Most organisms of the genus *Eubacterium* and anaerobic lactobacilli seem to be nonpathogenic. They are almost invariably isolated as part of mixed flora in the oral, vaginal and gastrointestinal areas. These organisms have been recovered most commonly in infections associated with predisposing or underlying conditions that include malignancy, previous surgery, immunodeficiency, diabetes mellitus, the presence of a foreign body, dental extraction and broad-spectrum antibiotic therapy.[10]

Propionibacterium spp. ordinarily are not pathogens, but can be found in association with implanted cardiac prostheses or central nervous system (CNS) shunts or as a cause of endocarditis on previously damaged valves. They have been recovered from parotid and dental infections, brain abscesses, conjunctivitis associated with contact lens, peritonitis and pulmonary infections. The most common species, *Propionibacterium acnes*, may be isolated from blood cultures but is associated only rarely with bacteremia or endocarditis. Because these organisms are part of the normal skin flora, they are common laboratory contaminants or may grow in blood cultures from skin contamination if the skin surface has been improperly decontaminated before the blood sample is drawn. *Propionibacterium acnes* can cause bacteremia, especially in association with shunt infections,[11] and is believed to play a role in the pathogenesis of acne vulgaris.

Gram-negative bacilli

Bacteroides fragilis group are the most frequently recovered species of Bacteroidaceae in clinical specimens (Fig. 232.3). *Bacteroides fragilis* group are resistant to penicillins, mostly through the production

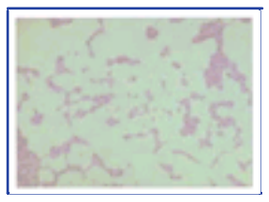

Figure 232-3 Gram stain of *Bacteroides fragilis.* *Courtesy of Mike Cox.*

of ß-lactamase. They include ten members — the most commonly isolated are *B. fragilis* (the most commonly recovered member), *Bacteroides thetaiotaomicron, Bacteroides distasonis, Bacteroides ovatus* and *Bacteroides vulgatus*. These organisms are part of the normal gastrointestinal flora[1] and predominate in intra-abdominal infections and other infections that originate from the gut flora (i.e. perirectal abscesses, decubitus ulcers).[3] [5]

Pigmented *Prevotella* spp. (*Prevotella melaninogenica* and *Prevotella intermedia*), *Porphyromonas* spp. (*Porphyromonas asaccharolytica*) and nonpigmented *Prevotella* spp. (*Prevotella oralis, Prevotella oris*) are part of the normal oral and vaginal flora and are the predominant Gram-negative anaerobic species isolated from respiratory infections and their complications, aspiration pneumonia, lung abscess, chronic otitis media, chronic sinusitis, abscesses around the oral cavity, human bites, paronychia, brain abscesses and osteomyelitis.[12] *Prevotella bivia* and *Prevotella disiens* are important isolates from obstetric and gynecologic infections.

Fusobacterium species

Fusobacterium spp. are moderately long and thin organisms with tapered ends, and have typical fusiform morphology (Fig. 232.4). The species of *Fusobacterium* seen most often in clinical infections are *Fusobacterium nucleatum, Fusobacterium necrophorum, Fusobacterium mortiferum* and *Fusobacterium varium. Fusobacterium nucleatum* is the predominant *Fusobacterium* sp. from clinical specimens, and is often associated with oral, pulmonary and intracranial infections.[13] *Fusobacterium* spp. are frequently isolated from abscesses, obstetric and gynecologic infections, blood and wounds.

A growing resistance of Gram-negative anaerobic bacilli to penicillins has been noticed in the past decade.[14] These include the pigmented *Prevotella* and *Porphyromonas, Prev. oralis, Prev. disiens, Prev. bivia* and *Fusobacterium* spp. The main mechanism of resistance is through the production of the enzyme ß-lactamase. Testing for antimicrobial susceptibility and the ability to produce ß-lactamase of all Gram-negative anaerobic bacilli can assist in the selection of proper antimicrobials.

The recovery rates of the different anaerobic Gram-negative bacilli in infected sites are similar to their distributions in the normal flora.[3] [5] *B. fragilis* group were more often isolates in sites proximal to the gastrointestinal tract (abdomen, bile), pigmented *Prevotella* spp. were more prevalent in infections proximal to the oral cavity (bones, sinuses, chest), and *Prev. bivia* and *Prev. disiens* were more often isolates in obstetric and gynecologic infections (see Table 232.2). Knowledge of this common mode of distribution allows for logical choice of antimicrobials that are adequate for the therapy of infections in these sites.

Gram-positive cocci

The species most commonly isolated are *Peptostreptococcus magnus, Peptostreptococcus asaccharolyticus, Peptostreptococcus anaerobius, Peptostreptococcus prevotii* and *Peptostreptococcus micros.*

Figure 232-4 Gram stain of *Fusobacterium nucleatum.* *Courtesy of Mike Cox.*

Additional anaerobic cocci include *Coprococcus, Peptococcus, Ruminococcus sarcina* and *Staphylococcus saccharolyticus*. These organisms are part of the normal flora of the mouth, upper respiratory tract, intestinal tract, vagina and skin.

