial hydrogen bound.[9]

Pharmacodynamics

Glycopeptide antibiotics show a very slow bactericidal activity, which is not very dose-dependent, for reasons that are unclear. It has been proposed that their inhibition of cell wall synthesis blocks the growth of bacteria and therefore the synthesis of DNA, RNA and proteins, whereas the autolytic enzymes could continue to function. As their activity is time-dependent, glycopeptides need repeated

TABLE 188-1 -- Functional classification of ß-lactamases.[§]

FUNCTIONAL CLASSIFICATION OF ß-LACTAMASES				
Group	**Molecular class**	**Preferred substrates**	**Active ß-lactams**	**Typical examples**
Group 1: serine cephalosporinases not inhibited by clavulanic acid	C	Cephalosporins I and II (» cephalosporins III, monobactams, penicillins)	Carbapenems	AmpC from Gram-negative; variable upon the species
			Temocillin (cephalosporins III and IV, variable upon level of expression)	
Group 2: serine ß-lactamases				
2a: penicillinases inhibited by clavulanic acid	A	Penicillins (penicillin, ampicillin » carbenicillin » oxacillins)	Amoxicillin + clavulanic acid	Penicillinases from Gram-positive
			Cephalosporins	
			Carbapenems	
2b: broad-spectum ß-lactamases inhibited by clavulanic acid	A	Penicillins (penicillin, ampicillin » carbenicillin » oxacillins)	Cephalosporins III and IV,	TEM-1, TEM-2, SHV-1 from Enterobacteriacea, *Haemophilus* spp.
			Monobactams[*]	
		Cephalosporins I and II	Carbapenems	*Neisseria gonorrhoeae*
			Amoxicillin + clavulanic acid	
2be: extended-spectrum ß-actamases inhibited by clavulanic acid (ESBL)	A	Penicillins	Carbapenems	TEM-3 to -26 from Enterobacteriacea
		Cephalosporins I II III (IV)	Temocillin	SHV-2 to -6 from *Klebsiella* spp.
		Monobactams		K1-OXY from *Klebsiella oxytoca*
2br: broad-spectrum ß-lactamases with reduced binding to clavulanic acid	A	Penicillins	Most cephalosporins	TEM-30 to -41 (=IRT-1 to IRT-12) from *Escherichia coli*
			Monobactams[*]	
			Carbapenems	
2c: carbenicillin-hydrolyzing ß-lactamases generally inhibited by clavulanic acid	A	Penicillins	Piperacillin + tazobactam	PSE-1, PSE-3, PSE-4 from *Pseudomonas aeruginosa*
		Carbenicillin	Cephalosporins III and IV	
		(Cephalosporins I and II)	Monobactams[*]	
			Carbapenems	
2d: cloxacillin-hydrolyzing ß-lactamaxes generally inhibited by clavulanic acid	D	Penicillins	Carbapenems	OXA-1 to -11, PSE-2 from Enterobacteriacea and *P. aeruginosa*
		Cloxacillin	Cephalosporins III	
		Cephalosporins I and II	Monobactams[*]	
			Piperacillin + tazobactam	
2e: cephalosporinases inhibited by clavulanic acid	A	Cephalosporins I and II	Cephalosporins III and IV	FPM-1 from *Proteus vulgaris*
			Monobactams[*]	Cep-A from *Bacteroides fragilis*[†]
			Penems	
2f: carbapenem-nonmetallo-hydrolyzing ß-lactamases	A	Penicillins	(Cephalosporins III and IV)	NMC-A, IMI-1 from *Enterobacter cloacae*
		Cephalosporins	(Monobactams[*])	Sme-1 from *Serratia marcescens*
		Carbapenems		
Group 3: Metallo ß-lactamases inhibited by EDTA	B	Most ß-lactams, including carbapenems	Monobactams[*] [‡]	L-1, XM-A from *Stenotrophomonas maltophilia*
				CcrA from *Bacteroides fragillis*
				A2h, CphA from *Aeromonas hydrophila*
				IMP-1 in *Pseudomonas* spp. and *Serratia* spp.
Group 4: Penicillinases not inhibited by clavulanic acid		Penicillins, including carbenicillin and oxacillin	Monobactams[*] [†] [‡] and generally carbapenems	SAR-2 from *Burkholderia cepacia*
The number of enzymes as well as their spectrum of activity is continually evolving.				

§ *Data from Bush et al.*[6]

* Monobactams are not active on Gram-positive bacteria
† Penems are the only molecules active in this case
‡ Remain active for most of the rare published studies

administration, yet, they show a moderate (2-hour) postantibiotic effect, which combined with their long half-life (6 hours for vancomycin, and more than 24 hours for teicoplanin), makes continuous infusion of less interest than for ß-lactams.

Glycopeptides show, at least *in vitro,* a synergistic effect with aminoglycosides, probably by facilitating the penetration of these polar molecules into bacteria.

Future developments

New derivatives with a hydrophobic substituent (e.g. oritavancin) act against vancomycin-resistant strains and show a very fast and highly concentration-dependent bactericidal effect, which suggests a distinct mode of action that could involve drug dimerization and membrane destabilization.[11]

Other agents that act on cell wall synthesis

D-cycloserine is a broad-spectrum antibiotic active through its similarity with D-Ala (see Fig. 188.2 ; Fig. 188.5), inhibiting the conversion of L-Ala into D-Ala (reaction

catalyzed by a racemase) and the dimerization of D-Ala (reaction catalyzed by the D-Ala:D-Ala ligase). [12]

Fosfomycin, which bears structural similarities to phospho-*enol*-pyruvate, inhibits a very early stage of peptidoglycan synthesis by impairing the formation of uridine diphosphate (UDP)-*N*-acetylglucosamine-*enol*-pyruvate, a precursor of UDP-*N*-acetylmuramic acid (see Fig 188.2 , Fig 188.5). [13]

Bacitracin is a polypeptide of complex structure. It acts as an inhibitor of peptidoglycan synthesis at the level of translocation of the precursor across the bacterial membrane (see Fig. 188.2).[14]

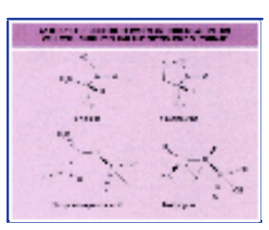

Figure 188-5 Analogy of structure between antibiotics acting on cell wall synthesis and the physiologic substrate. The two antibiotics act as analogs of the corresponding substrate.

ANTIBIOTICS THAT ACT ON PROTEIN SYNTHESIS

Bacterial ribosomes comprise:

- a 30S subunit, which binds mRNA and initiates the protein synthesis; and
- a 50S subunit, which binds aminoacyl tRNA, catalyzes the peptide bond formation and controls the elongation process.

The main sites identified in the ribosome are the donor peptidyl site (P-site), where the growing peptide chain is fixed, and the acceptor aminoacyl site (A-site), where peptide bond formation occurs.

Aminoglycosides

Chemical structure

Streptomycin was discovered in 1944, but this compound had a relatively limited spectrum of activity. Several other compounds, with a broader spectrum of activity, especially towards aerobic and facultative Gram-negative bacilli, were extracted from bacteria or semisynthesized over the subsequent 20 years (aminoglycosides from kanamycin or gentamicin families). In the 1970s, netilmicin and amikacin demonstrated the possibility of developing compounds active against strains resistant to earlier aminoglycosides.

Aminoglycosides are made of several aminated sugars joined by glycosidic linkages to a dibasic cyclitol.[15] The latter is streptidine in streptomycin and derivatives, fortamine in the fortimicin series, and two-deoxystreptamine in most aminoglycosides used clinically. The two-deoxystreptamine moiety links to cyclic sugars either at positions 4 and 5 (neomycin and paromomycin) or 4 and 6 (kanamycin, tobramycin, amikacin and dibekacin in the kanamycin family; gentamicin C_1 , C_{1a} , C_2 , and isepamicin in the gentamicin family, sisomicin and netilmicin; Fig. 188.6). All compounds are positively charged at physiologic pH.

Bacterial targeting

Aminoglycosides selectively disturb the protein synthesis of bacteria because they bind to the 30S subunit of bacterial ribosomes, which does not exist in eukaryotic cells. However, molecules that display a hydroxyl function in C6' in place of an amino function affect also protein synthesis in cultured mammalian cells, as do high doses of gentamicin, probably through nonspecific binding to ribosomes or nucleic acids.

Mode of action

As a result of their highly polar character, aminoglycosides are unable to diffuse through membranes, and therefore require specific mechanisms of transport. Their passage across the outer membrane of Gram-negative bacteria occurs by a process that is not energy dependent and involves the drug-induced disruption of Mg^{2+} bridges between adjacent lipopolysaccharide molecules. By contrast, their transport across the cytoplasmic (inner) membrane is dependent upon electron transport, and is therefore termed energy-dependent phase I (EDP-I). The greater the transmembrane electrical potential, the greater the antibacterial effect of the aminoglycoside. In an anaerobic environment, at low external pH and in high osmolar culture media, this transmembrane electrical potential is decreased, which explains the low activity against anaerobes as well as in purulent collections.

Once in the bacterial cytosol, aminoglycosides bind to the aminoacyl site of the 30S subunit of ribosomes[17] (and, to a lesser extent, to specific sites of the 50S subunit), again through an energy-dependent process (EDP-II), disturbing the elongation of the nascent peptide. Their mechanism of action is complex, involving inhibition of the transfer of the peptidyl tRNA from the A-site to the P-site and impairment of the proofreading process that controls translational accuracy. The latter action leads to misreading or premature termination in protein synthesis. The final effects vary somewhat from one compound to another, which possibly explains differences in the killing rates. The aberrant proteins may be inserted into the cell membrane, which results in altered permeability and further stimulation of aminoglycoside transport.

Resistance

Resistance occurs mostly by the production of enzymes that inactivate the functions responsible for activity of the natural aminoglycosides (Fig. 188.7 , see Chapter 189). Semisynthetic derivatives (e.g. netilmicin, amikacin, isepamicin) were therefore made specifically to afford protection against these enzymes. However, whereas previously resistant bacteria harbored only one of a very few types of enzymes, the simultaneous production of several enzyme types is increasingly more common, causing multiple resistance. It is believed that most of these enzymes have physiologic effects on natural substrates and acted on aminoglycosides only opportunistically in the initial introduction of these antibotics. However, point mutations and selection may have quickly increased their specificity and efficacy.[18] [19]

A second mechanism of resistance is membrane impermeability, which confers resistance to all aminoglycosides. Its molecular mechanism is unclear.

Pharmacodynamics

Aminoglycosides demonstrate a rapid, concentration-dependent bactericidal effect and an important postantibiotic effect (probably because of a largely irreversible binding to the ribosomes). A once-a-day regimen is therefore the optimal mode of administration for these antibiotics, allowing elevated serum peak concentrations (over eight times the MIC, thereby maximizing efficacy while minimizing toxicity) to be reached.

Aminoglycosides show a synergistic activity with antibiotics that act on cell wall synthesis, because they facilitate the penetration of aminoglycosides into the bacteria. In contrast, their activity is antagonized by bacteriostatic agents such as chloramphenicol and tetracyclines, probably by inhibition of their energy-dependent uptake and by interference with the movement of the ribosome along mRNA.

Future developments

Efforts are being undertaken in two directions:

- to increase the binding affinity while retaining binding selectivity; and

¦ to develop new aminoglycoside derivatives resistant to these enzymes.

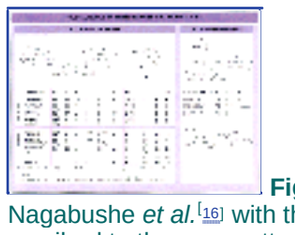

Figure 188-6 Structural formulae of the 2-deoxystreptamine-containing aminoglycosides. The numbering of the atoms shown here follows the recommendations from Nagabushe *et al.*[16] with the primed numbers (') being ascribed to the sugar attached to C4 of the 2-deoxystreptamine (as this C is of the R configuration) and the doubly primed numbers ('') being ascribed to the sugar attached to either the C6 (S configuration) for the 4,6-disubstituted 2-deoxystreptamine or the C5 (R configuration) for the 4,5-disubstituted 2-deoxystreptamine. Molecules indicated in bold denote the aminoglycosides in widespread clinical use.

Although some derivatives have been made by pharmacochemical approaches, little success has been obtained. A more innovative approach could be to use our understanding of the aminoglycoside-inactivating enzymes to produce enzyme inhibitors or to design totally new aminoglycoside derivatives that would be intrinsically resistant to these enzymes.

Tetracyclines

Chemical structure

The first tetracyclines discovered were isolates from *Streptomyces* spp. (tetracycline, oxytetracycline), whereas more recent long-acting compounds (doxycycline, minocycline) are semisynthetic. All such molecules, contain four hydrophobic fused rings, which are diversely substituted, but principally by oxygenated hydrophilic groups (see Chapter 200).

Bacterial targeting

Tetracyclines penetrate the outer membrane of Gram-negative organisms through porins. Accumulation inside the bacteria depends on the pH gradient between the cytosol and the external medium, but it is unclear whether transmembrane transport occurs by diffusion or via a proton-driven carrier. The main argument in favor of the latter is that it could explain the selective action of tetracyclines by preferential transport in bacterial cells (Fig. 188.8).

Mode of action

Tetracyclines interfere with the initiation step of protein synthesis (see Fig. 188.8). More precisely, they inhibit the binding of aminoacyl tRNA to the A-site of the ribosome. The 7S protein and the 16S RNA show the best affinity for tetracyclines, and are therefore the main targets involved pharmacologically.[20] This binding inhibits the fixation of a new aminoacyl tRNA on the ribosome. At higher concentrations, tetracyclines also bind to the 23S RNA, which is part of the peptidyl transferase region of the ribosome. However, the enzymatic activity of this site does not seem not to be disturbed by tetracyclines. Additional actions on ribosomal functions have been proposed:[21]

¦ tetracyclines bind, or at least protrude, in the P-site, thanks to the change in ribosome conformation in the post-translocational state; and
¦ tetracyclines modify the ribosome conformation at the head of the 30S subunit and at the interfacial side of the 50S subunit.

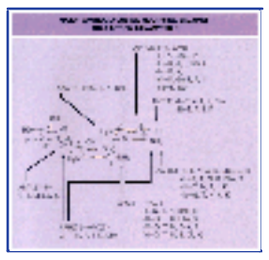

Figure 188-7 Major aminoglycoside-modifying enzymes that act on kanamycin C. This aminoglycoside is susceptible to the largest number of enzymes. The *N*-acetyltransferases (AACs) affect amino functions and the *o*-nucleotidyltransferases affect hydroxyl functions. Each group of enzymes inactivates specific sites, but each of these sites can be acted upon by distinct isoenzymes (Roman numerals) with different substrate specificities (phenotypic classification). At least one enzyme is bifunctional and affects both positions 2'' (*o*-phosphorylation) and 6' (*N*-acetylation). The main aminoglycosides used clinically on which these enzymes act are amikacin (A), dibekacin (DbK), commercial gentamicin (G), gentamicin B (Gmb), kanamycin A (K), isepamicin (I), netilmicin (N), sisomicin (S) and tobramycin (T). The drug abbreviations that appear in parentheses are those for which resistance was detectable *in vitro* although clinical resistance was not conferred. *Data from Shaw et al.*[19]

More recently, it has been shown that tetracyclines have chondroprotective effects in inflammatory arthritis models, an action related to their ability to inhibit the expression of nitric oxide synthases induced by inflammatory conditions.[22] Clinical evaluation is, however, needed to document further the potential usefulness of tetracyclines as modulators of the inflammatory response. A possible application would be the treatment of arthritis of bacterial origin (e.g. Lyme disease).

Resistance

Resistance to tetracyclines is now widespread, and is related to a decrease in the bacterial drug content caused by an active drug efflux (see Fig. 188.8).[23] Efflux mechanisms appear more important and are somehow largely, but not entirely unrelated to the drug structure (see fluoroquinolones and macrolides below; see also Chapter 189).

Pharmacodynamics

Tetracyclines are essentially bacteriostatic, but demonstrate persistent effects. They need to be administered at intervals short enough, in terms of the drug half-life, to maintain their serum level above the infecting organism's MIC for as long as possible. The total dose administered also appears to be important.

Future developments

Glycylcyclines are tetracyclines derivatives that bear a glycyl substituent and are able to bind to the tetracycline binding site on the ribosome. [24] Their main advantage is that they conserve their activity against strains with acquired resistance to conventional tetracyclines by the production of efflux pumps or by a mechanism of ribosomal

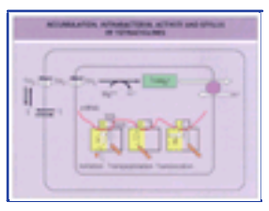

Figure 188-8 Accumulation, intrabacterial activity and efflux of tetracyclines. Tetracyclines diffuse freely through the extracellular membrane of Gram-negative bacteria. Penetration inside bacteria is an energy-dependent process depending on the pH and Mg^{2+} gradient between the extracellular medium of Gram-positive bacteria or the periplasmic medium of Gram-negative bacteria and the intracellular medium. Only the protonated form is highly diffusible, so accumulation is favored by lowering of the extracellular pH. Once inside the cytosol the tetracycline molecule forms a nondiffusible complex with Mg^{2+} . This type of complex with a bivalent cation is also the substrate of the efflux pumps present in the membrane of resistant bacteria and acting as H^{+} antiports (pink circle). The antibacterial action of the teracyclines (T) is due to the binding to the 30S subunit of the ribosomes. In the pretranslocational state, tetracyclines inhibit the binding of aminoacyl tRNA (arrow 1) to the A-site (yellow part of the ribosome). In the post-translocational state, tetracyclines protrude in the P-site (white part of the ribosome) and inhibit the binding of the

peptidyl tRNA (arrow 2). *Data from Geigenmüller and Nierhaus*[21] *and Yamaguchi et al.*[23]

protection (acquisition of a gene that encodes a Tet protein, (i.e. an elongation factor able to displace the tetracycline bond on the ribosome). However, mutants resistant to glycylcyclines have already been selected *in vitro*, with the possibility that such mutants may emerge in clinical strains.

Fusidic acid

Chemical structure

Fusidic acid is a steroid-like structure and a member of the fusidane class. It is used in its sodium salt form.

Mode of action

Fusidic acid prevents the dissociation of the complex formed by guanosine diphosphate, the elongation factor 2 and the ribosome. It thereby inhibits the translocation step of the peptidyl tRNA from the P-site to the A-site of the ribosome and, therefore, the elongation of the nascent polypeptide chain.

Pharmacodynamics

Fusidic acid is bacteriostatic, but may be bactericidal at high concentrations.

Mupirocin

Chemical structure

Mupirocin contains a short fatty acid side chain (9-hydroxynonanoic acid) linked to monic acid by an ester linkage. Mupirocin is also called pseudomonic acid because its major metabolite is derived from submerged fermentation by *Pseudomonas fluorescens*. Pseudomonic acid A is responsible for most of the antibacterial activity;

three other minor metabolites of similar chemical structure and antimicrobial spectrum are called pseudomonic acids B, C, and D.

Mode of action

Mupirocin inhibits bacterial RNA and protein synthesis by binding to bacterial isoleucyl tRNA synthetase, which catalyzes the formation of isoleucyl tRNA from isoleucine and tRNA. This prevents incorporation of isoleucine into protein chains, and so halts protein synthesis. This unique mechanism of action results in no cross-resistance between mupirocin and other antimicrobial agents.[25]

Pharmacodynamics

Mupirocin is bacteriostatic at low concentrations, but becomes bactericidal at concentrations achieved locally by topical administration. *In vitro* antibacterial activity is greatest at acidic pH, which is advantageous in the treatment of cutaneous infections because of the low pH of the skin.

Future developments

The recognition of the peculiar mode of action of mupirocin has triggered a large genomic-based research towards similar targets at the level of the other amino acids.[26]

Macrolides

Chemical structure

The main active macrolides are 14-, 15- or 16-membered lactone rings, substituted by two sugars, of which one bears an aminated function. Erythromycin, the first clinically developed macrolide, is a natural product. Most of the molecules developed in the mid 1980s are semisynthetic derivatives, and have been designed to be stable in acidic milieu. They are therefore essentially characterized by an improved oral bioavailability. 16-membered macrolides are intrinsically acid stable. In 15-membered macrolides (azithromycin), an additional aminated function is inserted in the lactone ring, conferring to this subclass of molecule the name of 'azalides'. They are acid stable and characterized by an exceptionally large volume of distribution and prolonged half-life. Ketolides are 14-membered macrolides in which the cladinose is replaced by a keto function and which possess in their macrocycle a carbamate linked to an alkyl-aryl extension (Fig. 188.9).[27] They are also intrinsically acid stable. Moreover, they remain active against most of the strains resistant to other macrolides.

Bacterial targeting

Macrolides specifically bind to the 50S subunit of the ribosomes (more precisely, to the 23S rRNA), which does not exist in eukaryotic cells.

Mode of action

Macrolides reversibly bind to the peptidyl transferase center, located at the 50S surface, which results in multiple alterations of the 50S subunit functions.[28] [29] While macrolides bind to the domain V of the 23S rRNA, ketolides have a dual anchoring to the ribosome. They not only bind to domain V, like other macrolides, but also bind to domain II of 23S rRNA (see Fig. 188.9).[30] [31] This additional binding involves the carbamate extension, which is absent in conventional macrolides.[27] Because of their double interaction, ketolides are characterized by a higher affinity for their target and therefore by an improved efficacy. Macrolides are classically thought to block the peptide bond formation or the peptidyl tRNA translocation from the A- to the P-site. However, additional consequences of macrolides binding to ribosomes have been reported. A proposal is that they could also favor the premature dissociation of peptidyl tRNA from the ribosome during the elongation process, leading to the synthesis of incomplete peptides.[28] A further suggestion is that erythromycin prevents the assembly of the 50S subunit, but this does not appear to be applicable to other macrolides.

Resistance

Clinically meaningful resistance occurs primarily by modification of the bacterial target and therefore affects all macrolides (and will also affect lincosamides and streptogramins). This resistance may be inducible or constitutive. Ketolides (due to their lack of cladinose) and 16-membered macrolides are not inducers and therefore show activity on a subset of resistant strains.[27] Moreover, as a result of their double anchoring to the ribosome, ketolides remain able to bind to domain II of the 23S ribosomal RNA of strains resistant by methylation of the domain V.[30] [31] [32] They can therefore maintain antibiotic activity against strains resistant to other macrolides.

Efflux mechanisms are also now being observed and, again, 16-membered macrolides are spared this effect. The frequency of strains susceptible to 16-membered macrolides and resistant to 14- and 15-membered macrolides remains small, however.

Pharmacodynamics

Macrolides are essentially bacteriostatic antibiotics, except at high concentrations. Thus, their concentration at the infected site needs to be consistently maintained above the MIC of the pathogen.[33]

As their mode of action is similar, macrolides, streptogramins, lincosamides and chloramphenicol have antagonistic pharmacologic activity. Moreover, the common

binding site to ribosomes of macrolides, streptogramins, and lincosamides shows that a mutation of the target causes cross-resistance to these three classes of antibiotics.

Future developments

Efforts are still being made to discover macrolide derivatives active against bacteria resistant to the macrolides used at the present time in the clinics. Research in the field of ketolides is still active. Erythromycylamines modified at their cladinose moiety show activity against inducible resistant strains and also against strains resistant through the production of efflux pumps.

Lincosamides

Chemical structure

Lincomycin and its 7-chloro-7-deoxy derivative, clindamycin, comprise a propylhygrinic acid linked to an aminosugar.

Mode of action

Lincosamides bind to the 50S ribosomal subunit and have a mode of action similar to that of macrolides.[29] They inhibit early chain elongation by interfering with the transpeptidase reaction.

Resistance

The main mechanism of resistance to lincosamides is similar to that found in resistance to macrolides and streptogramins, and consists of alteration of the 50S subunit. Rare cases of enzymatic inactivation of the antibiotic have also been described for clindamycin (adenylation reaction).

Pharmacodynamics

Lincosamides are bacteriostatic, and are antagonists of macrolides and streptogramins, which bind at the same site on the ribosomes.

Streptogramins

Chemical structure

Streptogramins are antibiotics that comprise a pair of synergistic constituents, namely a depsipeptide (group I) and a lactone macrocycle (group II). The combination of quinupristin and dalfopristin is used in the clinic.[34]

Mode of action

Streptogramins bind to the 50S subunit of bacterial ribosomes and interfere with the protein synthesis by a double mechanism, involving an inhibition of the incorporation of the aminoacyl tRNA in the ribosomes

Figure 188-9 Chemical structure of the macrolides. The upper panel shows the degradation of erythromycin in the gastric milieu (substituents responsible for the instability of the miolecule are shown in gray). 16-membered macrolides and ketolides are intrinsically stable. The structural modifications conferring stability in acidic milieu to 14- and 15-membered macrolides are highlighted in gray in the middle panel. The lower panel compares the binding of macrolides and ketolides to the petidyl transferase site of the 50S subunit of ribosomes. Macrolides are characterized by a single anchoring point and ketolides by a double anchoring point, which increases the affinity of ketolides for wild type and methylated ribosomes.

and of the translation of the mRNA. The synergy between the two components could be due to a modification of the conformation of the ribosome caused by the binding of the group I component, which exposes a site of fixation for the group II component. [28]

Resistance

Resistance by mutation of the ribosomal target will also result in resistance to macrolides and lincosamides. Resistance to streptogramins alone is rare and occurs by enzymatic inactivation (involving an hydrolase and an acetylase).

Pharmacodynamics

Streptogramin constituents are highly synergistic and show a dose-dependent bactericidal activity if given together.[33] In addition, they increase the antibiotic activity of aminoglycosides and rifamycins.

Streptogramins also exhibit prolonged bacteriostasis, which consists of a delay of regrowth when the antibiotic concentration falls under its MIC. This could be interpreted as a consequence of the persistent binding of the drug to its target.

Future developments

Streptogramins are not largely used today. However, their potential role for bacteria resistant to other antibiotics (MRSA, vancomycin-resistant enterococci) may reactivate research in this area.

Chloramphenicol and thiamphenicol

Chemical structure

Chloramphenicol and thiamphenicol are based on dichloroacetamide bearing a diversely substituted phenyl group (see Chapter 200).

Bacterial targeting

Chloramphenicol acts principally by binding to the 50S subunit of the bacterial ribosomes. However, it can also interact with mitochondrial ribosomes of eukaryotic cells,

which results in its toxicity.

Mode of action

Chloramphenicol enters the bacteria by an energy-dependent process. Its antibiotic activity results from competitive inhibition of aminoacyl tRNA binding to the peptidyl transferase domain of the 50S subunit. This induces conformational changes of this part of the ribosomes, which slows or even inhibits (at high enough concentrations) the incorporation of the aminoacyl tRNA and, therefore, the transpeptidase reaction.[35]

Resistance

Resistance to chloramphenicol derives mainly from the production of a specific acetyl transferase that inactivates the antibiotic.[36] The gene encoding the transferase is often located on plasmids that also confer resistance to other antibiotic classes. Another mechanism of resistance is reduced entry of the drug into the bacteria.

Pharmacodynamics

Chloramphenicol is bacteriostatic. It competes in binding to the ribosomes with macrolides and lincosamides, making its combination with these drugs useless.

Oxazolidinones

Chemical structure

Oxazolidinones are totally synthetic molecules. The first derivatives endowed with antimicrobial activity were described at the end of the 1970s. Structures were then refined on the basis of structure-activity relationships[37] to give rise so far to linezolid, the first clinically available molecule (Fig. 188.10). The 5-(S)-configuration of the oxazolidinone ring is essential for activity, which is further improved by its substitution by an N-fluorinated aryl group and a C5 acylaminomethyl group.

Mode of action

Oxazolidinones inhibit protein synthesis at an earlier step that other antibiotics acting on the ribosome. Their binding site is located in the vicinity of the peptidyl transferase center of the 50S subunit.[38] This interaction prevents the formation of the initiation ternary complex which associates $tRNA^{met}$, mRNA, and the 50S subunit of the ribosome,[39] and therefore the binding to the ribosome as well as the synthesis of peptide bonds, and the translocation of $tRNA^{met}$ into the P-site.[40]

Resistance

Because of the unique mode of action of oxazolidinones, there is no cross-resistance with other antibiotics acting on protein synthesis. The introduction of linezolid in clinics is too recent to draw any conclusion concerning the incidence and mechanisms of resistance. Case reports of resistant clinical isolates emerging during therapy have, however, been published.[41] Mutation of the 23S rRNA *in vitro* confers resistance to linezolid.[38]

Pharmacodynamics

Oxazolidinones are bacteriostatic, time-dependent antibiotics, with a short post-antibiotic effect.[41] They can compete for binding to the 50S subunit of the ribosome with other antibiotics (e.g. lincosamides, chloramphenicol).

Future developments

Other molecules are currently under investigation. Efforts are essentially directed towards broadening the spectrum of activity and increasing intrinsic activity.

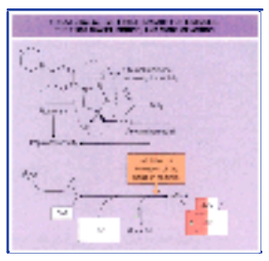

Figure 188-10 Structural activity relationship for linezolid, the first oxazolidinone, and mode of action. The drug prevents the formation of the ternary complex between mRNA, ribosome subunits and $tRNA^{met}$ necessary for protein synthesis.

DRUGS THAT AFFECT NUCLEIC ACIDS

Fluoroquinolones

Chemical structure

Fluoroquinolones are totally synthetic products originally derived from nalidixic acid (see Chapter 198). All current compounds have a dual ring structure, with nitrogen at C1, a free carboxylate at C3 and a carbonyl at C4. A fluorine substituent at C6 usually greatly enhances activity, whereas the substituents at C7, C8 and N1 modulate the spectrum, pharmacokinetics and side-effects of the drugs (Fig. 188.11).[42] In this respect, new molecules (among which moxifloxacin and gatifloxacin are now used in the clinic) have been designed to better cover Gram-positive organisms, keep activity against Gram-negative organisms and also be, to some extent, active against anaerobes.[43] They all present a small hydrophobic substituent on N1 and a diaminated small-sized ring substituent in 7.

Bacterial targeting

Fluoroquinolones cross the outer membrane of Gram-negative bacteria via porins. Their affinity for the bacterial target is 1000 times greater than that of the corresponding eukaryotic enzyme, which ensures their specificity.

Mode of action

Fluoroquinolones inhibit the activity of topoisomerases, which are enzymes responsible for the supercoiling of the DNA (DNA gyrase) and relaxation of supercoiled DNA (topoisomerase IV). Both enzymes have a similar mode of action, which implies:

- binding of DNA to the enzyme;
- cleavage of the DNA;
- passage of the DNA segment through the DNA gate;
- resealing of the DNA break and the release from the enzyme.

Gyrase and topoisomerase IV are tetramers made of two types of subunits, namely two GyrA or ParC that catalyze DNA cutting and resealing, and two GyrB or ParE responsible for the transduction and binding of adenosine triphosphate. The main target of fluoroquinolones

Figure 188-11 Structure-activity, structure-pharmacokinetics and structure-toxicity relationships of the fluoroquinolones. These considerations form the basis of the rational development of the new molecules of this class, which have a very extended spectrum (including Gram-positive bacteria and anaerobes), a long half-life and minimal phototoxicity and metabolic interactions.

is DNA gyrase in Gram-negative bacteria and topoisomerase IV in Gram-positive bacteria. [44]

Fluoroquinolones form a ternary complex with DNA and the enzyme (Fig. 188.12).[45] This binding site for fluoroquinolones is formed during the gate-opening step of the double-stranded DNA. Cooperatively, four fluoroquinolone molecules are fixed to single-stranded DNA. Their stacking is favored by the presence of coplanar aromatic rings in their structure and by the tail-to-tail interactions between the substituents at N1. Interaction with DNA occurs by hydrogen bonds or via Mg^{2+} bridges established with carbonyl and carboxylate groups. Interaction with the enzyme is mediated by the fluorine at C6 and substituents at C7. The binding of the fluoroquinolones stabilizes the cleavable complex (formed by the cut DNA and the enzyme) and leads to the dissociation of the enzyme subunits. The latter action is observed only for potent molecules or at higher concentrations.

Quinolones have other effects on bacterial cells, such as induction of the DNA repair response, which involves three proteins (RecA, LexA and RecBCD). Induced RecA cleaves the repressor part of the SOS regulon (LexA), stimulating repair of damage caused by fluoroquinolones to DNA. Induced RecBCD binds to the chromosome at the double-strand break created by the ternary complex of topoisomerase-DNA-quinolone, and results in mutagenesis as well as increased cell survival in the presence of quinolones. This system therefore protects against the antibacterial activity of fluoroquinolones.[42]

Resistance

Resistance occurs mostly by mutation of the topoisomerases (reducing drug-binding ability), by porin impermeability or by efflux. These mechanisms affect all fluoroquinolones and result in progressive slight increases in the MIC. New fluoroquinolones may remain active against resistant strains based upon higher intrinsic activity, which is a structure-related property. In particular, the presence of a methoxy substituent in position 8 reduces the potential for selecting resistant mutants (see Fig. 188.11). [46]

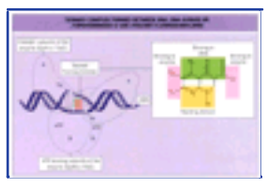

Figure 188-12 Ternary complex formed between DNA, DNA-gyrase or -topoisomerase IV and stacked fluoroquinolones. Subunits A form covalent bonds via Tyr122 with the 5' end of the DNA chain. The binding site for fluoroquinolones is located in the bubble formed during the local opening of the DNA molecule. The right panel shows the parts of the antibiotic molecules interacting with DNA, with the enzyme or favoring the stacking of the fluoroquinolone molecules. *Adapted from Shen et al.*[45]

Pharmacodynamics

The mechanism described above requires RNA and protein synthesis as well as cell division for bactericidal action. The latter probably results from cutting of the DNA and the subsequent creation of a barrier for its transcription. Alternative mechanisms, however, confer bactericidal activity to certain molecules either in the absence of protein and RNA synthesis or without bacterial multiplication.

The activity of fluoroquinolones is largely concentration dependent, but these drugs show also persistent effects. Accordingly both the peak/MIC and the 24-hour area under the serum concentration curve (AUC)/MIC ratios are important for activity (pharmacodynamic studies have shown that effective doses often need to be considerably higher than was originally tought; breakpoints should be revised to lower values, and based on pharmacodynamic considerations, should be <1µg/ml; [47] recent studies also suggest that the a peak/MIC ratio >10 protects or retards the emergence of resistance). Fluoroquinolones also show a postantibiotic effect, the duration of which varies according to the pathogen, drug concentration and period of exposure.

Future developments

New molecules with extended spectrum and high intrinsic activity are still in development, among which des-fluoroquinolones (i.e. molecules lacking the F substituent in position 6).[48] When applied to molecules of high intrinsic activity, this structural change was shown to not affect activity while maintaining the mode of action of fluoroquinolones. These molecules have also a low potential for selecting resistance.

Nitroimidazoles and nitrofurans

Chemical structure

The nitroheterocyclic drugs include nitrofuran and nitroimidazole compounds (Fig. 188.13).

Mode and spectrum of action

The activity of nitroheterocyclic drugs requires activation of the nitrogroup attached to the imidazole or furan ring, which must undergo single- or two-electron enzymatic reduction in the bacteria.[49] [50] [51] Single-electron reduction of nitroaromatics is most frequently catalyzed by flavoenzyme dehydrogenase electrotransferases and bacterial oxygen-sensitive nitroreductases. Under aerobic conditions, the single electron reduction of nitroaromatics to give their anion radicals results in their reoxidation by oxygen with formation of superoxide and other activated oxygen species that damage proteins, nucleic acids, and lipids. Under hypoxic conditions, enzymes that transfer single electrons reduce nitroaromatics to amines or, less frequently, to hydroxylamines. Two-electron reduction of nitroaromatics to nitroso compounds and, subsequently, to hydroxylamines is catalyzed by bacterial oxygen-insensitive nitroreductases and mammalian DT-diaphorase NADPH:quinone reductase.

Although the nitro radicals generated by reduction of the parent drugs are similar for the nitroimidazoles and the nitrofurans, these drugs differ by their reduction potential, and, therefore in their effects on bacteria and their spectrums of activity. Thus, the reduction of nitroimidazoles causes depletion in the intracellular stock of reduced coenzymes. Moreover, reduced forms of these antibiotics are highly reactive and may damage the DNA molecule. Reduced nitrofurans also inhibit the activity of enzymes involved in the degradation of glucose and pyruvate. In addition, they covalently bind to proteins and DNA by an alkylation reaction.

Future developments

The variety of substitutions that can be attached to the ring structures may allow for a large amount of flexibility. The major interest in these drugs is the use of 2-nitroimidazole probes as radiosensitizers of hypoxic cells on a cell-to-cell basis and for noninvasive detection.

Ansamycins

Chemical structure

Ansamycins, which are macrocyclic antibiotics, are lipophilic and therefore easily diffuse through membranes. They comprise two aromatic rings (containing a quinone),

connected by a long chain (or 'ansa' — hence the name given to this class of antibiotics), which confers a rigid character to the whole molecule.

Mode of action

Ansamycins inhibit the initiation of DNA transcription to mRNA and therefore the subsequent protein synthesis.[52] The RNA polymerase contains five subunits (a_2 ßß's):

- a subunits establish contact with transcription factors;
- ß' subunit is a basic polypeptide that binds DNA;

- ß subunit is an acidic polypeptide and is part of the active site;
- s-subunit initiates the transcription and then leaves the polymerase nucleus.

Figure 188-13 Modes of action of nitrofurans and nitroimidazoles. The modes of action include passage through the cell membrane, reduction to highly reactive products, interaction with intracellular targets and release of inactive end products.

The core polymerase (a_2 ßß') therefore retains the ability to synthesize RNA but is defective in its ability to bind and initiate DNA transcription.

Inhibition by rifamycins follows binding of the antibiotic to the ß subunit of the RNA polymerase or, to a lesser extent, of the DNA-RNA complex. This binding is mediated by hydrophobic interactions between the aliphatic ansa chain and the ß subunit. The precise site of binding has been identified only partly, by studying mutants in RNA polymerase that have acquired resistance to rifampin (rifampicin). All the mutations that affect drug binding belong to three clusters of amino acids in the central domain of the ß subunit.

Inhibition of transcription caused by rifamycins is essentially noncompetitive. A model has been proposed in which rifamycins block the translocation event during transcription initiation, without hindering the synthesis of the first phosphodiester bridge between the two first nucleotide triphosphates of the mRNA molecule.[53] Specificity of action depends on the fact that ansamycins alter mammelian cell metabolism only at concentrations 10,000 times those necessary to cause bacterial cell death (Fig. 188.14).

Pharmacodynamics

Rifamycins are bactericidal — an effect that results either from the high stability of the complex formed between rifampin and the enzyme or from the formation of superoxide ions on the quinone ring of the antibiotic molecule. As their action is to hinder bacteria multiplication, they are, at least *in vitro*, antagonists to antibiotics that require active bacterial growth to exert their activity (ß-lactams) or other antibiotics that act on protein synthesis (macrolides and aminoglycosides). This antagonism is, however, not observed *in vivo*, because of the different distribution of these antibiotics (intracellular for rifamycins; extracellular for ß-lactams and aminoglycosides). Their postantibiotic effect is longlasting because of the irreversible

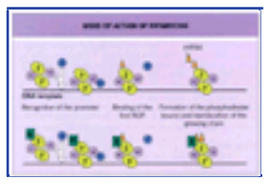

Figure 188-14 Mode of action of rifamycins. Synthesis of mRNA by RNA polymerase is shown in the upper panel and inhibition by rifamycins (R in the green squares) is shown in the lower panel. The RNA polymerase core is made up of four subunits, of which the ß' subunit binds to the DNA template and the ß subunit binds the ribonucleotide diphosphate (NDP; triangle). The s factor only participates to the initiation step by allowing for the recognition by the enzyme core of promoter sequences on the DNA template. Rifamycins bind to the ß subunit. They do not interfere with the binding of the nucleotide diphosphate, but rather inhibit the transcription initiation either by impairing the formation of the first phosphodiester bond or the translocation reaction of the newly synthesized dinucleotide.

nature of their binding. The efficient cell penetration of ansamycins gives them excellent activity against sensitive intracellular organisms.

Future developments

Benzoxazinorifamycins constitute a new group of semisynthetic molecules that show greatly enhanced activity against *Mycobacteria* spp., the main clinical target of this class of antibiotics.[54]

ANTIMETABOLITES

Sulfonamides and diaminopyrimidines

Prontosil (sulfamidochrysoidine) was one of first synthetic compounds with antibacterial activity found by Domagk in 1932. In fact, this product was a prodrug and elucidation of its metabolism led to the development of the sulfonamides. With diaminopyridines, they inhibit the folate pathway in bacteria.

Chemical structure

Sulfonamides are derived from *p*-aminobenzenesulfonamide which is a structural analog of *p*-aminobenzoic acid, a factor required by bacteria for folic acid synthesis. A free amino group at C4 and a sulfonamide group at C1 are required for antibacterial activity. Heterocyclic or aromatic rings substituting the sulfonamide enhance this activity by modifying absorption and gastrointestinal tolerance.

Diaminopyrimidines, such as trimethoprim and pyrimethamine, are pyrimidines substituted at C5 by an aromatic group. Pyrimethamine has an additional substituent at C6.

Mode of action

Sulfonamides inhibit tetrahydrofolic acid synthesis.[55] [56] Briefly, this synthesis requires successive enzymatic reactions, among which are:

- formation of pteroic acid from *p*-aminobenzoic acid and dihydropteridin catalyzed by the dihydropteroate synthetase, and
- reduction of dihydrofolic acid in tetrahydrofolic acid (the active form of folic acid) catalyzed by the dihydrofolate reductase.

Sulfonamides act via a double mechanism. First, as analogs as *p*-aminobenzoic acid, they are competitive inhibitors of dihydropteorate synthetase. Second, they can also function as alternative substrates for the synthetase and become incorporated into a product with pteridine.

Diaminopyrimidines are specific inhibitors of bacterial dihydrofolate reductase[55] [56] and act as competitive inhibitors of this enzyme. Even though dihydrofolate

reductase is present in bacteria as well as in eukaryotic cells, action selectivity occurs; this might be explained by the different conformation formed in the cavity of the bacterial enzyme compared with the conformation in the eukaryotic enzyme [radiographic cocrystallization data (trimethoprim-enzyme) suggest that trimethoprim in bacterial enzymes establishes more binding interactions than in the eukaryotic enzymes]. In addition, the NADPH cofactor may stabilize the enzyme-trimethoprim complex in the bacteria.

Resistance

For sulfonamides, resistance mainly occurs by hyperproduction of *p*-aminobenzoic acid or by reduction of the affinity of the dihydrofolate reductase for the antibiotic, which causes resistance to the whole class. For diaminopyrimidines, resistance mostly occurs by enzyme mutations that prevent binding [a single point mutation (e.g. Phe98?Tyr) is sufficient to prevent any binding of trimethoprim to the enzyme, because of the loss of a critical hydrogen bound].[57]

Pharmacodynamics

Sulfonamides are only bacteriostatic. Their combination with diaminopyrimidines confers to them a bactericidal activity because of synergism.

ANTIBIOTICS ACTING ON THE MEMBRANE

Cyclic polypeptides (polymyxins/colistins)

Chemical structure

These are a collection of cyclic, branched polypeptides (molecular masses about 1000Da) containing both cationic and hydrophobic aminoacids. Some of these are the D configuration or are non-DNA coded, which confers resistance to mammalian peptide-degrading enzymes (60–90% of a parenterally-administered dosis is excreted intact in the urine). Polymyxins are obtained from *Bacillus polymyxa* and colistins from *Aerobacillus colistinus*. Only polymyxin B and colistin A (identical to polymyxin E) are used in clinical practice.

Mode of action

Because of their amphipathic character, polymyxins and colistins act as detergents and alter the permeability of the cytoplasmic membrane.[58] They, therefore, affect bacteria at all stages of development. However, they cannot easily diffuse through the thick peptidoglycan layer of Gram-positive bacteria. In contrast, they easily bind to the phospholipids of the outer membrane of Gram-negative bacteria from where they reach the cytoplasmic membrane through polar as well as nonpolar channels. These properties explain both their strong and fast bactericidal activity through major perturbation of the inner membrane permeability properties (but recent findings have challenged this mechanism) and their narrow spectrum, which is essentially limited to Gram-negative organisms.

Resistance

Acquired resistance to polymyxins and colistins is chromosomal and results from a decreased permeability of the outer membrane secondary to changes in its biochemical composition. Bacteria with decreased sensitivity are indeed characterized by a decreased phospholipid/lipid ratio and a higher content in divalent cations (Ca^{2+} , Mg^{2+}). Protein H1 from *P. aeruginosa* (presently known as OprH) prevents binding of polymyxins and colistins to lipopolysaccharide and its overproduction has been correlated with less sensitivity [this change is, however, not sufficient *per se* and must be combined with other modifications of the membrane; two genes downstream to OprH (PhoP and PhoQ) coregulate OprH and polymyxin B resistance]. Although still exceptional, resistance to polymyxins and colistins has now been described in strains exhibiting multiple resistance to ß-lactams and aminoglycosides.[59]

Pharmacodynamics

Colistin A and polymyxin B show concentration-dependent activity but no or little post-antibiotic effect (rapid regrowth after the concentration falls below the MIC), justifying the administration of repeated daily doses.[60]

Nonantibiotic pharmacologic and toxicologic properties related to chemical structure

As membrane-disrupting and lipid-binding agents, polymyxins and colistins display a number of non-antibiotic effects, some of which are potentially useful [inactivation of endotoxins (immobilized polymyxin B is currently used to remove endoxins from protein solutions), and synergy with serum bactericidal activities], but many others are highly detrimental to the host [activation of the alternate pathway of complement, mast cell degranulation with histamine release, decreased production of cytokines (but increased TNF-a release), increase in membrane conductance in epithelia, apoptosis].

Future developments

Because of the widespread emergence of resistance to other antimicrobials, polymyxins are being re-evaluated for chronic, difficult-to-treat infections (e.g. pulmonary infections in cystic fibrosis) and new, potentially less toxic derivatives are therefore being synthesized and evaluated.[61] The use of polymyxin B as an anti-endotoxin agent is also being investigated.[62]

Chapter 189 - Mechanisms of Antibacterial Resistance

Franz-Josef Schmitz
Ad C Fluit

INTRODUCTION

Although treatment of infections is often initiated empirically, the determination of bacterial susceptibility to an antimicrobial agent is an essential test in clinical microbiology because of widespread resistance to all classes of antimicrobial agents. Standardized methods for the determination of susceptibility and resistance have been formulated.[1] Bacterial isolates that are considered resistant to an antibiotic by these methods usually cannot be treated by this antibiotic, although the successful clinical outcome for isolates deemed susceptible is not guaranteed.

There is a strong correlation between the presence of some determinants of bacterial resistance and the outcome of antimicrobial therapy. The presence of a ß-lactamase in *Neisseria gonorrhoeae* strongly correlates with penicillin treatment failure. The presence of the *mecA* gene in *Staphylococcus aureus* is highly predictive for treatment failure with oxacillin, and in fact oxacillin-resistant *S. aureus* (usually called methicillin-resistant *S. aureus* (MRSA) because of their resistance to the oxacillin analog methicillin) are by definition also considered resistant to all other ß-lactam antibiotics.

However, the presence of a resistance gene is not equivalent to treatment failure. The gene should also be expressed in sufficient levels to lead to phenotypic resistance, and expression may differ depending on culture conditions or site of infection. For example ß-lactamase production is common among Enterobacteriaceae but resistance to penicillins depends on the mode and amount of expression.

Antibiotic resistance can be divided into six basic groups depending on the mechanism involved:

- the presence of an enzyme that inactivates the antibiotic;
- the presence of an alternative enzyme for that inhibited by the antibiotic;
- mutation in the target, which reduces binding of the antibiotic to the target;
- modification of the target, which reduces binding of the antibiotic to the target;
- reduced uptake of the antibiotic; and
- active efflux of the antibiotic.

The genetic determinants for resistance against antimicrobial agents can be located on the bacterial chromosome or on plasmids. The analysis of resistance genes and their distribution through the use of modern DNA techniques has provided new insights into the mechanisms of resistance and the spread of resistance genes through hospitals and the community.

RESISTANCE TO ß-LACTAM ANTIBIOTICS

Penicillin is the oldest ß-lactam antibiotic; since its introduction we have witnessed the development of a whole array of ß-lactam-based antibiotics, such as the first-generation cephalosporins through to the fourth-generation cephalosporins, carbapenems and monobactams. Almost immediately after the introduction of penicillin, resistance was observed in staphylococci. The ß-lactam antibiotics interfere with cell wall synthesis by binding to the enzymes involved in the process. These enzymes are called penicillin-binding proteins (PBPs). Resistance to ß-lactams is mainly caused by either the presence of ß-lactamases, which destroy the lactam ring, or the presence of altered PBPs, which are not inhibited by these antibiotics. In Gram-positive bacteria the ß-lactamase is excreted into the environment, and in Gram-negative bacteria the ß-lactamase is excreted in the periplasm. Whether the ß-lactam antibiotic is effective against the bacterium depends on a number of factors (Fig. 189.1), including:[2]

- the concentration of the antibiotic in the environment;
- the rate of entry through the outer membrane (in the case of Gram-negative bacteria);
- the amount of ß-lactamase;
- the hydrolysis rate for the antibiotic by the ß-lactamase; and
- the affinity of the PBPs for the antibiotic.

The number of ß-lactamases has steadily risen since the introduction of penicillin. The ß-lactamases have been classified according to their functional aspects. [3] This system is based on hydrolysis rates for a number of substrates and the level of inhibition by clavulanic acid, but simple point mutations may alter the classification. They have also been classified according to the nucleotide sequences that encode ß-lactamase.[4] Classes A, B and D have a serine at their active site, whereas class B has a zinc atom at the active site. Class A enzymes are encoded mostly on plasmids, whereas class C enzymes are generally chromosomally encoded. Class A enzymes are generally constitutively expressed. Class C enzyme genes are present in almost all Gram-negative bacilli, except *Salmonella* spp., but their presence (e.g. in *Escherichia coli*) does not necessarily lead to resistance. Class C enzymes are usually inducible and a total of four genes are required for expression of ß-lactamase activity. *Escherichia coli* possesses the *ampC, ampD* and *ampG* genes, but lacks the *ampR* gene. Why *E. coli* possesses three of these genes and lacks the fourth is unclear. Class D is a limited group of enzymes able to hydrolyze oxacillin; they are related to class C enzymes. Class B is of increasing importance because many act as carbapenemases. The ß-lactamases range between 30 and 40kDa in size.

The commonest ß-lactamases in Enterobactericeae are TEM-1, TEM-2 and SHV-1 (TEM are the first three letters of the patient from which the isolate came that harbored the first TEM ß-lactamase; SHV stands for sulfhydryl variable). These are simple penicillinases and their activity can be inhibited by compounds such as clavulanic acid and tazobactam, thereby rendering penicillin derivatives active again. However, TEM and SHV enzymes can easily obtain a broader spectrum through mutations, which may lead to resistance against third-generation cephalosporins. Inactivation of aztreonam, ceftazidime, cefotaxime or ceftriaxone is considered an indication for the presence of such an extended-spectrum ß-lactamase (ESBL). However, these antibiotics can also be inactivated by the overproduction of ampC. True ESBLs are determined by their inhibition with clavulanic acid.

Resistance to third-generation cephalosporins was first described in 1983 and was mediated by a plasmid encoding for a TEM-related

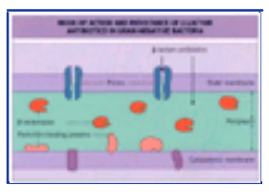

Figure 189-1 Mode of action and resistance of ß-lactam antibiotics in Gram-negative bacteria.

ß-lactamase. The majority of ESBLs are found in *Klebsiella pneumoniae* isolates. Extended spectrum ß-lactamases are encoded by plasmids, and these are highly transmissible. More than 60 TEM-type ESBLs have been described (Table 189.1). [5] In addition, more than 30 SHV-type ESBLs are known. Besides these common ESBL-types, some ESBLs have been described that do not belong to these two classes. Some plasmid-encoded cephalosporinases, which are also called

cephamycinases, have properties similar to ampC but are produced constitutively. Spread of these genes through the hospital or the community may further endanger the use of cephalosporins.

Another group is formed by the carbapenemases. These enzymes are encoded chromosomally and inactivate the highly active carbapenems, imipenem and meropenem, but resistance is still rare.

Altered PBPs are also a major reason for resistance against ß-lactam antibiotics. An altered PBP is involved in methicillin resistance in staphylococci. Both MRSA and methicillin-resistant *Staphylococcus epidermidis* (MRSE) are important causes of nosocomial infections. These infections are difficult to treat because both MRSA and MRSE are generally multiresistant and are susceptible to only a limited number of antibiotics.

This PBP2a is encoded by the *mecA* gene. Regulation of methicillin is complex. Expression can be heterogeneous and only a few cells express the phenotype, although all cells are genotypically identical and possess the *mecA* gene. Through mutation the resistance phenotype may become homogeneous. Expression is also influenced by the plasmid-encoded ß-lactamase regulatory (blaR) systems blaR1 and blaI inducer-repressor system, which interacts with the mec-associated mecR1 and mecI system.[6] The *mec* determinant appears to originate in coagulase-negative staphylococci, which have a much higher prevalence of the gene, and horizontal transfer appears to take place on a regular basis. The *mecA* gene appears to be located on a transposon, but the genetic environment of the *mecA* gene may vary considerably among different strains of staphylococci, although there is a core region and some specific genetic determinants are frequently associated with the presence of *mecA* (Fig. 189.2).[7] Besides the presence of *mecA*, some methicillin-resistant strains are overproducers of ß-lactamases.[8] [9]

Resistance to penicillin in *Streptococcus pneumoniae* is also due to the presence of altered PBPs, and this mechanism can be responsible for chromosomally mediated penicillin resistance in *N. gonorrhoeae*.

RESISTANCE TO AMINOGLYCOSIDES

The first clinically effective aminoglycoside was streptomycin, which was isolated from *Streptomyces griseus* and first described in 1944. Numerous aminoglycosides have been isolated from species belonging to the genera *Streptomyces*, *Micromonospora*, *Bacillus* and *Pseudomonas*. Also, synthetic derivatives were produced, such as amikacin. Clinically, the most important aminoglycoside antibiotics are gentamicin, tobramycin, amikacin and streptomycin. They have a broad antimicrobial spectrum and are effective against both Gram-positive and Gram-negative organisms. However, they are not effective against anaerobes. Aminoglycosides bind to the ribosomes and thus interfere with protein synthesis (see Chapter 188).

Aminoglycosides enter the bacterial cell in several phases. In the first phase the aminoglycosides bind to anionic sites on the cell and, after binding, diffuse through outer membrane proteins. In *Pseudomonas aeruginosa* the entry is enhanced; the lipopolysaccharides of *P. aeruginosa* are rich in phosphate groups to which the aminoglycosides bind. This binding displaces magnesium ions, thus allowing entry of the aminoglycoside. The second and third phases are energy dependent and transport the aminoglycoside molecules across the cytoplasmic membrane. The lack of activity of aminoglycosides against anaerobes is explained by the fact that the transport of aminoglycosides across the cytoplasmic membrane depends on aerobic respiration.

Inactivation of aminoglycosides is the major mechanism of resistance against these antibiotics, but ribosomal modification and reduced permeability may also lead to resistance. The enzymes that are responsible for inactivation belong to three classes, depending on the type of modification that causes inactivation: phosphotransferases (APH), acetyltransferases (AAC) and nucleotidyltransferases (ANT). Each class is subdivided on the basis of the site of modification on the substrate and substrate specificity (Table 189.2). Often these enzymes are able to modify several closely related antibiotics, which is not surprising in view of their chemical similarity. The enzymes have to inactivate their targets before they reach the ribosomes and they appear to be either located inside the cell or associated with the inside or the outside of the cytoplasmic membrane.[10]

Resistance to aminoglycoside antibiotics is widespread and of clinical importance. It is observed in both Gram-negative and Gram-positive bacteria. Studies concerning the evolution of resistance using nucleotide sequencing clearly show that, at least within enzyme classes, the genes are related. For example, immunologic and hybridization tests have shown that the APH(3') enzymes from streptococci and staphylococci are closely related, as are those enzymes on the Gram-negative transposons (Tn), Tn*5* and Tn*903*. However, there is far less homology between enzymes from Gram-negative bacteria compared to enzymes from Gram-positive bacteria. Nevertheless, the genes from Gram-negative bacteria appear to be more closely related to a gene of *Streptomyces fradiae*. In fact it was concluded that it is likely that gene transfer had taken place between these species. Aminoglycoside resistance genes are believed to have originated from genes involved in the production of aminoglycosides in aminoglycoside-producing species.[11]

Besides the transfer of genes between bacteria and aminoglycoside-producing species, transfer between Gram-positive and Gram-negative species has been documented. [12] It should be noted, however, that transfer of a functional resistance gene from one species or even within one species does not necessarily lead to the expression of resistance.

Aminoglycoside resistance in staphylococci is well documented. [13] Up to six genes have been identified. Often more than one resistance gene is present. One of the most remarkable aminoglycoside enzymes is the bifunctional AAC(6')APH(2") enzyme, which is found on Tn*4001* of *S. aureus* and in *Enterococcus faecalis* isolates. Nucleotide sequencing data suggest that the enzyme arose through the fusion of two genes, each encoding one of the partners. The epidemiology of Tn*4001* is well studied and illustrates that substitutions, insertions

and deletions play an important role in the adaptation of these elements to new hosts.

Hybridization studies in Australia showed that Tn*4001* could be present on the bacterial chromosome as well as on a number of structurally related plasmids, and this was linked to the rapid spread of gentamicin- and tobramycin-resistant *S. aureus* in Australia. The same transposon was also observed in the USA but with shorter inverted repeats and insertion sequences flanking the resistance gene.

The presence of multiple genes is also well known for other species, especially Gram-negative organisms, but the myriad aminoglycoside resistance genes makes it difficult to study the extent of this problem.

Initially, only resistance against the naturally occuring aminoglycosides was observed and only APH(3')-II and APH(3')-III were capable of modifying amikacin in vitro, but the introduction of this antibiotic quickly changed this. In the San Juan Veterans Administration Medical Center, the prevalence of amikacin resistance increased from 0.2 to 3.6% among aerobic Gram-negative bacilli in 4 years through the use of amikacin as a first-line antibiotic. Analysis of plasmids obtained from amikacin-resistant *Serratia marcescens* and *K. pneumoniae* showed that these were almost identical. This suggested that the plasmid disseminated through the hospital and that this dissemination occurred in a relatively short time span.[14]

Resistance to streptomycin is often caused by mutation of the S12 protein in the small ribosomal subunit (30S subunit).

RESISTANCE TO MACROLIDES, LINCOSAMIDES AND STREPTOGRAMINS

Macrolide, lincosamide and streptogramin (MLS) antibiotics are chemically distinct inhibitors of bacterial protein synthesis. Macrolides are composed of a minimum of two amino sugars or neutral sugars attached to a lactone ring of variable size. Macrolides can be subdivided according the chemical structure of their lactone ring (into 14-membered, 15-membered or 16-membered lactone ring macrolides). These classes differ in their pharmacokinetic properties and in their responses to bacterial resistance mechanisms. Lincosamides are alkyl derivatives of proline and are devoid of a lactone ring. Streptogramin antibiotics are mixtures of naturally occurring cyclic peptide compounds. They are composed of two factors, A and B (e.g. pristinamycin II and I, virginiamycin M and S), with synergistic inhibitory and bactericidal activities[15] [16] (see Chapter 194).

Intrinsic resistance to macrolide, lincosamide and streptogramin B (MLS_B) antibiotics in Gram-negative bacilli is due to low permeability of the outer membrane to these hydrophobic compounds.

Three different mechanisms of acquired MLS resistance have been described in Gram-positive bacteria. First, target modification alters a site in 23S rRNA that is common to the binding of MLS_B antibiotics. Modification of the ribosomal target confers cross-resistance to MLS_B antibiotics (MLS_B -resistant phenotype) and remains the most frequent mechanism of resistance, although enzymatic modification of the antibiotics and active efflux appear to be increasingly prevalent. [15] [17] [18]

Target modifications

Macrolide, lincosamide and streptogramin antibiotics bind to 50S ribosomal subunits and inhibit elongation of peptide chains. Resistance to MLS_B antibiotics is mostly

due to acquisition of erythromycin resistance methylase (*erm*) genes that encode enzymes that N^6 -dimethylate an adenine residue of 23S rRNA. The precise site of methylation has been located in a highly conserved region of the

TABLE 189-2 -- Characteristics of aminoglycoside-modifying enzymes.

CHARACTERISITICS OF AMINOGLYCOSIDE-MODIFYING ENZYMES

rRNA. Nucleotide alterations in 23S rRNA, both mutational and post-transcriptional, cluster in the peptidyltransferase region in 23S rRNS domain V, providing a physical basis and a common location for MLS_B antibiotic sites of action. Methylation of rRNA probably leads to a conformational change in the ribosome that results in decreased affinity and leads to co-resistance to all MLS_B antibiotics. This suggests that the binding sites for these drugs overlap or at least functionally interact. Streptogramin A-type antibiotics are unaffected, and synergy between the two components of streptogramin against MLS-resistant strains is maintained.

A sequence comparison of *erm* genes from various bacterial species and results of hybridization experiments under stringent conditions led to the recognition of at least nine classes of resistance determinants (Table 189.3). Because a number of these genes cross-hybridize, clinical isolates can be assigned to one of four hybridization classes: *ermA, ermC, ermAC* and *ermF*. This gene distribution is relatively species specific. The amino acid sequences of the methylases encoded by these determinants are related, indicating that the *erm* genes are derived from a common ancestor, possibly belonging to an antibiotic producer. However, various degrees of similarity among the enzymes can be observed.

Expression of MLS_B resistance can be constitutive or inducible. The character of resistance is not related to the class of *erm* determinant but, rather, depends on the sequence of the regulatory region upstream from the structural gene for the methylase. Regulation by these regions occurs by a translational attenuation mechanism in which mRNA secondary structure influences the level of translation. In laboratory mutants and clinical isolates, single nucleotide changes, deletions or duplications in the regulatory region convert inducibly resistant strains to constitutively resistant ones that are cross-resistant to MLS_B antibiotics.

Expression of MLS resistance in staphylococci may be constitutive or inducible. When expression is constitutive, the strains are resistant to all MLS_B antibiotics. Streptogramin A-type antibiotics escape

resistance, and synergy with streptogramin B-type antibiotics is retained. When expression is inducible, the strains are resistant to 14- and 15-membered macrolides only. The 16-membered macrolides, the commercially available lincosamides and the streptogramin antibiotics remain active. This dissociated resistance is due to differences in the inducing abilities of MLS antibiotics; only 14- and 15-membered macrolides are effective inducers of methylase synthesis in staphylococci.

Resistance to MLS antibiotics in streptococci can also be expressed constitutively or inducibly. However, unlike the situation with staphylococci, various macrolides or lincosamides may act as inducers to various degrees. Thus, in streptococci, whether inducible or constitutive, ribosomal methylation leads to cross-resistance among macrolides, lincosamides and streptogramin B antibiotics.

In addition, alterations in ribosomal protein L4 account for resistance in pneumococcal strains selected in vitro by macrolide passage. The presence of alterations in the L4 ribosomal protein is consistent with the interpretation that this protein is in contact with or near the peptidyltransferase region in domain V of 23S rRNA. Thus, this alteration may act indirectly to alter 23S rRNA confirmation. [19] In some cases, these modifications also reduce the in-vitro activities of ketolides, derivatives of macrolides, which were designed in order to act against macrolide-resistant micro-organisms.

Antibiotic inactivation

Unlike target modification, which causes resistance to structurally distinct antibiotics, enzymatic inactivation confers resistance only to structurally related drugs.[15] [17] [18] [19]

Enzymes (ErmA and ErmB) that hydrolyze the lactone ring of the macrocyclic nucleus and phosphotransferases (type I (*mphA*) and type II) that inactivate macrolides by introducing a phosphate on the 2'-hydroxyl group of the amino sugar have been reported in members of the family Enterobacteriaceae and in *S. aureus*. The gene *linA* mediates resistance to lincosamides. The product of *linA* has been partially purified and demonstrated to act as a lincosamide O-nucleotidyl transferase. Lactonases that are capable of cleaving the macrocyclic lactone ring structure of type B streptogramins have been identified in staphylococci (*vgb* gene). Two staphylococcal-related determinants, *vat* and vat_B , encoding an acetyltransferase that inactivates type A streptogramins, have been characterized. The *vat* and *vgb* genes are adjacent to each other on plasmid pIP630. This vat-vgb region is flanked by inverted copies of the insertion sequence IS257, suggesting a role for this element in dissemination of these determinants.

Active efflux

The presence of multicomponent macrolide efflux pumps in staphylococci (msrA, msrB) and *N. gonorrhoeae* (mtr), as well as an efflux system in streptococci (mefA, mefE), has also been documented.[20] [21] [22] [23] *msr* genes confer resistance only to 14- and 15-membered ring macrolides. Recent epidemiologic surveys have shown that some erythromycin-resistant strains of pneumococci and group A streptococci have been shown to have the M phenotype, namely resistance to macrolides but susceptibility to lincosamide and streptogramin B antibiotics. These strains contain the *mefA* or *mefE* gene coding for an efflux pump for 14- and 15-membered macrolides. The presence of a plasmid-mediated gene, *vga*, encoding for a putative ATP-binding protein, has been associated with an active efflux of streptogramin A group compounds. An overview on macrolide resistance genes was recently published.[19]

RESISTANCE TO FLUOROQUINOLONES

Fluoroquinolone antibiotics exert their antibacterial effects by inhibition of certain bacterial topoisomerase enzymes, namely DNA gyrase (bacterial topoisomerase II) and topoisomerase IV.[13] [23] [24] [25] [26] These essential bacterial enzymes alter the topology of double-stranded (ds) DNA within the cell. In most bacteria, the chromosome exists as a single circle of dsDNA, which is maintained in a highly negatively supercoiled state. This energetically activated form is required for critical cellular processes such as replication and transcription.

Deoxyribonucleic acid gyrase and topoisomerase IV are heterotetrameric proteins composed of two subunits, designated A and B. The genes encoding the A and B subunits are referred to as *gyrA* and *gyrB* (DNA gyrase) or *parC* and *parE* (DNA topoisomerase IV (*grlA* and *grlB* in *S. aureus*)).

Deoxyribonucleic acid gyrase is the only enzyme that can effect supercoiling of DNA. Inhibition of this activity by fluoroquinolones is associated with rapid killing of the bacterial cell. Topoisomerase IV also modifies the topology of dsDNA, but whereas DNA gyrase seems to be important for maintenance of supercoiling, topoisomerase IV is predominantly responsible for separation of daughter DNA strands during cell division.

In Gram-negative organisms, DNA gyrase is the primary target for quinolones, whereas topoisomerase IV appears to be the primary target in *Staphylococcus aureus* and *Streptococcus pneumoniae*. In Gram-positive species, mutations in genes encoding topoisomerase IV appear to precede mutations in DNA gyrase. Nevertheless, in *S. pneumoniae* it has been shown that different quinolones can have different primary targets in the same bacterial species (i.e. quinolone structure determines the mode of antibacterial action). Thus, the primary target seems to be dependent on the bacterial species as well as on the quinolone structure.

Target modification

Alterations of the target enzymes appear to be the most dominant factors in expression of resistance to quinolones.[13] [23] [24] [25] [26] [27] Many Gramnegative fluoroquinolone-resistant organisms contain a *gyrA* mutation, resulting in inhibition of supercoiling of DNA and elevated minimum inhibitory concentrations (MICs; Table 189.4). The first molecular characterization of a quinolone resistance mutation in *gyrA* was reported

** Adapted from Everett and Piddock.*[24]

in 1988 from *E. coli*. The mutations found were situated in a relatively hydrophilic region of the polypeptide and close to a tyrosine residue at amino acid 122 at the active site, which has been shown to be the site covalently bound to the DNA. The small region from codon 67 to 106 was designated the quinolone resistance determining region (QRDR). In almost all instances, amino acid substitutions within the QRDR involve the replacement of a hydroxl group with a bulky hydrophobic residue. This suggests that mutations in *gyrA* induce changes in the binding site conformation or charge (or both) that may be important for interactions between quinolones and DNA gyrase.

Although quinolones are thought to interact primarily with the A subunit of DNA gyrase, there are mutations in the B subunit that also confer quinolone resistance in some species, such as *E. coli*. However, the frequency of *gyrB* mutations has been shown to be relatively low compared with the frequency of *gyrA* mutations in clinical isolates of *E. coli* and other Gram-negative organisms. Until now, no *gyrB* mutations have been reported as resulting in cross-resistance between quinolones and the B subunit inhibitors coumermycin and novobiocin. This is consistent with evidence that suggests that the GyrB protein comprises two distinct domains: an *N*-terminal domain containing the sites for hydroloysis of adenosine triphosphate and binding of coumermycin, and a *C*-terminal domain containing the QRDR of GyrB.

Topoisomerase IV is a secondary target for fluoroquinolone action in *E. coli* in the absence of a sensitive DNA gyrase. Mutations in *parC* result in further decreased susceptibility. These mutations in *parC* have been shown to occur at Ser80 and Glu84, which are analogous to codons Ser83 and Asp87 of *E. coli gyrA*, and to be common in fluoroquinolone-resistant clinical isolates of *E. coli*. A mutation has also been reported in the *parE* gene that results in decreased fluoroquinolone susceptibility. However, as in the case with *gyrB*, such mutations appear to be rare in clinical isolates.

In *Staphylococcus aureus*, topoisomerase IV is the primary target of fluoroquinolones. Strains with mutations in *gyrA* and *gyrB* without *grlA* mutations resulting in high-level fluoroquinolone resistance can be isolated by single-step selection with fluoroquinolones in *E. coli* but not in *S. aureus*. Previously, 116 clonally unrelated *S. aureus* isolates originating from nine different countries were screened for mutations in the *gyr* and *grl* gene loci.[27] In correlating the characterized mutations to the resulting MIC of ciprofloxacin, it is clear that all studied isolates without the *grlA* mutation at position Ser80 were susceptible to ciprofloxacin. All ciprofloxacin-resistant isolates had the *grlA* mutation Ser80 in combination with either a Ser84 mutation or a Glu88 mutation within the *gyrA* gene. In two isolates a Ser80 to Phe mutation was combined with no mutations in the *gyrA* gene, resulting in a MIC value for ciprofloxacin of 2µg/ml, which, although elevated from a wild-type level, is still below the breakpoint for resistance. These data support the finding that in *S. aureus*, *grlA* mutations precede *gyrA* mutations in developing resistance to ciprofloxacin. Combinations of single point mutations within the *gyrA* gene from various species have been shown to be associated with higher MIC values for ciprofloxacin than single point mutations. Similarly, two combinations of single point mutations within *grlA*, of a Glu84 to Val mutation or a Ala48 to Thr mutation in combination with a Ser80 to Phe mutation, were associated with relatively higher ciprofloxacin MIC values (64–256µg/ml) than only a single Ser80 to Phe mutation (8–64µg/ml). Sequence data show that some *grlA* and *gyrA* mutations are conserved in both MRSA and methicillin-sensitive *S. aureus* from unrelated clones of *S. aureus* isolated from different countries.

Topoisomerase IV mutations have now been characterized in several other organisms. In *Streptococcus pneumoniae* topoisomerase IV also appears to be the primary target for fluoroquinolone action. Ciprofloxacin-resistant mutants of *S. pneumoniae* were

generated by stepwise selection at increasing drug concentrations. First-step mutants exhibiting low-level resistance had no detectable changes in their topoisomerases QRDR, suggesting altered permeation or another novel resistance mechanism. Second step mutants exhibited an alteration in ParC at Ser79 to Tyr or Ser79 to Phe or at Ala84 to Thr. Third and fourth step mutants displaying high-level ciprofloxacin resistance were found to have, in addition to ParC alteration, a change in GyrA at residues equivalent to *E. coli* GyrA resistance hot spots Ser83 and Asp87 or in GyrB at Asp435 to Asn, equivalent to *E. coli* Asp426. ParC mutations preceded those in GyrA, suggesting that topoisomerase IV is the primary topoisomerase target and gyrase the secondary target for ciprofloxacin in *S. pneumoniae*. Additionally, it has been shown that in *S. pneumoniae* different quinolones can have different primary targets. The targeting of DNA gyrase by sparfloxacin in *S. pneumoniae* but of topoisomerase IV by ciprofloxacin indicates that target preference can be altered by change in quinolone structure.

Decreased uptake

Deoxyribose nucleic acid gyrase and topoisomerase IV are both located in the cytoplasm of the bacterial cell. In order to reach their targets, fluoroquinolone antibiotics must traverse the cell envelope. In Gram-positive bacteria this consists of the cell wall and a single membrane, whereas in Gram-negative bacteria the fluoroquinolone must first cross the outer membrane. Changes in the cell envelope of Gram-negative bacteria, particularly in the outer membrane, have been associated with decreased uptake and increased resistance to fluoroquinolones.[23] [24] [25] [26] Some of these changes may be due to the effect of quinolones or *gyrA* mutations, or both, on differential expression of outer membrane proteins, because it has been shown that *gyrA*-mediated changes in supercoiling of DNA can affect the expression of porin genes. In contrast, decreased uptake has not been demonstrated to be a mechanism of resistance in Gram-positive bacteria.

Active efflux

Increased efflux as a mechanism of fluoroquinolone resistance has been reported in fluoroquinolone-resistant *Staphylococcus aureus*. The *norA* gene encodes the multidrug efflux pump NorA.[28] The NorA protein has a hydropathic amino acid profile consistent with a location in the cytoplasmic membrane and it exhibits a low level of fluoroquinolone efflux, with a preference for hydrophilic fluoroquinolones. Efflux is an active process and can be inhibited by protonophores. NorA-mediated fluoroquinolone resistance is due to overexpression of the wild-type gene *norA*. In *P. aeruginosa*, resistance to fluoroquinolones as well as to a number of other antimicrobial agents has often been associated with decreased accumulation and increased expression of outer membrane proteins, often with concomitant increase in cytoplasmic membrane proteins. Resistance is due to overexpression of one or more efflux systems (i.e. OprK) capable of removing fluoroquinolones and other antibiotic compounds. *Escherichia coli* has also been shown to possess efflux systems, notably EmrAB and AcrAB.[24]

MAR operon

Escherichia coli and a number of other organisms possess mechanisms that provide intrinsic protection against a wide range of chemically unrelated toxic substances, including quinolone antibiotics. Multiple antibiotic resistance (MAR) in *E. coli* has been shown to be the result of mutations in the *mar* locus of the *E. coli* chromosome. A homolog of the *mar* locus exists in other members of the Enterobacteriaceae as well as in other bacteria. In *E. coli*, the *mar* locus consists of two divergently expressed operons, marC and marRAB, both of which are required for full expression of the MAR phenotype. Expression of the MAR phenotype, whether by induction or mutation, protects the cells

from fluoroquinolone killing at up to four times the MIC. This may be more clinically important than the relatively modest increases in MIC associated with MAR because cells that escape death would have the potential to mutate to higher levels of fluoroquinolone resistance.[23] [24] [29]

RESISTANCE TO TETRACYCLINES

Tetracyclines probably penetrate bacterial cells by passive diffusion. Tetracycline acts by reducing the affinity of the A and P sites of the 30S ribosomal subunit for aminoacyl transfer RNA, resulting in the inhibition of protein synthesis. [13] [23] [30] [31] [32] [33]

A growing number of bacterial species are acquiring resistance to the bacteriostatic activity of tetracycline. Until now, at least 16 tetracycline-resistance (Tet)

determinants and three oxytetracycline-resistance (Otr) determinants, first found in oxytetracyline-producing *Streptomyces* spp., have been described and characterized, with new Tet determinants being identified continually. Of these determinants, at least 13 are frequently associated with plasmids, whereas others are on the chromosome (Table 189.5). Resistance to tetracyclines is primarily due to acquisition of Tet determinants rather than to mutation of existing chromosomal genes.

The two widespread mechanisms of bacterial resistance do not destroy tetracycline: one is mediated by energy-dependent efflux pumps; and the other involves an elongation-factor G-like protein that confers ribosome protection. Both mechanisms are widespread among Gram-negative and Gram-positive bacteria (Table 189.6 and Table 189.7). Oxidative destruction of tetracycline has been found in a few species. Nevertheless, the enzymatic inactivation of the antibiotic is not thought to be important in nature. The classification of Tet determinants according to their mechanism of resistance is shown in Table 189.8 .

Reduced intracellular concentration of tetracycline

Because the ribosome is the target, antibiotic activity of tetracycline depends on the presence of the drug in the cytoplasm. A reduced tetracycline concentration in the cytoplasm can be achieved by two means:[13] [23] [30] [31] [32] [33]

- the permeability of the cell envelope may be lowered; or
- tetracycline may be pumped out of the cytoplasm in an energy-dependent fashion.

Bacteria differ in their cell wall composition, causing differences in permeability and hence insensitivity to antibiotics. The peptidoglycan

TABLE 189-6 -- Distribution of tetracycline-resistance determinants among Gram-negative bacteria.*

Ribosomal-protection encoding genes have not yet been found in enteric genera, and when these genes are cloned into *Escherichia coli* the level of resistance to tetracycline conferred is relatively low. Tet, tetracycline-resistance determinant.			

* *Data from Roberts.*[30]

layer surrounding most Gram-positive bacteria does not reduce cytoplasmic accumulation of low molecular weight antibiotics such as tetracycline. In contrast, the outer membrane of Gram-negative bacteria is an effective permeability barrier for hydrophobic compounds. The effects of permeability barriers are usually supported by additional resistance mechanisms to achieve high-level resistance. Energy-dependent efflux of tetracycline causes high-level resistance in bacteria by itself. Two different types of efflux pumps are involved in tetracycline resistance: multidrug-resistance pumps and tetracycline-specific transporters. A multidrug-resistance pump belonging to the Acr family is responsible for the reduced tetracycline accumulation in *P. aeruginosa*. Furthermore, *E. coli* has a chromosomal multidrug resistance efflux system that is associated with the *mar* locus. Multidrug efflux pumps transport their substrate straight out of the cell into the surrounding medium. In contrast to the broad substrate range of multidrug transporters, many of the efflux pumps identified in Gram-positive and Gram-negative bacteria specifically transport tetracycline (see Table 189.8). The efflux proteins exchange a proton for a tetracycline-cation complex and are antiporter systems. Efflux determinants from Gram-negative bacteria (TetA-E, TetG-H) share a common genetic organization, which is different from the one in Gram-positive bacteria. Both Gram-negative and Gram-positive contain a structural and a repressor gene that are expressed in opposite directions from overlapping operator regions. The Gram-positive *tetK* and *tetL* genes encoding tetracycline-efflux proteins are regulated by mRNA attenuation in a similar way to that described for Gram-positive *erm* genes encoding rRNA methylase and *cat* genes encoding chloramphenical acetyltransferases.

Tetracycline-specific exporters pump their substrate into the periplasm and not across the outer membrane, as found for the multidrug efflux pumps.

Protection of the ribosome

Protection of the ribosome from the action of tetracycline as a mechanism of tetracycline resistance was discovered in streptococci. Tetracycline resistance can result from production of a protein that interacts with the ribosome such that protein synthesis is unaffected by the presence of the antibiotic. To date, six classes of Tet determinants that confer tetracycline resistance on the level of protein synthesis have been identified (see Table 189.8). Most of the work on the mechanism of ribosomal protection has been done on TetM. The ribosomal protection proteins encoded by the other classes have an amino acid sequence similarity of at least 40% to TetM. Therefore, the mechanism of action may be similar for all ribosomal protection proteins. TetM ribosomal protection protein resembles elongation factors (EFs) in three properties:

- it has amino acid sequence similarity to EF-G (which translocates the peptidyl transfer RNA during protein synthesis) and EF-Tu;
- it has a ribosome-dependent guanosine triphosphatase activity; and
- it seems to confer resistance by reversible binding to the ribosome.

However, to date, the biochemical basis of tetracycline resistance mediated by TetM remains unclear. One possibility is that TetM stabilizes the ribosome-transfer RNA interaction in the presence of tetracycline.[13] [23] [30] [31] [32] [33]

RESISTANCE TO CHLORAMPHENICOL

Chloramphenicol is a bacteriostatic antibiotic that binds to the 50S ribosomal subunit and inhibits the peptidyltransferase step in protein synthesis. Resistance to chloramphenicol is mostly due to inactivation of the antibiotic by a chloramphenicol acetyltransferase (CAT) enzyme that acetylates the antibiotic. Chloramphenicol resistance most commonly results from the acquisition of plasmids that encode CAT, but in certain Gram-negative bacteria decreased outer membrane permeability can confer resistance to chloramphenicol and structurally unrelated compounds.[13] [23]

Enzyme inactivation

Chloramphenicol contains two hydroxyl groups that are acetylated in a reaction catalyzed by CAT. Monoacetylated and diacetylated derivatives are unable to bind to the 50S ribosomal subunit to inhibit prokaryotic peptidyltransferase. Expression of the *cat* genes in *Staphylococcus aureus*, *Streptococcus pneumoniae* and *Enterococcus faecalis* is typically inducible, and expression appears to be regulated by translational attenuation in a similar manner to the *erm* genes

TABLE 189-7 -- Distribution of tetracycline-resistance determinants among Gram-positive bacteria.*

DISTRIBUTION OF TETRACYCLINE-RESISTANCE DETERMINANTS AMONG GRAM-POSITIVE BACTERIA	
Genus	**Tet determinant**
Actinomyces	TetL
Aerococcus	TetM, O
Bacillus	TetK, L
Clostridium (anaerobic spp.)	TetK, L, M, P
Corynebacterium	TetM
Enterococcus	TetK, L, M, O
Eubacterium	TetK, M
Gardnerella	TetM
Gernella	TetM
Lactobacillus	TetO
Listeria	TetK, L, M, S
Mobiluncus (anaerobic spp.)	TetO
Mycobacterium (acid-fast bacteria)	TetK, L, OtrA, B
Mycoplasma (cell-wall-free bacteria with a Gram-positive metabolism)	TetM
Peptostreptococcus (anaerobic spp.)	TetK, L, M, O
Staphylococcus	TetK, L, M, O
Streptococcus	TetK, L, M, O
Streptomyces (multicellular bacteria)	TetK, L, OtrA, B, C
Ureaplasma (cell-wall-free bacteria with a Gram-positive metabolism)	TetM
Tet, tetracycline-resistance determinant; Otr, oxytetracycline-resistance determinant.

conferring resistance to macrolides. The *cat* gene is preceded by a nine-amino acid leader peptide, and the leader mRNA can form a stable stem-loop structure, which masks the ribosome binding site of the *cat* gene. Chloramphenicol appears to cause the ribosome to stall on the leader sequence, opening the stem-loop structure, thereby exposing the *cat* ribosome binding site and allowing *cat* expression. In Gram-negative bacteria, resistance to chloramphenicol is usually mediated by plasmid-mediated or transposon-mediated genes that are generally expressed constitutively.

Decreased permeability

In Gram-negative bacteria, resistance may also be due to chromosomal mutations that result in decreased outer membrane permeability. In *P. aeruginosa*, nonenzymatic chloramphenicol resistance is associated with the presence of the *clmA* gene. The ClmA protein appears to result in reduced expression of the outer membrane porins OmpA and OmpC and decreased chloramphenicol uptake. In *E. coli*, resistance to chloramphenicol and structurally unrelated antibiotics is part of the MAR phenotype.[34]

RESISTANCE TO GLYCOPEPTIDES

The glycopeptide antibiotics vancomycin and teicoplanin inhibit cell wall synthesis in Gram-positive bacteria by interacting with the terminal D-alanyl-D-alanine (D-Ala-D-Ala) group of the pentapeptide side-chains of peptidoglycan precursors. This interaction prevents the transglycosylation and transpeptidation reactions required for polymerization of peptidoglycan. Almost all bacteria synthesize peptidoglycan terminating in D-Ala-D-Ala, but the exclusion limits of the porin proteins of Gram-negative outer membranes prevent transport of the glycopeptides, and so only Gram-positive species are susceptible to clinically achievable concentrations of this class of antibiotics.

Glycopeptide resistance in enterococci

The vancomycin enterococci can be divided into six different phenotypic groups: A, B, C, D, E and H (Table 189.9).[13] [23] [35] [36] [37] [38] [39] [40]

The origin of the *van* genes in enterococci is not known. The *vanA* gene has 52% amino acid sequence identity to the D-Ala-D-Ala ligase of *Salmonella* spp. and can complement a temperature-sensitive ligase mutant of *E. coli*. The D-Ala-D-Ala ligase is responsible for the production of the D-Ala-D-Ala dipeptide, which in Gram-positive bacteria is the target for glycopeptide antibiotics. The *vanB* and *vanC* genes are also both highly comparable in sequence to D-Ala ligases.

VanA resistance phenotype

The *vanA* gene is carried within a transposon together with several other genes, many but not all of which are required for the expression of resistance to vancomycin. The VanA product is a D-Ala-D-lactate (D-Lac) ligase. The *vanH* gene apparently encodes an enzyme that catalyzes the conversion of pyruvate to D-lactic acid. The VanA ligase uses this as a substrate to form the depsipeptide D-Ala-D-Lac, which is than incorporated into an alternative, vancomycin-resistant peptidoglycan precursor (Fig. 189.3). The VanX protein appears to cleave the D-Ala-D-Ala dipeptide, decreasing the amount of substrate that is available for the formation of the normal pentapeptide. The VanX protein does not hydrolyze the D-Ala-D-lactate pentapeptide or pentadepsipeptide.

Most vancomycin-resistant strains of enterococci also produce a carboxypeptidase. The structural gene for this carboxypeptidase in VanA-harboring strains is *vanY*. The carboxypeptidase may reduce the levels of the normal precursor so that the alternative precursor predominates. The *vanY* gene, however, is not required for resistance to cyclic glycopeptides. The inducible nature of glycopeptide resistance in most VanA enterococci suggests that expression is regulated at the genetic level. The genes *vanR* and *vanS* are involved in the regulation of VanA resistance, and the analysis of the amino acid sequences of the gene products has indicated similarity with two-component signal transducing regulatory systems that sense and respond to environmental stimuli. VanR seems to act as a transcriptional activator and seems to be stimulated by VanS. The phosphorylated VanR peptide acts on a promoter that lies between *vanS* and *vanH* and from which the *vanH*, *vanA* and *vanX* genes are co-transcribed. The environmental stimulus that triggers the initial phosphorylation of VanS has not been identified, but it is probably related to the presence of vancomycin and its interaction with the D-Ala-D-Ala target site, which inhibits transglycosylation. In addition to the high-level glycopeptide resistance mediated by the *vanH*, *vanA*, *vanX* and *vanY* genes, a second mechanism of resistance

TABLE 189-9 -- Resistance to enterococcal glycopeptides.*

GLYCOPEPTIDE RESISTANCE IN ENTEROCOCCI						
Resistance	**Acquired**					**Intrinsic**
Phenotype	VanA	VanB	VanD	VanG	VanE	VanC

exists. The *vanZ* gene mediates resistance to teicoplanin while vancomycin MICs are unaffected. The mechanism by which the VanZ peptide confers this low-level teicoplanin resistance has yet to be established.

VanB and VanC resistance phenotypes

The drug resistance of VanB-harboring strains appears to be similar to that of VanA-harboring strains, except that the VanB-harboring strains originally described remained susceptible to teicoplanin. However, it has become clear that glycopeptide-resistant enterococci containing the *vanB* gene are phenotypically diverse, exhibiting a wide range of vancomycin MICs, including high-level resistance. In addition, the emergence of mutants that express *vanB* constitutively has been described. Resistance mediated by *vanB* may also be transferable, with the gene located either on the chromosome or on plasmids. The *vanC* resistance determinants are present on the chromosome in *Enterococcus casseliflavus* and *Enterococcus gallinarum* and are intrinsic characteristics of these species. VanC-harboring enterococci have low-level resistance to vancomycin and remain susceptible to teicoplanin. The pentapeptide that results from the action of the VanC ligase terminates in D-Ala-D-Ser. This substitution probably reduces vancomycin binding, albeit not to the same degree as the depsipeptide found in VanA and VanB enterococci. Insertional inactivation of *vanC* caused reversion to vancomycin susceptibility, suggesting the existence of a second chromosomal ligase that synthesizes vancomycin-susceptible precursors.

VanC-harboring strains with high-level resistance to glycopeptides as a result of the acquisition of the *vanA* gene cluster have also been isolated. The biochemical basis for the VanC phenotype displayed by most isolates of *E. casseliflavus* and *Enteroccocus flavescens* remains to be clarified in detail. Two genes, designed *vanC-2* and *vanC-3*, have been identified in these species. There is extensive similarity between the *vanC-2* or *vanC-3* gene and the *vanC* gene, now designated *vanC-1*, from *E. gallinarum*, although they do not cross-hybridize.

Glycopeptide resistance in staphylococci

Resistance to glycopeptides among staphylococci is phenotypically diverse[40] *S. aureus* strains resistant to vancomycin have been obtained in vitro either by selection of resistant mutants or by the conjugational transfer of *vanA* from enterococci.[41] Recently, the first vancomycin-resistant *S. aureus* isolate has been detected in the

USA. This strain contained the *vanA* gene, probably originating from a vancomycin-resistant *E. faecium* isolate. One of the enterococcal plasmids containing the *vanA* gene was found to be able to transfer to a strain of *S. aureus* and to be able to express resistance to vancomycin in an inducible fashion, and the resultant staphylococcal strain appears to have stably inherited the resistance. [41] Probably the same mechanism has appeared now in vivo. Teicoplanin-resistant derivatives of teicoplanin-susceptible *S. aureus* strains have also been obtained in vitro.