These organisms can be isolated in all types of anaerobic infections. They also predominant in all types of respiratory infections (including chronic sinusitis, mastoiditis, acute and chronic otitis media, aspiration pneumonia and lung abscess), and necrotizing, subcutaneous and soft tissue infections.[15] They are generally recovered mixed with other aerobic or anaerobic organisms, but in many cases they are the only pathogens recovered. This may be of particular significance in cases of bacteremia. Microaerophilic Gram-positive cocci include *Streptococcus anginosus, Streptococcus constellatus, Streptococcus intermedius* and *Gemella morbillorum.* Microaerophilic streptococci are of particular importance in chronic sinusitis and brain abscesses. They are also recovered from obstetric and gynecologic infections and abscesses.[16]

Gram-negative cocci

There are three genera described as anaerobic Gram-negative cocci: *Veillonella, Acidaminococcus* and *Megasphaera* spp. There are two described species of *Veillonella* and only one each of the other two genera. *Veillonella* is the most frequently involved of the three genera and *Veillonella* spp. are part of the normal flora of the mouth, vagina and the small intestine of some persons. Although they are rarely isolated from clinical infections, these organisms have been recovered occasionally from almost every type of anaerobic infection. [17]

PATHOGENICITY

Anaerobes as part of the normal flora

The human body mucosal and epithelial surfaces are colonized with aerobic and anaerobic micro-organisms.[1] Differences in the environment, such as oxygen tension, pH and variations in the ability of bacteria to adhere to these surfaces, account for changing patterns of colonization. Microflora also vary in different sites within the body system, as in the oral cavity; for example, the micro-organisms present in the buccal folds vary in their concentration and types of

TABLE 232-3 -- Normal flora.

NORMAL FLORA			
Site	**No. of organisms/g fecal material**		**Predominant anaerobic bacteria**
	Aerobes	**Anaerobes**	
Skin	-	-	*Propionibacterium acnes*
			Peptostreptococcus spp.
Mouth/upper respiratory tract	10^8 –10^9	10^9 –10^{11}	Pigmented *Prevotella* and *Porphyromonas* spp.
			Fusobacterium spp.
			Peptostreptococcus spp.
			Actinomyces spp.
Gastrointestinal tract:			
Upper	10^2 –10^5	10^3 –10^7	*Bacteroides fragilis* group
			Clostridium spp.
Lower	10^5 –10^9	10^{10} –10^{12}	*Peptostreptococcus* spp.
			Bifidobacterium spp.
			Eubacterium spp.
Female genital tract	10^8	10^9	*Peptostreptococcus* spp.
			Prevotella bivia
			Prevotella disiens
For predominant anaerobic bacteria in the gastrointestinal tract, all organisms can be found both in the upper and lower gastrointestinal tracts.			

strains from those isolated from the tongue or gingival sulci. However, the organisms that prevail in one body system tend to belong to certain major bacterial species, and their presence in that system is predictable. The relative and total counts of organisms can be affected by various factors, such as age, diet, anatomic variations, illness, hospitalization and antimicrobial therapy. However, these sets of bacterial flora, with predictable pattern, remain stable through life, despite their subjection to perturbing factors. Anaerobes outnumber aerobic bacteria on all mucosal surfaces, and certain organisms predominate in the different sites (see Table 232.3).

Knowledge of the composition of the flora at certain sites is useful for predicting which organisms may be involved in an infection adjacent to that site and can assist in the selection of a logical antimicrobial therapy, even before the exact microbial etiology of the infection is known. Recognition of the normal flora can also help the clinical microbiology laboratory to choose proper culture media that will be selective in inhibiting organisms that may interfere with the growth of certain anaerobic bacteria.

The anaerobic microflora of the skin is largely made up of the genus *Propionibacterium*[11] (mostly *Propionibacterium acnes*) and, to a lesser extent, *Peptostreptococcus* spp. The perineum and lower extremity may harbor members of the colonic and vaginal flora.

The microflora of the upper airways, including oral cavity, nasopharynx and oropharynx, is complex and contains many types of obligate anaerobes. The distribution of bacteria within the mouth seems to be a function of their ability to adhere to the oral surfaces. The differences in numbers of the anaerobic microflora probably occur because of considerable variations in the oxygen concentration in parts of the oral cavity. The ratio of anaerobic bacteria to aerobic bacteria in saliva is approximately 10:1. The total count of anaerobic bacteria in the saliva and elsewhere in the oral cavity reach 10^7 –10^8 bacteria/ml. The predominant anaerobic bacteria in the upper airways include *Fusobacterium* spp. (especially *F. nucleatum*), pigmented *Prevotella* and *Porphyromonas* spp., *Prev. oralis* and *Peptostreptococcus* spp. These organisms also predominate in oropharyngeal, otolaryngologic and pulmonary infections.

The gastrointestinal flora varies in bacterial concentration at different levels. The stomach acidity reduces the number of organisms swallowed from the oropharynx. The stomach, duodenum, jejunum and

proximal ileum normally contain relatively few bacteria. However, the flora becomes more complex, and the number of different bacterial species increase in the distal portion of the gastrointestinal tract. However, interruption in intestinal motility may result in an increase in the number of anaerobic and aerobic bacteria. The bacterial counts in the small intestine are relatively low, with total counts of 10^2 –10^5 organisms/ml. The organisms that predominate up to the ileocecal valve are Gram-positive facultative, whereas below that structure *Bacteroides, Peptostreptococcus* and *Clostridium* spp., and coliform bacteria are the major isolates.[2] The mean number of bacteria in the colon exceeds 10^{11} bacteria/g fecal material. Approximately 99.9% of these bacteria are anaerobic (ratio of aerobes to anaerobes is 1:1000–10,000). In the colon 300–400 different species or types of bacteria can be found, many of whom are not yet identified.