Recently, *S. aureus* isolates with reduced vancomycin susceptibility were described worldwide (GISA isolates — isolates with reduced susceptibility to glycopeptides).[40] As far as has been studied, all of these isolates contained thickened cell walls. Furthermore, all of them with the exception of the Illinois isolate

showed a reduced cross-linking when compared with isogenic revertants. Interestingly, only some of them (Michigan, New Jersey, Duesseldorf) showed a reduction in D-glutamic acid amidation.[40] The data described so far on GISA strains seem to indicate that, depending on the strain studied, several independent mutations have been accumulated in these strains, which in various combinations lead to the observed resistance phenotype.

Probably the following mechanisms are associated with the appearance of GISA strain:[40]

- ¦ accelerated cell wall synthesis, which leads to a thickened cell wall capable of affinity trapping large amounts of vancomycin and shielding the membrane-associated lipid II target molecules;
- ¦ most probably caused by the accelerated cell wall synthesis — in addition, cross-linking will be reduced due to the fact that nonamidated precursors are poor substrates for the staphylococcal transpeptidation reaction; and
- ¦ since lower nonamidation and lower cross-linking both lead to even higher consumption of vancomycin per unit cell wall weight, they also contribute positively to the resistance phenotype.

Glycopeptide resistance in other Gram-positive species

Glycopeptide resistance is intrinsic in some Gram-positive species such as *Lactobacillus* spp., *Leuconostoc* spp., *Pedicoccus* spp. and *Erysipelothrix rhusiopathiae*. The exact resistance mechanism is these species has not yet been clarified.

RESISTANCE TO TRIMETHOPRIM AND SULFONAMIDES

Trimethoprim and sulfonamides are synthetic agents that affect the biosynthesis of tetrahydrofolic acid, an essential derivative used in amino acid and nucleotide synthesis.[13] [23] [42] [43] [44] Sulfonamides are analogs of *p*-aminobenzoic acid. They competitively inhibit the enzyme dihydropteroate synthase (DHPS), which catalyzes the condensation of dihydropteridine with *p*-aminobenzoic acid synthesis. Trimethoprim is an analog of dihydrofolic acid. It competitively inhibits the enzyme dihydrofolate reductase (DHFR). Dihydrofolate reductase catalyzes the reduction of dihydrofolic acid to tetrahydrofolic acid, the final step in tetrahydrofolic acid synthesis. Trimethoprim-sulfamethoxazole (co-trimoxazole) is a combination of trimethoprim with a sulfonamide.

Intrinsic resistance to trimethoprim and sulfonamides

Outer membrane impermeability results in trimethoprim and sulfonamide resistance in *P. aeruginosa*. Intrinsic resistance to trimethoprim in a number of species is due to host DHFR enzymes with low affinity for the drug. Folate auxotrophs such as *Enterococcus* spp. and *Lactobacillus* spp. that are able to use exogenous pre-formed folates exhibit reduced susceptibilities to sulfonamides and trimethoprim.

Resistance to trimethoprim

Both high- and low-level resistance has been reported in several species. In some cases, chromosomally encoded trimethoprim resistance may be due to

- ¦ overproduction of the host DHFR;
- ¦ mutations in the DHFR structural gene *folA*; or
- ¦ mutations that inactivate thymidylate synthetase, an enzyme that converts deoxyuridylate to thymidylate.

These *thy* mutants require exogenous thymine or thymidine for DNA synthesis and are thus resistant to folate pathway antagonists.

High-level resistance to trimethoprim in enterobacteria is almost always caused by the acquisition of DNA that specifies a trimethoprim-resistant DHFR with an altered active site. At least 11 modified DHFRs have been characterized in Gram-negative organisms. In staphylococci, trimethoprim resistance is encoded by the *dfrA* gene, which encodes a trimethoprim-resistant type S1 DHFR. The transposon encoded *dfrA* gene appears to be responsible for both high- and low-level trimethoprim resistance in *S. aureus* and coagulase-negative staphylococci. The differences in resistance level correlate with differences in transcription caused by deletions adjacent to a copy of IS*257* in Tn*4003*, which affects the promoter used by *dfrA*. The *S. epidermidis* trimethoprim-sensitive chromosomal DHFR gene *dfrC* differs from *dfrA* by only four base pairs, strongly suggesting that *dfrA* originated from the *S. epidermidis* chromosomal gene. Site-directed mutagenesis of *dfrA* and kinetic analyses of the purified DHFRs indicate that a single alteration (Phe98 to Tyr) is responsible for the trimethoprim resistance of the type S1 DHFR.

Resistance to sulfonamides

Chromosomally encoded sulfonamide resistance has been described and resistance seems to be due to increased production of *p*-aminobenzoic acid. Furthermore, alterations of DHPS could lead to low affinity for sulfonamides. Acquired sulfonamide resistance can result from the acquisition of plasmids that encode a drug-resistant DHPS.

RESISTANCE IN *MYCOBACTERIUM TUBERCULOSIS*

Mycobacterial resistance to first-line antimicrobial agents is a considerable concern to health care. The slow growth rate of *M. tuberculosis* and the serious consequences of inappropriate therapy make the study of the mechanisms of antibiotic resistance of particular importance. The main antibiotics for the treatment of mycobacterial infections are isoniazid and rifampin (rifampicin). Resistance was reported soon after the introduction of isoniazid in 1952. Isoniazid acts by inhibiting an oxygen-sensitive pathway in the mycolic acid biosynthesis of the cell wall. The mechanism of resistance appears to multifactorial, and genetic modifications in a number of genes may have an effect. These genes include the *katG* gene-encoded catalase, the isoniazid target encoding *inhA* gene, the *oxyR* and neighboring *aphC* genes and their intergenic region. [45]

The molecular basis of rifampin resistance is understood better. Rifampin interferes with RNA synthesis. At least eight amino acid substitutions in the rpoB subunit of RNA polymerase have been described as conferring resistance. [46]

MULTIPLE RESISTANCE

Bacteria are often resistant to more than one antimicrobial agent. Multiple resistance is conferred by three mechanisms:

- ¦ reduced permeability,
- ¦ active efflux, and
- ¦ multiple resistance genes.

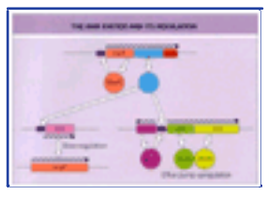

Figure 189-4 The MAR system and its regulation.

Reduced permeability is generally caused by alteration in the cell wall of the bacterium, especially the reduced expression of porins. The best studied is the outer membrane protein (omp) ompF, from *E. coli*.

Multidrug resistance pumps may play an important role in antibiotic resistance. Several families of these efflux pumps have been described in both Gram-positive and Gram-negative bacteria. Some of these pumps not only recognize diverse classes of antibiotics, but also a number of disinfectants such as chlorhexidine.[47] In the socalled MAR system in *E. coli*, reduced uptake and active efflux are combined in a single regulatory system. The MAR system was discovered by Levy and coworkers, who observed that resistant mutants were obtained at a frequency of 10^{-7} when *E. coli* was plated on agar media containing either tetracycline or

chloramphenicol. Usually, mutants obtained with one antibiotic were also resistant to the other, but cross-resistance to ß-lactams, puromycin, rifampin and nalidixic acid was also observed. Genetic mapping studies revealed that a three-gene operon, containing the *marRAB*, was involved (Fig. 189.4).

Sequencing studies revealed that resistant mutants had either mutations in the putative operator-promoter region of the operon or in the *marR* gene. The MarR product acts as a negative regulator for the mar operon. The MarA product is required for resistance. The MarA product is supposed to act on at least two different promoter regions. The first is involved in the expression of OmpF protein. Expression of OmpF is regulated by the *micF* gene. Transcription of this gene leads to the production of an antisense RNA for the ompF mRNA. Stimulation of micF RNA production by the MarA product causes reduced translation of the OmpF mRNA owing to its blockage by the micF antisense RNA and thereby reduced permeability through OmpF. The MarA product also interacts with the acr operon. This operon encodes two subunits of an efflux pump. Inactivation of this efflux system results in hypersensitivity to a wide variety of antimicrobial agents. The expression of the acr operon appears to regulated by AcrR, the product of the third gene of this operon. MarA apparently interacts with the binding of AcrR to its operator, resulting in increased expression of the two subunits of the efflux pump. However, the expression of the pump is also increased by a variety of environmental stimuli, such as ethanol and high concentrations of salt, but these stimuli apparently do not operate through either MarA or AcrR. Despite the detailed molecular knowledge about this mechanism of multiple resistance, its clinical impact is not clear.[48]

Multiple resistance caused by the presence of a number of different resistance genes can originate from the sequential acquisition of mutations or resistance genes, but often these genes are transferred as complete units. These units are located either on transposons or

Figure 189-5 Class I integrons. Open arrows point in the direction of transcription from each promotor site. orf, open reading frame.

multiresistance plasmids that have acquired these genes over time. An example of plasmid-borne multiple resistance comes from a study into eight strains of *Enterococcus* [49] that were resistant to chloramphenicol, erythromycin, minocycline and tetracycline. Genetic analysis showed that all these genes were transferred on a conjugative plasmid, except in the case of three strains. In these strains the chloramphenicol and erythromycin resistance was located either on a nonconjugative plasmid or on the chromosome.

Transposons, easily mobilizable genetic elements that range in size from a few kilobases to more than 150 kilobases, are an important source for the spread of antibiotic resistance. Numerous different transposons have been described and many of them carry one or more antibiotic resistance determinants. Resistance to any class of antimicrobial agent may be encoded on a transposon. Transposons may integrate either in plasmids or the bacterial chromosome and may be present in multiple copies, thereby enhancing their effectiveness in the expression of resistance. A number of transposons have been well studied. These include Tn*5*, Tn*7*, Tn*10* and Tn*21* from Gram-negative bacteria and Tn*554*, Tn*916* and Tn*4001* from Gram-positive bacteria.[50] Transposition may be very efficient and the spread of Tn*4001* described above is an example. Tn*916*, found in *E. faecalis*, was one of the first conjugative transposons discovered. It encodes resistance against tetracycline and chloramphenicol. Tn*916* is a member of a large family of related conjugative transposons, but other families have also been described. Conjugative transposons are not limited to Gram-positive bacteria; they are also present in Gram-negative bacteria. Tn*916* has also been found in *N. gonorrhoeae* for example. Conjugative transposons have a somewhat different mechanism of transfer from the more common transposons such as Tn*5* and Tn*10*, but they are well equipped for dissemination between species, although transfer is regulated. For some conjugative transposons, this transfer may be upregulated (by up to 10,000 times) by antibiotics, which enhances the dissemination of antibiotic resistance determinants. In addition, these conjugative transposons may mobilize co-resident plasmids, which also may carry antibiotic resistance determinants, resulting in the transfer of multiple antibiotic resistance.[51]

Integrons are a special group of genetic elements. The most common are class I integrons, but two other classes are known as well. The class I integrons are characterized by two conserved sequences (CSs). The 5'-CS contains the *int* gene, which encodes a protein homologous to other members of the integrase family. The 3'-CS consists of the *qacE?1*[52] and *sulI*[53] genes and an open reading frame, orf5.[54] The *qacE?1* and *sulI* genes define resistance against quaternary ammonium compounds and sulfonamide, respectively (Fig. 189.5). Integration of gene cassettes by the integrase takes places between the conserved segments. Cassettes can also be excised by the integrase and cassettes can exist as free circular DNA molecules. This process can also lead to the rearrangement of the

TABLE 189-10 -- The first gene cassettes.

order of cassettes in an integron. Each gene cassette has an imperfect inverted repeat element. This so-called 59-base pair element, which may vary in length between 57 and 141 base pairs, is unique for each gene cassette.[55] At least 42 gene cassettes have been described, including genes defining resistance against ß-lactam antibiotics, aminoglycosides, trimethoprim, chloramphenicol and antiseptics and disinfectants (Table 189.10).[56] Generally the cassettes do not have promoters, but transcription occurs from one of two promoter sequences present in the 5'-CS. Integrons are widespread in Enterobacteriaceae but are also found in pseudomonads. Isolates may carry more than one integron.[57] Remarkably, the 59-base pair elements show a close relationship with *Vibrio cholerae* repetitive sequences; these are 123–126 base pairs in length and there may be up to 100 copies. The role of these sequences is unknown, but if they are part of gene cassettes, then integration of gene cassettes may play a significant role in bacterial evolution.[55]

CONCLUSION

Worldwide antibiotic resistance is widespread and increasing. The best-known examples are MRSA, vancomycin-resistant enterococci, penicillin-resistant *Streptococcus pneumoniae* and ESBL-carrying Enterobacteriaceae. Studies into the molecular mechanisms of antimicrobial resistance help us to understand the problem and to monitor outbreaks, but other measures are required to quell the spread of resistance genes. Local, national and international antimicrobial surveillance studies are required to gain insight into trends in antimicrobial resistance on which empiric treatment of patients can

be based. However, only the prudent use of antibiotics and infection prevention measures will limit or even prevent the spread of antibiotic resistance.

It is not only the use of antimicrobial agents for the treatment of humans that plays a role in the spread of resistance; their use for the treatment of animals also plays a role. The practice in animal husbandry of using antibiotics in subtherapeutic concentrations as growth enhancers is a particular cause for concern. This practice started in the 1950s. In the 1960s it became controversial and experts questioned the wisdom of adding antibiotics to feed owing to the emergence of multidrug-resistant Enterobacteriaceae. (In fact, the first multidrug-resistant Enterobactericeae had been observed in the 1950s.) In 1966 a multi-resistant *Salmonella* strain ingested via food caused an outbreak that resulted in six deaths. Many studies were issued, but on a political level little action has been taken and the controvesy continues today. An example is avoparcin, which gives rise to cross-resistance to vancomycin. Evidence was recently provided that transfer of vancomycin-resistant enterococci from animals to humans may be possible.[58] Although transfer of resistant strains from animals to humans has been demonstrated, it is often contended that strains of bacteria living in animals are not able to survive in humans because they are not well adapted. However, animal strains of at least some multiresistant strains are able to survive for weeks in humans. They may not cause disease directly, but they provide a reservoir of resistance determinants, which can spread easily between strains and species.[59]

Interestingly, in Europe the use of avoparcin has been high and the use of vancomycin in hospitals low, but the levels of vancomycin-resistant enterococci causing infections in patients are low. In the USA avoparcin was not used in feed and the amount of vancomycin used in hospitals was high and vancomycin-resistant enterococci are often isolated from patients. This suggests that the use of antibiotics in hospitals may pose a greater threat for the spread of resistance than use of subtherapeutic concentrations of antibiotics in feed.

Therefore, inappropriate use of antibiotics in both veterinary and medical practice contributes to the spread of antibiotic resistance, a situation that leads to potentially untreatable common infections.

Chapter 190 - Antibiotic Prophylaxis in Surgery

Joseph S Solomkin

INTRODUCTION

The prevention of surgical site infection (SSI) remains a focus of attention because wound infections continue to be a major source of expense, morbidity and even death. The US Centers for Disease Control and Prevention (CDC) refers to postoperative wound infections as 'surgical site infection' and divides these into superficial (involving skin and subcutaneous tissue) and deep (involving the fascia and muscle) incisional infections, and organ/space infections.

A patient who develops a wound infection while hospitalized has an approximately 60% greater risk of being admitted to the intensive care unit, and an attributable extra hospital stay of 6.5 days, at an extra direct cost of $3000. Risk of re-admission within 30 days is five times more likely for infected patients, at a cost of more than $5000.[1] [2]

The epidemiologic data testifying to the significance of SSI are overwhelming. Surgical site infections are the third most frequently reported nosocomial infection, accounting for 14–16% of nosocomial infections in hospitalized patients. Approximately 40% of nosocomial infections occurring among surgical patients are SSIs, two-thirds of which affect the incision and one-third involve organ/space infection. Three-quarters of deaths of surgical patients with SSI are attributed to that infection, nearly all of which are organ/space infections.[3]

Because of the importance of these infections following operation, considerable effort has been expended to identify other potentially controllable variables that influenced infection rates. A major review of this subject and an extensive list of recommendations for preoperative patient preparation and operating room environment has recently been published by the Hospital Infection Control Practices Advisory Committee (HICPAC) of the CDC.[4]

An early finding of surveillance research was that there were variations in infection rates by surgeon. In an extension of the Hawthorne effect, in which the act of studying a human process improves results, it was then shown that the existence of a wound surveillance system and the reporting of the results normalized surgeon-specific infection rates.[5] This information supported the development of hospital-based surgical wound surveillance programs as a quality monitoring and improvement activity.[6] The trend to more rapid hospital discharge has, however, significantly decreased the accuracy of these programs, which are dependent upon in-hospital examination of wounds and reporting, and no generally applicable technique has replaced it. Surgeon and patient questionnaires have been employed, as well as computerized screens for physician visits and antibiotic prescribing. None have been found as reliable as wound inspection.[7] [8] [9] [10] So, we are now flying blind and an appreciation for the fundamental mechanisms involved in preventing wound infection gains in importance.

This chapter describes current notions of risk factors for SSIs and discusses problems relating to knowing what our infection rates really are. The chapter will then provide recommendations for practices and describe the data supporting these practices. Guidelines published by several expert groups have created a near uniform approach to antibiotic usage for prophylaxis. Nonetheless, it is important to note that administration of systemic anti-infectives is only part of a broad program of infection control involving adequate operating room ventilation, sterilization, barrier usage and delicate surgical technique.[11]

RISK FACTORS FOR SURGICAL SITE INFECTION

Information on appropriateness of antimicrobial prophylaxis is of considerable significance because of the cost of infection that might have been prevented had prophylaxis been given and, conversely, the cost of providing antimicrobial therapy to a very large number of patients if the yield is only the prevention of a relatively small number of infections or even the prevention of no infection. The costs of providing therapy extend far beyond the acquisition and administration charges. They include costs of treating adverse reactions and the more ominous potential cost of dealing in future times with drug-resistant bacteria. Therefore, enormous effort has been expended to identify factors that increase the risk of infection and would, at least potentially, suggest providing antimicrobial prophylaxis.

Whether surgical prophylaxis has any substantial impact on bacterial resistance patterns is unknown but unlikely. In comparison to the raw tonnage of antibiotics prescribed in the community for upper respiratory infections, the amount provided to surgical patients for prophylaxis is quite small. Furthermore, within the hospital, antimicrobial resistance is principally engendered in the intensive care units. The intensive care unit is home to patients at great risk of infection by virtue of acute and chronic disease and by the insertion of a range of monitoring and infusion catheters. These elements lower the inoculum needed to initiate infection and provide portals of entry.

HISTORICAL ASPECTS

Administration of antibiotics to decrease the incidence of postoperative wound infection is a surprisingly recent strategy. The investigational background for the use of anti-infectives for this purpose was developed only in the 1950s and 1960s, considerably later than the initial availability of anti-infectives.[12] In fact, early studies of anti-infective prophylaxis, performed in the 1950s, reported either no decrease in infection rates or even higher rates than control. These results are explained by the fact that anti-infectives were begun only in the postoperative period. During the late 1950s and 1960s, important developments were made to rationalize antimicrobial prophylaxis. The most fundamental was definition of the decisive period, the time following wound contamination that antibiotics would still reduce the incidence of infection.

WOUND CLASSIFICATION SYSTEMS FOR IDENTIFYING RISK OF INFECTION

It is assumed that at least three categories of variables serve as predictors of SSI risk:

- those that estimate the intrinsic degree of microbial contamination of the surgical site;
- those that measure the duration of the operation and other less easily quantifiable elements of the procedure; and
- those that serve as markers for host susceptibility.

In 1964, the National Research Council sponsored an examination of the efficacy of ultraviolet irradiation, and that provided the data to validate a wound classification scheme describing risk of infection in relation to the extent of wound contamination. [13] That document is a landmark in this area, and the classification scheme has remained useful to the present day. This classification is presented in Table 190.1 . A clear connection between the contaminating flora at various surgical sites and subsequent infecting pathogens was established. This microbiologic correlation included the recognition of the role of anaerobes in postoperative wound infection and abscess formation.

Two subsequent CDC efforts, the SENIC project (Study of the Efficacy of Nosocomial Infection Control) and NNIS (National Nosocomial Infection Surveillance), sought to examine these other variables as predictors of infection.[3] [14] These showed that even within the category of clean wounds, the SSI risk varied from 1.1 to 15.8% (SENIC) and from 1.0 to 5.4% (NNIS), depending on the presence of other risk factors.

The size of these studies is truly phenomenal. Information was collected on 58,498 patients undergoing operations in 1970 to develop a simple multivariate risk index. Analyzing 10 risk factors with stepwise multiple logistic regression techniques, they developed a model that combined information on four of the risk factors to predict a

patient's probability of getting a wound infection. Information was then collected on another sample of 59,352 surgical patients seen in 1975–6 to validate the proposed index.

TABLE 190-1 -- Surgical wound classification.[13]

SURGICAL WOUND CLASSIFICATION		
Class	**Description**	**Definition**
I	Clean	An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital or uninfected urinary tract is not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Operative incisional wounds that follow nonpenetrating (blunt) trauma should be included in this category if they meet the criteria
II	Clean-contaminated	An operative wound in which the respiratory, alimentary, genital or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered
III	Contaminated	Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g. open cardiac massage) or gross spillage from the gastrointestinal tract, and incisions in which acute nonpurulent inflammation is encountered are included in this category
IV	Dirty-infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation

The variables that were significantly and independently associated with subsequent SSI included:

- an abdominal operation;
- an operation lasting over 2 hours,
- a surgical site with a wound classification of either contaminated or dirty/infected and
- an operation performed on a patient having at least three discharge diagnoses.

Each of these variables contributes one point when present, and the risk index varies from 0 to 4. This means that each variable has the same significance as any other. Using this index predicted SSIs about twice as well as relying on wound classification. With the simplified index, a subgroup, consisting of half the surgical patients, can be identified in whom 90% of the surgical wound infections will develop. By the inclusion of factors measuring the risk due to the patient's susceptibility as well as that due to the level of wound contamination, the simplified index predicts surgical wound infection risk about twice as well as the traditional classification of wound contamination.

The problem with this system is that it is not operation specific and depends on variables collected after the operation (at discharge). To further refine the risk scoring system, a second study was then performed through the NNIS System from 44 hospitals from January 1987 through December 1990.[14] A risk index was developed to predict a surgical patient's risk of acquiring a surgical wound infection. The risk index score, ranging from 0 to 3, is the number of risk factors present from among the following:

- a patient with an American Society of Anesthesiologists preoperative assessment score of 3, 4 or 5;
- an operation classified as contaminated or dirty-infected; and
- an operation lasting over T hours, where T depends upon the operative procedure being performed.

The surgical wound infection rates for patients with scores of 0, 1, 2 and 3 were 1.5, 2.9, 6.8 and 13.0, respectively. The risk index is a significantly better predictor of surgical wound infection risk than the traditional wound classification system and performs well across a broad range of operative procedures.

It is important to note that this system provides little insight into risk of infection in clean or clean-contaminated wounds, other than identifying a correlation with length of operation.

SURVEILLANCE TECHNIQUES FOR IDENTIFYING SURGICAL SITE INFECTIONS: WHAT YOU GET IS WHAT YOU LOOK FOR

Given the clinical and economic importance of SSIs, all hospitals are required to have a program to monitor the incidence of post-operative infections. The methods for monitoring such infections were developed at a point in time when most surgical procedures were occurring in the hospital and patients were generally hospitalized for the procedure and remained in hospital for several days post-operatively. One of the weak points, in fact, of the SENIC and NNIS data presented above is that they by and large relied on in-hospital patient monitoring. Identification and reporting schemes for infections occurring outside the hospital were not well developed or tested. This means that the available data primarily address major surgical procedures, primarily done for intra-abdominal or intrathoracic pathology, for which patients were confined in hospital.

It is known that approximately half of SSIs occur post-discharge, with most occurring within 21 days after operation.[10] Although SSIs occurring after hospital discharge cause substantial morbidity, their epidemiology is not well understood, and methods for routine post-discharge surveillance have not been validated. A post-discharge surveillance program including self-reporting of infections by patients

and return of questionnaires by patients and surgeons is labor and resource intensive. A variety of techniques have been tested, including physician questionnaires, direct patient contacts and computer screens of pharmacy, outpatient, microbiologic and re-admission databases. None has been found superior to others, and it is likely that as more and more elements of patients' medical care are computerized, automated surveillance systems will become increasingly effective.

ACCEPTED INDICATIONS FOR ANTI-INFECTIVE PROPHYLAXIS

There is a wide consensus on specific procedures that warrant antimicrobial prophylaxis. Consensus statements by the Surgical Infection Society, the Infectious Diseases Society of America, the American Society of Hospital Pharmacists, the Canadian Infectious Diseases Society and the French Society of Anesthesia and Intensive Care all agree on a number of indications (Table 190.2).[15] [16] [17] [18] [19] There is also considerable agreement as to which procedures do not warrant prophylaxis.

Controlled trials of antimicrobial prophylaxis in minimally invasive procedures have recently been reported. In low risk laparoscopic

TABLE 190-2 -- Pathogens causing surgical site infections and antimicrobial drugs of choice for prophylaxis.

PATHOGENS CAUSING SSIs AND ANTIMICROBIAL DRUGS OF CHOICE FOR PROPHYLAXIS			
Procedure	**Likely pathogen(s)**	**Drug/dosing**	**For history of anaphylactoid reactions**
Clean procedures for which prophylaxis is accepted	*Staphylococcus aureus* and *Staphylococcus epidermidis*	Cefazolin 1g preoperatively	Clindamycin 600mg or vancomycin 1g
Head and neck procedures entering the oropharynx; esophageal procedures	Streptococci; oropharyngeal anaerobes (e.g. peptostreptococci)	Cefazolin 1g preoperatively	Clindamycin 600mg or vancomycin 1g
High-risk gastroduodenal and biliary	Enterobacteriaceae and streptococci	Cefazolin 1g preoperatively	Quinolone selected for low cost[†]
Placement of all grafts, prostheses or implants	*S. aureus*; coagulase-negative staphylococci	Cefazolin 1g preoperatively	Clindamycin 600mg or vancomycin 1g

Cardiac	*S. aureus*; coagulase-negative staphylococci	Cefazolin 1g preoperatively	Clindamycin 600mg or vancomycin 1g
Neurosurgery	*S. aureus*; coagulase-negative staphylococci	Cefazolin 1g preoperatively	Clindamycin 600mg or vancomycin 1g
Breast	*S. aureus*; coagulase-negative staphylococci	Cefazolin 1g preoperatively	Clindamycin 600mg or vancomycin 1g
Orthopedic — total joint replacement, closed fractures/use of nails, bone plates, other internal fixation devices, functional repair without implant/device, trauma	*S. aureus*; coagulase-negative staphylococci; Gram-negative bacilli	Cefazolin 1g q8h × 3	Gentamicin 2mg/kg + clindamycin 600mg q1 2h × 2
Noncardiac thoracic — thoracic (lobectomy, pneumonectomy, wedge resection, other noncardiac mediastinal procedures), closed tube thoracostomy	*S. aureus*; coagulase-negative staphylococci; *Streptococcus pneumoniae*; Gram-negative bacilli	Cefazolin 1g × 1	Clindamycin 600mg
Vascular	*S. aureus*; coagulase-negative staphylococci	Cefazolin 1g × 1	Clindamycin 600mg
Appendectomy*	Gram-negative bacilli; anaerobes	Cefazolin 1g + metronidazole 500mg q8h × 3 or cefotetan 1g × 1 or cefoxitin 1g × 4	Quinolone selected for low cost† + metronidazole 500mg q1 2h × 2
Colorectal	Gram-negative bacilli; anaerobes	Cefazolin 1g + metronidazole 500mg preoperatively or cefotetan 1g preoperatively or cefoxitin 1g†	Quinolone selected for low cost† + metronidazole 500mg preoperatively
Obstetric and gynecologic	Gram-negative bacilli; enterococci; group B streptococci; anaerobes	Cefazolin 1g preoperatively	Quinolone selected for low cost† + metronidazole 500mg preoperatively
Urologic (may not be beneficial if urine is sterile)	Gram-negative bacilli	Cefazolin 1g preoperatively	Quinolone selected for low cost preoperatively†

†† Ciprofloxacin, levofloxacin, gatifloxacin or moxifloxacin
* For nonperforated appendicitis. If perforated, treatment is therapeutic
† Re-dose if procedure lasts >4 hours

cholecystectomy and arthroscopic surgery, routine prophylaxis is not indicated.[20] In contaminated laparoscopic procedures, such as high-risk cholecystectomy and bowel surgery, it is best to apply the standards for similar open procedures.

In many areas of antibiotic administration sufficient numbers of studies have been carried out to allow synthesis of the data.[21] [22] [23] [24] [25] While there is some skepticism regarding this process, termed meta-analysis, there is no doubt that it is useful in selected situations where the primary literature is of good quality, heterogeneity in the response to treatment is small and well-understood, and there is a specific, critical parameter of outcome. Prophylaxis lends itself well to this, in that much of the literature is of good quality, the response to therapy is uniform, and the outcome parameter (SSI) is a specific and well-defined event.

It is worthwhile to note that one benefit of meta-analysis is the identification of benefit early in the evolution of a practice concept, thereby sparing many patients either the extra risk that their procedure might carry were prophylaxis not given or the extra risk of an adverse event from receiving a medication that would not benefit them. This is perhaps best illustrated with regards to antibiotic prophylaxis for elective colon surgery.

CHOICE OF ANTI-INFECTIVES FOR PROPHYLAXIS

It is certainly not necessary to cover the entire spectrum of contaminants of a surgical wound. The anticipated pathogens from various operative sites are detailed in Table 190.2 .

Little investigational work has been done on appropriate dosing. In general, doses of the selected agent that would be used for the treatment of established infection are recommended. The more important issue for prophylaxis concerns the need to maintain effective antibiotic levels throughout the procedure. This is typically accomplished by providing repetitive dosing for lengthy procedures. This is in part a function of the half-life of the agent selected, and is an additional argument in favor of agents such as cefazolin that have half-lives approaching 2 hours. A current recommendation is to re-dose the patient at intervals of twice the half-life of the agent provided. It is important to note that increasing the dose of an agent provides less benefit than shortening the dosing interval because drug clearance is logarithmic.

A large number of studies now document effective prophylaxis with no further dosing after the patient leaves the operating room.[26]

Gastroduodenal procedures

Prophylaxis is recommended for most gastrointestinal procedures. The density of organisms and proportion of anaerobic organisms progressively increase along the gastrointestinal tract, so the recommendation depends on the segment of gastrointestinal tract entered during the procedure. The intrinsic risk of infection associated with procedures entering the stomach, duodenum and proximal small bowel is quite low and does not support a routine recommendation for prophylaxis. However, any disease or therapeutic intervention that decreases gastric acidity causes a marked increase in the number of bacteria and the risk of wound infection. Therefore, previous use of antacids, histamine blockers or a proton pump inhibitor qualifies the patient for prophylaxis. Prophylaxis is also indicated for procedures treating upper gastrointestinal bleeding. Stasis also leads to an increase in bacterial counts, and so prophylaxis is warranted in procedures to correct obstruction. In addition, the intrinsic risk of infection in patients with morbid obesity and advanced malignancy is sufficiently high to warrant prophylaxis in these cases. Although the local flora is altered in these patients, cefazolin provides adequate prophylaxis and is the recommended agent.

Generally, elective surgery on the stomach or duodenum for ulcer disease is often not included in those procedures requiring prophylaxis. The highly acidic environment results in a very low endogeneous bacterial density, and rates of postoperative infection without prophylaxis are low. High-risk gastroduodenal procedures include operations for cancer, gastric ulcer, bleeding, obstruction and perforation, as well as operation in the presence of acid-reducing medical or surgical therapy. Prophylaxis is also recommended for gastric procedures for morbid obesity.

Colorectal procedures

Colorectal procedures have a very high intrinsic risk of infection and warrant a strong recommendation for prophylaxis. Several studies have demonstrated efficacy with rates of infection decreasing from over 50% to less than 9%. Antibiotics are directed at Gram-negative aerobes and anaerobic bacteria.

Mechanical cleansing

Commonly used colon preparation routines have changed substantially in that most patients self-administer these regimens at home and are admitted to hospital the morning of surgery. All prophylactic regimens begin with a mechanical bowel preparation, intended to greatly reduce the amount of feces present. Most commonly, polyethylene glycol (PEG) regimens are used. It is worth noting that the true value of these preparative activities is primarily to facilitate the operative procedure. Several trials have recently documented that mechanical cleansing does not alter wound infection rates if systemic antibiotic prophylaxis is used.

A current standard is a 4-liter PEG preparation. Bowel preparation with bisacodyl and 2 liters of PEG is reportedly more acceptable to patients than a 4-liter regimen and is equally effective in cleansing the colon.

It is important to be aware of the fluid losses that occur following PEG preparations. Compared with patients who receive inpatient preparation, patients receiving outpatient preparation require significantly more intraoperative fluid and colloid administration, greater amounts of fluid in the first 24 hours postoperatively and significantly more postoperative fluid challenges. Patients with multiple medical problems may not tolerate extensive fluid shifts; therefore, other preoperative arrangements, such as inpatient or outpatient intravenous fluid therapy, need to be considered to minimize complications that may outweigh potential cost savings.

Another alternative is 90ml of sodium phosphate (NaP) and bisacodyl. This is available in kit form. In one study comparing the two, patient tolerance to NaP was superior to PEG with less trouble drinking the preparation, less abdominal pain, less bloating and less fatigue. The preparations clear the colon equally well. Patients undergoing afternoon surgery may take their preparation early in the morning so that they have nothing by mouth for 6 hours before operation.

These regimens decrease fecal bulk but do not decrease the concentration of bacteria in the stool. In fact, the risk of infection with mechanical preparation alone is still 25–30%. The gastrointestinal side-effects of the osmotic mechanical preparations now used complicate the oral administration of antibiotics.

Antibiotics

In the USA, it is common to use a regimen of erythromycin base and neomycin given at 1 p.m., 2 p.m. and 11 p.m. (1g of each drug per dose) the day before a colorectal procedure scheduled for 8 a.m. Times of administration are shifted according to the anticipated time of starting the procedure, with the first dose given 19 hours before operation. Metronidazole can be substituted for erythromycin. If this regimen is used, there is no advantage to also providing parenteral prophylaxis.

Outside the USA, however, oral nonabsorbable antibiotic preparation have largely been abandoned in favor of parenteral treatment. A major systematic review has recently been reported for colorectal prophylaxis.[27] [28] This review examined trials published between 1984 and 1995, and some 147 trials were suitable for analysis. These included over 23,0000 patients and 70 different regimens were tested. The results confirmed that the use of antimicrobial prophylaxis is effective for the prevention of surgical wound infection after colorectal surgery. There was no significant difference in the rate of surgical wound infections between many different regimens. However, certain regimens were found to be inadequate. Inadequate regimens included metronidazole alone (which lacks activity again facultative and aerobic Gram-negative organisms), doxycycline alone, piperacillin alone (which lacks activity against anaerobes), and oral neomycin plus erythromycin on the day before operation. The addition of an effective parenteral agent reduced infection rates seen with neomycin-erythromycin to the same level as that seen with the parenteral agent alone. Several trials showed extra benefit of oral antibiotics if inadequate parenteral antibiotics such as metronidazole alone or piperacillin alone were employed. These authors found that a single dose administered immediately before the operation (or short-term use) is as effective as long-term postoperative antimicrobial prophylaxis.

This study also found no evidence to suggest that the new-generation cephalosporins are more effective than first-generation cephalosporins. Antibiotics selected for prophylaxis in colorectal surgery should be active against both aerobic and anaerobic bacteria. No additional benefit was observed in six trials that compared parenteral anti-infectives alone with parenteral plus topical.

Oral or topical application of antibiotics in addition to the parenteral administration of appropriate anti-infectives is of no benefit. Antibiotics selected for prophylaxis in colorectal surgery should be active against both aerobic and anaerobic bacteria. Administration should be timed to make sure that the tissue concentration of antibiotics around the wound area is sufficiently high when bacterial contamination occurs. Guidelines should be developed locally to achieve a more cost-effective use of antimicrobial prophylaxis in colorectal surgery.

Prophylaxis is also recommended for appendectomy. Although the intrinsic risk of infection is low for uncomplicated appendicitis, the preoperative status of the patient's appendix is typically not known. Cefotetan or cefoxitin are acceptable agents, although a high rate of *Bacteroides fragilis* resistance to cefotetan has recently been identified.[29]

Metronidazole combined with a quinolone is also an acceptable regimen. For uncomplicated appendicitis, coverage need not be extended to the postoperative period. Complicated appendicitis (e.g. with accompanying perforation or gangrene) is an indication for antibiotic therapy, thereby rendering any consideration of prophylaxis irrelevant.

Biliary tract procedures

The recommendations for antibiotic prophylaxis for procedures of the biliary tract depend on the presence of specific risk factors. In general, prophylaxis for elective open cholecystectomy (either open or laparoscopic) may be regarded as optional. Risk factors associated with an increased incidence of bacteria in bile and thus of increased risk for postoperative infection include age over 60 years, disease of the common duct, diagnosis of cholecystitis, presence of jaundice and previous history of biliary tract surgery. Only one factor is necessary to establish the patient as high risk. In most cases of symptomatic cholelithiasis meeting high-risk criteria, cefazolin is an acceptable agent. Agents with theoretically superior antimicrobial activity have not been shown to produce a lower postoperative infection rate.

Neurosurgical procedures

Studies evaluating the efficacy of antibiotic prophylaxis in neurosurgical procedures have shown variable results. Nonetheless, prophylaxis is currently recommended for craniotomy, laminectomy and shunt procedures. Coverage targets *Staphylococcus aureus* or *Staphylococcus epidermidis*.

Head and neck procedures

For procedures entailing entry into the oropharynx or esophagus, coverage of aerobic cocci is indicated. Prophylaxis has been shown to reduce the incidence of severe wound infection by approximately 50%. Either penicillin or cephalosporin-based prophylaxis is effective. Cefazolin is commonly used. Prophylaxis is not indicated for dentoalveolar procedures, although prophylaxis is warranted in immunocompromised patients undergoing these procedures.

General thoracic procedures

Prophylaxis is routinely used for nearly all thoracic procedures. Antimicrobial prophylaxis is particularly important when there is high likelihood of encountering high numbers of micro-organisms during the procedure. Pulmonary resection in cases of partial or complete obstruction of an airway is a procedure in which prophylaxis is clearly warranted. Likewise, prophylaxis is strongly recommended for procedures entailing entry into the esophagus. Although the range of micro-organisms encountered in thoracic procedures is extensive, most are sensitive to cefazolin, which is the recommended agent.

Cardiac procedures

Prophylaxis against *S. aureus* and S. *epidermidis* is indicated for patients undergoing cardiac procedures. Although the risk of infection is low, the morbidity of mediastinitis or a sternal wound infection is great. Numerous studies have evaluated antibiotic regimens based on penicillin, first-generation cephalosporins, second-generation cephalosporins or vancomycin. Cardiopulmonary bypass reduces the elimination of drugs, and so additional intraoperative doses typically are not necessary.

Antistaphylococcal penicillins and first-generation cephalosporins have traditionally been the prophylactic antibiotics of choice for patients undergoing cardiothoracic operations. Recently published studies have claimed improved outcomes with respect to postoperative wound infection when second-generation cephalosporins were used for prophylaxis.

A meta-analysis of placebo-controlled trials of cardiothoracic prophylaxis demonstrated a consistent benefit from the administration of antibiotic prophylaxis, with an approximate 5-fold reduction in wound infection rate.[22] The second-generation cephalosporins, cefamandole and cefuroxime, performed better than cefazolin, with an approximate 1.5-fold reduction in wound infection rate. Administration of prophylaxis beyond 48 hours was not associated with improved infectious outcomes.[22]

Obstetric and gynecologic procedures

Prophylaxis is indicated for cesarean section and abdominal and vaginal hysterectomy. Numerous clinical trials have demonstrated a reduction in risk of wound

infection or endometritis by as much as 70% in patients undergoing cesarean section. For cesarean section, the antibiotic is administered immediately after the cord is clamped to avoid exposing the newborn to antibiotics. Despite the theoretic need to cover Gram-negative and anaerobic organisms, studies have not demonstrated a superior result with broad-spectrum antibiotics compared with cefazolin. Therefore, cefazolin is the recommended agent.

When 25 randomized controlled trials of antibiotic prophylaxis that used rigorous protocols were analyzed,[25] overall 21.1% (373 of 1768) of the patients who did not receive antibiotic prophylaxis had serious infections after abdominal hysterectomy. Among patients who received any antibiotics, 9.0% (166/1836) had serious postoperative infections. Cefazolin was evaluated in 615 patients. The differences in the prevalence of infection between women who received prophylaxis and women who did not receive prophylaxis were statistically significant (any antibiotics, p=0.00001; cefazolin, p=0.00021) The authors concluded that preoperative antibiotics are highly effective in the prevention of serious infections associated with total abdominal hysterectomy, and that they should be used routinely. They also noted that the use of controls who receive no treatment is no longer justified in trials of antibiotic prophylaxis for total abdominal hysterectomy.

Urologic procedures

The range of potential urologic procedures and intrinsic risk of infection vary widely. In general, it is recommended that preoperative sterilization of the urine be achieved if clinically feasible. For procedures entailing the creation of urinary conduits, recommendations are similar to those for procedures pertaining to the specific segment of the intestinal tract being used for the conduit. Procedures not requiring entry into the intestinal tract and performed in the context

of sterile urine are regarded as clean procedures. It should be recognized, however, that prophylaxis for specific urologic procedures has not been fully evaluated.

Orthopedic procedures

Antibiotic prophylaxis is clearly recommended for certain orthopedic procedures. These include the insertion of a prosthetic joint, ankle fusion, revision of a prosthetic joint, reduction of hip fractures, reduction of high-energy closed fractures and reduction of open fractures. Such procedures are associated with a risk of infection of 5–15%, but this is reduced to less than 3% by the use of prophylactic anti-biotics.[3] *Staphylococcus aureus* and *S. epidermidis* predominate in wound or joint infections. Cefazolin provides adequate coverage. The additional use of aminoglycosides and extension of coverage beyond the operative period is common but lacks supportive evidence.

Noncardiac vascular procedures

Available data support the recommendation for coverage of procedures using synthetic material, those requiring groin incisions and those affecting the aorta. Cefazolin is the recommended agent because most infections are caused by *S. aureus* or *S. epidermidis*. Prophylaxis is not recommended for patients undergoing carotid endarterectomy.

Anti-infective prophylaxis for clean procedures

The biggest controversy regarding antibiotic prophylaxis centers around prophylaxis for clean surgery. Prophylaxis has prevented postoperative wound infection after clean surgery in a majority of clinical trials with sufficient power to identify a 50% reduction in risk. The low control rates of infection means that very large studies must be carried out to see a significant effect; studies of more than 1000 procedures are needed to detect such reductions reliably.

The major study on this subject was a randomized, double-blind trial of 1218 patients undergoing herniorrhaphy or surgery involving the breast, including excision of a breast mass, mastectomy, reduction mammoplasty and axillary-node dissection.[30] The prophylactic regimen was a single dose of cefonicid (1g intravenously) administered approximately half an hour before surgery. The patients were followed up for 4–6 weeks after surgery.

The patients who received prophylaxis had 48% fewer probable or definite infections than those who did not. For patients undergoing a procedure involving the breast, infection occurred in 6.6% of the cefonicid recipients (20 of 303) and 12.2% of the placebo recipients (37 of 303); for those undergoing herniorrhaphy, infection occurred in 2.3% of the cefonicid recipients (7 of 301) and 4.2% of the placebo recipients (13 of 311). There were comparable reductions in the numbers of definite wound infections, wounds that drained pus and those infected with *S. aureus*. There were comparable reductions in the need for postoperative antibiotic therapy, nonroutine visits to a physician for problems involving wound healing, incision and drainage procedures, and re-admission because of problems with wound healing.

An observational study was then carried out on the effects of antibiotic prophylaxis on definite wound infections:[31] 3202 patients undergoing herniorrhaphy or selected breast surgery procedures were identified preoperatively and monitored for 4 or more weeks; 34% of patients received prophylaxis at the discretion of the surgeon; 86 definite wound infections (2.7%) were identified. Prophylaxis recipients were at higher risk for infection, with a higher proportion of mastectomies, longer procedures and other factors. Patients who received prophylaxis experienced 41% fewer definite wound infections and 65% fewer definite wound infections requiring parenteral antibiotic therapy after adjustment for duration of surgery and type of procedure. Additional adjustment for age, body mass index, the presence of drains, diabetes and exposure to corticosteroids did not change the magnitude of this effect. The effect of prophylaxis was similar for all procedures studied.

The argument then is not whether such therapy lowers infection rates but rather whether it is worth the cost. Additionally, the control infection rate is so low that physicians will not be aware of a decreased infection rate unless very careful surveillance is performed, and then only for patients from several practices. Comparing one effective regimen with another, as has been done with colorectal surgical prophylaxis, is simply not going to happen. Effective regimens are effective against *S. aureus* and other pathogens that may be carried in the nares or on the skin. In addition, relatively long half-life in the serum and low cost are important considerations. Cefazolin is a good prophylaxis agent for many clean surgical procedures.

To justify the use of prophylaxis for clean procedures at a single institution, an accurate assessment of infection rates must be available. This requires a considered effort at post-discharge follow-up. When these data are available, the risk/benefit ratio can be more knowledgeably assessed. Without accurate information on infection rates by procedure, known risk factors described above may serve as guides. Extremes of age, poor nutritional status, diabetes and obesity are recognized as significant additional risk factors.

The use of systemic prophylaxis for hernia repairs entailing the insertion of mesh is considered desirable because the morbidity of infected mesh in the groin is substantial. However, no prospective trials demonstrate the effectiveness or necessity of this practice. Modified radical mastectomy and axillary node dissection also warrant prophylaxis because wounds near or in the axilla have an intrinsic risk of infection. If prophylaxis is desired or indicated for any of these procedures, cefazolin is the agent of choice.

Laparoscopic and thoracoscopic procedures

Specific data supporting a recommendation of antibiotic prophylaxis for laparoscopic or thoracoscopic procedures are lacking. Therefore, pending the availability of new data, recommendations for the same procedure performed using the 'open technique' should be followed.

Chapter 191 - Home Therapy with Antibiotics

Benjamin P Howden
M Lindsay Grayson

INTRODUCTION

Most antibiotics given at home are administered orally. However, over the past 20 years, home intravenous antimicrobial therapy has developed as an important component of health care delivery. Over a quarter of a million patients are treated in the USA annually in this manner.[1] The use of home intravenous antimicrobial therapy was first reported in 1974 for children who had cystic-fibrosis-associated pneumonia and subsequently for patients who had osteomyelitis.[2] [3] In addition to the USA, home intravenous antimicrobial therapy is now a common treatment modality in many regions, including Europe and Australia.

This chapter focuses on the home antibiotic treatment of patients who, because of the serious nature of their infections, would otherwise require in-hospital therapy. The use of intravenous antimicrobial therapy outside the hospital has been termed outpatient parenteral antimicrobial therapy (OPAT) in the USA, and hospital-in-the-home (HITH) in some other parts of the world.[1] [4] These programs are useful both for patients who have infections requiring prolonged intravenous antibiotic therapy (e.g. osteomyelitis or endocarditis) and for patients who have common infections such as cellulitis, in whom in-hospital admission may be avoided entirely. The potential advantages and disadvantages of OPAT are summarized in Table 191.1 , but a crucial component for successful OPAT is that patients are clinically stable and have appropriate home circumstances. Although there have been very few randomized trials of OPAT, those that have been done, as well as the many published case series, have reported good treatment outcomes.[5] [6]

MODELS FOR HOME INTRAVENOUS ANTIMICROBIAL THERAPY

The delivery of high-quality, safe home therapy is best achieved by an OPAT team consisting of physicians, nurses and pharmacists who use clearly delineated treatment protocols.[6] [7] Physicians should be experienced in the treatment of infectious diseases and have a good understanding of antimicrobial pharmacokinetics to allow appropriate decisions regarding the selection and duration of therapy, as well as drug monitoring. Since nursing staff administer therapy, they have regular contact with the patient and carer(s) and are often the initial contact when problems arise. Outpatient parenteral antimicrobial therapy pharmacists assist in the choice and mode of therapy, drug supply and compounding.

Many OPAT units have an infusion center (generally located within a hospital or clinic) where patients can be medically reviewed and receive directly observed therapy. outpatient parenteral antimicrobial therapy can be administered either by a nurse visiting the patient at home, the patient receiving treatment in an infusion center, or patients (or their relatives) self-administering therapy. Self-administration requires a well-motivated patient and carer who are capable of being educated regarding safe drug administration. It can be particularly useful for patients requiring prolonged or multidose therapy, or for those who require repeated courses of intravenous therapy (e.g. patients who have cystic fibrosis). The keys to a successful OPAT program include:

- a well structured OPAT team;
- appropriate patient selection based on medical need and suitability for treatment at home;
- informed patient and carer consent;
- careful monitoring of patients for response to therapy and adverse events; and
- 24 hour access to OPAT staff, particularly for emergencies.

The decision to accept a patient for home intravenous antimicrobial therapy should be based on medical need and appropriateness and should not be driven by bureaucratic or economic factors.

TECHNOLOGY USED IN OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY

Recent advances in medical technology have allowed development of new venous access devices and drug delivery systems that have improved the safety of home intravenous antibiotic administration.

Venous access devices

The optimal choice of vascular access is generally based on a number of factors, including the proposed treatment duration, the medication to be infused and the type of delivery system to be used.

Peripherally inserted central catheters

Peripherally inserted central catheters (PICCs) are a convenient form of intravenous access for OPAT therapy. They are made of flexible silicone, are introduced into the cubital vein and advanced into the superior vena cava, and are easily held in position with an adhesive dressing. Advantages of PICCs include the fact that they can be inserted and removed in the outpatient setting, are very durable, can be kept patent with an infrequent saline flush and have a relatively low infection rate.[8] Because of their central positioning, they are suitable for administration of concentrated antibiotic solutions such as used in continuous-infusion dosing.

Peripheral intravenous cannulae

Peripheral intravenous cannulae are generally used for short-duration therapy, but to minimize the risk of phlebitis they should be changed every 2–3 days. Thus, nursing staff need to be skilled in cannula insertion.

Long-term central venous catheters

These catheters (e.g. Hickman's, Port-A-Cath) are occasionally used in patients who have few other options for intravenous access, or who require them for administration of parenteral nutrition or cancer chemotherapy. In-hospital admission and anesthesia are generally required for insertion; however, they have a low infection rate and provide effective access for patients who require prolonged or repeated intravenous therapy.

TABLE 191-1 -- Potential advantages and disadvantages of outpatient parenteral antimicrobial therapy.*

POTENTIAL ADVANTAGES AND DISADVANTAGES OF OPAT	
Potential advantages	**Potential disadvantages**
Patient at home with family	Disruption to home environment

Continue work, school	Increased patient/family stress
Decreased nosocomial infections	Non-adherence with therapy
Fewer cannula-associated infections	Misuse of intravenous access
Improved utilization of hospital beds	Decreased supervision
Patient sense of empowerment	Feeling of abandonment
Reduced health care costs (possible)	Inappropriate antibiotic selection
	Non-adherence to bed rest, leg elevation
	Potential for unnecessarily prolonged duration of OPAT because of less medical incentive to stop treatment

** Adapted from Howden and Grayson.* [6]

Drug delivery systems

Like the choice of intravenous access, the optimal OPAT drug delivery system is influenced by the agent to be delivered and the proposed treatment duration. [6] [9]

Direct push

Intravenous injection over 5–10 minutes is useful for antibiotics such as cephalosporins and penicillins. Spring-loaded devices are available that can deliver an intravenous push using small (e.g. 10–20ml) syringes.

Gravity

Drug administration by gravity is usually used for agents that require dilution in larger volume solutions (e.g. 100–1000ml) before infusion, or where infusions require administration over an extended period of time (e.g. vancomycin, amphotericin B).

Controlled-rate infusion devices

A number of compact, battery-operated, computerized infusion pumps are available that can be programmed to deliver antibiotic by either continuous infusion or intermittent bolus. They can be readily carried in a small bag around the waist or neck, and allow the patient to continue with normal activities while receiving therapy. These pumps are generally expensive to purchase but are reusable and most models will alarm if the intravenous line becomes blocked or develops in-line air bubbles. Nonprogrammable continuous-infusion devices are also available that are either spring-loaded or elastomeric — in these the tension in either the spring or the elastomeric 'bladder' propel the infusion. Although these pumps are cheaper, they are generally not reusable and will not alarm if the infusion is interrupted. Both devices are ideal for the continuous infusion of antimicrobials that are stable in solution over a 24-hour period and that have optimal activity when stable high serum concentrations are maintained (e.g. antistaphylococcal penicillins).[10] [11] [12]

INTRAVENOUS ANTIBIOTIC REGIMENS

Although there may be a tendency for the practicalities of home antibiotic administration to influence the choice of antibiotic used (e.g. once-daily agents), the principles used for appropriate antibiotic prescribing should be similar to those applied to patients managed in hospital. Appropriate antimicrobial agent(s) include those with the narrowest antibacterial spectrum appropriate for the responsible pathogen, most practical dosing regimen and lowest purchase and delivery costs. Patient-specific factors are also important, such as avoiding aminoglycosides in patients who have significant renal impairment. Antibiotics that can be administered by continuous infusion or that have a long serum half-life (and therefore require infrequent dosing) are most appropriate for OPAT. Agents, such as ceftriaxone or glycopeptides, that are simple to use because they require only once-daily dosing but often have an antibacterial spectrum that is broader than necessary for many indications should be used only cautiously. Antibiotics that would be considered optimal for in-hospital use should, where possible, be used for OPAT, although in some cases these may require innovative delivery methods.

Beta-lactams

The clinical efficacy of ß-lactams against many pathogens is related to the proportion of the dosing interval during which the serum drug concentrations are maintained above the minimum inhibitory concentration (MIC) of the infecting pathogen(s).[10] Thus, ß-lactams with a short half-life (e.g. penicillin, ampicillin, antistaphylococcal penicillins) should either be dosed frequently (e.g. q4-6h, which is generally impractical for OPAT) or administered by continuous infusion. There is increasing experience with the successful use of continuous-infusion antistaphylococcal penicillins (e.g. flucloxacillin, oxacillin) and some cephalosporins (e.g. ceftazidime) for the treatment of a range of conditions, including osteomyelitis, endocarditis and pneumonia.[11] [12] [13] Limiting factors with continuous-infusion administration include the availability and cost of accurate drug delivery devices and the instability in solution of some agents (e.g. ampicillin) after compounding (Table 191.2).

Cephalosporins such as ceftriaxone, which have a sufficiently long serum half-life to allow once-daily dosing, can be extremely useful for OPAT. Similarly, recent studies in which oral probenecid was used to prolong the half-life of the first-generation cephalosporin cefazolin have established that this combination given once-daily is effective in the treatment of conditions such as cellulitis. [14] [15]

Aminoglycosides

A number of clinical studies suggest that administration of aminoglycosides (e.g. 4–5mg/kg/d gentamicin) as a once-daily dose rather than as two or three divided doses is associated with similar efficacy and probably reduced toxicity as compared with multidosing regimens when treating Gram-negative infections.[23] Once-daily gentamicin is now the preferred regimen when treating infections such as pyelonephritis, cholangitis and moderate-severe Gram-negative pneumonia. However, data regarding the efficacy of once-daily aminoglycoside therapy is limited or lacking in some settings, including pregnancy, neonates, burns patients, cystic fibrosis and some cases of endocarditis; in these situations, the use of once-daily aminoglycosides may not be appropriate.

Glycopeptides

Glycopeptides (e.g. vancomycin, teicoplanin) are effective against many Gram-positive pathogens. Vancomycin generally needs to be administered twice daily over at least 1–2 hours, while teicoplanin, after initial loading, may be given rapidly once daily. Although glycopeptides have been used in OPAT because of their infrequent dosing requirements, they are usually only an appropriate choice when used to treat resistant bacteria such as methicillin-resistant *Staphylococcus aureus* (MRSA), or patients who are anaphylactic to ß-lactams. The efficacy of teicoplanin in some situations has been questioned and the emergence of resistant pathogens such as vancomycin-resistant enterococci reinforce the view that glycopeptides should only be used when clearly indicated.[6]

TABLE 191-2 -- Outpatient parenteral antimicrobial therapy treatment regimens, monitoring and potential complications. £

OPAT TREATMENT REGIMENS, MONITORING AND POTENTIAL COMPLICATIONS					
Condition	**Intravenous regimen**	**Oral alternative available**	**Monitoring** *	**Complications and side effects**	**Comments and references**

Cellulitis	**Recommended:**	Yes[†]	Clinical response	Nausea and drug interactions a potential problem with probenecid	Cefazolin has narrower antimicrobial spectrum than ceftriaxone[14] [15] [16] [17]
	cefazolin 2g iv q12h *or* 2g q24h + probenecid 1g po q24h				
	Alternative:				
	ceftriaxone (1g iv q24h)				
Osteomyelitis and septic arthritis (MSSA)	**Recommended:**	Usually none	Clinical response	Nausea, vomiting, liver dysfunction from antistapylococcal penicillin	Vancomycin generally reserved for patients who have ß-lactam allergy[11] [12]
	antistaphylococcal penicillin[‡] 8–12g/d by continuous infusion for 4–6 weeks		Inflammatory markers		
	Alternative:		Drug levels		
	vancomycin 1g iv q12h for 4–6 weeks				
Endocarditis (*viridans* streptococci, uncomplicated)[§]	**Recommended:**	None	Clinical response	Cardiac decompensation	Most authorities recommend 2–3 doses of gentamicin per day for endocarditis
	ceftriaxone 2g iv q24h for 4 weeks		Echocardiogram	Emboli	Published reports regarding continuous infusion penicillin are limited, although this regimen is recommended by some authors[18] [19] [20]
	Alternative:		Gentamicin levels	Renal or vestibular damage from aminoglycosides	
	ceftriaxone 2g iv q24h + gentamicin 3mg/kg q24h for 2 weeks *or* penicillin 8.4g/d by continuous infusion for 4 weeks		Audiometry		
			Renal function		
Endocarditis (MSSA)	**Recommended:**	None	Clinical response	Nausea, vomiting, liver dysfunction from antistaphylococcal penicillin	Uncomplicated disease and in-hospital stabilization crucial prior to OPAT[11] [12]
	antistaphylococcal penicillin[‡] 8–12g/d by continuous infusion for 6 weeks		Echocardiogram		
			Drug levels		
Pyelonephritis	**Recommended:**	Yes[†]	Clinical response	Renal or vestibular damage from aminoglycosides	Complete 14 days therapy with oral agents
	gentamicin 4–6mg/kg/d iv *or* ceftriaxone 1g iv q24h		Renal function		Exclude prostatitis
			Aminoglycoside levels		
			Urine microscopy and culture		
Pneumonia (moderate severity — pneumonia severity index III)	**Recommended:**	Yes[†]	Clinical response	Respiratory failure	Careful patient selection[7] [21]
	ceftriaxone 1g iv q24h		Chest radiography		
Cystic fibrosis (infective exacerbation)	**Recommended:**	None	Clinical response		Treatment guided by results of sputum culture
	cefepime 2g iv q12h + tobramycin 4–6mg/kg q24h iv		Chest radiography		
Meningitis	**Recommended:**	None	Clinical response	Seizures	Tice *et al.*[22]
	ceftriaxone (2g iv q24h-q12h)				
Cytomegalovirus (CMV) disease (induction therapy)	**Recommended:**	Yes[†]	Clinical response	Neutropenia	May follow with long-term suppressive therapy
	ganciclovir 5mg/kg iv q12h for 2–3 weeks		CMV antigenemia or viral load		
Invasive fungal infection (e.g. cryptococcal meningitis)	**Recommended:**	Yes[†]	Clinical response	Renal impairment	
	amphotericin B 0.6–1.5mg/kg daily or 3 times per week		Cerebrospinal fluid glucose, antigen titer	Hypokalemia	
			Renal function, electrolytes	Nausea, chills	
MSSA, methicillin-susceptible *Staphylococcus aureus*					

£ Adapted from Howden and Grayson.[6]
* Generally, all patients receiving OPAT should have routine hematology and biochemistry monitored weekly.
† See Table 191.3 .
‡ Includes nafcillin, oxacillin, flucloxacillin.
§ Native valve, no complications, penicillin MIC of organism <0.1mg/ml.

Antiviral agents

Ganciclovir is effective for both acute treatment and long-term suppression of serious cytomegalovirus disease and is administered once or twice daily. Such regimens are suitable for OPAT administration, although the availability of oral ganciclovir and the recent availability of the highly bioavailable valganciclovir have reduced the need for long-term intravenous suppressive therapy and may avoid the need for intravenous induction therapy in some patients.[24] Other intravenous antiviral agents (e.g. foscarnet) may occasionally be used in OPAT.

INDICATIONS FOR HOME INTRAVENOUS ANTIMICROBIAL THERAPY

A wide variety of infections can be safely and conveniently treated with OPAT, should such treatment be appropriate (see Table 191.2).[4] [6] [25] Although this latter point may seem rather obvious, there is a growing body of data to support the use of some highly bioavailable oral antibiotic regimens for conditions such as osteomyelitis and pyelonephritis — conditions that previously were thought to require intensive parenteral therapy (Table 191.3). Infections that are relatively common and generally

require only brief OPAT include cellulitis, pyelonephritis, pneumonia, bacterial

TABLE 191-3 -- Oral antibiotics with excellent bioavailability that may be an alternative to intravenous therapy.[†]

ORAL ANTIBIOTICS WITH EXCELLENT BIOAVAILABILITY THAT MAY BE AN ALTERNATIVE TO INTRAVENOUS THERAPY				
Antibiotic	**Adult dose**	**Peak serum concentration (µg/ml)**	**Key indications**	**Notable side effects**
Fluoroquinolones:				
Ciprofloxacin	500–750mg q12h	1.8–2.8	UTI, OM, GI, STI	GI symptoms, rash, dizziness, headache
Ofloxacin	400mg q12h	4.0–6.0	UTI, RTI, OM, GI, STI	Seizures in elderly patients
Levofloxacin	500mg q24h	5.7	UTI, RTI	
Gatifloxacin	400mg q24h	4.2–4.6	RTI, STI	QT prolongation, drug interactions, rash, occasional hypoglycemia, dizziness, GI symptoms
Moxifloxacin	400mg q24h	4.5	RTI, STI	
Macrolides:				
Azithromycin	500mg q24h	0.4	RTI, STI, Myc	GI symptoms, rash, drug interactions
Clarithromycin	250–500mg q12h	0.8–3.0	RTI, Myc, HPY	GI symptoms, rash, drug interactions
Metronidazole	200–500mg q8h	6.2–25	ANA, C diff	GI symptoms, peripheral neuropathy
Clindamycin	150–600mg q6h	2.5–8.0	SKN, ANA	GI symptoms, pseudomembranous colitis, rash
Cephalosporins:				
Cefixime	400mg q24h	3–5	RTI, UTI, STI	Rash, GI symptoms
Cefpodoxime	100–200mg q12h	2.9	RTI, STI	Rash, GI symptoms
TMP-SMX	160/800mg tabs (1q12h to 2 q6h)	1–2/40–60 (1 tab)	UTI, RTI, PCP, *Nocardia*	Rash, GI symptoms, neutropenia, thrombocytopenia, renal dysfunction
Doxycycline	100mg q24h-q12h	1.5–2.1	RTI, STI, malaria	GI symptoms, photosensitivity, fetal effects
Oxazolidinones:				
Linezolid	600mg q12h	15–20	SKN, RTI (resistant organisms)	GI symptoms, rash, thrombocytopenia
Antivirals:				
Valganciclovir	900mg q24h-q12h	4.0–8.8 (ganciclovir)	CMV disease	Neutropenia, diarrhea
Valacyclovir	500mg q24h to 1g q6h	5.0 (1g q6h)	HSV, VZV	Headache, nausea, diarrhea
Famciclovir	125–500mg q8h	2.8–4.0 (500mg)	HSV, VZV	Headache, nausea
Triazoles:				
Fluconazole	100–400mg q24h	20–30 (400mg)	Cryptoc, *Candida*	Rash, GI symptoms, elevated liver enzymes, drug interactions
Itraconazole	100–400mg q24h	0.4–2.0[*]	Dermatophytes, *Candida*, molds, dimorphic fungi	Rash, GI symptoms, elevated liver enzymes, drug interactions

ANA, anaerobic infection; C diff, *Clostridium-difficile*-associated diarrhea; CMV, cytomegalovirus; Cryptoc, *Cryptococcus neoformans.*; GI, infective diarrhea; HPY, *Helicobacter pylori*; HSV, herpes simplex virus; Myc, mycobacterial infection; OM, osteomyelitis; PCP, *Pneumocystis carinii* pneumonia; RTI, respiratory infection; SKN, skin and soft tissue infection; STI, some sexually transmitted infections; TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection; VZV, varicella-zoster virus.

† *Data on peak serum concentration from Kucers et al.*[26] *and Gilbert et al.*[27]
* Use of the itraconazole formulated in cyclodextrin leads to improved oral absorption and higher serum levels.

meningitis and infective exacerbations associated with chronic lung disease. Such patients do not generally need long-term venous access and ideally can be treated with agents that require only infrequent dosing (e.g. once or twice daily). Serious diseases that are often suitable for OPAT include endocarditis, osteomyelitis, septic arthritis, deep abscesses (e.g. brain, psoas, liver — generally after initial drainage), and invasive fungal and cytomegalovirus disease in transplant recipients and HIV-infected patients. Since these conditions usually need prolonged intravenous antibiotic therapy, long-term venous access (e.g. PICC) is often required and innovative treatment regimens (e.g. continuous-infusion agents) may be appropriate, depending on the responsible pathogen(s). Although these conditions are not common, they are often large consumers of in-hospital bed days; hence, OPAT may substantially improve in-hospital bed utilization by treating a relatively small number of patients.

Patient selection

Appropriate patient selection is a crucial component in ensuring a safe and successful OPAT program. Both patient-specific and disease-specific factors are important in the decision to accept a patient for OPAT (Fig. 191.1). In particular, special care should be taken when assessing for OPAT, elderly or isolated patients, who often do not cope well with medical illness, and patients who have serious

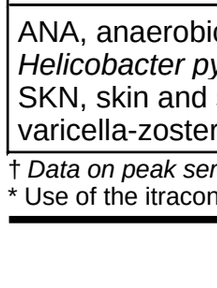

Figure 191-1 Clinical pathway for selection of patients for outpatient parenteral antimicrobial treatment of infections.

diseases such as endocarditis, where potentially catastrophic disease-related complications can occur.

Patient-specific factors

Factors that may be potential contraindications to OPAT include:

- patients who live alone or in isolated areas, or who do not have a telephone or other means of rapid communication;
- active substance abuse;
- aggressive patients, relatives or pets — these generally argue against patient suitability for OPAT care, since OPAT nurse safety is crucial; and
- the presence of a language barrier between patient and staff that cannot be overcome with the assistance of interpreters or family members — this suggests that

safety at home cannot be assured and that in-hospital therapy may therefore be more appropriate.

Disease-specific factors

A clearly defined diagnosis is important before embarking on OPAT. Patients who have common, less serious, conditions such as cellulitis can often be transferred directly from the emergency department to the OPAT program, avoiding in-hospital admission. Patients who have more serious conditions such as endocarditis, osteomyelitis and meningitis generally require a period of inpatient assessment, treatment and stabilization before transfer to an OPAT program to complete their treatment course.

Disease-specific indications

General recommendations for disease-specific therapy are outlined in Table 191.2 . However, further discussion regarding some common conditions is warranted.

Cellulitis

Cellulitis is usually the most common indication for OPAT. Since *Streptococcus pyogenes* and *Staphylococcus aureus* are the most frequent responsible pathogens, treatment with a first-generation cephalosporin or antistaphylococcal penicillin is often appropriate. Numerous US studies have demonstrated the efficacy of once-daily ceftriaxone 1–2g for cellulitis, although the appropriateness of this relatively broad-spectrum agent for this indication has been questioned. The first-generation cephalosporin cefazolin, when given 2g twice daily, or 2g once daily together with oral probenecid 1g once daily, is effective. Both regimens have comparable clinical efficacy to that of once-daily ceftriaxone and represent practical, appropriate OPAT treatment options.[14] [15] [16] Subsequent switching to oral agents such as

dicloxacillin (500mg q6h), cephalexin (500mg q6h) or clindamycin (300mg q6h) after initial improvement usually results in cure.

Pyelonephritis

Gentamicin (4–5mg/kg intravenously q24h), ceftriaxone (1g intravenously q24h) or ciprofloxacin (500–750mg orally q12h) are appropriate empiric single agents for pyelonephritis, since the usual pathogens are often Gram-negative bacilli. Ampicillin or penicillin may also be given empirically to treat possible enterococcal infections, although this is an uncommon pathogen in young patients. Antibiotic selection should be reviewed once the results of urine and blood cultures are available. Recent studies have demonstrated that oral fluoroquinolones are highly effective for treatment of many cases of pyelonephritis, and they may be considered as an alternative to parenteral therapy for patients in whom adherence is assured. [28] Although ciprofloxacin would not usually be the first-line choice for in-hospital care of pyelonephritis, the fact that its use may avoid the need for intravenous access offers a significant practical advantage.

Community-acquired pneumonia

Ceftriaxone 1–2g once daily is the agent most commonly used for the home intravenous treatment of pneumonia. However, in many regions ceftriaxone would not be the drug of first choice for in-hospital care of community-acquired pneumonia and the drug's broad spectrum of activity may be unnecessary. There are currently few data regarding the OPAT use of continuous-infusion penicillin for community-acquired pneumonia.

Endocarditis

The treatment of endocarditis currently accounts for about 5% of US OPAT treatment courses but almost certainly a higher proportion of treatment days.[29] Endocarditis can be successfully treated with OPAT but poses a particular problem because of the risk of life-threatening complications.[7] [11] [12] Outpatient parenteral antimicrobial therapy selection criteria for patients who have endocarditis have been proposed.[30] They suggest that most patients who have endocarditis should generally be managed in hospital for the initial 2 weeks. One exception may be patients with uncomplicated viridans streptococcal endocarditis who have rapidly become afebrile and cleared their bacteremia; such patients may be suitable for transfer home after 1 week. Patients who have complicated endocarditis (heart failure, conduction abnormality, perivalvular abscess), aortic valve disease, prosthetic valve endocarditis, acute endocarditis or infection caused by virulent organisms such as *S. aureus* should generally be managed primarily as inpatients.

Various OPAT options for common pathogens are shown in Table 191.2 . Ceftriaxone (2g/d) has been most commonly used for the home treatment of uncomplicated viridans streptococcal endocarditis; it appears to be effective when given either alone for 4 weeks or together with an aminoglycoside for 2 weeks. [18] [19] [20] Monitoring of renal and auditory function is particularly important if aminoglycosides are being used for prolonged periods. Although there are some case reports of treatment with intermittent-dose (and occasionally continuous-infusion) penicillin via a computerized pump for viridans streptococcal endocarditis, this is not currently a common OPAT regimen.

There are a number of reports of successful OPAT for staphylococcal endocarditis. Treatment options include the use of antistaphylococcal penicillins given by computerized pump as a continuous infusion or by intermittent bolus.[11] [12] [13] Vancomycin may be used in ß-lactam-allergic patients but appears to be less effective than ß-lactams for susceptible staphylococcal strains.[31] There are very limited OPAT data for endocarditis caused by other organisms such as enterococci, HACEK organisms, and fungi. Outpatient parenteral antimicrobial therapy for endocarditis generally requires central venous access (e.g. PICC) and close weekly clinical and drug monitoring.

Osteomyelitis

Most forms of osteomyelitis require 4–6 weeks of parenteral antimicrobial therapy, although the treatment duration and need for surgery may differ depending on the responsible pathogen(s), host factors and the bone involved. *Staphylococcus aureus* is the most common cause of osteomyelitis, but other pathogens such as coagulase-negative staphylococci, *Pseudomonas* spp. and Enterobacteriaceae may be involved when osteomyelitis is nosocomial in origin or associated with foreign bodies or intravenous drug abuse.[32] Thus, various treatment options may need to be considered (see Table 191.2). Long-term intravenous access is generally required unless oral fluoroquinolones are considered appropriate.[32] [33]

STEP-DOWN AND ORAL THERAPY

So-called 'step-down' therapy is a relatively recent term that can be applied to either the transfer from in-hospital to OPAT management or to the switch from parenteral to oral therapy. Used in this latter context, 'step-down' is simply a fashionable means of describing a routine component of managing many infectious diseases.

The decision to switch a patient from intravenous to oral therapy is dependent on a number of factors, including the nature of the disease and the bioavailability of effective oral agents. For some infections such as endocarditis or meningitis, oral antibiotics rarely play a significant role in therapy as, once intravenous therapy is completed, antimicrobials can usually be stopped. For a number of other infectious diseases (e.g. osteomyelitis or cytomegalovirus disease) intravenous therapy has, until recently, been the mainstay of treatment. However, the availability of more potent oral therapy (e.g. fluoroquinolones, valganciclovir) may allow an early switch to oral therapy, or possibly even the avoidance of intravenous therapy altogether. For the common conditions such as cellulitis and pyelonephritis the timing of switching to oral therapy is dependent on the severity of illness and the response to initial intravenous therapy. There are no strict criteria for the duration of intravenous treatment in these conditions.

A number of antimicrobials with excellent oral bioavailability are now available (see Table 191.3). As clinical trials evidence accumulates, treatment with some of these agents is likely to be considered a reasonable alternative to intravenous therapy for a range of serious infections; the use of ciprofloxacin for Gram-negative pyelonephritis is one such example. Such oral agents allow simple home therapy while avoiding the need for intravenous access devices. However, ensuring such agents have an appropriate spectrum of activity (not too broad) and that patients adhere to these oral regimens will be crucial to avoid the emergence of resistance and treatment failures.

MONITORING PATIENTS RECEIVING OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY

Patients require careful monitoring while receiving both OPAT and oral therapy. Although the home environment has many advantages for the patient, the careful regular monitoring that generally occurs in hospital is not present at home. In general, patients should be reviewed by the OPAT physician at least once a week, usually

in the outpatient department or office. Specific factors to assess on review include:

- patient's reaction to OPAT;
- response to therapy;
- drug side effects; and
- other complications (e.g. venous cannula infection).

Routine hematology and biochemistry, as well as serum drug levels, are also often monitored weekly.

Since in some situations more frequent reviews, or even emergency assessments, may be necessary, all good OPAT programs should have a system to manage these.

SUMMARY

Given recent trends worldwide, an increasing proportion of medical care that previously would have been administered in hospital is likely to be delivered at home. To be successful, patient selection should be based primarily on medical suitability rather than economic considerations. Ensuring appropriate antibiotic selection, safe delivery systems and continuity of care will be key challenges.

Chapter 192 - Short-course Antibiotic Therapy

Debby Ben David
Gili Regev-Yochay
Ethan Rubinstein

INTRODUCTION

The length of antibiotic course of therapy has been rarely studied in conventional infections while in tuberculosis, malaria and, interestingly, in venereal diseases it has been investigated thoroughly. The reasons for this discrepancy may be that in out-of-hospital studies, where compliance has always been a problem, investigators attempted to formalize the shortest possible course, to increase patient adherence and reduce the medical workload and costs. In the hospital until 15 years ago, the questions of compliance and cost were not as vital as they are today. In addition, the issue of bacterial resistance was 20 years ago of far less importance and wide implication as it is today. The introduction of new bactericidal agents with a rapid onset of action as well as better definition of patient population and deeper understanding of pharmacodynamics have also contributed to the shortening of antibiotic therapy courses. The best possible examples are the single-dose therapy for gonorrhea with ceftriaxone, cefixime, ciprofloxacin, ofloxacin, azithromycin or doxycycline. The reduction of the very long courses of tuberculosis treatment from around 18–24 months to much shorter periods (4–6 months in immunocompetent hosts[1] due in part to the introduction of rifampin, a highly bactericidal agent) and the introduction of directly observed therapy (DOT), which assured better compliance and therefore lower rates of resistance development, have lead to shorter therapy courses. The ability to treat meningococcal meningitis in children with 4 days of ceftriaxone therapy or even a single administration of long-acting penicillin,[2] or in adults for 2 days with ceftriaxone or for 4 days with penicillin G also demonstrates the changes occurring in our understanding of the necessary length of therapeutic periods. In hospitals also, the reduction of presurgical prophylaxis to a single dose,[5] with no untoward effect on wound infection, but with a significant reduction in resistant Gramnegative wound isolates, demonstrates the utility of short and ultrashort therapy (and prophylaxis) courses.

A course of therapy is conventionally defined as the time period during which an antimicrobial is administered. Due to the presence of counterfeit agents with decreased activity, irregular absorption and other uncontrolled parameters, a better definition may be the period during which therapeutic concentrations are maintained at the site of infection.

The advantage of a short therapy (or prophylaxis) period is that patient compliance improves with the reduction of the number of dosages to be administered and the time period necessary for a full treatment course.[3] A short-term therapy course is conventionally less expensive than prolonged courses because of the decreased amounts of drugs used and decreased cost of physicians, medical personnel and laboratory tests associated with more prolonged courses. In short-course therapy, if the full course is interrupted, there is less waste of unused antibiotics. Obviously when fewer antibiotics are prescribed the risk of adverse events and drug-drug interaction would be less. There is less risk of bacterial resistance development of the treated pathogen as well as of commensals if therapy is short. This has been shown to be true in the community,[4] where therapy of URTI in children for >7 days increased the risk of selection of penicillin-resistant *Strep. pneumoniae* (PRSp; OR = 3.5, 95% CI 1.3–9.8) compared to shorter treatment courses, as well as in the hospital, where prophylaxis of >48 hours increased the risk of acquired antibiotic resistance of Enterobacteriaceae and enterococci (OR 1,6, CI 1.1–2.6) compared to prophylaxis of <48 hours.[5] There is potentially less harm done to the environment in the immediate vicinity of the patient and less risk to his family members of becoming carriers of resistant bacteria, if fewer antibiotics are excreted and secreted from the patient into his immediate surroundings.

Evidently there is a lower limit under which short-course therapy becomes ineffective. Thus, for example, it was shown that for uncomplicated cystitis in women short therapy of 3 days was as effective as 5 days and as 7 days therapy with ß-lactam antibiotics, trimethoprim-sulfamethoxazole and fluoroquinolones. Nevertheless, reduction of the therapy course to <3 days was associated with an increasing rate of relapses and is thus not recommended.[6] In endocarditis also, reducing the duration of therapy to less than 28 days in aortic valve endocarditis was associated with unsatisfactory results compared with conventional duration of therapy. Another example is the observation that treating staphylococcal bacteremia for <10 days was associated with a high relapse rate.[7] Similarly, in catheter-related *Staph. aureus* bacteremia, antistaphylococcal therapy for >14 days was associated (albeit not significantly) with favorable outcome, fewer complications and less attributable death.[8] Other investigators also confirmed the need for 10–15 days, therapy for catheter-associated bacteremia.

A successful abbreviated treatment course depends on several mandatory factors on the part of the patient, pathogen, infection and therapeutic agent, as detailed in Table 192.1 .

The patient needs to be fully immunocompetent to be able to be cured with short courses of therapy and needs the full number of active leukocytes and macrophages. He needs to be able to produce adequate antibodies and to mount a satisfactory cell-mediated immune response. He must have adequate concentration of albumin to carry the antibiotic in the circulation and to have adequate distribution of intra- and extracellular water to allow the agent to penetrate or diffuse to the sites of infection.

The pathogen involved must be highly susceptible to the administered agent and not have the tendency to develop resistance to the agent used (low spontaneous mutation rate). The pathogen should preferably be extracellular and should be able to divide frequently enough to allow for prolonged antibiotic-vulnerable periods. The pathogen, at the site of infection, should preferably be in a planktonic form and not adherent to solid phases like bone and cartilage.

The infection should be at a site that is easily accessible to antibiotics; thus infections in sanctuaries like the brain, the prostate and eye are not good candidates for abbreviated therapy courses. The infection should not be life threatening and should not be localized in or around foreign bodies to which the pathogen is adherent and at which it forms a biofilm. It should be caused by a single pathogen and should not be an abscess, empyema, granuloma, etc., that would

TABLE 192-1 -- Features necessary for successful abbreviated therapy courses.

FEATURES NECESSARY FOR SUCCESSFUL ABBREVIATED THERAPY COURSES			
Patient factors	**Pathogen factors**	**Infection factors**	**Antibiotic factors**
Immunocompetence	Susceptible to antibiotics	At an easily accessible site	Bactericidal
Adequate WBC	Low spontaneous mutation rate	Not as a biofilm	Rapid onset of action
Normal albumin level	Extracellular	Lack of foreign body	Lack of propensity to induce mutations
Adequate hydration	Rapid multiplication rate	Not life-threatening	Easy penetration to tissues
Adequate compliance		Caused by a single pathogen	Active against nondividing bacteria
		Not a closed space infection	Not affected by adverse conditions
		Lack of adverse environmental factors	
		Early infectious state	

not allow antibiotics to penetrate or that have conditions of low pH, WBC debris and other factors that inhibit antibiotic action. Experience has shown that infections on mucosal surfaces (like upper and lower respiratory tract infections, intestinal infections and genitourinary infections) are best suited for abbreviated courses of therapy

while infections in bones, joints, the brain or intracellular infections are not suited for such treatment modality.

In order for the agent to be successful in abbreviated mode therapy, it has to be bactericidal and act rapidly, be associated with the lowest rate of resistance induction, be able to penetrate easily to tissues and body fluids (that is, having a low molecular weight and being lipophilic) and be present at the site of infection in sufficiently high concentrations for those agents with concentration-dependent killing (e.g. aminoglycosides, fluoroquinolones and imidazoles) and in concentrations above the MIC for long enough periods for agents that possess time-dependent bacterial killing (ß-lactams, macrolides, glycopeptides, etc.).[9]

GROUP A STREPTOCOCCAL PHARYNGITIS

Therapy of group A streptococcal (GAS) pharyngitis is intended to prevent both suppurative and nonsuppurative complications (rheumatic fever and perhaps poststreptococcal glomerulonephritis).

The treatment currently recommended by the American Heart Association, Infectious Disease Society of America and other organizations is 10 days of penicillin. [10] Prevention of acute rheumatic fever is believed to require eradication of the infecting streptococci from the pharynx, an effect that depends on prolonged rather than high-dose penicillin therapy.

The efficacy of 10-day treatment with penicillin was first documented in the early 1950s. By 1953 the American Heart Association recommended treatment of GAS pharyngitis with oral penicillin for 10 days.[11] In 1981 Schwartz *et al* re-evaluated the duration of treatment in a study which compared patients with proven GAS infection treated for 7 or 10 days with penicillin V in 8 hourly regimens.[12] They concluded that the 10-day regimen was more effective than a 7-day regimen in eradicating GAS, but also concluded that persistence of GAS after adequate therapy may be common. It is now accepted that approximately 15% of patients continue to harbor the original infecting GAS serotype in their pharynx after completing a course of oral penicillin.[10]

Gerber *et al*[13] compared 5 versus 10 days of penicillin V treatment in a randomized controlled trial. Patients in the two treatment groups were comparable with respect to clinical findings, compliance and serologic response to GAS. The same serotype of GAS was present in the follow-up in 18% of the 73 patients treated for 5 days versus 6% of 99 patients treated for 10 days. Thus, the need for 10 days of penicillin V treatment was confirmed.

Macrolides are an alternative choice, especially for penicillin-allergic patients. Several studies have examined short courses of various macrolides as an optional treatment for GAS pharyngitis. McCarty *et al* [14] compared clarithromycin to penicillin V and demonstrated comparable rates of clinical success and a higher eradication rate with clarithromycin (94% vs 78%). Boccazzi *et al*[15] compared a 3-day azithromycin regimen to 5-day cefibuten. They showed a somewhat higher eradication rate after cefibuten than after azithromycin treatment. Yet, the widespread use of macrolides has been associated with the development of resistance by GAS and this should limit the use of macrolides for GAS pharyngitis only to penicillin-allergic patients.

Oral cephalosporins are also highly effective in treating streptococcal pharyngitis. A meta-analysis of 19 studies suggested that streptococcal eradication rates and clinical cure rates attained with these agents are even slightly higher than those achieved with penicillin.[16]

Since the mid-1990s several randomized controlled studies have been carried out to compare shorter therapeutic courses (4–5 days of treatment) of cephalosporins with either the standard 10-day penicillin V regimen or with 10-day treatment with cephalosporins. These studies demonstrated that the shorter treatments were equivalent or superior in bacteriological eradication and clinical response. However, none of these studies evaluated the incidence of post-streptococcal sequelae. The general concern that shorter treatment courses might lead to an increased incidence of post-streptococcal sequelae was increased by clusters of rheumatic fever which occurred in the USA in the late 1980s.

Two recent large-scale European studies were performed by Adam *et al*,[17] to compare short-course treatments with the standard 10-day penicillin treatment. They evaluated 4782 culture-proven cases of GAS pharyngitis and also measured the incidence of post-streptococcal sequelae for a follow-up of 1 year. They examined 5-day regimens with six antibiotics that have been shown effective in previous trials: amoxicillin/clavulanate, ceftibuten, cefuroxime axetil, loracarbef, clarithromycin and erythromycin estolate. The 5-day regimens were as effective as the 10-day penicillin treatment. Both bacteriologic eradication and clinical success rates were equivalent. However, among the patients treated with the short course

there were four cases of poststreptococcal late sequelae (three cases of rheumatic fever and one glomerulonephritis), while only one patient in the 10-day penicillin group developed glomerulonephritis. The authors claim that the poststreptococcal sequelae in these cases could not be definitely related to the streptococcal episode treated in the study according to their histories. A separate evaluation for cefuroxime axetil (5-day) versus penicillin (10-day) showed equivalence with no streptococcal sequelae.

In summary, abbreviated courses (less than 10 days) of penicillin V were unsuccessful. Short courses of macrolide drugs have led to equivalent clinical and bacterial eradication results, but the concern of resistance development in GAS should limit these drugs to treating penicillin-allergic patients. Short courses of cephalosporins were equivalent or slightly better in clinical and bacterial eradication, but it is difficult to prove that poststreptococcal sequelae will not increase with these treatments and the concern about antibiotic resistance should probably limit these drugs to treating special cases. In addition, most of these agents are more expensive than penicillin, even when administered for short courses. Therefore, the best choice is probably still penicillin.

OTITIS MEDIA

Acute otitis media (AOM) remains one of the most common bacterial infections in childhood and the leading indication for antimicrobial use in this population. The objective of treating AOM is achieving a rapid clinical relief and preventing complications such as mastoiditis, meningitis, jugular vein thrombosis, etc. Failure to eradicate the causative pathogens in the middle ear was shown to lead to a higher risk of relapse and long-term sequelae. Thus, most expert panels have recommended treating children with AOM. However, other studies demonstrated that even among bacterial infections, the majority will resolve spontaneously, with only a minor advantage of antibiotic treatment over nontreatment, and thus have recommended withholding antimicrobial treatment entirely in some or all cases of AOM unless symptoms persist or worsen.[18]

Most clinical guidelines and expert panels still recommend 10 days of ß-lactams (first drug of choice being amoxicillin) for most patients, some limiting this treatment to children younger than 2 years, and allowing a shorter course of treatment (5 days) for older children.[19]

Recently, interest in shortening the course of antibiotic therapy from the traditional 10 days to 5 days has emerged for the reasons previously mentioned. Cefpodoxime, cefdinir and azithromycin are the only oral antibiotics currently approved by the US FDA for 5-day short-course therapy of AOM.

A meta-analysis[20] of randomized, controlled trials of shortened antibiotic therapy in AOM suggested that a 5-day course of a short-acting antibiotic was an effective treatment. However, patient subgroup sizes were too small to provide a reliable estimate of the risk of treatment failure in children younger than 2 years. Yet it is precisely children in this age group who gain the greatest benefit from treatment and who have the highest risk of treatment failure.

When evaluating the results of AOM studies it is particularly important to critically review the criteria used for diagnosis and for assessing outcome. In some of the previous trials, a combination of middle ear effusion and one or more nonspecific signs or symptoms has been considered sufficient. Outcomes in some of the studies have been based on symptomatic response alone, without regard to specific tympanic membrane findings, thus permitting inclusion of patients who do not actually have AOM but have otitis media with effusion (OME), a condition that is self-limiting and with minor symptoms.

In summary, abbreviated 5-day courses have been shown to be equivalent to standard therapies in children older than 2 and may be equivalent in those younger than 2 years who do not attend a daycare center. Children younger than 2 years of age who attend a daycare center should continue to receive the standard 10-day treatment in order to achieve good clinical success and prevent relapses.

ACUTE BACTERIAL SINUSITIS

Acute bacterial sinusitis is a common upper respiratory tract infection, with an estimated 20 million cases reported in the US annually. There are no specific clinical features to distinguish between bacterial and viral etiologies. It is, however, accepted that patients who have symptoms of rhinosinusitis (purulent nasal secretions and maxillary facial pain) for less than 7 days are unlikely to have bacterial infection. The presence of symptoms for more than 7 days is a sensitive but nonspecific predictor of bacterial sinusitis. Two recent meta-analyses[21] [22] have concluded that antibiotics are statistically more efficacious than placebo in reducing symptoms,

although their benefit is relatively small. It is generally recommended that treatment should be initiated with narrow-spectrum agents, e.g. amoxicillin, doxycycline or trimethoprim-sulfamethoxazole (TMP-SMX); however, these recommendations do not consider the increasing incidence of penicillin-resistant *Strep. pneumoniae* as a causative pathogen. The Sinus and Allergy Health Partnership guidelines for treatment of bacterial rhinosinusitis recommend stratifying patients according to severity of disease, rate of progression, recent antibiotic exposure and local resistance data.[23] Recommendations for initial therapy for adults with mild disease who have not received antibiotics include the following choices: amoxicillin/clavulanate, amoxicillin (1.5–3g/day), cefpodoxime proxetil or cefuroxime axetil. However, the duration of therapy is not indicated in these guidelines.