The female genital flora is composed of mixed aerobic and anaerobic flora. However, the concentration and type of bacteria is less stable than that of the gastrointestinal flora and can be influenced by antimicrobial therapy, pregnancy and gynecologic surgery. A concentration of 10^8 organisms/ml is found during the reproductive years. Changes occur in the number of organisms at the various stages of the menstrual cycle.[18] The predominant aerobic organisms are aerobic lactobacilli, and the predominant anaerobic bacteria are anaerobic *Lactobacillus, Peptostreptococcus, Prevotella* and *Bacteroides* and *Clostridium* spp. Other anaerobic isolates include *Porphyromonas, Fusobacterium, Bilophilia, Bifidobacterium, Actinomyces, Eubacterium* and *Propionibacterium* spp. Enterobacteriaceae can be found in postmenopausal flora. Bacterial vaginosis is associated with an increase in the number of anaerobic flora and a decrease in the concentration of lactobacilli.[19]

Most infections caused by anaerobic bacteria originate from the endogenous mucosal membrane and skin flora. An exception is *C. difficile*, the major cause of antibiotic-associated colitis. Anaerobes belonging to the indigenous flora of the oral cavity can be recovered from various infections adjacent to that area, such as cervical lymphadenitis, subcutaneous abscesses and burns in proximity to the oral cavity, human and animal bites, paronychia, tonsillar and retropharyngeal abscesses, chronic sinusitis, chronic otitis media, periodontal abscess, thyroiditis, aspiration pneumonia and bacteremia associated with one of the above infections.[3] [5] The predominant anaerobes recovered in these infections are *Prevotella, Porphyromonas, Fusobacterium* and *Peptostreptococcus* spp., which are all part of the normal flora of the mucous surfaces of the oropharynx (Fig. 232.5).

A similar correlation exists in infections associated with the gastrointestinal tract. Such infections include peritonitis after rupture of a viscus, liver and spleen abscess, abscess and wounds near the anus, intra-abdominal abscess, and bacteremia associated with any of

Figure 232-5 Recovery of anaerobic bacteria in different infectious sites.

these infections.[3] [5] The anaerobes that predominate in these infections are *B. fragilis* group, *Clostridium* spp. (including *C. perfringens*) and *Peptostreptococcus* spp.

Another site where a correlation exists between the normal flora and the anaerobic bacteria recovered from infected sites is the genitourinary tract. The infections involved are amnionitis, septic abortion and other pelvic inflammations. [3] [5] The anaerobes usually recovered from these sites are species of anaerobic Gram-negative bacteria and *Peptostreptococcus* spp. Organisms belonging to the vaginal-cervical flora are also important pathogens of neonatal infections. They can be acquired by the newborn before delivery in the presence of amnionitis or during passage through the birth canal.

Conditions predisposing to anaerobic infection

The clinical situations that predispose to anaerobic infections include exposure of the sterile body sites to a high inoculum of indigenous mucous membrane flora. Poor

blood supply and tissue necrosis lower the oxidation and reduction potential and favor the growth of anaerobic bacteria. Any condition that lowers the blood supply to an affected area of the body can predispose to anaerobic infection. Therefore, trauma, foreign body, malignancy, surgery, edema, shock, colitis and vascular disease may predispose to anaerobic infection. Other predisposing conditions include diabetes mellitus, splenectomy, immunosuppression, hypogammaglobinemia, neutropenia, leukemia, collagen vascular disease and cytotoxic drugs. Previous infection with aerobic or facultative organisms may make the local tissue conditions more favorable for the growth of anaerobic bacteria. The human defense mechanisms may also be impaired by anaerobic conditions and anaerobic bacteria. The noted effects include impairments in phagocytosis and intracellular killing (often caused by encapsulated anaerobes [20] and by succinic acid produced by *Bacteroides* spp.), inhibition of chemotaxis (by *Fusobacterium, Prevotella* and *Porphyromonas* spp.), degradation of serum proteins by proteases (by *Bacteroides* spp.) and production of leukotoxins (by *Fusobacterium* spp.).[21]

Suppuration, abscess formation, thrombophlebitis and gangrenous destruction of tissue associated with gas formation are the hallmarks of anaerobic infection (Table 232.4). Anaerobes are especially common in chronic infections, and they are commonly seen after failure of therapy with antimicrobials that are effective against them, such as aminoglycosides, trimethoprim-sulfamethoxazole (cotrimoxazole) and earlier quinolones.

Certain infections are very likely to involve anaerobes as important pathogens, and their presence should always be assumed. Such infections include brain abscess, oral or dental infections, human or animal bites, aspiration pneumonia and lung abscesses, peritonitis after perforation of viscus, amnionitis, endometritis, septic abortions,

TABLE 232-4 -- Clinical signs of anaerobic infection.

CLINICAL SIGNS OF ANAEROBIC INFECTION
• Infection adjacent to a mucosal surface
• Foul-smelling discharge
• Necrotic gangrenous tissue and abscess formation
• Free gas in tissue
• Bacteremia or endocarditis with no growth on aerobic blood cultures
• Infection related to the use of antibiotics effective against aerobes only
• Infection related to tumors or other destructive processes
• Infected thrombophlebitis
• Infection after bites
• Black discoloration of exudates containing *Bacteroides melaninogenicus*, which may fluoresce under ultraviolet light
• 'Sulfur granules' in discharges caused by actinomycosis
• Clinical presentation of gas gangrene
• Clinical condition predisposing to anaerobic infection (after maternal amnionitis, perforation of bowel, etc.)

tubo-ovarian abscess, abscesses in and around the oral and rectal areas, pus-forming necrotizing infections of soft tissue or muscle and postsurgical infections following procedures on the oral or gastrointestinal tract or female pelvic area. Certain solid malignant tumors, such as colon, uterine and bronchogenic carcinomas, and necrotic tumors of the head and neck, have the tendency to become infected with anaerobic bacteria.[22] The anoxic conditions in the tumor and exposure to the endogenous adjacent mucous flora may predispose to these infections.