As the optimal duration of antimicrobial treatment for acute sinusitis has not been adequately studied until recently, the duration of treatment was not well defined and was therefore generally based on physician preference. The standard duration of antibiotic treatment for acute bacterial sinusitis ranges between 7 and 14 days. All the controlled studies published between 1990 and 2002 that compared the efficacy of short-course treatment (fewer than 7 days) with that of a long course (more than 7 days) showed equivalent clinical and bacteriologic efficacy results for 3–5 days, compared with 8–14 days of therapy with all agents studied. A single randomized, double-blind, placebo-controlled study[24] has compared amoxicillin/clavulanate administrated for 5 days with a 10-day course. Risk factors for failure in the abbreviated course were a history of more than four bouts of sinusitis during the 2 years prior to therapy or a history of surgical drainage. Thus, longer treatment courses might be indicated for certain risk groups. Further studies are needed to resolve this question.

Azithromycin has a prolonged half-life ranging between 2 and 5 days and a slow release from tissues. These properties suggest that a short course of azithromycin could be comparable to prolonged antimicrobial therapy. Several studies demonstrated high efficacy of azithromycin in acute sinusitis when administrated for 3–5 days. The response rates are comparable with those of prolonged therapy.

In summary, several studies have demonstrated similar efficacy of a short antimicrobial course compared with 8–14 days of antimicrobial treatment. Nevertheless, most studies included patients with maxillary sinusitis and the results cannot be extrapolated to patients with frontal, ethmoidal and sphenoidal or pan-sinusitis. It is important to emphasize that most studies did not verify the bacterial etiology of sinusitis by the use of sinus punctures. As most cases of acute rhinosinusitis are caused by viruses and less than 2% are complicated by bacterial infection and since there are no specific clinical features to distinguish between bacterial and viral etiologies, the true efficacy of prolonged antibiotic therapy compared to short-course therapy is difficult to assess.

COMMUNITY-ACQUIRED PNEUMONIA

There are no controlled trials that compare short antimicrobial courses in community-acquired pneumonia (CAP) with long courses (more than 7 days). The Infectious Disease Society of America[25] recommends treating pneumonia caused by *Strep. pneumoniae* until the patient is afebrile for 72 hours. Pneumonia caused by bacteria that can cause necrosis of pulmonary parenchyma (e.g. *Staph. aureus* or *P. aeruginosa*) should be treated for longer than 2 weeks, and pneumonia caused by atypical pathogens (e.g. *M. pneumoniae* or *C. pneumoniae*) should be treated for at least 2 weeks. However, these recommendations are not based on randomized clinical trials and are supported by expert opinion only.

ACUTE EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Approximately 5% of Americans in their middle and late years have chronic bronchitis, which predisposes them to frequent episodes of illness. Acute infectious exacerbation of chronic obstructive pulmonary disease (AE-COPD) contributes considerably to the morbidity and mortality of this population. The benefit of antibiotics in AE-COPD in reducing mortality and morbidity has been demonstrated in several randomized placebo-controlled studies. A meta-analysis has demonstrated a small but statistically significant improvement due to antibiotic therapy in acute exacerbations of COPD. [26]

The administration of therapy for 10–14 days has been the standard treatment. A large number of studies have been published during the last few years which support the use of short-course antimicrobial therapy in AE-COPD. Most studies used different antibiotic regimens that compared the efficacy of a short course (fewer than 7 days) with that of a long course (more than 7 days). All trials enrolled patients with a clinical diagnosis of AE-COPD. Across studies involving 6629 patients published between 1988 and 2001, clinical and bacteriologic efficacy of various classes of antibiotics were equivalent for 3–5 days compared with 8–14 days of therapy.

The new fluoroquinolones have a wide antimicrobial activity (including penicillin-resistant *Strep. pneumoniae, H. influenzae* and atypical pathogens), favorable pharmacokinetics and pharmacodynamics, including high bio-availability, extensive distribution into respiratory fluids, long elimination half-life and potent and rapid killing. Based on their pharmacokinetic and pharmacodynamic profile, a shorter course of fluoroquinolones could have equivalent efficacy to the traditional 10–14 days therapy for AE-COPD. Several randomized trials have demonstrated high efficacy of the new fluoroquinolones in the treatment of AE-COPD. Abbreviated courses of various fluoroquinolones of 5 days' duration had similar efficacy compared to standard duration therapy.

In summary, most studies have demonstrated similar efficacy of a short course of antimicrobial therapy in AE-COPD compared with standard duration therapy. Therefore, abbreviated therapy should be considered for AE-COPD.

URINARY TRACT INFECTIONS

When considering treatment for UTI the prognosis of the untreated infection and the long-term results to be expected from therapy should be measured and compared to the side-effects, cost and inconvenience of different therapeutic regimens. As the prognosis of UTI in nonpregnant adult women is excellent and reinfection is common, therapy probably makes little contribution to the patient's well-being other than alleviating the symptoms. Hundreds of patients have been followed for years with persistent or recurrent infections without documenting progression of renal disease caused by the infection.

Bacteriuria in the elderly is associated with degenerative and debilitating diseases, but does not seem to aggravate the underlying condition. Routine treatment of asymptomatic bacteriuria in the elderly is thus not recommended by most experts.

Asymptomatic as well as symptomatic bacteriuria in preschool children with vesicourethral reflux can result in stunted growth of the kidney, scar formation and, rarely, renal failure. Bacteriuria in pregnancy may also have serious implications — for example, preterm deliveries, low birth weight, etc. Thus, treatment of children and pregnant women is most likely to be beneficial. Symptomatic patients, regardless of age, should be adequately treated, even when infection is likely to recur.

In the past, 7–10 days of therapy were routinely recommended for patients with lower urinary tract symptoms. However, in recent years it has become apparent that most women with lower UTI have only a superficial mucosal infection that can be cured with much shorter courses of therapy, even with a single dose of an antimicrobial agent.

Short-course therapy for UTI with sulfonamides has been intensively studied and more than 70 reports have been published. A meta-analysis of these trials revealed that a single-dose therapy was less effective than longer duration regimens (87% eradication vs 94%), but 3-day regimens were equivalent to longer duration treatments and were associated with lower rates of adverse events.[6] Several trials have demonstrated the efficacy of a single-dose of ciprofloxacin; however, this drug, like most agents studied, appeared to be more effective when given as a 3-day regimen.[27]

Since then, several randomized controlled studies have confirmed that low-dose, short courses (3 days) of fluoroquinolones and short-course TMP-SMX are superior to 7-day treatments of many commonly used drugs (fluoroquinolones, TMP-SMX and nitrofurantoin), mainly due to the lower rate of adverse events.[28] [29] [30]

ß-Lactam short-course studies revealed that all ß-lactam regimens (amoxicillin, pivamecillinam, cefadroxil, etc.) were less effective when given in a shorter than 7 day regimen, demonstrating higher recurrence and lower eradication rates with the short courses.

To summarize: ß-lactam and nitrofurantoin short-course regimens have failed and are less effective than the standard 7-day regimens. Three-day regimens of TMP-SMX are equivalent to longer duration treatments and may be the drug of choice in areas in which resistance to this drug is low. Three-day regimens of fluoroquinolones are equivalent to longer duration regimens and may be more effective than 3-day regimens of TMP-SMX in areas where resistance to the latter is high.

INTESTINAL INFECTIONS

These infections would be the most amenable to abbreviated courses of therapy as in most instances the pathogen is located on the epithelial surface or has penetrated the intestinal epithelial cell but does not proceed to invade other tissues. The pathogen is classically a rapidly dividing bacteria, there is no foreign body and

the peristalsis of the intestine would inhibit biofilm formation. The major obstacles to abbreviated therapy are the penetration of the antibiotic into the intestinal lumen and into the epithelial cells, the adverse effect of fecal material on the antibacterial activity of the agent (binding to fecal material), and the inactivation of the antimicrobial agent by neighboring bacteria that may produce extracellular enzymes, e.g. ß-lactamases, aminoglycoside-inactivating enzymes, etc.

In shigellosis, a randomized double-blind controlled trial compared 5 days of therapy with ciprofloxacin or azithromycin in 70 hospitalized adults men in Bangladesh.[31] Clinical success (determined as disappearance of loose stools on day 5 and temperature <37.8° on day 3) and bacteriological eradication rates were equal in both groups. A study in 135 Vietnamese children with bacillary

dysentery, in a region with a high rate of multidrug-resistant shigellosis (of 63 isolates, 62% were MDR), compared the conventional therapy of nalidixic acid (55mg/kg for 5 days) with two doses of ofloxacin (total 15mg/kg). Resolution times for fever and diarrhea were similar, excretion time for stool pathogens was longer in the nalidixic acid group, there were 25% treatment failures in the nalidixic acid group compared to 10% in the ofloxacin group (p>0.1). The authors concluded that the two regimens were equally effective and thus a preference for the shorter therapy was obvious.[32]

TYPHOID FEVER

Typhoid fever has traditionally been treated with 10–14 days of therapy with chloramphenicol, ceftriaxone, etc. Attempts have been made to shorten this treatment period from 10–14 days to 5–7 days but the long-term relapse rate remained undefined.[33] The current practice is to administer systemic antibiotic until the patient defervesces and to continue with an oral cephalosporin for a total of 10–14 days. The fluoroquinolones, because of their *in vitro* activity against Salmonellae, intracellular penetration and transepithelial intestinal elimination reaching high intraepithelial concentrations, were considered attractive for shorter treatments of typhoid fever and other systemic salmonellosis.[34] Seven days of treatment with ciprofloxacin 500mg twice daily were compared with azithromycin 1g initial oral dose followed by 500mg once daily for 6 additional days in 123 Egyptian patients. Cure was similar in the two groups with similar time to defervescence in both groups with no relapse in either group.[35] When ofloxacin 5-day course (200mg twice daily) was compared with ceftriaxone 3g once daily for 3 days, ofloxacin cured 100% of patients (22/22) while ceftriaxone cured 18/25 patients (72%) (p=0.01) with defervescence in the ofloxacin group occurring far earlier than in the ceftriaxone group.[36] In a study that compared ofloxacin 3 days to 5 days in MDR typhoid fever in 438 patients in Vietnam, both regimens were equally effective.[37] For fluoroquinolone-resistant and nalidixic acid-resistant *S. typhi* (NARST) treated with ofloxacin, the time for blood clearance was double (156h) that for susceptible strains and a third of the NARST patients required retreatment (compared to 0.4% of the susceptible strains). NARST-infected patients were, however, effectively treated with short-course (5 days) azithromycin therapy with rapid defervescence, sterilization of stool cultures and no relapses.[38]

ENDOCARDITIS

In 1971, Paul Beeson wrote that in cases where signs and symptoms were favorable, 2- or 3-week therapy was sufficient whereas in abacteremic patients, in those with long-standing disease, those with large vegetations and those with relatively resistant organisms, it is wiser to continue therapy for 6–10 weeks. Today infections with penicillin-susceptible streptococci and *Streptococcus bovis* (with a penicillin MIC of =0.1µg/ml) require a 2-week regimen of ceftriaxone or penicillin G combined with gentamicin as long as the patient does not have extracardiac foci of infections, myocardial abscesses or prosthetic valve endocarditis. When the pathogen is relatively resistant to penicillin (MIC =0.1 but =0.5µg/ml) penicillin (or ceftriaxone) for 4 weeks are required accompanied in the first 2 weeks by gentamicin. In right-sided staphylococcal endocarditis in intravenous drug abusers, 2-week therapy with methicillin (or nafcillin) combined with gentamicin is effective.[39] [40] The reason for shortening the therapy duration may be greater awareness of the possibility of endocarditis that is now supported by echocardiography, allowing for earlier diagnosis, and a deeper understanding of the pharmacokinetics and pharmacodynamics of the antibiotics used for treating this infection.

NOSOCOMIAL INFECTIONS

The widespread use of antibiotics in hospitals has substantial implications for the cost of care, side effects and spread of resistant micro-organisms. Generally, nosocomial infections are treated for 10–14 days. However, there are no randomized clinical studies evaluating the optimal duration of antimicrobial treatment in most nosocomial infections. As the majority of the hospitalized patients who develop infections are critical patients, immunocompromised or patients who have undergone surgery, or elderly and those with foreign bodies, an abbreviated antimicrobial course could lead to therapeutic failure or relapse. On the other hand, prolonged antimicrobial therapy exposes these patients to drug toxicity and the emergence of resistant micro-organisms at an individual level and also influences the hospital or unit ecology.

Nosocomial pneumonia

Respiratory tract infections account for approximately 50% of all antibiotics prescribed in intensive care units. The American Thoracic Society recommends that the duration should be adapted to the severity of the disease, the time to clinical response and the micro-organism involved.[41] Prolonged antimicrobial treatment is recommended for the following situations: multilobar involvement, cavitation and isolation of *P. aeruginosa* or *Acinetobacter* spp. and pneumonia associated with bacteremia. A short antimicrobial treatment (7–10 days) is recommended for *Staph. aureus* and *H. influenzae* pneumonia.

A prospective nonrandomized clinical study in ventilator-associated pneumonia (VAP) evaluated the efficacy of a clinical guideline restricting the total duration of antimicrobial therapy to 7 days.[42] The mean duration of treatment in the first period was 14.8 days compared to 8.6 days. No significant differences in hospital mortality and hospital lengths of stay were found between the two study groups. However, patients in the before-evaluation group were more likely to develop a second episode of VAP compared with those in the after-evaluation group (24.0% vs 7.7%, p = 0.030).

Currently there are no randomized clinical studies comparing the efficacy of shorter antimicrobial treatment courses in severe VAP. However, in many cases, antibiotic treatment is prescribed for pulmonary infiltrates without pneumonia. Because VAP in the ICU has a high attributable mortality, empiric antimicrobial treatment is prescribed when new pulmonary infiltrates appear, despite a low likelihood of infection. In a randomized clinical study,[43] patients with low likelihood of nosocomial pneumonia (CPIS <6) were randomized to receive ciprofloxacin (experimental group) for 3 days or standard therapy (choice and duration of antibiotics at the physician's discretion). Antibiotics were continued beyond 3 days in 90% of patients in the standard therapy compared with 28% in the ciprofloxacin group. The duration of antibiotics in patients with CPIS <6 and no other documented infection was 3 days compared to 9.8 days in the standard therapy group. Mortality and length of hospital stay did not differ between the two groups. Nevertheless, antimicrobial resistance or superinfection was documented in 15% of patients in the ciprofloxacin group compared with 35% in the control group. Antimicrobial cost was significantly lower in the ciprofloxacin group. Such an approach, in patients with mild-moderate nosocomial pneumonia, including VAP, may lead to significantly lower antimicrobial therapy costs, antimicrobial resistance rates and superinfections. A recent French study[44] compared 8 vs. 15 days of antibiotic therapy in 401 VAP patients. No excess motility or pulmonary infections were detected on day 28 in the short treatment group, favoring short duration therapy for patients with ICU-VAP.

Catheter-related bloodstream infections

Currently, there are no randomized controlled clinical trials evaluating the optimal duration of therapy for bloodstream infection.

Patients with catheter-related bacteremia are separated into those with complicated infections (e.g. endocarditis, septic thrombosis) and those with uncomplicated infections. Patients with an uncomplicated infection should receive 10–14 days of antimicrobial therapy. Patients with complicated bacteremia should receive a prolonged course of antimicrobial therapy (4–6 weeks). There are no randomized trials evaluating the efficacy of abbreviated courses.

Nosocomial *Staph. aureus* bacteremia is a serious and common disease often associated with serious complications including septic thrombosis, infective endocarditis, osteomyelitis and metastatic abscesses. Despite several studies, the optimal duration of antimicrobial treatment for catheter-related *Staph. aureus* bacteremia (CRSAB) remains unknown. In the past, CRSAB has been treated for 4–6 weeks, but recent studies have reported a low complication rate when the duration of treatment was 10–14 days. In several retrospective studies among patients with CRSAB and no early complications, a 10–15-day course of parenteral antibiotics was equivalent to longer courses of therapy.[45] However, treatment with antimicrobial agents for less than 10 days appeared to be inadequate due to a high rate of relapse. Delayed removal of the catheter is associated with a high rate of relapse. A meta-analysis of studies reporting outcome for patients with *Staph. aureus* bacteremia treated with short-course therapy (=2 weeks) has identified 11 studies. [46] Late complication rates ranged from 0% to 29% and the relapse rate was 6.1%. However, most of the studies were uncontrolled.

No controlled trials have assessed the optimal duration of antibiotic treatment of catheter-related bloodstream infection due to Gram-negative bacilli. Randomized trials are necessary to determine the optimal duration of treatment for bloodstream infection caused by various micro-organisms.

CONCLUSION

In summary, there is good evidence for shortening antibiotic therapy provided the correct treatment is applied to the appropriate patient in a well-defined patient population for a clearly defined infection caused by a known pathogen with known antibiotic susceptibilities. Most effort in this field was dedicated to infections that can be treated on an outpatient basis; for severe infections, length of therapy still needs additional data.

Chapter 193 - ß-Lactam Antibiotics

Jason S Kendler
Barry J Hartman

INTRODUCTION

In 1928, Alexander Fleming observed that a mold of the genus *Penicillium* inhibited the growth of bacteria in culture.[1] Over a decade later in 1941, Florey, Chain and Abraham used penicillin for the first time in patients with staphylococcal and streptococcal infections.[2] [3] More than a half century later, the ß-lactam antibiotics remain the mainstay of treatment for a variety of bacterial infections (Table 193.1) and now include:

- penicillins (natural penicillins, penicillinase-resistant penicillins, aminopenicillins, carboxypenicillins and ureidopenicillins);
- cephalosporins (first-, second-, third- and fourth-generation);
- monobactams;
- carbapenems; and
- ß-lactamase inhibitor combinations.

PENICILLINS

The natural penicillins are used primarily for the treatment of selected Gram-positive and anaerobic infections as well as selected Gram-negative infections. The penicillinase-resistant penicillins are primarily used for the treatment of infections due to staphylococci, but are also active against other Gram-positive organisms. The aminopenicillins have a similar spectrum of activity as the natural penicillins, but have additional coverage of Gram-negative organisms including many Enterobacteriaceae. When used in conjunction with ß-lactamase inhibitors, they have extended coverage against Gram-positive, Gram-negative and anaerobic organisms that produce ß-lactamases, which normally hydrolyze these agents. The carboxypenicillins and ureidopenicillins cover Gram-negative bacilli that are resistant to the aminopenicillins, in particular *Pseudomonas aeruginosa*. The carboxypenicillins and ureidopenicillins can also be used in conjunction with ß-lactamase inhibitors for extended activity against ß-lactamase-producing organisms.

Cephalosporins

The first-generation cephalosporins have excellent activity against Gram-positive cocci, but can also treat some community-acquired Gram-negative infections. The second-generation cephalosporins have improved Gram-negative coverage compared with that of the first-generation cephalosporins, and selected agents (i.e. cefoxitin and cefotetan) have excellent activity against anaerobes. Third-generation cephalosporins have further improved Gram-negative coverage; ceftazidime is used for *P. aeruginosa* infections, but has limited Gram-positive coverage. Ceftriaxone, a third-generation cephalosporin, not only has excellent Gram-negative activity but also provides excellent coverage of *Streptococcus pneumoniae* and other viridans streptococci. The fourth-generation cephalosporins (cefepime is the only drug available in the USA at this time) have excellent Gram-positive and Gram-negative coverage. No cephalosporin has any activity against *Enterococcus* spp.

Monobactams

The monobactams (aztreonam is the only available agent in this class) are effective only against aerobic Gram-negative organisms and have no activity against Gram-positive organisms or anaerobes.

Carbapenems

The carbapenems (imipenem, meropenem and ertapenem) have the broadest bacterial coverage of the ß-lactam antibiotics, treating most infections with Gram-positive, Gram-negative and anaerobic bacteria.

Mechanism of action

ß-Lactam antibiotics are bactericidal. Their mechanism of action involves interference with bacterial cell wall synthesis. More specifically, they attach to penicillin-binding proteins on the inner surface of the bacterial cell membrane, thereby interrupting the transpeptidation process that cross-links the amino acids of the individual petidoglycan components of the forming bacterial cell wall. Ultimately, loss of viability and, in some bacteria, lysis occurs as the result of the activation of autolytic enzymes through a poorly understood mechanism. [4] Of all ß-lactam agents, only the carbapenems possess an extended inhibitory effect on bacterial growth after levels of these agents are below inhibitory levels (postantibiotic effect). In fact, only the carbapenem class of ß-lactam antibiotics exhibits concentration-dependent killing — maximal bactericidal activity occurs at 4–5 times the minimum inhibitory concentration (MIC) of the organism, whereas all other ß-lactam classes (penicillins, cephalosporins, monobactams) exhibit time-dependent killing pharmacodynamics (activity is greatest only during a period when the concentration is above the MIC) and there is no postantibiotic effect. In addition, regrowth of bacteria occurs rapidly after withdrawal of cephalosporins.

Bacterial resistance

Three major mechanisms lead to bacterial resistance to ß-lactam antibiotics:

- failure of the antibiotic to penetrate the bacterial cell membrane;
- alterations in the penicillin-binding proteins that reduce the binding affinities of the ß-lactams (intrinsic resistance);[5] and
- bacterial production of ß-lactamases, which hydrolyze the ß-lactam ring and render it inactive.

The most important and most common cause of resistance is the production of ß-lactamases. [6] Strategies to combat resistance, including the use of ß-lactamase inhibitors, are discussed later in this chapter.

PHARMACOKINETICS AND DISTRIBUTION

Absorption

The ß-lactams have variable absorption from the gastrointestinal tract. Some agents, such as the antipseudomonal penicillins and methicillin, are acid-labile and cannot be taken orally. The absorption characteristics and pharmacokinetics of the ß-lactams are shown in Table 193.2 . Of note, amoxicillin is almost totally absorbed when administered orally whereas ampicillin is only partially absorbed.

TABLE 193-1 -- The different classes of ß-lactam antibiotics and sample indications for selected agents.

THE DIFFERENT CLASSES OF ß-LACTAM ANTIBIOTICS AND SAMPLE INDICATIONS FOR SELECTED AGENTS			
Class of ß-lactam	**Example**	**Route**	**Sample indication**
Penicillins			
Natural penicillin	Penicillin V (phenoxymethyl penicillin)	po	Streptococcal pharyngitis
	Penicillin G (benzylpenicillin)	iv	Neurosyphilis
Penicillinase-resistant penicillin	Flucloxacillin	po	Cellulitis
	Nafcillin	iv	*Staphylococcus aureus* endocarditis
Aminopenicillin	Amoxicillin	po	Endocarditis prophylaxis
	Ampicillin	iv	*Listeria monocytogenes meningitis*
Amidinopenicillin	Piv-mecillinam	po	Urinary tract infection
Carboxypenicillin	Ticarcillin	iv	*Pseudomonas aeruginosa* pneumonia
Ureidopenicillin	Piperacillin	iv	Cholangitis
Cephalosporins			
First-generation	Cephalexin	po	Cellulitis
	Cefazolin	iv	Prophylaxis before surgery
Second-generation	Cefuroxime	po	Sinusitis
	Cefaxitin	iv	Intra-abdominal infection
Third-generation	Cefixime	po	*Escherichia coli* urinary tract infection (cystitis)
	Ceftriaxone	iv	Pneumococcal meningitis
	Ceftazidime	iv	*P. aeruginosa* pneumonia
Fourth-generation	Cefepime	iv	Septicemia secondary to Enterobacteriaceae resistant to other agents
Monobactam	Aztreonam	iv	Gram-negative septicemia
Carbapenems	Imipenem	iv	Monotherapy for intra-abdominal infections
	Meropenem	iv	Monotherapy for ultra-abdominal infections
	Ertapenem	iv	Complicated skin and soft tissue infections
ß-Lactamase inhibitors	Clavulanic acid (+ amoxicillin)	po	Animal bite
	Clavulanic acid (+ ticarcillin)	iv	Neutropenic sepsis
	Sulbactam (+ ampicillin)	iv	Head and neck infection
	Tazobactam (+ piperacillin)	iv	Nosocomial sepsis

The presence of food in the stomach can delay absorption and can lower the peak serum concentration attainable for some ß-lactams, such as ampicillin, cefaclor, cefixime and ceftibuten. In contrast, food can increase the absorption of cefuroxime and cefpodoxime.

Distribution

Following absorption, ß-lactams are variably bound to serum proteins, mostly albumin. Protein-bound drug does not exert antimicrobial activity, but binding is reversible. In general, the degree to which a ß-lactam antibiotic is protein bound does not influence the decision to use the antibiotic and the effect of protein binding on drug efficacy is not clear.[14] Excretion of the ß-lactams is primarily renal (glomerular filtration and tubular secretion) and, in general, the serum half-life of these drugs is short.

Procaine penicillin G and benzathine penicillin G are intramuscular preparations that are absorbed slowly, allowing for longer dosing intervals, but the half-life of the drug is the same. Nafcillin, the ureidopenicillins (20–30%), cefoperazone (70%), ceftriaxone (40%) and cefotetan (20%) have significant excretion in bile.[10]

Imipenem is inactivated by an enzyme present on the renal brush border, dehydropeptidase I. Cilastatin is a dehydropeptidase inhibitor administered along with imipenem to prevent subtherapeutic levels of the antibiotic in urine. Cilastatin does not possess any antimicrobial activity nor does it alter the pharmacokinetics of other drugs.[15]

The ß-lactam antibiotics achieve therapeutic concentrations in most tissues such as lung, kidney, bone, muscle and liver, and in secretions such as synovial fluid, pleural fluid, pericardial fluid, peritoneal fluid and bile. The microenvironment that may be found in an abscess, including a low pH, the presence of neutrophils and associated proteins, and low oxygen tension, does not inhibit the function of ß-lactam antibiotics. However, ß-lactams do not penetrate host cells and are therefore ineffective against intracellular organisms. Low concentrations of ß-lactams are found in prostatic secretions, brain tissue, intraocular fluid and cerebrospinal fluid (CSF; Fig. 193.1). In the presence of inflammation, however, concentrations in the CSF are much higher, accounting for the efficacy of some ß-lactams in the treatment of meningitis.[16] The penicillins and cephalosporins can penetrate the aqueous humor of the eye, but do not reach therapeutic levels in the posterior chamber.

ROUTE OF ADMINISTRATION AND DOSAGE

ß-Lactams are available for oral, intravenous and intramuscular use. Generic and trade names, routes of administration and standard dosages for adult and pediatric patients with normal renal function are listed in Table 193.3 . In dosing the ß-lactam antibiotics, it is important to remember that:

- food can have an effect on oral absorption (e.g. food decreases absorption of ampicillin); and
- absorption of both cefuroxime and cefpodoxime are decreased by H_2 -blockers or nonabsorbable antacids.[17]

In general, high doses of a ß-lactam antibiotic should be used in patients who are neutropenic and for severe infections such as bacteremia, meningitis and otitis media in children. Dosages must be reduced in patients with renal failure (with the exception of nafcillin, cefoperazone and ceftriaxone) and in neonates, in whom renal function is not yet fully developed. Dosages of nafcillin, the ureidopenicillins and cefoperazone must be reduced in patients with severe liver disease (see Dosage in special circumstances, below).

INDICATIONS

The ß-lactam antibiotics can be effectively used for the treatment of a variety of infections. These agents are widely distributed following administration and are routinely used in the treatment of sinusitis, otitis, pharyngitis, epiglottitis, dental infections, bronchitis, pneumonia, meningitis, infections of the genitourinary tract (including cervicitis and urethritis caused by *Neisseria gonorrhoeae*), peritonitis, biliary and gastrointestinal infections, skin and soft tissue infections, osteomyelitis, septic arthritis and infection of prosthetic devices, including venous access catheters. The choice of antibiotic and recommended duration of therapy for these infections is discussed in the chapters on the specific diseases. The remainder of this section focuses on the use of the ß-lactam antibiotics in special circumstances. Table 193.4 summarizes the relative susceptibilities of various micro-organisms to the ß-lactam antibiotics.

TABLE 193-2 -- Pharmacokinetics for selected ß-lactam antibiotics. [7] [8] [9] [10] [11] [12] [13]

PHARMACOKINETICS FOR SELECTED ß-LACTAM ANTIBIOTICS

Figure 193-1 Concentrations of ß-lactam antibiotics in different tissues.

Prophylaxis

Antimicrobial prophylaxis in surgery (see also Chapter 190)

ß-Lactam antibiotics are commonly used to decrease the incidence of infection for selected surgical procedures.[18] A single dose of cefazolin has been shown to decrease the incidence of wound infection for selected 'clean' procedures and is used commonly for cardiac, noncardiac thoracic, vascular, orthopedic, ophthalmic and neurosurgical procedures. For 'clean-contaminated' procedures in which colonized mucosa is violated, such as head and neck surgery, abdominal surgery and gynecologic surgery, antibiotic prophylaxis may also be used. Cefazolin or ampicillin-sulbactam can be used before head and neck surgery. Patients who are obese, who have reduced intestinal motility or who have decreased gastric acidity may be at high risk for infection following abdominal surgery and may also be candidates for prophylaxis with cefazolin.

Similarly, patients undergoing biliary tract surgery who are at high risk of infection due to advanced age, acute cholecystitis, a nonfunctioning gallbladder, obstructive jaundice, or choledocholithiasis may benefit from preoperative cefazolin. In the setting of acute appendicitis, cefoxitin or cefotetan have been shown to decrease the incidence of infection postoperatively. Women undergoing vaginal or abdominal hysterectomy, emergency cesarean section or first trimester abortion may be candidates for antibiotic prophylaxis with cefazolin or other agents.

Antibiotics should be used not only as prophylaxis but also as treatment for 'dirty' surgical procedures in which the surgical site is obviously contaminated by bacteria (e.g. a perforated viscus). Antimicrobial prophylaxis in surgery is summarized periodically in the publication *The Medical Letter*.[18]

Prophylaxis is not routinely recommended for patients undergoing cardiac catheterization, gastrointestinal endoscopy, herniorrhaphy, varicose vein surgery, most plastic surgery, arterial puncture, thoracentesis, paracentesis, repair of simple lacerations, outpatient treatment of burns, dental extractions or root canal therapy. Antimicrobial prophylaxis before breast surgery is controversial. A recent study suggests that antibiotic prophylaxis for endoscopic retrograde cholangiopancreatography does not prevent cholangitis.[19]

Endocarditis prophylaxis

Patients who have underlying cardiac or congenital valvular abnormalities are candidates for antibiotic prophylaxis when they undergo procedures that can cause transient bacteremia. Cardiac conditions that place a patient at increased risk of endocarditis include prosthetic valves, a previous history of endocarditis, most congenital cardiac abnormalities (except an isolated secundum atrial septal defect), rheumatic and other acquired valvular dysfunction, hypertrophic cardiomyopathy and mitral valve prolapse when accompanied by regurgitation.

Procedures that can cause transient bacteremia and may place a patient at risk of endocarditis include:

- dental procedures (including professional cleaning),
- tonsillectomy and/or adenoidectomy,
- surgical procedures involving intestinal or respiratory mucosa,
- rigid bronchoscopy,
- sclerotherapy for esophageal varices,
- esophageal dilatation,
- gallbladder surgery,
- cystoscopy,
- urethral dilatation,
- urethral catheterization and/or urinary tract surgery if there is infection,
- prostatic surgery, and
- incision and drainage of infected tissue.

The antibiotic of choice for prophylaxis for dental, oral or upper respiratory tract manipulations is a single dose of amoxicillin 2g taken orally 1 hour before the procedure. For high-risk patients undergoing genitourinary or gastrointestinal procedures, ampicillin 2g intravenously with gentamicin 1.5mg/kg intravenously should be given within 30 minutes of starting the procedure and then ampicillin or amoxicillin 1g orally should be given 6 hours later. Alternatives exist for patients who are allergic to penicillins.[20]

Rheumatic fever prophylaxis

Because patients who have had acute rheumatic fever are at risk of recurrent attacks if they have group A streptococcal infections, the American Heart Association recommends prophylaxis with penicillin for these patients. The dose is either a single injection of benzathine penicillin G 1.2 million U intramuscularly every 4 weeks or penicillin V 250mg orally q12h. It seems that prophylaxis can be safely discontinued in patients with a history of carditis after 10 years or at age 25. In patients without a history of carditis, prophylaxis can be stopped after 5 years or at age 18. The decision to stop prophylaxis, however, must be individualized because a patient who is at continued risk of streptococcal infection (e.g. teacher or pediatrician) may benefit from continued antibiotic prophylaxis (see also Chapter 60).[21]

Pneumococcal infections

Penicillin is the antibiotic of choice for infections (such as pneumonia, bacteremia or meningitis) caused by susceptible strains of *S. pneumoniae*. However, an increasing proportion of isolates of this pathogen are resistant to penicillin. Intermediate resistance is defined as a strain with an MIC of 0.1–1µg/ml and high-level resistance is defined by an MIC greater than or equal to 2µg/ml. The E test (an antibiotic strip with graded concentrations) is a convenient and reliable method for the detection of penicillin or cephalosporin resistance in pneumococci.[22] In the early 1990s, 4–5% of clinical isolates in the USA were found to be either intermediately or highly resistant to penicillin.[23] [24] In a study that examined isolates collected from outpatients at different sites in the USA between 1994 and 1995, 14.1%

TABLE 193-3 -- ß-Lactams — spectrum of activity, trade names, routes of administration and dosage in patients with normal renal function. [9] *

ß-LACTAMS — SPECTRUM OF ACTIVITY, TRADE NAMES, ROUTES OF ADMINISTRATION AND DOSAGE IN PATIENTS WITH NORMAL RENAL FUNCTION					
Class	**Antimicrobial spectrum**	**Generic name**	**Trade name**	**Route**	**Adult dose (pediatric dose) for normal renal function**
Penicillins					

Natural penicillins	Gram-positives, anaerobes, selected Gram-negatives	Penicillin V	Betapen, Ledercillin, Pen-Vee, Robicillin, S-K penicillin, V-cillin, Veetids	po	250–500mg q6h (25–50mg/kg/day divided q6h)
		Penicillin G, benzathine	Bicillin, Permapen	im	600,000–1.2 million U every 1–4 weeks (300,000–600,000U every 1–4 weeks for weight <27kg; 900,000–1.2 million U every 1–4 weeks for weight >27kg)
		Penicillin G, procaine	Crysticillin, Duracillin, Wycillin	im	600,000–1.2 million U q12-24h
		Penicillin G, sodium or potassium		iv	1–4 million U q4h
Penicillinase-resistant penicillins	Penicillin-resistant *Staphylococcus aureus* and *Staphylococcus epidermidis*. Also active against streptococci	Cloxacillin	Tegopen	po	250–500mg q6h
		Dicloxacillin	Dynapen, Pathocil, Veracillin	po	125–500mg q6h (12–25mg/kg/day divided q6h)
		Flucloxacillin*	Floxapen	po	500mg q6h
				im/iv	1–2g q6h
		Methicillin	Celbenin, Staphcillin	im/iv	1–2g q4-6h
		Nafcillin	Unipen	im/iv	1–2g q4-6h (50mg/kg/day divided q4-6h)
				po	250–500mg q4-6h
		Oxacillin	Bactocill, Prostaphlin	im/iv	1–2g q4-6h (50–100mg/kg/day divided q4-6h)
				po	250–500mg q4-6h
Aminopenicillins	Same as penicillin G plus added Gramnegative cocci and Enterobacteriaceae	Amoxicillin	Amoxil, Larotid, Polymax	po	250–500mg q8h (20–40mg/kg/day divided q8h)
		Ampicillin	Alpen, Amcil, Omipen, Penbritin, Polycillin, Principen, Probampcin, Totacillin	po	250–500mg q6h
				im/iv	1–2g q4-6h (50–200mg/kg/day divided q4-6h)
		Bacampicillin		po	400–800mg q12h (25mg/kg/day divided q12h)
	ß-Lactamase inhibitors expand Gram-positive, Gram-negative and anaerobic coverage	Amoxicillin-clavulanic acid	Augmentin	po	250–500mg q8-12h or 875mg q12h (20–40mg/kg/day divided q8-12h)
		Ampicillin-sulbactam	Unasyn	im/iv	1.5–3.0g q6h
Carboxypenicillins	Gram-negative aerobic rods resistant to ampicillin, including *Pseudomonas aeruginosa*	Ticarcillin	Ticar	im/iv	3–4g q4-6h (200–300mg/kg/day divided q4-6h)
		Ticarcillin-clavulanic acid	Timentin	iv	3.1g q4-6h (200–300mg/kg/day ticarcillin divided q4-6h)
Ureidopenicillins	Similar to carboxypenicillins	Azlocillin	Azlin	im/iv	3–4g q4-6h (90–120mg/kg/day divided q6-8h)
		Mezlocillin	Mezlin	im/iv	3–4g q4-6h (300mg/kg/day divided q4h)
		Piperacillin	Pipral, Pipracil	im/iv	3–4g q4-6h
		Piperacillin-tazobactam	Zosyn	iv	3.375g q4-6h
Cephalosporins					
First-generation	Gram-positive cocci and some community-acquired Gram-negative bacilli	Cefadroxil	Duricef, Ultracef	po	1–2g/day q24h or q12h (30mg/kg/day divided q12h)
		Cefazolin	Ancef, Kefzol	im/iv	0.5–1.5g q6-8h (25–100mg/kg/day divided q6-8h)
		Cephalexin	Biocef, Keflex, Keftab	po	250–500mg q6h (25–100mg/kg/day divided q6h)
		Cephalothin	Keffin, Seffin	im/iv	0.5–2g q4-6h (100mg/kg/day divided q4-6h)
		Cephapirin	Cefadyl	im/iv	0.5–2g q4-6h
		Cephradine	Anspor, Velosef	po	1–2g/day divided q6-12h
				im/iv	1g q6h

Second-generation	Improved Gram-negative coverage as compared with first-generation; some agents have activity against anaerobes	Cefaclor	Ceclor	po	250–500mg q8h (20–40mg/kg/day divided q8h)
		Cefamandole	Mandol	im/iv	0.5–1.0g q4-8h (50–100mg/kg/day divided q4-8h)
		Cefdinir	Omnicef	po	300mg po q12h or 600mg po q24h (7mg/kg po q12h or 14mg/kg po q24h)
		Cefmetazole	Zefazone	im/iv	2g q6-12h
		Cefonicid	Monocid	im/iv	1–2g q24h
		Cefotetan	Cefotan	im/iv	1–2g q12h
		Cefoxitin	Mefoxin	im/iv	1–2g q6-8h (80–160mg/kg/day divided q6h)
		Cefprozil	Cefzil	po	250–500mg q24h or divided q12h (7.5–15mg/kg/day divided q12h)
		Ceftibuten	Cedax	po	400mg q24h (9mg/kg/day)
		Cefuroxime	Ceftin	po	250–500mg q12h (20–30mg/kg/day divided q12h)
			Kefurox, Zinacef	im/iv	0.75–1.5g q8h (50–240mg/kg/day divided q8h)
		Loracarbef	Lorabid	po	200–400mg q12h (15–30mg/kg/day divided q12h)
Third-generation	Improved Gram-negative coverage; excellent *Streptococcus pneumoniae* coverage (ceftriaxone, cefotaxime), modest staphylococcal coverage, excellent *P. aeruginosa* coverage (ceftazidime, cefoperazone)	Cefditoren	Spectracef	po	200–400mg po q12h
		Cefixime	Suprax	po	400mg/day q24h or divided q12h (8mg/kg/day q24h or divided q12h)
		Cefoperazone	Cefobid	im/iv	2–4g q12h
		Cefotaxime	Claforan	im/iv	1–2g q4-12h (50–180mg/kg/day divided q4-6h)
		Cefpodoxime	Vantin	po	200mg q12h (10mg/kg/day q24h or divided q12h)
		Ceftazidime	Fortaz, Tazicef, Tazidime	im/iv	1–2g q8-12h (90–150mg/kg/day divided q8h)
		Ceftizoxime	Cefizox	im/iv	0.5–4g q8-12h (150–200mg/kg/day divided q6-8h)
		Ceftriaxone	Rocephin	im/iv	1–2g q24h (50–100mg/kg/day divided q12-24h)
Fourth-generation	Excellent Gram-positive and Gram-negative coverage (including *P. aeruginosa*)	Cefepime	Maxipime	im/iv	0.5–2g q12h
Monobactam	Gram-negatives including *P. aeruginosa*, but no Gram-positives and no anaerobes	Aztreonam	Azactam	im/iv	0.5–2g q6-12h
Carbapenems	Excellent activity against Gram-positives, Gram-negatives (including *P. aeruginosa*) and anaerobes	Ertapenem	Invanz	im/iv	1g q24h
		Imipenem-cilastatin	Primaxin	im/iv	0.25–1g q6-8h
		Meropenem	Merrem	iv	1–2g q8h (60–120mg/kg/day divided q8h)

* Not available in the USA. Note that the trade name may differ in other parts of the world.

had intermediate resistance and 9.5% were highly resistant.[25] Because of the emergence of resistance, some suggest that suspected cases of pneumococcal pneumonia and meningitis should be treated with vancomycin and/or a third-generation cephalosporin such as ceftriaxone until susceptibilities are known (see Chapter 34). There have been reports of failure of third-generation cephalosporins in the treatment of penicillin-resistant pneumococcal meningitis, again suggesting that vancomycin should be included until susceptibilities are known.[26]

Staphylococcal infections

Soon after the introduction of penicillin for the treatment of staphylococcal infections, penicillinase-producing strains became so common that it was no longer effective. Penicillinase-resistant penicillins (nafcillin, oxacillin, methicillin, dicloxacillin, cloxacillin and flucloxacillin) are now the agents of choice for susceptible strains of *Staphylococcus aureus*. Other ß-lactam antibiotics that are effective in the treatment of staphylococcal infections are:

- the aminopenicillins in combination with a ß-lactamase inhibitor (ampicillin-sulbactam or amoxicillin-clavulanate);
- the antipseudomonal penicillins in combination with a ß-lactamase inhibitor (ticarcillin-clavulanate, piperacillin-tazobactam); and
- the carbapenems (ertapenem, imipenem and meropenem).

The first-generation cephalosporins, which are as effective as the penicillinase-resistant penicillins in the treatment of staphylococcal

* Methicillin-sensitive *Staphylococcus aureus* and *S. epidermidis*. All methicillin-resistant *S. aureus* and *S. epidermidis* are resistant to all ß-lactams.
†Primarily *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter cloacae*, *Enterobacter aerogenes* and *Proteus mirabilis*.
1. Discontinued in the USA. MMWR 2002;51:1052.

infections, require less frequent dosing and may be used in patients with a history of mild penicillin allergy.

It is extremely important to remember that isolates of *S. aureus* or *Staphylococcus epidermidis* that are resistant to methicillin should be considered to be resistant to all other ß-lactam antibiotics, including the cephalosporins and carbapenems, even if in-vitro testing suggests otherwise.[27]

Gram-positive bacilli

Penicillin G is the treatment of choice for:

- infections (oral-cervicofacial, thoracic, abdominal) due to actinomycosis;
- elimination of the carrier state of diphtheria;
- infections (pulmonary, cutaneous, gastrointestinal) due to anthrax;
- gas gangrene caused by species of *Clostridium* spp.; and
- erysipeloid caused by *Erysipelothrix rhusiopathiae*.

Either penicillin G or ampicillin may be used for infections caused by *Listeria monocytogenes*. No cephalosporin has any activity against *L. monocytogenes*.

Infections caused by Gram-negative organisms including *Pseudomonas aeruginosa*

The ß-lactam antibiotics that have activity against *P. aeruginosa* are ticarcillin, carbenicillin, azlocillin, mezlocillin, piperacillin, ceftazidime, cefoperazone, cefepime, aztreonam, imipenem and meropenem. During treatment of pseudomonal infections, resistance to all ß-lactam agents used as sole therapy has been observed.[28] For this reason, a suitable ß-lactam antibiotic is generally used in conjunction with an aminoglycoside.

Antipseudomonal penicillins are often used in conjunction with a ß-lactamase inhibitor — for example ticarcillin-clavulanic acid or piperacillin-tazobactam — to extend their spectrum. The ß-lactamase inhibitor does not usually confer activity against *Pseudomonas* spp. that are resistant to the ß-lactam because the mechanism of resistance is not due to ß-lactamase production.[29] Treatment failures of nosocomial pneumonia caused by *P. aeruginosa* have occurred when piperacillin-tazobactam was used in the dose recommended by the manufacturer (3.375g intravenously q6h), and so this agent should be used in higher doses and in conjunction with an aminoglycoside when treating infections caused by or thought to be caused by *P. aeruginosa*.

The development of drug-resistant isolates of *P. aeruginosa* and other Gram-negative bacilli has become a problem in nosocomial infections. These micro-organisms are commonly found in intensive care units where patients can be on broad-spectrum antibiotics for prolonged periods of time. Many organisms produce inducible and extended-spectrum ß-lactamases. In fact, certain bacteria (*Citrobacter freundii* and *Serratia* spp., *Proteus, Providencia, Pseudomonas, Enterobacter* and *Acinetobacter*) have developed resistance to cephalosporins during therapy.[30] [31] Many recommend the concurrent use of an aminoglycoside in conjunction with a cephalosporin for the treatment of infections caused by these bacteria to prevent therapeutic failures.

Because of its broad antibiotic spectrum of activity against Gramnegative organisms resistant to other antibiotics, imipenem is frequently used in the treatment of nosocomial infections. Alternatives to the use of imipenem for resistant Gram-negative infections are now available and are discussed in the following two paragraphs.

Cefepime is a fourth-generation cephalosporin that is effective in the treatment of severe infections of the lower respiratory and urinary tracts, the skin and soft tissue, the female reproductive tract and neutropenic patients with fever. It has been shown to be more effective than ceftazidime in the treatment of pneumonia in patients with cystic fibrosis where *P. aeruginosa* is a common pathogen.[32] In addition to having activity against strains of *P. aeruginosa* resistant to ceftazidime, cefepime has also shown activity against *Enterobacter* spp. that are resistant to other ß-lactam antibiotics.[33] It has a low potential for inducing bacterial resistance, excellent activity against nonenterococcal streptococci and activity against staphylococci similar to that of cefotaxime. It has little or no activity against *Bacteroides fragilis* and other anaerobes.

Meropenem is a carbapenem antibiotic that has a very broad spectrum of activity, similar to that of imipenem. Imipenem has more activity than meropenem against staphylococci and enterococci, but meropenem provides better coverage of *Pseudomonas*, *Enterobacter, Klebsiella, Morganella, Providencia, Alcaligenes, Aeromonas, Moraxella, Kingella, Actinobacillus, Pasteurella* and *Haemophilus* spp.[34] [35] In one in-vitro study many isolates of *P. aeruginosa* resistant to imipenem were found to be sensitive to meropenem. [36] Meropenem has been effective in abdominal infections, meningitis in children and adults, community-acquired and nosocomial pneumonia, and neutropenic fever.[37]

Anaerobic infections

Anaerobic bacteria may play a significant role in brain abscess, dental infection, sinusitis, lung abscess, intra-abdominal abscess and bone and soft tissue infection. ß-Lactam antibiotics have been used extensively in the treatment of anaerobic infections, but there is a trend for an increased resistance of anaerobes to some ß-lactam antibiotics. As with the aerobes, the most common mechanism of resistance is the production of ß-lactamase.[38]

Most *Clostridium* strains (with the exception of some strains of *C. ramosum, C. clostridiforme* and *C. innocuum*) remain susceptible to penicillin. Penicillin resistance is increasingly seen in the genus *Fusobacterium*, most commonly in *F. varium* and *F. mortiferum,* and although generally still sensitive to penicillin, the MICs for *F. nucleatum* have increased. Penicillin resistance is a major problem encountered in the treatment of infections caused by *B. fragilis* and other *Bacteroides* spp.

Penicillin is more effective than nafcillin against anaerobes. Ticarcillin, mezlocillin and piperacillin also have excellent activity against anaerobes, although there has been an increase in *B. fragilis* strains resistant to ticarcillin. Of the ß-lactamase stable cephalosporins, cefoxitin, cefotetan, cefmetazole and ceftizoxime all show activity against anaerobes. Cefoxitin remains the most active cephalosporin against *B. fragilis*. Resistance to these cephalosporins is seen with some species of *Clostridium*, *Fusobacterium* and non-spore-forming Gram-positive rods. The first-generation cephalosporins such as cefazolin and cephalothin have poor activity against the Gram-negative anaerobes whereas the third-generation cephalosporins cefotaxime, cefoperazone and ceftriaxone have only modest activity (resistance seen in 30–60% of strains) and are therefore not the agents of choice for the empiric treatment of anaerobic infections. Cefotaxime has a desacetyl metabolite that works synergistically with the parent compound in the treatment of some anaerobic species in vitro, but is still not a primary agent for anaerobic infections in vivo. Ceftazidime has poor activity against both Gram-positive and Gram-negative anaerobes.

ß-Lactamases are responsible for most resistance to ß-lactam antibiotics in anaerobes. The ß-lactamases in the *B. fragilis* group are typically cephalosporinases, whereas those in non-fragilis *Bacteroides* spp., *Clostridium* spp. and *F. nucleatum* are penicillinases. Almost all *B. fragilis* isolates produce ß-lactamases. ß-Lactamase production has not been reported in strains of *Clostridium perfringens*.

The addition of a ß-lactamase inhibitor increases the activity of some of the ß-lactams against ß-lactamase producing anaerobes, in particular *Bacteroides* spp., and so ticarcillin-clavulanate, piperacillin-tazobactam, amoxicillin-clavulanate and ampicillin-sulbactam

are effective. The most active ß-lactam agents against anaerobic isolates in the USA are imipenem, meropenem and ertapenem. Interestingly, in Japan, anaerobe resistance to imipenem is becoming a clinical problem, but this has not yet occurred in the USA. Aztreonam has no activity against anaerobes and must be used with other agents when treating mixed aerobic and anaerobic infections.[39]

Central nervous system infections (meningitis)

Certain ß-lactam antibiotics are able to penetrate inflamed meninges and are commonly used to treat meningitis (e.g. penicillin G, ampicillin, nafcillin, oxacillin, cefotaxime, ceftizoxime, ceftriaxone, ceftazidime and meropenem). The most common pathogens in a series of adult patients with meningitis in descending order were *S. pneumoniae*, *Neisseria meningitidis* and *L. monocytogenes*.[40] In the pediatric population, *Haemophilus influenzae* also plays a role, but disease caused by this organism is less frequent as a result of the *H. influenzae* B vaccine. Penicillin G at a dose of 20–24 million U/day intravenously q4h for 14 days is the treatment of choice for susceptible strains of *S. pneumoniae*. The existence of resistance may necessitate the use of ceftriaxone and/or vancomycin until sensitivities are known. In an animal model, a combination of ceftriaxone and vancomycin was found to be synergistic against penicillin-resistant pneumococci. [41]

Penicillin or ampicillin are usually sufficient to treat *N. meningitidis* meningitis; however, a few ß-lactamase producing strains have been seen and ceftriaxone has been used effectively. ß-Lactams are not sufficient to eliminate the carrier state of *N. meningitidis*, and so rifampin (rifampicin) must be given at the completion of therapy. The agent of choice for the treatment of meningitis due to *L. monocytogenes* is ampicillin or penicillin alone or in combination with gentamicin; of note, the cephalosporins have no activity against this organism.

In children, the preferred agents for the treatment of *H. influenzae* meningitis are the third-generation cephalosporins cefotaxime or ceftriaxone.[42] There are several case reports that document the failure of cefuroxime to treat meningitis caused by *H. influenzae*[43] and there are instances where patients on cefuroxime have developed *H. influenzae* meningitis while being treated with cefuroxime for a non-meningeal infection caused by this organism. These failures are thought to occur as a result of resistant organisms or as a result of the inoculum effect whereby an increase in the inoculum of bacteria can significantly increase the apparent MIC/minimum bactericidal concentration (MBC) of the antibiotic to above attainable levels. A randomized trial found that ceftriaxone resulted in less hearing impairment and sterilized the CSF earlier than cefuroxime when used as treatment for meningitis in children.[44]

Patients with staphylococcal meningitis (which is usually seen after trauma or neurosurgical procedures) are best treated with high doses of nafcillin or oxacillin if the organism is susceptible. *Pseudomonas aeruginosa* meningitis has been effectively managed with ceftazidime, and meropenem may prove to be an alternative.[37]

Corticosteroids have been shown to reduce the neurologic sequelae of meningitis. In an animal model, corticosteroid treatment diminished the penetration of ceftriaxone into the CSF and markedly diminished the penetration of vancomycin. [45] Levels of rifampin in the CSF were not affected and the use of ceftriaxone with rifampin was successful in the treatment of meningitis in this model, whether or not the animal received corticosteroids. However, a recent prospective, randomized, double-blind trial demonstrated that the use of dexomethasone early in the treatment of patients with bacterial meningitis resulted in improved morbidity and mortality,

particularly for patients with pneumococcal meningitis. [45A]

Biliary system infections (cholangitis)

Infection of the biliary tract generally occurs if there is an abnormality such as gallstones, strictures or a stent. Infection rarely complicates malignant obstruction of the biliary tree. In the obstructed biliary tract, there is very little excretion of any antibiotic. For example, biliary excretion of cefoperazone is responsible for 70% of the excretion of this compound, yet no levels are detectable in the biliary tract when there is an obstruction. However, after an obstruction in the biliary tree is relieved, therapeutic levels of antibiotics can be achieved within 24 hours.[46] The ß-lactams that achieve significantly higher biliary than serum levels are nafcillin, mezlocillin, piperacillin, cefamandole, cefmetazole, cefoperazone and ceftriaxone. Ampicillin and carbenicillin achieve concentrations in the bile equal to or greater than those in serum. Interestingly, biliary levels are higher after oral amoxicillin or ampicillin than they are after intravenous administration. Biliary concentrations of ticarcillin, cefazolin, cefotaxime, ceftazidime and cefuroxime are all less than serum concentrations.[47]

For this reason, the ureidopenicillins mezlocillin and piperacillin are commonly used in biliary tract infections. Cefoperazone has been successful in the treatment of biliary infections. Cefoxitin, cefuroxime and ceftriaxone are also commonly used in conjunction with an aminoglycoside in patients with cholangitis.

In patients undergoing biliary surgery, adequate serum levels of antibiotic have been shown to be more important than biliary levels when the goal is to reduce postoperative infection.

Intra-abdominal infections (see Chapter 47)

Intra-abdominal infections, such as acute appendicitis, penetrating abdominal trauma and bowel perforation, are generally polymicrobial in nature and caused by a combination of aerobic, anaerobic and facultative anaerobic organisms. Historically, a regimen consisting of clindamycin and an aminoglycoside was the first to demonstrate superior efficacy in treating patients with penetrating abdominal trauma.[48] Since then, a number of studies have confirmed the efficacy of the ß-lactam antibiotics alone or in combination with other agents for various intra-abdominal infections.[49] Cefoxitin, imipenem, cefotetan, piperacillin and ticarcillin-clavulanic acid have all been shown to be effective in treating intra-abdominal infections when used as monotherapy. Meropenem has been shown to have efficacy similar to that of imipenem for the treatment of intra-abdominal sepsis.[50] [51] Ertapenem has similar efficacy in treating intra-abdominal infections as piperacillin-tazobactam.[52] [53] [54] The combination of clindamycin with either ceftazidime or aztreonam has been successful in the treatment of intra-abdominal infections. Failures of ampicillin-sulbactam have occurred when pseudomonal infections occur.

Although enterococci are commonly isolated from intra-abdominal infections (14–33%), many physicians do not include anti-enterococcal therapy in the initial treatment of these infections. There is a high incidence of enterococcal superinfections when moxalactam and ceftazidime are used; this phenomenon is not seen with cefotaxime, ceftizoxime or imipenem. 'Breakthrough' enterococcal infections occur in patients who have been hospitalized for long periods of time with persistent or recurrent intra-abdominal sepsis or who are immunosuppressed.[55]

Spontaneous bacterial peritonitis

Few studies have evaluated the efficacies of different antibiotics in the treatment of spontaneous bacterial peritonitis (SBP). The organisms that typically cause SBP are the Gram-negative bacilli (especially *Escherichia coli* and *Klebsiella* spp.), Gram-positive cocci (including pneumococci, other streptococci, enterococci and staphylococci) and anaerobes. When used in conjunction with an aminoglycoside, ampicillin had a cure rate of 76% in one study. Cefotaxime was shown to be more effective (cure rate 85%) than ampicillin and tobramycin (cure rate 56%) in another study of severe infections in patients with cirrhosis of which approximately 75% were SBP. In

another uncontrolled study, amoxicillin and clavulanic acid had a cure rate of 80% for SBP. Aztreonam monotherapy has been associated with Gram-positive superinfection. Therefore, if aztreonam is to be used for SBP, then an additional antibiotic providing Gram-positive coverage is needed.[56] [57]

Pancreatitis and its complications (see Chapter 47)

The prophylactic use of antibiotics in uncomplicated acute pancreatitis is controversial. Early studies that used ampicillin, an antibiotic that does not achieve therapeutic levels in pancreatic tissue, showed no benefit. However, several recent studies have shown a potential benefit. Patients with acute necrotizing pancreatitis treated with imipenem for 14 days had a lower incidence of pancreatic sepsis than those not treated; however, a trend toward a decreased mortality rate was not statistically significant.[58] A study that used cefuroxime in patients with acute necrotizing pancreatitis found that rates of bacteremia and mortality were both lower than those of controls.[59]

It is clear that ß-lactam antibiotics have a role in the management of infectious complications of pancreatitis such as abscess or infected pseudocyst. The agents commonly used in addition to cefuroxime and imipenem include ticarcillin-clavulanic acid, piperacillin-tazobactam, ampicillin-sulbactam and meropenem.

Endovascular infections (endocarditis) (see Chapter 59)

A recent review provides guidelines for the treatment of endocarditis in adults.[60] The drug of choice for the treatment of endocarditis caused by the viridans streptococci is penicillin G. Depending upon the drug susceptibility of the organism, gentamicin can be added for part or all of the course and the duration of treatment can be 2–6 weeks. Alternatively, a 4-week course of ceftriaxone can be used.[61]

Enterococcal endocarditis is best treated with ampicillin or penicillin in combination with an aminoglycoside for 4–6 weeks.

The treatment of choice for native-valve endocarditis caused by *Staphylococcus aureus* is nafcillin or oxacillin for 4–6 weeks. Gentamicin has been used for the first 3–5 days to decrease the number of days of bacteremia, but has not been shown to change the outcome.[62]

Intravenous drug users with right-sided staphylococcal endocarditis have been successfully treated with 2 weeks of nafcillin and tobramycin.[63] Prosthetic valve endocarditis with coagulase-negative staphylococci is optimally treated with nafcillin or oxacillin (if the organism is sensitive) in combination with rifampin and gentamicin (for the first 2 weeks) for at least 6 weeks.

Endocarditis caused by the slow-growing fastidious Gram-negative organisms *Haemophilus parainfluenzae, H. aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens* and *Kingella kingae* (the HACEK group) can be treated with ampicillin and gentamicin for 4 weeks or ceftriaxone alone for 4 weeks.

Neutropenic fever

ß-Lactam antibiotics (for those who are not allergic to them) are the agents of choice for the management of fever in patients with cancer and treatment-induced neutropenia. Because life-threatening infections can occur with Gram-negative rods, including *P. aeruginosa*, ticarcillin-clavulanic acid is used in conjunction with an aminoglycoside for the treatment of neutropenic fever in our institution. However, monotherapy with agents such as ceftazidime or imipenem has also been shown to be effective.[64] A combination of an extended-spectrum ß-lactam antibiotic with a third-generation cephalosporin (a double ß-lactam combination) has also been found to be effective. [65] In patients allergic to the penicillins, aztreonam provides excellent coverage of the Gram-negative bacilli and is an acceptable alternative, along with Gram-positive coverage, such as vancomycin (see Chapter 100).

Lyme disease

Early infection caused by *Borrelia burgdorferi* can be managed with either amoxicillin or doxycycline. Since co-infection with *Ehrlichia* spp. is known to occur in many areas, many clinicians now prefer to use doxycycline. For later manifestations of Lyme disease, however, the ß-lactams are the agents of choice. Lyme carditis can be successfully treated with either a 2-week course of ceftriaxone or intravenous penicillin G. Lyme meningitis and Lyme arthritis can also be treated with ceftriaxone or penicillin G, but for 2–4 weeks. A 30-day treatment course of amoxicillin and probenecid has been used for the treatment of Lyme arthritis. In pregnant women, doxycycline cannot be used, amoxicillin is used in early Lyme disease and intravenous penicillin G is used for disseminated early Lyme disease or any manifestation of

late disease (see Chapter 54).[66] [67]

Syphilis

Parenteral penicillin G is the preferred agent for treating all stages of syphilis and is the only therapy that has proved effective for neurosyphilis, syphilis in pregnancy and congenital syphilis.[68] Primary and secondary syphilis can be treated with a single dose of benzathine penicillin G (2.4 million U in adults, 50,000U/kg intramuscularly in children up to the adult dose). Late latent syphilis is treated with benzathine penicillin G 2.4 million U intramuscularly every week for 3 weeks. Procaine penicillin can be used where benzathine penicillin in unavailable, and there are alternatives for patients who are allergic to penicillin (see Chapter 75).

It is important to remember that patients being treated for any of the spirochete diseases — syphilis, Lyme disease or borreliosis — may develop a Jarisch-Herxheimer reaction, which may produce fever, tachycardia, chills, headaches, sore throat, malaise, myalgias, arthralgias, rash and, rarely, hypotension. This reaction has been observed in approximately 50% of patients treated for primary syphilis and 75% of patients with secondary syphilis.[69] Generally, it occurs a few hours after the first dose of penicillin, lasts for only a few hours and does not occur with subsequent doses of the antibiotic. Pre-treatment of patients with louse-borne relapsing fever (caused by *Borrelia recurrentis*) with hydrocortisone or acetaminophen does not prevent the Jarisch-Herxheimer reaction.[70] It is important to distinguish the reaction from penicillin allergy so that appropriate treatment is not discontinued.

DOSAGE IN SPECIAL CIRCUMSTANCES

Renal impairment

The majority of the ß-lactam antibiotics are excreted almost entirely via the renal route, and so dose adjustments are necessary in the presence of kidney disease. Failure to reduce the dose of penicillin in uremic patients has resulted in toxicity, most notably encephalopathy.[71] As biliary secretion plays a major role in the excretion of ceftriaxone, cefoperazone, nafcillin and oxacillin, the doses of these antibiotics do not need to be adjusted in renal failure. Because biliary secretion plays a lesser, although significant role in the excretion of the ureidopenicillins, the dosages of these drugs do not have to be reduced as much as for the other penicillins. Some ß-lactams must be re-dosed after peritoneal dialysis, which removes variable amounts of the drug. With the exception of ceftriaxone, cefoperazone, cefonicid, mezlocillin, methicillin, nafcillin, cloxacillin, dicloxacillin and oxacillin, the ß-lactams need must re-dosed following hemodialysis. Specific dose adjustments are needed for patients with renal impairment and for patients on hemodialysis or peritoneal dialysis (Table 193.5).

Hepatic impairment

The dosages of some ß-lactams must be adjusted in patients with severe hepatic disease. As a result of reduced desacetylation in

TABLE 193-5 -- Drug dosages in patients with renal failure. [7] [11] [72] [73] [74] [75]

DRUG DOSAGES IN PATIENTS WITH RENAL FAILURE									
Generic name	**Dose in normal renal function**	**Max. daily dose with normal renal function**	**Adjustment in dose (D) or interval (I)**	**GFR (ml/min) >50**	**GFR (ml/min) = 10–50**	**GFR (ml/min) <10**	**Supplement after HD**	**Supplement with PD**	**CVVHD**
Penicillins									
Amoxicillin	250–500mg q8h	1.5g/day	I	q8h	q8-12h	q24h	Yes	250mg q12h

CVVHD, continuous venovenous hemodialysis. GFR, glomerular filtration rate; HD, hemodialysis; PD, peritoneal dialysis.									

patients with liver disease, the half-life of cefotaxime may increase slightly, but the half-life of cefoperazone may increase significantly and dosage reductions are required. Although biliary excretion plays a role in the excretion of ceftriaxone, no dose adjustment is needed in patients with liver disease.

Extremes of age

Dose reductions of the ß-lactam antibiotics should be made in the elderly in the presence of renal dysfunction (see Table 193.5). Otherwise, elderly patients tolerate standard doses of the ß-lactam antibiotics.

Because neonates do not have fully developed renal function, special modifications in dosage are necessary. In addition, because children have a high risk of cholestatic complications with ceftriaxone, another agent should be used when possible (see Adverse reactions and interactions, below).

ß-Lactams in pregnancy

The penicillins, the ß-lactamase inhibitors and the cephalosporins, aztreonam and meropenem (as of May, 1997) are considered category B in pregnancy (Table 193.6). This means that animal studies have shown no risk to the fetus, but adequate human studies have not been performed, or that animal studies have shown risk and human studies have shown no risk. When they are indicated, these antibiotics are commonly used in clinical practice in pregnant women.

Imipenem-cilastatin and moxalactam are pregnancy category C, meaning that animal studies show toxicity to the fetus and human studies are inadequate. However, the benefit of using these drugs may exceed the risk of not treating a serious infection in a pregnant woman when no alternatives exist.[76] Meropenem, category B, may be a suitable alternative to imipenem, category C, for infections with resistant Gram-negative aerobic organisms.

ß-Lactam antibiotics that are not protein bound are transported across the placenta and reach the drug levels that are present in maternal serum. ß-Lactams that are highly protein-bound reach only low concentrations in amniotic fluid and the fetus.[77]

As a general principle, the ß-lactam antibiotics have accelerated elimination and lowered plasma concentrations in pregnant women as compared with nonpregnant women. As a result, the dose or frequency of administration should be increased in pregnant women.[76]

ADVERSE REACTIONS AND INTERACTIONS

Adverse reactions that occur with the ß-lactam antibiotics are summarized in Table 193.7 .

Allergic reactions

The most common adverse event associated with the use of ß-lactam antibiotics is an allergic reaction. The reported frequency of allergic reaction to penicillin varies from 0.7 to 10%, and anaphylaxis, the most feared reaction, occurs in 0.004–0.015% of patients.[78] A maculopapular rash occurs late in the treatment course of 2–3% of patients receiving a course of penicillin. Ampicillin and amoxicillin induce rashes in a higher percentage than other ß-lactams of patients treated (5.2–9.5%) and almost invariably cause a rash when given during acute infectious mononucleosis (Epstein-Barr virus) or cytomegalovirus, and rarely when given to patients with acute lymphocytic leukemia. Such patients may tolerate ß-lactam antibiotics when re-challenged after the acute illness has resolved. Reactions to penicillins are characterized according to the time of onset following administration of the drug:

- immediate reactions occur in the first hour;
- accelerated reactions occur 1–72 hours after drug administration; and
- late reactions occur 72 hours or more after starting a course of the antibiotic.

TABLE 193-6 -- **Pregnancy categories of the ß-lactam antibiotics (as of May 1997).**

PREGNANCY CATEGORIES OF THE ß-LACTAM ANTIBIOTICS	
Class of ß-lactam	**Pregnancy category**
Penicillins — all	B
ß-Lactamase inhibitors — all	B
Cephalosporins — all	B
Moxalactam	C
Aztreonam	B
Imipenem-cilastatin	C
Meropenem	B
Ertapenem	B
Category B means that animal studies have shown no risk to the fetus, but adequate human studies have not been performed, or animal studies have shown risk and human studies have shown no risk. Category C means that animal studies show toxicity to the fetus and human studies are inadequate.	

TABLE 193-7 -- Adverse reactions with ß-lactam antibiotics.

ADVERSE REACTIONS WITH ß-LACTAM ANTIBIOTICS	
Reaction	**Examples**
Local	Pain, induration, tenderness at sile of im injection; burning during iv administration, phlebitis
Hypersensitivity	Rash, pruritus, urticaria, fever, chills, Stevens-Johnson syndrome, anaphylaxis
Gastrointestinal	Diarrhea, nausea, vomiting, abdominal pain, *Clostridium difficile* diarrhea
Hematologic	Eosinophilia, leukopenia, anemia, positive Coombs' test, hemolytic anemia, neutropenia, lymphopenia; thrombocytosis, thrombocytopenia, elevated prothrombin time, bleeding, abnormal clotting time, abnormal platelet aggregation
Hepatic	Elevated transaminases (aspartate transaminase, alanine transaminase), hepatitis, elevated alkaline phosphatase, elevated bilirubin
Renal	Elevated blood urea nitrogen and creatinine, falsely elevated creatinine, casts in urine
Central nervous system	Headache, dizziness, somnolence, confusion, tremor, myoclonus, seizures, encephatopathy
Genitourinary	Vaginitis
Superinfection	Thrush, vaginal candidiasis, infection with resistant bacteria

Both immediate and accelerated reactions may result in urticaria and anaphylaxis.

Previous exposure to penicillin does not seem to increase the risk of penicillin allergy. However, it is clear that people who have had allergic reactions to penicillin have a higher risk of allergic reactions than people who have tolerated therapy in the past. In patients with a history of penicillin allergy, re-challenge with penicillin results in acute reactions in an estimated 65% of patients, anaphylaxis in 5–10% and fatal anaphylaxis in 0.2–0.5%.

Skin testing is a useful technique in the evaluation of patients with a history of penicillin allergy, but is not useful as a screening test for

the general population because many skin test positive patients without a history of penicillin allergy can tolerate penicillin therapy. Skin testing is not useful for identifying non-IgE-mediated adverse drug reactions such as drug fever.

Although fatalities have occurred as a result of the skin test itself, the procedure is generally regarded as safe. A wide range in the incidence of positive skin tests in patients with a previous history of penicillin allergy has been noted (8.75–63%), and therefore a significant proportion of patients who give a history of penicillin allergy can tolerate the drug.[79] In one large study, penicillin skin testing allowed the safe use of penicillin in 90% of patients who gave a history of penicillin allergy.[80] The incidence of positive skin test results in patients who have tolerated penicillin in the past range from 4 to 7%.[81] When penicillin is administered to patients with a previous history of penicillin allergy, but with a negative skin test, the overall reaction rate (early and accelerated) is low and similar to the rate of allergy reported in the general population. In addition, the reactions are generally mild and self-limiting. In one study, only 1.2% of patients who had a history of penicillin allergy and a negative skin test had a possible IgE-mediated reaction.[82] Anaphylaxis has occurred in patients with negative skin tests, but is extremely rare. Skin test reactivity declines with time in patients with a history of penicillin allergy. People with dermatitis and allergic rhinitis do not have an increased risk of penicillin allergy, but the risk may be increased for atopic individuals.[83]

Patients with a history of penicillin allergy are four times as likely to have a reaction to first-generation cephalosporins than patients without a history of allergy (8.1 vs 1.9%). Second- and third-generation cephalosporins have an incidence of skin reaction (rash) ranging from 1 to 3%, similar to the incidence of rash with penicillin. Anaphylaxis, however, is uncommon with cephalosporins. There seems to be a lower incidence of allergy to second- and third-generation cephalosporins in patients with a history of penicillin allergy. Patients with allergy to penicillins should be considered allergic to the carbapenems, but there seems to be no cross-reactivity with aztreonam. No major adverse reactions to aztreonam have been reported, but rarely patients will develop a rash. There is more allergic cross-reactivity among penicillin derivatives than among cephalosporin derivatives. However, allergic cross-reactivity between cephalosporin derivatives is greater than cross-reactivity between cephalosporins and penicillins.[84] For example, a patient who is known to be allergic to ceftriaxone is more likely to be allergic to ceftazidime than a patient who is known to be allergic only to penicillin.[85]

At times, it may be necessary to administer penicillin to patients with a previous severe reaction to the drug. For instance, penicillin is the only acceptable treatment for a pregnant woman with syphilis. Effective methods of desensitization have been described,[86] but adverse reactions are common and the patient should be in an intensive care unit for close monitoring.

Hematologic effects

Hematologic toxicity is rare, but leukopenia (occurring in 0.2% of patients on mezlocillin in one study) has been observed when the penicillins or cephalosporins are used at high doses,[87] and also rarely with imipenem. Counts return when the drug is discontinued, and lower dosages can often be tolerated without neutropenia. Isolated eosinophilia can occur in patients on cephalosporins (1–7%). A Coombs' positive hemolytic anemia is rarely observed with the penicillins[88] and cephalosporins.[89]

Dose-dependent defects of platelet aggregation and a prolongation of the bleeding time can be seen with carbenicillin and ticarcillin and can occur with all of the penicillins at high doses. Clinically significant bleeding can occur but is uncommon.[90] Hypoprothrombinemia has occurred frequently with cephalosporins that possess a methylthiotetrazole (MTT) group (cefamandole, cefoperazone, cefotetan, moxalactam, cefmetazole, cefmonoxime), which may interfere with the activation of factors II, VII, IX and X, and may also prevent the activation of vitamin K.[84] [90] [91] Patients with renal failure, malnutrition, intra-abdominal infection or recent gastrointestinal surgery seem to be at the highest risk and may benefit from weekly prophylaxis with vitamin K when being given one of these antibiotics.[89] The frequent occurrence of bleeding complications with moxalactam has led to minimal use of this antibiotic. [92] No coagulation abnormalities have been associated with imipenem.

Isolated thrombocytopenia rarely complicates the use of the ß-lactam antibiotics. An immune mechanism has been documented.[93] Thrombocytopenia can occur as soon as 5 days after the initiation of the antibiotic and generally resolves when the agent is withdrawn.[94] [95]

Renal effects

Interstitial nephritis, characterized by fever, rash, eosinophilia, proteinuria, hematuria, eosinophiluria and occasionally renal insufficiency can be seen with the penicillins, most commonly methicillin.[96] ß-Lactam antibiotics that exist as sodium salts, particularly carbenicillin and ticarcillin, can induce hypokalemia.[97] Cephalothin can cause renal damage that histopathologically resembles that of nafcillin.[98] The concurrent use of aminoglycosides may add to the nephrotoxicity of cephalosporins [99] such as cephalothin. About 1% of patients on ceftazidime have elevated blood urea nitrogen or creatinine, but these are generally not clinically significant.[100] The sodium load of some penicillins can be high, most notably with ticarcillin (4.7mEq/g), but also with ampicillin, methicillin, penicillin G, azlocillin, mezlocillin and pipercillin, thereby posing a problem for patients with cognestive heart failure.

Neurologic effects

Many of the ß-lactams can cause neurotoxicity and, in particular, seizures. Seizures have been reported following the use of penicillin,[70] ampicillin, amoxicillin, oxacillin, nafcillin, carbenicillin, ticarcillin, piperacillin, cefazolin, cefonicid, cephalexin, ceftazidime and imipenem. Benzylpenicillin, cefazolin and imipenem have the highest neurotoxic potential of the ß-lactam antibiotics. In fact, seizures occur in 0.4–1.5% of patients taking imipenem.

Several risk factors that may predispose a patient to neurotoxicity have been identified, for example:

- high doses;
- renal insufficiency;
- disruption of the blood-brain barrier,
- pre-existing central nervous system (CNS) disease;
- advanced age;
- concurrent administration of nephrotoxic drugs;
- concurrent drugs that may reduce the seizure threshold; and
- concurrent administration of other ß-lactam antibiotics.[101]

Neurotoxicity of penicillins is clearly related to elevated CSF antibiotic levels, such as may occur when high doses are being used in patients with impaired renal function. Penicillin levels in CSF should not exceed 5mg/l. Seizures have occurred in patients receiving meropenem only if they have underlying CNS abnormalities.

Gastrointestinal effects

Gastrointestinal upset and diarrhea are common side-effects of the ß-lactams. Enterocolitis caused by *Clostridium difficile* may result from use of any of the ß-lactams, but particularly ampicillin.

Hepatitis is a rare side-effect of carbenicillin,[102] mezlocillin and nafcillin, and resolves after discontinuation of therapy. Hepatitis as a result of intravenous oxacillin can occur as early as 2 days into treatment,

is thought to result from a hypersensitivity reaction, does not appear to be dose-related, and is reversible on discontinuation of the drug.[103] [104] Mild elevations in transaminases and alkaline phosphatase also occur with the cephalosporins and carbapenems, but the drug can usually be continued.[105] Serum transaminases become elevated in 2–4% of patients receiving aztreonam.

Gallbladder sludge formation[106] [107] and cholelithiasis[108] have occurred in patients on ceftriaxone. Children, patients receiving prolonged or high doses, and patients on total parenteral nutrition appear to be at risk of this complication.

A disulfuram-like reaction has been associated with the cephalosporins with an MTT group.[109] [110] Patients taking these agents and then ingesting alcohol have developed flushing, tachycardia, diaphoresis, headache, nausea, vomiting and dizziness.

Other reactions

Local side-effects of the ß-lactam antibiotics are not uncommon. At the intramuscular injection site, patients may experience pain, tenderness and edema. Thrombophlebitis can occur in up to 5% of patients receiving parenteral therapy with some agents.

Other reactions to penicillin are less common. Serum sickness, consisting of fever, urticaria, joint pains and angioneurotic edema, can occur and, rarely, exfoliative dermatitis, the Stevens-Johnson syndrome and allergic vasculitis. Late-onset morbilliform rashes can develop as a result of penicillin therapy and may disappear, even if the penicillin is continued, but desquamation can occur.

Drug interactions

The most clinically important drug interaction with the ß-lactam antibiotics occurs with probenecid, a uricosuric and renal tubular blocking agent. Probenecid causes a 2- to 4-fold increase in the peak serum concentration of the ß-lactam antibiotics. It also prolongs serum levels for these antibiotics. It is used most often with penicillin (e.g. in the treatment of gonococcal infections), but can also be used with ampicillin, methicillin, oxacillin, cloxacillin and nafcillin. The recommended dose in adults is 2g/day in divided doses, and in children a 25mg/kg initial dose is followed by 40mg/kg/day in four divided doses (adult dose used for children who weigh over 50kg). The mechanism of action involves not only inhibition of renal tubular secretion of the ß-lactams, but also a decrease in the apparent volume of distribution of the drug.[111] Probenecid has little effect on the serum levels of imipenem and aztreonam and has no effect on drug levels of ceftazidime. Adverse reactions, including anaphylaxis, can occur with probenecid and the clinician must also be aware that toxicity can result from supratherapeutic levels of the ß-lactam antibiotics when used with probenecid.

As cephalosporins with the MTT side-chain can interfere with hemostasis, care must be taken when using these antibiotics in patients taking warfarin.

Synergistic activity against various bacteria occurs when the penicillins, cephalosporins, carbapenems and monobactams are used in conjunction with aminoglycosides.[112] [113] [114] However, using two ß-lactam antibiotics together may result in either synergy or antagonism.

The bactericidal effect of ampicillin may be reduced when other antibiotics (chloramphenicol, erythromycin, sulfa drugs and tetracycline) are used simultaneously. The

clinical significance of this is unclear.

When ampicillin is used in patients who are taking oral contraceptive agents, breakthrough bleeding may occur and the contraceptive may be less effective.

Piperacillin and ticarcillin must be used cautiously in any patient on vecuronium because the neuromuscular blockade can be further prolonged. Piperacillin can also lower serum levels of tobramycin if the drugs are used together.

Chapter 194 - Macrolides, Ketolides, Lincosamides and Streptogramins

Claude J Carbon
Ethan Rubinstein

INTRODUCTION

Macrolides, lincosamides and streptogramins are chemically unrelated compounds but they possess closely related properties, such as mechanisms of action, antibacterial spectrum, pharmacokinetics and pharmacodynamics, and clinical use. They are considered in parallel in this chapter.

Macrolides

Erythromycin is considered as the reference macrolide antibiotic. First reports on this compound appeared in 1952. Other natural macrolides were launched soon after this. In the past few decades, efforts have been made to generate new semisynthetic compounds with improved chemical, biologic and pharmacokinetic properties and fewer side effects. The recent modifications of the macrolides, leading to the new class of ketolides, seem to be promising because they allow persistent activity against some micro-organisms that are otherwise resistant to the macrolides.

Lincosamides

Two compounds represent the lincosamide group:

- lincomycin, which is currently of limited clinical use, and
- clindamycin, which is still currently used in the treatment of anaerobic and some parasitic infections.

Streptogramins

Streptogramins are a group of cyclic peptides produced by various *Streptomyces* spp. Pristinamycin and virginiamycin are water-insoluble mixtures of naturally occurring compounds. More recently, the synthesis of water-soluble derivatives has allowed the development of an injectable streptogramin, namely Synercid (RP 59500). A common pattern to streptogramins is that they are composed of at least two structurally unrelated molecules (group A and group B), which act synergistically against most susceptible bacteria.

STRUCTURE

Macrolides and ketolides

The chemical structure of the macrolides is characterized by a large lactone ring containing between 12 and 16 atoms of carbon to which are attached one or more sugars, mainly desosamine and cladinose, by way of glycosidic bonds. Simplified classifications of the macrolides divide the compounds according to the size of the lactone ring (i.e. 12-, 14-, 15- or 16-membered rings; Fig. 194.1).[1] Within each of these groups, compounds are classified according to their natural or semisynthetic origin. The lactone ring is modified by a hydroxyl or alkyl group, one ketone at C7 in the 12-membered macrolides, at C9 in the 14-membered macrolides, and one aldehyde in the 16-membered compounds. The only compound with a 15-membered ring, the azalide azithromycin, contains a tertiary amino group. Neutral or basic sugars can substitute one, two or three hydroxyl groups of the lactone ring, conferring a more or less basic character to the molecule. The most basic compounds are the most active.[2]

The 12-membered macrolides have never become important in clinical practice. Numerous derivatives have been synthesized from the 14-membered macrolides derivatives of erythromycin A.[3] Efforts at extending the biochemical modifications of the 16-membered compounds have been less productive. The objective of this research was to retain the antibacterial activity of erythromycin while improving acid stability and thereby enhancing bioavailability.

In order to overcome the problem of bacterial resistance to macrolides, attempts have been made to modify the basic structure of 14-membered compounds. This has led to new derivatives, called ketolides because a ketone group replaces the L-cladinose of erythromycin A in position 3, a sugar long considered as essential for the antibacterial activity of macrolides. [4] Several additional modifications have allowed the isolation of several molecules. One of them, telithromycin, is already marketed in a number of countries; the others are currently under preclinical or clinical investigation. The telithromycin molecule has a second site of modification at positions C11,12 of the lactone ring, where an alkylaryl extension has been added to a carbamate group.

Lincosamides

Lincomycin was isolated from *Streptomyces lincolnensis*. It is an alkyl derivative of proline that is composed of an amino acid linked to an amino sugar; it is devoid of a lactone ring. Clindamycin is closely related; a hydroxyl group was substituted by a chlorine atom in position 7.

Streptogramins

Streptogramins, as mentioned above, are composed of two unrelated molecules. Group A streptogramins are polyunsaturated macrolactones. Group B streptogramins are cyclic hexadepsipeptides. Table 194.1 presents a summary of streptogramins and lists the compounds available for clinical use.[5]

MODE OF ACTION

Macrolides, ketolides lincosamides and streptogramins, although chemically unrelated, have similar modes of action against bacteria. The hydrophobicity of these molecules explains why they penetrate poorly through the external membrane of Gram-negative bacilli, thus inducing a limited effect against these bacteria. Macrolides and lincosamides exhibit a slow bactericidal effect against susceptible pathogens. Both components A and B of streptogramins demonstrate a synergistic effect that is responsible for a more rapid bactericidal action against some bacteria in their spectrum of activity.

Macrolides and lincosamides inhibit protein synthesis by binding to the 50S subunit of prokaryotic ribosomes, especially to the peptidyl transferase domain of 23S ribosomal RNA, close to the *P* site. Sites of fixation are different for the different classes of drugs. However, they partially overlap. The key sites of interaction for

** Data from Pechère.*[5]

those drugs are at nucleotides A2058 and A2059 within domain V of the 23S RNA, A752 within domain II, and parts of ribosomal proteins L4 and L22, which together form a single drug-binding pocket. Telithromycin binds to wild-type ribosomes with 10-fold greater affinity than erythromycin A.[6] As a result of this binding, a blockade of the peptide bond formation has been reported, with an inhibition of peptide elongation during synthesis.[7] It has also been suggested that the binding could block the peptidyl-transfer (t)RNA translocation from the *A* to the *P* site of the ribosome.[8] Because some mutations can confer resistance simultaneously to macrolides and lincosamides, it is possible that both classes inhibit protein synthesis by stimulating peptidyl-tRNA dissociation from ribosomes.

The relevant target of macrolides and parent compounds against protozoan parasites such as *Toxoplasma gondii* remains unknown. Even very high concentrations have no effect on intracellular parasite survival in the parasitophorous vacuole, extracellular survival or invasion into the subsequent host cell. Replication with the second host cell is inhibited immediately upon entry, suggesting that a key event could be the establishment of the new parasitophorous vacuole.

Both group A and group B streptogramins bind to the ribosome and inhibit the translation of mRNA during the elongation step (Fig. 194.2).[5] Group A compounds interfere with the function of the peptidyl transferase. They block two steps of the peptide chain elongation process. Group B compounds interfere with the correct positioning of peptidyl-tRNA at the *P* site. They inhibit peptide bond formation, resulting in the release of incomplete peptide chains (see Chapter 188).

MECHANISMS OF RESISTANCE

Intrinsic resistance

As mentioned above, Gram-negative bacilli, in particular members of the family Enterobacteriaceae, *Pseudomonas* spp. and *Acinetobacter* spp., are resistant to macrolides, lincosamides and streptogramins owing to the relative impermeability of their cellular outer membrane to these hydrophobic compounds. However, concentrations of erythromycin far above those achievable in serum have proven efficacy against Gram-negative bacilli in the intestinal tract and have been used for intestinal selective decontamination. Furthermore, high intra-cellular levels achieved by the newest macrolides can inhibit some Gram-negative bacteria. Enterococci are resistant to lincosamides and *Enterococcus faecalis* is resistant to streptogramins. *Mycobacterium tuberculosis* is not susceptible.

Acquired resistance

Three mechanisms account for acquired resistance to the macrolides: [9] [10] [11]

- modification of the target of the antibiotics, by methylation or mutation;
- inactivation of the antibiotics; and
- active efflux.

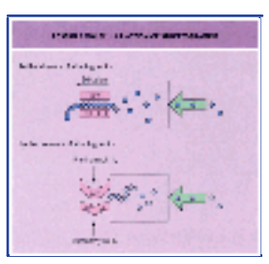

Figure 194-2 Possible molecular action of streptogramins. In the absence of streptogramins, the exit channel for peptide chains is free. In the presence of streptogramins, type A may induce a conformational change of L10 and L11, leading to an increase in the association of type B streptogramins for L24 and to a constriction of the exit channel. L10, L11 and L24 are the main proteins of the exit channel of peptide chains. *Adapted from Pechère.*[5]

In the first type of resistance, a single alteration in 23S rRNA confers cross-resistance to macrolides, lincosamides and group B streptogramins: the so-called MLS_B phenotype. The other two types confer resistance to structurally related compounds only.

Resistance by target methylation

Resistant strains produce an enzyme that demethylates an adenine residue in the 23S rRNA. This methylation leads to a conformational change in the ribosome, which in turn leads to co-resistance to MLS_B -type antibiotics. Streptogramin-A-type compounds are unaffected, and synergy between the two components of streptogramins against MLS_B -resistant strains is maintained. This enzyme production is under the control of erythromycin ribosome methylation (*erm*) genes. The distribution of *erm* genes among clinically important bacterial species is shown in Table 194.2 . These genes may be located on chromosomes but are mainly present on plasmids or transposons. The existence of cross-transfer of genetic material from Gram-positive to Gram-negative bacteria under natural conditions has been demonstrated. In Gram-positive cocci, the expression of MLS resistance may be constitutive and the strains are therefore resistant to all macrolides, lincosamides and streptogramin-B-type compounds. Streptogramin-A-type antibiotics escape resistance, and the combination of group A and group B compounds still exhibits a synergistic bacteriostatic effect. However, depending on the level of resistance to the group B component, the in-vivo bactericidal activity of the combination can be limited, especially against *Staphylococcus aureus*. Resistance to macrolides, lincosamides and group B streptogramins can be divided into constitutive resistance, when the methylating enzyme is produced continuously, and inducible resistance, when the presence of an inducing antibiotic is required for enzyme production. When

the expression of resistance is inducible, staphylococci are resistant to

** Data from Leclercq and Courvalin.*[9] [10]

14-membered and 15-membered macrolides. The 16-membered antibiotics, the lincosamides and the streptogramin antibiotics remain active, because only 14- and 15-membered macrolides are inducers of methylase synthesis. Ketolides are not inducers. In the case of streptococci, various macrolides and lincosamides can be inducers. Thus, among streptococci, there is a cross-resistance in any case, whether the expression of resistance is constitutive or inducible. As telithromycin is not an inducer of methylase production, it is effective against bacterial subpopulations harboring this type of resistance, but constitutively resistant bacteria are often resistant to telithromycin.[6]

Resistance among anaerobes (*Bacteroides* spp., *Clostridium* spp.) is mainly of the MLS_B constitutive phenotype, although inducibility has been reported. This resistance is either plasmid- or chromosome-mediated. Among *Campylobacter* spp., *Mycoplasma pneumoniae* and *Corynebacterium diphtheriae,* the resistance profile is of the MLS_B phenotype.

Resistance by target mutation

The clinical importance of this mechanism was only recently recognized, with identification of mutations at either A2058 or A2059 domain V of rRNA. A2058 and A2059 confer MLS_B resistance and ML resistance respectively. This mechanism has been identified in *Mycobacterium avium, Helicobacter pylori, Treponema pallidum* and *Streptococcus pneumoniae*. Mutations in ribosomal proteins L4 and L22 have been identified in *S. pneumoniae*.

Resistance by antibiotic modification

Various enzymes are responsible for this type of resistance by inactivation. This mechanism confers resistance to structurally related antibiotics only. Its clinical impact seems rather limited. Phosphotransferases encoded by *mph* (C) have been shown in *S. aureus.* Lincosamide nucleotidyltransferases encoded by *lnu*(A) and *lnu*(B) genes isolated in staphylococci and *Enterococcus faecium* inactivate

lincomycin and, to a lesser degree, clindamycin, which loses any bactericidal effect.

Resistance by active efflux

Two types of resistance by active efflux have been identified first in coagulase-negative staphylococci. The different types of resistance shown by bacteria are summarized in Table 194.3 & Table 194.4 . Resistance through active efflux is increasingly recognized in *Streptococcus pyogenes* and *S. pneumoniae*. The protein encoded by the macrolide efflux (*mef*)A or *mef*E gene causes resistance to 14- and 15-membered macrolides but not to other macrolides and lincosamides. This phenotype is called the M phenotype. Telithromycin does not appear to fit into this efflux pump and thus remains largely unaffected by *mef*.

Adequate in-vitro testing by combining disks of different MLS compounds may allow the interpretation of the phenotype of resistance and therefore help in choosing the best compound to use. The antibacterial effect of macrolides in vitro varies essentially according to the pH of the medium used; it decreases in acidic conditions and increases in alkaline conditions (see Chapter 188).

CLINICALLY RELEVANT SPECTRUM OF ACTIVITY

Macrolides

The clinical spectrum of macrolides (Table 194.5) is a function of several parameters:

- intrinsic activity;
- spread of resistance mechanisms;
- actual concentrations of active drug achieved in extracellular fluids; and
- intracellular concentrations able to reach intracellular pathogens.

TABLE 194-5 -- Clinically relevant antimicrobial spectrum of the macrolides.*

CLINICALLY RELEVANT ANTIMICROBIAL SPECTRUM OF THE MACROLIDES				
Type of infection	**Extracellular bacteria**	**Intracellular bacteria**	**Mycobacteria**	**Parasites**
Upper or lower respiratory tract infections*	*Streptococcus pneumoniae*	*Chlamydia pneumoniae*		
	Haemophilus influenzae	*Mycoplasma pneumoniae*

			Mycobacterium fortuitum	

*; spectrum of clinical activity of telithromycin.

As discussed below in the sections on pharmacokinetics and pharmacodynamics, predicting in-vivo efficacy on the basis solely of extracellular levels of free drug is difficult with MLS compounds. Therefore, the clinically relevant spectrum can be better established on the basis of animal experiments and clinical trials than from in-vitro results and pharmacokinetic data alone.

The prevalence of resistance to macrolides such as erythromycin is highly variable among different countries.[12] Resistance of *S. aureus* to erythromycin ranges from 1% to 50%, with marked differences between community isolates (usually 70–90% susceptible) and hospital isolates, where less than 25% of methicillin-resistant *S. aureus* isolates remain susceptible. Generally more than 75% of methicillin-resistant *Staphylococcus epidermidis* are resistant to macrolides. An increase in the frequency of erythromycin resistance was noted in many hospitals when erythromycin was extensively used.[13] A similar phenomenon has been noted in Finland regarding the influence of macrolide prescription on the development of resistance of group A streptococci to erythromycin. In Finland, after a nationwide reduction in

the use of macrolides for outpatient therapy, a significant decline in the frequency of erythromycin resistance among group A streptococci was observed.[12]

Resistance of *S. pneumoniae* to macrolides is also highly variable: 34% worldwide, with rates ranging from 77% in Asia to 7% in Australia. It is especially frequent in penicillin-resistant isolates. The efflux mechanism seems to be more frequent in the USA than in Europe, the *erm*-mediated mechanism being more frequent in Europe.[12] Telithromycin is active against 97.6% of erythromycin-resistant strains.

Enterococcal resistance has increased over the years and is probably a source of resistance in streptococcal species and staphylococci. Macrolide activity against *Haemophilus influenzae* is variable since the systemic levels of macrolides are similar to the minimum inhibitory concentration (MIC). Some strains of *H. influenzae* are resistant to clinically achievable blood levels of the macrolides. Some Gram-negative organisms, mainly *Campylobacter jejuni* and *H. pylori*, are major therapeutic targets of macrolides.

Some differences in terms of in-vitro activity and demonstration of in-vivo efficacy have been reported between erythromycin and the newest macrolide compounds (see Indications). However, it should be emphasized again that these compounds share the main resistance patterns with erythromycin.

Ketolides are active against Gram-positive cocci that are resistant to erythromycin by an efflux mechanism or by an inducible MLS_B mechanism.

Lincosamides

Lincosamides offer advantages of efficacy against anaerobes, including *Bacteroides* spp. (mainly *B. fragilis*), *Fusobacterium* spp., anaerobic cocci, *Clostridium perfringens* and other clostridia, certain non-spore-forming Gram-positive rods and *Capnocytophaga* spp. Resistance has been described with an increased incidence among anaerobes isolated from patients previously treated with clindamycin. The antiparasitic spectrum of clindamycin includes *Plasmodium* spp. and *T. gondii*.

Streptogramins

Streptogramins have a broad spectrum of antibacterial activity in vitro, roughly the same as that of the macrolides. However, interesting differences can be pointed out; the parenteral compound Synercid® is effective against staphylococci with the inducible type of resistance and against some of the constitutively resistant ones. Macrolide-resistant *S. pneumoniae* remain susceptible to streptogramins. These compounds are also active against constitutively macrolide-resistant strains of streptococci. Multiple-resistant *Enterococcus faecium* are susceptible in vitro to Synercid®.[14]

PHARMACOLOGY

Pharmacokinetics

Macrolides

The major drawback of earlier macrolides was their poor intestinal absorption (with large variations both within and between subjects), short half-life, high degree of binding to serum proteins (mainly the a-1 acid glycoprotein) and poor gastrointestinal tolerance. The main kinetic properties of macrolides are listed in Table 194.6 .[15] It is important to note wide variations in peak serum concentrations, elimination half-lives and areas under the serum concentration curve (AUC). Furthermore, differences in terms of C_{max} (peak blood level) have been described for the different erythromycin preparations. Generally, the bioavailability of macrolides is low to moderate. Various factors may affect their absorption: the nature of the salt

TABLE 194-6 -- Pharmacokinetics of macrolides and azalides.

PHARMACOKINETICS OF MACROLIDES AND AZALIDES						
Antibiotic	**Oral dose (mg)**	**C_{max} (mg/l)**	**t_{max} (hours)**	**Half-life (hours)**	**Area under serum concentration curve (mg/l hour)**	**Protein binding (%)**
Erythromycin base	500	2.00	3.7	2.0	7.7	74
Roxithromycin	300	10.8	1.6	11.9	116.9	95

that is administered (as mentioned above for erythromycin) and the presence of food. Therefore, specific conditions of oral administration should be checked for each compound (Table 194.7). The free fraction of macrolides diffuses into most tissues. Penetration into the cerebrospinal fluid is poor.

All macrolides exhibit intracellular accumulation mainly in polymorphonuclear leukocytes and macrophages; some of them have prolonged persistence of high intracellular levels. This phenomenon has also been observed in nonphagocytic cells and it has been proposed as the reason for the sustained bioactivity of macrolides against intracellular pathogens. Important variations in intracellular levels (with average intracellular to extracellular concentration ratios of more than 10) and half-lives have been described. The entry of macrolides into cells is rapid and almost complete within 15 minutes. The highest intracellular concentrations are currently achieved by azithromycin, which also has the longest intracellular half-life. The uptake rates of the compounds correspond to their lipid solubility, and this process is not saturable. The mechanisms underlying macrolide cellular uptake are still poorly understood, apart from the role of lipid solubility. One possible mechanism involves active transport systems, especially those used by nucleosides. A likely mechanism for the accumulation of macrolides involves their weak basic nature and the possibility of trapping by protonation within acidic cellular compartments, lysosomes and polymorphonuclear neutrophil granules. [16]

Efflux of macrolides from the cells into a drug-free medium is rapid but highly variable from one drug to another. It is therefore possible to distinguish three types of macrolides by comparing them with erythromycin:

- azithromycin, with low extracellular levels, high intracellular penetration, and long extracellular and intracellular elimination half-lives;
- roxithromycin, with relatively high serum levels and shorter half-life than azithromycin; and
- clarithromycin, which has properties of both compounds; some older compounds such as spiramycin and josamycin are also in this intermediate position.

Obviously, the high intracellular concentrations go a long way to explaining the high tissue concentrations that are observed following the administration of macrolides. The therapeutic relevance of these high intracellular levels is less clear. Indeed, high intracellular levels are a prerequisite for the cure of intracellular organisms. However, the location of the offending agent within the cell and the acidic intracellular pH are not always compatible with the expected effect. Furthermore, the concept of the transport of the drug to the infected focus by the means of phagocytic cells remain rather theoretic in the absence of direct proof that the release of the drug from the cell is able to maintain extracellular levels that are sufficient to inhibit extracellular bacteria.

The primary site of metabolism of macrolides is the liver, with the metabolites excreted into the bile. The cytochrome P450 enzymes play a key role. A lesser degree of metabolism occurs in kidneys and lungs. The known metabolic pathways exhibit some features that are common to many members of the class and others that are unique to specific compounds.[17] Within the 14-membered compounds, *N*-demethylation of desosamine and hydrolysis of cladinose are commonly observed. Some specific events can occur, such as the hydroxylation at C14 of clarithromycin, leading to a 14-hydroxy derivative, which acts synergistically with the mother compound

on *H. influenzae*. Azithromycin, a 15-membered macrolide, is not highly metabolized; the unaltered parent compound accounts for 75% of drug-related substances excreted in humans. Within the family of 16-membered macrolides, cleavage of the 4''-O-acyl group on the terminal neutral sugar by liver esterases commonly occurs. In addition, oxidations at either the ß-carbon of the 4''-ester or at the C14 of the lactone ring are frequently observed. Interactions of macrolides with hepatic enzymes, especially cytochrome P450-dependent mono-oxygenases, is very important. Several drug interactions involve this system, which controls the oxidative metabolism and elimination of medicinal compounds. Erythromycin and troleandomycin (a macrolide that is no longer available in most countries) exert a marked disturbance of liver cytochromes P450 of the 3A subfamily in humans. This is the consequence of three concomitant phenomena:

- the induction of a cytochrome P450 3A;
- its inactivation by the formation of an iron-metabolite complex caused by the strong binding of a nitrosoalkane metabolite derived from the macrolide to P450 iron(II); and
- the accumulation of this complexed P450 through its stability in the presence of degrading enzymes.

Three structural factors are important in the formation of inhibitory P450-iron-metabolite complexes during macrolide oxidation:

- the presence of an $N(CH_3)^2$ amine function;
- the accessibility of this amine function, which is required for the strong binding of the nitrosoalkane metabolite to heme; and
- the hydrophobicity of the molecule.

All macrolides that are prone to forming these complexes are good inducers of P450 3A. Metabolism can be affected by liver function abnormalities. Binding of a-1 acid-glycoprotein can be decreased by a reduction in the production of this protein, with a subsequent

TABLE 194-7 -- Mode of administration of macrolides and modification of dosage in specific conditions.

MODE OF ADMINISTRATION OF MACROLIDES AND MODIFICATION OF DOSAGE IN SPECIFIC CONDITIONS					
Macrolides	**Presentation**	**Route of administration**	**Dosage**	**Effect of food**	**Modification of dosage in specific conditions**
Azithromycin	Capsules (250mg)	po	500mg on day 1, then 250mg q24h	50% reduction in AUC	If creatinine clearance >30ml/minute, no modification
	Pediatric suspension				
	or				If creatinine clearance <30ml/minute, situation uncertain
	Granules	po	10mg/kg/day then 5mg/kg q24h		
					Caution in severe hepatic failure
Clarithromycin	Tablets (250mg)	po	250–1000mg q12h	No effect	50% reduction in dose if creatinine clearance <30ml/minute
	Tablets (500mg modified release)				No data in hepatic failure
Dirithromycin	Tablets (250mg)	po	500mg q24h	Increased bioavailability	50% reduction in dose if creatinine clearance <5ml/minute and in those aged over 80 years
Erythromycin lactobionate	Vials (500mg and 1000mg)	iv	2000mg/day by continuous infusion or 500mg q6h (infused over 1 hour) in adults; 30–40mg/kg/day in children	No effect	50% reduction in dose in case of renal failure
					Caution in the elderly
Erythromycin ethylsuccinate	Pediatric suspension or power (125mg and 250mg)	po	30–50mg/kg/day in children	No effect	Avoid in hepatic failure
	Tablets (500mg and 1000mg)		2000–3000mg/day in adults		No modification in renal failure
Erythromycin propionate	Tablets (500mg)	po	500mg q12h	Decreased bioavailability	Avoid in hepatic failure
					Reduce dose in severe renal failure
Dihydrated erythromycin	Capsules (250mg)	po	500mg q12h	Decreased bioavailability	Avoid in hepatic failure
					Reduce dose in severe renal failure
Midecamycin diacetate	Tablets (400mg)	po	800mg q12h	No effect	Avoid in hepatic failure
					No modification in renal failure
Josamycin	Sachets (1000mg)	po	500–1000mg q12h	No effect	Avoid in hepatic failure
	Tablets (500mg)				No modification in renal failure
	Pediatric suspension				
	Granules				
Roxithromycin	Tablets (100mg or 150mg)	po	150mg q12h	No effect	Avoid in case of hepatic failure
	Pediatric suspension		3mg/kg q12h		No modification in renal failure
Spiramycin	Tablets (1.5×10^6 units or 3×10^6 units)	po	3×10^6 units q8-12h	No effect	No modification in renal failure
	Granules or suspension (1.5×10^6 units)	iv			

increase in the free fraction of the macrolide. In normal conditions, the main route of elimination of macrolides is the liver. Renal elimination contributes little to total clearance. Changes in macrolide pharmacokinetics due to hepatic or renal impairment depend on the molecule considered, the route of administration and the extent of disturbance in renal or hepatic functions. Table 194.7 indicates the changes to be considered in the dosages in the case of renal or hepatic functional disturbances.

The route of administration of macrolides is usually oral, except for erythromycin and, in some countries, azithromycin and spiramycin, which have a parenteral form. The number of daily doses (usually two) depends on the elimination half-life of the drug and the severity of infection (see Table 194.7).

Ketolides

Telithromycin is administered orally at a 800mg od daily dose. (Max is 2.3mg/L, AUC 0.24h:12.5µg.h/mL; elimination half-life 9.8h.) The compound is 70% bound to serum proteins. Hepatic metabolism (through CYP 3 A4) represents 37% of the elimination process.

Lincosamides

Orally administered clindamycin has good bioavailability (about 90%), and food does not interfere with its absorption. Protein binding varies from 60% to 95%. Serum C_{max} is around 4.5mg/l after a 300mg dose. The elimination half-life is about 3 hours. Penetration into the cerebrospinal fluid is limited. Lincosamides are actively transported into phagocytic cells. Approximately 95% of administered clindamycin is excreted unchanged or is metabolized through the liver; 5% is excreted unchanged into the urine. Active metabolites represent 20% of the total amount excreted. Lincomycin can be administered orally or intravenously. The common doses for adults are 300mg q8h orally or 600mg q8h intravenously, and for children 10–30mg/kg/day (divided into three doses). No dose adjustment is necessary for patients who have renal insufficiency but a 50% reduction in the dose may be needed for patients who have severe hepatic impairment.

Streptogramins

The data on the pharmacokinetics of pristinamycin are very limited, owing to the complexity of the components of the commercial preparation, the number of metabolites and the great instability of the drug in biologic fluids. In some countries, pristinamycin is available for oral administration, 2–3g/day (50–100mg/kg/day in children), to be given as two to four doses. No dosage modification is needed in renal or hepatic failure.

The pharmacokinetic properties of the two components of Synercid® given intravenously in a 30:70 ratio (quinapristin:dalfopristin) at doses

of 5, 10 and 15mg/kg have been studied in healthy human volunteers.[18] Mean maximal concentrations (mg/ml) were 1.3, 2.4 and 3.3 for quinupristin and 5.1, 7.1 and 8.5 for dalfopristin. Elimination half-lives ranged between 0.6 hours and 1 hour for quinupristin and between 0.3 hours and 0.4 hours for dalfopristin. Plasma clearance was high for both compounds: 1l/h/kg for quinupristin and 0.8l/h/kg for dalfopristin. The plasma levels of the active metabolite of dalfopristin were 20–45% those of the parent drug, showing a trend to increase with the dose. Synercid® must be administered by intravenous infusion using a central vein. The recommended doses are 7.5mg/kg q8-12h, depending on the organism responsible for infection and the severity of the infection.

Pharmacodynamics

Antibacterial mechanisms

Macrolides

The efficacy of macrolides against extracellular pathogens depends on the extracellular concentrations of free drug and the level of susceptibility of the organisms.[19] Macrolides exhibit a time-dependent bactericidal effect against most bacteria of their clinical spectrum, particularly against streptococci. They are slowly bactericidal and increasing the concentration has little influence on the rate of killing. The size of the inoculum affects the antistreptococcal effect and also antistaphylococcal activity. In the presence of serum, the MIC of some macrolides (e.g. roxithromycin, rokitamycin) against *S. pyogenes* increases 1- to 4-fold. In contrast, the MIC for *S. pneumoniae* does not change. The optimal effect is observed at pH 8, with a significant decrease in efficacy at pH less than 6. Against extracellular pathogens, the time during which the concentration of free extracellular drug is above the MIC is the major determinant of the efficacy of macrolides.

Ketolides

Telithromycin exhibits a concentration-dependent effect against *S. pneumoniae*, the AUC to MIC ratio being the best predictive factor of bacterial outcome both in animal and human studies.[20]

Streptogramins

The two components of Synercid® are bacteriostatic against MLS_B -susceptible and methicillin MLS_B inducibly resistant *Staphylococcus aureus*, whereas the MLS_B constitutively resistant strains are resistant to quinupristin. Synergy between antibiotics in vitro is a phenomenon found at concentrations close to the MIC, except for strains with constitutive resistance. High-level resistance to quinupristin does not significantly reduce the activity of the combination, and generally the MIC index is found to be less than 0.5. The bactericidal effect of Synercid® against *S. aureus* appears to be time-dependent but not concentration-dependent, because neither quinupristin nor dalfopristin alone is bactericidal. Synercid® is more rapidly bactericidal against *S. pneumoniae* (1h) than against *S. aureus* (6h); it is slowly active against *E. faecium*.

Postantibiotic effect

The presence of a postantibiotic effect (PAE) is a feature common to all macrolides (see Chapter 188). Several factors may affect the in-vitro PAE of these drugs.[21] The duration of this effect is longer with Gram-positive cocci than with *H. influenzae*. Increasing macrolide concentrations and exposure time prolongs the duration of PAE to a point of maximum response.

The PAE of Synercid® has been evaluated against a variety of bacteria, mainly staphylococci, pneumococci and streptococci. The PAE is constantly observed at concentrations above the MIC.[21]

Nonantibacterial pharmacologic effects

Erythromycin and 14-membered macrolides exhibit agonistic activity to motilin receptors and are therefore able to accelerate gastric emptying.

In relation to their high and prolonged intracellular concentrations in phagocytic and nonphagocytic cells, macrolides show an effect on some cellular functions (e.g. they enhance phagocytosis, bacterial killing and chemotaxis). These effects are observed mainly with very high extracellular levels. The macrolides with antibacterial effect have very few immunosuppressive effects, if any. Some molecules derived from this class of macrocyclic antibiotics, such as FK506, are used as immunosuppressive agents.

INDICATIONS

Macrolides in adult patients

Macrolides have a number of uses in both immunocompetent and immunocompromised patients (Table 194.8).[22]

In respiratory tract infections, the use of a macrolide as a first-line monotherapy is, in some areas, made difficult by a high rate of resistance of *S. pneumoniae* to erythromycin. In community-acquired pneumonia, the use of a macrolide in patients who are aged less than 60 years and who have no risk factors or signs of severe pneumonia has been proposed.[23] However, this point is considered controversial by some authors, who argue that the role of intracellular pathogens as etiologic agents of community-acquired pneumonia is limited in this subgroup of patients. As far as *Legionella pneumophila* or *Chlamydia pneumoniae* can be recognized or highly suspected as responsible for the infection, a macrolide is considered a useful therapy.[24] Finally, in cases of severe infection, the prescription of a combination of a ß-lactam with a macrolide is recommended (see Chapter 34).[23]

Macrolides are used to treat some sexually transmitted diseases. [25] Azithromycin, given as a single dose of 1g, has been documented as effective in cervicitis and urethritis caused by *Chlamydia trachomatis*.[26] Conversely, such a short course of therapy is not effective in gonococcal infections, which require longer administration. For gonococcal infections and syphilis, macrolides are considered a second-choice treatment, even in cases of allergy to ß-lactams, because more efficient alternatives exist. Activity of macrolides has been documented in donovanosis and lymphogranuloma venereum (see Chapter 74 & Chapter 78).

Given their limited activity against staphylococci, macrolides are not considered major agents in the therapy of skin and soft tissue infections, except when streptococci are highly suspected (impetigo) or documented, and in cases of allergy to ß-lactams.

Azithromycin and clarithromycin have been evaluated as major components of the combinations that are active against *H. pylori*, including metronidazole and an

inhibitor of the proton pump. The selection of strains with high-level resistance after the use of macrolide has been demonstrated as the major drawback of macrolide monotherapy. *Campylobacter jejuni* is highly susceptible in vivo to macrolides. However, the use of macrolides in acute gastroenteritis supposes a precise bacteriologic documentation (see Chapter 43). Azithromycin has been shown to be effective in typhoid fever.[27] The clinical experience remains limited and this drug is considered a second-choice alternative therapy.

The C16 macrolide spiramycin is marketed in a limited number of countries. Very few well-designed clinical studies have been performed. Some studies indicatethat its activity is equivalent to that of other macrolides in the major indications allowing the oral route. In some countries, spiramycin is considered as a drug of choice for the treatment of toxoplasmosis occuring during prenancy. Data on the efficacy of the compound in such an indication are of limited scientific value. Tolerance of spiramycin is good with very limited drug-drug interactions.

The impact of a large use of C16 macrolide in a community on the level of resistance of streptococci and pneumococci, actually depends on the respective prevalence of the different genotypes of resistance to macrolides amongst those organisms.

TABLE 194-8 -- Potential uses of macrolides in adult patients.

POTENTIAL USES OF MACROLIDES IN ADULT PATIENTS		
	Condition	**Comments**
Respiratory tract infections	Acute sinusitis	Not first-line agents
	Otitis media	Not first-line agents
	Pharyngitis	In cases of allergy to penicillins
	Acute exacerbation of chronic bronchitis	In areas with low rate of pneumococcal resistance to macrolides
	Community-acquired pneumonia	First-line drug in adults aged over 60 years and without risk factors, signs of severe pneumonia or evidence of pneumococcal infection; alternatives in cases of allergy to ß-lactams; evidence of infection with *Legionella* spp. or *Chlamydia* spp.; combine with a ß-lactam in severe cases
Sexually transmitted diseases	Chlamydial urethritis or cervicitis	Single dose (1g) or azithromycin
	Donovanosis or lymphogranuloma venereum	Demonstrated efficacy
	Syphilis	Alternatives to ß-lactams (limited activity)
	Gonococcal infection	Alternatives to ß-lactams (limited activity)
Skin and soft tissue infections	Streptococcal infections	Limited activity versus staphylococcal infections
Gastrointestinal infections	*Helicobacter pylori*	Azithromycin or clarithromycin in triple combinations
	Campylobacter jejuni	See text
	Typhoid fever	Azithromycin is an alternative to other therapies (limited experience)
Specific organisms	*Borrelia burgdorferi*	See text
	Rickettsia typhus group	See text
	Bartonella spp.	Azithromycin can be used in cat-scratch disease (limited experience)
Immunocompromised host	Mycobacteria (*Mycobacterium leprae, M. chelonae, M. fortuitum*)	See text
	Mycobacterial disseminated infections (*M. avium*)	In combination with other agents
	Toxoplasmal encephalitis	Minor alternative to other regimens (in combination)
	Cryptosporidial intestinal infection	Azithromycin has a limited activity at high doses
	Rhodococcus equi infection	Limited experience
	Bacillary angiomatosis	Activity has been demonstrated
Nonantibacterial use	Gastric paresis	Erythromycin has documented activity
Possible future uses	Atherosclerosis	Possible role in control of coronary restenosis and prevention

The use of azithromycin or clarithromycin in the treatment of Lyme disease remains speculative and some studies indicate that amoxicillin might be superior (see Chapter 54). Macrolides are active against *Rickettsia* spp. of the typhus group, and josamycin may be considered a safe alternative to treat Mediterranean spotted fever.[28] Both *Bartonella henselae* and *Bartonella quintana* are susceptible to macrolides. Azithromycin has been demonstrated to be of potential use in the treatment of cat-scratch disease (Chapter 91).[29] The clinical experience with macrolides is still limited in the treatment of other forms of infections caused by *Bartonella* spp. in immunocompetent patients.

Monthly regimens that include clarithromycin and minocycline have demonstrated a significant clinical efficacy in the treatment of lepromatous leprosy. Further investigations are needed to determine the proper dosage of both drugs. [30] Infections due to *Mycobacterium chelonae* and *M. fortuitum* may be susceptible to azithromycin or clarithromycin (see Chapter 3 and Chapter 233). [31]

Erythromycin is used for its effects on gastric and intestinal motility to treat gastric paresis or gastrointestinal disturbances in diabetic or postsurgical patients.

In immunocompromised patients, mainly those infected by HIV, the newest macrolides are considered helpful agents in the treatment of disseminated *M. avium* infections. Monotherapy with azithromycin or clarithromycin causes the rapid selection of resistant variants, and therefore a multiple combination is required. Neither azithromycin nor clarithromycin is very helpful in the treatment of encephalitis caused by *T. gondii* because they need to be given in high doses, often intravenously and in combination with other compounds. Azithromycin, even at high doses, has shown limited activity against diarrhea caused by *Cryptosporidium parvum.* Bacillary angiomatosis and some forms of *Rhodococcus equi* infections are susceptible to macrolides.

Macrolides have a number of potential prophylactic uses (Table 194.9). In surgical prophylaxis, erythromycin can be used in combination with neomycin and enemas for the preparation of the large bowel before surgery. Macrolides are included in the recommendations for the prevention of bacterial endocarditis in low-risk patients undergoing dental procedures who are intolerant of ß-lactams. [32] There is a still limited experience in the use of azithromycin for the prevention of malaria.[33]

In immunocompromised hosts, macrolides are mainly used in the prevention of disseminated *M. avium* complex infection (see Chapter 129).[34] Azithromycin has been shown to be effective in primary prevention when given once weekly as has daily clarithromycin.[35] A combination of clarithromycin (or azithromycin) and another drug can be considered as an effective choice for the prevention of recurrences.

TABLE 194-9 -- Potential prophylactic uses of macrolides in adult patients.

POTENTIAL PROPHYLACTIC USES OF MACROLIDES IN ADULT PATIENTS		
	Indication	**Comments**
Immunocompetent host	Surgical prophylaxis (large bowel preparation)	Oral therapy in combination with neomycin and enema
	Bacterial endocarditis	Alternatives to ß-lactams in allergic patients
	Malaria	Limited experience with azithromycin
Immunocompromised host	Primary prevention of *Mycobacterium avium* complex infections	Weekly administration of azithromycin or daily clarithromycin has documented activity
	Prophylaxis of recurrences of *Mycobacterium avium* complex infections	Clarithromycin or azithromycin combined with another agent

TABLE 194-10 -- **Specific uses for macrolides in pediatric patients.**[*]

SPECIFIC USES FOR MACROLIDES IN PEDIATRIC PATIENTS		
	Indication	**Comments**
Upper respiratory tract infections	Acute otitis media	Not first-line choice
		Combine with sulfonamides
	Sinusitis	Not first-line choice
	Tonsillitis	Alternative to penicillin G and penicillin V in allergic patients
	Diphtheria	Eradication of acute and chronic carrier states
	Acute bronchitis	Antibiotic therapy has questionable efficacy
	Pneumonia	Not first-line choice as single agents
		Combination with ß-lactam in severe cases if infections caused by *Legionella* spp. and *Chlamydia* spp. a concern
	Whooping cough	Shortens the duration of disease
		Eliminates carrier state
Skin and soft tissue infections	*Campylobacter jejuni* enteritis	Treatment of choice
	Ureaplasmal or chlamydial infections in neonates	Treatment of choice
Local uses	Acne	See text
	Conjunctivitis	Alternatives as prophylaxis of ophthalmia neonatorum
Prophylactic uses	Endocarditis	Alternatives to ß-lactams in case of allergy
	Recurrences of rheumatic fever	Alternatives to ß-lactams in case of allergy

** Data from Guay.*[36]

Ketolides

Telithromycin has demonstrated equivalent activities to those of the comparators in the following indications: mild to moderate community-acquired pneumonia, acute exacerbations of chronic bronchitis, acute maxillary sinusitis and streptococcal pharyngitis, in adult patients at a single daily dose of 800mg. In most of those indications, a duration of treatment of 5 days has been shown to be acceptable.[20] Its use as a first-line choice for the treatment of community-acquired pneumonia is considered in many countries.

Use of macrolides in special circumstances

Some indications, more or less specific to children, are presented in Table 194.10 .[36] Macrolides are no longer considered to be first-choice drugs in the treatment of otitis media, owing to major changes in the susceptibility of pneumococci to erythromycin. [37] The combination of a macrolide and a sulfonamide has been shown to increase the effect against *H. influenzae*. The use of macrolides in tonsillitis should be considered in patients who are intolerant to ß-lactams in areas where group A streptococci have a low rate of resistance to erythromycin. The newest macrolides allow a reduction in the duration of treatment from 7–10 days to 4–5 days.[38] Topical preparations are used in the treatment of acne and for the prevention of ophthalmitis in neonates.

Table 194.11 gives some points to consider when choosing a particular compound once it has been established that the use of a macrolide is indicated. Efficacy for the indication should be the first point to be taken into consideration, together with the risk of side effects, drug interactions and poor patient compliance.

Table 194.7 mentions the modifications to be made in dosing in case of renal failure for the macrolides, and cautions around the use of those drugs in case of hepatic failure. In elderly patients, the degree of deterioration of the renal function should be taken into consideration to adapt the dose and dosing regimen of the intravenous forms of the macrolides. Also, as indicated in Table 194.12 , special attention should be paid to drugs currently taken by the patients at the moment when a macrolide is prescribed. The same type of measures are to be envisaged with telithro-mycin. For this latter drug, no specific adaptation of the dose is needed in patients who have renal failure or in elderly patients. Similar reasoning is acceptable for lincosamides and synergistins. Macrolides and lincosamides are not contraindicated during pregnancy. There are no data regarding Synercid® in that

TABLE 194-11 -- Advantages and disadvantages of specific macrolides.

ADVANTAGES AND DISADVANTAGES OF SPECIFIC MACROLIDES		
Agent	**Advantages**	**Disadvantages**
Erythromycin	Long clinical experience	Poor bioavaliability
	Good documentation of efficacy	Poor tolerance 2–4 doses per day
	Low cost	Drug-drug interactions
		Acquired resistance
Roxithromycin	Increased absorption	Drug-drug interactions
	Decreased side effects	Same resistance profile as erythromycin
	Adequate extracellular levels	
	Improved activity against mycobacteria than erythromycin	

Clarithromycin	Improved activity against some Gram-negative bacteria and some mycobacteria	Drug-drug interactions
	Increased absorption	Same resistance profile as erythromycin
Azithromycin	High intracellular levels	Poor extracellular levels
	Improved activity against some Gram-negative bacteria and mycobacteria than erythromycin	Poor documentation in bacteremic pneumococcal diseases
	Limited drug-drug interactions	Same resistance profile as erythromycin
	Once-daily administration	
	Short course of therapy	
	Single dose in *Chlamydia trachomatis* infection	
Dirithromycin	Improved biovailability than erythromycin	Same resistance profile as erythromycin
	Once-daily administration	
	Few drug-drug interactions	
Spiramycin	Improved bioavailability than erythromycin	Limited clinical documentation
	Good tolerance	Same resistance profile as erythromycin
	Limited drug interactions	
Josamycin	Good tolerance	Same resistance profile as erythromycin
		Drug-drug interactions

TABLE 194-12 -- Macrolide drug interactions.[*]

MACROLIDE DRUG INTERACTIONS	
Erythromycin	Avoid concomitant use of theophylline, ergotamine, bromocriptine, warfarin, carbamazepine, triazolam, midazolam, alfentamil, cyclosporin, terfenadine, cisapride and astemizole
	Caution in the use of digoxin (increased bioavailability — check serum levels)
Josamycin	Avoid concomitant use of astemizole, cisapride, ergotamine, bromocriptine, terfenadine, triazolam
	Caution in the use of theophylline and cyclosporin
Roxithromycin	Avoid concomitant use of triazolam, midazolam, cisapride, astemizole and cyclosporin
Clarithromycin	Avoid concomitant use of terfenadine, carbamazepine, ergotamine and cisapride
	Take zidovudine 2 hours apart from macrolide
	Caution in the use of theophylline
Midecamycin	Avoid concomitant use of ergotamine, cisapride and bromocriptine
	Caution in the use of cyclosporin and warfarin
Dirithromycin	Caution in the use of cyclopsorin and cisapride (?)
Spiramycin	Caution in the use of levodopa and cisapride (?)
Azithromycin	Avoid concomitant use of ergotamine, cisapride and bromocriptine
	Caution with use of cyclosporin

** Data from Guay.*[36]

situation. However, the risks related to the infection caused by multiresistant organisms should be considered if Synercid® represents the only therapeutic option.

Future developments in macrolide use

The potential use of the newest compounds in the treatment of atherosclerosis, because of their activity against *C. pneumoniae*, one of the micro-organisms potentially involved in the pathogenesis of atherosclerosis, is the most attractive future development in the use of macrolides.[39] On the basis of controversial results, investigations are in progress to delineate their role in the therapy and possibly the prevention of the disease. Other areas of potential interest could be the effects of macrolides on the expression of bacterial virulence factors, the formation of bacterial biofilms and their use as immunomodulators.

Synergistins

Oral pristinamycin is marketed in a limited number of countries. It is used in minor or moderately severe infections such as community-acquired pneumonia and community-acquired staphylococcal infections. The development of the parenteral streptogramin Synercid® is focused on methicillin-resistant *S. aureus, E. faecium* resistant to glycopeptides, macrolide- or penicillin-resistant pneumococci, and the treatment of Gram-positive cocci infections in patients not able to tolerate a more conventional agent.[40]

Clindamycin

Clindamycin is used in polymicrobial infections outside the central nervous system, including intra-abdominal, gynecologic, bronchopulmonary, and skin and soft tissue infections.[41] Its use may be compromised by the development of resistance among staphylococci and some anaerobes such as *B. fragilis*. Clindamycin has been shown to improve the efficacy of doxycycline in the treatment of severe malaria caused by *Plasmodium falciparum* and that of quinine in the treatment of babesiosis.

Topically, clindamycin is used for the treatment of acne and bacterial vaginosis.

It is used in combination with pyrimethamine as an alternative for the treatment or prevention of *T. gondii* encephalitis in HIV-infected patients.[34]

ADVERSE REACTIONS AND INTERACTIONS

Macrolides

Adverse reactions

In general, the macrolides have a high degree of safety.[36] The main adverse effects are referable to the gastrointestinal tract. Those effects are partly related to the dose-dependent prokinetic effects of the macrolides, with a higher incidence in young adults than in people over 70 years old. The 14-membered macrolides exhibit the most important effect on intestinal motility; the 16-membered have no such effects. These effects include nausea, vomiting, diarrhea and abdominal discomfort. Erythromycin is responsible for the highest percentages of gastrointestinal side effects, with values around 30% and a rate of discontinuation of therapy around 5%. These effects are significantly lower with the newest compounds, partly as a result of better bioavailability allowing lower oral doses (gastrointestinal side effects in

between 3% and 10% of patients and discontinuation of therapy in 1–4%).

Reversible cholestatic hepatitis has been reported with erythromycin estolate, mainly in children, in about one case in 1000. A hypersensitivity mechanism has been suggested in view of the rapid development of cholestatic hepatitis in patients who have previous drug-induced hepatitis. Erythromycin estolate is contraindicated in pregnancy. The frequency of hepatitis with other erythromycin preparations, mainly ethylsuccinate, is much lower. In patients who have had a previous episode of hepatitis induced by erythromycin estolate, the other macrolides should be used with caution or even considered as contraindicated. No cases of hepatitis have been reported with the newest macrolides. Transient elevation of hepatic enzymes have been rarely reported; this has been observed in about 10% of patients receiving high doses of clarithromycin (2g/day or more).

Erythromycin can cause a dose-dependent, reversible hearing loss, usually in patients who have renal or hepatic impairment. Hearing loss has rarely been reported with high doses of clarithromycin.

Hypersensitivity reactions can be observed with any macrolide.

Prolongation of the QT interval on electrocardiography leading in some cases to recurrent *torsades de pointes* may rarely occur following erythromycin lactobionate administration. Cases of *torsades de pointes* have also been described in patients receiving clarithromycin and azithromycin. Telithromycin and presumably other ketolides have also the potential to cause a prolongation of the QT_c interval, especially in elderly patients who have predisposing conditions or those who are concurrently receiving drugs that are substrates for CYP2D6 and 3A4.[41] Macrolides should be used with caution in patients at risk of these disorders, such as elderly female patients, patients who have inborn prolonged QT_c interval, patients who have congestive heart failure, patients who have hypomagnesemia or hypokalemia, those on diuretic therapy and patients receiving concomitant drugs able to potentiate the toxic effects of the macrolide (e.g. antiarrhythmic agents from class II, amiodarone, certain antihistaminics, certain fluoroquinolones). Disturbances of the intestinal microbial flora, with selection of staphylococci, enterococci or *Candida* spp., have been reported. Like many other oral antimicrobial agents, macrolides can induce *Clostridium difficile* colitis.

Ketolides

The ketolides have a similar spectrum of adverse events as the macrolides. In clinical trials in which a daily dose of 800mg was used the adverse events rate and profile were similar to the comparator agent, with diarrhea (13.3%) and nausea (8.1%) being the most common; other less frequent adverse events were vomiting, abdominal pains and elevation of liver enzymes.[42] From more than 1.5 million patient treated with telithromycin, no unexpected adverse event was reported. QT_c prolongation was not reported. In 0.6% of the cases, blurred vision related to a transient, fully reversable, trouble with accomodation was reported.

Drug interactions

Apart from the interaction of macrolides with digoxin, which is related to the destruction by the macrolide of enteric flora that are partly responsible for digoxin metabolism, most of the interactions between macrolides and other drugs involve inhibition of drug metabolism via cytochrome P450 microsomal enzymes (see Pharmacology). Erythromycin and troleandomycin are the macrolides that are most involved in these interactions. Azithromycin, rokitamycin and spiramycin neither activate the cytochrome P450 nor form complexes with it, and therefore they are unable to modify the pharmacokinetics and metabolism of other drugs.[15] Clarithromycin, roxithromycin, josamycin and midecamycin induce cytochrome P450 isoenzymes but, unlike erythromycin, they do not form complexes with the glucocorticoid-inducible isoenzymes.

Some of these interactions suggest that the concomitant use of a macrolide and the other drug in question should be avoided. If the combination cannot be avoided, then serum concentrations of the concurrently administered drug should be monitored and patients observed for signs of toxicity. Table 194.12 summarizes the main macrolide drug-drug interactions and their clinical relevance.[36] [42]

Streptogramins

Local pain and erythema in the vein used for infusion of this antibiotic has been frequent and dose-dependent. In 5% of patients this tolerance leads to discontinuation of the therapy and in more than 6% a change in the infusion site is required. Venous tolerability is improved by dissolving quinupristin-dalfopristin in larger quantities (over 250ml) of 5% dextrose and by using a central vein. Moderate and transient elevation of liver enzymes has also been reported in doses exceeding 10mg/kg. Itching, burning and erythema of the front of the neck and upper torso have also been reported in a few patients.[40] Arthralgia, myalgia, nausea and a rash are also common and elevation of liver enzymes are not uncommon. Synercid is a potent inhibitor of CYP3A4 and should be used with caution in patients taking drugs that are substrates of 3A4. Elevation of serum levels of nifedipine, midazolam and cyclosporin have been observed. Synercid has also the potential to prolong the QT_c interval when administered with drugs metabolized by 3A4 (e.g. cisapride).

Clindamycin

Adverse reactions include a morbilliform-rash, urticaria and, rarely, anaphylactoid reactions. Liver injury has also been reported rarely. Clindamycin-related diarrhea is reported in 2–30% of patients. It is usually a self-limiting problem, disappearing once clindamycin therapy is stopped. A small number of patients develop *C. difficile* colitis with various degrees of severity. [41]

Chapter 195 - Oxazolidinones

Franklin D Lowy

The oxazolidinones are a relatively new family of bacteriostatic antimicrobials that are protein synthesis inhibitors. Because this new family works at the early stage of protein synthesis involving formation of the 70S initiation complex, there does not appear to be cross-resistance with other protein synthesis inhibitors. Originally developed as an agent for the treatment of bacterial and fungal infections of plants, the agents were subsequently found to have activity against Gram-positive bacteria. Upjohn originally developed two oxazolidinones, eperezolid and linezolid. Based on its more advantageous pharmacologic profile, linezolid was selected for further investigation. At present linezolid is the sole oxazolidinone available. The discussion below is therefore limited to this product. A number of comprehensive reviews of oxazolidinones and linezolid have recently been published.[1] [2] [3] [3A]

PHARMACOKINETICS AND DISTRIBUTION

Linezolid has similar pharmacokinetics whether administered parenterally or orally. It is completely absorbed following oral administration achieving a bioavailability of 100%. Food causes a slight decrease in the rate of absorption but not in the overall amount absorbed. In normal volunteer studies peak plasma concentrations were achieved in 1–2 hours. Steady state concentrations were approximately 12 and 18mg/l following oral doses of 375 and 625mg twice daily respectively. Following intravenous administration of 625mg twice daily to volunteers for 7.5, days the steady state level was 3.8mg/l.[4] [5] The half-lives of oral and intravenously administered linezolid are 5.4 and 4.8 hours, respectively. The drug is excreted by both renal and non-renal routes; 90% of circulating drug is not metabolized, but there are two inactive metabolites that are the result of oxidation of the morpholine ring. The P450 system does not appear to be involved in the metabolism of linezolid thus limiting the number of possible drug-drug interactions.

Linezolid is 31% bound to plasma proteins. It has a relatively large volume of distribution of 40–50l. Information on tissue penetration is still incomplete, however linezolid appears to penetrate well into tissue blister fluid, pulmonary alveolar macrophages, and sweat.[2] [6] Preliminary studies suggest reasonable penetration of bone, fat and muscle. Mean ratios of linezolid in tissue fluid/plasma were 0.55, 1.2 and 0.71 for sweat, saliva and cerebrospinal fluid, respectively. There is little additional information at present on the tissue distribution of linezolid in humans.

ROUTE AND DOSAGE

As noted, linezolid can be administered orally or intravenously. Adjustment of dosage is not necessary when switching from one route to the other. The recommended dosage for serious infections such as nosocomial pneumonia or complicated skin and soft tissue infections is 600mg q12h. For uncomplicated infections including community acquired pneumonias or uncomplicated cutaneous infections 400mg q12h is adequate.

In patients with mild-to-moderate renal impairment (creatinine clearance 10–79ml/min) dosage adjustment is not necessary. However with more severe forms of renal disease dosage adjustment may be necessary.

The pharmacokinetics of linezolid appears unaffected by age. Dosage adjustment for the elderly is unnecessary. The clearance of linezolid is more rapid in children than in adults. As a result, the dose recommended for infants and children is 10mg/kg q8–12h. The only dosage schedule investigated to date in children has been q12h.

INDICATIONS

The oxazolidinones are primarily indicated for the treatment of bacterial infections caused by the Gram-positive staphylococci, streptococci and pneumococci, although their spectrum of antibacterial activity extends beyond these species. Linezolid has excellent *in-vitro* activity against staphylococcal species including methicillin-susceptible and resistant strains. There is little difference in the average minimal inhibitory concentrations (MICs) for methicillin-resistant and susceptible staphylococcal isolates. Linezolid is also active against the recently described *Staphylococcus aureus* isolates that are intermediate in susceptibility to glycopeptides — *Staph. aureus* with intermediate susceptibility to vancomycin (VISA) or *Staph. aureus* with intermediate susceptibility to glycopeptides (GISA) isolates.

In contrast with the protein synthesis inhibitor combination dalfopristin/quinupristin, linezolid is active against all enterococci, including *Enterococcus faecalis* and *Enterococcus faecium*, as well as those enterococcal strains that are vancomycin-resistant. It is also active against penicillin-susceptible and resistant *Streptococcus pneumoniae*, again with comparable MIC values (Table 195.1). In addition to these common Gram-positive pathogens, linezolid also has activity (MIC =4µg/ml) against some of the less frequently encountered Gram-positive organisms such as *Corynebacterium spp.*, *Bacillus spp.*, *Listeria monocytogenes*, *Erysipelothrix rhusiopathiae* and *Rhodococcus equi*.

Linezolid is moderately active against some anaerobes including *Clostridium spp.*, *Peptococcus spp.*, *Bacteroides fragilis* and *Fusobacterium nucleatum* and *F. meningosepticum*. It has limited activity against some Gram-negative bacteria such as *Moraxella*, *Bordetella* and *Haemophilus* spp. and has no activity against Enterobacteriaceae or *Pseudomonas* species. Of considerable interest for future development, is linezolid's *in-vitro* activity against *Mycobacterium tuberculosis* and *M. avium* complex.[7] [8] This activity includes several multidrug resistant *M. tuberculosis* isolates. Chemical modification of linezolid is currently being explored to develop new drugs within the oxazolidinone class with enhanced antimycobacterial activity.

In animal studies linezolid has shown activity against methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *E. faecium* in the endocarditis model.[9] [10] In a rabbit model of penicillin-resistant and susceptible pneumococcal meningitis, meningeal penetration of linezolid was good (38% of serum levels), however overall it was less effective than ceftriaxone.[11]

TABLE 195-1 -- **In-vitro antimicrobial susceptibility for linezolid against common Gram-positive pathogens.**†

IN-VITRO ANTIMICROBIAL SUSCEPTIBILITY FOR LINEZOLID AGAINST COMMON GRAM-POSITIVE PATHOGENS			
Organism	**MIC (µg/ml) 50%***	**MIC(µg/ml) 90%**	**Overall (µg/ml)**
***Staph. aureus* (n**=2256)			
Oxacillin susceptible	1–4	1–4	0.5–8
Oxacillin resistant	1–4	1–4	0.5–8
Coagulase-negative staphylococci (n=48)			
Oxacillin susceptible	0.5–2	1–4	0.25–4
Oxacillin resistant	0.5–2	1–2	0.5–4
ß-haemolytic streptococci (n=47)	1–2	2–4	1–4
***Strep. pneumoniae* (n**=454)			
Penicillin susceptible	0.5	1	<0.016–1
Penicillin resistant	0.5–1	1	0.06–4
***Enterococcus* spp. (n**=980)			
Vancomycin susceptible	1–4	1–4	0.5–4
Vancomycin resistant	2–4	2–4	1–4

TABLE 195-2 -- Potential clinical indications for the use of linezolid.

POTENTIAL CLINICAL INDICATIONS FOR THE USE OF LINEZOLID	
FDA-approved Indications Nature of infection	**Potential pathogens**
Skin & soft tissue (complicated)	MSSA, MRSA, *Streptococcus pyogenes*, *Streptococcus agalactiae*
Skin & soft tissue (uncomplicated)	MSSA, *Streptococcus pyogenes*
Infection with bacteremia	*Enterococcus faecium*
Nosocomial pneumonia	MRSA, MSSA, *Streptococcus pneumoniae* (penicillin susceptible)
Community-acquired pneumonia	*Streptococcus pneumoniae* (penicillin susceptible), MSSA
Potential future indications for linezolid	
Serious vancomycin-resistant *Enterococcus faecium* and *faecalis* infections or vancomycin-susceptible infections that are poorly responsive to therapy	
Serious MRSA, VISA (*Staphylococcus aureus* isolates that are intermediate in susceptibility to vancomycin), VRSA (vancomycin-resistant *Staphylococcus aureus*) infections, or infections that are poorly responsive to vancomycin therapy	
Complicated infections requiring long-term oral therapy with an antistaphylococcal or enterococcal agent where ß-lactams cannot be used (e.g. chronic osteomyelitis)	
Treatment of infections (e.g. nosocomial pneumonia, endocarditis, meningitis) caused by highly resistant (but linezolid susceptible) Gram-positive bacteria where alternative agents are not available or are contraindicated	
Combination therapy for antimycobacterial infections where first- and second-line agents cannot be used	
MRSA, methicillin-resistant *Staphylococcus aureus;* MSSA, methicillin-susceptible *Staph. aureus*	
VISA, *Staphylococcus aureus* with intermediate susceptibility to vancomycin	

At present linezolid is approved for the treatment of infections caused by vancomycin-resistant *E. faecium* with an associated bacteremia, nosocomial infections caused by both MRSA and methicillin-susceptible *Staph. aureus* (MSSA) as well as penicillin-susceptible *Staph. pneumoniae*, complicated skin and soft tissue infections caused by MRSA or MSSA, *Streptococcus pyogenes* and *Streptococcus agalactiae* and uncomplicated skin/soft tissue infections caused by MSSA and *Strep. pyogenes*. [12] [13] It is also approved by the FDA for the treatment of community-acquired pneumonia due to *Staph. pneumoniae* (penicillin-susceptible) and MSSA (Table 195.2). Stevens *et al.*[14] recently reported that linezolid was comparable to vancomycin in the treatment of MRSA infections in a randomized open-label trial.

There is additional clinical and experimental experience with linezolid suggesting that it may ultimately have a broader therapeutic role although these other indications have not been FDA approved. These reports include the successful treatment of enterococcal endocarditis and meningitis (the latter a case of vancomycin-resistant *E. faecium*), MRSA prosthetic hip infections and the elimination of nasal carriage with *Staph. aureus*. [15] [16] [17] It is at present not clear how effective linezolid will be in the treatment of infections, such as endocarditis, that require bactericidal activity.

Linezolid is an important addition to the Gram-positive armamentarium. It is an alternative agent for the treatment of resistant Gram-positive infections (see Table 195.2). It has an antibacterial spectrum that is similar to vancomycin with advantageous pharmacokinetics. The availability of an oral preparation allows completion of therapy with the same therapeutic agent and therefore may help reduce the duration of hospital stays.[18]

Dosage in special circumstances

As noted above adjustment of dosage for moderate degrees of renal failure is not necessary. Because linezolid (as well as the linezolid metabolites) are cleared during hemodialysis, it is recommended that patients receive a supplemental dose following dialysis. For moderate degrees of hepatic disease dosage adjustment is not necessary.

ADVERSE REACTIONS AND INTERACTIONS

Linezolid has, in general, been well tolerated. The most common adverse events in the comparator-controlled trials were diarrhea (2.8–11%), nausea (3.4–9.6%) and headaches (0.5–11.3%).

Potentially, the most serious adverse event, thrombocytopenia, was seen in 2.4% of patients. It was seen most often during prolonged therapy (longer than 2 weeks) and resolved upon completion of therapy. Others have reported a higher incidence of thrombocytopenia.[19] [20] As a result, hematologic monitoring of these parameters is recommended during prolonged therapy, especially for subjects who are already immunocompromised.

The oxazolidinones are monoamine oxidase (MAO) inhibitors. Linezolid appears to be a relatively weak MAO inhibitor. No evidence of adverse events related to this potential interaction has been reported to date. However, it is recommended that patients taking linezolid avoid tyramine-containing foods. There is also the potential for interaction with both serotonergic and adrenergic compounds.

Chapter 196 - Aminoglycosides

Richard Quintiliani Jr
Richard Quintiliani
Charles H Nightingale

INTRODUCTION

Despite predictions that aminogylcosides would in time become obsolete, or at best, of limited usage because of their ototoxic and nephrotoxic potential, they have increased in popularity and clinical importance. With continued usage since the 1940s, it has become apparent that their toxicity is modest as long as the dose is adjusted for renal function, and they are not administered for extended periods. In addition, with once-daily aminoglycoside dosing rather than the traditional intermittent dosing method, their toxicity has been reduced further.

A major reason for their increased use has been the increasing number of nosocomial infections by bacteria that are either initially resistant or develop resistance to ß-lactam and the fluoroquinolone antibiotics. Many of these organisms have, however, not only retained their susceptibility to aminoglycosides, but seldom develop resistance during therapy. Unlike ß-lactam antibiotics, which are often less active in the presence of high concentrations of bacteria, the aminoglycosides are not subject to this inoculum effect. In contrast to penicillins and cephalosporins, aminoglycosides continue to suppress regrowth of aerobic Gram-negative bacteria for hours after the blood levels fall below the minimum inhibitory concentrations (MICs) for these organisms.

Another important attribute of aminoglycosides is their ability to achieve an additive or synergistic effect against most aerobic Gram-negative bacilli and Gram-positive cocci when combined with ß-lactam antibiotics and a similar effect against Gram-positive cocci when combined with vancomycin or teicoplanin.

BACKGROUND

The aminoglycosides were discovered following systematic screening of soil actinomycetes for the production of substances with antimicrobial activity. These compounds exhibited particular activity against aerobic Gram-negative bacilli and Gram-positive cocci. Streptomycin, the first clinically useful aminoglycoside, was isolated from *Streptomyces griseus* in 1944. Neomycin, kanamycin, tobramycin and paromomycin are also natural compounds that were subsequently isolated from various species of streptomyces. Gentamicin and sisomicin (not marketed in the USA) are natural products produced by *Micromonospora* spp. Amikacin and netilmicin are semisynthetic aminoglycosides derived from kanamycin and sisomicin, respectively. The suffix 'mycin' and 'micin' indicates that the compound was isolated directly or indirectly from *Streptomyces* spp. or *Micromonospora* spp., respectively.

CHEMISTRY

The chemical structures of the aminoglycosides are shown in Figure 196.1 . All aminoglycosides include a central six-membered ring containing amino groups termed an aminocyclitol, which is linked to two or more amino- or non-amino-containing sugars by glycosidic bonds. Spectinomycin is a pure aminocyclitol and is often considered with the aminoglycosides, but is not strictly speaking an aminoglycoside because it contains neither aminosugars nor glycosidic bonds. For this reason, the complete group of compounds is more accurately referred to as aminoglycoside-aminocyclitol antibiotics.

Microbiologic activity

When evaluating the microbiologic activity of the aminoglycosides, it is useful to divide them into two groups:

- one that includes gentamicin, tobramycin, netilmicin and amikacin; and
- the other including streptomycin, neomycin, kanamycin, spectinomycin and paromomycin.

The former group of agents are closely similar in their microbiologic activity and clinical usage, whereas the latter group of drugs have more limited clinical indications.

Owing to the impressive broad-spectrum microbiologic activity of gentamicin, tobramycin, netilmicin and amikacin, they have gained wide popularity in the empiric treatment of patients in whom the suspected pathogens can be multiple (Table 196.1).

Although aminoglycosides alone do not inhibit enterococci and streptococci, they are often used in the therapy of serious infections caused by these organisms because of their frequent additive or synergistic effect when combined with other antibiotics.

In contrast to the cephalosporins and penicillins, the microbiologic effect of aminoglycosides is the same at low or high inocula of organisms.[1] This observation has particular relevance in the treatment of intra-abdominal infections where the density of bacteria may be high. In addition, aminoglycosides show a significant postantibiotic effect (PAE), which is the persistent suppression of bacterial growth after exposure to an antibiotic, against both Gram-negative and Gram-positive bacteria. [2] Except for the carbapenems such as imipenem and meropenem, ß-lactams show no significant PAE against Gram-negative bacteria. The duration of the PAE with aminoglycosides that have activity against *P. aeruginosa* and Enterobacteriaceae is about 1–3 hours and 0.9–2 hours, respectively.[3] These PAEs are even longer if the once-daily aminoglycoside dosing technique discussed later in this chapter is used.

Absorption

Because of their highly charged nature, there is minimal absorption of aminoglycosides when given by mouth, topical application or rectal instillation. [4] Nevertheless, in patients with hepatic encephalopathy and renal impairment, large and frequent doses of neomycin have been associated with sufficient absorption into the systemic circulation to produce deafness.[5] Similarly, detectable blood levels of aminoglycosides can be found if they are used topically in burn patients with large areas of denuded skin. Because aminoglycosides penetrate extremely well into body spaces with large serosal surfaces (e.g. pleural space, peritoneal cavity, pericardial space, synovial fluid), it is unwise to instill them directly into these sites, and there have been reports of neuromuscular blockade (see Adverse reactions, below) associated with large doses injected into the peritoneal

Figure 196-1 Chemical structures of the aminoglycosides. All aminoglycosides include an aminocyclitol (a central six-membered ring containing amino groups), which is linked to two or more amino- or non-amino-containing sugars by glycosidic bonds. For streptomycin, the aminocyclitol ring is a streptidine, whereas for the remainder of the clinically available aminoglycosides it is 2-deoxystreptamine. Neomycin contains approximately equal amounts of neomycin B (R_1 =H; R_2 =CH_2 NH_2) and neomycin C (R_1 =CH_2 NH_2 ; R_2 =H). Kanamycin is principally

kanamycin A, as shown. Gentamicin is gentamicin C complex with roughly equal amounts of C_1 (R_1 =R_2 =CH_3), C_{1a} (R_1 =R_2 =H) and C_2 (R_1 =CH_3 ; R_2 =H).

cavity.[6] Following endotracheal administration or aerosolization of aminoglycosides, systemic absorption is usually modest. However, significant concentrations can be achieved via aerosolized generators that use high pressure and small droplets (1–3mm).[7]

Distribution

Because aminoglycosides demonstrate linear pharmacokinetics, there is a direct proportionality between dose and area under the plasma concentration curve (AUC).[8] Although following an intravenous dose they exhibit a three-compartment model — initial distribution (alpha) phase, a rapid elimination (beta) phase and a slow elimination (gamma) phase — a one-compartment model can be used clinically for establishing dosage regimens.

After an intravenous or intramuscular dose of an aminoglycoside, peak serum concentrations occur in 30 and 45 minutes, respectively. In patients such as those with diabetes mellitus who have poor vascular perfusion into soft tissue structures, there may be a delay in the time to peak concentration. Because aminoglycosides are highly water soluble, their volume of distribution (Vd) is similar to that of the extravascular compartment. As predicted, the mean aminoglycoside concentration in interstitial fluid approximates the mean plasma concentration. Studies performed in normal adult volunteers have found a Vd of 0.2–0.3l/kg.[8] In patients with excess fluid in the extravascular space, as in patients with ascites or burns, the Vd is increased, whereas in markedly obese patients it is decreased.

The low serum protein binding (10%) of aminoglycosides increases the ease with which they are distributed into the extravascular space. In the unobstructed biliary tract, aminoglycoside levels are about 30% of the serum concentration; however, as with ß-lactam antibiotics, bile levels are exceedingly low in the presence of biliary tract obstruction.

Aminoglycosides penetrate poorly into human cells because of the large size of the molecules, their low lipid solubility, and their high polycationic charge. High concentrations are observed only in specialized cells such as the tubular cells of the renal cortex and the hair cells of the ear, which have an active transport mechanism for aminoglycosides, and levels in these cells can even exceed those of plasma or interstitial fluid. Aminoglycoside levels can remain above therapeutic concentrations for extended periods of time (48–200 hours) as a result of renal tubular cell absorption and the prolonged release of aminoglycosides into urine. [9]

Aminoglycosides penetrate poorly into the cornea and the aqueous and vitreous humors of the eye.[10] In patients with serious eye infections such as bacterial endophthalmitis, direct intravitreal injections are usually needed. Subconjunctival injections achieve high aqueous humor levels. The penetration of aminoglycosides into cerebrospinal

Neisseria meningitidis, N. gonorrhoeae	
Moraxella catarrhalis	
Legionella spp.	

fluid (CSF) is poor, both in the presence and absence of meningeal inflammation. [11] Penetration of gentamicin into CSF was studied in 26 patients aged 6–20 years with mumps meningoencephalitis after administration of a single intramuscular dose of 1.2–4.0mg/kg. Activity was found in only five of the 26 patients, with the highest level being 0.19µg/ml.[12]

Elimination

After a rapid distributive phase of 15–30 minutes, the elimination phase begins with 99% of the drug excreted unchanged in the urine and a half-life of 1.5–3.5 hours.[13] In patients with increased extravascular fluid, the Vd increases, resulting in a longer half-life. Because of this type of elimination, any impairment in renal function can result in considerable prolongation of the serum aminoglycoside half-life. There is active reabsorption of aminoglycoside into the proximal renal tubular cells, as indicated by the observation that renal clearance of these agents is somewhat less than that of simultaneous creatinine clearance. In neonates less than 1 week of age or in small premature babies, the half-life is typically prolonged to 8–11 hours.[14]

Following the elimination phase, there is a final extremely slow terminal elimination phase of 30–700 hours secondary to prolonged release from the proximal renal tubules back into the urine.[15] Because the amount of aminoglycoside eliminated is so low, it has no effect on dosing. Less than 1% of aminoglycoside is eliminated into feces, bile and saliva. Aminoglycosides are not metabolized.

Pharmacodynamic concepts

In the past 5 years, much has been learnt from animal models of infection, *in-vitro* pharmacodynamic studies, volunteer experiments and clinical trials that enable us to

establish the best mode of antibiotic administration to maximize bacterial killing and minimize toxicity. From this information, we know that the higher the aminoglycoside concentration, the faster the rate of bacterial eradication.[16] As a result, this type of killing is designated concentration- or dose-dependent killing. For the aminoglycosides, the rate of bacterial eradication increases with increasing concentration up to approximately 10–12 times above their MICs.[17] Thereafter, increasing the concentration does not improve the rate of bacterial killing. If this favorable peak to MIC ratio is obtained, most bacteria die within a short period of time, and as a result the effect of the drug exposure time is minimal and can even be ignored.

In neutropenic and non-neutropenic animal models of infection, significantly more animals survive a potentially lethal challenge of bacteria if the animals are treated with a single large dose of an aminoglycoside than with the same dose divided on an 8-hour schedule.[18] [19] Compared with intermittent dosing, once-daily dosing results in a larger probability that aminoglycoside concentrations will exceed the MIC by a factor of 10–12 times, and also result in a longer PAE with a lower chance for the emergence of aminoglycoside-resistant pathogens.[20]

ROUTE OF ADMINISTRATION AND DOSAGE

Once-daily dosing in adults

Recently, considerable attention has been given to using these pharmacodynamic concepts by giving the entire dose of the aminoglycoside on a once-daily basis in order to maximize bacterial killing and minimize toxicity. Different approaches have been used to monitor and adjust the dose in patients on once-daily aminoglycoside therapy with normal and diminished renal function to ensure adequate treatment and to minimize toxicity. In the USA, the most popular dosing method used by hospitals has been modelled after the one developed at Hartford Hospital, Hartford, Connecticut. [21] To optimize the serum peak to MIC ratio against *Pseudomonas aeruginosa*, the organism that most often warrants aminoglycoside therapy, a 7mg/kg dose is given. Through computer simulation of gentamicin and tobramycin concentrations versus time profile for once-daily dosing, 7mg/kg and 5mg/kg, respectively, would be the best dose to optimize the serum peak to MIC ratio (=10) against *P. aeruginosa*, an organism that is typically inhibited by 2µg/ml of these agents. This dose, when diluted in 50ml of a compatible intravenous solution and given over 1 hour attains the target peak serum concentration of 20µg/ml (Fig. 196.2).

In this simulation, a one-compartment intravenous model was used with a fixed apparent Vd of the aminoglycoside of 0.3l/kg. In patients with normal renal function, the serum concentrations typically fall below 0.5µg/ml within 12 hours and then remain essentially undetectable for the remainder of the day (Fig. 196.3). This drug-free interval is crucial for reduced toxicity (see Adverse Reactions, below), for it allows a greater amount of aminoglycoside to egress from the renal tubular and inner ear cells than with the conventional intermittent dosing method.

In patients receiving the intermittent dosing approach of gentamicin or tobramycin (1.5mg/kg q8h), peak serum levels of only about 4–5µg/ml are obtained with a trough level still slightly above

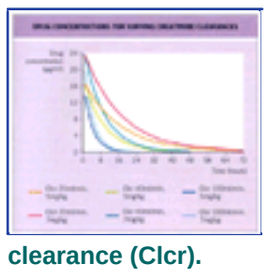

Figure 196-2 Simulated concentration versus time profiles for once-daily 7mg/kg and 5mg/kg gentamicin regimens in patients with varying degrees of creatinine clearance (Clcr).

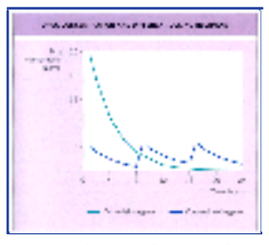

Figure 196-3 Simulated concentration versus time profiles for once-daily (7mg/kg q24h) and conventional (1.5mg/kg q8h) gentamicin regimens in patients with normal renal function.

0.5µg/ml (see Fig. 196.3). Therefore, the absence of any prolonged drug-free period with intermittent dosing slows the egress of aminoglycosides from these cells, resulting in greater tissue accumulation. It is this lower accumulation of aminoglycosides with once-daily dosing than with intermittent dosing that results in less nephrotoxicity and ototoxicity (see below).

Although a dosing weight may be individualized for each patient, dosing is usually based on actual body weight unless the patient is obese [i.e. greater than 20% over ideal body weight (IBW)]. Calculation of IBW is accomplished by the following formulas:

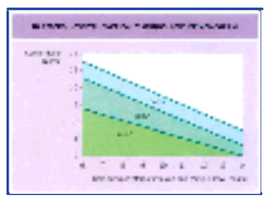

Figure 196-4 Hartford Hospital once-daily aminoglycoside nomogram for gentamicin and tobramycin using the 7mg/kg dose.

- IBWmale = 50kg + 2.3kg for every inch (2.54cm) over 5 feet (1.524m);
- IBWfemale = 45.5kg + 2.3kg for every inch (2.54cm) over 5 feet (1.524m).

For the obese patient, a dosing weight can be calculated using the following: obese dosing weight = IBW + 0.4 (actual body weight — IBW).

Monitoring of patients on once-daily aminoglycoside therapy involves measuring a single random aminoglycoside serum concentration 6–14 hours following a 60-minute infusion of the 7mg/kg dose of gentamicin or tobramycin. Depending upon where the concentration falls on a nomogram (Fig. 196.4), the patient is then given the same 7mg/kg dose every 24, 36 or 48 hours. If the concentration falls on the line of the nomogram that separates the dosing intervals, then the longer interval is chosen. If the random level falls off the nomogram, then the dosing interval should be based on more frequent serum concentration determinations to decide on the most appropriate time for the next dose.

Although it is unnecessary to draw two serum samples in most patients, it may be necessary to obtain additional levels in some patients with rapidly changing creatinine clearance. If once-daily aminoglycoside therapy is continued beyond 4 days, a random concentration should be obtained on the fifth day, and then weekly thereafter. Serum creatinine should be measured every 2–3 days.

In certain patients the risk of toxicity is low and it is even unnecessary to obtain a random determination of the aminoglycoside level. This subset of patients includes adults under 60 years of age who have a normal serum creatinine concentration who are not receiving concurrent nephrotoxic agents (e.g. amphotericin B, ciclosporin, vancomycin) or contrast media, and are neither quadriplegic nor amputees. Even in this subset of patients, however, determinations of serum creatinine should be performed at 2- or 3-day intervals, and for those patients on once-daily therapy for longer than 5 days, a random serum aminoglycoside concentration should be obtained on the fifth day and weekly thereafter. Because of insufficient clinical or pharmacokinetic data or both, once-daily aminoglycoside dosing is not recommended for:

- those on chronic peritoneal dialysis or hemodialysis.
- pregnant women; and
- those with major burns (>20%), ascites or enterococcal endocarditis.

In hospitals where it is difficult to measure serum concentrations of gentamicin or tobramycin, the appropriate dosing interval can be

selected based on the patient's creatinine clearance, which can be easily calculated by using the Cockcroft-Gault equation.[22] With this method, the creatinine clearance can be determined in males by multiplying (140-age) with (weight in kg) and then dividing this value by (serum creatinine concentration × 2), and in females, by using the same equation, but the calculated creatinine clearance is multiplied by 0.85. For those patients who have a creatinine clearance of =60, 40–60, and 20–40ml/min, the aminoglycoside should be given every 24, 36 and 48 hours, respectively.

In the USA, gentamicin and tobramycin are by far the most commonly used aminoglycosides. Nevertheless, a once-daily dose of amikacin could also be employed by administering a single dose of 15mg/kg with the dosing interval determined by the estimated creatinine clearance. In addition, because aminoglycosides exhibit linear pharmacokinetics, the amikacin dosing interval can also be determined by applying the same nomogram used for gentamicin and tobramycin by merely halving the random amikacin level obtained 6–14 hours after the infusion of a 15mg/kg dose.

Results from a number of studies using both neutropenic and non-neutropenic animal models of sepsis and clinical trials have shown that high peak concentrations and long dosing intervals of aminoglycosides improve efficacy and reduce toxicity. [23] [24] In a recent meta-analysis comparing once-daily aminoglycoside with intermittent dosing in immunocompetent adults, once-daily dosing was equivalent with regard to bacteriologic cure, but showed a trend towards reduced mortality rates and reduced toxicity.[25]

In the largest outcome study in adults (2184 patients) treated with once-daily gentamicin or tobramycin, nephrotoxicity (as defined as an increase in serum creatinine concentration to 0.5mg/dl or more over baseline during aminoglycoside therapy) was detected in only 1.2% (27 patients) and ototoxicity in 0.1% (three patients). [21] The incidence of nephrotoxicity was significantly lower than the 3–5% observed from the same hospital when aminoglycosides were given in the conventional dosing technique. Furthermore, in the 27 patients referred to above, there were other possible explanations for nephrotoxicity (e.g. concomitant nephrotoxic agents, volume-related renal dysfunction). Of these patients 94% received gentamicin, 5% tobramycin and less than 1% amikacin. In the three patients who developed vestibular dysfunction, it was transient in two and permanent in the other, but this patient had received over 5 weeks of aminoglycoside therapy. The major exclusion criterion for once-daily aminoglycoside therapy was any patient who had enterococcal endocarditis.

The same investigators performed a detailed pharmacoeconomic analysis of their conversion program from intermittent to once-daily aminoglycoside and noted the movement to once-daily aminoglycoside dosing saved the hospital US$128,000 due to reductions in preparation, administration, monitoring and nephrotoxicity costs. [26] In a recent review of the economic impact of nephrotoxicity at six Philadelphia hospitals involving 1756 patients, it was determined that the mean total additional cost of an episode of aminoglycoside nephrotoxicity in a patient was US$2501. These costs were mainly related to a prolongation of hospital stay, additional consultations and increased laboratory tests and ancillary services. [27]

Once-daily dosing in children

Although the clinical outcome data on once-daily aminoglycoside dosing in children are much more limited, there is no reason why the same pharmacodynamic concepts should not apply. Although children have slightly higher Vd and elimination rates for drugs than adults, it is unlikely that these differences are of a significant magnitude to necessitate major changes in the once-daily aminoglycoside dosing method outlined above for adults. In fact, aminoglycoside dosing in children may require higher dosing. In children 6–12 months of age and those older than 1 year given a single intravenous dose of 20mg/kg dose of amikacin, the Vds were 0.5l/kg and 0.33l/kg, respectively.[28] Therefore, the Vd in children under 1 year of age is slightly higher than that of an adult, whereas that in children over 1 year of age is similar to that in adults. In addition, in this same study, the half-life in the younger children was longer than that in the older children and in adults, yet the peak and trough levels were similar. These observations suggest that children under 1 year of age require a higher single dose (20mg/kg) of amikacin than the dose (15mg/kg) in older children and in adults. Other studies using a 20mg/kg once-daily dose of amikacin in children undergoing bone marrow transplantation or with serious Gram-negative bacterial sepsis have shown no differences in efficacy or toxicity compared with standard intermittent dosing.[29] [30]

Similarly, netilmicin given as a single 2mg/kg dose q8h, or gentamicin given as a single 6mg/kg/day dose or divided into two or three daily doses for treatment of infections in children showed no difference in clinical efficacy, ototoxicity or nephrotoxicity.[31] Identical results were also obtained in the treatment of 20 full-term neonates who received a single 4mg/kg dose of gentamicin given either once or in divided doses.[32]

Intermittent or traditional dosing

In the intermittent dosing technique, a loading dose is given and followed by a maintenance dose.[33] Because the loading dose is independent of renal function, it is the same in patients with abnormal or normal renal function. The loading dose should be calculated according to IBW as discussed above in the once-daily dosing method. The peak serum concentration is usually obtained 30–60 minutes after the infusion of the initial dose or after the first maintenance dose. The usual loading dose is:

- 2mg/kg for gentamicin, tobramycin and netilmicin; and
- 7.5mg/kg for amikacin and streptomycin.

In patients who have a creatinine clearance =90ml/min, the usual maintenance doses are:

- gentamicin 1.7mg/kg q8h;
- tobramycin 1.7mg/kg q8h;
- netilmicin 2.0mg/kg q8h;
- amikacin 7.5mg/kg q12h; and
- streptomycin 7.5mg/kg q12h.

The desired peak serum and trough concentrations are:

- 4–10µg/ml and 1–2µg/ml, respectively, for gentamicin, tobramycin and netilmicin; and
- 15–30µg/ml and 5–10µg/ml, respectively, for amikacin and streptomycin.

In patients with renal impairment, there are two ways to modify the dose, of which one is to lengthen the dosing interval and the other is to reduce the dose. Of these two methods, increasing the dosing interval is preferable because it provides the best peak to MIC ratios and thereby maximizes concentration-dependent bacterial killing. In this method the dose remains the same, but the dosing interval changes based on the patient's estimated creatinine clearance using the Cockcroft-Gault equation. [22]

For instance, in patients with an estimated creatinine clearance (ml/min) of 80–90, 50–80, 10–50 and <10, the dosing intervals become every 12h, 12–24h, 24–48h and 48–72h, respectively. The serum creatinine concentration should be measured every 3–5 days, and if it remains stable there is no reason to perform repeat measurements of peak and trough concentrations. If there is, however, a significant increase in serum creatinine concentration, then a new dosage is recalculated.

INDICATIONS

Use in patients with fever and neutropenia, sepsis syndrome and nosocomial infections

Gentamicin, tobramycin, netilmicin and amikacin have assumed a major clinical role for decades in the empiric treatment of the febrile neutropenic patient (see Chapter 100) and in patients with serious hospital-acquired infections (see Chapter 56) because of their broad spectrum of bactericidal activity against common and unusual Enterobacteriaceae, *P. aeruginosa*, and staphylococci. In addition, these agents usually exhibit synergy against these bacteria in combination with ß-lactam antibiotics and against enterococci in combination with penicillins or vancomycin or teicoplanin. With the increasing usage of carbapenems such as imipenem and meropenem, and fluoroquinolones such as ciprofloxacin and ofloxacin, there has been a significant increase in the emergence of multiantibiotic resistant bacteria (e.g. *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, enterococci), which often require treatment with an aminoglycoside alone or in combination with other antibiotics.

Although physicians often try to avoid aminoglycosides because of concerns for toxicity, these adverse events are actually infrequent, as discussed below, especially if one uses once-daily administration and avoids prolonged administration. Their low acquisition costs also make them attractive choices in the need for fiscal restraints in the health care system of all countries. In the USA, 100mg of gentamicin costs under US$1.

Once gentamicin and the carboxypenicillins (e.g. carbenacillin, ticarcillin), agents with antipseudomonal activity, became available the usage of both kanamycin and polymyxin as part of a 'fever regimen' for neutropenic patients became negligible. As a result, the preferred empiric approach for febrile neutropenic patients or those considered to have a serious bacteremia became gentamicin and carbenicillin. With time, the empiric approach to patients such as these has remained quite similar in that the traditional approach remains an aminoglycoside in combination with an antipseudomonal penicillin (e.g. ticarcillin, piperacillin, mezlocillin, ticarcillin-clavulanate, piperacillin-tazobactam) or cephalosporin (e.g. ceftazadime, cefepime).

The choice of the antipseudomonal penicillin has changed to a greater use of the newer carboxypenicillin ticarcillin, or the ureidopenicillins mezlocillin or piperacillin. Because neither ticarcillin nor piperacillin has significant antistaphylococcal activity and the intrinsic activity of these drugs by themselves against anaerobes is moderate, these two agents are often given in their new formulations in which they are combined with a ß-lactamase inhibitor such as clavulanate or tazobactam. In combination with these inhibitors, ticarcillin-clavulanate and piperacillin-tazobactam, are active against almost all anaerobes with MICs typically below 2µg/ml. The MICs of these penicillins by themselves against anaerobes such as *Bacteroides* spp. is about 32–64µg/ml.

Although the aminoglycosides are often used clinically in combination with ß-lactams, the combination may lead to inactivation of both drugs. The reaction, which is time and concentration dependent, occurs by nucleophilic opening of the ß-lactam ring and acylation of an amino group of the aminoglycoside resulting in a biologically inactive amide.[34] [35] Gentamicin and tobramycin appear to be more susceptible to inactivation than amikacin or netilmicin. This phenomenon is probably clinically meaningful only in patients with significant renal failure in whom ß-lactams accumulate to very high concentrations. [36] [37] [38] [39] On account of this interaction aminoglycosides should not be mixed with penicillins before infusion and serum samples used for aminoglycoside assay should be run immediately or frozen until used.

Gentamicin, tobramycin and amikacin usually exhibit the same activity against Enterobacteriaceae, although *Serratia marcescens* is somewhat more susceptible to gentamicin, whereas tobramycin is more active than the other aminoglycosides against *P. aeruginosa*. Some gentamicin-resistant *P. aeruginosa* remain susceptible to tobramycin. Because these enzymes are a poor substrate for amikacin, and occasionally netilmicin, these two aminoglycosides may be effective against organisms that are resistant to both gentamicin and tobramycin. However, with the use of once-daily aminoglycoside dosing, these modest differences in microbiologic activity appear to have little, if any, clinical relevance, except for isolated patients.

Vancomycin or teicoplanin (not available in the USA) is often added to the ß-lactam-aminoglycoside combination in the initial treatment of the febrile neutropenic patient if one or more of the following findings are present:

- clinically suspected intravenous catheter-related infections;
- known colonization with ß-lactam-resistant pneumococci or staphylococci (methicillin-resistant *Staphylococcus aureus* — MRSA);
- positive blood cultures for Gram-positive bacteria;
- evidence of cardiovascular impairment;
- patient on previous prophylaxis with a fluoroquinolone;
- abrupt increase in temperature to =104°F (40°C).

Therapy of enterococcal infections

Aminoglycosides are used in the therapy of systemic enterococcal infection because no single antibiotic by itself exhibits bactericidal activity against these bacteria. Usually the aminoglycoside, either gentamicin or streptomycin, is combined with either a penicillin or vancomycin to obtain a bactericidal effect, and this is crucial in the therapy of endocarditis. Although all enterococci are resistant to aminoglycosides based on achievable serum concentrations, synergistic activity with penicillins (usually ampicillin) or vancomycin results in effective therapy.

Therapy of enterococcal infection is, however, becoming more difficult owing to the increasing frequency of enterococcal isolates that have high-level resistance to aminoglycosides (MIC >2000µg/ml), penicillins and even vancomycin. Enterococci with high-level resistance to gentamicin contain the bifunctional aminoglycoside-modifying enzyme acetyltransferase (AAC) (6')-phosphotransferase (APH) (2'), which abolishes synergy with all aminoglycosides except streptomycin. It is important to note that, although the bifunctional enzyme modifies amikacin and abolishes synergy with ß-lactams and vancomycin, it does not lead to a resistant phenotype. For these reasons, amikacin should not be used against strains with high-level resistance to gentamicin even if the strain is reported to be susceptible. Streptomycin remains the only alternative for strains with high-level resistance to gentamicin. In the case of high-level resistance to streptomycin, this aminoglycoside should also not be used.

Treatment of other infections

Streptomycin

The major uses of streptomycin have been as part of combination therapy for enterococcal and mycobacteria infections and monotherapy for tularemia, brucellosis and plague (see Chapter 176 , Chapter 177 and Chapter 180). The clinical role of streptomycin as well as the other aminoglycosides in the treatment of mycobacterial infections is discussed in detail in Chapter 37 and Chapter 38 .

Paromomycin

Because paromomycin is too toxic following intravenous administration and is not absorbed following oral administration, its usage has been restricted to the treatment of intestinal infections, particularly cryptosporidiosis in patients who have AIDS.[40] The usual oral dose to

treat cryptosporidiosis is 1g q12h for 1 month. For the treatment of intestinal amebiasis, the usual dose in adults and children is 25–35mg/kg/day q8h with meals for 5–10 days. Paromomycin has been used for treatment or prevention of traveler's diarrhea because it is also active against *Escherichia coli* and *Salmonella* spp.

Unlabeled uses of paramomycin include treatment of other parasitic infections such as:

- *Dientamoeba fragilis* (25–30mg/kg/day q8h for 7 days);
- *Diphyllobothrium latum*, *Taenia saginata*, *Taenia solium*, *Dipylidium caninum* (adults — 1g every 15 minutes for four doses; pediatric — 11mg/kg every 15 minutes for four doses); and
- *Hymenolepis nana* (45mg/kg/day for 5–7 days).

Like neomycin, paromomycin has been used to treat hepatic coma where the usual adult dose of neomycin is 4g/day in divided doses administered at regular intervals for 5–6 days. The activity of paromomycin closely parallels that of neomycin and kanamycin and there is complete cross-resistance between these agents.

Neomycin

Like paromomycin, neomycin is too toxic for systemic use. It has mainly been used by mouth as a prophylactic agent along with erythromycin in colonic surgery and in hepatic coma to reduce the number of aerobic enteric organisms. When it is used for preoperative prophylaxis for elective colorectal surgery, it usually given as a 1g oral dose along with a 1g oral dose of erythromycin, at 1p.m., 2p.m. and 11p.m. on the day before surgery. Metronidazole can be used in place of erythromycin and is usually given at 7p.m. and 11p.m. on the day before surgery.

In the treatment of hepatic coma, the usual dose in adults is 4–12g/day in divided doses, whereas in children the recommended dose is 50–100mg/kg/day in divided doses. Treatment is usually continued for 5–6 days. In patients with chronic hepatic insufficiency, neomycin may be required (in adults up to 4g/day) indefinitely.

The use of neomycin topically has been mainly for the treatment of external otitis media, usually with other antibiotics in the formulation.

Infections by Listeria *spp.,* Neisseria *spp. and* Haemophilus *spp.*

An infrequent use of gentamicin is to combine it with a penicillin, usually ampicillin, in the therapy of *Listeria monocytogenes* meningitis or endocarditis to achieve more rapid killing of the organism. In patients allergic to penicillin, trimethoprim-sulfamethoxazole (co-trimoxazole) can be used either alone or in combination with the gentamicin.

Although all aminoglycosides exhibit activity against *Neisseria* spp., only the aminocyclitol spectinomycin is used for gonococcal infection; this is, however, very uncommon because most gonococci are susceptible to third-generation cephalosporins and the fluoroquinolones such as ofloxacin and ciprofloxacin.

Haemophilus and *Legionella* spp. are often susceptible to aminoglycosides. Although their use as single agents for infections by these organisms has never been studied, it is useful to be aware that if a patient is on an aminoglycoside for some other infection, these organisms should be covered.

DOSING IN PATIENTS ON CHRONIC HEMODIALYSIS OR CHRONIC AMBULATORY PERITONEAL DIALYSIS

Because aminoglycosides are dialyzable, a supplemental dose should be given after each hemodialysis. The usual supplemental doses are:

- 1–2mg/kg for tobramycin and gentamicin;
- 2mg/kg for netilmicin; and
- 5–7mg/kg for amikacin.[41]

For patients on chronic ambulatory peritoneal dialysis (CAPD) who develop peritonitis without evidence of systemic infection, the aminoglycoside can be added directly to the dialysis fluid by one of two methods.[42] Most patients on CAPD have four 2l-exchanges/day with a dwell time of 6 hours:

- in the first method, 'therapeutic' concentrations (e.g. 4–8mg/l gentamicin, tobramycin or netilmicin; 6–12mg/l amikacin) are added to each bag of dialysis fluid; and
- in the second method, high concentrations (e.g. 20mg/l gentamicin, tobramycin or netilmicin; 60mg/l amikacin) are added to only one of the usual four exchanges of dialysis fluid.

ADVERSE REACTIONS

General

The major adverse effects associated with aminoglycosides include:

- neuromuscular blockade;
- nephrotoxicity; and
- ototoxicity (auditory and vestibular).

Aminoglycosides seldom produce hypersensitivity reactions, hematologic dyscrasias, hepatitis or drug fevers. Because they do not produce inflammatory reactions, they seldom produce phlebitis on intravenous injection, pain on intramuscular injection, or irritation of serosal surfaces on direct instillation into pleural space, joint space or the peritoneal cavity, or when incorporated into methylmethacrylate prosthetic joint cement. In addition, they are extremely well tolerated when injected into the CSF and have not been associated with epileptogenic reactions.

Neuromuscular blockade

The potential for neuromuscular blockade can be avoided if aminoglycosides are not given by bolus administration or instilled in large concentrations into the peritoneal cavity. Intravenous aminoglycosides should be administered over at least 20–30 minutes, especially if once-daily aminoglycoside therapy is used. The risk of neuromuscular blockade is increased in patients who are concomitantly receiving D-tubocurarine or succinylcholine, or possibly calcium channel blockers.[43] [44] Infant botulism, myasthenia gravis, hypocalcemia and hypomagnesemia have also been associated with an increased risk for this adverse reaction.[45]

The classic manifestations of neuromuscular blockade include weakness of the respiratory musculature, flaccid paralysis and dilated pupils. Blockade results from the ability of aminoglycoside to prevent internalization of calcium into the presynaptic region of the axon, which is essential for the release of acetylcholine. When the neuromuscular blockade occurs, it can be rapidly reversed by the administration of calcium gluconate. With supportive care alone, in time, the blockade will resolve. Neomycin is the most likely aminoglycoside to cause this adverse reaction.

Nephrotoxicity

Except for spectinomycin, all aminoglycosides are capable of producing nephrotoxicity by interfering directly with renal tubular function and indirectly with glomerular filtration. Among the commonly prescribed aminoglycosides, such as gentamicin, tobramycin, netilmicin and amikacin, there appear to be no clinically relevant differences in toxicity. Using a definition of nephrotoxicity as a rise in serum creatinine concentration of 0.5mg/dl above the baseline, approximately 3–5% of patients on these agents develop this adverse reaction using standard dosing regimens.

Neomycin is the most nephrotoxic aminoglycoside and streptomycin the least. The most important molecular basis for nephrotoxicity appears to be the number of amino groups (NH_3). Neomycin, gentamicin, tobramycin, netilmicin, amikacin and streptomycin

contain six, five, five, four, four and three amino groups, respectively.[46] The magnitude of the toxicity has been shown to be the greatest when the daily dose is divided into multiple small doses rather than as the same dose given once.[47] This observation has been the basis for the recent popularization of once-daily aminogycoside dosing (see Once-daily dosing, above). Loop diuretics such as ethacrynic acid aggravate aminoglycoside renal toxicity through volume depletion or hypokalemia or by increasing renal tubular uptake of aminoglycosides.

The concomitant use of aminoglycosides with vancomycin, *cis*-platinum, foscarnet, amphotericin B, methoxyflurane and intravenous radiocontrast agents has also been shown to accentuate nephrotoxicity.[48] Although elderly patients are traditionally considered to be at a higher risk for aminoglycoside nephrotoxicity, they may actually not be at an increased risk if one adjusts for an age-related decrease in glomerular filtration rate. High serum levels of aminoglycosides are not considered to be a risk factor for toxicity because there is a saturable movement of aminoglycosides into the renal tubular cell. Certain agents (e.g. potassium supplements, thyroid hormone, high-dose calcium, extended-spectrum penicillins) may reduce aminoglycoside toxicity, but there have been no controlled attempts to evaluate them.

Aminoglycosides bind to specific receptors on the proximal convoluted renal tubule causing an increased excretion of brush border enzymes, magnesium and calcium into the urine. Although there was considerable interest in using enzymuria as a marker of renal toxicity, it never became clinically useful because significant amounts can be detected in the urine even after a single dose. After binding to the renal cell, aminoglycosides are rapidly internalized into the cell by pinocytosis. Once inside the cell, they interfere with ribosomal-mediated protein synthesis and mitochondrial respiration, resulting in cell damage and necrosis.[49] Interference with liposomal enzyme production also occurs, resulting in a deposition of a material that resembles myelin by electron microscopy (myeloid bodies).[49] These myeloid bodies can be detected in the urine. Injury to the lysosome also results in an increased excretion of phospholipids into the urine (lysosome phospholipidosis).

The renal tubular cell is relatively resistant to the toxic effect of aminoglycosides as it takes several days of drug administration to produce functional or anatomic evidence of toxicity.[50] This is important since it reinforces the observation that the best way to prevent renal toxicity is to avoid prolonged administration of these agents. Even when renal tubular necrosis occurs, it is reversible, and surprisingly the renal tubule can even regenerate despite continued administration of the aminoglycoside.

Of equal clinical relevance is the observation that the aminoglycoside enzyme transfer system has a finite capacity for internalizing all aminoglycosides within the renal tubular cell.[51] This saturable transport system means that the amount of aminoglycoside that enters the cell is the same over 24 hours whether the dose is given in the traditional divided fashion or as a single dose. Because of the low or undetectable levels of aminoglycosides for 10–12 hours during the 24-hour period with once-daily dosing, most of the previously internalized drug gets transported out of the cell, resulting in less accumulation.

How damage of the renal tubular cell results in diminished glomerular filtration as indicated by an increase in serum creatinine concentration and the use of creatinine clearance remains controversial. The most frequent explanations mentioned include a release of vasoconstrictive hormones affecting the afferent arterioles, cellular debris obstructing nephrons, and a change in glomerular fenestrae.[48] After discontinuing aminoglycoside therapy, evidence of nephrotoxocity usually disappears within several days in the absence of other causes of nephrotoxicity.