Virulence factors

Anaerobes contribute to the severity of infection through their synergy with their aerobic counterparts and with each other.[23] Anaerobic bacteria generally take longer than aerobic bacteria to become virulent. This is because some of the major virulence factors of certain anaerobic bacteria (i.e. the production of a capsule) are expressed only after the infection has become chronic.[20]

Anaerobic bacteria possess several virulence factors that assist them to adhere and invade epithelial surfaces. These factors include the presence of surface structures (such as capsule polysaccharide or lipopolysaccharide), production of superoxide dismutase and catalase, immunoglobulin proteases, coagulation promoting, spreading factors (such as hyaluronidase, collagenase and fibrinolysin), adherence factors, and the production of toxins.[21] Other factors that enhance the virulence of anaerobes include mucosal damage, oxidation-reduction potential drop and the presence of hemoglobin or blood in an infected site.

An indirect pathogenic role of some anaerobes is their ability to produce the enzyme ßlactamase. Several anaerobic bacteria can

TABLE 232-5 -- Principal ß-lactamase-producing anaerobes.

PRINCIPAL ß-LACTAMASE-PRODUCING ANAEROBES
• *Fusobacterium* spp.: *F. nucleatum*, *F mortiferum*, *F. varium*
• Pigmented *Prevotella* and *Porphyromonas* spp., *Prevotella oralis* group
• Other *Prevotella* spp.: *P. oris*, *P. buccae*, *P. bivia*, *P. disiens*
• *Bacteroides fragilis* group, *Bacteroides splanchnicus*
• *Bilophila wadsworthia*
• *Clostridium* spp.: *C. ramosum*, *C. clostridioforme* and *C. butyricum*

produce ß-lactamase (Table 232.5). ß-lactamase-producing bacteria (BLPB) can protect not only themselves but also other penicillin-susceptible organisms from the activity of penicillins. This can occur when the enzyme ß-lactamase is secreted into the infected tissue or abscess fluid in sufficient quantities to degrade the ß-lactam ring of penicillin before it can kill the susceptible bacteria.[24]

In-vitro and *in-vivo* studies have demonstrated protection of penicillin-susceptible bacteria from penicillin by aerobic and anaerobic BLPB (i.e. protection of group A streptococci by *Staphylococcus aureus* or *Bacteroides* spp.).[24] The predominant anaerobic BLPB are pigmented *Prevotella* and *Porphyromonas, Bacteroides* and *Fusobacterium* spp.

PREVENTION

Proper therapy of acute infections can prevent the occurrence of chronic infections where anaerobes predominate. In settings where anaerobic infections are expected to occur, such as intra-abdominal and wound infections after surgery, proper antimicrobial prophylaxis reduces the chance of such infections.

Prevention and early therapy of conditions that may lead to anaerobic infection can reduce their rate. Preventing oral flora aspiration by improving the neurologic status of the patient, repeated suctioning of oral secretion, improving oral hygiene and maintaining lower stomach pH can reduce the risk of aspiration pneumonia and its complications. Skin and soft-tissue infections can be prevented by irrigation and debridement of wounds and necrotic tissue, drainage of pus and improvement of blood supply.

Prophylactic therapy before surgery is generally administered when the operative field is expected to be contaminated by the normal flora of the mucous membrane at the operated site. Cefazolin is effective in surgical prophylaxis in sites distant from the oral or rectal areas, when anaerobic cover is not required. Cefoxitin or cefotetan

are used in procedures that involve the oral, rectal or vulvovaginal surfaces because their spectrum includes the anaerobic flora likely to be encountered.

DIAGNOSTIC MICROBIOLOGY

Collection of specimens for anaerobic bacteria

The proper management of anaerobic infection depends on appropriate documentation of the bacteria causing the infection. Without such an approach, the patient may be exposed to inappropriate, costly and undesirable antimicrobial agents with adverse side-effects. Some laboratories may fail to recover certain or all of the anaerobes present in a specimen. This situation can occur particularly when the specimen is not promptly placed under anaerobic conditions for transport to the laboratory. If care is not taken to avoid specimen contamination with normal flora, anaerobes may not be recovered.

Appropriate cultures for anaerobes are especially important in polymicrobial infections.[4] Techniques or media that are inadequate for isolation of anaerobes because of a lack of an anaerobic environment or because of an overgrowth of aerobic organisms, can be misleading. This may cause the clinician to direct therapy toward only the isolated aerobic organisms.

The most acceptable documentation of an anaerobe is through recovery of anaerobic organisms from the infected site. Three essential elements require the physician's cooperation with the microbiology laboratory for appropriate documentation of anaerobic infection: collection of appropriate specimens, their expeditious transportation and careful laboratory processing.

Specimens must be obtained free of contamination so that saprophytic organisms or normal flora are excluded and culture results can be interpreted correctly. Because indigenous anaerobes are often

TABLE 232-6 -- Methods for collection of specimens for anaerobic bacteria.

METHODS FOR COLLECTION OF SPECIMENS FOR ANAEROBIC BACTERIA	
Infection site	**Methods**
Abscess or body cavity	Aspiration by syringe and needle
	Incised abscesses: syringe or swab (less desirable); specimen obtained during surgery after cleansing the skin
Tissue or bone	Surgical specimen using tissue biopsy or curette
Sinuses or mucus surface abscesses	Aspiration after decontamination or surgical specimen
Ear	Aspiration after decontamination of ear canal and membrane; in perforation, cleanse ear canal and aspirate through perforation
Pulmonary	Transtracheal aspiration, lung puncture, bronchoscopic aspirate (using double lumen catheter and quantitative culture)
Pleural	Thoracentesis
Urinary tract	Suprapubic bladder aspiration
Female genital tract	Culdocentesis after decontamination, surgical specimen
	Transabdominal needle aspirate of uterus
	Intrauterine brush (using double lumen catheter and quantitative culture)

present on the surfaces of skin and mucous membranes in large numbers, even minimal contamination of a specimen with normal flora can give misleading results. On this basis, specimens can be designated according to their acceptability for anaerobic culture to the acceptable or the unacceptable category. Materials that are appropriate for anaerobic cultures should be obtained using a technique that bypasses the normal flora (Table 232.6). Unacceptable or inappropriate specimens can yield normal flora also and therefore have no diagnostic value.

Acceptable specimens (Table 232.7) include blood specimens, aspirates of body fluids (pleural, pericardial, cerebrospinal, peritoneal and joint fluids), urine collected by percutaneous suprapubic bladder aspiration, abscess contents, deep aspirates of wounds and specimens collected by special techniques, such as transtracheal aspirates or direct lung puncture. Specimens of the lower respiratory tract are difficult to obtain without contamination with indigenous flora. Double-lumen catheter bronchial brushing and bronchoalveolar lavage, cultured quantitatively, can be useful. Direct needle aspiration is probably the best method of obtaining a culture, and the use of swabs is much less desirable. Specimens obtained from sites that are normally sterile may be collected after thorough skin decontamination, as is the case for the collection of blood, or spinal, joint or peritoneal fluids.

Transportation of specimens

Prompt delivery of specimens to the laboratory to allow for microbiologic processing is essential. Various transport devices are available that generate an oxygen-free environment. These systems generally contain an oxygen-free environment provided by mixture of carbon dioxide, hydrogen and nitrogen, plus an indicator that illustrates aerobic conditions. The specimens should be placed into an anaerobic transporter as soon as possible after collection. Aspirates of liquid specimen or tissue are always preferred to swabs, although systems for the collection of all culture forms are commercially available.

Liquid specimens may be inoculated into a commercially available anaerobic transport vial. A plastic or glass syringe and needle may

TABLE 232-7 -- Appropriate and inappropriate specimens for anaerobic culture.

APPROPRIATE AND INAPPROPRIATE SPECIMENS FOR ANAEROBIC CULTURE	
Inappropriate	**Appropriate**
Feces or rectal swabs	All normally sterile body fluids other than urine (e.g. blood, pleural and joint fluids)
Throat or nasopharyngeal swabs	
Sputum or bronchoscopic specimens	Urine obtained by suprapublic bladder aspiration
Routine or catheterized urine	Percutaneous transtracheal aspiration or direct lung puncture
Vaginal or cervical swabs	Culdocentesis fluid obtained after decontamination of the vagina
Material from superficial wound or abscesses not collected properly to exclude surface contaminations	Material obtained from closed abscesses
Material from abdominal wounds obviously contaminated with feces (e.g. an open fistula)	Material obtained from sinus tracts or draining wounds

TABLE 232-8 -- Bacteriologic findings suggestive of anaerobic infection.

BACTERIOLOGIC FINDINGS SUGGESTIVE OF ANAEROBIC INFECTION
• Organisms seen on Gram stain that cannot be grown in aerobic cultures
• Typical morphology for anaerobes on Gram stain
• Anaerobic growth on proper media containing antibiotic-suppressing aerobes
• Growth in anaerobic zone of fluid or agar media

• Gas, foul-smelling odor in specimen or bacterial culture
• Characteristic colonies on anaerobic plates
• Colonies of pigmented *Prevotella* or *Porphyromonus* spp. may fluoresce red under ultraviolet light, and older colonies produce a typical dark pigment

also be used for transport. After the specimen is collected and all air bubbles are expelled from the syringe and needle, the needle tip should be inserted into a sterile rubber stopper. Because air gradually diffuses into the plastic syringe, no more than 30 minutes should elapse before the specimen is processed. This inexpensive transport device for liquid specimens is especially useful in the hospital situation where it can be rapidly transported to the microbiology laboratory.

Swabs may be placed in the sterilized tubes containing carbon dioxide or prereduced, anaerobically sterile Carey and Blair semisolid media. Tissue specimens or swabs can be transported in an anaerobic jar or in a Petri dish inside a sealed plastic bag that can be rendered anaerobic by use of a catalyzer.

Laboratory diagnosis

Certain findings are suggestive of anaerobic infection (Table 232.8). However, laboratory diagnosis of anaerobic infections begins with the examination of a Gram-stained smear of the specimen (see Fig. 232.1). The appearance of the Gram-stained organisms will give important preliminary information regarding types of organisms present, suggest appropriate initial therapy and serve as a quality control on the final culture analysis. The laboratory should be able to recover all of the morphologic types in the approximate ratio in which they are seen.

The techniques for cultivation of anaerobes should provide optimal anaerobic conditions throughout processing. Detailed procedures of these methods can be found in microbiology manuals.[4]

Figure 232-6 Anaerobic glove-box used in the microbiology laboratory for processing of specimens and identifying anaerobic bacteria. *Courtesy of Mike Cox.*

Briefly, these methods could be the prereduced tube method, the anaerobic glove-box technique (Fig. 232.6), which provides an anaerobic environment throughout processing, or the anaerobic jar or bag systems, which are more simplified.

As a minimum requirement for the recovery of anaerobes, specimens should be inoculated onto enriched blood agar medium (containing vitamin K1 and hemin) and a selective medium (for *Bacteroides* spp.), such as laked sheep blood agar with kanamycin and vancomycin, should be used. The use of selective media along with a nonselective one increases the recovery rate and can shorten the time to identification of organisms.

Although prereduced vitamin K1 enriched thioglycolate broth is generally used as a back-up culture, this media alone should never be used as a substitute for a solid media. The major limitation of liquid media is the possibility of overgrowth of slow-growing strict anaerobes by rapid-growing aerobic and facultative organisms. Selective media can supplement nonselective media in increasing the bacterial yield and facilitating recovery.