The major clinical manifestations of distal nephron damage by aminoglycosides include:

- decreased urine concentrating ability; and
- polyuria.

Because of excessive magnesium losses in the urine, hypomagnesemia may occur, which in turn can lead to secondary hypocalcemia and hypokalemia.[52] Progression to anuric renal failure as a result of aminoglycoside nephrotoxicity is rare.

Ototoxicity

Auditory

Auditory toxicity occurs as a result of the accumulation of aminoglycosides in the perilymph of the inner ear with subsequent damage of the sensory cells of the organ of Corti. A reduction in the number of cochlear ganglion cells has also been reported as an additional cause of this adverse reaction.[53] Penetration of aminoglycosides into this space is facilitated by elevated trough levels, which impairs their back-diffusion into the plasma.

The exact mechanism by which aminoglycosides destroy hair cells is unknown, but possible explanations include saturation of the detoxification capabilities of the hair cells, binding of aminoglycosides to polyphosphinositides, mitochondrial dysfunction and inhibition of decarboxylase.[54]

Unlike patients with serious nephrotoxicity which is generally reversible, severe cochlear damage is usually permanent because cochlear hair cells do not regenerate. Interestingly, there may be a hereditary component to hearing loss caused by aminoglycosides due to a mutation of mitochondrial DNA.[55]

Symptoms of auditory toxicity include:

- hearing loss;
- tinnitus; and
- a sensation of fullness in the ear.

Although they may develop unilaterally or bilaterally, most patients experience symptoms in both ears. Both auditory and vestibular toxicity can occur in the same patient. The onset of symptoms may occur during or after cessation of treatment.

Cochlear toxicity is usually assessed by pure-tone audiometric testing of air and bone conduction by increasing the frequency from 0.5 to 8kHz. In general, an increase in threshold from the baseline of at least 15dB at any of two or more frequencies is considered to be a significant hearing loss.[56] The earliest signs of cochlear toxicity are usually detected at frequencies above 8kHz. Because perception of human speech occurs in the 0.3–3kHz range, significant cochlear damage can occur before the patient becomes aware of it. Many audiometers do not test for frequencies above 8kHz.

Clinical studies show that the incidence of cochlear toxicity due to aminoglycoside use varies from 5 to 15% with conventional intermittent dosing of aminoglycosides. The frequency varies and depends upon the method of establishing toxicity and whether the investigators include high-frequency loss. The frequency of ototoxicity may be less with once-daily aminoglycoside dosing, presumably because less drug accumulates in the perilymph.

In a guinea pig model evaluating the ototoxicity of amikacin, the investigators found that it was related to total perilymph accumulation rather than to peak concentrations.[57] Therefore, as in the renal tubular cell, there appears to be a saturable transport system into the sensory hair cells.

There is considerable controversy regarding the comparative potential for cochlear damage among the aminoglycosides, but it appears that there is little, if any, clinically relevant difference between gentamicin, tobramycin, amikacin and netilmicin. Compared with these agents, neomycin more often has a greater association with cochlear damage.

Risk factors for cochlear damage include:

- age (= 60 years);
- elevated plasma trough levels (i.e. drug accumulation);
- pre-existing ear disease;
- prolonged therapy;
- repeated treatment with aminoglycoside; and
- concomitant use of loop diuretics (e.g. ethacrynic acid) and other ototoxic drugs.[58]

Of these risk factors, duration of therapy remains the most important. When aminoglycosides are given for less than 10 days, toxicity is seldom a problem. In fact, if ototoxicity or nephrotoxicity occur during the first week of aminoglycoside usage, it is wise to search for another cause.

The potential for ototoxicity in humans with topical preparations remains controversial, but animal studies have shown sensorineural hearing loss with the administration of neomycin and gentamicin.[59] In a study of 44 children with chronic suppurative otitis media given topical preparations containing five different aminoglycosides (four neomycin; one gentamicin), there was no evidence of ototoxicity.[60]

Vestibular

As with cochlear toxicity, vestibular toxicity results from excessive accumulation of aminoglycoside in the perilymph of the inner ear, but the targets for damage differs and are the sensory hair cells of the vestibular epithelia located at the summit of the ampullar cristae.[61] Serious damage to these cells typically results in a permanent deficit because these sensory hair cells, like those of the organ of Corti, do not regenerate.

The risk factors for vestibular toxicity are identical to those mentioned above for auditory toxicity. As with cochlear damage, vestibular toxicity can occur during or after therapy and be unilateral or bilateral. Occasionally it occurs together with auditory toxicity.

Symptoms of vestibular toxicity include:

- nausea;
- vomiting;
- vertigo;
- nystagmus;
- difficulty with gait; and

¦ difficulty fixating on objects.

Difficulty with gait is especially prominent in the dark because of the loss of sight, which compensates for vestibular dysfunction.

The frequency of vestibular toxicity is difficult to establish because vestibular function testing is poorly standardized. The usual method is to record the response to caloric stimulation with water or air on an electronystagmogram. It is speculated that the frequency of vestibular toxicity is comparable to that of cochlear damage. Streptomycin more often has a much greater association with vestibular toxicity than neomycin, gentamicin, tobramycin and amikacin. This differential toxicity is the basis for the choice of streptomycin to obliterate vestibular function in patients with Ménière's disease.

Chapter 197 - Folate Inhibitors

S Ragnar Norrby

INTRODUCTION

Sulfonamides

Sulfonamides are competitive inhibitors of para-aminobenzoic acid (PABA), which is essential for folic acid synthesis in most bacteria, some protozoa and *Pneumocystis carinii* (Fig. 197.1).[1] A consequence of the mode of action is that sulfonamides lack activity against organisms for which PABA is not an essential metabolite (e.g. *Enterococcus* spp.). The eukaryotic cell does not use PABA and sulfonamides do not interfere with human folic acid synthesis.

Trimethoprim

Trimethoprim is a diaminopyrimidine that competitively inhibits dihydrofolate reductase.[1] [2] [3] Compared with many other diaminopyrimidines with antimicrobial activity (e.g. pyrimethamine), trimethoprim has a higher affinity for bacterial dihydrofolate reductase than for the human enzyme, thus reducing the risk of folic acid deficiency in the treated patient.[4] Pyrimethamine is also a competitive dihydrofolate reductase inhibitor. It has a high affinity for protozoal enzyme.

In addition to the above modes of action, it has been proposed that trimethoprim may inhibit the adhesion of bacteria to human mucosal cells.[5]

Combinations of sulfonamides and trimethoprim or pyrimethamine

Combinations of sulfonamides and trimethoprim or pyrimethamine interfere with two consecutive steps in the same metabolic chain in the micro-organism. This may lead to synergistic antimicrobial activity. The rationale for a fixed combination of trimethoprim and sulfamethoxazole is that, although both antibiotics alone are bacteriostatic, the combination may be bactericidal. The optimal trimethoprim-sulfamethoxazole (TMP-SMX) ratio for synergism is 1:20 and is obtained systemically with a 1:5 dosage combination.[6]

The clinical relevance of the synergism is difficult to prove in experimental infections and even more so in clinical trials. This has led to questioning of the clinical usefulness of the combination in comparison with trimethoprim alone for the treatment of bacterial infections.[7] An argument in favor of the combination is the possibility of the reduced risk of resistance; organisms initially susceptible to both sulfonamides and trimethoprim are less likely to develop resistance to combinations than to single drugs.

Folate inhibitor combinations are used for treating bacterial as well as fungal and protozoal infections. Because of the emergence of bacterial resistance and risks for adverse reactions, the sulfonamides have most of their usefulness as single agents. Emphasis will be put on combinations of sulfonamides and trimethoprim, especially the most widely used, namely TMP-SMX and pyrimethamine-sulfadoxine.

PHARMACOKINETICS

The sulfonamides are classically subdivided on the basis of their elimination time into short-acting (plasma half-life, $t_{½}$ <8h), medium-acting ($t_{½}$ =8–16h), long-acting ($t_{½}$ =17–48h) and ultra-long-acting ($t_{½}$ >48h). Sulfonamides used as single agents today are short- or medium-acting.

Plasma kinetics

The sulfonamides used today, as well as trimethoprim and pyrimethamine, are well absorbed after oral administration and have high bioavailability. Following an oral dose of 160mg of trimethoprim and 800mg of sulfamethoxazole, maximal plasma concentrations of 1.6–1.9mg/l and 26–41mg/l, respectively, are achieved. [8] After intravenous administration of 240mg trimethoprim and 1200mg sulfamethoxazole q12h, peak plasma concentrations in the steady state are about 6mg/l for trimethoprim and 180mg/l for sulfamethoxazole.[9] The protein binding of the sulfonamides varies from less than 50% for sulfadiazine to more than 90% for sulfadoxine. Importantly, sulfonamides bind firmly to albumin and may displace other compounds (e.g. bilirubin). In newborns this may lead to toxic levels of unbound bilirubin with a subsequent risk of 'kernicterus' (see Central nervous system reactions, below).

Distribution

Trimethoprim is lipid-soluble at physiologic pH and has a large volume of distribution (100–120l), whereas sulfamethoxazole is a weak acid with poor lipid solubility at pH values above 7, leading to a volume of distribution corresponding to that of the extracellular space (i.e. 12–18l). In tissues concentrations similar to or higher than those in plasma are achieved with trimethoprim, whereas considerably lower levels of sulfamethoxazole reach peripheral compartments. Concentration above the minimum inhibitory concentrations (MICs) of trimethoprim-susceptible strains are achieved in most tissues and tissue fluids. With sulfamethoxazole, the peripheral concentrations are sometimes so low that it should be questioned whether therapeutic levels are reached. All of the sulfonamides as well as trimethoprim achieve high urine concentrations.

Elimination

The main routes of elimination of sulfonamides, trimethoprim and pyrimethamine are via liver metabolism and renal excretion.[10] In patients who have normal renal function, half-life varies from less than 6 hours for sulfisoxazole and sulfamethizole to 11–17 hours for sulfamethoxazole and sulfadiazine and more than 200 hours for sulfadoxine. Trimethoprim has a half-life of about 15 hours and pyrimethamine is eliminated slowly, with a half-life of about 100 hours.

Kinetics in children

The kinetics of both sulfamethoxazole and trimethoprim differ between children and adults (Table 197.1). Elimination is faster in children, who must be given higher doses than adults.

ROUTE OF ADMINISTRATION AND DOSAGE

Most sulfonamides, trimethoprim and pyrimethamine are available for oral use. Trimethoprim, sulfamethoxazole and sulfadiazine are

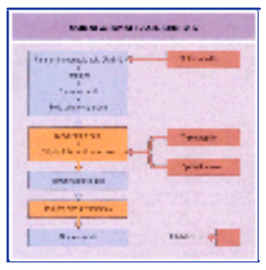

Figure 197-1 Mode of action of folate inhibitors.

TABLE 197-1 -- Comparative kinetics of trimethoprim (T) and sulfamethoxazole (S) in children and adults.

COMPARATIVE KINETICS OF TRIMETHOPRIM AND SULFAMETHOXAZOLE IN CHILDREN AND ADULTS				
Parameter	**Age (years)**			
	<1	**1–9**	**10–19**	**20–63**
T dose (mg/kg)	32	20	14	13
S dose (mg/kg)	160	100	70	65
Peak T concentration (mg/l)	6.5	7.2	6.7	8.7
Peak S concentration (mg/l)	146	176	126	176
T volume of distribution (l/kg)	2.0	1.6	1.5	1.4
S volume of distribution (l/kg)	0.5	0.5	0.4	0.4
T plasma half-life (h)	11	5.6	10	16
S plasma half-life (h)	7.5	9.8	10	15

also used intravenously; intravenous use of TMP-SMX is recommended when patients are unable to take the drug orally. Dosages for some of the sulfonamides and for combinations of sulfonamides and dihydrofolic acid inhibitors are given in Table 197.2 .

INDICATIONS

Table 197.3 summarizes the current antibacterial spectrum of TMP-SMX; little information is available on the current activity of the individual components. The activity of TMP-SMX against enterococci is controversial. There are reports in the literature of enterococcal bacteremia during treatment with TMP-SMX despite full in-vitro sensitivity pre-therapy, and of high failure rates and rapid emergence of resistance in enterococcal urinary tract infections (UTIs).[11] [12]

Reduced susceptibility or resistance to penicillin G by *Streptococcus pneumoniae* seems to be coupled to resistance to TMP-SMX

TABLE 197-2 -- Adult dosages of some folate inhibitors.

ADULT DOSAGES OF SOME FOLATE INHIBITORS	
Drug	**Indication and recommended dose for adults**
Pyrimethamine	Malaria prophylaxis (with sulfadoxine) 25mg once weekly; malaria therapy (with sulfadoxine; Fansidar) 50–75mg as single dose; toxoplasmosis therapy (with sulfadiazine) 75–200mg loading dose followed by 25–100mg q24h for 3–6 weeks followed by 25–50mg q24h (maintenance therapy in AIDS)
Sulfadiazine	UTI (with trimethoprim, not licensed in USA) 410mg q12h; toxoplasmosis therapy (with pyrimethamine) 0.5–1.5g q6h
Sulfadoxine	Malaria prophylaxis 500mg once weekly (with pyrimethamine; Fansidar); malaria therapy 1–1.5g (with pyrimethamine; Fansidar) as single dose
Sulfamethizole	UTI 500mg q6h
Sulfamethoxazole (with trimethoprim)	UTI 1.6g single dose or 400–800mg q12h; systemic bacterial infections 800mg q12h; pneumocystis pneumonia treatment 18.75–25mg/kg q6h; pneumocystis pneumonia prophylaxis 800mg thrice weekly or daily
Sulfisoxazole	UTI 500mg q6h
Trimethoprim	UTI 100mg q12h or 200mg q24h; UTI (with sulfadiazine, not licensed in USA) 90mg q12h; UTI (with sulfamethoxazole) 320mg single dose or 80–160mg q12h; systemic bacterial infections (with sulfamethoxazole) 160mg q12h; pneumocystis pneumonia treatment (with sulfamethoxazole) 3.75–5mg/kg q6h; pneumocystis pneumonia prophylaxis (with sulfamethoxazole) 160mg thrice weekly or daily
For pediatric doses, see the manufacturers' recommendations.	

in a very high percentage of strains studied (Table 197.4).[13] [14] [15] [16] Overall, resistance to TMP-SMX in pneumococci is a rapidly increasing problem.[17]

Streptococcus pyogenes is normally sensitive to TMP-SMX, but resistance has been reported in macrolide-resistant isolates. [18] Of other Gram-positive organisms, *Listeria monocytogenes* is susceptible to the combination.[19]

In *Escherichia coli* there is a very marked variation of susceptibility to TMP-SMX, not only between but also within countries. However, there is a clear trend towards increasing frequencies of resistance and in most countries 12% or more of *E. coli* isolates are resistant to trimethoprim and TMP-SMX.[20] [21] [22]

Shigella and *Salmonella* spp. also show varying sensitivity to TMP-SMX, with frequencies of resistance ranging from less than 5% to over 50%.

Several studies have indicated a relatively high frequency of selection of resistance to TMP-SMX in Enterobacteriaceae when the antibiotic is used therapeutically or, in particular, prophylactically.[23]

In *Haemophilus influenzae* also, reduced rates of susceptibility to TMP-SMX have been reported.[17]

The spectrum of the folate inhibitors also includes micro-organisms other than bacteria. The treatment of choice for *Toxoplasma gondii* remains a combination of pyrimethamine and sulfadiazine. The combination of sulfadoxine and pyrimethamine is used for treatment but less often for prevention of falciparum malaria in areas

TABLE 197-3 -- Susceptibility of common bacterial pathogens to trimethoprim-sulfamethoxazole.

SUSCEPTIBILITY OF COMMON BACTERIAL PATHOGENS TO TMP-SMX

Generally susceptible species (>90% susceptible)	*Streptococcus pyogenes*
	Staphylococcus saprophyticus
	Listeria monocytogenes
	Bordetella pertussis
	Yersinia enterocolitica
	Aeromonas spp.
	Burkholderia pseudomallei
	Burkholderia cepacia
	Stenotrophomonas maltophilia
Varying susceptibility	*Streptococcus pneumoniae*
	Staphylococcus aureus
	Coagulase-negative staphylococci
	Enterococcus spp.
	Escherichia coli
	Enterobacter spp.
	Klebsiella spp.

* MIC of trimethoprim of <2mg/l with a 1:19 TMP-SMX ratio.
† MIC <0.1mg/l.
‡ MIC >0.1mg/l.

with chloroquine resistance. However, unlike *T. gondii,* for which no resistance against pyrimethamine-sulfadiazine has yet been reported, resistance against pyrimethamine-sulfadoxine is not uncommon in *Plasmodium falciparum* and might become a problem also in *Pneumocystis. carinii.*[24] [25]

Use of sulfonamides alone

Sulfonamides for systemic use are recommended only for the treatment of uncomplicated UTIs. There are several arguments for reducing or abandoning such use:

- resistance to sulfonamides is relatively common in *E. coli* and other urinary pathogens;
- short-term treatment is poorly documented; and
- treatment times of 5 days or longer are associated with a risk of serious adverse reactions (see below).

TABLE 197-5 -- Clinical use of trimethoprim-sulfamethoxazole.

CLINICAL USE OF TMP-SMX	
Type of infection	**Limitations**
Uncomplicated UTI	None for short-term therapy (single dose or 3 days)
Other types of UTI	Resistance and safety
Shigellosis	Resistance
Salmonellosis	Resistance
Enteric fever	Resistance
Travelers' diarrhea	Safety and resistance
Otitis media	Resistance
Community-acquired pneumonia	Resistance, safety
Melioidosis	Resistance, efficacy
Prophylaxis in immunocompromised patients	Safety, resistance, efficacy
Pneumocystis carinii pneumonia	None

Use of trimethoprim-sulfamethoxazole

Trimethoprim-sulfamethoxazole has lost some of its usefulness through the emergence of resistance and increased awareness of the risk of adverse reactions, which may be serious or life-threatening.

Urogenital infections

Urogenital infections are the most common indications for TMP-SMX (Table 197.5). High frequencies of clinical and bacteriologic cure have been documented in women who have uncomplicated cystitis as well as in patients who have pyelonephritis, complicated UTIs or prostatitis.

Importantly, the use of TMP-SMX is well documented for single-dose or short-term treatment of uncomplicated cystitis in women.[26] It is equally effective if given for 3 days compared with treatment for 5–10 days, and a single dose is only slightly less effective than 3-day treatment. For other types of UTI, longer treatment times are required. In countries where resistant uropathogens are uncommon, single-dose or short-term TMP-SMX is an inexpensive and effective treatment of cystitis in women. For other types of infection, where longer treatment times are required, the relatively high frequency of potentially serious adverse reactions must be taken into account, and in adults a fluoroquinolone would probably be preferred in most patients.

Prostatitis is commonly treated with TMP-SMX and the few studies evaluating its use for this infection indicate a high degree of efficacy.[27]

For uncomplicated gonorrhea a single-dose of 640mg trimethoprim and 3200mg sulfamethoxazole was shown to be effective for 96% of 1069 patients and did not mask concurrent infections with *Treponema pallidum*. [28]

For *Haemophilus ducreyi* infections 160mg of trimethoprim plus 800mg sulfamethoxazole q12h for 3 days has given high cure rates, whereas shorter treatment times seem ineffective.[29] [30]

Infections caused by *Chlamydia trachomatis* respond poorly to TMP-SMX.[30]

Enteric infections

These have been extensively treated with TMP-SMX because of its activity against *Salmonella* spp. (including *Salmonella typhi*), *Shigella* spp., *Vibrio cholerae* and enterotoxigenic *E. coli*. In a well-controlled trial in patients who had enteritis of verified etiology, the

causative pathogens were eliminated on treatment day 2 in 41% of patients treated with TMP-SMX compared with 23% of those receiving placebo and 91% of patients on norfloxacin.[31]

A review of patients who had shigellosis showed that 97% of 149 patients treated with TMP-SMX responded clinically and 90% bacteriologically.[32] With the comparators (ampicillin, furazolidone or sulfadimidine) the clinical success rate was 78%. However, TMP-SMX may have lost some of its usefulness in shigellosis through the emergence of resistance.

Trimethoprim-sulfamethoxazole has been shown to be as effective as chloramphenicol for the treatment of enteric fever caused by susceptible strains of *S. typhi*.[33] [34] However, a study comparing TMP-SMX with pefloxacin for this indication demonstrated a shorter time to defervescence with pefloxacin. [34]

In salmonellosis TMP-SMX is effective for treatment of invasive infections caused by sensitive strains, but, like other antibiotics, it seems less effective in eliminating the carrier state of *Salmonella* spp.[35]

Treatment of cholera should be aimed mainly at rehydration of the patients. However, antibiotics may reduce symptoms and shorten the duration of the carrier state of *V. cholerae*, thereby reducing the risk of transmission. Trimethoprim-sulfamethoxazole has proved effective in patients who have cholera and one study showed that it was better than tetracycline or sulfamethoxazole alone.[36]

In several studies TMP-SMX has been shown to be effective in preventing travelers' diarrhea.[37] [38] [39] However, it has also been found to select for resistance.[40] This aberration, plus the fact that serious adverse reactions are not uncommon, makes this type of prophylaxis of doubtful value.

Respiratory tract infections

Considering the etiology of such infections and the fact that the most important pathogen is *S. pneumoniae*, which at present is often resistant to TMP-SMX, the antibiotic has lost much of its usefulness in the treatment of community-acquired pneumonia. Also, its role in the treatment of acute exacerbations of chronic bronchitis should be questioned, although invasive pneumococcal infections are less common in this category of patients.

Trimethoprim-sulfamethoxazole has become a common alternative to ß-lactam antibiotics for acute otitis media in children who have failed to respond to other antibiotics. This is probably due to its activity against *H. influenzae*. However, again the problem of resistant pneumococci limits its usefulness and TMP-SMX can not be recommended as empiric treatment.

In pneumonia caused by *Burkholderia pseudomallei*, melioidosis, TMP-SMX remains a choice for oral long-term treatment after standard treatment with ceftazidime, although some doubt exists about its effectiveness.[41]

Trimethoprim-sulfamethoxazole is the drug of choice for the treatment and prevention of *P. carinii* pneumonia.[42]

Other infections

Both trimethoprim and sulfamethoxazole penetrate the blood-cerebrospinal fluid barrier and the combination has been found to be effective in experimental bacterial meningitis.[43] Trimethoprim-sulfamethoxazole has therefore been used as a second-line drug for the treatment of bacterial meningitis. Favorable clinical results have been reported in the treatment of meningitis caused by *L. monocytogenes* as well as other types of meningitis. [44] [45]

In patients who have brucellosis TMP-SMX can be considered a second-line drug.

Several studies have shown excellent clinical results with TMP-SMX, alone or in combination with aminoglycosides, in the treatment of actinomycosis or nocardiosis.[46]

A controversial field for the use of TMP-SMX is prophylaxis in neutropenic patients. Early studies showed significant protection against bacterial infections but others have shown the emergence of resistance, superinfections and high frequencies of side effects.[47] A reason for reassessing this indication is the possibility that some of these patients (e.g. those with megaloblastic leukemia) may be prone to develop serious hematologic side effects. Another argument against the use of TMP-SMX for prophylaxis in neutropenic patients is the possibility of reduced resistance to colonization with fecal flora. [4]

Pyrimethamine-sulfadiazine and pyrimethamine-sulfadoxine

Pyrimethamine-sulfadiazine remains the first-line drug combination for the treatment of toxoplasmosis.[48]

Pyrimethamine-sulfadoxine is an alternative for the treatment of *P. falciparum* malaria in areas with chloroquine resistance.[49] However, as pointed out above, resistance to pyrimethamine-sulfadoxine is not uncommon and safety aspects reduce its usefulness for prophylaxis.

DOSAGE IN SPECIAL CIRCUMSTANCES

Renal impairment results in prolonged elimination times. Table 197.6 gives dosages of sulfamethoxazole and trimethoprim in patients who had decreased renal function. This includes patients of advanced age. As pointed out, the above doses used in children should be higher than those in adults because of different kinetic profiles (see Table 197.1). All sulfonamides should be avoided in patients aged less than 6 weeks because of the risk of cerebral accumulation of free bilirubin (kernicterus). There are no recommendations for reduced dosage of folate inhibitors in patients who have hepatic disease. Most of the folate inhibitors pass to breast milk but at concentrations that make effects on the child unlikely. During pregnancy, trimethoprim and pyrimethamine should be avoided because of the possible risk of altered folate metabolism in the fetus. Sulfonamides should not be given during the last trimester of the pregnancy because of the risk of kernicterus.

ADVERSE REACTIONS AND INTERACTIONS

A summary of the potential adverse effects of folate inhibitors is given in Table 197.7 .

TABLE 197-6 -- Effect of renal function on dosage of trimethoprim and sulfamethoxazole.

EFFECT OF RENAL FUNCTION ON DOSAGE OF TRIMETHOPRIM AND SULFAMETHOXAZOLE		
Creatinine clearance	**Serum creatinine**	**Dosage**
>25ml/min	<320µmol/l	Normal dose
15–25ml/min	320–405µmol/l	160mg trimethoprim + 800mg sulfamethoxazole q12h for 2 days and then every day until the serum concentration of sulfamethoxazole reaches >600µmol/l
<15ml/min	>405µmol/l	160mg trimethoprim + 800mg sulfamethoxazole q12h until the serum concentration of sulfamethoxazole reaches >600µmol/l

TABLE 197-7 -- Adverse actions of folate inhibitors in humans.

ADVERSE ACTIONS OF FOLATE INHIBITORS IN HUMANS		
Body system	**Sulfonamides**	**Trimethoprim/pyrimethamine**
Central nervous system	'Kernicterus' in newborns	Aseptic meningitis, especially in patients who have collagen diseases
Liver	Toxic hepatitis	Probably none
Lung	None	None
Kidney	Crystalluria	Increased serum creatinine (inhibition of creatinine excretion)
Prostate/genitourinary	None	None

General safety profile

Several studies have shown a correlation between the treatment time and the risk of adverse reactions to TMP-SMX when used for uncomplicated UTIs. [26] As no differences have been found in the efficacy of short-term treatment and treatment for 5 days or longer, the use of TMP-SMX for more than 3 days for uncomplicated cystitis is discouraged.

Hematologic reactions

The mode of action of trimethoprim has caused concerns over possible bone marrow toxicity. Studies in patients treated for 1 month or more with TMP-SMX have shown moderate folate deficiency.[50] [51] [52] The possibility of immune reactions causing hematologic adverse effects has been proposed.[53]

Serious and even fatal hematologic adverse reactions to TMP-SMX have been reported. In a Swedish study of about 50 million daily doses an approximate frequency of fatal reactions to TMP-SMX was calculated to be 3.7/million treatments (data from SWEDIS, Medical Products Agency, Uppsala, Sweden). It was noteworthy that the mean age of the patients who died was 78 years (range 41–96 years) and that only three of 18 patients were below the age of 70. Taking into consideration the effect of aging on renal function, the doses of TMP-SMX were high. In addition, the treatment time was long (range 3–73 days, mean 17 days, median 12 days).

Pyrimethamine hematologic toxicity is less well described. Many use folinic acid to avoid folic acid deficiency. Support is lacking and hematologic reactions may very well be due to other mechanisms.

Skin, mucocutaneous and allergic reactions

These reactions may in some cases be serious, for example Stevens-Johnson or Lyell syndromes.[54] [55] Such reactions seem to be related to the sulfonamide component rather than to trimethoprim.

It is worth noting that, in most reports on the safety of TMP-SMX or sulfonamides, skin reactions are only rarely reported in children. Possible explanations for this are the reduced risk for overdosing in children due to efficient elimination and less risk of sensitization to trimethoprim or sulfamethoxazole from previous exposures.

High numbers of serious cutaneous reactions have been reported following treatment with pyrimethamine-sulfadoxine.[56] Between 1974 and 1989, 126 cases of mucocutaneous syndromes were reported, giving an estimated risk of about 1.1/million treatments. This risk, which is most probably related to the sulfadoxine component, is considered to be high enough to discourage routine use of the combination for malaria prophylaxis.

Patients who have AIDS and *P. carinii* pneumonia and are treated with high doses of TMP-SMX have high frequencies of cutaneous reactions as well as other adverse reactions.[57] [58] [59] These reactions seem to be related to dose and treatment time, and many patients who have AIDS who have developed skin reactions later tolerate low-dose TMP-SMX prophylaxis against *P. carinii*.

Hepatic side effects

Cases of severe hepatic reactions to TMP-SMX have been reported and are most likely to be caused by the sulfonamide component.[60]

Gastrointestinal adverse reactions

Like many other orally administered antibiotics, TMP-SMX causes upper gastrointestinal adverse effects in some patients. Because of its low activity on the intestinal anaerobic flora it causes diarrhea only infrequently.

Renal safety

Sulfonamides with poor solubility can cause crystalluria. With sulfamethoxazole this does not seem to be a problem but, with sulfadiazine in high doses, crystalluria has been reported in AIDS patients who had toxoplasmal encephalitis. [61]

Increased serum creatinine in patients treated with TMP-SMX has been reported, but in most cases seems to be related to competitive inhibition of the renal excretion

of creatinine by trimethoprim.[62]

Central nervous system reactions

Aseptic meningitis is related to trimethoprim therapy. Several cases have been reported in the literature with some over-representation of patients who have collagen vascular diseases (e.g. Sjögren's syndrome).[63] [64] The pathogenesis remains obscure but seems to be of an allergic nature, with rapid onset and relapses after provocation.

Sulfonamides can cause central nervous system toxicity in newborns (kernicterus) because of displacement of bilirubin from albumin, resulting in toxic bilirubin concentrations in the brain.

TABLE 197-8 -- Interactions between trimethoprim-sulfamethoxazole and other drugs.

INTERACTIONS BETWEEN TMP-SMX AND OTHER DRUGS	
Drug	**Interaction**
Sulfonylureas	Reduced clearance of tolbutamide; possible hypoglycemia
Dicoumarol	Reduced metabolism of dicoumarol
Warfarin	Reduced metabolism of warfarin
Digoxin	Reduced tubular secretion of digoxin
Procainamide	Reduced clearance of procainamide
Methotrexate	Possible increased risk of hematologic side effects
Ciclosporin A	Reversible decrease of renal function; risk of accumulation
Phenytoin	Reduced metabolism of phenytoin
Amantadine	Possible reduced excretion of amantadine
Zidovudine	Reduced excretion of TMP-SMX
Ritonavir	Reduced metabolism of sulfamethoxazole

Drug-drug interactions

Considering the liver metabolism of trimethoprim, pyrimethamine and many of the sulfonamides, there is surprisingly little published on drug-drug interactions involving these drugs.[65] [66] Table 197.8 lists possible interactions. The field needs further systematic evaluation, especially because TMP-SMX is likely to be used increasingly by patients who also receive other drugs (e.g. those who have AIDS and are treated for fungal and viral infections).

Chapter 198 - Quinolones

Robin Howe
Alasdair MacGowan

INTRODUCTION

The quinolones are a heterogeneous group of synthetic antimicrobial agents. Originally deriving from 1,8-naphthyridine compounds (e.g. nalidixic acid), modern quinolones have evolved as shown in Figure 198.1 to give compounds initially with improved activity against Gram-negative bacteria (e.g. ciprofloxacin, ofloxacin) and more recently with greater activity against Gram positives (e.g. gatifloxacin, moxifloxacin). A number of broader spectrum agents have been developed (e.g. clinafloxacin, trovafloxacin) but have had to be withdrawn due to problems with toxicity.

Quinolones have excellent tissue and tissue fluid penetration so that they are suitable for infections in a wide range of organ systems. Adverse reactions are uncommon in marketed agents and relate mainly to the skin, the gastrointestinal system and central nervous system (CNS) and rarely warrant cessation of therapy. However, there are a number of potentially more serious adverse effects such as arthropathy, cardiotoxicity and phototoxicity. These occur as a class effect (although to different extents in different compounds) and have been a problem in drug development.

Modern fluoroquinolones are available in both intravenous and oral formulations. One of their major advantages has proved to be the ability to treat many serious infections with oral or intravenous-oral switch regimens, for example in the management of enteric fever, Gram-negative pyelonephritis, osteomyelitis, nosocomial pneumonia, severe exacerbations of both chronic bronchitis and cystic fibrosis. Many of the above previously demanded lengthy therapy with intravenous ß-lactams, aminoglycosides or their combinations.

The activity of fluoroquinolones such as ciprofloxacin and ofloxacin in Gram-positive infections, notably those caused by pneumococci, has been disputed. Newer compounds, such as gatifloxacin and moxifloxacin, have markedly improved activity against Gram-positive pathogens and may find a place in the management of infections caused, for example, by penicillin-resistant pneumococci.

ANTIBACTERIAL SPECTRUM AND POTENCY

The antibacterial spectrum of quinolones is shown in Table 198.1 . Quinolones are notable for the considerable knowledge that has been gained regarding structure-activity relationships.[1] The activity of the original naphthyridine and quinolone compounds (e.g. nalidixic acid) was limited to Gram-negative pathogens, primarily the Enterobacteriaceae, including Shigellae and Salmonellae. A major step forward in the development of the class was the addition of a fluorine at position 6, giving rise to the fluoroquinolones (Fig. 198.2). These agents are 10–100 times more active than their precursors against Gram-negative pathogens, including *Pseudomonas aeruginosa*, and have gained activity against the organisms causing atypical pneumonia. Potency, spectrum of activity and adverse effects/drug interactions are largely determined by substitutions at positions 1, 5, 6, 7 and 8:

- substitutions at position 1 (e.g. trovafloxacin) can alter potency (particularly against anaerobes) but may also affect interactions with theophyllines;
- substitutions at position 5 (e.g. grepafloxacin) can increase potency but may cause increased cardiotoxicity;
- substitutions at position 7 (e.g. moxifloxacin, gemifloxacin, garenoxacin) can increase activity against Gram-positive organisms and increase the plasma half-life;
- substitutions at position 8 (moxifloxacin, garenoxacin) can increase potency and reduce the rate selection of resistant mutants but can be associated with increased phototoxicity (sparfloxacin).

Early representatives such as ciprofloxacin only have borderline activity against Gram-positives pathogens. However, developments such as the addition at position 7 of a five-membered ring (gemifloxacin) or an azabicyclo group (moxifloxacin, garenoxacin) have brought increased Gram-positive activity. Unfortunately, this has been partly at the expense of some activity against *P. aeruginosa*. Agents with good activity against both Gram-positive and Gram-negative bacteria have been developed (e.g. clinafloxacin) but have been withdrawn due to toxicity problems.

Fluoroquinolones have good activity *in vitro* against many intracellular pathogens such as *Legionella* spp., *Mycoplasma* spp., *Ureaplasma urealyticum, Chlamydia* spp., *Brucella* spp., *Salmonella typhi* and *Coxiella burnettii*. This may be enhanced by the concentration of fluoroquinolones within cells (see below). As shown in Table 198.1 , *Mycobacterium tuberculosis* is susceptible to most of the fluoroquinolones with greater activity displayed by most of the newer agents. Of the other Mycobacteria, *M. kansasii, M. marinum* and *M. fortuitum* tend to be fluoroquinolone susceptible, whereas *M. avium* complex, *M. chelonae* and *M. scrofulaceum* are more resistant.[2]

The quinolones are rapidly bactericidal against most susceptible species in a concentration-dependent manner and have a postantibiotic effect (PAE) of 2–4 hours. The pharmacodynamic determinants of efficacy are C_{max} /MIC (ratio of the maximum plasma concentration to MIC) and AUC_{0-24} /MIC (ratio of the area under the 24h drug concentration curve to MIC). Various groups have attempted to define the AUC_{0-24} /MIC ratio that would predict a successful outcome. It appears that the optimal ratio varies for different organisms so that a ratio of >125 has been proposed for infection caused by Gram-negative enteric pathogens and *P. aeruginosa*, but a much lower ratio of >34 is proposed for pneumococcal lower respiratory tract infections. [3] [4]

MODE OF ACTION

Quinolones act by the rapid inhibition of bacterial DNA synthesis, leading to cell death. The primary targets are DNA gyrase and topoisomerase IV which are involved in the maintenance of the superhelical structure of DNA. Both enzymes are composed of two subunits that are homologous: DNA gyrase subunits encoded by *gyrA* and *gyrB*; topoisomerase IV encoded by *parC* (*grlA* in *Staphylococcus aureus*) and *parE* (*grlB* in *Staph. aureus*). Although inhibition of these enzymes is the most important determinant of antibacterial activity it appears that secondary activities may affect bactericidality.

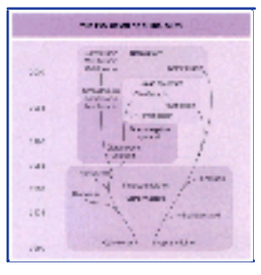

Figure 198-1 The evolution of quinolones.

The addition of RNA and protein synthesis inhibitors or the use of high quinolone concentrations (which also inhibit RNA synthesis) can lead to a diminution in the cidality of some quinolones, suggesting that synthesis of some gene products contributes to the killing effect.

BACTERIAL RESISTANCE

The major mechanism for acquired resistance to quinolones is by mutational modification of the antimicrobial target site. Mutations around the active site of *gyrA* have been identified in many strains of *E. coli* and many other Gram-negative bacilli, giving rise to greater resistance to nalidixic acid than the fluoroquinolones. Alterations in *gyrB* are less common and cause lower levels of resistance.[5] The main site for resistance mutations in Gram positives such as *Staph. aureus* and *Streptococcus. pneumoniae* is the *parC* gene although mutations in *parE* have been described. In both Gram-negative and Gram-positive pathogens resistance develops in a stepwise fashion as mutations arise in one and then both targets. Following an initial mutation, the susceptibility to a quinolone will depend on the specificity of the agent for the alternative target. For example, in clinical practice it has been shown that an isolated *gyrA* mutation in *E. coli* will confer high-level resistance to nalidixic acid but only reduced susceptibility to ciprofloxacin. The acquisition of an additional *parC* mutation confers high-level resistance to ciprofloxacin.[6] For bacteria such as *P. aeruginosa* that inherently have less susceptibility to fluoroquinolones, a single mutation can give rise to clinically significant resistance.

Resistance to quinolones can also be achieved by active efflux of the drug from the bacterial cell. This has been best described in *P. aeruginosa* in which quinolone resistance has been associated with increased expression of the MexAB-OprM, MexCD-oprJ or MexEF-oprN efflux pumps.[7] In *E. coli* the pump is the acrAB-tolC system. Among Gram-positive pathogens, the *norA* pump has been described in *Staph. aureus* and the PmrA pump in *Strep. pneumoniae*.[8] [9] On their own, efflux pumps will generally only cause low-level resistance and therefore may not be clinically important in inherently highly susceptible pathogens such as *E. coli*. However, the overexpression of efflux pumps becomes more significant in less susceptible organisms such as *P. aeruginosa*.

Resistance rates to quinolones have increased over the last decade. Ciprofloxacin resistance in the UK among *E. coli* increased from 0.8% to 3.7% between 1990 and 1999 when resistance was seen in 8.1% of *P. aeruginosa*.[10] Although methicillin-sensitive *Staph. aureus* is usually sensitive to fluoroquinolones, some clones of MRSA (e.g. EMRSA-16 seen in the UK) are resistant. Resistance among pneumococci remains uncommon although in some areas there is evidence that resistance is more common among penicillin-resistant pneumococci.[11]

Cross-resistance between fluoroquinolones is almost complete and minor differences in activity are not usually clinically exploitable. Cross-resistance to unrelated antimicrobials only occurs with over-expression of efflux pumps. In *P. aeruginosa*, for example, this leads to a low-level increase in resistance to chloramphenicol, tetracycline and macrolides.

PHARMACOKINETICS AND DISTRIBUTION

The quinolones are generally well absorbed and are widely distributed in body tissues and fluids, including the intracellular environment. They are excreted either by glomerular filtration or hepatic biotransformation or a combination of these routes, and by biliary or transintestinal elimination. Bio-availability is high and protein binding usually low to intermediate. Fluoroquinolone kinetics are summarized in Table 198.2 .

Absorption

Fluoroquinolones are well and rapidly absorbed after oral administration and exhibit linear absorption kinetics so that doubling the dose produces twice the plasma level.[12] Peak plasma concentrations are usually present 1–2 hours after an oral dose. Absorption may be delayed by food and is impaired by co-administration of antacids and ferrous iron, and possibly by zinc in multivitamin preparations.

Distribution

The fluoroquinolones are extensively distributed to the tissues as can be seen in Table 198.3 . Apparent volumes of distribution are usually 2–31/kg although values for precursor compounds are lower (e.g. 0.51/kg). Protein binding varies from 15–40% with norfloxacin, ofloxacin and ciprofloxacin[12] to 65% for gemifloxacin and higher still for garenoxacin and trovafloxacin (>80%).

Fluoroquinolones are concentrated approximately 10 times in polymorphoneutrophils (PMNs). Although it has been suggested that this may increase their *in vivo* efficacy against intracellular pathogens, there is evidence that the intracellular activity of different fluoroquinolones is variable, possibly related to where they are concentrated within the cell.[13] An additional result of the intracellular concentration of fluoroquinolones is that they may be transported by PMNs to a site of infection and then released.[14]

Elimination

Elimination half-lives vary from 1–2 hours for nalidixic acid to 3–5 hours for ciprofloxacin and 7–14 hours for newer agents.

Excretion of fluoroquinolones is primarily by renal glomerular filtration, hepatic metabolism and transintestinal elimination. The relative importance of glomerular filtration varies between agents and some compounds such as ofloxacin, levofloxacin and gatifloxacin exhibit minimal metabolism and are excreted largely unchanged in the urine. For these agents renal clearance almost equals total clearance and dose modification is required in renal

impairment.[12] [15] Others, such as ciprofloxacin and moxifloxacin, have moderately extensive hepatic biotransformation (to oxo-, desethyl- and sulfo- derivatives — subsequently partly eliminated as inactive glucuronides in the bile). For these compounds renal clearance is half of the total clearance and dosage modification may not be required in renal impairment as long as other routes of elimination are intact.[16]

In hepatic impairment, the dosage of agents primarily cleared by the kidney (ciprofloxacin, ofloxacin and levofloxacin) rarely requires modification. However, for extensively metabolized drugs such as grepafloxacin, dose modification is necessary in patients with cirrhosis.

Fluoroquinolones that are not primarily eliminated by the kidney are present in significant quantities in the stool, partly by biliary excretion and, notably with ciprofloxacin, by transintestinal elimination. The majority is bound to ligands in the stool.

ROUTE OF ADMINISTRATION AND DOSAGE

Most agents are available in both oral and intravenous formulations. The high oral bio-availability of fluoroquinolones means that oral administration is adequate in most situations unless this route is unavailable. The manufacturer's dosage recommendations for quinolones are given in Table 198.4 .

INDICATIONS

Early quinolones such as nalidixic acid were largely used for Gram-negative UTI and shigellosis. The development and evolution of fluoroquinolones have led to a number of agents with differences in spectrum of activity and therefore indications. Some, such as norfloxacin, are used almost exclusively for UTI. Agents such as ciprofloxacin and ofloxacin have been used for a broad range of infective syndromes. Newer compounds, such as levofloxacin, grepafloxacin, gatifloxacin and moxifloxacin, have improved activity against Gram-positive pathogens and may be more appropriate for respiratory tract infections.

Genitourinary tract infections

Uncomplicated lower urinary tract infection

Oral fluoroquinolone therapy is highly effective but to limit selection pressure for resistance should be used only when bacterial resistance precludes the use of other agents. Fluoroquinolones eradicate bowel reservoirs of uropathogenic *E. coli* and may reduce the incidence of early recurrence. Long-term suppression with low-dose norfloxacin or ciprofloxacin has been shown to be effective in preventing recurrent UTI in selected patients.[17] [18]

Complicated ascending urinary tract infection

Fluoroquinolones given for 1–2 weeks are the recommended agents for the treatment of ascending or complicated UTI.[19] Oral ciprofloxacin has proved as efficacious as an intravenous regimen for initial empiric therapy.[20]

Prostatitis

Fluoroquinolones are concentrated in prostatic tissue and are recommended therapy for both acute and chronic bacterial prostatitis.[21] Ciprofloxacin for 28 days can give a clinical response of 98% in chronic bacterial prostatitis although relapse may occur in up to 40% of patients.[22]

Gonorrhoea

Single-dose oral therapy with ciprofloxacin or ofloxacin is equivalent to other parenteral single-dose regimens and is therefore a recommended choice in the management of uncomplicated urethral gonorrhea.[23] Pharyngeal and rectal disease also respond. However, quinolone resistance is emerging, particularly in South East Asia where high-level resistance can be found in up to 50% of isolates.[24]

Nongonococcal urethritis/cervicitis

The antichlamydial activity of fluoroquinolones varies and ofloxacin is the most potent of the established agents. A 7-day course of ofloxacin is as effective as doxycycline therapy.[25] Newer compounds such as moxifloxacin have excellent *in vitro* activity and may have a role in therapy.

Chancroid

A 3-day course of ciprofloxacin gives excellent cure rates, equivalent to standard ß-lactam or trimethoprim-sulfamethoxazole (cotrimoxazole) therapy. [26]

Pelvic inflammatory disease

The ideal antimicrobial treatment for acute pelvic inflammatory disease has not been established by randomized clinical trials. However, ofloxacin is active against many of the potentially causal pathogens and is included in recommended treatment regimes.[23]

Respiratory tract infections

The fluoroquinolones ciprofloxacin and ofloxacin have been used extensively for upper and lower respiratory tract infections. However, there have been concerns regarding their activity against *Strep. pneumoniae*. Newer agents, such as gatifloxacin, gemifloxacin, moxifloxacin and garenoxacin, have improved activity against pneumococci, including macrolide- and penicillin-resistant strains, and are often termed 'respiratory quinolones'.

Sinusitis

Oral fluoroquinolones have comparable efficacy to macrolides or cephalosporins and give cure rates of >85% in acute sinusitis.[27] [28] [29]

Ear infections

Topical preparations of ofloxacin or ciprofloxacin are effective for the treatment of acute otitis media in children with tympanostomy tubes and for chronic suppurative otitis media.[30] Clinical cure rates of >85% for otitis externa can be obtained with the topical preparations. Malignant otitis externa, which is usually caused by *P. aeruginosa*, can be treated with oral ciprofloxacin. A prolonged course is required (3 months) and gives cure rates in excess of 90%.[31]

Acute exacerbations of chronic bronchitis

Fluoroquinolones are among the agents of choice for the management of moderate to severe exacerbations of chronic bronchitis. They have equivalent efficacy to macrolides or ß-lactam/ß-lactamase inhibitor combinations and achieve cure rates of >90%.[32] [33]

Community-acquired pneumonia

Older quinolones are not indicated for pneumococcal pneumonia when alternative antibiotics are available. However, results with

Inhalational anthrax (postexposure)				500mg bd (60 days)	400mg bd (60 days)			

ciprofloxacin and ofloxacin suggest clinical response and bacterial eradication rates of 90% or greater and with levofloxacin, equivalence or superiority to ceftriaxone.[34] However, concerns have been raised regarding the efficacy of ciprofloxacin in severe pneumococcal pneumonia following reports of clinical failures.[35] Failures with levofloxacin have also been reported and in Europe it is suggested that it should be given at an increased dose of 500mg BD or in combination with benzyl penicillin in cases of severe pneumonia.[36] [37] Newer agents such as gatifloxacin, gemifloxacin and moxifloxacin, which have improved activity against pneumococci and also atypical pathogens, show promising results in clinical trials with clinical cure rates in excess of 90%.[38] Although there are few specific data regarding infections with penicillin-resistant pneumococci, trovafloxacin gives clinical success rates of over 95%. Legionellosis can be successfully treated with quinolones such as ciprofloxacin, ofloxacin or levofloxacin. There are few clinical data to show whether or not they are superior to macrolides and often they are given in combination with a macrolide or rifampicin.[39]

Nosocomial pneumonia

A large-scale study of ciprofloxacin showed equivalence with imipenem in moderately to severely ill patients, most of whom required ventilation and treatment in an intensive care unit.[40] In the 20–25% with infection caused by *P. aeruginosa*, the results with both regimens were less satisfactory, underlining the need for combination therapy. Newer fluoroquinolones such as gemifloxacin, gatifloxacin and moxifloxacin have reduced *in vitro* potency against *P. aeruginosa* and will probably not have a role in the management of hospital-acquired pneumonia where *Pseudomonas* is a likely etiological agent.

Cystic fibrosis

Oral ciprofloxacin is effective for exacerbations caused by *P. aeruginosa*, producing results equivalent to those of standard ß-lactam and aminoglycoside therapy. In the UK a 3-week course of ciprofloxacin combined with colistin is recommended for the treatment of early pseudomonal infection.[41]

Mycobacterial infections

Ofloxacin and ciprofloxacin have moderate activity against *Mycobacterium tuberculosis* and are bactericidal *in vivo*. [42] Their role in therapy is currently limited to use in combination regimens for the treatment of multiply drug-resistant *Mycobacterium tuberculosis* infection.[43] Newer agents such as moxifloxacin have enhanced anti-mycobacterial activity and animal studies suggest they may have a future role in antituberculous chemotherapy.[44]

As noted above, the susceptibility of nontuberculous mycobacteria to fluoroquinolones is variable. *Mycobacterium avium* complex is relatively resistant to quinolones. Nevertheless, the addition of ciprofloxacin to standard therapeutic combinations has been shown to be of benefit in HIV patients with disseminated disease.[45]

Skin and soft tissue infections

The fluoroquinolones give excellent results when compared with cephalosporins for the treatment of both uncomplicated and complicated skin and soft tissue infections.[46] [47] However, more effective agents are routinely available for Gram-positive infections and usefulness in MRSA infections is limited by high rates of quinolone resistance.

Skeletal infections

Oral fluoroquinolones are highly effective for Gram-negative mixed acute (or chronic) contiguous osteomyelitis, giving cure rates of 80–90% after 3–6-month courses. They are also effective for post-surgical cases, salmonella osteitis and in some cases of chronic *P. aeruginosa* osteomyelitis (ciprofloxacin), although resistance may emerge causing a failure of treatment or relapse.[48] In patients with orthopedic prostheses infected with staphylococci, ciprofloxacin or ofloxacin in combination with rifampicin have been successfully used for conservative management (i.e. preserving the prosthesis).[49] [50]

Gastrointestinal infections

Typhoid and paratyphoid fevers

Ciprofloxacin or ofloxacin are the agents of choice for typhoid and paratyphoid fevers.[51] Convalescent excretion states and long-term fecal carriage are rare after fluoroquinolone therapy, thereby reducing the human reservoir and possibly leading to a fall in incidence. Carriage states persisting after other antibiotic therapy may

also respond to fluoroquinolones.

Decreased quinolone susceptibility has emerged in Asia over the last 10 years. Strains are typically resistant to nalidixic acid and have raised MICs of ciprofloxacin of 0.5–1mg/l. These strains are ciprofloxacin susceptible by NCCLS or BSAC criteria but there is evidence that infection by such strains responds less well to ciprofloxacin and longer courses or alternative agents are recommended. [52]

Salmonellosis

A 5–7-day course of oral fluoroquinolone is effective in reducing the duration and severity of severe salmonellosis.

Cholera

Three-day courses of oral fluoroquinolones are equal to standard trimethoprim-sulfamethoxazole or tetracycline regimens. A cure rate of >90% can be achieved with a single 1g dose of ciprofloxacin.[53]

Shigellosis

Fluoroquinolones are drugs of choice for invasive shigellosis. A single oral dose (ciprofloxacin 1g) is effective in adults.

Campylobacter

Fluoroquinolones have been used for gastrointestinal *Campylobacter* infections. However, resistance levels are increasing and may be as high as 50% in some areas of the world.[54]

Travelers' diarrhea

Ciprofloxacin or norfloxacin in full oral dosage for 5 days is effective for 80% of unprotected subjects who develop profuse diarrhea (>3–5 watery stools/day).

Other treatment indications

Ocular infections

Topical fluoroquinolones are effective for the treatment of bacterial conjunctivitis and keratitis. Penetration of systemic quinolones into the vitreous is relatively good but may not exceed the MICs of all likely pathogens. Intravitreal ciprofloxacin has been used in the treatment of endophthalmitis.[55]

Infections associated with chronic ambulatory peritoneal dialysis

Ciprofloxacin and ofloxacin have been used with success both orally and intraperitoneally. However, the emergence of resistant staphylococcal infection has limited their usefulness as monotherapy.

Q fever

Fluoroquinolones are active against *Coxiella burnetii in vitro* and a combination of a fluoroquinolone (ofloxacin) with doxycycline has been suggested for Q fever endocarditis.[56]

Anthrax

A 60-day course of ciprofloxacin is recommended for postexposure prophylaxis against anthrax.[57] In patients with inhalational anthrax a combination of ciprofloxacin plus another active agent (e.g. doxycycline) is recommended.[58]

Meningitis

Fluoroquinolones have been successfully used for Gram-negative meningitis.[59] Newer agents such as moxifloxacin show promising results in animal models of pneumococcal meningitis.[60] Trovafloxacin had comparable efficacy to ceftriaxone in a trial of pediatric meningitis. [61]

Chemoprophylaxis

Meningococcal infection

Single-dose (500mg) ciprofloxacin is effective in eradicating nasopharyngeal carriage in over 95% of subjects.[62]

Neutropenic patients

Norfloxacin, ofloxacin and ciprofloxacin have been widely used in the prophylaxis of opportunistic infection among neutropenic patients. Although prophylaxis has been shown to prevent febrile episodes of an infectious nature, current recommendations do not suggest their use due to concerns regarding the emergence and spread of antimicrobial resistance.[63]

Travelers' diarrhea

Once-daily prophylactic use of a fluoroquinolone (e.g. norfloxacin 400mg or ciprofloxacin 500mg) for the duration of potential exposure gives 75–90% protection from travelers' diarrhea caused by enterotoxigenic *E. coli* and other bacterial enteropathogens.

Surgical infections

Fluoroquinolones have been used effectively for the prevention of infection following transurethral prostatectomy and biliary surgery.

Pediatric use of fluoroquinolones

Pediatric use of fluoroquinolones has been limited by concerns regarding arthropathy observed in weight-bearing diarthrodial joints in juvenile dogs after prolonged high-dose administration. Nevertheless, accumulated experience has established some situations when the benefits of fluoroquinolones outweigh potential risks. These include typhoid fever, cholera and shigellosis, complicated UTI due to multiresistant pathogens, chronic suppurative otitis media caused by *P. aeruginosa*, multiresistant Gram-negative sepsis (including osteomyelitis), prophylaxis of meningococcemia (single-dose) and infection in neutropenia.

Treatment of pseudomonal infections in patients with cystic fibrosis is one of the commonest indications for the use of fluoroquinolones in children. Prolonged courses are often given but there has been little evidence of related arthropathy and fluoroquinolones continue to be widely used.

TABLE 198-5 -- Manufacturers' dosage recommendations for patients with renal impairment.

MANUFACTURERS' DOSAGE RECOMMENDATIONS FOR PATIENTS WITH RENAL IMPAIRMENT			
	Renal impairment		**Hemodialysis/CAPD**
	Mild	**Moderate/severe**	
Ciprofloxacin (iv)		200–400mg 18–24 hourly (CC = 5–29ml/min)	
Ciprofloxacin (po)	250–500mg bd (CC = 30–50ml/min)	250–500mg 18 hourly (CC = 5–29ml/min)	250–500mg od after dialysis
Ofloxacin	400mg od (CC = 20–50ml/min)	200mg od (CC <20ml/min)	
Levofloxacin	250mg od* (CC = 20–50ml/min)	250mg 48 hourly* (CC = 10–19ml/min)	250mg 48 hourly* (CC = 10–19ml/min)
Norfloxacin		400mg od (CC <30ml/min)	
Gatifloxacin		200mg od* (CC <40ml/min)	200mg od* (CC <40ml/min)
Moxifloxacin	No adjustment required		
CC, creatinine clearance			

* Initial loading dose of 500mg
** Short courses up to 3 days do not require dosage alteration

DOSAGE IN SPECIAL CIRCUMSTANCES

Renal impairment

The extent to which the dosage requires modification is dependent on the degree of renal elimination. Table 198.5 shows the manufacturer's recommendations for selected quinolones. Essentially, agents such as ofloxacin and levofloxacin that are extensively renally excreted have the dose reduced to one-quarter of the normal daily dose in severe renal impairment and most other agents have the dose halved. However, as noted above, there is evidence that ciprofloxacin may not require dose modification as long as alternative routes of elimination are intact.[16] Moxifloxacin, which has only 20% renal excretion, does not require dose modification.

Hepatic impairment

Apart for extensively metabolized quinolones, such as pefloxacin, dose modification is not necessary in patients with hepatic impairment. However, experience with newer agents such as moxifloxacin in patients with severe liver failure (Child Pugh Class C) is limited.

Elderly patients

No specific changes in dosage are required for the elderly provided appropriate changes are made for reduced renal clearance.

Pediatrics

Optimal pediatric doses have not been established. Suggested doses of ciprofloxacin are 7.5–40mg/kg/day (oral) or 5–10mg/kg/day (intravenous) administered on a 8–12-hourly basis.

Pregnancy and lactation

Quinolones are not approved for use in pregnancy or during lactation.

ADVERSE REACTIONS AND INTERACTIONS

Adverse drug reactions

Fluoroquinolones are generally well tolerated although there are a number of potentially serious adverse effects that have been seen in some agents. [64] When adverse effects are reported, they are usually gastrointestinal (2–20%), dermatologic (0.5–3%) and CNS (0.5–2%) reactions which rarely necessitate withdrawal of therapy (1–3%). In most cases there are no specific age or racially related effects, but adverse drug reactions are more common in neutropenic patients and possibly in people who have AIDS.

Most fluoroquinolone adverse drug reactions are class effects, but incidence varies between compounds and can often be related to the specific structure of different agents. Certain group members have specific effects or more serious class effects that have led to restrictions on use or withdrawal. For example, the phototoxicity of sparfloxacin has restricted licensing by some registration authorities and temafloxacin, which caused hemolytic uremic syndrome and hypoglycemia, was withdrawn in 1992.

Gastrointestinal reactions

The usual reported symptoms are nausea, anorexia and dyspepsia. While diarrhea, abdominal pain and vomiting are less frequent, they are more likely to result in discontinuation of treatment. Antibiotic-associated diarrhea caused by *Clostridium difficile* is uncommon following fluoroquinolone therapy. Liver enzyme abnormalities occur in 2–3% of patients receiving fluoroquinolones and are usually mild and reversible. However, more severe liver abnormalities have been seen with some agents which, in the case of trovafloxacin, led to its withdrawal.

Dermatologic reactions

Although non-specific skin rashes, pruritus and urticaria have been reported, it is phototoxicity that has received most attention. This is a class effect and is thought to be related to the photodegradation of the fluoroquinolone and its ability to induce free radicals. The incidence and severity of phototoxicity differ between agents. Structurally, a fluorine moeity at position 8 causes more phototoxicity and sparfloxacin, which has this moiety, has caused a higher rate of phototoxicity. Phototoxic reactions are rare with ciprofloxacin, ofloxacin and levofloxacin. Gemifloxacin can cause a nonphototoxic rash which is seen particularly in female patients between the ages of 20 and 40 years.

Central nervous system reactions

These occur in less than 2% of patients with most fluoroquinolones and usually manifest as headache, dizziness, mild tremor or drowsiness.

Convulsions occur rarely both as a primary effect and as a result of interactions with theophylline or nonsteroidal anti-inflammatory drugs (NSAIDs). Although the mechanism of quinolone toxicity has not been fully elucidated, it is believed to be due to inhibition of $GABA_A$ receptors.

Musculoskeletal effects

Fluoroquinolones as a class produce destructive arthropathy in weight-bearing, diarthrodial joints of juvenile animals, notably dogs, by production of cartilage erosions

after prolonged high dosage. Some agents, notably precursors such as nalidixic acid, are considerably more likely to induce arthropathy. This effect has never been observed in human children and MRI follow-up and autopsy studies in children receiving both nalidixic acid and modern fluoroquinolones have revealed no evidence of joint damage.[65] Experience with ciprofloxacin in 1500 children noted reversible arthralgia in 3.2% of patients treated for pulmonary exacerbations of cystic fibrosis.[66]

Tendinitis occurs rarely as a class effect although it may be more common with concomitant corticosteroid therapy. The Achilles tendon is most commonly affected and patients are usually >50 years of age. MRI can be useful for early detection of damage and discontinuation is recommended at the first sign of tendon pain or inflammation.

Cardiovascular effects

Cardiotoxicity is manifest as prolongation of the QT interval with the potential to cause ventricular arrhythmias. The significance of this effect varies between agents and appears to be affected by substitutions at position 5 (see Fig. 198.2).[67] Adverse effects due to cardiotoxicity are rare although recently grepafloxacin was withdrawn voluntarily following reports of seven cardiac-related fatalities.

Other (rare) effects

Hypersensitivity occurs at a frequency of ~1%. Crystalluria and secondary interstitial nephritis are rare and relate to pH-associated solubility of fluoroquinolones in urine.

Interactions with other drugs

Interactions largely occur as a result of interference with fluoroquinolone absorption or by inhibition of biotransformation of unrelated drugs by the hepatic cytochrome P450 isoenzyme system. Central nervous system interactions due to GABA receptor inhibition occur with NSAIDs, notably fenbufen, and convulsions may follow, as reported with enoxacin.

Interactions affecting absorption of fluoroquinolones

The absorption of fluoroquinolones is reduced by up to 80% by co-administration of aluminium and magnesium-containing antacids, probably by the formation of insoluble complexes and, to a lesser extent, by calcium antacids, sucralfate and ferrous iron preparations. H_2 -antagonists have no effect.

Interactions affecting drug metabolism

Fluoroquinolones reduce the hepatic clearance of xanthines via the P450 cytochrome system. The effect is most marked with enoxacin and grepafloxacin, but ciprofloxacin and pefloxacin also reduce clearance of theophylline by 30% and co-administration may result in theophylline toxicity, usually nausea but possibly convulsions. Dosage of theophylline should be interrupted or reduced and serum levels monitored if enoxacin, pefloxacin or ciprofloxacin is to be administered.

A similar effect, induced by the same fluoroquinolones, is responsible for inhibition of caffeine metabolism and resultant insomnia. Metabolism of warfarin, cimetidine and cyclosporin is affected much less by P450 cytochrome inhibition and interaction may not be clinically significant.

Chapter 199 - Glycopeptides

Jihad Slim
Leon Smith

VANCOMYCIN

Vancomycin is a tricyclic glycopeptide antibiotic obtained from *Amycolaptosis orientalis*, which is found in the soil of Borneo and India. This antibiotic-producing bacterium was also known in the past as *Streptomyces orientalis* and *Nocardia orientalis*. Vancomycin has been used clinically since 1956 but recent improvements in its manufacture have increased its purity and reduced its toxicity. It is an extremely valuable and relatively safe antibiotic against the major Gram-positive organisms. In the past few years the emergence of resistance in enterococci, and especially in staphylococci, has become an important clinical issue.[1]

PHARMACOKINETICS AND DISTRIBUTION

Vancomycin is bactericidal and appears to exert its effect by binding to the precursor units of peptidoglycan synthesis (D-alanyle-D-alanine units) inhibiting the transpeptidase reaction. This step is necessary for cross-linking newly synthesized peptidoglycan precursors into a complete structure. The net result is an alteration of bacterial cell wall permeability. In addition, RNA synthesis is inhibited. Perhaps because of this dual mechanism of action, resistance to vancomycin is uncommon, although it has been reported in strains of enterococci, coagulase-negative staphylococci and a few strains of *Staphylococcus aureus*. Gram-negative organisms are not sensitive to vancomycin, perhaps because porin channels in the cell wall of the Gram-negative organism do not accommodate the large, bulky vancomycin molecule. Vancomycin exhibits concentration-independent (or time-dependent) bactericidal action against susceptible bacteria. It kills better in aerobic conditions than in anaerobic conditions.

Concomitant use with streptomycin or gentamicin is usually synergistic against susceptible pathogens, especially enterococci and *viridans* streptococci, while rifampin (rifampicin) exhibits synergism with vancomycin against most coagulase-negative staphylococci but not against *Staph. aureus*.

TABLE 199-1 -- Concentration of vancomycin in body tissues and fluids.*

CONCENTRATION OF VANCOMYCIN IN BODY TISSUES AND FLUIDS				
Body fluid or tissue	**Dose**	**Route of administration**	**Sampling time (hours after administration of vancomycin dose)**	**Mean vancomycin concentration in sample (µg/ml)**
Pericardial fluid	500mg	Intravenous	1.5–5.5	0.6–5.5
Lung	1g	Intravenous	6	1.3
Synovial fluid	500mg	Intravenous	1	5.7
Ascitic fluid	500mg	Intravenous	1.5–5.2	3.6
Bile	500mg	Intravenous	1	3.1
Urine	500mg	Intravenous	1	30–90
Stools	500mg	Oral	6	100–350

** Data from Cunha and Klein.[6]*

Generally, vancomycin is only administered intravenously, although oral administration is important in treatment of pseudomembranous colitis; the oral bioavailability of vancomycin is too low to treat systemic infections. Patients who have colitis, however, develop detectable serum levels after oral administration, especially if they have renal impairment.

A two- or a three-compartment model best explains the pharmacokinetics of vancomycin. A 500mg dose of vancomycin hydrochloride results in a mean peak serum concentration of approximately 30µg/ml immediately after infusion. Concentrations after 1 hour are approximately 6µg/ml, and after 6 hours they are approximately 3µg/ml. After a slow intravenous infusion of 1g vancomycin, peak serum levels are approximately 48µg/ml, with trough concentrations of 2µg/ml at 12 hours. Ideally, peak concentrations of approximately 30µg/ml and trough concentrations of 10µg/ml or less are desirable. After 24 hours, concentrations are less than 1µg/ml.[2] [3] [4] [5]

Vancomycin is distributed into most body tissues and fluids, including pericardial, pleural, ascitic and synovial fluids (Table 199.1). Unless the meninges are inflamed, there is little diffusion into cerebrospinal fluid. Vancomycin is about 55% bound to serum protein. It is not known whether any metabolism takes place. Excretion is mainly by glomerular filtration, with about 80% of the drug excreted in 24 hours in the urine and only small amounts excreted in the feces. Owing to poor bioavailability, oral doses are excreted mainly in the feces. Vancomycin given by the oral route concentrates intraluminally in the distal gastrointestinal tract, resulting in high intraluminal vancomycin concentrations. There is approximately 1000µg/ml in the stool after a dose of 2g/day. Low serum concentrations may occur in patients who have a damaged intestinal mucosa. [3] [4] [7] [8] [9] [10]

The kidneys eliminate vancomycin through glomerular filtration. Urine concentrations are approximately 300µg/ml after a 500mg intravenous dose, and tubular reabsorption is not important in the renal handling of vancomycin. Because vancomycin is eliminated via the renal route, it accumulates in the presence of renal insufficiency. The serum half-life of vancomycin in anuric patients is approximately 7 days, in contrast to 4–6 hours in adults who have normal

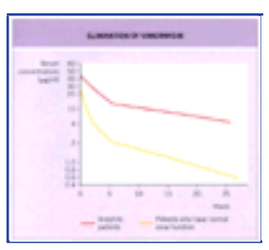

Figure 199-1 Elimination of vancomycin by anephric patients and by patients who have normal renal function. *Adapted with permission from Cunha et al.[11]*

renal function (Fig. 199.1). If F60 or F80 polysulfone filters are used, significant amounts of vancomycin can be removed during hemodialysis.

ROUTE OF ADMINISTRATION AND DOSAGE

Adults and children who have normal renal function

The usual dose is 2g/day divided into two or four doses and administered intravenously at a rate no faster than 10mg/minute or over a total of at least 60 minutes.

Oral vancomycin is effective for pseudomembranous enterocolitis or staphylococcal enterocolitis, and the dose is 500–2000mg/day in three or four daily doses for 7–10 days.

For children the usual dosage is 10mg/kg q6h.

Vancomycin serum level is readily available in most laboratories and should be measured to monitor efficacy and prevent toxicity, especially in patients who have fluctuating renal function.

INDICATIONS

Most strains of *Staph. aureus* and *Staphylococcus epidermidis* are susceptible to vancomycin, as are streptococci (including enterococci), *Corynebacterium* spp. and *Clostridium* spp. (Table 199.2). Vancomycin is particularly useful against methicillin-resistant *Staphylococcus aureus* (MRSA) infections and for treating Gram-positive infections in patients who are allergic to penicillin. Some strains of Gram-positive bacteria — *Leuconostoc* spp., *Lactobacillus* spp., *Pediococcus* spp. and *Erysipelothrix* spp. — possess inherent resistance to vancomycin. Gram-negative bacteria, fungi, viruses and mycobacteria are resistant to vancomycin.

Synergistic bactericidal effects can be achieved when vancomycin is combined with aminoglycosides against enterococci and MRSA, but this increases possible renal toxicity. Vancomycin is useful against a wide variety of clinical infections caused by these organisms (Table 199.3), although it should not be used in patients who have meningitis unless absolutely necessary because of its poor penetration

TABLE 199-2 -- Organisms treatable by vancomycin.

ORGANISMS TREATABLE BY VANCOMYCIN
Actinomyces spp.
Bacillus cereus and *Bacillus subtilis*
Clostridium difficile and other *Clostridium* spp.
Corynebacterium jeikeium and other *Corynebacterium* spp.
Enterococcus faecalis and *Enterococcus faecium*
Listeria monocytogenes
Staphylococcus spp. including *Staphylococcus aureus, Staphylococcus epidermidis* and methicillin-resistant staphylococci
Streptococcus spp. including *Streptococcus agalactiae* (group B streptococci), *Streptococcus bovis, Streptococcus pneumoniae, Streptococcus pyogenes* and *viridans* streptococci
Resistant strains of enterococci and staphylococci may occur.

TABLE 199-3 -- Conditions treatable by vancomycin.

CONDITIONS TREATABLE BY VANCOMYCIN	
Diabetic foot ulcers	Skin and soft tissue infections
Endocarditis	Urinary tract infections
Osteomyelitis	Lower respiratory tract infections
Peritonitis	Intra-abdominal infections
Pneumonia	Bone and joint infections
Pseudomembranous colitis	Some forms of meningitis
Sepsis	
These conditions are treatable by vancomycin if they involve the organisms listed in Table 199.2 .	

into the cerebrospinal fluid. Oral vancomycin is used for severe colitis caused by *Clostridium difficile*. Metronidazole should be used as the first-line agent for most cases of *C. difficile* related diarrhea. This limits the risk of overuse of vancomycin with its attendant risk of selection of vancomycin-resistant bacteria.

Susceptible organisms are usually sensitive to concentrations of 1–5µg/ml.

DOSAGES IN SPECIAL CIRCUMSTANCES

Vancomycin should be used with caution in patients who have renal failure because it can accumulate. High serum concentrations increase the possibility of developing ototoxicity and nephrotoxicity (see below). Dose adjustments are necessary and lower doses of the drug are recommended for patients who have renal dysfunction or in patients receiving other ototoxic or nephrotoxic drugs. Renal function tests should be performed routinely during therapy.

In patients who have impaired renal function, the patient can be given a loading dose of 15mg/kg with a daily maintenance dose in milligrams of 150 plus 15 times the creatinine clearance, which provides a steady state concentration of 20µg/ml.[12] Alternatively, a nomogram can be used.

Hemodialysis usually removes little or no vancomycin, and 1g (15mg/kg as a pediatric dose or for a small adult (<50kg)) every 7–10 days usually provides adequate serum concentrations in functionally anephric adults.

Patients on continuous ambulatory peritoneal dialysis can be given vancomycin intravenously with a loading dose of 23mg/kg and a maintenance dose of 17mg/kg every 7 days,[13] or 1.5mg/kg q6h.[14] Monitoring of serum concentrations is recommended.

Vancomycin dosage for neonates is 15mg/kg bolus followed by 10mg/kg q12h in the first week of life, q8h up to 1 month of age. For children it is administered at 10mg/kg q6h.

In premature infants and elderly patients, vancomycin dosage needs to be adjusted to their clearance of creatine.

Vancomycin serum concentrations must be monitored carefully in patients who have severe hepatic impairment since accumulation can occur.

Serum levels above 40µg/ml can be associated with nephrotoxicity, and ototoxicity.

ADVERSE REACTIONS

Too rapid an infusion of vancomycin can trigger histamine release, which may cause anaphylactoid reactions including fever, chills, sinus tachycardia, pruritus, paresthesiae, flushing, rash or redness in the face, neck, upper body, arms or back, and muscular spasms. It is seen infrequently now following the introduction of improved pharmacological formulations. In some cases, hypotension occurs. This histamine release reaction is often referred to as the 'red man' syndrome. Slowing the infusion rates, administering a histamine-1 blocker or lowering the size of the dose may reduce the incidence or severity of the reaction. These reactions usually resolve within 20 minutes but may persist for several hours. In animal studies, hypotension and bradycardia occurred in animals given large doses of vancomycin at high concentrations and rates. Such events are infrequent if vancomycin is given by slow infusion over 60 minutes. In studies of normal volunteers, infusion-related events did not occur when vancomycin was administered at a rate of 10µg/min or less.

Rarely, vancomycin causes nephrotoxicity. Renal failure is principally manifested by increased serum creatinine or blood urea nitrogen concentrations, especially in patients who have been given large doses of vancomycin. Rare cases of interstitial nephritis have also been reported. Most of these have occurred in patients who were given concomitant aminoglycosides or who had pre-existing kidney dysfunction. When vancomycin was discontinued, azotemia resolved in most patients. Generally the nephrotoxicity risk is minimized if trough serum concentrations are kept below 10µg/ml.

A few dozen cases of hearing loss associated with vancomycin have been reported; these occurred at serum concentrations of about 60–80µg/ml. Most of these patients had kidney dysfunction or a pre-existing hearing loss, were receiving concomitant treatment with an ototoxic drug, were dehydrated, or were bacteremic. Vancomycin-induced hearing loss can be manifested as either cochlear toxicity (causing tinnitus or hearing loss or both) or vestibular toxicity (causing ataxia, vertigo, nausea, vomiting and nystagmus). Reducing the serum levels may reverse the ototoxicity.

Orally administered vancomycin should be used with caution with cholestyramine or colestipol. These anion-exchange resins can bind vancomycin and reduce its effectiveness. If patients must take both drugs, doses should be administered several hours apart.

Concomitant use of parenteral vancomycin with other nephrotoxic drugs (e.g. aminoglycoside, cidofovir, foscavir, amphotericin B) can lead to additive nephrotoxicity.

RESISTANCE

There has been increasing concern about the emergence of vancomycin-resistant bacteria, especially enterococci. High-level resistance is mediated by a gene complex found on plasmids known as the VanA genotype. The phenotypic expression of vancomycin resistance (inducible and associated with teicoplanin resistance) is known as the VanA phenotype (see Chapter 189). The VanA phenotype is carried on a transposon designated as transposon (Tn) 1546, which carries clusters of seven genes that code for vancomycin resistance, five of which are required for the expression of the VanA phenotype. Intermediate-level resistance is mediated by the VanB gene cluster. These genes are transferable by conjugal plasmids and mediate the VanB resistance phenotype. Teicoplanin will not induce the expression of VanB resistance. Transfer of these genes between organisms can spread resistance.

This has led to recommendations by several governmental agencies to prevent vancomycin resistance. The guidelines from the Centers for Disease for Disease Control and Prevention in the USA state that vancomycin is not recommended for:

- routine surgical prophylaxis;
- treatment of single positive blood culture of coagulase-negative *Staphylococcus* spp.;
- empiric treatment of a febrile neutropenic patient in whom no evidence of Gram-positive infection exists;
- continued empiric therapy;
- selective decontamination of the gut;
- colonization with MRSA;
- primary treatment of pseudomembranous colitis;
- topical application or irrigation;
- treatment of methicillin-sensitive *Staphylococcus aureus* in dialysis patients;
- prophylaxis in continuous ambulatory peritoneal dialysis;
- systemic or local prophylaxis for indwelling central or local catheters; or
- Lyme disease.

TEICOPLANIN

Teicoplanin (formerly called teichomycin A) is a complex of five closely related glycopeptides that have the same heptapeptide base and an aglycone that contains aromatic amino acids, with D-mannose and *N*-acetyl-D-glucosamine as sugars, with a molecular weight of 1562–1891Da. Teicoplanin is structurally similar to vancomycin. It is produced from the actinomycete *Actinoplanes teichomyceticus*.

Teicoplanin is similar but not identical to vancomycin in its spectrum of activity. Minimum inhibitory concentrations (MICs) for most Gram-positive bacteria and anaerobes are comparable, but teicoplanin is less active against some strains of *Staphylococcus haemolyticus* (MIC 16–64mg/l compared to =4mg/l for vancomycin). Its ease of administration and its low toxicity potential make it a potential alternative to vancomycin for the treatment of Gram-positive aerobic and anaerobic bacteria, in both the immunocompetent and the immunocompromised host. In-vitro activity against most Gram-positive organisms is equal to or greater than that of vancomycin.

In both open and comparative clinical trials, teicoplanin has been well tolerated, and adverse reactions have rarely prompted discontinuation of treatment. Nephrotoxicity caused by teicoplanin is uncommon, even when it is used concomitantly with aminoglycosides or cyclosporin A. Favorable pharmacokinetics allow for intramuscular administration as well as intravenous bolus dosing and, after appropriate loading doses, maintenance therapy may be given on a once-daily basis. The combination of all of these factors makes teicoplanin an effective, safe alternative to vancomycin in the treatment of Gram-positive infections. Although it is widely used in Europe, it is still yet to be approved by the Food and Drug Administration in the USA.

PHARMACOKINETICS AND DISTRIBUTION

Teicoplanin binds to the terminal D-alanine-D-alanine sequence of peptides that form the bacterial cell wall and, by sterically hindering the transpeptidase and transglycosylation reaction, inhibits the formation of peptidoglycan. Teicoplanin is a large polar molecule and, as

it cannot penetrate the lipid membrane of Gram-negative bacteria, they are resistant to it (see Chapter 188). Enterococci expressing VanA (high-level) vancomycin resistance are also resistant to teicoplanin. Teicoplanin is not significantly absorbed from the gastrointestinal tract but it can be administered intravenously or intramuscularly, in a once-daily dosing schedule. It has a long half-life of approximately 47 hours, allowing for once-daily dosing once therapeutic serum levels are attained. In a study in which healthy volunteers were given intravenous injections of teicoplanin, doses of 3mg/kg gave average peak plasma concentrations of 53.5µg/ml and doses of 6mg/kg gave average peak plasma concentrations of 111.8µg/ml.[15] Bioavailability after intramuscular injection of teicoplanin is 90%, with peak plasma concentration occurring 2 hours after injection.[15]

Teicoplanin is approximately 90% protein-bound. It is more lipophilic than vancomycin and has excellent penetration into tissues and tissue fluids with a large volume of distribution after intravenous administration. High concentrations are achieved in peritoneal and blister fluid, bile, liver, pancreas, mucosa and bone. [16] Penetration into cerebrospinal fluid across uninflamed meninges is poor.

Teicoplanin does not undergo extensive metabolism and is excreted almost entirely by the kidneys.[17] As with vancomycin, its half-life is prolonged by renal failure.[18] Neither hemodialysis nor peritoneal dialysis significantly affects the clearance of teicoplanin.

ADMINISTRATION AND DOSAGE

Dosing recommendations for adults who have normal renal function have been based both on pharmacokinetic properties and on results of open and comparative clinical trials. A single loading dose of 400mg on the first day followed by maintenance doses of 200mg/day (3mg/kg/day for pediatric dose) appears adequate for the treatment of urinary tract infections, skin and soft tissue infections and lower respiratory tract infections. For serious infections, including endocarditis, osteomyelitis and sepsis, it is necessary to maintain serum concentrations of teicoplanin at 10µg/ml or more.[19]

Treatment of endocarditis caused by *Staph. aureus* has been difficult with teicoplanin, especially when used as monotherapy. [19] [20] In these cases, it is recommended that an aminoglycoside should be added and that teicoplanin trough levels should be maintained in the range of 20–60µg/ml.

INDICATIONS

The indications for the use of teicoplanin are similar to those for vancomycin (Table 199.4). They include Gram-positive infections caused by strains that are resistant to penicillin, cephalosporin or methicillin, or Gram-positive infections in patients who are allergic to penicillin. In addition, teicoplanin may be used for subacute bacterial endocarditis or surgical prophylaxis, in patients who are allergic to ß-lactam drugs and as an alternative to vancomycin or metronidazole in the treatment of pseudomembranous colitis caused by *C. difficile* (approved in Europe).

Teicoplanin, alone or in combination with other antibiotics, has proved effective in the treatment of various Gram-positive infections, including sepsis, endocarditis, skin and soft tissue infections, osteomyelitis and lower respiratory infections. It has also been found to be effective in both prophylaxis and treatment of Hickman catheter infections in immunocompromised patients.[21] [22] Specially prepared catheters loaded with teicoplanin have been developed and tested *in vitro* and have been shown to prevent bacterial colonization for at least 48 hours, thus showing promise for inhibiting early-onset catheter infections.[23] Teicoplanin has also been used along with other

TABLE 199-4 -- Indications for the use of teicoplanin.

INDICATIONS FOR THE USE OF TEICOPLANIN	
Infections with:	*Staphylococcus* spp., including methicillin-resistant strains
	Streptococcus spp., *Streptococcus agalactiae, Streptococcus bovis, Streptococcus pneumoniae, Streptococcus pyogenes* and *viridans* streptococci
	Enterococci
	Clostridium spp., including *Clostridium difficile*
	Corynebacterium spp., including *Corynebacterium jeikeium*
The following types of infection with the above organisms:	Sepsis
	Endocarditis
	Skin and soft tissue infections
	Osteomyelitis
	Lower respiratory tract infections
	Diarrhea associated with *Clostridium difficile*
	Nosocomial intravascular catheter infections (prophylaxis and treatment)

antibiotics for empiric treatment of febrile neutropenic patients and in the treatment of documented Gram-positive infections in neutropenic patients.[24] [25]

Oral teicoplanin is as effective as vancomycin in the treatment of diarrhea associated with *C. difficile*. A 10-day course of regimen of 100mg oral teicoplanin q12h was found to be as effective as 500mg oral vancomycin q6h.[26] Again, the risk of glycopeptide resistance development argues for the use of metronidazole for routine

therapy for *C. difficile* associated diarrhea (see Chapter 44).

DOSAGE IN SPECIAL CIRCUMSTANCES

A dosage nomogram for teicoplanin has been designed,[27] based on the relationship between teicoplanin clearance and creatinine clearance and an average desired steady-state concentration of 20µg/ml. Although intravenous teicoplanin penetrates well into peritoneal fluid in normal patients, it does not penetrate well into the effluent of continuous ambulatory peritoneal dialysis patients and is not recommended for the treatment of peritonitis in these patients. Intraperitoneal teicoplanin has been effective in continuous ambulatory peritoneal dialysis patients who have Gram-positive peritonitis, however.

Another regimen for renal impaired patients includes a normal loading dose followed by doubling the dosage interval for patients who have a creatinine clearance of 30–80ml/minute and tripling the dosage interval for patients who have severe renal impairment (creatinine clearance <10ml/minute).

ADVERSE REACTIONS AND INTERACTIONS

Teicoplanin is generally well tolerated at therapeutic dosages, with side effects occurring in approximately 6–13% of the patients (Table 199.5).

Side effects (including nephrotoxicity) with teicoplanin are consistently less common than with vancomycin, even when teicoplanin is used concomitantly with aminoglycosides.[22] [24] The incidence of red man syndrome or anaphylactoid reactions caused by teicoplanin administration is exceptionally low.

The commonest side effects were injection site intolerance, skin rash, bronchospasm and eosinophilia. Nephrotoxicity and ototoxicity are uncommon.

TABLE 199-5 -- Adverse reactions to teicoplanin.

ADVERSE REACTIONS TO TEICOPLANIN	
Hypersensitivity	Skin rash
	Bronchospasm
	Anaphylaxis
Biochemical abnormalities	Increased liver function tests
Hematologic abnormalities	Eosinophilia
Local intolerance	Redness, pain (after intramuscular administration), phlebitis (after intravenous administration)
Non-specific reactions	Nausea
	Diarrhea
	Dizziness
	Tremor

Like vancomycin, teicoplanin is bound and inactivated by bile binding resins such as cholestyramine.[28]

DAPTOMYCIN

Daptomycin is a ovel cyclic lipopeptide antibiotic derived from *Streptomyces roseosporus*. Its mechanism of action is not very well elucidated yet, but it is different from that of vancomycin and teicoplanin. It exerts bactericidal activity against Gram-positive organisms by binding to cell membranes in the presence of free ionized calcium.

Daptomycin has a relatively long plasma half-life, approximately 8.5 hours, which allow for once-daily administration; it is highly protein-bound.

The in-vitro spectrum of activity includes most aerobic and anaerobic Gram-positive bacteria, including vancomycin-resistant *Enterococcus*, vancomycin-intermediate *Staph. aureus*, methicillin-resistant *Staph. aureus* and *Staph. epidermidis*, penicillin-resistant pneumococcus, *C. difficile*, *Clostridium perfringens* and *Bacillus anthracis*.[29]

Resistance in naturally occurring *S. aureus* is unusual.

As of February 2002, phase III studies documented daptomycin's good tolerability and efficacy compared with vancomycin and antistaphylococcal penicillin. The adverse event profile of 4mg/kg/day was similar to that of the standard dose of vancomycin.

Daptomycin may have an advantage over vancomycin, by virtue of its faster killing of *Staph. aureus* in vitro.[30]

ORITAVANCIN

Another glycopeptide in phase III studies, oritavancin differs from vancomycin by the addition of a lipophilic side chain (*N*3'-chlorobiphenyl) and of an aminated sugar (22-*O*-4-epivancosamine). This results in strongly amphiphilic molecule, which improves its ability to penetrate eucaryotic cells (e.g. macrophage) for better intracellular bactericidal activity.

Oritavancin is highly bound to human plasma protein (86–90%), and has a long terminal half-life, offering the potential of shorter treatment duration. [31] It is active against a broad range of Gram-positive organisms, including MRSA and vancomycin-resistant *Enterococcus*.

A double-blind controlled study in 517 patients who had complicated skin and skin-structure infection compared oritavancin 1.5mg/kg or 3 mg/kg for 3–7 days followed by oral placebo, versus vancomycin for 3–7 days followed by oral cephalexin, for a total therapy course of 10–14 days. At the conclusion of the study the three arms were comparable in efficacy and tolerability.[32]

Chapter 200 - Tetracyclines and Chloramphenicol

Kjell Alestig

TETRACYCLINES

INTRODUCTION

In 1948, Benjamin Duggar at the Lederle Laboratories isolated the first tetracycline, chlortetracycline, from a drop of Missouri mud containing a fungus producing a golden pigment. The fungus was therefore called *Streptomyces aureofaciens* and the antibiotic aureomycin.

In 1950 oxytetracycline was isolated from a strain of *Streptomyces rimosus* by workers at Charles Pfizer & Co. and in 1953 tetracycline was produced semisynthetically from chlortetracycline. Demeclocycline, derived from a mutant strain of *S. aureofaciens*, was introduced in 1957 and in the following years the semisynthetic derivatives rolitetracycline and methacycline were also introduced. A so-called second generation of long-acting tetracyclines, doxycycline and minocycline, were synthesized in 1966 and 1972 respectively.

Chemically, the tetracyclines have the structure of a hydronaphthacene nucleus containing four fused rings. The specific analogues are obtained by substitutions on the fifth, sixth or seventh position of the basic structure (Fig. 200.1).

Figure 200-1 Molecular structure of some tetracyclines.

Tetracyclines are mainly bacteriostatic and they act by binding to the 30S subunits of the ribosomes in susceptible micro-organisms, thereby inhibiting protein synthesis.

There are few reasons to use any of the older tetracyclines; doxycycline and to some extent minocycline should be preferred because they are better absorbed and distributed than the older drugs. However, one exception may be that dermatologists often seem to prefer tetracycline or another first-generation drug for the treatment of acne.

ANTIMICROBIAL SPECTRUM

When they were introduced the tetracyclines were effective against a variety of Gram-positive bacteria and Gram-negative organisms within the Enterobacteriaceae group. Development of resistance has, however, led to restricted use of the drugs for infections caused by streptococci, staphylococci, *Escherichia coli* or *Proteus* spp. More important now is the tetracyclines' good activity against *Mycoplasma*, *Chlamydia* and *Rickettsia* spp., *Borrelia* spp. (especially *Borrelia burgdorferi*) and *Propionibacterium acnes* (Table 200.1).[1]

Doxycycline and minocycline often have a better activity in vitro than the other tetracyclines[2] [3] but the differences are probably of little practical importance for clinical treatment.

TABLE 200-1 -- Resistance against tetracyclines.

RESISTANCE AGAINST TETRACYCLINES	
Generally susceptible species	*Mycoplasma pneumoniae*
	Ureaplasma urealyticum
	Chlamydia spp.
	Rickettsia spp.
	Brucella spp.
	Francisella tularensis
	Propionibacterium acnes
	Borrelia burgdorferi
	Yersinia spp.
Resistance common (great variations between countries)	Streptococci
	Staphylococci
	Enterobacteriaceae
	Haemophilus influenzae
	Meningococci
	Gonococci
	Legionella pneumophila
Resistance usually found	Enterococci
	Proteus spp.
	Pseudomonas spp.
	Serratia spp.
	Bacteroides spp.

RESISTANCE

Oral therapy with tetracyclines has a marked influence on the bowel flora and resistant strains may be quickly selected. This risk is somewhat reduced with doxycycline,[4] which is nearly completely absorbed.[5] Extensive use of tetracyclines leads to plasmid-mediated multiresistance, but chromosomal alterations may also occur.