Cultures should be placed immediately under anaerobic conditions and incubated for 48 hours or longer. Plates should then be examined for approximate number and types of colonies present. Each colony type should be isolated, tested for aerotolerance and identified.

An additional period of 36–48 hours is generally required to identify completely the anaerobic bacteria to a species or genus level using biochemical tests. Kits containing these biochemical tests are commercially available. These are good with fast growing anaerobes (i.e. *B. fragilis* and C. *perfringens*). Rapid enzymatic tests have recently been introduced. This panel test enables an identification of the anaerobes after only 4 hours of aerobic incubation and seems to be as good as the biochemical tests. Other rapid tests that have potential use and can also be used directly on clinical isolates are the direct fluorescent microscopy and direct gas liquid chromatography. Direct fluorescent microscopy can identify *Actinomyces* spp and *P. propionica*. This method is inaccurate in identification of *B. fragilis* group, pigmented *Prevotella* and *Porphyromonas* spp. Gas-liquid chromatography of metabolites can be employed to assist in the identification of anaerobes. Direct cellular fatty acid analysis using gas liquid chromatography with capillary column can also be useful. Nucleic acid probes and polymerase chain reaction methods are also being developed for rapid identification of anaerobic bacteria.

Most clinical microbiology laboratories are able to identify the major anaerobic bacteria. Peptostreptococci are generally not speciated because they are generally susceptible to commonly used antimicrobials. *Clostridium* spp. can be identified by the presence of spores and their ability to survive 30 minutes exposure to ethanol or heating to 176°F (80°C) for 10 minutes. Speciation requires biochemical testing. Nonspore-forming Gram-positive bacilli can be speciated by gas liquid chromatography and biochemical tests. *Propionibacterium* spp., which are often a contaminant, can be separated from other nonspore-forming Gram-positive bacilli by using a catalyze test and indole reaction. *Bacteroides fragilis* group organisms grow on 20% bile and are generally catalase positive. Pigmented *Prevotella* and *Porphyromonas* spp. produce black or brown pigment within a week when growing on rabbit blood agar medium. *Fusobacterium* spp. have a distinct morphology on Gram stain and, in contrast to *Bacteroides* spp., are susceptible to kanamycin.

Identification of an anaerobe to a species level is often cumbersome, expensive and time-consuming, taking up to 72 hours. Identification is most helpful in selecting an antibiotic against a species that has predictable antibiotic susceptibility. The level of speciation adequate for identifying an anaerobe is often controversial.

Occasionally, species identification of an organism will provide the diagnosis, as with *C. difficile* in patients who have colitis or *C. botulinum* in infants with botulism. However, because most anaerobes are endogenous, there are rarely epidemiologic reasons to perform complete identification. Identifying *B. fragilis* group, which often cause bacteremia and septic complications, has significant prognostic value.

Antimicrobial susceptibility testing

The antimicrobial susceptibility of anaerobes has become less predictable. Resistance to several antimicrobials, especially by anaerobic Gram-negative bacilli and *Fusobacterium* spp., has increased over the past decade.[13] It is important, therefore, to perform susceptibility testing for anaerobes recovered from sterile body sites, those with particular epidemiologic or prognostic significance (e.g. *C. difficile*), or those that are clinically important and have variable susceptibilities.

Screening of anaerobic Gram-negative bacilli isolates (particularly *Prevotella, Bacteroides* and *Fusobacterium* spp.) for ß-lactamase activity may be helpful. This can provide information regarding their penicillin susceptibility. However, occasional bacterial strains may resist ß-lactam antibiotics through other mechanisms.

Routine susceptibility testing of all anaerobic isolates is extremely time-consuming and in many cases unnecessary. Susceptibility testing should be limited to anaerobes isolated from blood cultures, bone, CNS and serious infections, as well as to those isolated in pure culture from properly collected specimens. Antibiotics tested should include penicillin, a broad-spectrum penicillin, a penicillin plus a ß-lactamase inhibitor, clindamycin, chloramphenicol, a second-generation cephalosporin (e.g. cefoxitin), metronidazole and a carbapenem (e.g. imipenem).

The method recommended by the National Committee for Clinical Laboratory Standards (NCCLS) includes agar dilution testing, microbroth and macrobroth dilution.[25] Newer methods include the E-test and the spiral gradient end-point system.

CLINICAL MANIFESTATIONS

Anaerobic bacteria have been recovered in infections at all anatomic locations. However, their frequency of isolation and the type of bacterial isolates depend on the microbial flora at their source, or at the adjacent mucocutaneous sites.

Central nervous system infections

Anaerobic bacteria can cause a variety of intracranial infections. These organisms induce brain abscess, subdural empyema and infrequently cause epidural abscess

and meningitis. The main source of brain abscess is an adjacent, generally chronic infection in the ears, mastoids, sinuses, oropharynx, teeth or lungs.[26] Ear or mastoid infection tend to spread to the temporal lobe or cerebellum, whereas facial sinusitis often causes abscess of the frontal lobe.

Hematogenous spread often occurs after dental, oropharyngeal or pulmonary infection. Rarely bacteremia of another origin or endocarditis can lead to such infection.

Meningitis caused by anaerobes is rare and can follow respiratory infection or develop as a complication of a cerebrospinal fluid shunt. Shunt infections are generally caused by skin flora such as *Prop. acnes*, [11] or in instances of ventriculoperitoneal shunts that perforate the gut, by anaerobes of enteric origin (i.e. *B. fragilis*).[27] *Clostridium perfringens* has been reported as a cause of brain abscesses and meningitis after head injuries or after intracranial surgery.[2]

The anaerobic bacteria generally recovered from brain abscesses that complicate respiratory and dental infections include *Prevotella, Porphyromonas, Bacteroides, Fusobacterium* and *Peptostreptococcus* spp. Microaerophilic and other streptococci are also often isolated. Actinomyces are less frequently encountered.

TABLE 232-9 -- Aerobic and anaerobic bacteria isolated in head and neck and upper respiratory tract infections.

AEROBIC AND ANAEROBIC BACTERIA ISOLATED IN HEAD AND NECK AND UPPER RESPIRATORY TRACT INFECTIONS			
Type of infection		**Aerobic and facultative organisms**	**Anaerobic organism**
Otitis media and mastoiditis:	acute	*Streptococcus pneumoniae*	*Peptostreptococcus* spp.
		*Haemophilus influenzae**	
		*Moraxella catarrhalis**	
	chronic	*Staphylococcus aureus**	Pigmented *Prevotella* and *Porphyromonas* spp.*
		*Escherichia coli**	*Bacteroides* spp.*
		*Klebsiella pneumoniae**	*Fusobacterium* spp.*
		*Pseudomonas aeruginosa**	*Peptostreptococcus* spp.*
Peritonsillar and retropharyngeal abscess		*Streptococcus pyogenes*	*Fusobacterium* spp.*
		*Staphylococcus aureus**	Pigmented *Prevotella* and *Porphyromonas* spp.*
Recurrent tonsillitis		*Streptococcus pyogenes*	*Fusobacterium* spp.*
		*Haemophilus influenzae**	
		*Staphylococcus aureus**	
Suppurative thyroiditis		*Streptococcus pyogenes*	Pigmented *Prevotella* and *Porphyromonas* spp.*
		*Staphylococcus aureus**	*Peptostreptococcus* spp.
Sinusitis:	acute	*Haemophilus influenzae**	*Peptostreptococcus* spp.
		Streptococcus pneumoniae	
		*Moraxella catarrhalis**	
	chronic	*Staphylococcus aureus**	Pigmented *Prevotella* and *Porphyromonas* spp.*
		Streptococcus pneumoniae	*Fusobacterium* spp.*
		*Haemophilus influenzae**	*Bacteroides fragilis* group*
Cervical lymphadenitis		*Staphylococcus aureus**	Pigmented *Prevotella* and *Porphyromonas* spp.*
		Mycobacterium spp.	*Peptostreptococcus* spp.
Postoperative infection disrupting oral mucosa		*Staphylococcus* spp.*	*Fusobacterium* spp.*
		Enterobacteriaceae*	*Bacteroides* spp.*
		Streptococcus pyogenes	Pigmented *Prevotella* and *Porphyromonas* spp.*
			Peptostreptococcus spp.
Deep neck abscesses and parotitis		*Streptococcus* spp.	*Bacteroides* spp.*
		Staphylococcus spp.*	*Fusobacterium* spp.*
			Peptostreptococcus spp.*
Odontogenic complications		*Streptococcus* spp.	Pigmented *Prevotella* and *Porphyromonas* spp.*
		Staphylococcus spp.*	*Peptostreptococcus* spp.
Oropharyngeal: Vincent's angina and necrotizing		*Streptococcus* spp.	*Fusobacterium necrophorum**
		Staphylococcus spp.*	

* Organisms that have the potential of producing ß-lactamase

At the stage of encephalitis, antimicrobial therapy accompanied by measures to control the increase in the intracranial pressure can prevent the abscess formation. Once an abscess has formed, surgical excision or drainage may be needed, combined with a long course of antibiotics (4–8 weeks). Some neurosurgeons advocate complete evacuation of the abscess, whereas others advocate repeated aspirations. [28] In patients who have multiple abscesses or in those who have abscesses in essential brain areas, repeated aspirations are preferable. High-dose antibiotics for an extended period may represent an alternative approach in this group of patients and have often replaced surgical drainage.[28]

Because of the difficulty involved in the penetration of various antimicrobial agents through the blood-brain barrier, the choice of antibiotics is restricted. The antimicrobials advocated for these infections are metronidazole, penicillins, carbapenems and

chloramphenicol. However, the choice may vary according to the specific isolates and their susceptibilities. A significant improvement in the mortality rate has been associated with the introduction of computed tomography (CT) and use of metronidazole therapy.

Head and neck and upper respiratory tract infections

Anaerobic bacteria can be recovered from a variety of head and neck and upper respiratory tract infections and predominate more in their chronic forms (Table 232.9). These include chronic otitis media, sinusitis and mastoiditis, tonsillar, peritonsillar and retropharyngeal abscesses, all deep neck space infections, parotitis, thyroiditis, odontogenic infections, and postsurgical and nonsurgical head and neck wounds and abscesses. The predominant organisms are of oropharyngeal flora origin and

include *Prevotella, Porphyromonas, Bacteroides, Fusobacterium* and *Peptostreptococcus* spp.

Most dental infections involve anaerobes. These include endodontal pulpitis and periodontal (gingivitis and periodontitis) infections, periapical and dental abscesses, and perimandibular space infection.[29] [30] Pulpitis may progress to an abscess and eventually involve the mandible and other neck spaces. In addition to the organisms mentioned above, microaerophilic streptococci and *Streptococcus salivarius* can also be involved.

Vincent's angina (or trench mouth) is a distinct form of ulcerative gingivitis; the causative organisms include *Fusobacterium* spp. and anaerobic spirochetes.[2]

Deep neck infections after oral, dental and pharyngeal infections are usually polymicrobial. These include mediastinitis after perforation of the esophagus, extension of retropharyngeal abscess or cellulitis, and dental abscess. [31]

Otitis media

Anaerobes were isolated in 5–15% of patients who had acute otitis media[32] and 42% of culture-positive aspirates of patients who had serous otitis media.[33] The predominant isolates in acute otitis media were *Peptostreptococcus* spp. and *Prop. acnes*. These organisms, as well as Gram-negative anaerobic bacilli, were recovered in serous otitis media.