Tetracyclines have been widely used in the veterinary field, not only to cure infections but also as a food additive to promote the growth of newborn animals. Penicillin and tetracyclines are not now permitted as growth stimulators within the European Union but are still used in the USA. In pigs, antibiotics promote an increase in weight of 8% and pigs are ready for slaughter 3 weeks earlier than animals that have not received antibiotics — an important economic advantage. This misuse of antibiotics is probably one important reason for the worldwide spread of tetracycline resistance within the Enterobacteriaceae group.[6] [7] [8] However, restrictions on the veterinary use of antibiotics have now been introduced in some countries. In Sweden the use of any antibiotic to promote the growth of animals was prohibited as early as in 1986, and similar legislation for the whole European Union is expected within the next few years.

Resistance to tetracyclines is now common among bacteria causing respiratory infections such as pneumococci, *Haemophilus influenzae* and *Moraxella catarrhalis*.[9]

PHARMACOKINETICS AND DISTRIBUTION

Clinical pharmacokinetics

After oral administration tetracyclines are absorbed from the stomach and the small intestine. Absorption is usually highest in the fasting state, but doxycycline and minocycline are also well absorbed with food. The degree of absorption and other pharmacokinetic parameters for some of the derivatives are shown in Table 200.2 . The usually nearly complete absorption of doxycycline salts is reduced if the gastric pH is increased, as can occur in people who have atrophic gastritis or be caused by acid-reducing drugs. In some countries doxycycline is available in tablets bound to a polysaccharide, carragenate, which has been shown to increase absorption at higher pH.[10] There are also gelatin capsules available containing coated pellets of doxycycline hydrochloride that are resistant to gastric acid so that absorption will occur in the duodenum.[11]

Distribution

The tissue distribution of tetracyclines is clearly related to their different lipid solubility, which is higher for doxycycline than for

TABLE 200-2 -- Pharmacokinetics of some tetracyclines.

PHARMACOKINETICS OF SOME TETRACYCLINES			
	Tetracycline	**Doxycycline**	**Minocycline**
Oral absorption in fasting state (%)	80	90–93	100
Serum half-life (h)	6–12	18–22	13
Serum protein binding (%)	24–65	80–90	55–75
Lipid solubility in comparison with tetracycline	1	5	10
Excretion in urine (%) after oral administration	20	35–40	4–9

all older tetracyclines. Doxycycline concentrations are therefore sufficient for treatment in the respiratory tract and lung tissue, the bile and the genital tract of both sexes.[12] [13] Levels achieved in the central nervous system (CNS) are increased in chronic meningeal inflammation,[14] enabling treatment of neuroborreliosis. [15] [16]
Tetracyclines cross the placenta and bind to metal ions in fetal bone and teeth. They are also excreted in human milk.

Minocycline is even more lipid-soluble than doxycycline. This may not be an advantage because side effects such as vertigo and other CNS symptoms may be caused by increased drug concentrations in the cerebrosides of the brain. [17]

Elimination

Tetracyclines are metabolized in the liver in small amounts only, chlortetracycline being an exception with rapid metabolism. However, inducers of liver enzymes such as diphenylhydantoin may cause some metabolism of doxycycline. There is biliary excretion of tetracyclines to a varying degree and possibly enterohepatic circulation.

Tetracyclines are partly excreted by glomerular filtration. For minocycline this excretion is less than 10% but it is more than 50% for tetracycline.

Incomplete absorption will contribute to high concentrations in feces for the older tetracyclines. Only a small fraction of doxycycline is found in active form in feces, the larger part being bound as chelate.

Doxycycline may be given in normal doses to patients who have renal insufficiency and to those undergoing hemodialysis as the reduced renal excretion is compensated for by intestinal excretion of bound substance.[18] For minocycline, caution is recommended because of a larger risk of side effects.

ROUTE OF ADMINISTRATION AND DOSAGE

Peak serum levels after an oral dose of 500mg tetracycline or 200mg of doxycycline or minocycline are usually 3–5mg/l after 2 hours. Half-life in serum is longest for doxycycline (16–18 hours), followed by minocycline (11–13 hours) and tetracycline (8 hours). Doxycycline and minocycline can therefore be given once daily. A higher starting dose on day 1 is recommended in order to achieve a steady state level of the drug as early as possible. Dosages for adults are given in Table 200.3 .

Doxycycline is also available for intravenous infusions but there is little difference in serum levels compared with oral administration.

DOSAGE IN SPECIAL CIRCUMSTANCES

In patients who have renal insufficiency or disease, doxycycline is the only tetracycline that can be used safely without risk of accumulation and toxicity.

TABLE 200-3 -- Usual adult dosages for some tetracyclines.

USUAL ADULT DOSAGES FOR SOME TETRACYCLINES		
General name	**Oral preparations**	
	First dose	**Common dosage**
Tetracycline	500mg	500mg q6h
Oxytetracycline	500mg	500mg q6h
Doxycycline	200mg	100mg q24h
Minocycline	200mg	100mg q12h
Doxycycline and minocycline may be given intravenously in the same doses. Higher doses of doxycycline are often used for sexually transmitted diseases and Lyme disease.		

In patients who have hepatic disease tetracyclines should generally be avoided. If treatment is important, liver tests should be performed repeatedly during treatment. However, toxicity has mostly been observed when older tetracyclines have been used at high doses or given during pregnancy.

During pregnancy tetracyclines should be avoided because of the depressive effect on the skeleton of the child. In lactating patients a small amount of a tetracycline is excreted in the milk but is harmless to the baby.

In elderly patients kidney function is reduced according to age and the daily dose of a tetracycline should be reduced unless doxycycline is used.

INDICATIONS

Respiratory infections

Tetracyclines were first used for many types of respiratory tract infection. Because of increasing resistance in pneumococci and *H. influenzae*, they have been replaced in many areas by other antibiotics, mainly ß-lactams.

Exacerbation of chronic bronchitis has been a classic indication for tetracyclines. Doxycycline has been found to be as effective as ampicillin. The advantage of one single dose per day may increase compliance in patients who have chronic respiratory diseases and many other medications (see Chapter 33).

Doxycycline is distributed to maxillary sinuses and can be used as a second-line drug in patients who have sinusitis and are allergic to ß-lactams or in whom treatment with such drugs has failed.

Tetracyclines have good activity in pneumonias caused by *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia psittaci* and *Coxiella burnetii*. Macrolides probably have an equal effect in infections caused by *M. pneumoniae* but clinical experience with the other infections is far greater with tetracyclines.

Sexually transmitted diseases

Tetracyclines are effective therapy for nongonococcal urethritis caused by *Chlamydia trachomatis* or *Ureaplasma urealyticum*. In an open evaluation of doxycycline in the treatment of urethritis and cervicitis caused by *C. trachomatis* the symptoms disappeared in 76%.[18] Treatment should usually be given for 10 days and concurrent treatment of sexual partners is recommended (see Chapter 74).

Tetracyclines are usually effective for the treatment of lymphogranuloma venereum and granuloma inguinale. Non-penicillinase-producing strains of gonococci are sensitive, which is an advantage in mixed infections with *C. trachomatis*.

Tetracyclines can be used as alternative therapy for syphilis in penicillin-allergic patients. Treatment time is 15 days for early disease and 30 days for later stages of the disease.

Lyme disease and ehrlichiosis

Doxycycline can be used in penicillin-allergic patients to treat erythema migrans and is as effective as penicillin in a dose of 200mg daily for 10 days. In erythema migrans with signs of dissemination such as multiple erythema and fever, doxycycline is often recommended as the primary drug. Treatment of neuroborreliosis with doxycycline 200mg daily for 2 weeks has given similar results to those achieved with penicillin G (see Chapter 54). [19]

Doxycycline is also the preferred drug for infections due to *Ehrlichia* spp (see Chapter 14).[20]

Other indications

Tetracyclines are very effective drugs for rickettsial infections (see Chapter 14). Doxycycline has been used for single-dose treatment of louse-borne typhus, but for other infections 7–10 days of treatment is usually needed. These infections can only be treated with tetracyclines or chloramphenicol. In children tetracyclines can often be given with minimal risk of staining the teeth if repeated treatments are avoided and the dose is kept as low as possible.

Doxycycline is also effective in a single dose for infections with *Borrelia recurrentis*. Tetracyclines are usually used in combination with other antibiotics such as streptomycin or rifampin (rifampicin) for brucellosis and tularemia.

For cholera in adults, tetracycline 500mg q6h for 5 days or a single dose of 300mg doxycycline have been recommended.[21]

Most tetracyclines have been used for oral treatment of chronic acne. The drugs have an antibacterial effect on *P. acnes* but also a general anti-inflammatory effect, which is probably of importance.[22] However, resistance of *P. acnes* to tetracyclines, including doxycyclines, has been reported from England and the USA. Cross-resistance does not include minocycline, which may be used clinically.[23]

Doxycycline may also be used for malaria prophylaxis in areas where *Plasmodium falciparum* is resistant to other antimalarial drugs.[24]

ADVERSE REACTIONS AND INTERACTIONS

Adverse drug reactions

All oral preparations of tetracyclines can cause nausea and epigastric discomfort. It is usually an advantage if the drugs can be taken with food without decreasing absorption, as with doxycycline and minocycline. Diarrhea is less common but may occur, especially when tetracyclines with low absorption are used.

Phototoxic reactions can occur with all tetracyclines.

Tetracyclines should not be used in children aged 8 years or less because of the risk of enamel hypoplasia and tooth discoloration. They should also not be used during pregnancy. Tetracyclines, except doxycycline, are contraindicated in patients who have renal impairment, because inhibition of protein synthesis increases azotemia from amino acid metabolism.

Vertigo and dizziness are CNS symptoms that occur with minocycline only and must be considered a major disadvantage of that antibiotic.

Hepatotoxicity and other severe organ reactions have occurred, mainly after parenteral therapy — often with high doses — and also when the drugs have had to be used during pregnancy.

Drug-drug interactions

Tetracyclines form chelate complexes with many drugs containing metal ions (Table 200.4). When combined with diuretics the risk of accumulation of urea increases, with the exception of doxycycline. Some drugs seem to stimulate liver enzymes, so increasing doxycycline metabolism and shortening its half-life.

TABLE 200-4 -- Drug interactions with tetracyclines.

DRUG INTERACTIONS WITH TETRACYCLINES	
Interacting drug	**Effect**

Antacids with metal ions, calcium, zinc, iron, didanosine	Chelate formation and impaired absorption
Diuretics	Risk of increased serum urea concentration — not with doxycycline
Rifampin, phenobarbital, phenytoin, carbamazepine	Half-life of doxycycline shortened

CHLORAMPHENICOL

INTRODUCTION

Chloramphenicol was first isolated in 1947 from a sample of soil from Venezuela and the actinomycete was called *Streptomyces venezuelae*.

MODE OF ACTION AND SPECTRUM

Chloramphenicol inhibits protein synthesis by binding to the larger 50S subunit of the 70S ribosome. It is mainly a bacteriostatic agent but a bactericidal effect on some bacteria, such as *H. influenzae*, *Streptococcus pneumoniae* and *Neisseria meningitidis*, has been reported.

Chloramphenicol has a very broad spectrum, similar to that of tetracyclines, and it includes aerobic and anaerobic bacteria, spirochetes, rickettsias, chlamydias and mycoplasmas. It is very active against most anaerobic bacteria of clinical interest, including *Bacteroides fragilis*.

Chloramphenicol resistance can occur and is mediated by a bacterial enzyme, acetyltransferase, which inactivates the drug. This mechanism is R-factor-mediated, and epidemics of chloramphenicol-resistant typhoid fever and *Shigella* infections have occurred.

Unrestricted use of chloramphenicol seems to result in a resistance problem very similar to that observed with tetracyclines.

ROUTE OF ADMINISTRATION AND DOSAGE

Chloramphenicol is conjugated with glucuronic acid and is then excreted in active form by the kidneys. The metabolites are not toxic and dose reduction is not needed in renal insufficiency.

Chloramphenicol is a rather small lipophilic molecule and is well distributed in the body. The serum protein binding is about 44%. It reaches the CNS better than most other antibiotics and its concentration in the cerebrospinal fluid is often 30–50% of the serum concentration. Chloramphenicol also crosses the placenta and is found in breast milk.

Chloramphenicol is well absorbed (over 90%) after oral administration. Chloramphenicol 1g gives a serum concentration of 10mg/l and the half-life is 3–4 hours. It may also be given intravenously as a succinate ester but intramuscular injections should be avoided as absorption is unreliable.

INDICATIONS

Chloramphenicol is toxic and therefore it should be used carefully in systemic infections, when other alternatives are lacking. It can be used instead of tetracyclines for the treatment of rickettsial infections and for bacterial meningitis in the few patients who have an allergy to ß-lactam drugs that includes third-generation cephalosporins and meropenem. It may also have a place as an oral alternative for CNS infections, especially brain abscesses.

Topical administration of chloramphenicol in drops or ointments is widely used for superficial bacterial infections of the eyes. Such treatment is still effective in comparison with the newer drugs such as quinolones or fusidic acid, which are also used locally for eye infections.[25] [26]

ADVERSE REACTIONS AND INTERACTIONS

Adverse drug reactions

Neonates have a diminished ability to conjugate chloramphenicol and to excrete the active form in the urine. A dose of 25mg/kg/day should not be exceeded[27] otherwise the 'gray baby syndrome' may develop, with severe cyanosis and circulatory collapse.

Dose-related reversible bone marrow depression can occur in adults given high doses of more than 4g/day. The daily dose should not exceed 3g, and when the accumulated dose exceeds 25g reticulocytes should be checked regularly (e.g. twice weekly) until treatment is stopped.

A very severe reaction is aplastic anemia, which occurs with a frequency of 1/25,000–40,000 treatment courses.[28] No clear correlation to dose or duration of treatment has been observed and no route of administration is exempt from causing this catastrophic complication. There are also reports to indicate that the use of chloramphenicol may increase the risk of leukemia in children.[29]

Drug-drug interactions

As chloramphenicol is almost completely metabolized in the liver by cytochrome P450 enzymes, there is a possible risk of interactions with other drugs if they are metabolized by the same enzyme system. Chloramphenicol will decrease the rate of metabolism of tolbutamide, phenytoin, cyclophosphamide and warfarin. Rifampin may lower chloramphenicol concentrations by induced metabolism.

Chapter 201 - Nitroimidazoles: Metronidazole, Ornidazole and Tinidazole

S Ragnar Norrby

INTRODUCTION

The nitroimidazoles were developed as antimicrobial agents against protozoa, initially *Trichomonas vaginalis* and subsequently *Entamoeba histolytica* and *Giardia lamblia*. During the 1970s it was recognized that they are also highly active against strictly anaerobic bacteria, including difficult-to-treat organisms such as *Bacteroides fragilis* and *Clostridium difficile*. The mechanism(s) by which nitroimidazoles exert their antiprotozoan and antibacterial activities are not known in detail. It seems clear, however, that, after anaerobic reduction, the various derivatives interact with DNA and possibly other metabolic processes in bacteria and protozoa.[1] [2] Although they are still used against protozoa, anaerobic infections and, recently, treatment of gastric ulcer caused by *Helicobacter pylori* have become the main indications for the nitroimidazoles. In addition they have also been used as radiosensitizing agents in patients who have solid tumors.

The nitroimidazoles that are available are metronidazole, tinidazole and ornidazole, but tinidazole and ornidazole are not available in the USA. In this chapter, the emphasis will be on metronidazole.

PHARMACOKINETICS

Following oral administration all nitroimidazoles are almost completely absorbed.[3] After rectal administration of metronidazole the absorption is estimated to be about 60%, with considerable variability between individuals. When given vaginally the bioavailability of metronidazole is 20% or less. Following a 400mg oral dose of metronidazole or tinidazole, peak plasma concentrations of about 10mg/l are achieved after 3–5 hours. Dose proportional kinetics have been seen for doses up to 2g. The concentrations after normal oral doses are well above the minimum inhibitory concentrations (MICs) for anaerobes but are borderline for *Gardnerella vaginalis*.

The nitroimidazoles are well distributed to peripheral compartments, including brain tissue and cerebrospinal fluid.[3] However, there are low concentrations (15% or less of concurrent serum levels) in subcutaneous fat.[4]

Nitroimidazoles are eliminated mainly via liver metabolism. The plasma half-life is about 8 hours for metronidazole and 12–13 hours for tinidazole. Metronidazole is partly metabolized to hydroxymetronidazole, which has a longer half-life (10–13 hours). Metronidazole elimination is prolonged in newborns and infants, and also in adults who have serious liver impairment (e.g. cirrhosis). Decreased renal function does not affect the half-life. The drugs are partly eliminated by hemodialysis. These antibiotics have no reported effects per se on the central nervous system, liver, lungs, kidneys, prostate or genitourinary system.

ROUTE OF ADMINISTRATION AND DOSAGE

The two most frequently used nitroimidazoles, metronidazole and tinidazole, are available for parenteral and oral use and also as suppositories and for vaginal administration. A metronidazole gel is used

TABLE 201-1 -- Dosages of metronidazole.

DOSAGES OF METRONIDAZOLE			
Type of infection	**Adult dose**	**Child dose**	**Duration of treatment (days)**
Trichomoniasis	2g	Not applicable	Single dose
Giardiasis	600mg q12h	15mg/kg q12h	6–7 days
Amebic dysentery	800mg q8h	20mg/kg q12h	5–10 days
Amebic abscess	800mg q8h	20mg/kg q12h	10 days
Vaginosis	400mg q12h	Not applicable	7 days
Helicobacter infection	400mg q8h	Not applicable	7–14 days
Clostridium difficile enteritis	800mg q8h	7.5mg/kg q12h	7–10 days
Anaerobic infections (treatment)	800mg q8h	7.5mg/kg q12h	7–14 days
Anaerobic infections (prophylaxis)	800mg	7.5mg/kg	Single dose
Child dose is for children aged 8 weeks or more.			

for periodontitis. Dosages of metronidazole are given in Table 201.1 . Those of tinidazole and ornidazole are similar but, because their half-lives are longer, these drugs can be given q24h or q12h instead of q12h or q8h. Recommendations in the USA are normally for shorter dose intervals (i.e. q6h) for metronidazole than are indicated in Table 201.1 . Considering the half-life, dose intervals shorter than q8h should not be needed and in most cases q12h regimens should be optimal.

In elderly patients the same doses should be used as in younger adults. Doses should be reduced in patients who have reduced liver function but full doses can be given irrespective of renal function. Metronidazole passes to breast milk but the concentrations achieved are unlikely to affect a child. There is no documentation on the use of metronidazole during pregnancy.

INDICATIONS

Bacterial infections

The spectrum of activity of nitroimidazoles against strictly anaerobic bacteria is summarized in Table 201.2 . No clinically important differences exist between the antianaerobic activities of the various derivatives in the group.[7] Nitroimidazoles are the most active antibiotics for the treatment and prevention of anaerobic infections and resistance is rare but has been reported.[8] However, their disadvantage is their lack of activity against aerobes. As anaerobic infections, with few exceptions, are mixed aerobic/anaerobic infections, nitroimidazoles are routinely combined with other antibiotics. The most common combinations are with cephalosporins or aminoglycosides. Anaerobic infections for which nitroimidazole use is well documented are brain

** Data from Wexler et al.[5] and Spangler et al.[6]*

abscesses, intra-abdominal infections, gynecologic infections and antibiotic-associated diarrhea or colitis caused by *C. difficile*. For the latter infection, metronidazole should be preferred over oral vancomycin, which might increase the risk of selection of resistant Gram-positive aerobic bacteria (e.g. enterococci) in the lower intestinal tract.

Two bacterial species that are not obligate anaerobes have also been found to be sensitive to metronidazole treatment:

- *G. vaginalis*, implicated in the etiology of vaginosis, is susceptible to nitroimidazoles with MIC values higher (8–16mg/l) than for anaerobes;[9] and
- *H. pylori*, which causes gastric ulcers and has been correlated to gastric cancer, is often susceptible to nitroimidazoles. Metronidazole is one of several antibiotics that, in combination with other antibiotics, can be used for treatment of gastric ulcers caused by *H. pylori* despite the fact that resistance to metronidazole is not uncommon.[10]

Protozoal infections

The nitroimidazoles seem to be uniformly active against protozoa. However, resistance has been reported in *T. vaginalis* and in some cases the organisms have been resistant to metronidazole but more sensitive to tinidazole.[11] Nitroimidazoles are first-line treatment for giardiasis, amebiasis and trichomoniasis. For these infections there are few alternatives outside this group.[12] This is also the case for bacterial vaginosis.[13]

ADVERSE REACTIONS AND INTERACTIONS

Although nitroimidazoles have been found to be mutagenic and carcinogenic in animal studies, they are generally well tolerated in humans. One meta-analysis of more than 1300 pregnant women who had received metronidazole during their pregnancies showed no indication of teratogenicity.[14] The most common side effect is a metallic taste, especially when high doses are used. Reversible neuralgia has been reported in patients receiving high doses for prolonged periods. If combined with alcohol, metronidazole may cause an Antabuse-like reaction. Severe psychotic reactions have been reported in patients receiving metronidazole and disulfiram together, and so nitroimidazoles should not be given with disulfiram.

Chapter 202 - Antituberculosis Agents

John M Grange
Alimuddin Zumla

INTRODUCTION

Tuberculosis is at least as old as recorded human history, and a major preoccupation of the medical profession over the millennia has been the search for a cure for this 'Captain of all of these Men of Death', as the evangelist John Bunyan termed it. Numerous remedies have been described; many, such as bleeding, purging and John of Gaddeston's prescription of a mixture of pigeon's dung and weasel's blood were undoubtedly worse than useless. In 1782, Sir William Buchan remarked that, apart from a trip to the West Indies, milk was probably as effective as the entire pharmacopeia. In the Indian ayurvedic medical system, the malabar nut (*Adhatoda vasica*) was advocated and several British military doctors of the 19th century were impressed with its efficacy. In Europe, cod liver oil was widely used after its introduction by Percival in 1770; indeed, it was the most widely prescribed remedy at the Brompton Hospital for Consumptives, London, for several decades after its foundation in the mid-19th century. Owing to its high vitamin D content, it may well have had a positive effect because calcitriol, the active metabolite of this vitamin, is involved in the activation of human macrophages.

The discovery of the tubercle bacillus raised serious hopes that an effective remedy would soon be found and many workers attempted to develop immunotherapeutic agents. The best known of these attempts was Robert Koch's development of old tuberculin, but the British bacteriologist Sir Almroth Wright also conducted extensive studies, which are immortalized in George Bernard Shaw's play *The Doctor's Dilemma*.

It was, however, the discovery of streptomycin in 1944 by Albert Schatz and Selman Waksman in the USA that opened the door to effective therapy and led many health workers to believe that the disease would soon be conquered. Early jubilation turned to disappointment when it was found that patients treated with streptomycin often made an initial improvement but soon relapsed with disease because their tubercle bacilli became resistant to this agent. Fortunately, other active antituberculosis agents were soon discovered and, as a result of extensive trials initiated by Sir John Crofton in the UK, multidrug regimens that cured patients and prevented the emergence of drug resistance were developed.[1]

Therapy of tuberculosis with these early drug regimens, usually consisting of streptomycin, isoniazid and *para*-aminosalicylic acid, was beset with problems. Streptomycin had to be given by injection and *para*-aminosalicylic acid caused such severe gastrointestinal effects that patients often failed to comply with therapy. In addition, it was necessary to treat patients for 18–24 months in order to achieve a cure.

The second therapeutic revolution came in the early 1970s when regimens containing rifampin (rifampicin) were developed. The introduction of this drug had three major effects on the treatment of tuberculosis. First, the duration of therapy could be reduced to only 6 months so that the era of 'short course' therapy had arrived. Secondly, regimens could be entirely oral ones and thirdly, as a consequence, hospitalization could often be avoided.

Modern short course therapy, properly used, can achieve a cure in around 98% of patients and is among the most effective and cost-effective of all therapeutic interventions for a chronic disease.[2] Far from being conquered, however, tuberculosis remains one of the most prevalent causes of mortality and morbidity; it is responsible for one in seven deaths among young adults and it was declared a global emergency by the World Health Organization (WHO) in 1993. The problem is currently fueled by the HIV pandemic and the increasing prevalence of multidrug-resistant tuberculosis (MDRTB), and there is accordingly a very urgent need to develop new therapies and to use the available therapies in a much more responsible manner.

CLASSIFICATION

Antituberculous agents can be classified in several ways (Table 202.1). First, they can be divided into those that are synthetic molecules and those that are antibiotics or semisynthetic antibiotic derivatives. Second, they can be divided into agents with a broad spectrum of activity and use and those only active against mycobacteria or, specifically, members of the *Mycobacterium tuberculosis* complex. Third, they can be divided into the first-line drugs that form the basis of the modern short-course regimens advocated by the WHO and the second-line drugs, which are used in cases of drug resistance and where toxic reactions prevent the use of one or more first-line drugs. Finally, they can be divided into bacteriostatic and bactericidal agents, with the latter being further divided into those that are bactericidal in vitro and those that are able to sterilize lesions of tubercle bacilli in vivo (Table 202.2). This distinction is a clinically important one.

MODE OF ACTION AND PHARMACOKINETICS

Previously poorly understood, there have been considerable advances in recent years in our understanding of the genetic basis of action of the drugs used specifically for treating mycobacterial disease as a result of the successful sequencing of the genome of *M. tuberculosis*.[3]

The targets of streptomycin and other aminoglycosides, rifampin and the fluoroquinolones are the same in mycobacteria as in *Escherichia coli*, and resistance is due to single amino acid substitutions in the target proteins. Some other drugs, notably isoniazid, pyrazinamide, ethambutol, ethionamide and prothionamide, target specific components of the complex and lipid-rich mycobacterial cell wall. The mode of action and target genes are discussed under the individual drug headings below and are summarized in Table 202.3 ; the targets are shown in Figure 202.1 . Most of the antituberculosis agents are readily absorbed from the gastrointestinal tract. Exceptions are streptomycin and other aminoglycosides, capreomycin and viomycin, which must therefore be given parenterally. Binding to serum proteins varies from agent to agent, as does entry into the cerebrospinal fluid (CSF). Agents that enter into the CSF poorly in health often pass the inflamed meninges so that therapeutically useful levels are achieved in cases of tuberculous meningitis. The pharmacokinetics of the conventional antimycobacterial drugs, their principal

TABLE 202-1 -- Spectrum of activity, class of compound and cross-resistances of the antituberculosis agents.

SPECTRUM OF ACTIVITY, CLASS OF COMPOUND AND CROSS-RESISTANCES OF THE ANTITUBERCULOSIS AGENTS			
Agent	**Class of compound**	**Spectrum of activity**	**Cross resistance to other antituberculosis agents**
First-line agents			
Rifampin	Antibiotic	Broad	Other rifamycins
Isoniazid	Synthetic	Tubercle bacilli	None
Pyrazinamide	Synthetic	Tubercle bacilli	None
Ethambutol	Synthetic	Tubercle bacilli	None
Streptomycin	Antibiotic	Broad	Other aminoglycosides, viomycin, capreomycin
Second-line agents			
Thiacetazone	Synthetic	Tubercle bacilli	Ethionamide and prothionamide

para-aminosalicylic acid	Synthetic	Tubercle bacilli	None
Ethionamide and prothionamide	Synthetic	Tubercle bacilli	Thiacetazone
Capreomycin	Antibiotic	Tubercle bacilli	Aminoglycosides, viomycin
Viomycin	Antibiotic	Tubercle bacilli	Aminoglycosides, capreomycin
Cycloserine	Synthetic	Broad	None
Ofloxacin	Antibiotic	Broad	None
Agents that are active against tubercle bacilli (*Mycobacterium tuberculosis* complex) may also show activity against some other species of mycobacteria. Strains of *Mycobacterium bovis* are naturally resistant to pyrazinamide. There are only limited data on other activities of capreomycin and viomycin.

TABLE 202-3 -- Antituberculosis agents: targets and genes for resistance.

ANTITUBERCULOSIS AGENTS: TARGETS AND GENES FOR RESISTANCE		
Agent	**Target**	**Gene(s) encoding target(s) or those in which mutations conferring resistance occur**
Isoniazid	Mycolic acid synthesis	*inhA, katG, KasA, oxyR-ahpC*
Rifampin	DNA-dependent RNA polymerase	*rpoB*
Pyrazinamide	Fatty acid synthetase-1	*pncA*
Ethambutol	Arabinosyl transferase, involved in cell wall arabinogalactan synthesis	*embA, embB and embC*
Streptomycin	30S ribosomal subunit	*rspL* (encodes for ribosomal protein S12)
Other aminoglycosides	30S ribosomal subunit	genes encoding 16S-rRNA (and possibly *aac(2')* encoding aminoglycoside acetyltransferase)
Thiacetazone	Mycolic acid synthesis	Unknown
para-aminosalicylic acid	Mycobactin synthesis (?)	Unknown
Ethionamide and prothionamide	Mycolic acid synthesis	*inhA*
Macrolides	50S ribosomal subunit	Gene encoding peptidyl transferase region in 23S rRNA
Capreomycin and viomycin	50S or 30S ribosomal subunit	*vicA* (50S) or *vicB* (30S)
Clofazimine	Unknown; possibly RNA polymerase	-
Cycloserine	Peptidoglycan	*alrA*
Fluoroquinolones	DNA gyrase (topoisomerase)	*gyrA*

metabolites and routes of excretion are summarized in Table 202.4 and Table 202.5 and are reviewed in depth elsewhere.[4]

DRUG TOXICITY

Although all antituberculosis drugs have some untoward side effects, drug toxicity is, in general, not a serious problem in modern short-course chemotherapy based on the first-line agents and is a small price to pay for the very real curative benefits. The major side effects are hepatotoxicity, peripheral neuropathy, mental disturbances, skin reactions (Fig 202.2 Fig 202.3 Fig 202.4) and fevers. Side effects are particularly likely to occur in HIV-positive patients and, of these, skin reactions due to thiacetazone are particularly serious and may be fatal.

The three principal drugs used in modern short-course regimens — isoniazid, rifampin and pyrazinamide — are all potentially hepatotoxic,

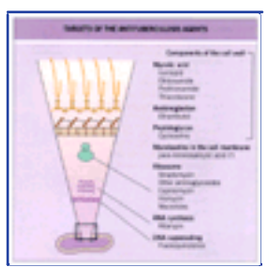

Figure 202-1 Targets of the antituberculosis agents.

but this is seldom a problem in clinical practice. Some physicians, however, take a more cautious view and advocate regular liver function tests during therapy.[5] The adverse effects of the various drugs are discussed under the individual headings below and are summarized in Table 202.6 .

FIRST-LINE DRUGS

Isoniazid (isonicotinic acid hydrazide)

The most widely used of all antituberculosis drugs, this is included in all modern regimens. It is also used as preventive

TABLE 202-4 -- Pharmacokinetics of the antituberculosis agents.

PHARMACOKINETICS OF THE ANTITUBERCULOSIS AGENTS			
Agent	**Binding to serum proteins**	**Absorption from gastrointestinal tract (time to reach peak serum level)**	**Entry into CSF (with healthy meninges)**
Isoniazid	Very low	Very rapid (30–60 minutes)	Good
Rifampin	High (up to 95%)	Rapid (2 hours)	Poor
Pyrazinamide	Very low	Rapid (1–2 hours)	Good
Ethambutol	Binds to erythrocytes	Rapid (2 hours); 80% of dose absorbed	Poor
Streptomycin	Moderate (30–35%)	Not absorbed	Poor
Thiacetazone	Not bound	Rapid (2 hours)	Limited data
para-aminosalicylic acid	High (60–65%)	Very rapid	Poor
Ethionamide and prothionamide	Limited data	Very rapid (30 minutes)	Good
Capreomycin	Limited data	Not absorbed	Poor
Viomycin	Limited data	Not absorbed	Poor
Clofazimine	Limited data	Slow (8–12 hours)	Limited data
Cycloserine	Not bound	Rapid (3 hours)	Good
Ofloxacin	Low	Rapid (1–1.5 hours)	Moderate

monotherapy for infected (tuberculin-positive) persons, particularly in the USA.

It has a powerful bactericidal action against actively replicating tubercle bacilli and thus rapidly reduces infectiousness by reducing the number of viable bacilli in cavities. It has little or no activity against slowly replicating bacilli but is included in the continuation phase of modern short-course therapy to kill any rifampin-resistant mutants that commence replication. It inhibits the synthesis of mycolic acids — long-chain fatty acids that form an important part of the mycobacterial cell wall. Although mycolic acids are common to all mycobacteria, and similar molecules occur in the genera *Nocardia* and *Corynebacterium*, susceptibility to isoniazid is virtually restricted to the *M. tuberculosis* complex, although some strains of *Mycobacterium xenopi* and *Mycobacterium kansasii* are susceptible. Some, but not all, isoniazid-resistant strains of *M. tuberculosis* lack catalase-peroxidase activity because of point mutations in, or deletion of, the *katG* gene that encodes this enzyme. Conversely, many strains from south India have either weak catalase-peroxidase activity or none at all but are fully susceptible to isoniazid. Other mutations associated with isoniazid resistance occur in the *inhA* gene, which encodes for long-chain enoyl-acyl carrier protein reductase required for synthesis of mycolic acids, and the *oxyR-ahpC* genes that encode for antioxidant proteins.[6] Thus, several mutational changes induce isoniazid resistance and the predominant mutation(s) show geographic variations in their distribution.

Isoniazid is readily absorbed from the gastrointestinal tract and is converted to inactive metabolites, principally by acetylation, the rate of which is genetically determined. Thus, patients can be divided into rapid acetylators and slow acetylators, in whom the elimination half-lives of the drug are 0.5–1.5 hours and 2–4 hours respectively. About half of Caucasian and black patients but over 80% of Chinese and Japanese patients are rapid acetylators. If administered regularly, response to therapy is unaffected by acetylator status but drug interactions (see below) are more likely to occur in slow acetylators.

Owing to its widespread use since the 1950s, resistance to isoniazid is common and many strains that are resistant to other antituberculosis drugs, particularly to rifampin, are also resistant to isoniazid.

Adverse events are usually mild and are more likely to occur in slow acetylators. They include several neurologic effects, including

TABLE 202-5 -- Principal metabolic products and excretion of the antituberculosis agents.

PRINCIPAL METABOLIC PRODUCTS AND EXCRETION OF THE ANTITUBERCULOSIS AGENTS		
Agent	**Principal metabolic products**	**Excretion**
Isoniazid	Acetyl derivatives: rate of acetylation is genetically controlled	Unchanged and as acetyl derivatives in urine (ratio depends on rate of acetylation)
Rifampin	Desacetyl derivative	As desacetylrifampin in bile
Pyrazinamide	Pyrazinoic acid	Mostly as pyrazinoic acid in urine
Ethambutol	Oxidation products and aldehydes	Mostly unchanged in urine; about 15% as metabolites
Streptomycin	None	Unchanged in urine
Other aminoglycosides	None	Unchanged in urine
Thiacetazone	Unknown	20% eliminated in urine, fate of remainder unknown
para-aminosalicylic acid	Acetylation products and glycine conjugates	About 80% in the urine, mostly in the acetylated form
Ethionamide and prothionamide	Sulfoxide (biologically active) and methyl derivatives	Less than 1% unchanged in urine
Capreomycin	None	Unchanged in urine
Viomycin	None	Unchanged in urine
Clofazimine	Very small amounts of unidentified metabolites	Unchanged in urine and feces
Cycloserine	Up to 35% converted to unidentified metabolites	Varying amounts unchanged in urine
Ofloxacin	5% metabolized to oxides and dimethyl derivatives	70–95% unchanged in urine, small amounts in bile

Figure 202-2 Severe dermal reaction to isoniazid. *Courtesy of Dr P Mwaba, Zambia.*

insomnia, restlessness, peripheral neuropathy, optic neuritis and various, but usually mild, psychiatric disturbances. More serious, but less common, neurologic effects include severe psychiatric disturbance and encephalopathy. The latter is particularly likely to occur in renal dialysis patients.[7]

Other adverse effects include hepatitis, particularly in patients aged over 35 years, arthralgia, fever and skin rashes. Very rare complications include hyperglycemia and agranulocytosis.

Figure 202-3 Erythema multiforme reaction to rifampin. *Courtesy of Dr P Mwaba, Zambia.*

Adverse effects, particularly neurologic ones, are usually preventable by administration of pyridoxine (vitamin B_6) 10mg daily. In particular, pyridoxine should be given to patients who have liver disease, pregnant women, alcoholics, renal dialysis patients, HIV-positive patients, the malnourished and the elderly. Encephalopathy in renal dialysis patients may not respond to pyridoxine but usually resolves when isoniazid is withdrawn.[7]

Rifampin

This is one of the rifamycins, semisynthetic derivatives of rifamycin S, a fermentation product of *Amycolatopsis (Streptomyces) mediterranei*. Rifampin inhibits protein synthesis by a very specific inhibition of bacterial DNA-dependent RNA polymerase, thereby blocking the synthesis of mRNA. The corresponding mammalian enzyme is

Figure 202-4 Stevens-Johnson syndrome induced by thiacetazone. *Courtesy of Dr P Mwaba, Zambia.*

inhibited only by very high concentrations of rifampin. Resistance is due to single amino acid mutational changes in the *rpoB* gene, which encodes for the ß subunit of the polymerase. Rifampin is the most effective of the antituberculosis drugs because it kills both rapidly dividing bacilli and those that exhibit only occasional short bursts of metabolism. Therefore, when cost considerations allow, it is given throughout the course of therapy. It is also used in the treatment of leprosy and for some other mycobacterial diseases.

Rifampin is rapidly absorbed from the gastrointestinal tract, although absorption is delayed if it is given with food, and it is widely distributed in the internal organs. Only small amounts enter the CSF in health but much more enters when the meninges are inflamed. Rifampin enters cells and is therefore active against intracellular mycobacteria. It is metabolized by hepatic microsomal enzymes to the desacetyl derivative, which is excreted in the bile. As this enzymatic activity is inducible, the rate of plasma clearance of rifampin increases as treatment proceeds. Although principally excreted in the bile, some rifampin and the desacetyl derivative enter the urine and impart an orange-red color to it. It also enters saliva and lachrymal secretions and may cause pink staining of soft contact lenses. The induction of microsomal enzymes may have clinically significant effects on the metabolism of several other drugs (see below).

Rifampin may cause an influenza-like syndrome, which, paradoxically, occurs less often if the drug is given daily rather than intermittently. It causes transient abnormalities in liver function and, occasionally, clinically evident hepatitis, although this is usually mild. Other adverse effects include gastrointestinal disturbances, skin rashes and antibody-mediated thrombocytopenia.

Acute renal failure is a rare complication, although in some regions it is more frequent; in one center in India it accounted for 11 of 607 (1.8%) of admissions for acute renal failure.[8] The renal prognosis is usually favorable. It typically occurs after reintroduction of rifampin and intermittent therapy is a risk factor.

Although the evidence that rifampin is teratogenic is very limited, it is best avoided if possible during the first 3 months of pregnancy. For the same reason, women receiving rifampin should avoid becoming pregnant. In this respect it is important to note that this drug interferes with the action of oral contraceptives.

Pyrazinamide (pyrazinoic acid amide)

This is regularly included in the initial intensive phase of short-course chemotherapy because it has the important property of killing intracellular tubercle bacilli and, possibly, extracellular bacilli in anoxic, acidic inflamed lesions. It is inactive in neutral or alkaline microenvironments. Its target is the fatty acid synthetase (FAS)-1 enzyme.[9] Pyrazinamide first requires conversion to pyrazinoic acid by mycobacterial pyrazinamidase enzymes encoded for by the *pncA* gene. Resistance is usually associated with mutations in this gene, which are detectable by a polymerase chain reaction (PCR)-based system,[10] and the enzymatic activity is not detectable in most pyrazinamide-resistant mutants of *M. tuberculosis* or in strains of *Mycobacterium bovis*, which are naturally resistant to this agent. A few pyrazinamide-resistant strains, however, lack mutations in the *pncA* gene, suggesting alternative mechanisms for resistance to this agent.[11]

It is readily absorbed from the gastrointestinal tract and freely enters the CSF, in which levels similar to those in plasma are found. It is metabolized in the liver; the metabolites, mostly pyrazinoic acid, are excreted in the urine.

Adverse effects are uncommon. It causes raised serum transaminase levels but overt hepatotoxicity, despite earlier reports, is uncommon. It should, however, be used with caution in alcoholics and in patients who have pre-existing hepatic disease, who should have regular liver function tests. Other adverse effects include anorexia, nausea, photosensitization of the skin,[12] arthralgia and gout caused by the inhibition of the excretion of uric acid by pyrazinoic acid.

Ethambutol

Ethambutol (*S*,*S*'-2,2'-(ethylenediimino)di-1-butanol) is now frequently used in short course therapy of tuberculosis as a fourth drug in the intensive phase of therapy. It is also included in therapeutic regimens for disease caused by other slowly growing mycobacteria, particularly *Mycobacterium avium* complex (MAC), *M. kansasii*, *M. xenopi* and *Mycobacterium malmoense*. In addition to its own activity, there is evidence that ethambutol may enhance the activity of some of the other drugs by affecting cell-wall permeability, particularly in the MAC but possibly also in multidrug-resistant strains of *M. tuberculosis*. [13]

Ethambutol inhibits the synthesis of the polysaccharide arabinogalactan, a macromolecule essential for the structural integrity of the mycobacterial cell wall, by inhibiting the enzyme arabinosyl transferase. Resistance is associated with mutations in the *embA*, *embB* and *embC* cluster of genes (principally *embB*), which encode for this enzyme.[14]

The drug is given orally and about 80% of the dose is absorbed from the gastrointestinal tract. Absorption is inhibited by antacids containing aluminum hydroxide. It does not cross the healthy meninges but up to 40% of the plasma level is found in the CSF in cases of tuberculous meningitis. It is mostly excreted unchanged in the urine but up to 15% is excreted as metabolites.

The principal side effect is optic neuritis, which may have an irreversible effect on vision. This complication is rare if the drug is given for no longer than 2 months at a daily dose of 25mg/kg body weight, or for longer at a dose not exceeding 15mg/kg. The 15mg/kg dose is used throughout therapy in some regimens. Nevertheless, care should be observed in the use of this drug, its recommended dose and duration of therapy should never be exceeded, and the patient should be informed of the risk of visual impairment and advised to discontinue the drug if such impairment occurs. Loss of color discrimination is the first sign of visual toxicity. Where facilities are

available, visual acuity should be assessed before therapy and at intervals during it.

Most guidelines recommend that the drug should not given to children under the age of 5 years because their visual acuity cannot be readily assessed, even though ocular complications in such young children are extremely rare.

TABLE 202-6 -- Adverse reactions to the antituberculosis agents.

ADVERSE REACTIONS TO THE ANTITUBERCULOSIS AGENTS	
Agent	**Adverse reactions**
Isoniazid	
Uncommon reactions	Hepatitis, cutaneous hypersensitivity reactions including erythema multiforme, peripheral neuropathy
Rare reactions	Vertigo; convulsions; optic neuritis and atrophy; psychiatric disturbance; hemolytic anemia; aplastic anemia; dermal reactions including pellagra, purpura and lupoid syndrome; gynecomastia, hyperglycemia, arthralgia
Rifampin	
Uncommon reactions	Hepatitis, flushing, itching with or without a rash, gastrointestinal upsets, 'flu-like syndrome', headache
Rare reactions (usually associated with intermittent therapy)	Dyspnea, hypotension with or without shock, Addisonian crisis, hemolytic anemia, acute renal failure, thrombocytopenia with or without purpura, transient leucopenia or eosinophilia, menstrual disturbances, muscular weakness, pseudomembranous colitis
Pyrazinamide	
Common reactions	Anorexia
Uncommon reactions	Hepatitis, nausea and vomiting, urticaria, nausea, arthralgia
Rare reactions	Sideroblastic anemia, photosensitization, gout, dysuria, aggravation of peptic ulcer
Ethambutol	
Uncommon reactions	Optic neuritis, arthralgia
Rare reactions	Hepatitis, cutaneous hypersensitivity including pruritis and urticaria, photosensitive lichenoid eruptions, parasthesia of the extremities, interstitial nephritis
Streptomycin	
Uncommon reactions	Vertigo, ataxia, deafness, tinnitus, cutaneous hypersensitivity
Rare reactions	Renal damage, aplastic anemia, agranulocytosis, peripheral neuropathy, optic neuritis with scotoma, severe bleeding due to antagonism of factor V, neuromuscular blockade in patients receiving muscle relaxants and in those with myesthenia gravis
Other aminoglycosides	
Uncommon reactions	Cutaneous hypersensitivity, vertigo, deafness
Rare reactions	Renal damage, hypoglycemia, hypokalemia
Thiacetazone	
Common reactions	Gastrointestinal upsets, cutaneous hypersensitivity, vertigo, conjunctivitis
Uncommon reactions	Hepatitis, erythema multiforme, exfoliative dermatitis, hemolytic anemia
Rare reactions	Agranulocytosis
***para*-aminosalicylic acid**	
Common reactions	Gastrointestinal upsets
Uncommon reactions	Cutaneous hypersensitivity, hepatitis, hypokalemia
Rare reactions	Acute renal failure, hemolytic anemia, thrombocytopenia, hypothyroidism
Ethionamide and prothionamide	
Common reactions	Gastrointestinal upsets, salivation, metallic taste
Uncommon reactions	Cutaneous hypersensitivity, hepatitis
Rare reactions	Alopecia, convulsions, deafness, diplopia, gynecomastia, hypotension, impotence, psychiatric disturbance, menstrual irregularity, hypoglycemia, peripheral neuropathy
Capreomycin and viomycin	
Common reactions	Eosinophilia (with capreomycin), pain and induration at injection site
Uncommon reactions	Loss of hearing, vertigo, tinnitus, electrolyte disturbances including hypokalemia, leukopenia or leukocytosis
Rare reactions	Renal impairment, hepatitis, thrombocytopenia
Clofazimine	
Common reactions	Discoloration of skin and body fluids, nausea, vomiting, abdominal pain, diarrhea
Uncommon reactions	Dryness of skin, ichthyosis, photosensitivity
Rare reactions	Intestinal obstruction
Cycloserine	
Common reactions (especially with daily doses exceeding 500mg)	Convulsions, drowsiness, sleep disturbance, headache, tremor, vertigo, confusion, irritability, aggression and other personality changes, psychosis (sometimes with suicidal tendencies)
Uncommon reactions	Cutaneous hypersensitivity, hepatitis, megaloblastic anemia
Rare reactions	Congestive heart failure
Ofloxacin	
Uncommon reactions	Gastrointestinal upsets, headache, dizziness, insomnia, cutaneous hypersensitivity reactions
Rare reactions	Restlessness; convulsions; psychiatric disturbances including psychotic reactions and hallucinations; edema of face, tongue and epiglottis; disturbance of taste and smell; anaphylactoid reactions

Other side effects of ethambutol include skin rashes, arthralgia, peripheral neuritis, hyperuricemia and, rarely, jaundice and thrombocytopenia.

Streptomycin

This was the first of the antituberculosis drugs to be discovered and it still has an important role in the treatment of tuberculosis. It inhibits

protein synthesis by binding to the 30S subunit of the bacterial ribosome. It is active in neutral or alkaline environments such as the cavity wall but not in the more acidic environment of the closed, inflammatory foci and is therefore not a good sterilizing drug. It is very poorly absorbed from the gastrointestinal tract and must be given parenterally.

Streptomycin is toxic for the eighth cranial nerve, including that of the fetus, and its use should therefore be avoided in pregnancy. Other adverse reactions include impairment of renal function and hypersensitivity reactions — usually mild skin rashes or fever but occasionally anaphylactic reactions or exfoliative dermatitis.

SECOND-LINE DRUGS

Aminoglycosides

In addition to streptomycin, the aminoglycosides kanamycin, amikacin and aminosidine (paromomycin) have activity against *M. tuberculosis*. Cross-resistance with streptomycin is usual. Kanamycin is included in some regimens for the treatment of MDRTB and amikacin in some regimens for the treatment of disease due to the MAC, particularly in HIV-positive patients. In common with streptomycin, these aminoglycosides are not absorbed from the gastrointestinal tract and must therefore be given parenterally.

Para-aminosalicylic acid

The mode of action of this bacteriostatic drug is not fully understood although there is some evidence that it inhibits the salicylate-dependent synthesis of the mycobactins — a class of iron-chelating lipids unique to the mycobacteria. It is readily absorbed from the intestine and rapidly acetylated in the liver. About 80% is excreted in the urine, mostly in the acetylated form.

It is rarely used as adverse effects are common. Gastrointestinal effects including nausea, abdominal pain and diarrhea occur in up to 30% of patients. Other adverse effects include thyroid dysfunction, crystalluria, blood dyscrasias and, rarely, Löffler syndrome and encephalitis.

Capreomycin and viomycin

These structurally closely related cyclic polypeptides are very rarely used and are seldom available. In common with the aminoglycosides, they inhibit protein synthesis by blocking ribosomal function. They are mutually completely cross-resistant and high-level resistance shows cross-resistance with the aminoglycosides. They are supplied as a water-soluble sulfate and, because they are not absorbed from the intestine, they are given by intramuscular injection. They do not readily enter cells or the CSF and are mostly excreted unchanged in the urine. Adverse effects include ototoxicity, nephrotoxicity and pain, bleeding and induration at the injection site.

Clofazimine

This is one of a group of iminophenazines originally developed for treatment of tuberculosis but now used principally for leprosy. It is occasionally used for treatment of MDRTB but there is only anecdotal evidence of efficacy. It was included in regimens for treatment of AIDS-related MAC infection but is now rarely used for this purpose on account of its toxicity in such patients.

Its mode of action is unclear. Some reports suggest that it potentiates intracellular killing by enhancing the generation of free oxygen radicals, whereas others suggest an interference with RNA polymerase activity. It is absorbed from the intestine; it has a very long half life — around 70 days — and is excreted in the urine and feces. Adverse effects include nausea, abdominal pain and diarrhea and, rarely, edema of the wall of the small intestine leading to subacute obstruction. It also causes skin discoloration, which may be a stigmatizing feature leading to nonadherence to therapy.

Ethionamide and prothionamide

Ethionamide (ethylthioisonicotinamide) and prothionamide (propylthioisonicotinamide) are closely related drugs that are structurally similar to isoniazid; in common with isoniazid they inhibit the synthesis of mycobacterial mycolic acids. Also in common with isoniazid, resistance is associated with mutations in the *inhA* gene encoding for long-chain enoyl-acyl carrier protein reductase but, surprisingly, cross-resistance to isoniazid does not develop. This may, in part, be explained by differences in the activation pathways of the two agents.[15] They are degraded into several metabolites in the liver and only a very small amount, less than 1%, is excreted unchanged in the urine.

The common occurrence of gastrointestinal irritation with these agents, even when they are given as enteric-coated tablets, limits their use in the treatment of tuberculosis. Prothionamide is slightly better tolerated and is used in some regimens for leprosy. Other adverse effects include skin reactions, hepatitis, impotence and gynecomastia in male patients, menstrual irregularities and various neurologic complications such as convulsions, mental disturbance and peripheral neuropathy.

Thiacetazone (acetylaminobenzaldehyde thiosemicarbazone)

In common with isoniazid, thiacetazone inhibits the synthesis of mycolic acid, but by a poorly understood mechanism. Resistance develops readily and is common in developing nations where, on account of its low cost, thiacetazone has been widely used. It is readily absorbed from the gastrointestinal tract. About 20% is eliminated in the urine but it is not known what happens to the remainder.

Adverse effects are common. Skin rashes frequently occur, particularly in patients of Chinese ethnic origin. A very high incidence of severe, sometimes fatal, skin reactions — exfoliative dermatitis and Stevens-Johnson syndrome — in HIV-positive patients has raised serious doubts as to the advisability of using this drug in regions where HIV-related tuberculosis is common. Less frequent adverse effects include gastrointestinal upsets, hepatitis, hemolytic anemia and, rarely, agranulocytosis.

Rifabutin and rifapentine

These are closely related to rifampin, being semisynthetic derivatives of rifamycin S. Although rifabutin (ansamycin) is considerably more active than rifampin in vitro, its in-vivo action against *M. tuberculosis* is similar to that of rifampin. Cross-resistance between the rifamycins is usual, so the place for rifabutin in the treatment of MDRTB is limited. Its principal use is for the prevention and treatment of HIV-related disease due to the MAC. Rifabutin, rifapentine and a new rifamycin derivative, benzoxazinorifamycin (KRM-1648), have long plasma half-lives and raise the possibility, currently under investigation, of once-weekly dosage for preventive therapy and during the continuation phase of therapy of active tuberculosis.[16]

Fluoroquinolones

Fluoroquinolones inhibit the enzyme DNA gyrase, which is responsible for the supercoiling of DNA. They have bactericidal activity against *M. tuberculosis* at clinically achievable levels in vitro, and there is increasing evidence that several of them, including ciprofloxacin, ofloxacin, sparfloxacin, levofloxacin and lomefloxacin, have a valuable place in the therapy of MDRTB.[17] Thus, for example, there is preliminary evidence that a combination of sparfloxacin, kanamycin and ethionamide is both safe and effective in the therapy of MDRTB.[18] [19] Fluoroquinolones are readily absorbed from the gastrointestinal tract and enter tissues and fluids, including the CSF. Although metabolized to some extent by the liver, they are

largely excreted unchanged in the urine. Doses therefore require modification in patients who have renal failure. Adverse effects include nausea and abdominal pain and various neurologic abnormalities including headache, vertigo, insomnia, restlessness, epileptiform attacks and psychiatric disturbances. They should be used with care in epileptic patients.

Cycloserine

This D-alanine analog inhibits synthesis of peptidoglycan. It is bacteriostatic and thus of limited efficacy, although it is used in some cases of MDRTB. Psychiatric symptoms, including psychotic episodes, occur commonly and further limit the usefulness of this drug, although the risk may to some extent be reduced by giving pyridoxine. Allergic skin rashes are rare. In-vitro synergy with ß-chloro-D-alanine, another peptidoglycan inhibitor, has been demonstrated and suggests that therapy with a greatly reduced dose of cycloserine may be possible.[20]

Macrolides

These are broad-spectrum antibiotics that inhibit protein synthesis by binding to the ribosomal 50S subunit. Erythromycin is active against some mycobacteria in vitro and there are anecdotal reports of its efficacy in the treatment of post-BCG (bacillus Calmette-Guérin) abscesses and disease due to *M. kansasii* and *M. xenopi*. The newer macrolides, clarithromycin, azithromycin and roxithromycin, are more active than erythromycin against MAC, and clarithromycin is used to treat HIV-related disease due to MAC. They have limited in-vitro activity against *M. tuberculosis* but there is evidence that they act in synergy with rifampin and isoniazid against this species, particularly against intracellular bacilli.[21] Macrolides are well absorbed from the gastrointestinal tract and are excreted in urine. Adverse effects include gastrointestinal upsets with occasional cases of pseudomembranous colitis and various psychiatric disorders, including acute mania.

EXPERIMENTAL AGENTS

Research into novel therapy for tuberculosis is based on new use of old drugs, new delivery of old drugs, new drugs within old classes and new classes of drugs. A number of new rifamycins, macrolides, pyrazinamide analogues, nitroimidazoles and isonicotinoylhydrazones are being evaluated.[22] [23] [24] Synergy between antituberculosis agents and cell-wall assembly inhibitors is also a promising approach, which may overcome drug resistance and permit lower concentrations of toxic drugs to be used.[20] [25]

Attempts to treat MDRTB by enhancing or modifying immune defense mechanisms have been made, either by the use of individual cytokines or bacterial adjuvants, and more clinical studies are indicated.[23] [26]

Certain agents usually used for other infections may have useful activity against *M. tuberculosis*. For example, a combination of amoxicillin and clavulanic acid has in-vitro activity against *M. tuberculosis* and there is anecdotal evidence of a beneficial effect against MDRTB.[27] It has been suggested that metronidazole might kill dormant *M. tuberculosis* in anaerobic situations. Although one study indicates that addition of metronidazole to short-course regimens hastens the clinical improvement in cases of advanced pulmonary tuberculosis, information from studies on murine models of dormancy is conflicting.[28]

Dynamics of action of antituberculosis drugs in vivo and the design of therapeutic regimens

The aims of modern chemotherapeutic regimens are:

- to cure the patient;
- to reduce infectivity as rapidly as possible; and
- to prevent the emergence of drug resistance.

In order to cure patients, it is necessary to destroy all the tubercle bacilli in the tissues; if even a few survive, there is a high chance of relapse. In this respect, drugs that are bactericidal in vitro may not be able to effectively sterilize the tissues in vivo.[29] This difference occurs because tubercle bacilli in vivo are in a number of different physiologic states or 'compartments'. These physiologic 'compartments' are:

- freely dividing extracellular bacilli, found mainly in the cavity walls;
- slowly dividing bacilli, found within macrophages and in acidic, inflammatory lesions; and
- dormant and near-dormant bacilli, within cells and in firm caseous material.

The antituberculosis drugs vary in their ability to destroy bacilli in these compartments and in preventing the emergence of resistance to a second drug.

During chemotherapy with modern short-course regimens, the freely replicating bacilli in the walls of the cavities are rapidly killed; this is termed the early bactericidal effect. Subsequently, the slowly replicating and near-dormant bacilli are destroyed, but at a much slower rate.

Isoniazid plays a key role in achieving the early bactericidal effect because it is particularly effective in destroying the freely multiplying extracellular bacilli, particularly those in the walls of cavities. It has little or no effect on near-dormant bacilli and is therefore not a good sterilizing drug. Rifampin also contributes to the early bactericidal effect.

Ethambutol has bactericidal activity in the early stage of therapy but is not a sterilizing drug. Streptomycin is bactericidal in the slightly alkaline cavity walls but is likewise not a sterilizing agent because it is ineffective in the acidic environment within cells and caseous lesions. By contrast, pyrazinamide is effective within macrophages and acidic, anoxic inflammatory lesions, but not in the neutral or alkaline environment.

Thus, modern regimens commence with an intensive phase of therapy, usually lasting for 2 months, to optimize the early bactericidal effect, thereby eliminating most of the bacilli and rendering the patient noninfectious. The principal drugs used are:

- isoniazid (active against bacilli in the cavity walls);
- pyrazinamide (active against bacilli in acidic closed lesions); and
- rifampin (active against both).

In view of the widespread and increasing prevalence of drug resistance, many regimens now include a fourth agent, usually ethambutol but sometimes streptomycin. The daily drug doses are listed in Table 202.7 and the intermittent doses in Table 202.8 .

The intensive phase is followed by a continuation phase, usually lasting 4 months, in which any remaining dormant or near-dormant bacilli are destroyed. For this purpose, rifampin is the most powerful sterilizing drug. Although isoniazid is not a sterilizing drug, it is, by its potent activity against replicating bacilli, very good at preventing the emergence of rifampin-resistant mutants. It is thus given together with rifampin throughout the regimen.

Accordingly, the most effective modern short-course regimens are based on a 2-month phase of rifampin, isoniazid, pyrazinamide and either ethambutol or streptomycin, followed by a 4-month phase of rifampin and isoniazid. The WHO has issued clear recommendations on drug regimens for the four categories of tuberculosis seen in clinical practice (Table 202.9).

In most regimens drugs are given daily but, provided that therapy is closely supervised so that all doses are taken, they may be given three times weekly during the continuation phase or, in some regimens, throughout. Such intermittent therapy renders the direct administration of the drugs less of a burden for both patients and supervisors.

There is general agreement, supported by clinical trials, that the modern chemotherapeutic regimens discussed above are suitable for the treatment of all types of tuberculosis, both pulmonary and non-pulmonary,

---

TABLE 202-7 -- Daily doses of the antituberculosis agents.

DAILY DOSES OF THE ANTITUBERCULOSIS AGENTS		
	Daily dose	
Agent	**Adults**	**Children**
Rifampin	450mg if body weight <50kg	10mg/kg to maximum of 600mg
	600mg if body weight =50kg	
Isoniazid	200–300mg	5mg/kg
Pyrazinamide	1.5g if body weight <50kg	25mg/kg
	2.0g if body weight =50kg	
Ethambutol	15mg/kg	
Streptomycin	750mg if body weight <50kg	As for adult
	1g if body weight =50kg	15mg/kg to maximum of 0.75g
	750mg if age =40 years	
	500mg if age =60 years	
Thiacetazone	150mg	50mg
para-aminosalicylic acid	10–12g	300mg/kg
Ethionamide and prothionamide	500mg if body weight <50kg	15–20mg/kg
	750mg if body weight =50kg	
Capreomycin	1g	Avoid
Viomycin	1g	Avoid
Cycloserine	500mg if body weight <50kg	Avoid
	750mg if body weight =50kg	
Ofloxacin	800mg	Avoid

TABLE 202-8 -- Doses of the first-line antituberculosis agents in three times weekly intermittent therapy.

DOSES OF THE FIRST-LINE ANTITUBERCULOSIS AGENTS IN THREE TIMES WEEKLY INTERMITTENT THERAPY		
Agent	**Dose (mg/kg (adults and children))**	**Maximum dose**
Isoniazid	15	750mg
Rifampin	15	600mg
Pyrazinamide	50	2.0g if body weight <50kg
		2.5g if body weight =50kg
Ethambutol	30	1.8g
Streptomycin	15–20	750mg if body weight <50kg
		1g if body weight =50kg

TABLE 202-9 -- Principal antituberculosis regimens recommended by the World Health Organization.

PRINCIPAL ANTITUBERCULOSIS REGIMENS RECOMMENDED BY WHO		
Intensive phase	**Continuation phase**	**Category of patient**
HRZE (HRZS) for 2 months	HR daily for 4 months	New patients with smear-positive pulmonary tuberculosis; extensive smear-negative pulmonary tuberculosis; severe nonpulmonary tuberculosis
HRZE (HRZS) for 2 months	HR three times weekly for 4 months	
HRZE (HRZS) for 2 months	HE daily for 6 months	
HRZES for 2 months + HRZE for 1 month	HRE daily for 5 months	Cases of relapse, treatment failure or recommencing treatment after interruption
HRZES for 2 months + HRZE for 1 month	HRE three times weekly for 5 months	
HRZ for 2 months	HR daily for 4 months	New smear-negative pulmonary tuberculosis (other than those in the first category); less severe nonpulmonary tuberculosis
HRZ for 2 months	HR three times weekly for 4 months	
HRZ for 2 months	HE daily for 6 months	
Treat as though drug-resistant		Case still positive after supervised retreatment
E, ethambutol; H, isoniazid; R, rifampin; S, streptomycin; Z, pyrazinamide.		

and even for life-threatening forms such as tuberculous meningitis. There is less agreement over the duration of therapy for non-pulmonary forms of tuberculosis; some physicians continue therapy for up to 12 months or even longer, particularly in the case of tuberculous meningitis, in which a relapse would be particularly devastating.

DRUG-RESISTANT TUBERCULOSIS

Resistance to any given anti-infective agent occurs by mutation at a low but constant rate, so that treatment with a single drug, however powerful, will inevitably lead to selection of resistant mutants.[5] The problem of treatment failure caused by the emergence of drug resistance became apparent soon after the introduction of antituberculosis chemotherapy and led to the universal advocacy of multiple-drug

regimens. Under ideal conditions and in the absence of drug resistance, relapses after completion of a modern short-course chemotherapeutic regimen are uncommon and are mostly due to drug-susceptible bacilli.[24] Unfortunately, ideal treatment conditions are the exception rather than the rule and many deficiencies in the use of multiple-drug regimens has led to the increasing emergence of strains resistant to one or more drugs.[30]

Although resistance to isoniazid or streptomycin, or to both, is common, patients whose disease is caused by such resistant strains usually respond to short-course chemotherapy. Resistance to rifampin is much more serious, in view of the unique ability of this drug to eliminate near-dormant persisting bacilli. Many strains resistant to rifampin are also resistant to isoniazid and, because these drugs are the principal components of modern regimens, this combination renders such regimens ineffective. Thus, the term multidrug resistance has been adopted by the WHO to refer to strains that are resistant to these two drugs, with or without resistance to

additional drugs.[31]

Two forms of drug resistance are encountered: acquired and primary (or initial). Acquired resistance is the result of suboptimal therapy that encourages the selective growth of mutants resistant to one or more drugs. Primary resistance is due to infection from a source case who has drug-resistant disease. In practice, it is often difficult to be sure that a patient who has apparent primary resistant tuberculosis has, in fact, not received any antituberculosis therapy, and some workers therefore prefer the term initial resistance. The division of resistance into acquired and primary forms is of epidemiologic value because an increasing incidence of the former indicates that drug regimens or the supervision of therapy are suboptimal, whereas the continuing occurrence of primary resistance indicates that the transmission of the disease in the community is not being adequately controlled.

The development of drug resistance is due to many avoidable failures in the management of the disease (Table 202.10).

The traditional explanation for treatment failure and emergence of drug resistance is noncompliance or nonadherence to therapy by the patient, thereby attempting to exonerate the health care services. While acknowledging that there will always be a small number of patients who will default on treatment in any situation, there is ample evidence that it is more often the health services than the patient that are at fault. In order to enhance effective tuberculosis control, the WHO has widely advocated the strategy of directly

TABLE 202-10 -- Factors leading to suboptimal therapy and the emergence of drug and multidrug resistance.

FACTORS LEADING TO SUBOPTIMAL THERAPY AND THE EMERGENCE OF DRUG AND MULTIDRUG RESISTANCE
Intermittent drug supplies
Use of time-expired drugs
Unavailability of combination preparations
Use of poorly formulated combination preparations
Prescription of inappropriate drug regimens
Unregulated over-the-counter sale of drugs, including cough mixtures containing isoniazid
Addition of single drugs to failing regimens in the absence of bacteriologic control
Poor supervision of therapy
Unacceptably high cost to patient in respect of the drugs, travel to the clinic and time off work

observed therapy, short course (DOTS). This is a six-point strategy incorporating:

- government commitment to tuberculosis control;
- provision of a regular supply of good-quality drugs free at the point of delivery;
- passive case finding by sputum microscopy;
- directly observed therapy;
- training and ongoing support of staff; and
- regular evaluation of the efficacy of the control program.

Combination drug preparations have been used to prevent patients from receiving monotherapy, but irregular and intermittent use of such preparations has led to drug and multidrug resistance.[30] In addition, the use of poorly formulated combination preparations has led to reduced bioavailability of the constituent agents and the risk of development of drug resistance.

There is no doubt that the blind addition of drugs to a failing regimen is very likely to generate multidrug resistance. Unfortunately, the determination of drug resistance is far from easy and most parts of the world lack the facilities for conducting drug susceptibility tests under good quality control. Errors are not uncommon even in the most sophisticated centers in the developed world and may be noticed only when laboratory reports are considered in the light of clinical data.

A combined initiative by the WHO and the International Union Against Tuberculosis and Lung Disease was launched in 1994 to perform a global survey of resistance to first-line antituberculosis drugs. The first report, published in 1997 and covering 35 countries, showed that resistance to these drugs was more widespread than was previously recognized and revealed certain areas with a very high incidence (Fig. 202.5).[32] These 'hotspots' included Estonia, Latvia, Russia, Argentina, China, the Dominican Republic and Côte d'Ivoire. The second report, published in 2000 and covering 72 countries, confirmed the widespread occurrence of MDRTB.[33] While, overall, the median prevalence of MDRTB in new cases was low, only 1% of all cases, a very high prevalence was found in the Henan province of China (35%), Ivanovo Oblast (Russian Federation; 32.4%), and Latvia (29.9%). Estonia showed 8.5% resistance to all four antituberculosis frontline drugs. On the other hand, no MDRTB was detected among new cases in Cuba, Finland, France and New Caledonia.

The situation in Russia is of particular concern.[34] Under the communist regime, tuberculosis in that country had been in decline for several decades, reaching an annual incidence of 34 cases per 100,000 population in 1991. Since the end of communism in 1991, however, the incidence of tuberculosis rose steadily to 85/100,000 by 1998. The cause of this upsurge appears to be a combination of poverty, malnutrition, poor housing, conflict and a fragmentation of health services. In addition, tuberculosis has flourished in overcrowded Russian prisons where there may be as many as 1 million prisoners, of whom 100,000 have active tuberculosis. The incidence of MDRTB is high; in one surveyed prison population it occurred in 24.6% of tuberculosis patients, rising to 92% among nonresponding cases. Despite implementation of a strict DOTS program in the prisons, and the use of WHO retreatment regimens for all new cases, there was a treatment failure rate of 35% in a tuberculosis referral prison in western Siberia.

The presence of HIV infection does not *per se* lead to an upsurge of MDRTB. Despite the increase in HIV-associated tuberculosis seen in most African countries, such an upsurge has not been documented. Exceptions include Mozambique and Côte d'Ivoire, where more than 3% of new cases are multidrug-resistant and in Yaonde, Cameroon, where the corresponding figure rises to 27.6%.

The problem of drug resistance is not encountered only in the developing nations. Several well documented epidemics of MDRTB have occurred in the USA, notably in New York City.[35] As mentioned above,

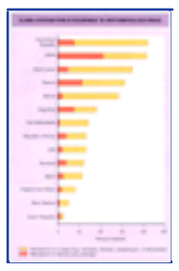

Figure 202-5 Global distribution of resistance to antituberculosis drugs. The resistance is given as a percentage of all isolates. *Data from the World Health Organization.*[32]

HIV infection *per se* does not generate multidrug resistance and although such an association has been found in New York and some other regions it has not been found in others. The reason for the association, where it occurs, is that HIV infection facilitates outbreaks of tuberculosis in hospitals, prisons or common lodging facilities where such immunocompromised persons are crowded together. Thus, if the source case has MDRTB, a mini-epidemic of such disease will ensue. The first such outbreak in the UK occurred in 1995; four patients who presented with tuberculosis in mid-June had been exposed to the source case in April in a six-bed ward in an HIV unit in London.[36]

Ethnic minority communities, originating in countries where drug resistance is common, often have higher levels of drug resistance than the majority populations.[37]

The incidence of single-drug-resistant tuberculosis in a community can be reduced by establishment of good disease control programs.[38] This raises the question of whether the implementation of the WHO DOTS strategy would also reduce the incidence of MDRTB in a region. According to one mathematical model,[39] it would have

such an effect, but the model assumes that multidrug-resistant strains of *M. tuberculosis* are less virulent than their drug-susceptible counterparts, an assumption for which there is no clear

TABLE 202-11 -- Principles for management of multidrug-resistant tuberculosis.

PRINCIPLES FOR MANAGEMENT OF MULTIDRUG-RESISTANT TUBERCULOSIS
Single agents should never be blindly added to failing regimens
Before drug susceptibility tests become available, patients should be started on three agents that they have never received before
All therapy should be fully supervised (use of an injectable agent enhances adherence to therapy)
Therapy should last at least 24 months and should be continued for at least 18 months after bacteriologic conversion
Drug susceptibility tests should be repeated if cultures remain positive after 3 months of therapy

supporting evidence. Thus, further field studies are required to answer this important question.

Therapy of multidrug-resistant tuberculosis

Tuberculosis due to bacilli resistant to isoniazid alone usually responds to short-course drug regimens based on four drugs during the intensive phase but, by contrast, resistance to both isoniazid and rifampin (i.e. multidrug resistance) requires prolonged treatment with drugs that are much more costly, less effective and more toxic. The cost of such therapy is high; in the USA it can exceed $US250,000, compared with the cost of $US2000 for treating a patient who has drug-susceptible disease. The prognosis for patients who have MDRTB has improved considerably and, provided that the patient is diagnosed before severe lung damage has occurred and that the best supervised therapy and laboratory support is available, the outlook is good in the majority of cases. Under these optimal conditions, cure rates of 96% have been achieved.[40]

The successful management of MDRTB requires laboratory support and a team of dedicated supervisors of therapy, the so-called 'DOTS-plus' strategy. [41] Ideally regimens should be designed for each patient on the basis of in-vitro susceptibility. Various regimens have been used and there have been few comparisons between them. Currently used regimens are usually based on a fluoroquinolone with at least two other drugs to which the strain is susceptible such as kanamycin and ethionamide (or prothionamide).[18] Other agents include rifabutin, the new macrolides, amikacin, capreomycin, clofazimine, cycloserine and *para*-aminosalicylic acid. Great care and dedication is required for the successful management of MDRTB (Table 202.11).

In many parts of the world, neither these drugs nor the requisite laboratory support are available, and MDRTB is thus often fatal. Alternative forms of treatment such as immunotherapy are therefore urgently required.

TREATMENT OF PATIENTS IN SPECIAL CIRCUMSTANCES

Patients who have renal or hepatic disease

Modification of drug regimens and dosages may be required when there is substantial liver disease or renal impairment. The first-line drugs (rifampin, isoniazid, pyrazinamide, ethionamide) and also ethionamide and prothionamide are either completely metabolized or eliminated in the bile. They may therefore be used safely at the normal doses in patients who have renal impairment. Isoniazid occasionally causes encephalopathy in patients who have renal failure and in those on dialysis but the risk is reduced, although not eliminated, by administering pyridoxine.[7] Although ethambutol is mainly

eliminated by the kidney it can be used in reduced doses in patients who have impaired renal function. Streptomycin and other aminoglycosides are eliminated entirely by the kidney and are potentially nephrotoxic and special care must be taken.

In severe renal failure the dose of isoniazid should be reduced to 200mg once daily (ensuring that pyridoxine is given to prevent peripheral neuropathy). Streptomycin and ethambutol are excreted by the kidney and adjustment to doses is necessary in renal failure. Streptomycin levels must be monitored and doses and spacing be adjusted to achieve a level of 4mg/ml to avoid toxicity. For patients on dialysis, streptomycin should be given 8 hours before commencing dialysis. Ethambutol dosages are dependent on creatinine clearances. For patients who have creatinine clearances between 50ml/min and 100ml/min, the dose is 25mg/kg three times weekly; at 30–50ml/min, the dose is 25mg/kg twice a week; and at 10–25ml/min the dose is 15mg/kg at 2-day intervals. Patients on hemodialysis may be given 25mg/kg ethambutol 6 hours before the procedure.

There is no clear evidence that the potentially hepatotoxic drugs rifampin and pyrazinamide are any more toxic in patients who have impaired hepatic function. Nevertheless, if they are used, hepatic function should be carefully and regularly monitored during therapy. Some physicians avoid them and treat such patients with isoniazid and ethambutol for 1 year, with the addition of streptomycin for the first 2–3 months. An alternative is to use a fluoroquinolone such as ofloxacin instead of rifampin.[42]

If rifampin is used, it should be used with caution; doses should be reduced in patients who have bilirubin concentrations exceeding 50mmol/l. Liver function should be regularly monitored, where possible, in alcoholics, the elderly, malnourished children and children under 2 years of age.

If jaundice develops during antituberculosis therapy, treatment should bm stopped until the jaundice resolves. In many cases resumption of treatment does not cause a recurrence of the jaundice. If the patient is seriously ill with tuberculosis, he or she may be treated with streptomycin and ethambutol even in the presence of jaundice.

HIV-positive patients who have tuberculosis

The treatment of tuberculosis in HIV-positive patients (see also Chapter 129) follows the same well-established principles used in the treatment of non-HIV infected patients. [43] Despite a good bacteriologic response to treatment, patients who have HIV-related tuberculosis in Africa are almost four times as likely to die within 13 months of diagnosis than HIV-negative patients, with most deaths occurring during the first month of treatment.[44] This is largely due to other opportunistic infections but may also, in part, be due to an apparent synergistic immunosuppressive action of HIV infection and active tuberculosis. For this reason, prevention of tuberculosis is preferable to cure in HIV-positive persons (see below). Drug reactions tend to be more severe in HIV-positive patients than in HIV-negative patients. In particular, thiacetazone often causes severe dermal reactions, with some patients developing fulminant and potentially fatal exfoliative dermatitis. Drug interactions are also a particular problem in HIV-infected patients (see Chapter 129).

Pregnancy and the postpartum period

There is general agreement that the management of tuberculosis in pregnancy and in the postpartum period should be similar to that in other patients, although some advocate avoiding pyrazinamide. Short-course regimens seem to have a minimal risk of causing fetal abnormalities, and side effects in the pregnant woman are no higher than in those who are not pregnant.[45] Opinions concerning the safety of pyrazinamide differ because there are limited experimental data on its effect on the fetus but, notwithstanding this, it is often used, particularly in regions where drug resistance is common. Streptomycin is avoided owing to its ototoxic properties. The treatment of drug-resistant tuberculosis, especially MDRTB, during pregnancy and the management of the neonate requires careful consideration, and experience is very limited.[46] Expert clinical and laboratory guidance, if available, is required.

An increased incidence of isoniazid-related epileptiform attacks and other neurologic symptoms has been reported in pregnant women but these are preventable by the prescription of pyridoxine 10mg daily. Mothers taking antituberculosis drugs at the time of birth can care for their infants with little risk, unless the mother's disease is drug-resistant or not responding to therapy. Likewise, although some of the drugs enter the milk in small concentrations, breast-feeding has no adverse effects on the infant.[47]

Adjunct corticosteroid therapy in tuberculosis

It has been postulated that corticosteroids, by reducing the host's immune response, would allow dormant bacilli to replicate freely and thereby facilitate killing by the drugs. There is little evidence to support this, and their use has not been shown to affect the outcome of modern short-course chemotherapy.[48] On the other hand, in

some forms of tuberculosis corticosteroids aid recovery and reduce long-term sequelae by suppressing inflammatory reactions and limiting subsequent scar formation. For details see Chapter 37 and Chapter 40.d and a review by Alzeer and FitzGerald.[49]

CHEMOPROPHYLAXIS AND PREVENTIVE THERAPY OF TUBERCULOSIS

Chemoprophylaxis is defined as the prescription of antituberculosis drugs for uninfected persons who are exposed to a risk of infection; preventive therapy refers to the treatment of persons who have already been infected with tubercle bacilli (as indicated by tuberculin testing) but who show no clinical or radiologic evidence of active disease. Chemoprophylaxis is principally used to protect children who are at risk of infections, particularly those under the age of 3 years, who are prone to develop serious extrapulmonary forms of tuberculosis, including meningitis.

Preventive drug therapy for those infected by *M. tuberculosis* (i.e. tuberculin reactors) is used in some countries, notably the USA, where tuberculosis is uncommon and where BCG is not used. Although highly efficacious, it is not without its problems. Isoniazid monotherapy, for up to 1 year, is the most widely used form of preventive therapy, although 6-month regimens are becoming more common. Although there is a theoretic risk of generating isoniazid resistance, this does not seem to happen in practice, probably because there are so few bacilli present. Hepatic toxicity has given cause for concern, particularly in older adults, and so such preventive therapy is not recommended for those aged over 35 years.[50]

Policies for the use of chemoprophylaxis vary from country to country. National guidelines should be consulted for indications for chemoprophylaxis and for the recommended drug regimens. In general, chemoprophylaxis in tuberculosis control in regions with a high incidence of tuberculosis has, in view of problems of compliance and organization, not played a major role in tuberculosis control programs.

Transplant recipients receiving corticosteroids and other immunosuppressive drugs are at risk of developing tuberculosis. It has been suggested that such patients should be given isoniazid 300mg, and pyridoxine 25–50mg daily if they have one or more of the following:[51]

- a history of inadequately treated tuberculosis;
- an abnormal chest radiograph;
- a positive tuberculin test of more than 10mm in diameter; and
- recent contact with a case of active tuberculosis.

Prophylaxis of tuberculosis in HIV-infected patients

In view of the very high risk of a co-infected person developing active tuberculosis, and the adverse effect of this disease on the immune status and survival of the patient, there is a very good theoretical case for provision of prophylactic treatment for those at risk. Several placebo-controlled studies of isoniazid monotherapy in patients co-infected with *M. tuberculosis* and HIV have shown that such chemoprophylaxis is effective.[52] In practice, serious problems have been encountered in diagnosing dual infection, ruling out active tuberculosis and ensuring compliance with therapy without breach of confidence or enhancement of stigma. Studies of varying design from Haiti, Zambia and Uganda have shown that chemoprophylaxis in HIV-infected adults significantly reduced the incidence of tuberculosis. The questions of how long the protection lasts, whether prophylactic treatment is safe and whether such therapy can lead to the emergence of drug-resistant strains of tuberculosis require attention.

Although prophylaxis leads to a reduction of the risk of tuberculosis by around 60% in tuberculin-skin-test-positive adults who have HIV infection, identifying HIV-infected individuals is difficult in resource-poor settings. A major problem is ensuring compliance with therapy.[53] The development of voluntary counseling and testing centres was seen as an effective tool to promote safer sex and to offer those who have HIV infection interventions such as preventive therapy for tuberculosis.

It is very important to ensure that HIV-positive persons receiving chemoprophylaxis do not have active tuberculosis or there is a strong risk of masking the disease and encouraging the emergence of drug resistance. It is also necessary to supervise the therapy, and this adds another burden to stretched tuberculosis control services.

Initially, 12-month courses of isoniazid monotherapy were evaluated but, subsequently, shorter combination regimens were also shown to be effective. These include a 3-month course of a rifamycin (rifampin or rifabutin) plus isoniazid, and a 2-month course of a rifamycin plus pyrazinamide, but the only clear advantage over isoniazid monotherapy is the shorter duration of treatment. A study in Zambia revealed that the 2-month combination regimens or 6 months of isoniazid, administered twice weekly, reduced the incidence of tuberculosis by about 40% compared with a placebo group, although the overall mortality due to all causes was not reduced. [54]

The relatively short-term benefit of preventive therapy is a further problem. By 18 months, the incidence of tuberculosis in those who receive prophylactic therapy is similar to that in those not receiving such therapy, indicating the need to consider repeated courses or, perhaps, lifelong prophylactic treatment.[55] As a general rule, prevention is more effective in those who have relatively limited immunosuppression (positive tuberculin tests, high lymphocyte counts and high hemoglobin levels). This, together with the difficulty in detecting co-infection, has led to the current recommendation to restrict preventive therapy to tuberculin positive, HIV-positive persons.

DRUG INTERACTIONS

Clinically significant interactions between the first-line antituberculosis drugs themselves are uncommon but such reactions could well occur when more complex regimens are used to treat MDRTB. Antituberculosis drugs may interact with drugs used to treat unrelated conditions (Table 202.12). Rifampin is the most important in this respect because it is a potent inducer of cytochrome isoenzymes involved in the metabolism of many drugs. The increased metabolism and clearance of these drugs may lead to therapeutic failure unless levels are adjusted and then readjusted when rifampin therapy ceases. Patients on oral contraceptives should be advised to use alternative forms of birth control.

TABLE 202-12 -- Clinically significant drug interactions with antituberculosis agents.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS WITH ANTITUBERCULOSIS AGENTS	
Effects opposed by rifampin	
Antiretroviral agents	Opioids
Azathioprine	Oral contraceptives
Corticosteroids	Phenytoin
Cyclosporin	Propranolol
Diazepam	Quinidine
Digoxin	Theophylline
Haloperidol	Tolbutamide
Imidazoles	Warfarin
Potentiates the effects of rifampin	
Trimethoprim-sulfamethoxazole	
Effects potentiated by isoniazid	
Phenytoin	
Carbamezapine	
Potentiates the effects of isoniazid	
Insulin	

Effects opposed by isoniazid
Enflurane
Opposes the effects of isoniazid
Prednisone
Antacids (inhibit absorbtion)
Effects potentiated by streptomycin
Neuromuscular blocking agents
Effects potentiated by quinolones
Aminophylline and theophylline
Potentiates the effects of quinolones
Cimetidine
Opposes the effects of quinolones
Antacids, iron preparations, sucralfate, didanosine (all inhibit absorbtion)

Rifampin reduces the plasma concentrations and half-lives of the imidazole and triazole antifungals and these agents reduce plasma levels of rifampin. Because some patients, notably those who are HIV-positive, may also require antifungal therapy, these interactions, which may lead to treatment failure, are of increasing importance.[56] Patients who are HIV-positive may also be receiving trimethoprim-sulfamethoxazole for prevention or treatment of *Pneumocystis carinii* infection. This agent significantly increases the serum levels and half-life of rifampin, leading to an increased incidence of adverse effects, including hepatotoxicity.[57]

Drug interactions with isoniazid are more pronounced in slow acetylators. The effects of isoniazid are potentiated by insulin and opposed by prednisone (prednisolone); its absorption from the intestine, and that of ethambutol and the quinolones, is inhibited by antacids containing aluminum hydroxide. The effects of carbamazepine and phenytoin are potentiated by isoniazid and those of enflurane are opposed.

A limited number of drug interactions with other antituberculosis agents have been described and reviewed.[58]

Drug interactions with antiretroviral agents

Protease inhibitors such as saquinavir, ritonavir, indinavir and nelfinavir all interact with rifampin.[58] [59] Rifampin accelerates the metabolism of protease inhibitors (through induction of hepatic P450 cytochrome), resulting in subtherapeutic levels of the protease inhibitors and thereby increasing the risk of the development of viral resistance. In addition, protease inhibitors retard the metabolism of rifampin, resulting in increased serum levels and the likelihood of increased drug toxicity (see Chapter 129).

When prescribing antiretrovirals with antituberculosis drugs, it is important to refer to the latest guidelines on the subject since these are updated frequently. As new antiretroviral agents are being discovered and used, new interactions with antituberculosis drugs are being discovered. Updates on these periodically appear on the US Centers for Disease Control and Prevention website — http://www.cdc.gov/epo/mmwr/mmwr_rr.html.

Two pharmacokinetic issues complicate treatment: the possibility of malabsorption of drugs and the complex drug-drug interactions between antiretroviral and antituberculosis drugs described above. While HIV-infected patients who have tuberculosis commonly experience adverse drug interactions, current recommendations are that highly active antiretroviral therapy (HAART) is commenced early in patients who have advanced HIV disease ($CD4^+$ counts <100 cells/mm^3). [60] In clinically stable patients who have $CD4^+$ cells in excess of 100×10^6 cells/mm^3 /l, HAART should be deferred until the continuation phase of tuberculosis treatment (i.e. after 2 months of antituberculosis therapy). The current recommendation in this case is to replace rifampin by rifabutin, a much less powerful inducer of cytochrome enzymes, and to commence or continue with the antiretroviral drugs.[61]

DRUG SUSCEPTIBILITY TESTING

The purpose of drug susceptibility testing is not to detect small numbers of drug-resistant mutants, which will inevitably be present in every patient who has tuberculosis and in every culture, but rather to determine whether the great majority of the bacilli are susceptible to levels of the drugs that are achieved clinically. In the developed nations with the requisite facilities, and particularly where MDRTB is common, susceptibility testing of all clinical isolates is definitely indicated.[62] In most developing countries, facilities for conducting drug susceptibility tests are very limited.

TABLE 202-13 -- Techniques used to determine susceptibility to antituberculosis agents in vitro.

TECHNIQUES USED TO DETERMINE SUSCEPTIBILITY TO ANTITUBERCULOSIS AGENTS IN VITRO		
Technique	**Where technique is used**	**Description of technique**
Proportion method	USA and some European countries	Drug-free and drug-containing media are inoculated with test strains and the colony counts are compared; strains are reported as resistant if the colony count on the drug-containing medium is over 1% of that on the drug-free medium
Absolute concentration method	Some parts of Europe	Based on growth on media containing doubling dilutions of a known concentration of drug, so that the minimal bactericidal concentrations of drugs may be determined
Resistance ratio method	UK and those countries influenced by British bacteriologists	Similar to the absolute concentration method except that results are expressed as the ratio of the drug concentration inhibiting the test and drug susceptible control strains, rather than as the actual inhibiting concentration
Disk diffusion method	Rarely used	Similar to absolute concentration method and resistance ratio method but technically simpler, as disks containing the drugs are placed on the solid media, thereby avoiding the need to prepare batches of media containing the various drugs

The epidemiologic importance of susceptibility testing has recently been emphasized by the need to monitor the global incidence and distribution of acquired and primary drug resistance. Unfortunately, susceptibility testing is expensive and time-consuming and requires good laboratory facilities, a high level of technical expertise and rigid quality-control procedures. There is no point in doing such testing unless high standards of accuracy can be maintained because much harm may be done by modifying regimens to include less effective and more toxic drugs on the basis of false reports of resistance.

Global surveys on drug resistance have been compromised by the variety of methods used for surveillance and for drug susceptibility testing and the lack of standardization of the methods. The WHO has therefore prepared guidelines for standardized surveillance techniques and has established a network of supranational reference laboratories to co-ordinate surveillance and to provide technical guidance and assistance.[32] [63]

Methods of susceptibility testing

Methods for drug susceptibility testing can be divided into:

- those that are based on inhibition of bacterial growth on drug-containing standard media;
- those that detect growth inhibition by automated radiometric and related systems;
- those that use biologic indicators of bacterial viability, such as enzyme activity and bacteriophage replication; and
- those that use nucleic-acid-based technology to detect mutations in genes determining susceptibility to drugs.

Conventional techniques

Methods for drug susceptibility testing based on growth on conventional media are well established but have the great disadvantage that there is a long delay before results are available. Four methods are currently in use (Table 202.13).

In an (unpublished) investigation carried out by members of the European Society of Mycobacteriologists, there were only minor discrepancies between results obtained by different workers using the first three of the methods listed in Table 202.13 . All these methods may be used either for direct susceptibility tests on smear-positive sputum or for indirect susceptibility tests on cultures. The relative merits and usefulness of these methods in differing circumstances are reviewed in several places.[64] [65]

Conventional tests for susceptibility to pyrazinamide pose particular problems because the drug acts only in acidic environments in which bacterial growth is poor. Thus, the tests require careful standardization and interpretation.

Rapid techniques

The radiometric technique has been widely used in the industrially developed countries.[66] It is more costly than the conventional methods but the rapidity of the results justifies the extra cost, especially where multidrug resistance is common. Susceptibility to all antituberculosis drugs, including pyrazinamide, can be determined by this method. Automated, nonradiometric systems for performing rapid drug susceptibility tests are increasingly used.[67] The latter systems are based on the unquenching of a fluorescent dye when oxygen is consumed by mycobacterial metabolism or on color changes in dyes when carbon dioxide is liberated from nutrients in the medium.

Several rapid methods for the detection of mutations in the *rpoB* gene conferring resistance to rifampin have been described; one of these, based on a number of DNA probes for wild-type and mutated regions of the gene (line hybridization assay), is available in a commercially available kit form. The sites of mutations responsible for resistance to some other antituberculosis drugs, including streptomycin, pyrazinamide, isoniazid and ethionamide, are also known, and so commercially available kits for rapid detection of resistance to these and other drugs may soon be available. [68]

Bacteriophages have been used to detect bacterial viability in the presence of antituberculosis agents.[69] Enzyme activity has been used for the same purpose and one rapid and inexpensive method is based on detection of nitrate reductase activity.[70]

CONCLUSIONS

Chemotherapy is the mainstay of tuberculosis control and modern short-course regimens are among the most effective and cost-effective of all therapeutic interventions for any human disease. Sadly, this potent intervention has been so badly used that tuberculosis remains the leading infectious cause of death worldwide and control of the disease is now seriously threatened by the emergence of multidrug resistance. Although recent advances in immunology and molecular biology may eventually yield novel preventive and therapeutic agents, the overwhelming need at the present time is ensure that the available disease control tools are universally deployed and used in the most effective ways possible.

Chapter 203 - Miscellaneous Agents: Fusidic Acid, Nitrofurantoin and Spectinomycin

S Ragnar Norrby

This chapter deals with three antibiotics that are chemically different and have different antibacterial spectra and clinical uses.

FUSIDIC ACID

Fusidic acid has a steroidal chemical structure. It inhibits protein synthesis in Gram-positive bacteria.

PHARMACOKINETICS, ROUTE OF ADMINISTRATION AND DOSAGE

Fusidic acid is available for intravenous, oral or topical administration. The bioavailability after oral administration is 75–90% with tablets but only about 23% in children given a suspension.[1] After an oral dose of 500mg given as tablets, the initial plasma concentration is approximately 30mg/l and in steady state the concentration is about 100mg/l after a dosage of 500mg q8h. The protein binding is about 97%.

Fusidic acid is lipid-soluble and is efficiently distributed to peripheral compartments, including brain tissue, but excluding cerebrospinal fluid. [2] The elimination half-life is about 9 hours. Fusidic acid is eliminated mainly by conjugation to glucuronide in the liver and subsequent biliary excretion. Fusidic acid *per se* has no known effects on the central nervous system, lung, liver, kidney or prostate/genitourinary system.

The dosage of fusidic acid is:

- 500mg q8h orally or intravenously for adults; and
- 15–20mg/kg q12h for children.

Doses should be reduced in patients who have hepatic diseases, particularly biliary obstruction. Full doses can be given to patients who have renal insufficiency and to elderly. Because of the high protein binding, administration of fusidic acid should be avoided during the last trimester of pregnancy and to newborn children (risk for accumulation of bilirubin in the central nervous system — 'kernicterus').

INDICATIONS

The antibacterial spectrum of fusidic acid includes mainly *Staphylococcus aureus* but also coagulase-negative staphylococci and Gram-positive anaerobes, including *Clostridium difficile*.[3] In addition, fusidic acid has been found to be active against *Mycobacterium kansasii* and *Mycobacterium leprae*.[4] [5] The antistaphylococcal spectrum includes methicillin-resistant strains, and sensitive strains typically have minimum inhibitory concentrations (MICs) of 0.25mg/l or less.[3]

Additive, synergistic or antagonistic antibacterial activity may result when fusidic acid is combined with other antibiotics.[3] [6] The lack of predictive interaction between fusidic acid and other antibiotics is a problem because fusidic acid should be combined when used in systemic infections to avoid the possible emergence of resistance. In experimental staphylococcal endocarditis it was shown that, when fusidic acid was used as a single agent, resistance emerged in five of 12 animals, whereas no resistance was seen in animals treated with vancomycin plus fusidic acid.[7]

The spectrum of fusidic acid makes it one of the few antibiotics that can be used for the oral treatment of methicillin-resistant staphylococci. It should then preferably be combined with another antibiotic to avoid the emergence of resistance. Candidates for combinations with fusidic acid are clindamycin, rifampin (rifampicin), and possibly linezolid. Fusidic acid is widely used for the treatment of bone and joint infections due to *S. aureus*, usually combined with flucloxacillin, although there are no formal studies showing that the combination is better than flucloxacillin alone. Topical fusidic acid has been used to eliminate carriage of methicillin-resistant *S. aureus*.

ADVERSE REACTIONS AND INTERACTIONS

Intravenous fusidic acid causes local irritation and thrombophlebitis in about 15% of patients treated, and hemolysis may occur following rapid infusion (normal infusion time is 2 hours or more). In newborns fusidic acid may cause kernicterus. Fusidic acid may interact with coumarin derivatives and oral contraceptives, reducing the bioavailability of these drugs through interference with the fecal flora.

NITROFURANTOIN

Nitrofurantoin interacts with bacterial protein synthesis in aerobic bacteria.

PHARMACOKINETICS, ROUTE OF ADMINISTRATION AND DOSAGE

Nitrofurantoin is administered orally as a microcrystalline or macrocrystalline formulation, of which the latter has a slower absorption rate. Absorption is almost complete, with 2–4% of the dose being recovered from the feces.[8] Serum concentrations are not measurable, except in patients who have severe renal failure. This is because of destruction of nitrofurantoin in the tissues and, in particular, a very rapid renal elimination by glomerular filtration (20%) and tubular secretion, resulting in a serum half-life of only 20 minutes in patients who have normal renal function.[8] Excretion is complete within 6 hours after intake and urine concentrations achieved are 200–400mg/l after a dose of 100mg q8h. In patients who have renal failure — who should not be given nitrofurantoin — there are measurable but still very low serum and urine concentrations.[9] Nitrofurantoin has no effects on the central nervous system and does not affect the kidneys, the prostate or the genitourinary system. It may cause toxic hepatitis or allergic lung reactions (see below).

Therapeutic doses of nitrofurantoin are 50–100mg q8h or q6h for adults and 3mg/kg/day q12h or q8h for children. Prophylactically, the adult dose is 50–100mg at bedtime, and the pediatric dose is 1–2mg/kg. The duration of treatment when nitrofurantoin is used therapeutically should be 5–7 days. Dosages are not affected by liver function. Nitrofurantoin can be used during pregnancy and lactation.

INDICATIONS

Nitrofurantoin is active against aerobic Gram-negative and Grampositive bacteria, including enterococci but excluding *Pseudomonas aeruginosa*. [10] Resistance is still rare in *Escherichia coli* but is frequently seen in *Klebsiella* spp.[11] Because nitrofurantoin loses most of its antibacterial activity in alkaline pH, it is not active against *Proteus, Morganella* and *Providencia* spp., even if susceptibility testing shows sensitivity. Nitrofurantoin should only be used for the treatment and prevention of urinary tract infections — complicated and uncomplicated bacterial cystitis.

In a study comparing 3-day treatment regimens of trimethoprim-sulfamethoxazole 160–800mg q12h, cefadroxil 500mg q12h, amoxicillin 500mg q8h and nitrofurantoin 100mg q6h for the treatment of uncomplicated cystitis in women, significantly better results were obtained with trimethoprim-sulfamethoxazole than with the other three regimens, which did not differ from each other.[12] Possible reasons for the lower activities of nitrofurantoin and the ß-lactams are lack of activity on the fecal and vaginal flora and the short duration of treatment. Despite these findings, nitrofurantoin has a place in the therapy of cystitis, especially for pregnant women and children. However, the duration of treatment should be at least 5 days; similar efficacy results have been reported for trimethoprim-sulfamethoxazole and nitrofurantoin when they are used for 7 days.[13]

The use of a single dose of nitrofurantoin at night to prevent cystitis is documented, albeit with some study design deficiencies.[14]

ADVERSE REACTIONS

Table 203.1 lists the most important adverse reactions to nitrofurantoin. They occur at low frequencies (<0.5%).[15] The risk for these reactions can be markedly reduced by:

- avoiding long-term (>7 days) treatment, especially in the elderly;
- avoiding daily doses higher than 300mg in adults; and
- reducing the dosage for elderly patients and patients who have renal impairment.

Nitrofurantoin should not be used for patients who have renal failure because the urine levels are too low and there is an increased risk of adverse reactions. Upper gastrointestinal adverse reactions (nausea, vomiting, anorexia) may occur and seem to be more common with the old microcrystalline formulation than with the macrocrystalline one that is now used.[13]

TABLE 203-1 -- Serious adverse reactions to nitrofurantoin.

SERIOUS ADVERSE REACTIONS TO NITROFURANTOIN	
Adverse reaction	**Risk factor**
Eosinophilic lung infiltrates, fever	Prolonged treatment time, high doses
Pulmonary fibrosis	Elderly female patients, high doses
Polyneuropathy	High dose relative to renal function
Hepatitis	Long treatment time
Hemolytic anemia	Hereditary glucose-6-phosphate dehydrogenase deficiency

SPECTINOMYCIN

Spectinomycin is an aminocyclitol antibiotic with a chemical structure similar to that of the aminoglycosides. Another similarity to the aminoglycosides is that spectinomycin acts by inhibiting bacterial protein synthesis at the 30S ribosomal level.[16]

PHARMACOKINETICS, ROUTE OF ADMINISTRATION AND DOSAGE

Spectinomycin is always given intramuscularly. It is rapidly and completely absorbed and a concentration of about 80mg/l is achieved after a dose of 2g.[17] Its protein binding is low (<5%) and it has an apparent volume of distribution of 0.3l/kg. The elimination is renal, with a half-life of about 1 hour. It has no reported effects *per se* on any organ system.

Spectinomycin is given as a single intramuscular dose of 2g for gonococcal urethritis and at a dose of 2g q12h for 3 days for disseminated gonorrhea. Dose reductions are not necessary in any patient category.

INDICATIONS AND ADVERSE REACTIONS

Spectinomycin was developed to act against the increasing number of strains of *Neisseria gonorrhoeae* resistant to ß-lactam antibiotics and other drugs used to treat gonorrhea. Resistance to spectinomycin is uncommon in gonococci.[18] The only indication for spectinomycin is gonococcal urethritis. It is not usually a first-line choice but should be considered as an alternative to other, and often more effective, regimens, for instance in pregnancy when the patient is allergic to cephalosporins.[19]

Chapter 204 - Antiretroviral Agents

Scott M Hammer
Christine J Kubin

INTRODUCTION

The field of antiretroviral therapy is approaching its 20th anniversary. It began shortly after the discovery of HIV-1 in 1983, following which in-vitro cultivation of the virus permitted the screening of agents for antiviral activity. The availability of viral-specific targets (Fig. 204.1) has facilitated high throughput screening and rational drug design efforts, which resulted in the availability of 19 US Food and Drug Administration (FDA)-approved agents by mid-2003 (Table 204.1).

The availability of potent combination therapy has led to dramatic reductions in morbidity and mortality in the developed world.[1] Despite these advances, the challenges of adherence, toxicities and drug resistance have placed recognizable limits on the currently available agents. Thus, continued drug development is a necessity if further progress is to be made and, in this respect, cautious optimism is justified. The developmental horizon includes the potential for several new agents within existing drug classes and promising agents in the novel drug classes. The clinical use of antiretroviral agents involves a pathogenesis-based, combination treatment approach. The principles and approach to antiretroviral therapy and clinical monitoring tools are addressed in Chapter 138 , Chapter 139 , Chapter 140 . The reader is also referred to published antiretroviral therapy guidelines from the Department of Health and Human Services[2] and the International AIDS Society—USA.[3] This chapter will review the characteristics of both approved and selected investigational agents. Although they will be discussed individually, it is critical to remember that these drugs must be used in appropriate combinations to provide sufficiently potent therapy to realize durable clinical benefits.

NUCLEOSIDE ANALOG REVERSE TRANSCRIPTASE INHIBITORS

Nucleoside analog reverse transcriptase inhibitors (NRTIs) were the first class of antiretroviral agents developed (Fig. 204.2). These drugs share a common mechanism of action. As purine or pyrimidine analogs, they require intracellular anabolic phosphorylation to triphosphate forms to be active inhibitors of the HIV reverse transcriptase. The NRTI triphosphates act as competitive inhibitors of the normal nucleoside triphosphates, are incorporated into the growing proviral DNA chain, and act as chain terminators.

Zidovudine

Description

Zidovudine — 3'-azido-,3'-deoxythymidine (AZT, ZDV; see Fig. 204.2) —is converted to ZDV triphosphate sequentially by cellular thymidine kinase, thymidylate kinase and nucleoside diphosphate kinase. Zidovudine triphosphate possesses a 100-fold greater selectivity for the HIV-1 reverse transcriptase than for the cellular DNA polymerase alpha, thus accounting for its viral specificity. The drug is active against HIV-1, HIV-2 and human T-cell lymphotropic virus type 1 (HTLV-1).

Pharmacokinetics and distribution

Zidovudine is rapidly and well absorbed following oral administration, but exhibits a mean systemic bioavailability of about 64% due to significant first-pass metabolism. Peak plasma concentrations of intravenous and orally administered ZDV range from 1.5 to 18µmol/l with single and multiple doses of 1–10mg/kg. [4] Zidovudine is highly lipophilic and widely distributed throughout the body.[5] Concentrations in the cerebrospinal fluid (CSF) in adults have ranged from 15 to 135% of plasma concentrations. Zidovudine is approximately 25% protein bound, primarily to albumin, and is primarily metabolized by hepatic 5'-glucuronidation forming a glucuronidated metabolite that is renally excreted.[5] [6] The serum half-life of ZDV is approximately 1 hour.

Route and dosage

Zidovudine is available as capsule, tablet, oral liquid and intravenous preparations. The latter is used nearly exclusively intrapartum to prevent maternal-fetal HIV-1 transmission. Oral formulations are available as ZDV alone or in fixed dose combinations with lamivudine (Combivir) or with lamivudine and abacavir (Trizivir). The usual adult therapeutic dosage of ZDV is 300mg q12h.

Indications

Zidovudine was the first approved antiretroviral agent in the USA and has been a cornerstone of therapy throughout the nucleoside monotherapy, dual nucleoside therapy and multiple drug combination therapy eras. It is indicated for the treatment of HIV-1 infection in combination with other antiretroviral agents. Typically, it is paired with another NRTI to form a dual nucleoside component of a three- or four-drug regimen. The second NRTI is most commonly lamivudine or didanosine but should never be stavudine because of demonstrated antagonism.[7] In antiretroviral naive patients, these dual nucleoside components need to be prescribed with a protease inhibitor (PI), a non-nucleoside reverse transcriptase inhibitor (NNRTI) or the potent NRTI abacavir, to form a combination regimen capable of suppressing plasma HIV-1 RNA to less than 50 copies/ml. The use of ZDV in treatment-experienced patients should be guided by the previous treatment history and the results of drug resistance testing. The presence of NRTI class cross-resistance often limits the efficacy of ZDV in second- and third-line regimens.

Zidovudine plays a role in the prevention of HIV-1 acquisition in the following circumstances:

- as a cornerstone of regimens to prevent maternal-fetal transmission following the landmark findings of the AIDS Clinical Trials Group, Study 076, in which transmission was reduced by two-thirds;[8] (see Chapter 135)
- following accidental needle-stick exposure in health care workers; and
- following unprotected sexual exposure, as in cases of rape.

In the setting of the prevention of maternal-fetal transmission, published guidelines suggest including ZDV as part of the regimen irrespective of the treatment history of the mother. In the setting of

accidental exposure, the risk of drug resistance in the index case should be factored into the choice of the appropriate prophylactic regimen.

TABLE 204-1 -- US Food and Drug Administration approved agents.

FDA APPROVED AGENTS			
Nucleoside/nucleotide reverse transcriptase inhibitors	**Non-nucleoside reverse transcriptase inhibitors**	**Protease inhibitors**	**Entry inhibitors**
Zidovudine (Retrovir)	Nevirapine (Virammune)	Saquinavir (Invirase, Fortovase)	Enfuvirtide (Fuzeon)
Didanosine (Videx, Videx EC)	Delavirdine (Rescriptor)	Indinavir (Crixivan)	
Zalcitabine (Hivid)	Efavirenz (Sustiva)	Ritonavir (Norvir)	
Stavudine (Zerit)		Nelfinavir (Viracept)	
Lamivudine (Epivir)		Amprenavir (Agenerase)	
Abacavir (Ziagen)		Lopinavir/ritonavir (Kaletra)	
Tenofovir disoproxil fumarate (Viread)		Atazanavir (Reyataz)	
Emtricitabine (Emtriva)			

Resistance

Zidovudine, being the first antiretroviral agent in widespread use, became the first drug to which the development of drug resistance was described in 1989.[9] The mechanism of resistance is thought to be mediated by pyrophosphorolysis, which facilitates the removal of ZDV after its incorporation into the proviral DNA chain. Resistance to ZDV is mediated primarily by six mutations, which include M41L, D67N, K70R, L210W, T215F/Y and K219Q/E. High level ZDV resistance requires the accumulation of three to four mutations. These ZDV-associated mutations are now referred to as nucleoside analog-associated mutations (NAMs) because of the increasing recognition of their role in cross-resistance to other members of the NRTI and nucleotide RTI classes (Fig. 204.3). Resistance to ZDV can also be mediated by two multinucleoside resistance complexes: the Q151M complex (A62V, V75I, F116Y, Q151M) and a T69S 6bp insertion in the presence of NAMs (see Fig. 204.3).

Dosage in special circumstances

Dosage adjustment is necessary in patients with severe renal disease (Table 204.2). In patients with hepatic dysfunction, ZDV clearance is reduced and dosage modification is recommended. Limited data are available regarding specific dosage recommendations for patients with liver disease. Based on limited pharmacokinetic data in 14 patients with liver cirrhosis, a ZDV dose reduction by 50% or a doubling of the interval has been recommended. [6]

Zidovudine crosses the placenta with concentrations in the fetal circulation approximately 85% of maternal plasma concentrations. Teratogenic effects with ZDV have only been reported in rodents when exposed to lethal maternal doses (pregnancy category C).[10]

Adverse reactions and drug interactions

The major toxicities of ZDV include nausea, headache, anemia, neutropenia and myopathy (Table 204.3). Nucleoside reverse transcriptase inhibitor class toxicities are listed in Table 204.4 . Clinically significant drug interactions are minimal because ZDV is predominantly renally excreted.

Didanosine

Description

Didanosine — 2',3'-dideoxyinosine (ddI; see Fig. 204.2) — is sequentially converted intracellularly to 2',3'-dideoxyinosine monophosphate by 5'-nucleotidase, and to 2',3'-dideoxyadenosine monophosphate by adenylosuccinate synthetase and adenylosuccinate lyase. It is then converted to the ddA-triphosphate, which is the active form of the drug, possessing activity against HIV-1 and HIV-2.

Pharmacokinetics and distribution

Didanosine bioavailability varies from 21 to 54% following oral administration in adults. It is recommended that didanosine be

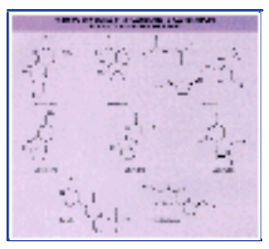

Figure 204-2 Chemical structures of approved nucleoside analog reverse transcriptase inhibitors.

administered on an empty stomach to increase absorption. Administration of didanosine tablets and delayed release capsules with food decreases the didanosine area-under-the-curve (AUC) by approximately 55 and 19%, respectively. Didanosine exhibits linear pharmacokinetics with peak plasma concentrations ranging from 0.52 to 2.79mg/l after oral doses of 125–375mg q12h.[11] Results of pharmacokinetic studies suggest similar AUC values comparing the standard twice daily regimen to the same total daily dose administered once daily.[12] Didanosine is less than 5% protein bound. Concentrations in the CSF have been reported to be approximately 21% of those in plasma.[11] The plasma half-life of didanosine is short (<2 hours), but the in-vitro intracellular half-life of the triphosphate appears prolonged (>25 hours).[13] Didanosine is partially metabolized to ddATP or uric acid, or enters the purine metabolic pool.

Route and dosage

Didanosine is given orally and exists as enteric-coated capsules, chewable tablets (buffered), and powder for oral solution formulations. Dosage is weight based. The enteric-coated preparation improves tolerance and is administered once daily. The other formulations may be administered q24h or q12h. In adults, the usual dosage is 400mg q24h for those weighing over 60kg and 250mg q24h for those under 60kg.

Indications

Didanosine is indicated for the treatment of HIV infection in combination with other antiretroviral agents. It has proven efficacious throughout the monotherapy, dual therapy and potent combination therapy eras. Like ZDV, it is typically prescribed as part of the dual nucleoside component of three- to four-drug combination regimens. It is most commonly paired with ZDV or stavudine, although the toxicity of stavudine-didanosine has raised concerns about this combination (see below).

Didanosine-containing dual NRTI components must be used with a PI and/or an NNRTI to provide a potent combination regimen. The drug can be used in both treatment naive and experienced patients. Its use in the latter situation should be driven by the treatment history and the drug resistance profile.

Hydroxyurea increases the intracellular activity of dideoxyadenosine triphosphate and has been studied in combination with didanosine or stavudine-didanosine. Although antiviral activity has been demonstrated, the blunting of CD4 cell responses and toxicity have dampened the enthusiasm for this adjunct to didanosine therapy.

Resistance

Low-fold changes in susceptibility to didanosine are sufficient to compromise the response to the drug and this must be recognized to properly interpret phenotypic resistance results. Genotypically, the signature mutation conferring didanosine resistance is L74V but K65R and M184V have also been associated with low-fold changes in susceptibility. The Q151M complex, the T69S insertions, and multiple NAMs also confer diminished susceptibility to didanosine (see Fig. 204.3).

Dosage in special circumstances

Didanosine clearance is significantly reduced in patients with renal disease and dosage modification is necessary (see Table 204.2). No dosage adjustment is recommended in patients with liver disease.

Didanosine crosses the placenta. Studies evaluating long-term carcinogenicity and teratogenicity have produced negative results (pregnancy category B).[10]

Adverse reactions and drug interactions

The major toxicities of didanosine include pancreatitis, peripheral neuropathy and diarrhea (see Table 204.3). The drug can also cause hepatotoxicity and has been associated with hepatotoxicity and

Figure 204-3 HIV drug resistance mutations. For each amino acid residue the letter above the bar indicates the amino acid associated with wild-type virus and the letter(s) below indicate the substitution(s) that confer viral resistance. The number shows the position of the mutation in the protein. HR1, first heptad repeat. *Courtesy of International AIDS Society — USA (for full details and footnotes see www.iasusa.org).*

TABLE 204-2 -- Nucleoside and nucleotide reverse transcriptase inhibitor dosage modifications in patients with renal dysfunction and with dialysis.

lactic acidosis when used in combination with stavudine in pregnant women. For NRTI class toxicities, see Table 204.4 .

The didanosine buffered tablets have the potential for drug interactions with agents affected by concomitant antacid administration and with any agents that require gastric acidity for absorption. Clinically significant drug interactions have been reported between didanosine formulations and tenofovir disoproxil fumarate (tenofovir DF), delavirdine and indinavir. Administration of once daily didanosine enteric-coated capsules (Videx EC) 2 hours before tenofovir DF administered with a light meal resulted in an approximate 46% increase in didanosine exposure. Co-administration with a light meal resulted in an approximate 60% increase in didanosine exposure. Co-administration of the didanosine buffered tablets with tenofovir DF in the fasting state resulted in an approximate 44% increase in didanosine exposure. There appears to be no effect of either didanosine formulation on the levels of tenofovir DF. If didanosine and tenofovir are used concomitantly, the dosage of didanosine should be reduced to 250mg q24h. Simultaneous administration of didanosine buffered tablets with delavirdine and indinavir resulted in significant decreases in AUC by 20 and 84%, respectively. Consequently, delavirdine or indinavir should be administered 1 hour before didanosine buffered tablets.

Zalcitabine

Description

Zalcitabine — 2',3'—dideoxycytidine (ddC; see Fig. 204.2) — is converted to its active, triphosphorylated form by cellular kinases. The drug is active against both HIV-1 and HIV-2.

Pharmacokinetics and distribution

Zalcitabine exhibits linear pharmacokinetics. Oral bioavailability exceeds 80%. Administration of zalcitabine with food decreases the rate and extent of absorption. With food, the peak concentration

decreases 39%, bioavailability decreases 14% and the time to reach the peak concentration doubles.[14] [15] Concentrations of zalcitabine in CSF have been reported as 14% of plasma levels. [16] Zalcitabine is not significantly metabolized and elimination is more dependent on renal mechanisms because approximately 75% of unchanged drug is recovered in the urine. The half-life of zalcitabine is less than 2 hours.

Route and dosage

Zalcitabine is available as a tablet formulation. It is administered orally with the usual adult dosage being 0.75mg q8h.

Indications

Major clinical end-point trials of zalcitabine reported in the mid-1990s in combination with ZDV demonstrated a clinical benefit to this combination over ZDV monotherapy in treatment naive patients.[17] [18] Despite these findings, the drug has a very limited, if any, role in current antiretroviral therapy. Its limited potency, ineffectiveness in treatment-experienced patients and neurotoxicity contribute to the drug's current position as a low-priority agent.

Resistance

The genotypic patterns that confer reduced susceptibility to zalcitabine are similar to those reported for didanosine. They include K65R, L74V, M184V, multiple NAMs, the Q151M complex and the T69S insertions; T69D also confers zalcitabine resistance (see Fig. 204.3).

Dosage in special circumstances

Dosage adjustment is necessary in patients with renal disease (see Table 204.2). No dosage adjustment is necessary with hepatic impairment.

Zalcitabine crosses the placenta. Zalcitabine has been shown to be carcinogenic in rodents and teratogenic in mice and rats at high doses (pregnancy category C).[10]

Adverse reactions and drug interactions

The major toxicities of zalcitabine include peripheral neuropathy and pancreatitis (see Table 204.3). For NRTI class toxicities, see Table 204.4 . Clinically significant drug interactions are minimal.

Stavudine

Description

Stavudine — 2',3'-didehydro-3'-deoxythymidine (d4T; see Fig. 204.2) — is a thymidine analog that is converted to the active form, stavudine triphosphate, by a series of cellular kinases; the initial phosphorylation is the rate limiting step. The drug has activity against both HIV-1 and HIV-2.

Pharmacokinetics and distribution

Stavudine is rapidly absorbed and exhibits linear pharmacokinetics. Peak concentrations of about 0.9mg/l are achieved within 2 hours. The oral bioavailability is 82–86%. The mean serum half-life is short and ranges between 1 and 1.67 hours, with an intracellular half-life of about 3–4 hours. Protein binding is minimal. Stavudine penetrates into the CSF achieving levels approximately 40% of plasma levels.[19] Stavudine is excreted by renal and non-renal routes with approximately 50% of a dose excreted unchanged in the urine.[20]

Route and dosage

Stavudine is administered orally with the dosage weight adjusted. It is available in capsule and oral solution formulations. For adults weighing over 60kg, the dose is 40mg q12h; for those under 60kg, the dose is 30mg q12h. For the extended-release preparation of stavudine that is currently under investigation, the dose for persons

over 60kg is 100mg q24h.

Indications

Like ZDV, stavudine is commonly used as part of dual NRTI components with lamivudine or didanosine. These are then typically combined with a PI, NNRTI or abacavir to form potent combination regimens. Stavudine can be used in treatment naive patients or as an alternative to ZDV in those patients who exhibit intolerance to ZDV in the first few weeks after initiation of therapy. The association of stavudine with lipoatrophy, perhaps more than with other NRTIs, has led to greater circumspection about using this agent in initial regimens. However, more data concerning the relative risks of the various NRTIs for peripheral lipoatrophy are needed. Its use in treatment-experienced persons should be dictated by the treatment history and the results of drug resistance testing.

Resistance

Low-fold changes in susceptibility can impair the response to stavudine in vivo and this is important to keep in mind in the interpretation of phenotypic resistance testing. Genotypically, the V75T has been thought to be a signature mutation for stavudine resistance but this mutation is only rarely seen in clinical isolates. Recent data suggest that stavudine and stavudine/didanosine can select for ZDV-associated mutations (NAMs) and the Q151M complex. Zidovudine and stavudine share cross-resistance at both the virion and enzyme levels. Zidovudine-resistant isolates should be considered resistant to stavudine (see Fig. 204.3).

Dosage in special circumstances

Stavudine requires dose adjustment in patients with renal disease (see Table 204.2). No dosage modification is recommended in patients with liver disease.

Stavudine crosses the placenta and teratogenicity studies in rodents were negative with a decrease in sternal calcium noted at high doses (pregnancy category C).[10]

Adverse reactions and drug interactions

The major toxicity of stavudine is peripheral neuropathy and the drug has been strongly implicated in peripheral lipoatrophy and mitochondrial dysfunction syndromes (see Table 204.3). For NRTI class toxicities, see Table 204.4 . Clinically significant drug interactions are minimal.

Lamivudine

Description

Lamivudine — (-)2',3'-dideoxy-3'-thiacytidine (3TC; see Fig. 204.2) — is the (-) enantiomer of a sulfur containing cytidine analog. This enantiomer was chosen on the basis of its potency and cytotoxicity profile. It is phosphorylated to its active form, lamivudine triphosphate, by cellular kinases. The drug is active against HIV-1 and HIV-2, and hepatitis B virus.

Pharmacokinetics and distribution

Lamivudine is well absorbed following oral administration with a mean bioavailability of over 80% in adults. Systemic drug exposure is not influenced by administration with food. Peak and trough concentrations of approximately 2µg/ml and 0.33µg/ml, respectively, have been achieved following oral administration of 150mg q12h.[21] The mean serum half-life is approximately 4–6 hours, with the intracellular half-life ranging from 10.5 to 15.5 hours.[22] Lamivudine is less than 36% protein bound. It penetrates the CSF, but the CSF to serum ratio is lower than that of other nucleoside analogs. Lamivudine is not significantly metabolized and is eliminated primarily unchanged via the kidney.

Route and dosage

Lamivudine is administered orally and is available in tablet and liquid formulations. The usual adult dosage is 150mg q12h but 300mg q24h dosing is being explored in clinical trials. The drug is also available as part of a fixed dose combination with ZDV (Combivir) and ZDV plus abacavir (Trizivir).

Indications

Lamivudine is one of the cornerstones of current antiretroviral therapeutics given its potency and excellent tolerability. It is commonly prescribed as part of the nucleoside component of initial regimens, typically paired with ZDV or stavudine. Recent data also suggest that it can be successfully paired with tenofovir DF. As noted previously, these dual NRTI components must be prescribed with a PI, an NNRTI or abacavir to create potent combination regimens. When lamivudine is not part of an initial regimen, it is useful in treatment-experienced patients if the key resistance mutation, M184V, is not present.

Lamivudine is widely used as part of maternal therapies and as part of maternal-fetal transmission interruption regimens. Concerns raised about potential fetal toxicity in a French study have not been borne out by larger reviews of experience in the USA.

Resistance

High-level phenotypic resistance (>500-fold change in susceptibility) quickly and nearly uniformly develops in patients treated with partially suppressive regimens containing lamivudine (e.g. dual nucleoside regimens). This is mediated through the lamivudine signature mutation, M184V. The latter has also been reported to increase the fidelity of the HIV reverse transcriptase and to decrease replicative fitness. The M184V mutation can delay the emergence of ZDV resistance and reverse ZDV resistance when the T215F/Y mutation is present. However, high-level ZDV/lamivudine co-resistance can develop when multiple ZDV associated mutations (NAMs) and the M184V are present.

Other genotypic correlates of resistance to lamivudine are the E44D and V118I mutations which, in the presence of NAMs, can reduce susceptibility to lamivudine in vitro; the clinical significance of these mutations, however, needs further confirmation. The Q151M complex and the T69S insertions also confer lamivudine resistance. Multiple NAMs alone, however, do not reduce susceptibility to lamivudine. This distinguishes lamivudine from the other approved NRTIs (see Fig. 204.3).

Dosage in special circumstances

Dosage adjustment is required in patients with renal disease (see Table 204.2). No dosage adjustment is necessary in patients with liver disease.

Lamivudine crosses the placenta. No carcinogenicity or teratogenicity has been observed in long-term animal studies (pregnancy category C).

Adverse reactions and drug interactions

Lamivudine is generally very well tolerated. Insomnia, headache, pancreatitis and peripheral neuropathy can occur (see Table 204.3). For NRTI class toxicities, see Table 204.4 . Clinically significant drug interactions are minimal. Pancreatitis has been described in children.

Abacavir

Description

Abacavir sulfate — (1S, 4R)-4-[2-amino-6-(cyclopropylamino)-9H-purin-9-yl]-2-cyclo pentene-1-methanol (ABC; see Fig. 204.2) — is converted to carbovir intracellularly. Adenosine phosphotransferase catalyzes the first phosphorylation step. A cytosolic 5'-nucleotidase then converts abacavir monophosphate to carbovir

monophosphate. Cellular kinases then complete the di- and triphosphorylation steps. Carbovir triphosphate is active against HIV-1 and HIV-2.

Pharmacokinetics and distribution

Abacavir is rapidly and well absorbed with a reported absolute oral bioavailability of approximately 83%. Administration with food does not significantly affect the oral bioavailability. Peak concentrations achieved following multiple dose administration of 300mg q12h were reported to be approximately 2.2mg/l.[23] The mean plasma half-life of abacavir is less than 2 hours. Abacavir is 50% protein bound. Its high lipophilicity facilitates its distribution and penetration into the CSF, where concentrations have been reported to be approximately 30% of plasma levels.[24] Abacavir undergoes extensive hepatic metabolism by alcohol dehydrogenase and glucuronyl transferase.

Route and dosage

Abacavir is administered orally and is available in tablet and oral solution formulations. The usual adult dosage is 300mg q12h but single daily dosing is being explored in clinical trials. As noted previously, abacavir is available in a fixed dose combination formulation with ZDV and lamivudine (Trizivir).

Indications

Abacavir's potency and efficacy has permitted a new option in antiretroviral naive patients — the triple NRTI regimen option. Data from two clinical trials comparing ZDV-lamivudine-abacavir with ZDV-lamivudine-indinavir have shown general comparability of these two combinations in intent-to-treat analyses. [25] More long-term efficacy data are needed in patients with high viral loads (e.g. >100,000 plasma HIV RNA copies/ml) and low CD4 cell counts (e.g. <50/mm^3) to provide clinicians with confidence about the triple NRTI option in this circumstance. Patients must be antiretroviral naive and harbor no NRTI-associated mutations to avoid a higher risk of virologic failure on this regimen.

Abacavir does not have to be solely reserved for the triple NRTI option and can be paired with any other NRTI as part of a PI- or NNRTI-based regimen. In previously naive individuals suppressed on a PI-containing regimen and harboring no NRTI-associated mutations, a switch of the PI to abacavir is virologically safe and can improve serum lipid abnormalities.[26] In treatment-experienced patients, abacavir's usefulness depends on the degree of cross-resistance that may have been conferred by previous NRTI therapy (see below).

Resistance

Changes in susceptibility of 8-fold or greater compromise the clinical efficacy of abacavir. Genotypically, a number of mutations confer resistance to abacavir. The M184V mutation alone confers a 2-fold change in abacavir susceptibility and the drug should still be useful in this situation. However, the M184V mutation in the presence of multiple NAMs and/or L74V and K65R will confer higher level abacavir resistance and compromise the drug's efficacy. The Q151M complex and the T69S insertion also confer abacavir resistance (see Fig. 204.3).

Dosage in special circumstances

Dosage adjustment is not necessary in patients with renal disease. No specific dosage modification is recommended in patients with liver disease.

Abacavir crosses the placenta. Developmental toxicity secondary to abacavir has been observed in rats (pregnancy category C).[24]

Adverse reactions and drug interactions

The major abacavir toxicity of concern is a hypersensitivity reaction, which has a 3–5% incidence and can be fatal (see Table 204.3). Abacavir hypersensitivity has been linked to the HLA B*5701 genotype.[27] For NRTI class toxicities, see Table 204.4 . Clinically significant drug interactions are minimal.

Emtricitabine

Emtricitabine — 5-fluoro-1-[(2R,5S)-2-(hydroxymethyl)-1,3-oxathiolan-5-yl]cytosine (FTC, Coviracil) — is a cytidine analog with activity against HIV and hepatitis B. It is more potent than lamivudine in vitro and can be administered q24h. It has proven efficacy in phase III trials. Resistance is mediated by M184V, the same mutation, which confers resistance to lamivudine. The drug has generally been well tolerated.

Selected investigational nucleoside analog reverse transcriptase inhibitors

A number of NRTIs are currently under development with the objectives of improving pharmacokinetics, avoiding toxicities and/or targeting drug-resistant virus.

Amdoxovir

Amdoxovir — (-)-B-D-2,6-diaminopurane dioxolane (DAPD) — is a prodrug of dioxolane guanosine (DXG), an agent with both anti-HIV and hepatitis B activity. Dioxolane guanosine is active against NRTI-resistant strains except for those bearing the Q151M multi-nucleoside complex. Resistance to DAPD/DXG is mediated by K65R and L74V in vitro. The drug has shown dose-dependent antiviral activity in both naive and experienced patients in a short-term phase I trial.

Others

ACH-126, 443 (ß-L-F-d4C) is a once daily NRTI with activity against NRTI-resistant strains and the potential for diminished mitochondrial toxicity given its L-nucleoside configuration. SPD-754 is the (-) enantiomer of dOTC (development of which was halted due to animal toxicity). SPD-754 is active against lamivudine and ZDV-resistant isolates in vitro and may have decreased potential for inducing mitochondrial toxicity. In vitro, K65R and V75I mutations can be selected. Clinical trial results with these two NRTIs are awaited.

NUCLEOTIDE ANALOG REVERSE TRANSCRIPTASE INHIBITOR

Tenofovir disoproxil fumarate

Description

Tenofovir DF — (R)-9-(2-phosphonomethoxypropyl)adenine (TDF; see Fig. 204.2) — is a prodrug of the nucleoside phosphonate 9-R-(2-phosphonomethoxypropyl)adenine (PMPA). Tenofovir DF represents a new class of antiretroviral agents, the nucleotide reverse transcriptase inhibitors (NtRTIs). These drugs differ from the NRTIs by having a phosphate group in the parent molecule. They thus require only diphosphorylation to be converted to their active compounds. Tenofovir DF is converted to tenofovir by serum esterases. Tenofovir is converted to its active diphosphate form serially by adenylate kinase and nucleotide diphosphate kinase. The drug is active against HIV-1, HIV-2 and hepatitis B virus.

Pharmacokinetics and distribution

Tenofovir is administered orally as a prodrug, tenofovir DF. The oral bioavailability of tenofovir is approximately 25 and 40% in the fasting and fed state, respectively, as compared with 1mg/kg intravenous dosing. Following oral administration of tenofovir DF 300mg q24h, mean steady state peak concentrations were reported as 303ng/ml with an estimated half-life of approximately 14 hours. [28] The intracellular half-life of tenofovir diphosphate ranges from 12 to 50 hours.[29] Tenofovir is primarily eliminated renally (70–80%) via a combination of glomerular filtration and active tubular secretion.

Route and dosage

Tenofovir DF is administered orally and is available in a tablet formulation. The usual adult dosage is 300mg q24h.

Indications

Tenofovir DF is approved for the treatment of HIV infection in combination with other antiretroviral agents. Its approval was based upon two randomized trials in treatment-experienced persons in which tenofovir DF was added to previous therapy. Plasma HIV-1 RNA declines of 0.6 $\log_{10}$ and modest CD4 cell rises were seen.[30] In antiretroviral-naive persons, the combination of tenofovir DF-lamivudine-efavirenz was comparable to a regimen of stavudine-lamivudine-efavirenz with respect to virologic suppression and CD4 cell increases.

Resistance

A phenotypic change in susceptibility of over 4-fold compromises the virologic response to tenofovir DF. The K65R is a signature mutation for tenofovir DF but its appearance in patients treated with tenofovir DF is infrequent. Four or more NAMs (especially M41L and L210W) and the T69S insertion also confer resistance to tenofovir DF. Interestingly, the M184V mutation enhances susceptibility to tenofovir DF, but the clinical significance of this finding is unclear. Specifically, the advisability of continuing lamivudine or abacavir to place selective pressure on the M184V mutation (to enhance susceptibility to tenofovir DF) in the setting of resistance to these drugs must be demonstrated in clinical trials before a formal recommendation can be made (see Fig. 204.3).

Dosage in special circumstances

Dosage adjustment and monitoring for drug toxicity are necessary in patients with renal disease. The pharmacokinetics of tenofovir have not been evaluated in patients with creatinine clearances less than 60ml/min and use in this patient population is not recommended until more information becomes available. The presence of hepatic insufficiency is likely to have a limited effect on tenofovir pharmacokinetics and no specific dosage modifications are recommended in this population.

Tenofovir is classified as pregnancy category B. In rats and rabbits, studies have found no evidence of impaired fertility or teratogenicity.

Adverse reactions and drug interactions

Neutropenia, headache, fatigue, pancreatitis, elevated creatinine and hypophosphatemia have been reported (see Table 204.3). As mentioned previously, concomitant use of tenofovir DF with didanosine increases exposure to didanosine and increases the potential for drug toxicity.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

The NNRTI class of antiretroviral agents is a chemically heterogeneous group of compounds that share a common mechanism of action. These agents differ from the NRTIs in that the parent compound is active and no intracellular metabolism is necessary. The drugs in this class allosterically bind in a noncompetitive fashion to a hydrophobic pocket near the active site of the reverse transcriptase and 'lock' the enzyme into an inactive state. The agents in this class also differ from NRTIs in that they are active against HIV-1 except for subtype O and are inactive against HIV-2 strains.

Nevirapine

Description

Nevirapine — 11-cyclopropyl-5,11-dihydro-4-methyl-6H-dipyrido [3,2-b:2',3'-][1,4]diazepin-6-one (NVP; see Fig. 204.4) — is the lead

compound in this class and was the first NNRTI approved in the USA.

Pharmacokinetics and distribution

Nevirapine is well absorbed with an oral bioavailability of 90%. Absorption does not appear to be affected by co-administration with food or antacids. Maximum concentrations are achieved approximately 2 hours after an oral dose with a second peak occurring approximately 14 hours after a dose, presumably due to enterohepatic recycling.[31] Nevirapine exhibits linear pharmacokinetics. Following administration of a single 200mg and 400mg dose, a peak concentration of 7.5µmol/l and 12.8 µmol/l is achieved, respectively. Average steady state plasma concentrations are peak concentrations of 27.1µmol/l and trough concentrations of 15–17µmol/l following 200mg daily. Nevirapine is very lipophilic and widely distributed throughout the body.[32] It is approximately 60% protein bound. Concentrations in the CSF are approximately 45% of those achieved in plasma.[32] Nevirapine is primarily metabolized by the CYP3A4 and CYP2B6 isoenzymes to hydroxy-nevirapine metabolites and induces both these enzyme systems.[33] Auto-induction of its own metabolism has been demonstrated. The half-life of nevirapine is approximately 25–30 hours.

Route and dosage

Nevirapine is administered orally and is available as tablet and oral suspension formulations. The usual adult dosage is 200mg q24h for 14 days followed by 200mg q12h. This dose escalation regimen is recommended to reduce the incidence and severity of rash during treatment initiation.

Indications

Nevirapine is indicated for the treatment of HIV-1 infection in combination with other antiretroviral agents. Due to the vulnerability of nevirapine to single-step, high-level resistance, this drug needs to be used in potent combination regimens designed to suppress plasma HIV-1 RNA levels to less than 50 copies/ml. Partially suppressive regimens or poor drug adherence carry a high risk of engendering nevirapine resistance.

Combination regimens of NNRTI/dual NRTI are now among the recommended first-line therapies for treatment-naive patients. In individuals intolerant to the central nervous system (CNS) side-effects of efavirenz or in women of child-bearing age for whom access to effective contraception is problematic, nevirapine is an appropriate alternative to efavirenz. In previously naive persons who are virologically suppressed on a PI-containing regimen, a switch of the PI to nevirapine can maintain virologic suppression and improve serum lipid abnormalities.

Drug class cross-resistance among currently approved NNRTIs (nevirapine, delavirdine, efavirenz) severely limits the use of NNRTIs as alternative agents in NNRTI-experienced persons with virologic failure. However, in NNRTI-naive persons failing a PI- or triple NRTI-based regimen, this class of agents is critical to the ability to successfully construct a salvage regimen.[34] It is important, however, to be able to support the NNRTI component with at least two other active agents in the alternative regimen to try to avoid the rapid emergence of NNRTI resistance.

Nevirapine has assumed an important role in the prevention of maternal-fetal HIV transmission in the developing world.[35] A single dose of nevirapine to the mother and the infant can reduce HIV transmission by 50%. When added to combination therapy that the mother may be receiving, single-dose nevirapine has not been shown to further reduce HIV transmission in the developed world.[36]

In the prophylaxis of accidental needle-stick exposure in health care workers, the use of nevirapine should be limited given the reports of severe hepatotoxicity when used in this setting.

Resistance

Low-level changes in susceptibility to nevirapine (and other NNRTIs), of the order of 2.5- to 10-fold, are the result of natural polymorphisms in wild-type strains and do not affect the response to these agents. Higher level resistance compromises or eliminates the virologic response to nevirapine. Genotypically, the signature mutation for nevirapine is Y181C, but other nevirapine-associated mutations include L100I, K103N, V106A, V108I, Y188C/I/H and G190A (see Fig. 204.3).

Dosage in special circumstances

Dosage modification is not required for patients with renal dysfunction. Limited data are available in patients with hepatic impairment and no specific dosage modification is currently recommended.

Nevirapine is not associated with teratogenicity in rabbits or rats (pregnancy category C).[10] It rapidly crosses the placenta.

Adverse reactions and drug interactions

The major toxicities associated with nevirapine are rash and hepatotoxicity (which can be fatal; Table 204.5). Nevirapine is a moderate inducer of CYP3A4. Clinically significant drug interactions are summarized in Table 204.6 , Table 204.7 and Table 204.8 .

Delavirdine

Description

Delavirdine — 1-(5-methanesulfonoamido-1H-indol-2-ylcarbonyl)-4-[3-(1-methylethylamino)pyridinyl]piperazine (DLV; see Fig. 204.4) — was the second approved NNRTI approved in the USA. Its use has been limited by the associated high pill burden.

Pharmacokinetics and distribution

Delavirdine is rapidly absorbed with peak concentrations occurring 1–2 hours after administration with an oral bioavailability of about 85%. Administration with food does not significantly affect steady state AUC within a dosage interval, trough plasma concentrations or time to peak concentrations, but reduces peak concentrations approximately 22%.[37] Absorption may be reduced in patients with gastric hypoacidity and with concomitant antacid administration. Delavirdine exhibits nonlinear pharmacokinetics. Mean C_{min} and C_{max} concentrations following delavirdine 400mg q8h are approximately 15µmol/l and 35µmol/l, respectively.[37] Delavirdine is approximately 98% protein bound. Penetration into the CSF is poor, with concentrations only 0.4% of plasma levels.[37] Delavirdine undergoes extensive metabolism into inactive metabolites primarily by CYP3A4 with less than 5% excreted unchanged in the urine. The mean half-life of delavirdine is approximately 6 hours.

Route and dosage

Delavirdine is administered orally and is available as a tablet formulation. The usual adult dosage is 400mg q8h.

DRUGS THAT ARE NOT RECOMMENDED FOR USE WITH NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS			
Drug class	**Nevirapine**	**Delavirdine**	**Efavirenz**
Anticonvulsants		Phenytoin, phenobarbital, carbamazepine	
Antihistamines		Astemizole, terfenadine	Astemizole, terfenadine
Antimycobacterials	(Insufficient data)	Rifampin (rifampicin), rifabutin	Rifampin, rifabutin*
Ergot derivatives		Dihydroergotamine, ergonovine, ergotamine, methylergonavine	Dihydroergotamine, ergonovine, ergotamine, methylergonavine
Gastrointestinal drugs		Cisapride	Cisapride
Herbal products	St John's wort†	St John's wort†	St John's wort†
Lipid lowering agents		Simvastatin, lovastatin	
Neuroleptics		Pimozide	
Oral contraceptives	All oral contraceptives		Ethinyl estradiol and all oral contraceptives
Sedatives/hypnotics		Alprazolam, midazolam, triazolam	Midazolam, triazolam

* Increase daily dose of rifabutin 50%. Consider doubling rifabutin dose in regimens where rifabutin administered two or three times a week
† Co-administration of NNRTIs with St John's Wort is expected to substantially decrease NNRTI concentrations

Indications

Delavirdine is indicated for the treatment of HIV-1 infection in combination with other antiretroviral agents. Its use in clinical practice has been very restricted because of the high pill burden, the reluctance to use this agent if a severe reaction to nevirapine or efavirenz has occurred and the cross-resistance within this class of agents. One advantage the drug does have is its ability to raise the levels of co-administered PIs.

Resistance

Resistance to delavirdine is conferred primarily by the K103N, Y181C and Y188L mutations. The P236L mutation, which was described as a unique delavirdine-associated mutation in vitro, is only rarely seen in clinical isolates (see Fig. 204.3).

Dosage in special circumstances

Delavirdine does not require dosage adjustment in patients with renal dysfunction. No specific recommendations are available for patients with hepatic disease.

Delavirdine crosses the placenta. Carcinogenesis studies are incomplete, with teratogenicity (ventricular septal defects) shown in rats at doses equivalent to human therapeutic exposure (pregnancy category C).[10]

Adverse reactions and drug interactions

The major toxicities of delavirdine are rash, nausea, fatigue and diarrhea (see Table 204.5). Delavirdine is a potent inhibitor of CYP3A4 and has the potential for serious drug interactions and toxicity with selected agents. Clinically significant drug interactions are summarized in Table 204.6 , Table 204.7 and Table 204.8 .

Efavirenz

Description

Efavirenz — (S)-6-chloro-4-(cyclopropylethynyl)-1,4-dihydro-4-(trifluoromethyl)-2H-3, 1-benzoxazin-2-one (EFZ; see Fig. 204.4) — is one of the most widely prescribed NNRTIs because of its potency, q24h administration and lower incidence of rash compared to nevirapine.

Pharmacokinetics and distribution

Efavirenz is well absorbed with peak concentrations achieved 5 hours after oral administration. Absorption appears unaffected by administration with meals containing a moderate fat content. When administered with high-fat meals, a mean increase in AUC of 50% has been shown, and concomitant administration with high-fat meals is not recommended. Efavirenz exhibits linear pharmacokinetics. Average steady state plasma C_{min} and C_{max} following oral administration of 600mg daily are approximately 6µmol/l and 13µmol/l, respectively. [32] Efavirenz is over 99% bound to plasma proteins, predominantly albumin, and crosses the blood-brain barrier, with CSF concentrations on average 0.69% of total plasma concentrations.[38] Efavirenz is metabolized in the liver, predominantly to inactive metabolites by CYP3A4 and CYP2B6. After multiple-dose oral administration, the half-life of efavirenz is approximately 40–55 hours. Efavirenz induces CYP3A4 in vivo, but has also been shown to inhibit CYP3A4, CYP2C9 and CYP2C19 in vitro.[39]

Route and dosage

Efavirenz is administered orally. The usual adult dosage is 600mg q24h, which is now available in a single tablet formulation.

Indications

Efavirenz is indicated for the treatment of HIV-1 infection in combination with other antiretroviral agents. Clinical trials have demonstrated the comparability of efavirenz-based regimens (i.e. combined with two NRTIs) with indinavir-based regimens in patients with both high and low viral loads. The drug now plays a major role in the initial treatment of antiretroviral-naive patients. Clinical trials have also demonstrated the value of efavirenz in patients with virologic failure, but the rapid emergence of NNRTI resistance can occur if the overall regimen potency is compromised by cross-resistance to the other components of the regimen. [34]

The drug should be avoided in patients with a history of significant psychiatric illness because of its CNS side-effect profile. It is also contraindicated in pregnancy because of demonstrated teratogenicity in primates.

Resistance

Resistance to efavirenz during in-vitro passage is mediated by mutations at the following positions: Y179D, Y181C, L100I, K103N and V108I. The drug maintains some degree of activity against viruses containing only the Y181C mutation, but virologic failure rates

TABLE 204-8 -- Significant drug interactions between non-nucleoside reverse transcriptase inhibitors and other drugs.

SIGNIFICANT DRUG INTERACTIONS BETWEEN NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS AND OTHER DRUGS				
		Nevirapine (NVP)	**Delavirdine (DLV)**	**Efavirenz (EFZ)**
Antiarrhythmics/cardiac	Bepridil		? Bepridil; use with caution	
	Amiodarone, lidocaine, quinidine, flecainide, propafenone		? Antiarrhythmics (concentration monitoring recommended); use with caution	
	Dihydropyridine calcium channel blockers*		? Calcium channel blocker; use with caution	
Anticoagulant	Warfarin		? Warfarin; monitor international normalized ratio (INR)	Potential to ? or ? warfarin; monitor INR
Anticonvulsants	Phenobarbital, phenytoin, carbamazepine	Use with caution; monitor anticonvulsant levels	May ? DLV levels	Potential to ? anticonvulsant and/or ? EFZ; monitor anticonvulsant levels
Antifungals	Ketoconazole	? Ketoconazole AUC 63%; ? NVP levels approximately 15–30%; not recommended		Potential to ? antifungal
Antimycobacterials	Rifampin	? NVP C_{min} approximately 37%; not recommended	? DLV AUC approximately 97%; not recommended	? EFZ AUC approximately 26%; not recommended
	Rifabutin	? NVP C_{min} approximately 16%	? Rifabutin AUC 230%, ? DLV AUC 82%; not recommended	? Rifabutin AUC approximately 38%; consider rifabutin ? 50% or doubling of rifabutin when given two or three times a week
	Clarithromycin	? NVP approximately 26%; ? clarithromycin 30%	? Clarithromycin AUC 100%; reduce clarithromycin dose in patients with renal dysfunction	? Clarithromycin AUC approximately 39%; consider use of azithromycin
Corticosteroids	Dexamethasone		? DLV; use with caution	
Immunosuppressants	Ciclosporin		? Immunosuppressant; monitor immunosuppressant levels	
	Tacrolimus			
	Rapamycin			
Lipid lowering agents	Atorvastatin, Fluvastatin		? Statin levels; use with caution or consider pravastatin	
Narcotic analgesics	Methadone	? Methadone; monitor for withdrawal	? Methadone	? Methadone AUC approximately 52%; monitor for withdrawal
Oral contraceptives	Ethinyl estradiol	? Ethinyl estradiol approximately 20%; consider alternative method of contraception	? Ethinyl estradiol	? Ethinyl estradiol approximately 37%; not well characterized; consider alternative method of contraception
Miscellaneous	Sildenafil		? Sildenafil; do not exceed 25mg sildenafil in 48-hour period	

* Dihydropyridine calcium channel blockers: amlodopine, felodipine, isradipine, nifedipine, nicardipine, nimodipine, nisoldipine

are high when this mutation is present at baseline.[40] The most common mutation encountered clinically is K103N, which confers cross-resistance to efavirenz and delavirdine. Other clinically relevant mutations are L100I, V108I, Y188L, G190S/A and P225H. High-level resistance is seen with the double mutations K103N-V108I and L100I-K103N (see Fig. 204.3).

Dosage in special circumstances

No dosage adjustment is required in patients with renal disease. Following a single-dose study in patients with chronic liver disease, efavirenz C_{max} was reduced and the half-life increased with no significant change in AUC compared to healthy volunteers.[32] Administration of the standard dose with close monitoring for toxicity is recommended in patients with liver disease.

Efavirenz crosses the placenta. Teratogenicity has been noted in primates (pregnancy category C).[10]

Adverse reactions and drug interactions

The major toxicities associated with efavirenz are CNS related (e.g. impaired concentration, abnormal dreams, euphoria, anxiety and depression) and rash (see Table 204.5). As above, the drug is teratogenic in primates. Efavirenz acts as an inducer or inhibitor of CYP3A4 depending on the concomitantly administered drug. Clinically significant drug interactions are summarized in Table 204.6 , Table 204.7 and Table 204.8 .

Selected investigational non-nucleoside reverse transcriptase inhibitors

Capravirine

Capravirine — 5-(3,5-dichlorophenyl)thio-4-isopropyl-1-(4-pyridyl) methyl-1H-imidazol-2-ylmethylcarbamate (CPV) — is active against a range of NNRTI-resistant isolates, including those bearing the K103N mutation. The drug has shown substantial antiviral activity in

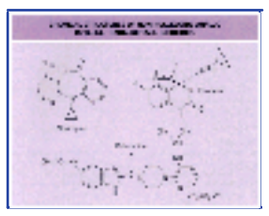

Figure 204-4 Chemical structures of approved non-nucleoside reverse transcriptase inhibitors.

a phase I trial in naive patients. Development was temporarily halted because of animal toxicity but is now continuing.

TMC 125

TMC 125 is a diarylpyrimidine compound that has potency in the nanomolar range against a broad range of NNRTI-resistant isolates. The flexibility of the molecule and its high binding affinity likely account for these favorable characteristics. The drug has demonstrated substantial antiviral activity in short-term, phase I trials in naive and experienced subjects.

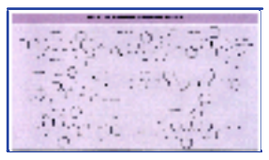

Figure 204-5 Chemical structures of approved protease inhibitors.

PROTEASE INHIBITORS

Mature HIV virions are produced as the virus buds off the cell surface and *gag* and *gag-pol* polyprotein precursors are cleaved by a virally encoded aspartyl protease. Successful inhibition of this enzyme marked a revolution in antiretroviral therapy starting in 1996. Enthusiasm for inclusion of this class of agents in initial regimens has waned with the growing awareness of the associated metabolic complications, but the value of this potent class of agents should not be forgotten. The six currently approved PIs are all peptidomimetic compounds, which bind to the active site of the enzyme and inhibit both HIV-1 and HIV-2.

Saquinavir

Description

Saquinavir — *N*-tert-butyldecahydro-2-[2(R)-hydroxy-4-phenyl-3-(S)-[[*N*-(2-quinolylcarbonyl)-L-asparaginyl]-amino]butyl](4aS,8aS)-isoquinoline-3(S)-carboxamide (SQV; Fig. 204.5) — was the first PI approved in the USA.

Pharmacokinetics and distribution

Saquinavir-hard gel capsule (hgc) is poorly bioavailable with the mean absolute bioavailability of a 600mg oral dose administered with food averaging 4%. This is presumed to be due to limited absorption and extensive first-pass metabolism. [41] The relative bioavailability of saquinavir-soft gel capsule (sgc) is estimated at over 3-fold higher than the hgc formulation. Absorption is improved upon administration with food or up to 2 hours after a meal. The mean C_{max} following oral administration of saquinavir-sgc 1200mg three times daily was 2477ng/ml. Saquinavir is approximately 97% bound to plasma proteins and is extensively hepatically metabolized to mono- and di-hydroxylated inactive compounds, primarily by CYP3A4 (>90%).[41] The half-life following intravenous administration is approximately 7 hours.

Route and dosage

Saquinavir is administered orally and is available as hard-gel and soft-gel capsule formulations. In the absence of pharmacoenhancement, the approved dose of saquinavir-hgc in adults is 600mg three times daily but the drug should not be used in this fashion. Given its poor oral bioavailability, the hgc formulation should only be prescribed with low dose ritonavir enhancement. The dose of saquinavir-sgc is 1200mg three times daily. Low-dose ritonavir is also commonly used to decrease the pill burden associated with the sgc formulation. Under investigation are the following saquinavir-ritonavir dosage regimens: 1000mg/100mg q12h and 1600mg/200mg q24h.

Indications

Saquinavir is indicated for the treatment of HIV infection in combination with other antiretroviral agents. The drug is most commonly used with low-dose ritonavir enhancement and for initial therapy is typically combined with two NRTIs. For the management of treatment-experienced patients with virologic failure, saquinavir as part of single or dual PI ritonavir-enhanced regimens can prove useful depending upon the previous regimen, the results of drug resistance testing and the number of other active agents in the regimen.

Resistance

Resistance to saquinavir is mediated principally by the L90M and to a lesser extent the G48V mutation. Other codon alterations that can contribute to saquinavir resistance include L10I, I54L, A71V/T, G73S, V77I, V82A and I84V (see Fig. 204.3). L90M is one of the major PI mutations associated with drug class cross-resistance.

Dosage in special circumstances

Saquinavir does not require dosage adjustment in patients with renal disease. The pharmacokinetics of saquinavir have not been studied in patients with liver disease. No specific dosage recommendations are available in this patient population.

TABLE 204-9 -- Drugs that are not recommended for use with protease inhibitors.

DRUGS THAT ARE NOT RECOMMENDED FOR USE WITH PROTEASE INHIBITORS						
Drug class	**Saquinavir**	**Indinavir**	**Ritonavir**	**Nelfinavir**	**Amprenavir**	**Lopinavir/r**
Anticonvulsants						
Antihistamines	Astemizole, terfenadine	Astemizole, terfenadine	Astemizole, terfenadine	Astemizole, terfenadine	Astemizole, terfenadine	Astemizole, terfenadine
Antimycobacterials	Rifampin*	Rifampin*	Rifampin*	Rifampin*	Rifampin*	Rifampin*
Cardiac			Bepridil, amiodarone, flecainide, propafenone, quinidine	Amiodarone, quinidine	Bepridil	Flecainide, propafenone
Ergot derivatives	Dihydroergotamine, ergotamine	Dihydroergotamine, ergotamine	Dihydroergotamine, ergotamine	Dihydroergotamine, ergotamine	Dihydroergotamine, ergotamine	Dihydroergotamine, ergotamine

Sedatives/hypnotics	Midazolam, triazolam	Midazolam, triazolam	Midazolam, triazolam	Midazolam, triazolam	Midazolam, triazolam	Midazolam, triazolam

* Rifampin decreases levels of protease inhibitors. Alternative antimycobacterial agents such as rifabutin (with dosage modification) should be considered.

Saquinavir only minimally crosses the placenta. Animal studies have shown no mutagenicity or teratogenicity at 40–50% of AUC values achieved in humans (pregnancy catgory B).[10]

Adverse reactions and drug interactions

Clinically significant drug interactions are summarized in Table 204.6 , Table 204.9 and Table 204.10 .

The major toxicity associated with saquinavir is gastrointestinal symptomatology (Table 204.11). For PI class toxicities, see Table 204.4 . Saquinavir is a weak inhibitor of CYP3A4.

Ritonavir

Description

Ritonavir — 10-hydroxy-2-methyl-5-(1-methylethyl)-1-[2-(1-methylethyl)-4-thiazolyl]-3,6-dioxo-8,11-bis(phenylmethyl)-2,4,7,12-tetraazatridecan-13-oic-acid, 5-thiazolyl-methyl ester [5S-(5R*, 8R*, 10R*, 11R*)] (RTV; see Fig. 204.5) — was the second PI approved in the USA. Its intolerability at full therapeutic doses and its potent CYP3A4 inhibitory activity have combined to position this drug largely, if not exclusively, as a pharmacoenhancer of other PIs, including saquinavir, indinavir, amprenavir and lopinavir.

Pharmacokinetics and distribution

Ritonavir's oral bioavailability is estimated to range from 60 to 80%.[42] Relative to the fasting state, the AUC of ritonavir from the capsule formulation is approximately 15% higher when administered with food. For the oral solution, the AUC is decreased 7% when administered with food.[42] Following oral administration of ritonavir 600mg q12h, the C_{max} and C_{min} were reported as 11mg/l and 4mg/l, respectively. Ritonavir is greater than 98% protein bound, both to albumin and a_1 -acid glycoprotein. Because of the high degree of protein binding, CSF concentrations are low and reported to be less than 0.05mg/l.[42] Ritonavir is extensively metabolized, primarily by CYP3A4 isoenzymes, with the CYP2D6 isoenzyme also contributing

to the production of the isopropylthiazolyl oxidation metabolite.[42] The half-life of ritonavir ranges from 3 to 5 hours.

Route and dosage

Ritonavir is administered orally and is available in capsule and oral solution formulations. It is also available as a co-formulation with lopinavir (Kaletra). When administered as the sole PI, the adult dose of ritonavir is 600mg q12h. As noted, however, ritonavir's major role is as a pharmacoenhancer of other PIs, given the gastrointestinal intolerance conferred by full doses of this agent. Pharmacoenhancement doses depend upon the co-administered PI(s) and whether an inducer of CYP3A4, such as efavirenz or nevirapine, is also included in the regimen. Most typically, ritonavir doses of 100–200mg q12h are used in pharmacoenhanced regimens.

Indications

Ritonavir in full dose carries an indication for the treatment of HIV infection in combination with other antiretroviral agents. As a pharmacoenhancer, it is approved as a co-formulation with lopinavir. It is also commonly used in combination with saquinavir, indinavir and amprenavir.

Resistance

The major mutations conferring resistance to ritonavir are V82A/F/T/S and I84V. Other important mutations include L10F/I/R/V, K20M/R, V32I, L33F, M36I, M46I/L, I54V/L, A71V/T, V77I and L90M (see Fig. 204.3). Cross-resistance between indinavir and ritonavir is nearly complete. When used in low dose as a pharmacoenhancer of a second PI, the pattern of mutations that emerges with virologic failure may be influenced by the presence of ritonavir. The ability to boost the levels of other PIs has brought into focus the importance of pharmacodynamics in the treatment of HIV infection. The relationship of achievable drug concentrations to the 50% inhibitory concentration (IC_{50}) of the individual patient's virus has reinvigorated the concept of the inhibitory quotient in treating microbial pathogens. This has resulted in an attempt to define phenotypic susceptibility cut-offs that are clinically relevant and the consideration of whether therapeutic drug level monitoring has a role in the management of patients with drug-resistant virus.

Dosage in special circumstances

Renal disease is expected to have little effect on ritonavir pharmacokinetics and no dosage modification is necessary. In patients with mild-to-moderate hepatic insufficiency, the ritonavir pharmacokinetics varied little compared to patients with normal hepatic function when the dosage was reduced by 20%.[42] In addition, the elimination half-life increased from 4.6 hours in patients with normal hepatic function to 6.3 hours in patients with moderate hepatic disease. No specific dosage recommendations are available in patients with liver disease.

Less than 10% of ritonavir appears to cross the placenta. Ritonavir was not mutagenic in bacteria or mammalian cells and teratogenicity has only been seen in rats at maternally toxic doses (pregnancy category B).[10]

Adverse reactions and drug interactions

The major toxicities associated with ritonavir are headache, diarrhea, altered taste, circumoral and peripheral paresthesias and hyperlipidemia (see Table 204.11). For PI class toxicities, see Table 204.4 . Ritonavir is the most potent inhibitor of the cytochrome P450 system of all the PIs. Ritonavir inhibits CYP3A4 and CYP2D6 and also increases glucuronosyltransferase activity. Ritonavir also induces CYP3A4 activity and has been shown to induce its own metabolism. Clinically significant drug interactions are summarized in Table 204.6 , Table 204.9 and Table 204.10 .

Indinavir

Description

Indinavir — *N*-(2(R)-hydroxy-1(S)-indanyl)-2(R)-(phenylmethyl)-4(S)-hydroxy-5-[1-[4-(3-pyridylmethyl)-2(S)-(*N*-tert-butylcarbamoyl)piperazinyl]]pentanamide (IDV; see Fig. 204.5) — was the third PI approved in the USA and contributed substantially to ushering in the modern era of potent antiretroviral chemotherapy.

Pharmacokinetics and distribution

Indinavir is rapidly absorbed with peak concentrations occurring within 1 hour. The oral bioavailability is approximately 70%.[43] Administration of indinavir with meals containing high fat, carbohydrate, or protein significantly reduces the AUC by approximately 35–70% compared to the fasting state.[44] Food has little effect on the pharmacokinetics of indinavir when administered concomitantly with low-dose ritonavir. Steady-state peak and trough concentrations were 12.6µmol/l and 0.25µmol/l, respectively, after oral administration of 800mg q8h.[43] Indinavir is approximately 60% protein bound. Studies have shown that indinavir concentrations in the CSF are 2 and 6% of plasma concentrations 2 and 3.75 hours after administration, respectively.[45] A more recent study of indinavir pharmacokinetics in the CSF of eight adults infected with HIV found the free indinavir concentrations in the CSF to be approximately 15% of plasma levels.[46] Indinavir is extensively metabolized by CYP3A4 isoenzymes. The half-life of indinavir is approximately 1.8 hours.

Route and dosage

Indinavir is administered orally and is available as a capsule formulation. The dosage in adults is 800mg q8h in the absence of ritonavir enhancement or the concomitant use of efavirenz or nevirapine. Ritonavir reduces variation in the pharmacokinetic profile of indinavir, eliminates the food effect and converts indinavir to a twice daily agent. Indinavir/ritonavir combinations of 800mg/100mg, 800mg/200mg, 400mg/400mg and 400mg/100mg, respectively, have all been studied and are used clinically. The dose of indinavir should be increased to 1000mg q8h when used with the NNRTIs efavirenz or nevirapine because of the CYP3A4-inducing effect of these drugs (see Table 204.6). This effect can be blocked, however, by the concomitant use of ritonavir. Adequate hydration (approximately 1l of water per day) needs to be maintained to try to prevent nephrolithiasis.

Indications

Indinavir is indicated for the treatment of HIV infection in combination with other antiretroviral agents. There is a considerable published experience with indinavir establishing its clinical and long-term virologic efficacy.[47] [48] It is one of the more commonly prescribed PIs for initial therapy, particularly in patients presenting with advanced disease. It is also useful in the management of antiretroviral failure if the patient's virus isolate remains susceptible and other active drugs remain available for inclusion in the regimen.

Resistance

The major PI mutations conferring resistance to indinavir are M46I/L, V82A/F/T and I84V. Other important mutations include L10I/R/V, K20M/R, L24I, V32I, M36I, I54V, A71V/T, G73S/A, V77I and L90M (see Fig. 204.3). Alterations at three or more codons are necessary before substantial changes in phenotypic susceptibility can be detected. Indinavir and ritonavir cross-resistance is nearly complete.

Dosage in special circumstances

Indinavir's pharmacokinetics are likely little affected by renal disease. In patients with mild-to-moderate hepatic insufficiency and cirrhosis, indinavir AUC was 60% higher following a single 400mg dose and the half-life was increased to 2.8 hours. It is recommended that the

TABLE 204-10 -- Significant drug interactions between protease inhibitors and other drugs.

SIGNIFICANT DRUG INTERACTIONS BETWEEN PROTEASE INHIBITORS AND OTHER DRUGS							
		Saquinavir (SQV)	**Indinavir (IDV)**	**Ritonavir (RTV)**	**Nelfinavir (NFV)**	**Amprenavir (APV)**	**Lopinavir/r (LPV; LPV/r)**

indinavir dose be reduced to 600mg q8h in patients with mild-to-moderate hepatic insufficiency due to cirrhosis.[43]

Indinavir crosses the placenta. In rats, carcinogenicity (an increased incidence of thyroid adenomas) and teratogenicity (increased incidence of supernumerary ribs and unilateral anophthalmia) have been shown (pregnancy category C).[10]

Adverse reactions and drug interactions

The major toxicities associated with indinavir include asymptomatic rises in indirect bilirubin and nephrolithiasis (see Table 204.11). For PI class toxicities, see Table 204.4 . Indinavir is a moderate inhibitor of CYP3A4. Clinically significant drug interactions are summarized in Table 204.6 , Table 204.9 and Table 204.10 .

Nelfinavir

Description

Nelfinavir — [3S-(3R*, 4aR*, 8aR*, 2'S*, 3'S*)]-2-[2'-hydroxy-3'-phenylthiomethyl-4'-aza-5'-oxo-5'-(2''-methyl-3''-hydroxyphenyl)pentyl[decahydroisoquinoline-3-*N*-t-butyl-carboxamide (NFV; see Fig. 204.5) — was the fourth PI approved in the USA.

Pharmacokinetics and distribution

Following administration of nelfinavir 1250mg q12h, peak and trough plasma concentrations were reported as 4mg/l and 1.3–2.2mg/l, respectively. When administered in the fasting state, the AUC of nelfinavir is reduced 27–50%. [49] Nelfinavir should be administered with food. It is 98% bound to plasma proteins. Nelfinavir is hepatically metabolized by CYP450 isoenzymes, primarily CYP3A4 followed by CYP2C19, CYP2D6 and CYP2C9, to two active metabolites with the major oxidative metabolite (M8) exhibiting comparable in-vitro antiviral activity.[49] [50] The half-life of nelfinavir is approximately 3.5–5 hours.

Route and dosage

Nelfinavir is administered orally and is available in tablet and oral powder formulations. The two approved dosage regimens in adults are 750mg q8h and 1250mg q12h.

Indications

Nelfinavir is indicated for the treatment of HIV infection in combination with other antiretroviral agents. It has been a mainstay of potent antiretroviral regimens for several years and has more commonly been used in the treatment of antiretroviral-naive patients (combined with two NRTIs) than as part of salvage regimens. It also has an established record of safety in pregnant women. Comparative clinical trials suggest that nelfinavir combined with two NRTIs is a less potent regimen than lopinavir-ritonavir or efavirenz-based regimens.[51]

Resistance

Resistance to nelfinavir may evolve along one of two pathways — either the D30N or the L90M. The factors that determine which pathway is chosen are not completely defined, but baseline polymorphisms and viral subtype may play a role. The D30N mutation by itself does not confer resistance to the other PIs and therefore successful alternative regimens in the face of virologic failure can often be constructed. When the L90M pathway is chosen, drug class cross-resistance may result. Additional relevant mutations include L10F/I, M36I, M46I/L, A71V/T, V77I, V82A/F/T/S, I84V and N88D/S (see Fig. 204.3).

Dosage in special circumstances

Dosage modification is not necessary in patients with renal disease. No dosage recommendations are available for patients with hepatic disease.

Nelfinavir concentrations in cord blood are low or undetectable compared to maternal concentrations (pregnancy category B). In animal studies, nelfinavir has not been found to be carcinogenic or teratogenic.[10]

Adverse reactions and drug interactions

The principal toxicity associated with nelfinavir is diarrhea (see Table 204.11). For PI class toxicities, see Table 204.4 . Nelfinavir is a moderate inhibitor of CYP3A4. Clinically significant drug interactions are summarized in Table 204.6 , Table 204.9 and Table 204.10 .

Amprenavir

Description

Amprenavir — (3S)-tetrahydro-3-furyl-*N*-[(1S, 2R)-3-(4-amino-*N*-isobutylbenzenesulfonamido)-1-benzyl-2-hydroxypropyl] carbamate (APV; see Fig. 204.5) — was the fifth PI approved in the USA. An amprenavir prodrug, GW 433908, designed to reduce pill size and burden, is under investigation.

Pharmacokinetics and distribution

Amprenavir is rapidly absorbed following oral administration. Peak concentrations of approximately 7.66µg/ml are achieved within 1 to

2 hours following administration of 1200mg q12h. The relative bioavailability of amprenavir oral solution is 14% less than amprenavir oral capsules. Effects of food on amprenavir pharmacokinetics (decreased AUC 23%) are not clinically significant except with high-fat meals, which should be avoided.[52] Amprenavir is approximately 90% protein bound, predominantly to a_1 -acid glycoprotein. Amprenavir is hepatically metabolized by CYP3A4. The plasma half-life of amprenavir ranges from 7.1 to 10.6 hours.

Route and dosage

Amprenavir is administered orally and is available as capsule and oral solution formulations. The dosage in adults is 1200mg q12h when administered without ritonavir enhancement (which increases amprenavir levels) or concomitant efavirenz (which diminishes amprenavir levels). The size and number of amprenavir pills at standard dosing poses a problem for tolerance and drug adherence. Therefore, amprenavir is mostly used with low-dose ritonavir enhancement at a dose of 600mg/100mg q12h, respectively. The dose to use when combined with efavirenz is uncertain but some advise increasing the amprenavir/ritonavir doses to 750mg/200mg q12h, respectively, to ensure adequate amprenavir levels in the face of drug-resistant virus.

Indications

Amprenavir is indicated for the treatment of HIV infection in combination with other antiretroviral agents. Although efficacy for naive patients has been established, the pill burden has generally restricted the drug to the management of treatment-experienced persons. Clinical trials have demonstrated the efficacy of amprenavir in this circumstance[34] and it is now commonly used as part of dual ritonavir-enhanced regimens with lopinavir.

Resistance

Viral isolates resistant to the other approved PIs may remain susceptible to amprenavir. The major mutations conferring amprenavir resistance are I50V (a signature mutation) and I84V. Other important mutations include L10F/I/R/V, V32I, M46I/L, I47V, I54L/V/M, G73S and L90M (see Fig. 204.3).

Dosage in special circumstances

The effects of renal disease on amprenavir pharmacokinetics are limited and no dosage modification is necessary. The AUC of amprenavir in patients with moderate and severe cirrhosis is significantly greater than in patients with normal hepatic function. It is recommended that patients with a Child-Pugh score of 5–8 receive a reduced amprenavir dosage of 450mg q12h, and patients with Child-Pugh score of 9 to 12 receive a reduced amprenavir dosage of 300mg q12h. The oral solution of amprenavir contains propylene glycol (55%) and is contraindicated in patients with renal failure or hepatic failure, in pregnant women and in patients receiving disulfiram or metronidazole.

Amprenavir is classified as pregnancy category C. In rabbits and rats, an increased incidence of abortions (rabbits) and ossification defects (rabbits and rats) have been shown.[10]

Adverse reactions and drug interactions

The major toxicities associated with amprenavir include gastrointestinal symptomatology and rash (see Table 204.11). For PI class toxicities, see Table 204.4 . Amprenavir is a moderate inhibitor of CYP3A4. Clinically significant drug interactions are summarized in Table 204.6 , Table 204.9 and Table 204.10 .

Lopinavir (co-formulated with ritonavir)

Description

Lopinavir — [1S-[1R*, (R*), 3R*, 4R*]]-*N*-[4-[[2,6-dimethylphenoxy) acetyl]amino]-3-hydroxy-5-phenyl-1-(phenylmethyl)pentyl] tetrahydro-alpha-(1-methylethyl)-2-oxo-1(2H)-pyrimidine-acetamide (LPV; see Fig. 204.5) — was the sixth PI approved in the USA. It is co-formulated with ritonavir (lopinavir/r).

Pharmacokinetics and distribution

Lopinavir is poorly bioavailable because it is rapidly metabolized by NADPH and cytochrome P450 3A4/5-dependent enzyme systems. As such, lopinavir is co-formulated with ritonavir. Ritonavir inhibits the metabolism of lopinavir such that the AUC for lopinavir is increased over 100-fold when co-administered with ritonavir.[53] Administration of lopinavir/r with food increased the AUC by 48 and 80% for the capsule and liquid formulations, respectively. Lopinavir is approximately 98–99% protein bound, both to albumin and a_1 -acid glycoprotein. At steady state, lopinavir peak and trough concentrations were reported as 9.6mg/l and 5.5mg/l following twice daily lopinavir/r 400/100mg.[53] Lopinavir undergoes extensive oxidative metabolism via CYP3A. The half-life of lopinavir/r has been reported to be approximately 6 hours.

Route and dosage

Lopinavir/r is administered orally and is available in capsule and oral solution formulations. Lopinavir/r capsules contain 133.3mg of lopinavir and 33.3mg of ritonavir. The usual adult dosage is 400mg/100mg q12h, respectively. When administered with efavirenz, the dose should be increased to 533mg/133mg q12h of lopinavir/r, respectively (see Table 204.6).

Indications

Lopinavir/r is indicated for the treatment of HIV infection in combination with other antiretroviral agents. In antiretroviral-naive patients, lopinavir/r in combination with two NRTIs has shown superior antiviral activity to nelfinavir plus two NRTIs.[51] Lopinavir/r has also shown substantial virologic efficacy in the treatment of NNRTI-naive subjects with both single and multiple PI experience. Lopinavir/r is also used in dual PI-enhanced regimens with amprenavir or saquinavir in the management of patients with drug-resistant virus. Formal studies of the efficacy of this latter approach are underway.

Resistance

The major mutations conferring lopinavir resistance are L10F/I/R/V, K20M/R, L24I, V32I, L33F, M46I/L, I47V, I50V, F53L, I54V/L, L63P, A71V/T, G73S, V82A/F/T/S, I84V and L90M (see Fig. 204.3). The pharmacoenhancement of lopinavir by ritonavir permits the drug to be active against viruses with up to 10- and possibly 40-fold changes in susceptibility to lopinavir.

Dosage in special circumstances

Dosage adjustment is not necessary in patients with renal disease. Close monitoring is advised in patients with liver disease. No specific dosage recommendations are available for this patient population.

Lopinavir has been shown to cross the placenta in rats. Developmental toxicities (skeletal variations and delayed ossification) have been shown in rats at maternally toxic doses (pregnancy category C).[10]

Adverse reactions and drug interactions

The principal toxicities associated with lopinavir/r include gastrointestinal symptomatology, hyperlipidemia and liver enzyme abnormalities (see Table 204.11). For PI class toxicities, see Table 204.4 . Lopinavir is a moderate inhibitor of CYP3A4 and the combination of lopinavir with ritonavir (a potent CYP3A4 inhibitor) is likely to have drug interactions similar to those of full-dose ritonavir alone, but potentially to a lesser degree. Clinically significant drug interactions are summarized in Table

204.6 , Table 204.9 and Table 204.10

Atazanavir

Atazanavir sulfate — dimethyl (3S, 8S, 9S, 12S)-9-benzyl-3,12,di-tert-butyl-8-hydroxy-4,11-dioxo-6-(p-2pyridylbenzyl)-2,5,6,10,13-pentaazatetradecanedioate sulfate (ATV, Zrivada) — is an azapeptide PI whose advantage is q24h administration and the lack of induction of hyperlipidemia. Clinical trials reported to date in antiretroviralnaive patients have suggested that atazanavir sulfate in combination with two NRTIs has comparable efficacy to nelfinavir and efavirenz-based regimens, although in the latter study the efavirenz arm appeared to perform less well than in previously reported trials.[55] The use of atazanavir sulfate in treatment-experienced persons is currently under study. The drug, when administered without ritonavir pharmacoenhancement, has been reported to engender a signature mutation, I50L, in the setting of virologic failure. This mutation confers diminished susceptibility to atazanavir sulfate and appears to induce sensitization to other PIs. This characteristic may be exploitable in future treatment strategies. Other relevant mutations include V32I, M46I, I54L, A71V, V82A, I84V, N88S and L90M (see Fig. 204.3). The drug, in general, has been well tolerated, with an absence of hyperlipidemia a notable feature. The major toxicity noted thus far has been an asymptomatic rise in indirect bilirubinemia, not dissimilar to that seen with indinavir. PR and QT prolongation have also been seen at higher doses of the drug, but the clinical significance of this remains to be clarified.

Selected investigational protease inhibitors

Tipranavir

Tipranavir disodium — [R-(R*, R*)]-N-[3-[1-[5,6-dihydro-4-hydroxy-2-oxo-6-(2-phenylethyl)-6-propyl-2H-pyran-3-yl]propyl]phenyl]5-(trifluoromethyl)-2-pyridinesulfonamide disodium salt (TPV) — is a dihydropyrone, non-peptidic PI whose molecular advantage is the flexibility it can demonstrate in binding to the active site of the HIV protease. It is highly active against viral strains with diminished susceptibility to the approved PIs.[54] Tipranavir disodium is being developed for co-administration with low-dose ritonavir to diminish the pill burden and permit q12h dosing. The major toxicity seen thus far has been gastrointestinal-associated, which appears to be dose related. Clinical trial results reported to date have been promising with phase III studies pending. Its role will likely be in the management of patients with PI-resistant virus.

TMC 114

TMC 114 is a highly potent PI with in-vitro anti-HIV activity in the nanomolar range. The drug is a flexible molecule that binds tightly into the active site of the HIV protease. These qualities help to confer its potency against PI-resistant variants. Phase I trials of this agent are underway.

ENTRY INHIBITORS

Remarkable advances have been made in the past few years in our understanding of the HIV entry process. Specifically, the identification of HIV co-receptors (e.g. CCR5 and CXCR4) and the understanding of the events involved in fusion of the viral envelope with the cell membrane have created new therapeutic targets. Entry inhibitors can be divided into three subcategories: attachment inhibitors, chemokine receptor antagonists and fusion inhibitors.[56] [57] Of these, the fusion inhibitors have demonstrated proven clinical efficacy and have come the furthest in development.

Enfuvirtide

Description

Enfuvirtide — C_{204} H_{301} N_{51} O_{64} , T-20 — is a 36-amino acid peptide derived from the HR2 region of HIV-1_{LAI} , which binds to the HR1 region of the HIV gp41 fusion peptide and prevents the coil-coil zipping reaction, which leads to six-helix bundle formation and eventual viral-host membrane fusion (Fig. 204.6). Enfuvirtide is active against both R5 and X4 viral strains with susceptibility influenced by the time that the gp41 HR1 target is exposed to the drug as the viral entry process proceeds. Co-receptor density and affinity may influence the susceptibility of HIV strains to enfuvirtide.

Pharmacokinetics and distribution

Enfuvirtide is rapidly digested by peptidases in the gastrointestinal tract and consequently is not orally bioavailable. Following subcutaneous dosing of enfuvirtide, the mean C_{max} and C_{min} at steady state were reported as 2626ng/ml and 972ng/ml, respectively, at 50mg q12h, and 4725ng/ml and 1774ng/ml, respectively, at 100mg q12h.[58] The time to maximal concentrations was approximately 4 hours. The serum half-life of enfuvirtide after intravenous administration has been reported as approximately 2 hours, but more sustained concentrations throughout the 12-hour dosing interval have been reported following subcutaneous administration.

Route and dosage

Enfuvirtide is administered by subcutaneous injection. The adult dosage is 90mg q12h.

Indications

Enfuvirtide is indicated for the treatment of HIV infection in combination with other antiretroviral agents. Given the parenteral nature of the drug and its activity against drug-resistant virus, its role lies in the management of patients with treatment failure in whom other options are constrained. It is important to try to have at least two (and preferably more) other active drugs to administer with enfuvirtide so that enfuvirtide-resistant virus does not quickly emerge. Two large phase III trials have demonstrated the efficacy of enfuvirtide when combined with background therapy optimized with the assistance of drug resistance testing. The enfuvirtide groups in both studies averaged a 0.9–1.0 $\log_{10}$ greater drop in plasma HIV-1 RNA than the control groups at 24 weeks.[59]

Resistance

Resistance to enfuvirtide has been documented to occur in vivo with most mutations mapping to positions 36–45 of the amino terminal (HR1 region) of gp41. The most commonly described mutations are G36D/S, I37V, V38A/M, Q39R, N42T and N43D (see Fig. 204.3). Interestingly, enfuvirtide-resistant viruses may be less fit than wild-type isolates. Thus an immunologic (and presumably clinical) benefit may persist beyond the point of virologic failure, similar to what has been described for PIs.

Dosage in special circumstances

The dose of the drug should not be influenced by renal or hepatic dysfunction given its peptide nature.

Adverse reactions and drug interactions

The major toxicity of enfuvirtide is injection site reaction, which occurs in a large proportion of patients to varying degrees. Bacterial infection at the injection sites can occur and has resulted in occasional bacteremia. A hypersensitivity syndrome has also been described.

Selected investigational entry inhibitors

Fusion inhibitors

T-1249 is a 39-amino acid peptide that binds to an overlapping but not identical region on the HR1 region of the HIV gp41 fusion peptide as enfuvirtide. It is somewhat more potent than enfuvirtide,

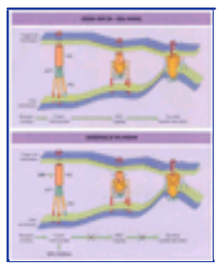

Figure 204-6 Mechanism of HIV fusion with host cell membrane and its inhibition by enfuvirtide (ENF, T-20).

can be administered subcutaneously q24h and is active against enfuvirtide-resistant viruses in vitro. In a phase I study, dose-dependent decreases in plasma HIV-1 RNA have been reported.

Attachment inhibitors

Attachment inhibitors bind to HIV gp120 and prevent virion attachment to the cell surface receptors. Two compounds in development are PRO 542 and BMS 806. PRO 542 is a tetravalent CD4-IgG2 fusion protein that binds to gp120. Proof of principle has been established in a single-dose, phase I study.[60] BMS 806 is an orally bioavailable molecule that inhibits gp120/CD4 interactions by direct binding to gp120.[61] Resistance can be selected in vitro and is mediated by mutations in the binding site on gp120. Clinical trials of BMS 806 are planned.

Chemokine receptor antagonists

Chemokine receptor antagonists targeting both CCR5 and CXCR4 are under development. Approaches include a monoclonal antibody to CCR5 (PRO 140) and small molecule inhibitors of CCR5 (SCH-C, SCH-D, UK 427857, TAK compounds) and CXCR4 (AMD 3100, AMD 070).[62] [63] [64] [65] Proof of principle in phase I human studies has been reported for SCH-C and AMD 3100. Development of the latter has been halted, however, due to limited potency.

INTEGRASE INHIBITORS

HIV integrase is essential for viral replication and has been a recognized target for several years. However, only recently have the characteristics of true integrase inhibitors been described and effective in-vitro screening approaches defined.[66] [67] Two compounds, S-1360, a diketo acid, and L-870810, a naphthyridine compound, are currently in phase I trials. L-870810 has shown substantial antiviral activity in the SHIV rhesus macaque model.

FUTURE APPROACHES

Although entry and integrase inhibition are likely to represent the next major breakthroughs in antiretroviral chemotherapy, a number of other novel approaches are being intensively investigated and bear watching over the next few years. These include inhibition of nucleocapsid zinc fingers, alpha-defensins, interference with the HIV gag chaperone protein, TSG 101, and the exploding area of RNA interference (RNAi).[68] [69] [70] [71]

CONCLUSION

The field of antiretroviral therapy has shown dramatic growth over the past 17 years with five drug classes now available to clinicians. On the near horizon, clinicians and patients are likely to have more choices within these existing drug classes as well as one additional class (i.e. integrase inhibitors) available (Table 204.12). Along with this will be the challenge of investigating and applying new drug regimens such as combinations of entry inhibitors and entry and integrase inhibitors, together with existing agents to formulate new strategies of therapy. On the more distant horizon, new molecular approaches hold promise for continued fundamental improvements in the treatment of those with HIV infection.

Chapter 205 - Drugs for Herpesvirus Infections

John W Gnann Jr
Michelle R Salvaggio

INTRODUCTION

Over the last 25 years, the armamentarium of antiviral compounds has expanded from a handful of drugs with low potency and substantial toxicity to over two dozen drugs now in widespread clinical use. Initial attempts at antiviral drug development were thwarted by the complex interactions between viral and host cellular metabolism. Compounds that blocked viral replication also frequently caused unacceptable host cell toxicity. Many of the early drugs evaluated as antiviral therapeutics were serendipitously discovered through screening of compounds for anticancer activity. More recently, better understanding of molecular virology has permitted rational design of drugs specifically targeted for unique steps in the viral replication cycle. While most of the first-generation drugs were developed for treatment of infections caused by herpesviruses, new compounds are now entering clinical use for treatment of a variety of viruses, including respiratory viruses, enteroviruses and hepatitis viruses. Another emerging trend is the use of combinations of drugs for therapy of serious viral infections, pioneered in the field of HIV therapy.

DRUGS FOR TREATMENT OF HSV AND VZV INFECTIONS

Aciclovir and valaciclovir

Mechanism of action and in vitro activity

Aciclovir, 9-(2-hydroxyethoxymethyl) guanine, an acyclic analogue of guanosine, is a selective inhibitor of the replication of herpes simplex virus (HSV) types 1 and 2 and varicella-zoster virus (VZV).[1] Valaciclovir is an orally administered prodrug of aciclovir with improved pharmacokinetic properties. Aciclovir is converted to its monophosphate derivative by virus-encoded thymidine kinase (TK), a reaction that does not occur to any significant extent in uninfected cells (Fig. 205.1). Subsequent diphosphorylation and triphosphorylation steps are catalyzed by cellular kinases, producing high concentrations of aciclovir triphosphate within HSV- or VZV-infected cells. Aciclovir triphosphate inhibits viral DNA synthesis by competing with deoxyguanosine triphosphate as a substrate for viral DNA polymerase. Since aciclovir triphosphate lacks the 3'-hydroxyl group required for further DNA chain elongation, incorporation into viral DNA results in obligate chain termination. Viral DNA polymerase has much higher affinity for aciclovir triphosphate than does cellular DNA polymerase, resulting in little incorporation of aciclovir into cellular DNA. Aciclovir exhibits good *in vitro* activity against HSV-1, HSV-2 and VZV, with median inhibitory concentrations necessary to reduce plaque counts by 50% (IC_{50}) of 0.04, 0.10 and 0.50µg/ml, respectively. Human cytomegalovirus (CMV) is not inhibited by aciclovir at clinically achievable concentrations.

Pharmacokinetics and distribution

Following oral administration, aciclovir is slowly and incompletely absorbed, with bio-availability of about 15–30%. After oral administration of multiple doses of 200 or 800mg of aciclovir, mean plasma peak concentrations at steady state are about 0.6 and 1.6µg/ml, respectively. Steady-state peak plasma aciclovir concentrations after intravenous doses of 5 or 10mg/kg of body weight every 8 hours are about 10 and 20µg/ml, respectively. Plasma protein binding is less than 20%. Aciclovir penetrates well into most tissues, including the central nervous system (Table 205.1). Relative to plasma, aciclovir concentrations in cerebrospinal fluid, aqueous humor and breast milk are about 50%, 37% and 300%, respectively. Aciclovir is minimally metabolized and about 85% of an administered dose is excreted unchanged in the urine via glomerular filtration and renal tubular secretion. The terminal plasma half-life of aciclovir is 2–3 hours in adults and 3–4 hours in neonates with normal renal function, but is extended to about 20 hours in anuric subjects.

Valaciclovir is an orally administered prodrug of aciclovir designed to overcome the problem of poor oral bio-availability.[2] Valaciclovir, the L-valine ester of aciclovir, is well absorbed from the gastrointestinal tract via a stereospecific transporter and undergoes essentially complete first- pass conversion in the gut and liver to yield aciclovir and L-valine. With this prodrug formulation, bio-availability of aciclovir is about 54%, yielding peak plasma aciclovir levels that are 3–5-fold higher than those achieved with oral administration of the parent compound. Oral doses of 500mg or 1000mg of valaciclovir produce peak plasma aciclovir concentrations of 3.3 and 5–6µg/ml, respectively. After administration of valaciclovir at a dose of 2gm orally four times daily, plasma aciclovir area under the curve (AUC) values approximate those produced by aciclovir given intravenously at a dose of 10mg/kg every 8 hours. Following enzymatic conversion of valaciclovir to aciclovir, the antiviral spectrum of activity, pharmacokinetic properties and excretion are the same as those described above.

Route of administration and dosage

Aciclovir is available in topical, oral and intravenous formulations. Outside the United States, aciclovir is also available as a 3% preparation for ophthalmologic use. The dermatologic preparation consists of 5% aciclovir in a polyethylene glycol ointment base. Topical aciclovir is intended for treatment of minor mucocutaneous or genital HSV infections. Oral aciclovir preparations include a 200mg capsule, 400 and 800mg tablets, and a liquid suspension (200mg/5ml). Aciclovir sodium for intravenous infusion is supplied as a sterile water-soluble powder that must be reconstituted and diluted to a concentration of 50mg/ml.

The recommended dose of aciclovir will vary with the specific indication (see Table 205.2). Because of the greater intrinsic resistance of VZV to aciclovir, the doses required for treating VZV infections are higher than those used for HSV infections. In adults with normal renal function, oral aciclovir is given at a dose of 200mg (for HSV) to 800mg (for VZV) five times daily. The recommended dose of intravenous aciclovir is 5mg/kg every 8 hours for HSV infections or 10mg/kg every 8 hours for VZV infections, although higher doses

Figure 205-1 Activation of aciclovir is dependent on monophosphorylation via viral thymidine kinase (TK). Aciclovir triphosphate inhibits the activity of viral DNA polymerase, thus blocking viral replication. Penciclovir and ganciclovir are activated by similar mechanisms.

(12–15mg/kg) are sometimes used for life-threatening infections, especially in immunocompromised patients.

Valaciclovir is available as 500mg and 1000mg tablets. The recommended doses are 500mg twice daily for episodic treatment of recurrent

TABLE 205-2 -- Indications for aciclovir therapy.

INDICATIONS FOR ACICLOVIR THERAPY	
Infection	**Route and dosage**†
Genital HSV	
Initial episode	200mg po 5 times/d (or 400mg tid) × 10 days
Initial episode with complications	5mg/kg iv q8h × 5–7 days
Recurrent episodes	200mg po 5 times/d (or 400mg tid) × 5 days
Suppression	400mg po bid daily
Mucocutaneous HSV in immunocompromised patient	400mg po 5 times/d × 10–14 days* ; or 5mg/kg iv q8h × 10 days
Disseminated or visceral HSV (including encephalitis)	10–15mg/kg iv q8h × 14–21 days
Neonatal HSV	10–15mg/kg iv q8h × 14–21 days*
Varicella (chickenpox)	
Normal host	20mg/kg (max. 800mg) po 4–5 times/d × 5 days
Immunocompromised patient	10–15mg/kg iv q8h × 7–10 days
Herpes zoster (shingles)	
Normal host	800mg po 5 times/d × 7–10 days
Immunocompromised patient (disseminated or visceral VZV)	10–15mg/kg iv q8h × 7–10 days

† Given doses are indicated for patients with normal renal function
* This indication is not approved by the US Food and Drug Administration

genital HSV infections and 1000mg three times daily for treatment of herpes zoster. A suspension preparation is not available.

Indications

HSV infections

Initial episodes of genital HSV infection can be treated with topical, oral or intravenous aciclovir. Intravenous aciclovir is the most effective treatment for initial genital herpes, but is not usually practical and should be reserved for patients with severe local disease or systemic complications. Oral aciclovir (200mg five times daily) is nearly as effective as intravenous therapy and significantly reduces the duration of symptoms, virus shedding and time to healing. Topical aciclovir is less effective than oral or intravenous therapy for initial genital herpes. Aciclovir treatment of acute HSV infection does not alter the risk of subsequent recurrences. Lesions associated with recurrent genital herpes are less severe than those seen in primary infection and the benefit from episodic therapy with oral aciclovir is relatively modest. A more effective approach in patients with frequent recurrences of genital herpes is to give aciclovir daily to prevent HSV reactivation. Daily administration of aciclovir will reduce the frequency of genital HSV recurrences in 90% of patients and a significant proportion will have no subsequent recurrences while taking suppressive medication. Titration of the dose of aciclovir (beginning with 400mg twice daily) may be required to establish the most effective dose. Periodic interruption of suppression to reassess the need for continued prophylaxis is recommended. There is no evidence of cumulative toxicity or emergence of drug-resistant

HSV in immunocompetent patients even after years of suppressive therapy.[3] Aciclovir suppression will also significantly reduce (but not eliminate) the frequency of asymptomatic viral shedding.[4]

In a study comparing valaciclovir (1000mg twice daily) with aciclovir (200mg five times daily) for treatment of first-episode genital herpes, both drugs were well tolerated and equivalent in efficacy.[5] For episodic treatment of recurrent genital herpes, valaciclovir (500mg twice daily for 3 days) reduced the duration of viral shedding and accelerated pain resolution and lesion healing.[6] For suppression of genital herpes, valaciclovir doses ranging from 250mg to 1000mg once daily and from 250mg to 500mg twice daily have been evaluated in clinical trials. A dose — response relationship is evident across the various valaciclovir regimens, with better suppression at higher doses, although all were significantly more effective than placebo. The recommended starting dose of valaciclovir for genital herpes suppression is 500–1000mg daily; patients who have breakthrough recurrences on this regimen may require 500mg twice daily for effective suppression. In general, aciclovir and valaciclovir are equally potent for suppression of genital herpes, although the once-daily dosing regimen for valaciclovir may be more convenient.

Oral aciclovir therapy can reduce the duration of symptoms for children with acute HSV gingivostomatitis. Topical aciclovir is relatively ineffective for recurrent herpes labialis. Treatment of herpes labialis with oral aciclovir (400mg five times daily for 5 days) offers some clinical benefit, if initiated during the prodromal or erythematous stage of lesion evolution. Oral aciclovir can be used for short-term prophylaxis of recurrent herpes labialis in situations where exposure to a known stimulus such as ultraviolet light is anticipated (e.g. a snow skiing or beach holiday). Patients with frequent recurrences of herpes labialis may benefit from long-term suppressive therapy with oral aciclovir (400mg twice daily), which can reduce the frequency of clinical recurrences by about 50%. A high-dose, short-course regimen of valaciclovir (e.g. 2g bid for 1 day) for treatment of herpes labialis has recently been approved in the United States.

Aciclovir prophylaxis of HSV infections is highly effective in severely immunocompromised patients, particularly those undergoing induction chemotherapy or organ transplantation. In bone marrow transplant recipients, aciclovir reduces the incidence of symptomatic HSV infection from approximately 70% to 10% and is especially valuable during the first 30 days following transplantation. A sequential regimen of intravenous followed by oral aciclovir (at doses ranging from 200mg three times daily to 800mg twice daily) for 3–6 months can virtually eliminate symptomatic HSV infections in organ transplant recipients. In immunocompromised patients with established mucocutaneous HSV infections, intravenous (5–10mg/kg every 8 hours) or oral aciclovir (400mg five times daily) can significantly reduce the duration of pain and accelerate lesion healing. Clinical experience suggests that intravenous aciclovir (10mg/kg every 8 hours) is the treatment of choice for disseminated or visceral HSV infection (e.g. pneumonitis, hepatitis, esophagitis, etc.) in immunocompromised patients, although data from controlled clinical trials are lacking.

HSV infection of the central nervous system is associated with substantial morbidity and mortality despite the use of antiviral therapy. Aciclovir was proven superior to vidarabine for HSV encephalitis and should be given intravenously at a dose of 10–15mg/kg for 14–21 days. Even with aggressive aciclovir therapy, the mortality rate at 6 months is 19% for patients with HSV encephalitis.

Neonatal herpes is a potentially devastating infection that can develop in infants born to mothers who are actively shedding HSV from the genital tract at the time of delivery. Intravenous aciclovir therapy can significantly reduce both morbidity and mortality among these infants. Studies are under way to establish the value of long-term aciclovir suppression for preventing progressive neurologic deterioration among surviving infants. Another promising approach currently under evaluation is the use of oral aciclovir or valaciclovir suppression during the third trimester in pregnant women with genital herpes. Data suggest that prophylaxis can significantly reduce the requirement for cesarian section due to active genital HSV lesions present at the onset of labor.[7]

VZV infections

Oral aciclovir therapy for immunocompetent children with chickenpox will reduce both the duration of fever and total lesion count if treatment is begun within 24 hours of disease onset. However, the benefits of aciclovir administration are relatively modest and many pediatricians consider antiviral treatment of chickenpox to be optional.

In immunocompetent children, the dosage of oral aciclovir for chickenpox is 20mg/kg (up to a maximum of 800mg) four times daily. Varicella can be a more severe disease in adolescents and adults, with higher lesion counts and a greater risk of complications, especially pneumonitis. For this reason, aciclovir therapy (800mg orally five times daily for 7 days) is recommended for adolescents and adults who present within 24–48 hours of disease onset. Valaciclovir is also likely to be effective in this setting, but data from controlled clinical trials are lacking. Because of the high frequency of visceral involvement in immunocompromised children (or adults) with chickenpox, aggressive therapy with intravenous aciclovir (10mg/kg or 500mg/m^2 every 8 hours for 7–10 days) is warranted. Controlled trials of intravenous aciclovir in immunocompromised patients with varicella clearly demonstrated a significant reduction in the frequency of progression to VZV pneumonitis. Although no data from controlled trials are available, clinical experience suggests that intravenous aciclovir is the treatment of choice for patients with VZV infections complicated by visceral involvement (e.g. pneumonitis, encephalitis, etc.).

For treatment of herpes zoster in immunocompetent adults, oral aciclovir (800mg five times daily for 7 days) accelerates cutaneous healing and reduces the severity of acute neuritis. Benefits are maximized when treatment is initiated within 48 hours of appearance of lesions. Aciclovir does not alter the incidence of postherpetic neuralgia, but can accelerate the resolution of pain.[8] Aciclovir is especially beneficial for preventing ocular complications in patients with herpes zoster ophthalmicus. Severely immunocompromised patients (e.g. bone marrow transplant, cancer chemotherapy, etc.) with herpes zoster are at high risk for disseminated VZV infection and should be treated with intravenous aciclovir (10mg/kg every 8 hours). AIDS patients with herpes zoster can usually be treated effectively with oral therapy.

Valaciclovir (1000mg three times daily for 7 days) was compared with aciclovir (800mg five times daily for 7 days) in over 1000 immunocompetent patients (>50 years of age) with herpes zoster.[9] The progression of cutaneous healing was similar in the two treatment groups. Patients in the valaciclovir treatment group had a slightly shorter duration of zoster-associated pain (38 days versus 51 days). Extending valaciclovir therapy to 14 days did not result in any additional benefit. Both aciclovir and valaciclovir are effective for treatment of localized herpes zoster in immunocompetent patients if therapy is initiated within 72 hours of rash onset. Valaciclovir has the advantage of a simpler dosing regimen.

Other viral infections

While aciclovir is ineffective for established CMV infections, high-dose oral aciclovir or valaciclovir may have value for CMV prophylaxis in high-risk populations such as AIDS patients and organ transplant recipients.[10] Administration of aciclovir does not alter the course of infectious mononucleosis, but can induce regression

of EBV-induced oral hairy leukoplakia in HIV-infected patients. Aciclovir is not effective for treatment of chronic fatigue syndrome. It is considered the drug of choice for therapy of rare human infections caused by cercopithecine herpesvirus-1 (B virus). Aciclovir is not active against HIV; studies of the survival benefit of aciclovir therapy in AIDS patients have reached varying conclusions.

Dosage in special circumstances

Aciclovir is cleared primarily by renal mechanisms and dosage modification of aciclovir and valaciclovir is required for patients with significant renal dysfunction (see

Table 205.3 , Table 205.4). The mean elimination half-life of aciclovir after a single 1g dose of valaciclovir is about 14 hours in patients with end-stage renal disease.[2] No specific dosage modification is required for patients with hepatic impairment. Aciclovir and valaciclovir are not approved for use in pregnancy, but have been widely used to treat serious HSV and VZV infections in pregnant women without evidence of maternal or fetal toxicity.[11]

Aciclovir AUC values after oral valaciclovir dosing are slightly higher in elderly individuals when compared with younger control groups, presumably due to declines in creatinine clearance associated with aging. Because no liquid valaciclovir preparation is available, experience with that drug in young children is limited.

Adverse reactions

Aciclovir is an extremely well-tolerated drug with very few significant adverse effects. With intravenous aciclovir therapy, inflammation and phlebitis may occasionally occur following localized drug extravasation. Renal dysfunction resulting from accumulation of aciclovir crystals in the kidney has been observed following administration of large doses of aciclovir by rapid intravenous infusion, but is uncommon and usually reversible. The risk of nephrotoxicity can be minimized by administering aciclovir by slow infusion (over 1 hour) and ensuring adequate hydration. A few reports have linked administration of aciclovir with CNS disturbances, including agitation, hallucination,

disorientation, tremors and mild clonus. Neurotoxicity has most often been recognized in elderly patients with underlying CNS abnormalities and renal insufficiency. Patients receiving oral aciclovir therapy occasionally complain of nausea, diarrhea, rash or headache, but these possible adverse effects have not differed significantly between aciclovir and placebo recipients in large-scale clinical trials. Oral aciclovir therapy is rarely associated with neurotoxicity or nephrotoxicity. The safety of oral aciclovir for long-term administration has been established in patients receiving the drug for over 5 years for suppression of recurrent genital herpes.

At standard doses, valaciclovir is a very well-tolerated drug with few significant adverse effects.[12] Headache, nausea and abdominal pain have been reported, but the incidence of these symptoms has not differed between valaciclovir and placebo recipients in clinical studies. A syndrome of thrombotic microangiopathy (TMA) was described in some HIV-infected patients, receiving high-dose valaciclovir (8g/day) for prevention of CMV disease in a clinical trial; a causal relationship between high-dose valaciclovir and TMA has not been proven. The TMA-like syndrome, which is characterized by fever, microangiopathic hemolytic anemia, thrombocytopenia and renal dysfunction, has not been observed in immunocompetent patients receiving valaciclovir at approved doses (up to 3g/day). There is no contraindication to using valaciclovir at standard doses in HIV-infected patients.

Significant interactions between aciclovir and other drugs are extremely uncommon. Probenecid decreases the renal clearance of aciclovir and can prolong the plasma excretion half-life. Additive aciclovir-induced nephrotoxicity in patients receiving concomitant cyclosporin-A therapy has been suggested, but does not appear to be clinically important. Lethargy has been reported in a few patients receiving both aciclovir and zidovudine, but a causative role for aciclovir has not been established. Concomitant administration of cimetidine and probenecid reduces the rate of valaciclovir conversion to aciclovir, but the effect is not clinically significant.

Resistance

HSV resistance to aciclovir can develop through mutation of the viral genes encoding thymidine kinase or DNA polymerase. Most aciclovir-resistant clinical HSV isolates are TK deficient and are therefore unable to phosphorylate aciclovir.[13] Aciclovir-resistant HSV isolates are recovered only from immunocompromised patients. The most common clinical presentation of infection caused by aciclovir-resistant HSV is chronic, progressive mucocutaneous lesions. Approximately 5–6% of HSV isolates recovered from HIV-seropositive patients are aciclovir resistant (IC_{50} >2.0µg/ml). Aciclovir-resistant VZV isolates (less frequently encountered than resistant HSV isolates) are recovered almost exclusively from AIDS patients. Most clinical disease caused by aciclovir-resistant VZV has been limited to cutaneous involvement, often characterized by atypical lesions. TK-deficient HSV and VZV isolates will also be resistant to other drugs that require TK for activation, including ganciclovir and penciclovir. The drug of choice for treatment of aciclovir-resistant HSV or VZV disease is foscarnet, a viral DNA polymerase inhibitor that is not dependent on TK for activation.

Penciclovir and famciclovir

Mechanism of action and in vitro activity

Penciclovir, 9-(4-hydroxy-3-hydroxymethylbut-1-yl) guanine, is an acyclic guanine derivative that is similar to aciclovir in structure, mechanism of action and spectrum of antiviral activity. In HSV-or VZV-infected cells, penciclovir is first monophosphorylated by virally encoded TK and then further phosphorylated to the triphosphate moiety by cellular enzymes. Penciclovir triphosphate blocks viral DNA synthesis through competitive inhibition of viral DNA polymerase. Unlike aciclovir triphosphate, penciclovir triphosphate is not an obligate chain terminator and can be incorporated into the extending DNA chain. Compared with aciclovir triphosphate, intracellular concentrations of penciclovir triphosphate are much higher. For example, the half-life values for penciclovir triphosphate and aciclovir triphosphate in HSV-1 infected cells are 10 hours and 0.7 hour, respectively. However, this potential advantage is offset by a much lower affinity of penciclovir triphosphate for viral DNA polymerase. The *in vitro* activities of penciclovir against HSV-1, HSV-2 and VZV are similar to those of aciclovir, with median IC_{50} values of 0.4, 1.5 and 4.0µg/ml respectively, in MRC-5 cells.[14]

Just as valaciclovir is a prodrug of aciclovir, famciclovir is a prodrug of penciclovir. Because penciclovir is very poorly absorbed, famciclovir (the diacetyl ester of 6-deoxy-penciclovir) was developed as the oral formulation. The first acetyl side chain of famciclovir is cleaved by esterases found in the intestinal wall. On first pass through the liver, the second acetyl group is removed and oxidation catalyzed by aldehyde oxidase occurs at the 6 position, yielding penciclovir, the active antiviral compound.

Pharmacokinetics and distribution

Penciclovir is very poorly absorbed after oral administration. Intravenous infusion of penciclovir at 10mg/kg over 1 hour yields a peak plasma concentration of 12.1µg/ml. Plasma protein binding of penciclovir is <20%. The drug is cleared by renal tubular secretion and passive filtration. The plasma elimination half-life of penciclovir is about 2 hours and approximately 70% of the administered dose is recovered unchanged in the urine.

When administered as the famciclovir prodrug, the bio-availability of penciclovir is about 77%. Following a single oral dose of 250mg or 500mg of famciclovir, peak plasma penciclovir concentrations of 1.9 and 3.5µg/ml are achieved at 1 hour. The pharmacokinetics of penciclovir are linear and dose independent over a famciclovir dosing range of 125–750mg. Food slows famciclovir absorption and lowers the peak plasma penciclovir concentration, but does not alter the AUC value.

Route of administration and dosage

Famciclovir is available as 125mg, 250mg and 500mg tablets. Recommended dosages will vary with indication. The usual dose of famciclovir is 125mg twice daily for episodic therapy of recurrent genital herpes and 500mg three times daily for herpes zoster. The intravenous preparation of penciclovir has not been commercially released. A topical preparation of penciclovir is available as a 1% cream for treatment of HSV labialis.

Indications

Genital HSV infections.

Oral famciclovir reduced the duration of viral shedding and was comparable to oral aciclovir for accelerating healing and symptom resolution in patients with first-episode genital herpes. Famciclovir has not been approved for treatment of initial genital herpes in the United States, but 250mg orally three times daily for 5 days is likely to be effective.

Famciclovir was significantly superior to placebo for treatment of recurrent genital herpes.[15] When therapy was initiated by the patient at the time of symptom onset, famciclovir accelerated the events of healing and time to loss of pain.[15] The recommended dosage of famciclovir for episodic therapy of recurrent genital herpes is 125mg twice daily for 5 days.

Famciclovir is also effective for suppression of recurrent genital herpes.[16] In a multinational study of 455 patients, the time to first genital herpes recurrence was 336

days in the group receiving

TABLE 205-5 -- Oral antiviral therapy for genital herpes.

ORAL ANTIVIRAL THERAPY FOR GENITAL HERPES†			
Drugs	**Initial episode**	**Recurrent episode**	**Suppression**
Aciclovir	200mg 5 times/d (or 400mg tid*) × 10 days	200mg 5 times/d (or 400mg tid*) × 5 days	400mg bid daily
Famciclovir	125mg tid × 10 days*	125mg bid × 5 days	250mg bid daily
Valaciclovir	1000mg bid × 10 days	500mg bid × 3–5 days	500 or 1000mg once daily

† Recommended doses for immunocompetent adults with normal renal function
* This treatment regimen is not approved by the US Food and Drug Administration

famciclovir (250mg twice daily), compared with 47 days in the placebo group.[16] In the same study, 72% of subjects treated with famciclovir 250mg twice daily were recurrence free at 12 months, compared with 22% of placebo recipients.

Three drugs (aciclovir, valaciclovir and famciclovir) with proven efficacy for long-term suppression of recurrent genital herpes are now available. Few data from direct comparative trials have been published to guide the clinician in selecting the most effective treatment (see Table 205.5). All three of the compounds are safe and well tolerated. Considerations in selecting the appropriate drug may include cost and dosing convenience. For any patient, the goal is to establish a suppressive regimen that is effective, economical and convenient. For these drugs, a dose-response relationship exists, meaning that higher total daily doses generally produce more complete suppression. Clinicians may need to titrate the daily dose of the selected drug to identify optimal treatment for an individual patient.

Herpes labialis

Topical 1% penciclovir cream is applied every 2 hours while awake for treatment of herpes labialis. In placebo-controlled trials, topical penciclovir reduced the duration of viral shedding and accelerated lesion healing and pain resolution. Time to lesion healing was 0.7 days faster (4.8 days versus 5.5 days) for penciclovir-treated patients compared to the control group.

HSV infections in AIDS patients

Famciclovir (500mg twice daily) is comparable to aciclovir (400mg five times daily) for treatment of recurrent mucocutaneous (orolabial and anogenital) infections in HIV-infected patients. In a placebo-controlled trial, famciclovir (500mg twice daily) was also shown to be highly effective for suppression of recurrent mucocutaneous HSV infections in HIV-seropositive individuals.[17]

Herpes zoster

Famciclovir has been evaluated for treatment of dermatomal herpes zoster in immunocompetent patients. In a placebo-controlled clinical trial, famciclovir accelerated cutaneous healing and reduced the duration of viral shedding and postherpetic neuralgia.[18] In a subset of subjects over 50 years of age, the duration of postherpetic neuralgia was reduced from a median of 163 days to 63 days in the placebo and famciclovir treatment groups, respectively. [18] In the United States, the recommended dose of famciclovir for uncomplicated herpes zoster is 500mg three times daily. Doses of 250mg three times daily and 750mg once daily are approved in Europe and the United Kingdom.

Three drugs (aciclovir, valaciclovir and famciclovir) are currently available for treatment of uncomplicated herpes zoster in immunocompetent patients (see Table 205.6). The drugs are all well tolerated and appear to be comparable in clinical efficacy. In a large randomized clinical trial, valaciclovir and famciclovir were shown to be therapeutically

TABLE 205-6 -- Oral antiviral therapy for herpes zoster.

ORAL ANTIVIRAL THERAPY FOR HERPES ZOSTER†
Treatment options
• Aciclovir 800mg q4h (5 times daily) × 7–10 days
• Famciclovir 500mg q8h (3 times daily) × 7 days
• Valaciclovir 1000mg q8h (3 times daily) × 7 days

† Recommended doses for immunocompetent adults with normal renal function

equivalent for treatment of herpes zoster.[19] Because of their improved pharmacokinetic profiles and simpler dosing regimens, valaciclovir and famciclovir are preferred over aciclovir for this indication.

Herpes zoster in immunocompromised patients.

In a study of herpes zoster in bone marrow transplant or cancer patients, famciclovir (500mg three times daily) or aciclovir (800mg five times daily) for 10 days were shown to be therapeutically equivalent.[20] Famciclovir was also effective in an open-label study of herpes zoster therapy in HIV-seropositive patients.

Dosage in special circumstances.

Penciclovir is cleared predominantly by renal mechanisms, so adjustments of famciclovir dosing are required in patients with advanced renal insufficiency, as shown in Table 205.7 . In patients with hepatic insufficiency, the rate of conversion of famciclovir to penciclovir is decreased, but the plasma AUC value for penciclovir is not significantly changed; no famciclovir dosage modification in hepatic impairment is necessary.[21] Plasma penciclovir concentrations are slightly higher in elderly patients treated with famciclovir due to age-related reduction in glomerular filtration rates, but dosage modifications on the basis of age are not required. Absorption after topical application is minimal and no dosage modifications are required for use of penciclovir 1% cream. No liquid preparation of famciclovir is currently available and few data regarding use in small children are available. Famciclovir has not been approved for use during pregnancy.

Adverse reactions

Safety data collected from over 3000 patients involved in clinical studies of famciclovir have shown the drug to be very safe and well tolerated.[22] The most frequently reported adverse experiences have included headache, nausea and diarrhea, but the frequency of these events was similar in both famciclovir and placebo recipients.

No clinically significant drug interactions have been noted with famciclovir. Co-administration of famciclovir with cimetidine or theophylline will increase the penciclovir AUC by about 20%. Co-administration of famciclovir and digoxin results in a 19% increase in the peak digoxin concentration, but no change in the AUC.

Topical penciclovir 1% cream is associated with no significant toxicities and has no known drug interactions.

Resistance

The majority of clinically encountered aciclovir-resistant HSV and VZV isolates are TK deficient and thus will also be resistant to penciclovir, which requires viral TK for activation. However, some HSV strains that are aciclovir resistant by virtue of altered TK or DNA polymerase mutations may retain susceptibility to penciclovir. In general, however, penciclovir or famciclovir should not be considered as appropriate drugs for treatment of infections caused by aciclovir-resistant HSV or VZV.

Other drugs

Vidarabine

Vidarabine (adenine arabinoside) was the first intravenous antiviral drug accepted for widespread clinical use. Intravenous vidarabine was shown to be effective for herpes simplex encephalitis, neonatal HSV infections and for HSV and VZV infections in immunocompromised patients. Vidarabine, however, was not effective for aciclovir-resistant HSV infections in AIDS patients. Vidarabine 3% ophthalmic ointment is used for treatment of HSV keratoconjunctivitis. Vidarabine has now largely been replaced by more effective and less toxic antiviral drugs.

Trifluridine

Trifluridine is a fluorinated pyrimidine nucleoside with good *in vitro* activity against HSV. Trifluridine triphosphate is a competitive inhibitor of HSV DNA polymerase. Trifluridine is too toxic for systemic administration, but has been used successfully as a 1% ophthalmic solution for topical therapy of HSV keratitis. Topical trifluridine has also been used with moderate success for treatment of aciclovir-resistant mucocutaneous infections in AIDS patients.

Idoxuridine

Idoxuridine is an iodinated thymidine derivative with activity against HSV. Use of idoxurdine has been limited to topical application, since systemic administration is associated with significant myelosuppression. Idoxuridine (in topical 1% solution and 0.5% ointment formulations) has been used successfully for treatment of HSV keratitis, but has largely been replaced by topical trifluridine and aciclovir for this indication. Topical application of 15% idoxuridine in dimethyl sulfoxide was shown to shorten the course of herpes labialis in a placebo-controlled trial, and is available in Europe but not in the United States.

Brivudin

Brivudin (bromovinyldeoxyuridine; BVDU) is a highly potent antiviral agent with selective activity against HSV-1 and VZV. The drug has been evaluated for herpes zoster and varicella in both immunocompetent and immunocompromised populations and appears to be therapeutically equivalent to aciclovir. Because of concerns about potential toxicity, commercial development of brivudin has halted in most countries. The drug is available in Germany as a 125mg tablet and as a 0.1% ointment for ophthalmologic use.

n-Docosanol

n-Docosanol is a 22-carbon fatty alcohol with *in vitro* activity against several enveloped viruses, including HSV-1 and HSV-2. The drug acts by interfering with viral entry into target cells. In a multicenter, placebo-controlled study of 743 patients with recurrent herpes labialis (pooled data from two separate studies), 10% docosanol cream or placebo was applied five times a day within 12 hours of onset of prodrome or erythema. Median time to healing was reduced by 17 hours in the docosanol treatment group. n-Docosanol is available over the counter in a 2g tube of 10% cream and is indicated for recurrences of herpes labialis. It is to be applied to the area five times each day with the beginning of prodomal symptoms for a maximum of 10 days.[23]

DRUGS FOR TREATMENT OF CYTOMEGALOVIRUS INFECTIONS

Ganciclovir and valganciclovir

Mechanism of action and in vitro activity

Ganciclovir, 9-[(1,3-dihydroxy-2-propoxy) methyl] guanine, is a nucleoside analogue that is structurally similar to aciclovir, but has a hydroxymethyl group at the 3'

position of the acyclic side chain.[24] This

relatively minor structural modification accounts for enhanced activity of ganciclovir against human CMV and also for the drug's greater toxicity. Ganciclovir triphosphate is a potent inhibitor of herpesvirus DNA replication, acting as both an inhibitor of and a substrate for viral DNA polymerase.[25] In HSV- or VZV-infected cells, monophosphorylation of ganciclovir is induced by viral TK, as also occurs with aciclovir. In CMV-infected cells, ganciclovir monophosphorylation is carried out by a protein kinase encoded by the UL97 gene. The di- and triphosphorylation steps are mediated by cellular kinases. On a molar basis, aciclovir triphosphate is actually a more potent inhibitor of CMV than is ganciclovir triphosphate. However, aciclovir is a poor substrate for phosphorylation by the UL97 gene product; consequently, the concentration of ganciclovir triphosphate in CMV-infected cells is 10-fold higher than that of aciclovir triphosphate. Furthermore, the half-life of ganciclovir triphosphate in CMV-infected cells is 16.5 hours, compared with 2.5 hours for aciclovir triphosphate. Ganciclovir triphosphate does not function as a chain terminator, and can be incorporated into elongating viral DNA (and, to a much lesser extent, human DNA) where it functions to slow DNA chain extension.

Ganciclovir and aciclovir have approximately comparable *in vitro* activity against HSV-1, HSV-2 and VZV. However, ganciclovir is much more active against CMV, with IC_{50} values of 0.1–1.8µg/ml against clinical isolates.

Pharmacokinetics and distribution

Intravenous infusion of ganciclovir at a dose of 5mg/kg yields peak and trough plasma levels of approximately 8 and 1µg/ml. Plasma protein binding is 1–2%. Reported plasma-to-CSF ratios for ganciclovir have ranged from 24% to 70%. Ganciclovir is not metabolized and is cleared by renal mechanisms, with an elimination half-life of about 3 hours. Ganciclovir is poorly absorbed after oral administration, with bio-availability of only 5–9%. Following oral dosing of ganciclovir at 1000mg three times daily, steady-state plasma peak and trough concentrations of 1.2 and 0.2µg/ml are achieved. To overcome the limited oral bio-availability of ganciclovir, a prodrug called valganciclovir has been developed.[26]

Valganciclovir, the L-valyl ester of ganciclovir, is rapidly and almost completely hydrolyzed to ganciclovir in the liver and intestinal wall. Bio-availability of ganciclovir is about 60% from the prodrug formulation and is significantly increased with food administration. Maximum plasma ganciclovir concentrations are 4–5-fold higher than those achieved after oral dosing with the parent drug. Oral valganciclovir doses of 450mg and 875mg once daily for 3 days produced peak plasma ganciclovir concentrations of 3.3 and 6.1µg/ml, respectively. The AUC of ganciclovir after administration of 900mg valganciclovir is about 26µg/ml/h, which is comparable to the AUC following administration of ganciclovir dosed at 5mg/kg intravenously.

Route of administration and dosage

Ganciclovir is available as an oral capsule, an intravenous formulation and as a delayed-release intraocular implant device. Recommended doses will vary with the indication. For treatment of acute CMV disease, the usual dose of intravenous ganciclovir is 5mg/kg every 12 hours. Oral ganciclovir, supplied as 250mg capsules, can be used for maintenance therapy of CMV disease at a dosage of 1000–2000mg three times daily, but has largely been replaced by oral valganciclovir.

Valganciclovir is available as a 450mg tablet. Recommended dose for induction therapy of acute CMV retinitis is 900mg by mouth with food twice daily for a total of 21 days, followed by maintenance therapy at a dose of 900mg by mouth once daily with food.

Indications

CMV retinitis

Ganciclovir was the first drug approved for treatment of CMV retinitis, a sight-threatening disease that occurs in AIDS patients and other immunocompromised hosts. The therapeutic approach for CMV retinitis is to halt disease progression with high-dose induction therapy, then prevent disease relapse by maintenance therapy continued for the duration of the immunosuppression.[27] The usual dose of ganciclovir for induction therapy is 5mg/kg given intravenous every 12 hours for 14–21 days. In uncontrolled studies, ganciclovir therapy halted progression of CMV retinitis in over 80% of patients. Without long-term maintenance therapy, virtually all AIDS patients will experience a relapse of retinitis within 30 days after induction therapy. Continuation of maintenance therapy can extend the interval to first relapse to a median of about 75 days. The usual maintenance regimen with intravenous ganciclovir is 5mg/kg once daily. High-dose oral ganciclovir (4500–6000mg daily) is almost as effective as intravenous ganciclovir for maintenance therapy and may be associated with fewer complications.

For oral therapy of CMV retinitis, ganciclovir has largely been supplanted by valganciclovir. In a study of 160 HIV-positive patients with newly diagnosed CMV retinitis, induction therapy with valganciclovir 900mg orally twice daily was shown to be as effective as ganciclovir given intravenously at 5mg/kg every 12 hours in halting progression of retinitis during the first 4 weeks of therapy. [28] Those receiving induction with valganciclovir experienced more diarrhea than those who received intravenous ganciclovir (19% vs 10%, $p = 0.11$), while those treated with intravenous ganciclovir developed more catheter-related events (9% versus 4%). The incidence of neutropenia was about 14% in both groups.[28] CMV retinitis is currently the only approved indication for valganciclovir.

Intravitreal injections of ganciclovir have been used effectively for treatment of CMV retinitis, although ganciclovir intraocular implants are a better option for patients who cannot tolerate systemic ganciclovir therapy. Median time to relapse of CMV retinitis is longer with ganciclovir intraocular implants then with oral or intravenous ganciclovir and their use should be strongly considered in patients whose retinal lesions are imminently sight threatening.[29] However, there is potential morbidity associated with surgical implantation of the devices, which must be replaced about every 6 months. Unlike systemic ganciclovir therapy, an intraocular implant will not prevent development of CMV retinitis in the contralateral eye or CMV disease in other organs.

Ganciclovir, valganciclovir, foscarnet and cidofovir (see below) are all effective for initial and maintenance therapy of CMV retinitis in AIDS patients (see Table 205.8). All of these drugs can be associated with significant toxicity; drug selection in an individual patient hinges, to some extent, on which adverse effects would be most tolerable. Ganciclovir is primarily myelosuppressive, while foscarnet and cidofovir are nephrotoxic. Ganciclovir would be preferred in a patient who has baseline renal dysfunction or who requires therapy with other nephrotoxic drugs. Conversely, foscarnet might be a better choice in a patient with significant baseline neutropenia. Despite the survival benefits for AIDS patients shown for foscarnet therapy in some studies, most clinicians use ganciclovir or valganciclovir for initial therapy on the basis of its more predictable adverse effects. Combination therapy (e.g. ganciclovir plus foscarnet) may be more effective for CMV disease in selected patients.

CMV gastrointestinal disease

In immunocompromised patients, CMV can cause esophagitis, gastritis, enteritis and especially colitis. Anecdotal data suggest that intravenous ganciclovir is effective for CMV colitis, although data from controlled studies are limited. In a placebo-controlled trial in AIDS

patients with CMV colitis, intravenous ganciclovir (5mg/kg twice daily) reduced virus shedding, improved mucosal appearance by colonoscopic examination and reduced the incidence of extracolonic CMV disease; however, symptom scores between the ganciclovir and placebo groups were similar.[30] A placebo-controlled trial of ganciclovir for CMV gastrointestinal disease in bone marrow transplant recipients also failed to demonstrate symptomatic improvement. Despite these findings, ganciclovir continues to be used for treatment of CMV gastrointestinal disease on the strength of clinical experience. There is no consensus regarding the necessity or duration of maintenance therapy in this setting.

CMV pneumonitis

CMV pulmonary infections following allogeneic bone marrow transplantation are associated with very high mortality rates. In early clinical studies, ganciclovir therapy of CMV pneumonia did not result in improved survival. More recent studies have demonstrated that combination therapy with ganciclovir plus intravenous immune globulin is more effective than either intervention alone, resulting in survival rates over 50%. A commonly used regimen for active CMV pneumonia is intravenous ganciclovir 5mg/kg twice daily plus intravenous immune globulin (0.5g/kg every other day) for 14–21 days, followed by maintenance therapy with ganciclovir 5mg/kg daily for at least 2 more weeks.

Other CMV infections

Case reports and uncontrolled clinical trials have ascribed benefit to ganciclovir therapy for a variety of indications. In solid organ transplant recipients, ganciclovir has been reported to be effective for CMV hepatitis, CMV pneumonia and disseminated CMV syndrome. Improvement in CMV-induced polyradiculopathy and encephalitis has been described in AIDS patients treated with ganciclovir. Controlled studies are required to accurately assess the value of ganciclovir for these indications.

Prophylaxis of CMV disease

Intravenous ganciclovir administered to bone marrow transplant patients either pretransplantation or at the time of engraftment significantly reduced the incidence of CMV disease.[31] [32] However, ganciclovir prophylaxis resulted in significant neutropenia, thus offsetting any survival benefit. An alternative scheme is to withhold ganciclovir until there is early laboratory evidence (e.g. by PCR or antigenemia assay) of CMV activation. [33] This approach permits initiation of therapy before CMV disease becomes symptomatic, while avoiding the risk of neutropenia associated with long-term ganciclovir administration. However, this 'pre-emptive' therapy approach is currently limited by lack of a sensitive, specific and readily available CMV diagnostic assay.

Benefits of intravenous ganciclovir therapy for prophylaxis of CMV infection in solid organ transplant recipients have varied with the transplant type, immunosuppressive regimen and CMV serologic status of the donor and recipient. [34] In general, high-risk patients (donor CMV positive, recipient CMV negative) require long-term (100 days) rather than short-term (28 days) prophylaxis to effectively prevent CMV disease. The 'pre-emptive therapy' approach discussed above has also been successfully employed for management of CMV disease in solid organ transplant recipients.[35] Oral ganciclovir and valganciclovir have shown promise for CMV prophylaxis in solid organ transplant recipients.

Dosage in special circumstances

Because ganciclovir is cleared by renal mechanisms, dosage reduction is necessary in patients with creatinine clearance of <70ml/min (see Table 205.9).[25] About 50% of an administered dose is removed during 4 hours of hemodialysis and dosing after dialysis is recommended. Valganciclovir dosage adjustment is required for patients with creatinine clearance <60ml/min; the drug is not recommended for patients on hemodialysis. No dosage adjustments for hepatic impairment are necessary. Ganciclovir is mutagenic, carcinogenic and causes reproductive toxicity in animal models.[25] Use of ganciclovir or valganciclovir in pregnant or nursing women is not recommended without careful consideration of the risk-benefit ratio. Data on ganciclovir use in children are currently limited, but the drug is being evaluated for therapy of congenital CMV infections.

Adverse reactions

The most important adverse effects of ganciclovir noted in AIDS patients being treated for CMV retinitis were neutropenia and thrombocytopenia. About 40% developed granulocytopenia (absolute neutrophil count <1000/mm^3) and 15% had thrombocytopenia (platelet count <50000/mm^3). Hematologic toxicity is also seen, although less commonly, in organ transplant recipients. Neutropenia and thrombocytopenia are usually reversible when ganciclovir therapy is discontinued. In many patients requiring ganciclovir therapy, neutropenia can be prevented or treated by co-administration of granulocyte colony-stimulating factor. Renal dysfunction has been reported in up to 20% of transplant recipients receiving ganciclovir prophylaxis, although this may be related to co-administration of other nephrotoxic drugs. In animal models, ganciclovir produces significant reproductive toxicity, especially azoospermia.[25] Valganciclovir appears to have similar hematological toxicity to intravenous ganciclovir. Pooled data from two different studies indicate that 50% patients developed granulocytopenia (absolute neutrophil count <1000/mm^3), 35% experienced anemia (hemoglobin <9.5g/dl) and 23% developed thrombocytopenia (platelets <100000/µl). Gastrointestinal complaints were also common: 41% reported diarrhea, 30% nausea, 21% vomiting and 15% abdominal pain.

In vitro, ganciclovir and zidovudine have mutually antagonistic antiviral activity, but this observation has not been shown to be clinically significant. Ganciclovir should be used with caution in

combination with other myelosuppressive drugs such as zidovudine because of the risk of additive hematologic toxicity. Probenecid can reduce renal clearance of ganciclovir, resulting in clinically significant increases in ganciclovir AUC. Seizures have been reported in patients receiving concomitant therapy with ganciclovir and imipenem.

Resistance

HSV and VZV isolates that are TK deficient and aciclovir resistant will also be cross-resistant with ganciclovir. Ganciclovir resistance *in vitro* is defined as an IC_{50} >6µM (1.5µg/ml). CMV isolates resistant to ganciclovir have been produced in the laboratory and isolated from patients with CMV disease.[36] In a study of 72 AIDS patients treated with ganciclovir, five of 13 culture-positive patients treated for >3 months excreted resistant virus.[37] Ganciclovir-resistant CMV has been identified as a cause of retinitis, encephalitis and poly-radiculopathy in AIDS patients. CMV resistance to ganciclovir is usually secondary to mutations in the UL97 gene, although alterations in the DNA polymerase gene have also been described. UL97 mutants remain susceptible to foscarnet, although polymerase mutants cross-resistant to both ganciclovir and foscarnet have been identified. Foscarnet or cidofovir are therapeutic options for treatment of disease caused by ganciclovir-resistant CMV.

Foscarnet

Mechanism of action and in vitro activity

Foscarnet (trisodium phosphonoformic acid) is an analogue of inorganic pyrophosphate that functions as a noncompetitive inhibitor of herpesvirus DNA polymerase. [38] Foscarnet blocks the pyrophosphate binding site, preventing cleavage of pyrophosphate from deoxynucleotide triphosphates. Viral DNA polymerase is inhibited at foscarnet concentrations 100-fold lower than those required to inhibit cellular DNA polymerase. Unlike the aciclovir-like drugs discussed above, foscarnet is not a nucleoside analogue, does not require intracellular activation by viral kinase and is not incorporated into the viral DNA chain. Therefore, thymidine kinase-deficient HSV and VZV isolates that are resistant to aciclovir will remain susceptible to foscarnet. Foscarnet has *in vitro* activity against HSV, VZV, CMV, EBV and HHV-6. The IC_{50} for most clinical isolates of CMV is in the range of 100–300µM, but varies considerably with the experimental conditions. Foscarnet can also inhibit viral reverse transcriptase and has *in vitro* activity against hepatitis B virus and HIV.[38]

Pharmacokinetics and distribution

Foscarnet has low oral bio-availability (approximately 17%) and is administered only by the intravenous route. Peak plasma concentrations after steady-state dosing at 60mg/kg every 8 hours or 90mg/kg every 12 hours are about 500µM and 700µM, respectively.[38] Plasma protein binding is about 15%. CSF foscarnet levels demonstrate wide interpatient variability, but average about 66% of plasma levels at steady state. Foscarnet is not metabolized and about 80% of an administered dose is excreted unchanged in the urine by glomerular filtration and tubular secretion within 36 hours. About 20% of the foscarnet dose is retained in bone, presumably due to the drug's structural similarity to inorganic phosphate. This results in a complex pattern of drug disposition, in which the initial elimination half-life is about 4.5 hours, followed by a prolonged terminal half-life of about 88 hours as drug is released from bone.[38] Plasma foscarnet levels are reduced about 50% following hemodialysis; dosing after dialysis is recommended.

Route of administration and dosage

Foscarnet is available only as an intravenous formulation. The usual dose for induction therapy of CMV retinitis is 90mg/kg every 12 hours, with a maintenance dose of 90–120mg/kg every 24 hours. When given via a central venous catheter, the drug can be diluted to 24mg/ml; for infusion through peripheral vein catheters, foscarnet must be diluted to 12mg/ml to avoid local phlebitis. The foscarnet dose must be administered over at least 1 hour using an intravenous infusion pump; bolus infusion can result in severe toxicity. A topical 3% foscarnet cream formulation has been evaluated for therapy of herpes labialis, but is not commercially available.

Indications

CMV retinitis

Intravenous foscarnet is approved for treatment of CMV retinitis in immunocompromised patients. In controlled clinical trials, foscarnet therapy was shown to significantly delay progression of CMV retinitis in AIDS patients.[39] As discussed above with ganciclovir, long-term maintenance with foscarnet is required to extend the time to subsequent relapse in patients with CMV retinitis. The recommended foscarnet dosage in patients with normal renal function is 90mg/kg every 12 hours for 14–21 days for induction, followed by 90–120mg/kg daily indefinitely. In a controlled trial comparing foscarnet with ganciclovir for CMV retinitis in AIDS patients, the two drugs were therapeutically equivalent for retinitis, but extended survival (12.6 versus 8.5 months) was shown in the foscarnet group.[40] Foscarnet clearly has antiviral activity against HIV, but it is uncertain whether this accounts for the survival benefit demonstrated in this and other studies. However, foscarnet therapy was significantly more toxic than ganciclovir and patients had to discontinue foscarnet three times more often because of adverse effects.[41] Limited clinical experience has shown intravitreal foscarnet to be effective for CMV retinitis. Foscarnet is an effective alternative therapy for some patients with retinitis caused by ganciclovir-resistant strains of CMV, although dually resistant isolates can rarely occur. Combination therapy with ganciclovir plus foscarnet has been used successfully to treat refractory CMV infections in AIDS patients.[42]

Other CMV infections

Evidence for foscarnet efficacy for CMV infections other than retinitis is derived primarily from uncontrolled studies and clinical experience. Foscarnet

has been used to treat CMV pneumonia and CMV colitis in AIDS patients. Attempts to use foscarnet for therapy or prophylaxis of CMV infections in bone marrow transplant recipients have met with variable success.

Aciclovir-resistant HSV and VZV infections

Foscarnet is the drug of choice for treatment of infections caused by aciclovir-resistant HSV and VZV.[43] In a controlled trial, foscarnet was clearly superior to vidarabine for treatment of aciclovir-resistant mucocutaneous HSV infections in patients with AIDS.

Dosage in special circumstances

Foscarnet is excreted by renal mechanisms and dosage adjustment is required even for minor degrees of renal insufficiency (see Table 205.10). Serum creatinine should be monitored at least every other day during foscarnet therapy to assess the need for further dose adjustment. Dosage adjustment in hepatic impairment is not required. The safety of foscarnet during pregnancy has not been adequately evaluated and use is not recommended unless no other alternative therapy is available. Little information has been published regarding foscarnet safety and tolerance in neonates and children.

Adverse reactions

The most important adverse effect caused by foscarnet is nephrotoxicity. [41] Dose-limiting renal toxicity occurs in at least 15–20% of patients treated with foscarnet for CMV retinitis. The primary mechanism of renal toxicity appears to be acute tubular necrosis, although interstitial nephritis and crystalline nephropathy have also been described. Loading the patient with intravenous saline prior to foscarnet infusion can help reduce the risk of nephrotoxicity. In most cases, the renal dysfunction is reversible and serum creatinine will return to normal within 2–4 weeks after foscarnet therapy is discontinued. However, irreversible renal failure may occur in patients who are volume depleted or who receive concomitant therapy with other nephrotoxic medications. Foscarnet can induce a variety of electrolyte and metabolic abnormalities, most notably hypocalcemia.[44] Hypercalcemia, hypomagnesemia, hypokalemia and hypo- and hyperphosphatemia have also been reported. The acute decline in ionized serum calcium that can occur with foscarnet infusion may be due to formation of a complex between foscarnet and free calcium.[44] Further depletion of total serum calcium seen with

long-term drug administration may be caused by renal calcium wasting, abnormal bone metabolism, concurrent hypomagnesemia or some combination of these factors. Foscarnet-induced electrolyte disturbances can predispose the patient to cardiac arrhythmias, tetany, altered mental status or seizures. It is mandatory that serum creatinine and electrolyte levels be closely monitored during foscarnet therapy. Foscarnet is much less myelosuppressive than ganciclovir, but anemia was reported in 10–50% of AIDS patients receiving foscarnet. Patients, especially uncircumcised males, may develop genital ulcerations due to local toxicity of high foscarnet concentrations in urine. Nausea and vomiting has been reported by 20–30% of patients receiving foscarnet. Other infrequent adverse effects include headache, diarrhea and abnormal liver function tests. When possible, foscarnet should be administered through a central venous line to avoid peripheral thrombophlebitis.

Specific drug interactions with foscarnet have not been described, although there is significant potential for additive toxicity. Concurrent therapy with foscarnet and intravenous pentamidine can result in severe and potentially fatal hypocalcemia. Concomitant administration of foscarnet with other potentially nephrotoxic drugs such as amphotericin B or aminoglycosides can compound the risk of serious nephrotoxicity. Foscarnet can be safely administered to patients receiving zidovudine, although there may be an increased risk of anemia.

Resistance

Although uncommon, foscarnet-resistant isolates of CMV, VZV and HSV have been encountered in AIDS patients receiving foscarnet therapy. Resistance is due to a mutation in the DNA polymerase gene which means that, in some circumstances, the foscarnet-resistant isolate may remain susceptible to aciclovir or ganciclovir. However, CMV isolates cross-resistant to both ganciclovir and foscarnet (containing both polymerase and UL97 mutations) have been recovered from AIDS patients. Cidofovir may be an effective alternative drug in this setting, but in vitro antiviral susceptibility testing is necessary to guide drug selection.

Cidofovir

Mechanism of action and in vitro activity

Cidofovir is a nucleotide analogue of cytosine monophosphate with potent broad-spectrum antiviral activity. Unlike aciclovir and other nucleoside analogues which require monophosphorylation by viral kinases for activation, cidofovir already carries a phosphonate group and does not require viral enzymes for conversion to cidofovir diphosphate, the active antiviral compound. Cidofovir diphosphate competitively inhibits the DNA polymerases of herpesviruses, thereby blocking DNA synthesis and viral replication. Cidofovir diphosphate inhibits viral DNA polymerases at concentrations much lower than those required to inhibit cellular DNA polymerases, accounting for its selectivity of action.[45] Cidofovir has potent in vitro activity against human CMV, with IC_{50} values in the range of 0.1–0.9µg/ml. Cidofovir retains activity against most CMV clinical isolates that are resistant to ganciclovir. Cidofovir also demonstrates in vitro activity against HSV and VZV (including TK-deficient, aciclovir-resistant isolates), adenovirus, poxvirus (including variola or smallpox virus) and human papillomavirus.

Pharmacokinetics and distribution

Serum cidofovir concentrations are dose proportional over a dosing range of 1.0–10.0mg/kg. Intravenous infusion of cidofovir at a dosage of 5mg/kg produces peak plasma concentrations of about 11µg/ml. The terminal half-life is 2.6 hours. Approximately 90% of the intravenous cidofovir dose is excreted by the kidneys within 24 hours, with clearance involving both glomerular filtration and tubular secretion. At cidofovir doses higher than 3mg/kg, concomitant administration of probenecid can block tubular secretion of cidofovir and reduce its renal clearance. [45] Cidofovir diphosphate and its metabolites have prolonged intracellular half-lives, which permit cidofovir to be effectively administered at extended dosing intervals.

Route of administration and dosage

Cidofovir for intravenous administration is supplied as 375mg of an aqueous solution (75mg/ml). The selected dose is diluted in 100ml of normal saline prior to administration. For induction therapy, the usual dose of cidofovir is 5mg/kg infused over 1 hour once weekly. The dose for maintenance therapy for CMV disease is 5mg/kg administered once every 2 weeks. To minimize nephrotoxicity, patients should receive 1 liter of normal saline intravenously over 1–2 hours immediately prior to cidofovir dose and an additional 1 liter of normal saline immediately following the cidofovir dose. Probenecid is given at a dose of 2g orally 3 hours before the cidofovir dose, then 1 doses at 2 hours and 8 hours after completion of the cidofovir infusion, for a total probenecid dose of 4g. Prodrugs of cidofovir (e.g. cyclic HPMPC) are under development.

Indications

CMV infections

Cidofovir has been approved in the United States for treatment of CMV retinitis. In a study of 48 AIDS patients with CMV retinitis, time to progression of disease was significantly longer in the cidofovir treatment group (120 days) compared with the deferred treatment group (22 days).[46] [47] Cidofovir has also been shown to be effective for CMV retinitis in patients who have relapsed on, or were intolerant to, ganciclovir or foscarnet. Efficacy of intravenous cidofovir was similar to oral ganciclovir plus ganciclovir implant in 61 AIDS patients with CMV retinitis, but adverse effects differed between the two treatment groups.[48] These data indicate that intravenous cidofovir is effective for both initial and salvage therapy of CMV retinitis in AIDS patients.

Cidofovir has a potential role for pre-emptive treatment of CMV disease in bone marrow transplant recipients, but has been evaluated in only a limited number of patients and should currently be considered as second-line therapy.

HSV infections

Because cidofovir is not dependent on thymidine kinase for activation, the drug retains activity against aciclovir-resistant HSV. Published case reports suggest that cidofovir is effective for treatment of aciclovir- and foscarnet-resistant mucocutaneous HSV infections, but data from controlled clinical trials are currently lacking.[49] An investigational topical preparation of cidofovir has also been evaluated for this indication. Cidofovir gel (0.3% or 1%) applied topically to mucocutaneous HSV lesions in AIDS patients resulted in >50% reduction in lesion surface area in half of the cidofovir-treated patients. Six of 20 cidofovir-treated patients (versus 0 of 10 placebo-treated patients) had complete lesion healing.

Human papillomavirus

Cidofovir has potent *in vitro* activity against HPV. Topical preparations and intralesional injections are under evaluation for treatment of laryngeal papillomatosis and genital warts.

Poxvirus infections

Topical 3% cidofovir has been used on an investigational basis to treat severe cases of molluscum contagiosum. Cidofovir has activity against orthopoxvirus infections in animal models and has been suggested as a treatment for smallpox, monkeypox and disseminated vaccinia infections in humans.

Dosage in special circumstances

Because intravenous cidofovir can cause significant nephrotoxicity, initiation of therapy in patients with pre-existing renal dysfunction (serum creatinine >1.5mg/dl, calculated creatinine clearance =55ml/min or proteinuria >100mg/dl [=2+]) is not recommended. Declining renal function during cidofovir therapy mandates dosage adjustment. If the serum creatinine increases by 0.3–0.4mg/dl above baseline, the cidofovir dose should be reduced from 5 to 3mg/kg. If the serum creatinine increases =0.5mg/dl above baseline or if proteinuria =3+ develops, cidofovir therapy should be discontinued. Dosage adjustment in patients with hepatic impairment is not required. Cidofovir is embryotoxic in animals and the drug should not be used during pregnancy unless there are no other therapeutic options. Cidofovir has not been systematically evaluated in children or elderly patients.

Adverse reactions

The most important safety concern with cidofovir therapy is nephrotoxicity. Pretreatment with intravenous hydration and probenecid (which blocks cidofovir tubular secretion) reduces the incidence of nephrotoxicity. In a clinical trial using cidofovir 5mg/kg plus probenecid, proteinuria occurred in five of 41 patients (12%) and elevated serum creatinine levels in two of 41 patients (5%). Neutropenia (ANC <750 WBC/ mm^3) was observed in 15% of cidofovir recipients.[46] Anemia, thrombocytopenia and hepatotoxicity have not been observed with cidofovir therapy. Ocular complications (including iritis, anterior uveitis and hypotony) have been described following intravenous or intravitreal cidofovir administration.

Probenecid, a benzoic acid derivative with a sulfa moiety, can cause allergic symptoms (e.g. fever, chills, rash) in patients allergic to sulfonamides. Patients with a history of severe sulfa hypersensitivity should not be treated with probenecid and, consequently, should not receive cidofovir. Other probenecid-related adverse effects include headache, nausea and vomiting, which can be minimized by administering the drug on a full stomach. In a CMV retinitis trial, probenecid-related adverse effects occurred in 23 of 41 patients (56%) and were dose limiting in three patients (7%).[46]

Cidofovir injections in rats were associated with mammary adenocarcinomas, but surveillance studies in treated patients have not demonstrated any excess frequency of tumors. Cidofovir administration causes embryotoxicity and impaired spermatogenesis in animals; male and female patients are advised to use adequate birth control during and for 3 months after completion of cidofovir therapy.

No specific drug interactions with cidofovir have been described, although concomitant therapy with other nephrotoxic drugs may result in additive toxicity. Probenecid, however, is known to alter the renal excretion of a wide variety of drugs. The dose of zidovudine should be reduced to 50% on days when probenecid administration is planned.

Resistance

Instances of clinical failure of cidofovir therapy due to drug resistance have been reported. CMV resistance to cidofovir results from a mutation in the viral polymerase gene and resistant isolates may exhibit cross-resistance to ganciclovir and/or foscarnet. *In vitro* susceptibility testing is necessary in this circumstance to guide appropriate drug selection.

Fomivirsen

Mechanism of action and in vitro activity

Fomivirsen is a 21-nucleotide phosphorothioate oligonucleotide designed as an antisense molecule with activity against CMV.[50] The oligonucleotide is complementary to mRNA from the immediate-early region 2 of CMV. Antisense inhibition of target gene expression, while necessary for optimal antiviral activity, only partially explains the activity of fomivirsen against CMV. Nonspecific interactions between the oligonucleotide and virus particles may prevent adsorption or lead to inhibition of enzymes required for viral DNA synthesis. Fomivirsen has activity against clinical CMV isolates, including isolates resistant to conventional antiviral drugs, with a median IC_{50} of 0.37µM in tissue culture.

In an open-label, dose-ranging study, increasing doses of fomivirsen were given to 22 AIDS patients (28 eyes) with refractory CMV retinitis. Decreased retinal CMV activity was noted in patients who received 300µg of fomivirsen by intravitreal injection every 1–2 weeks. In another study, 28 AIDS patients with newly diagnosed CMV retinitis (with less than 25% retinal involvement) were randomized to receive prompt treatment with fomivirsen or to defer treatment. In the treatment arm, 18 patients

received 150µg of fomivirsen every week for 3 weeks then every other week. Median time to progression was 71 days in patients who received prompt treatment versus 14 days in the deferred group (p = 0.0056).

Pharmacokinetics and distribution

When cynomolgus monkeys were given 11, 57 or 115µg of fomivirsen intravitreally, maximum vitreal concentrations (ranging from 0.11 to 1.28µM) were achieved 2 days after injection of all doses. For the same dosages, retinal concentrations increased in a logarithmic pattern, with maximal concentration obtained 2 days after injection for all doses, ranging from 0.12 to 0.88µM. For the 115µg dose, the vitreal and retinal half-lives were 22 hours and 78 hours, respectively. Electrophoretic analyses of retina and vitreous specimens indicate the oligonucleotide is metabolized by exonucleolytic cleavage. Both intact drug and its metabolic products diffuse from the vitreous humor to the retina and it is hypothesized that the active metabolism occurs in both compartments.

Route of administration and dosage

Fomivirsen is supplied in single-use vials containing 0.25ml of 6.6mg/ml solution. Dosage for induction therapy of CMV retinitis is 330µg given intravitreally every other week for two doses. Maintenance therapy is 330µg given intravitreally every 4 weeks.

Indications

Fomivirsen is indicated for treatment of CMV retinitis in AIDS patients who have failed or are intolerant of other CMV therapies, including those with CMV that is resistant to ganciclovir and foscarnet. It is not recommended for use in patients who have received intravitreal or intravenous cidofovir. Fomivirsen is not indicated for systemic CMV therapy and will not protect the contralateral eye from involvement.

Dosage in special circumstances

As there is little systemic exposure to fomivirsen after intravitreal injection, no dose adjustments are required. This drug has not been studied in pregnant or lactating women or in pediatric or geriatric populations.

Adverse reactions

The most common adverse reactions reported were increased intraocular pressure and mild to moderate intraocular inflammation of the anterior and posterior chambers. The combined incidence of ocular reactions was 10–12% of patients treated every other week and 20% in patients treated weekly. Other adverse reactions reported in 5–20% patients included abnormal or blurred vision, conjunctival hemorrhage, retinal detachment and retinal edema. Topical steroids have been used with success to ameliorate some of these effects.

Resistance

A fomivirsen-resistant CMV isolate has been developed by exposing a laboratory strain to increasing concentrations of the drug. This resistant virus did not prove to have mutations which would have altered specificity for the fomivirsen target sequence. This provides more evidence that both antisense specific and nonspecific mechanisms are involved in the drug's activity against CMV. There have been no reports of formivirsen-resistant CMV isolates recovered from patients.

Chapter 206 - Antiviral Agents against Respiratory Viruses

Michael Ison
Frederick G Hayden

M2 INHIBITORS

Overview

Amantadine and rimantadine are symmetric tricyclic amines that specifically inhibit the replication of influenza A viruses at low concentrations (<1.0µg/ml) by blocking the action of the M2 protein. M2, an acid-activated ion channel found only in influenza A viruses, is a membrane protein required for efficient nucleocapsid release after viral fusion with the endosomal membrane.

Amantadine and rimantadine share two concentration-dependent mechanisms of antiviral action.[1] [2] Low concentrations of the drugs inhibit the ion channel function of the M2 protein, which inhibits viral uncoating or disassembly of the virion during endocytosis and, in H7 subtypes, alters HA maturation during viral assembly. Amantadine and rimantadine also increase the lysosomal pH, which in turn may inhibit virus-induced membrane fusion events for several enveloped viruses. However, such effects are generally not seen at drug concentrations observed in humans and clinically relevant antiviral activity is confined to influenza A viruses, although studies in chronic hepatitis C are in progress (see Table 206.1).

Resistance

Resistance to the two agents occurs as the result of amino acid substitutions in the transmembrane portion of the M2 protein. Although resistant wild-type virus is uncommonly found (<1%),[3] resistant viruses may rapidly emerge within 2–4 days after the start of therapy in up to 30% of patients.[4] Emergence of resistant virus does not appear to cause a rebound in illness in immunocompetent adults but may be associated with protracted illness and shedding in immunocompromised hosts. [5] Importantly, resistant virus can be spread to others and has caused failures of antiviral prophylaxis under close contact conditions, as in nursing homes and households.[4] The resistant virus appears to retain wild-type pathogenicity and causes an influenza illness indistinguishable from susceptible strains. Cross-resistance occurs to all M2 inhibitors without affecting susceptibility to the neuraminidase inhibitors and ribavirin.

Pharmacokinetics and distribution

Amantadine is rapidly absorbed, with a 53–100% bioavailability, and reachs peak plasma levels of 475µg/l within 4.5 hours after a 100mg dose in healthy adults.[6] The drug is predominantly excreted unchanged in the urine by glomerular filtration and tubular secretion. The plasma elimination half-life is about 11–15 hours in persons with normal renal function. Elimination is markedly prolonged in patients with renal impairment and decreases about 2-fold in the elderly so that dose adjustments are required (Table 206.3). Amantadine is widely distributed with salivary levels equivalent to those of blood and nasal mucus comparable to plasma at 8 hours after dosing.[7] [8] Amantadine crosses the placenta and blood-brain barrier, with cerebrospinal fluid(CSF) levels equal to 56–96% of serum levels, and distributes in breast milk (see Table 206.2).

In experimental human influenza infection, a trough concentration at steady-state of 300µg/l, which corresponds to that observed after 200mg/day dosing, was associated with a lower infection rate than placebo.[8] Adverse events are dose related and daily doses of 200mg in young adults and 100mg in the elderly institutionalized are associated with excess central nervous system (CNS) adverse effects.[6]

Rimantadine has nearly complete oral bioavailability and achieves maximal plasma concentration 3–5 hours after ingestion. Peak concentrations average 416µg/l after a 200mg oral dose. Rimantadine levels in nasal secretions average 1.5 times those of plasma levels. The plasma half-life is long and ranges from 24 to 36 hours. Rimantadine undergoes extensive metabolism, including hydroxylation, conjugation and glucuronidation in the liver, before being excreted in the urine. Only 25% of the parent drug is excreted unchanged in the urine. Dose adjustments are recommended for advanced renal or hepatic failure and older age (see Table 206.3).

Route of administration and dosage

Amantadine and rimantadine come as 100mg tablets and a syrup formulation (50mg/5ml). In adults, the usual dose for treatment or prevention of influenza A infection is 100mg q12h for both drugs (see Table 206.3).

Indications

Amantadine and rimantadine are indicated for the prevention and treatment of influenza A virus illness. Most placebo-controlled studies of these drugs in the management of influenza have been conducted in previously healthy persons. [8]

Prophylaxis

Prophylaxis with amantadine or rimantadine is approximately 70–90% effective in preventing symptomatic influenza A infections.[9] Administration is advised for postexposure prophylaxis in nursing home populations at 100mg/day for 14 days or for at least 7 days after the last culture-confirmed illness in the ward or building; this regimen should be given with concomitant influenza vaccination for those not previously provided.[10] Rimantadine is better tolerated in this population.[11] Seasonal prophylaxis, during the 4–8 weeks of peak influenza virus circulation within the community, can be used for protection of high-risk patients who cannot tolerate immunization, who do not develop an adequate immune response to vaccine or when the strain circulating in the community does not match the vaccine strain. Postexposure prophylaxis in households appears protective when not used in conjunction with treatment of an ill index case.

Treatment

Amantadine or rimantadine therapy reduces duration of fever and symptoms in patients with documented influenza by about 1 day compared with placebo, when the medication is initiated within 48 hours of symptom onset.[12] Treatment is also associated with more rapid functional recovery[12] and resolution of small airways functional abnormalities. Studies comparing the therapeutic activity of

Note: Concentrations for inhibition in cell culture are express in µM, whereas those for neuraminidase enzyme inhibition are expressed in nM. Results of representative publications.			

amantadine and rimantadine are few but generally show comparability.[12] Amantadine appears safe and efficacious in reducing length of fever and illness in children older than 2 years of age.[12] Pediatric studies have found variable clinical benefits relative to acetaminophen controls and document the frequent emergence of drug-resistant variants.[12]

Prospective controlled data to support the use of M2 inhibitors in treating severe influenza or in preventing complications are lacking; one retrospective study found no important differences in duration of illness or hospitalization between the amantadine-treated and untreated patients hospitalized with influenza.[13] In hematopoietic stem cell transplant (HSCT) and acute leukemia patients who received therapy with one of the M2 inhibitors, a reduced risk of progression to pneumonia (35% vs 76%) was found compared with no treatment.[14] However, emergence of resistance is common in such patients.[5] One retrospective study of nursing home residents suggested that early treatment might reduce lower respiratory complications.[15] Amantadine is ineffective for treating influenza B or C infections.

*Values are mean (SD)
**values are median (range).

Dosage in special circumstances

Dosing of amantadine and rimantadine should be adjusted in the setting of renal failure (see Table 206.3). Neither M2 inhibitor is cleared by hemodialysis. Patients over 65 years of age should have the dose of both medications reduced to 100mg once daily to avoid side effects. Rimantadine needs dose adjustment to 100mg per day for serious hepatic insufficiency. Amantadine and rimantadine are embryotoxic and teratogenic in preclinical tests and amantadine may be associated with birth defects. As a result, neither drug should be used in pregnant women unless the benefits of therapy clearly outweigh the potential risks (pregnancy category C). The recommended pediatric dosage of both amantadine and rimantadine is 5mg/kg/day to a maximum of 150mg/day, divided twice daily in children younger than 10.[10]

Adverse effects and drug interactions

The most common side effects of the M2 inhibitors are minor CNS complaints (anxiety, difficulty concentrating, insomnia, dizziness, headache and jitteriness) and gastrointestinal upset. Patients who receive amantadine may develop antimuscarinic effects, orthostatic hypotension and congestive heart failure at low frequencies. Particularly in the elderly or those with renal failure, serious CNS side-effects due to amantadine, and less often rimantadine, include confusion, disorientation, mood alterations, memory disturbances, delusions, nightmares, ataxia, tremors, seizures, coma, acute psychosis, slurred speech, visual disturbances, delirium, occulogyric episodes and hallucinations.[8] Amantadine causes CNS side-effects in about 15–30% of persons, as well as dose-related abnormalities in psychomotor testing.[8] The incidence and severity of CNS adverse effects are less common with rimantadine.[11] Amantadine and possibly rimantadine may increase the risk of seizures in those with a history of seizures.

Concomitant ingestion of antihistamines or anticholinergic drugs increases the CNS effects of amantadine. Trimethoprim-sulfamethoxazole and triamterene-hydrochlorothiazide decrease the renal clearance of amantadine, which enhances the risk of CNS toxicity. Quinine and quinidine also reduce the clearance of amantadine. Co-administration with monoamine oxidase inhibitors may precipitate life-threatening hypertension. The drug does not appear to interact with the cytochrome P450 system. Cimetidine is associated with 15–20% increases and aspirin or acetaminophen with 10% decreases in plasma rimantadine concentrations, but such changes are unlikely to be of clincial significance.[16] Patients receiving either amantadine or rimantadine along with drugs affecting

TABLE 206-3 -- Agents used to prevent and treat influenza.[10]

Recommendations based on those provided by the Advisory Committee on Immunization Practices.[10] § Hemodialysis contributes minimally to clearance.				

+ Duration of treatment is usually 5 days. Duration of prophylaxis depends on clinical setting.
*** Investigational: not approved for treatment in children by the US Food and Drug Administration.
** Investigational: not approved for prophylaxis by the US Food and Drug Administration.
¶ No treatment or prophylaxis dosing recommendations are available for patients undergoing renal dialysis.
* Volume of suspension.

CNS function, such as antihistamines, antidepressants or minor tranquilizers, should be monitored closely.

NEURAMINIDASE INHIBITORS

Overview

Influenza A and B viruses possess a surface glycoprotein with neuraminidase activity whereas influenza C viruses do not. This enzyme cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin. This activity is essential for release of virus from infected cells, for prevention of viral aggregates and for viral spread within the respiratory tract.[17] Zanamivir and oseltamivir are sialic acid analogues that potently and specifically inhibit influenza A and B neuraminidases by competitively and reversibly interacting with the active enzyme site.[18] These drugs are active against all nine neuraminidase subtypes in nature including the avian strains of influenza A H5N1 and H9N2 that infected humans (see Table 206.1).

Resistance

Zanamivir and oseltamivir carboxylate resistance in vitro results from mutations in the viral hemagglutinin and/or neuraminidase.[19] [20] In the hemagglutinin variants, mutations in or near the receptor binding site make the virus less dependent on neuraminidase action, whereas neuraminidase mutations directly affect interaction with the inhibitors. The altered neuraminidases typically show reduced activity or stability and the mutated viruses usually have decreased infectivity in animals.[19] The particular neuraminidase mutation determines the degree of resistance and cross-resistance (i.e. R229K causes high-level resistance in oseltamivir but not zanamivir).[19] Several hemagglutin and neuraminidase mutants have been described in immunocompromised patients with prolonged virus shedding.[22] Oseltamivir-resistant variants have been recovered from <1% of treated adults and about 4% of treated children.[18] The possible clinical and epidemiologic significance of such variants requires study and a global Neuraminidase Inhibitor Susceptibility Network has been established to address these concerns.[20]

ZANAMIVIR

Pharmacokinetics and distribution

The oral bioavailability of zanamivir is low (<5%) and most clinical trials have used intranasal or dry powder inhalation delivery. The commercial dry powder formulation is mixed with lactose (5mg zanamivir per 20mg lactose). Following inhalation of the dry powder, approximately 7–21% is deposited in the lower respiratory tract and the remainder in the oropharynx.[23] [24] Median zanamivir concentrations are above 1000ng/ml in induced sputum 6 hours after inhalation and remain detectable up to 24 hours (see Table 206.2). The peak plasma concentration averages 46µg/l after a single 16mg inhalation of zanamivir. The proprietary inhaler device for delivering zanamivir is breath activated and requires a co-operative patient.[25]

In both experimental and natural influenza, once-daily dosing appears protective.[26] Twice-daily administration is therapeutically active but increasing the dose frequency to four times per day does not appear to increase efficacy in treating natural influenza.[26] Intranasal dosing is protective against experimental infection but not natural infection and does not substantially increase the overall therapeutic response to inhaled zanamivir.

Route of administration and dosage

Zanamivir is delivered by inhalation with a proprietary breath-activated device (Diskhaler). The usual adult treatment dose is two inhalations (10mg) twice a day for 5 days.

Indications

Prophylaxis

Although not US Food and Drug Administration approved for prophylaxis, once-daily inhaled zanamivir for 4 weeks was 84% efficacious in preventing laboratory-confirmed illness with fever and 31% effective in preventing influenza infection, irrespective of symptoms.[26] When used for postexposure prophylaxis, inhaled zanamivir for 10 days reduced the risk of secondary influenza illness by 79% in households.[26] In nursing homes experiencing influenza outbreaks, inhaled zanamivir was more effective for prevention of influenza A illness than oral rimantadine, in part because of frequent resistance emergence to the M2 inhibitor.[26]

Treatment

In the USA zanamivir is indicated for the treatment of uncomplicated acute illness due to influenza A and B virus in adults and pediatric patients 7 years and older who have been symptomatic for no more than 2 days. Inhaled zanamivir in adults has consistently shown at least one less day of disabling influenza symptoms and most studies have found a reduction in the number of nights of disturbed sleep, in time to resumption of normal activities and in the use of symptom relief medications. [26] [27] Similar therapeutic benefits have also been shown in children aged 5–12 years.[28] Greatest benefit was noted in patients who were febrile at the time of enrollment, those started on therapy within 30 hours after the onset of symptoms and in adults aged 50 years and older.[26] Zanamivir has also been associated with a 40% reduction in lower respiratory tract complications of influenza leading to antibiotics, particularly bronchitis and pneumonia.[29] It appears generally well tolerated and effective in treating influenza in patients with mild to moderate asthma or, less often, chronic obstructive pulmonary disease (COPD).[27] [29] An uncontrolled study found zanamivir to be safe and possibly effective in allogeneic stem cell transplant recipients, although viral shedding persisted for an average of 2 weeks on therapy.[21] Further studies are needed in immunocompromised populations.

Dosage in special circumstances

Although the plasma elimination half-life increases with creatinine clearance =70ml/min, drug accumulation is negligible after inhalation and dose adjustment is not necessary for renal or hepatic dysfunction. Certain populations, particularly very young, frail or cognitively impaired patients, may have difficulty using the drug delivery system.[25]

Adverse effects and drug interactions

Topically applied zanamivir is generally well tolerated in controlled studies, including those involving patients with asthma and COPD.[27] No difference in adverse events between zanamivir and placebo (lactose) recipients has been found.[27] Less than 5% of zanamivir recipients have reported diarrhea, nausea, sinusitis, nasal signs and symptoms, bronchitis, cough, headache, dizziness and ear, nose and throat infections. Postmarketing reports indicate that bronchospasm may be an uncommon but potentially severe problem, particularly in patients with acute influenza and underlying reactive airways disease.[30] Anecdotal reports of hospitalization and fatality indicate that inhaled zanamivir should be used cautiously in such patients. Current guidelines advise against the use of zanamivir in patients with underlying airway disease, unless the patient is closely monitored and has a fast-acting inhaled bronchodilator available when inhaling zanamivir.[10]

Low bioavailability is associated with low exposure to circulating zanamivir and no clinically significant drug interactions have been recognized. In-vitro studies suggest that zanamivir does not inhibit or induce cytochrome P450 enzymes. The drug does not affect the immunogenicity of concomitant immunization with inactivated virus vaccines. It is uncertain whether inhaled zanamivir might reduce the immunogenicity of intranasal, live-attenuated vaccine if administered concurrently. Although not associated with teratogenic effects in preclinical studies, zanamivir should only be used in pregnancy when the potential benefit justifies the potential risk to the fetus (pregnancy category C).

OSELTAMIVIR

Pharmacokinetics and distribution

Oral oseltamivir ethyl ester is well absorbed and rapidly cleaved by esterases in the gastrointestinal tract, liver or blood. The bioavailability of the active metabolite, oseltamivir carboxylate, is estimated to be approximately 80% in previously healthy persons.[31] Mean peak oseltamivir carboxylate concentrations of 456µg/l are reached at 5 hours after oral administration of 150mg doses in healthy adults and the plasma elimination half-life is 6–10 hours (see Table 206.2). Although drug concentrations over time are 25–35% higher in the elderly at steady-state, no dose adjustment is deemed necessary. Administration with food appears to decrease the risk of gastrointestinal upset without decreasing bioavailability. Both the prodrug and parent are eliminated primarily unchanged through the kidney by glomerular filtration and anionic tubular secretion. The dose should be reduced by half for patients with a creatinine clearance less than 30ml/min.[32] Distribution is not well characterized in humans, but peak bronchoalveolar lavage levels are similar to plasma levels in animals.[31] Drug levels in middle ear fluid and sinus aspirates are similar to those in blood. [31]

There is no clear association between the plasma AUC for the oseltamivir carboxylate drug and viral titer after experimental infection; early therapy of experimental infection is associated with reduced median nasal lavage concentrations of interleukin-6, tumor necrosis factor-a and interferon-? as compared with placebo.[31] In natural influenza, once-daily dosing appears as effective as twice-daily dosing for prevention of influenza illness.[31] Doses of 75mg and 150mg twice daily provide comparable antiviral and clinical effects in treatment of acute influenza A illness[31] and of experimental influenza B in adults.

Route of administration and dosage

Oseltamivir comes as 75mg tablets and as a suspension in bottles containing 25ml of suspension after constitution equivalent to 300mg oseltamivir base. The suspension comes in bottles containing 25ml of suspension after constitution equivalent to 300mg oseltamivir base. The typical adult dose for treatment is 75mg twice daily for 5 days and for prophylaxis is 75mg once daily. Pediatric dosing is based on weight and is outlined in Table 206.3 .

Indications

In the USA oseltamivir is indicated for the treatment of uncomplicated acute illness due to influenza infection in patients 1 year and older who have been symptomatic for no more than 2 days and for the prophylaxis of influenza in adult patients and adolescents 13 years and older.

Prophylaxis

The efficacy of once-daily oseltamivir 75mg for 6 weeks in preventing influenza illness in healthy, nonimmunized adults was 84% and in preventing influenza infection irrespective of symptoms was 50%.[31] In immunized nursing home residents, the efficacy of prophylaxis was

92% against illness compared with placebo.[31] Similar efficacy was seen in a household-contact prophylaxis study,[31] and protection against influenza has been shown in children.[31]

Treatment

Oseltamivir 75mg twice daily for 5 days, when started within the first 2 days of symptoms, was associated with a shorter time to alleviation of illness (29–35 hours shorter) and with reductions in severity of illness, duration of fever, time to return to normal activity, quantity of viral shedding, duration of impaired activity, and complications leading to antibiotic use, particularly bronchitis, compared with placebo in previously healthy adults.[31] Preliminary analyses indicate that early treatment can reduce hospitalizations. In a pediatric study enrolling children between the ages of 1 and 12 years, oseltamivir 2mg/kg twice daily for 5 days significantly reduced illness duration and severity, time to resumption of full activities and the occurrence of complications leading to antibiotic use, particularly acute otitis media.[33] Little published information is available about therapeutic efficacy in elderly or high-risk persons, including those with underlying cardiopulmonary conditions or immunodeficiency.

Dosage in special circumstances

Oseltamivir dose should be reduced to 75mg once a day for treatment and 75mg every other day or 30mg of suspension daily for prophylaxis when a patient has a creatinine clearance of less than 30mg/dl. Doses of oseltamivir should be given after hemodialysis. The safety and pharmacokinetics in patients with hepatic impairment have not been evaluated. Oseltamivir should not be used in pregnant women unless the benefits of therapy clearly outweigh the potential risks (pregnancy category C). The recommended pediatric dosages are listed in Table 206.3 .

Adverse effects and drug interactions

Oral oseltamivir is generally well tolerated and no serious end-organ toxicity has been found in controlled clinical trials. Oseltamivir is associated with nausea, discomfort and, less often, emesis in a minority of treated patients. Nausea and vomiting occur at approximately 10–15% excess in oseltamivir recipients. Gastrointestinal complaints are usually mild to moderate in intensity, usually resolve despite continued dosing and are ameliorated by administration with food.[34] Clinical studies comparing 75mg and 150mg twice daily doses found similar frequencies of adverse events with the two doses. Other infrequent possible adverse events include insomnia, vertigo and fever. Postmarking reports suggest that oseltamivir may be associated rarely with skin rash, hepatic dysfunction or thrombocytopenia.

No clinically significant drug interactions have been recognized. However, probenecid blocks tubular secretion and doubles the half-life of oseltamivir. Studies with amoxicillin, aspirin and acetaminophen have found no clinically important interactions. No interactions with the cytochrome P450 enzymes occur in vitro. Protein binding is below 10%. Oseltamivir should not affect the immunogenicity of concomitant vaccination with inactivated virus but might impair the immunogenicity of concurrent live-attenuated intranasal influenza vaccine.

RIBAVIRIN

Overview

Ribavirin is a guanosine analogue with a wide range of antiviral activity including influenza viruses, respiratory syncytial virus (RSV), parainfluenza viruses and adenoviruses. Ribavirin is rapidly phosphorylated by intracellular enzymes and the triphosphate inhibits influenza virus RNA polymerase activity and competitively inhibits the guanosine triphosphate-dependent 5'-capping of influenza viral messenger RNA. In addition, ribavirin depletes cellular guanine pools.[35] [36] Although it has no antiviral activity when used alone, for the treatment of hepatitis C infection, the combination of ribavirin and interferon-a is more effective than interferon-a alone (see Chapter 207).

Pharmacokinetics and distribution

Oral ribavirin has a bioavailability of 33–45% in adults and children and achieves peak plasma concentrations of 0.6μg/ml 1–2 hours after ingestion of a 400mg dose in adults. Ribavirin has a short initial (0.3–0.7 hours) and long terminal-phase half-life (18–36 hours) and is eliminated by hepatic metabolism and renal clearance.[37] [38] [39] [40] After aerosol administration, plasma levels increase with exposure and range from 0.2 to 1μg/ml. Respiratory secretions have levels of up to 1000μg/ml, which declines with a half-life of 1.4–2.5 hours.

Route of administration and dosage

Ribavirin comes in three formulations: oral, intravenous (investigational in the USA) and aerosol. Ribavirin for aerosolization is available as a 6g/100ml solution, which is diluted to a final concentration of 20mg/ml and delivered by small-particle aerosol for 12–18 hours with a proprietary device (SPAG-2 nebulizer). A higher concentration of aerosol solution (60mg/ml) has been given over 2 hours three times daily in some studies and appears well tolerated. Ribavirin also comes in 200mg tablets and sterile solution for injection.

Indications

Ribavirin aerosol is currently indicated for the treatment of severe RSV infection in children. Trials of aerosolized ribavirin for the treatment of severe RSV infection in infants have shown no consistent effect on duration of hospitalization time or mortality.[41] Earlier studies were confounded by the use of water aerosol as placebo, which may induce bronchospasm. Long-term follow-up of ribavirin recipients has likewise found no consistent benefits on pulmonary function.[41] Current guidelines recommend that aerosolized ribavirin be considered in the treatment of high-risk infants and young children, as defined by congenital heart disease, chronic lung disease, immunodeficiency states, prematurity and age <6 weeks, as well as for those hospitalized with severe illness.[41] [42] Administration of a more concentrated aerosol solution (60mg/ml) over 2 hours thrice daily appears well tolerated and easier to administer.[43] Aerosolized ribavirin has shown minimal efficacy in treating influenza in hospitalized children.[44]

Ribavirin has also been studied for the treatment of RSV and parainfluenza virus infections in immunocompromised patients. Intravenous ribavirin appears to be ineffective in reducing RSV-associated mortality in human stem cell transplant with RSV pneumonia.[45] Aerosolized ribavirin may provide benefit in selected patient groups with less severe RSV disease. Survival is improved when treatment is started before respiratory failure or when infection is limited to the upper respiratory tract.[45] Although no prospective studies of aerosolized ribavirin alone versus combined ribavirin-antibody therapy (IVIG, RespiGam or palivizumab) have been reported, combination therapy may be more effective, particularly when started before severe respiratory distress. [45] In the management of parainfluenza virus (PIV) pneumonia in bone marrow transplant recipients, aerosolized ribavirin failed to improve 30-day mortality or reduce the duration of viral replication relative to no treatment. [45] Intravenous ribavarin may be beneficial in treating PIV or influenza virus infections in some immunocompromized patients.[46] High oral doses of ribavarin (30–60mg/kg/day in divided doses) have been used in early treatment of RSV and PIV infections in HSCT. High oral doses (8.4g over 2 days) provided modest benefit in acute influenza in otherwise healthy adults.[48]

Recently. oral and intravenous ribavirin have been used in treatment of SARS coronavirus illness with uncertain clinical and virologic effects.[48A] [48B]

Dosage in special circumstances

Systemic ribavirin is contraindicated in patients with creatinine clearance of less than 50mL/min and the dose should be reduced by one-third for patients under the age of 10 years. Dose adjustment is needed if there is a substantial decline in hematocrit and the drug should be discontinued if the hematocrit drops below 8.5g/dl. Ribavirin is contraindicated in pregnant women and in male partners of women who are pregnant because of teratogenicity of the drug. Pregnancy should be avoided during therapy and 6 months after completion of therapy in both female patients and in female partners of male patients taking ribavirin (pregnancy category X).

Adverse effects and drug interactions

Systemic ribavirin can cause a dose-related extravascular hemolytic anemia and, at higher doses, suppression of bone marrow release of erythroid elements. Severe anemia may require dose adjustment or cessation or use of erythropoietin. Aerosolized ribavirin can cause bronchospasm, mild conjunctival irritation, rash, psychologic distress if administered in a oxygen tent and, rarely, acute water intoxication. Bolus intravenous administration may cause rigors. Antagonism of both drugs occurs in vitro when ribavirin is combined with zidovudine; the in-vivo significance is unknown.