Several studies reported the recovery of anaerobes in about 50% of the patients who have chronic suppurative otitis media.[3] [5] [34] [35] The infection is often polymicrobial and the predominant anaerobes were Gram-negative bacilli and peptostreptococci, and the common aerobes were *Pseudomonas aeruginosa* and *S. aureus*. Many of these organisms can produce ß-lactamase and might have contributed to the high failure rate of ß-lactam antibiotics in the therapy of this infection. Anaerobes were isolated from 23 out of 24 (96%) specimens of chronic mastoiditis[36] and from most patients who have intracranial abscesses that complicate chronic suppurative otitis media.[3] [5] [26]

Anaerobes were recovered from infected cholesteatomas.[37] [38] The production of organic acids by anaerobic bacteria may promote the process of bone destruction in cholesteatoma.[38] Because infected cholesteatoma contains bacteria similar to those recovered from chronically infected ears, it may serve as a nidus for chronic infection.

Sinusitis

Sinus disease may develop when allergy, viral infection, or anatomic obstruction occurs, preventing normal drainage. In the first stages of infection, the most common pathogens are similar to those recovered in acute otitis media: *Streptococcus pneumoniae, Haemophilus influenzae* and *Moraxella catarrhalis*. Anaerobic organisms become involved as the infection becomes chronic and the levels of tissue oxygen decline. [39] The transition in the bacterial flora from aerobic to anaerobic flora has been demonstrated.[40] An elevated serum antibody level to *Prevotella* and *Fusbacterium* spp. was demonstrated in patients with chronic sinusitis.[41] Although anaerobes are generally isolated from only about 7% of patients who have acute sinusitis (generally in maxillary sinusitis secondary to periodontal infection), they can be isolated from up to 67% of patients who have chronic infection.[3] [5] [42] An average of three anaerobes per aspirate were recovered in patients who had chronic sinusitis.[43]

Sinus infection may spread via anastomosing veins or contiguously to the CNS. Complications include orbital cellulitis[44] meningitis, cavernous sinus thrombosis, and epidural, subdural and brain abscesses. [3] [5]

Parotitis

Viral parotitis can be caused by paramyxovirus (mumps), Epstein-Barr virus, coxsackievirus, HIV, and influenza A and parainfluenza virus. Acute suppurative parotitis is generally caused by *S. aureus*, streptococci and, rarely, aerobic Gram-negative bacteria. Anaerobes, mostly *Peptostreptococcus, Bacteroides*, and pigmented *Prevotella* and *Porphyromonas* spp., have also been recognized as an important cause of this infection.[45] Empiric antibiotic therapy should be directed against both aerobic and anaerobic bacteria. Surgical drainage may be indicated when pus has formed.

Cervical lymphadenitis

The anterior cervical, the submandibular or the posterior cervical nodes are the most prevalent sites of infection. The most common causes in children are viruses. The organisms causing acute unilateral infection associated with facial trauma or impetigo are *S. aureus* and *Streptococcus pyogenes. Bartonella henselae* and mycobacterial infections are important in chronic infections. Anaerobes (mostly *Fusobacterium* and *Peptostreptococcus* spp.) were isolated in about 25% of the infections, often in pure culture.[46] Their recovery was associated with a primary dental, periodontal, or tonsillar infection.

Thyroiditis

Anaerobic Gram-negative bacilli and peptostreptococci were identified as causative agents in thyroiditis.[3] [5] [47] *Eikenella corrodens* and *Actinomyces* spp. were also reported.

Infected cysts

Thyroglossal duct, branchial cleft and dermoid cysts, cystic hygromas and laryngoceles can become infected. The organisms that can cause these infections can originate from either the skin or the oropharynx. *Staphylococcus aureus* and *S. pyogenes* are the predominant aerobic isolates, whereas pigmented *Prevotella* and *Porphyromonas* spp. are the predominate anaerobes. [48]

Infection after head and neck surgery

Infections after head and neck surgery are caused by the exposure of the surgical site to the oropharyngeal flora, by the decreased blood supply and by the presence of necrotic tissues. They are common after surgery for malignant tumors. The wounds are generally infected by polymicrobial aerobic and anaerobic flora; the average number of isolates varies from one to nine (average six).[49] The most common isolates are peptostreptococci, *S. aureus,* anaerobic Gram-negative bacilli (i.e. *Bacteroides* spp.), *Fusobacterium* spp. and Enterobacteriaceae. The presence of this flora warrants the use of antimicrobial agents that are effective against these organisms in the prophylaxis and therapy of this infection.[50]

Tonsillitis

Indirect evidence is mounting that anaerobes are involved in both acute and chronic tonsillitis. The evidence is mainly derived from

studies of complications of anaerobic tonsillitis (i.e. bacteremia, abscesses) where anaerobes play a major role. The organisms associated with the infection are *Fusobacterium* spp., peptostreptococci and Gram-negative anaerobic bacilli. Polymicrobial flora predominate in peritonsillar and retropharyngeal abscesses, where the number of isolates is between one and 12 (average five anaerobes and two aerobes).[3] [5] [51] Anaerobes have also been isolated from the cores of tonsils of children with recurrent group A ß-hemolytic streptococci (GABHS) infection[24] [42] [52] and non-GABHS tonsillitis.[52] These organisms can be isolated from 25% of suppurative cervical lymph nodes and are mostly associated with the presence of dental or tonsillar infections.[46] Anaerobic organisms were associated with thrombophlebitis of the internal jugular veins, which often causes postanginal sepsis.[3] [5]

The pathogenic role of anaerobes in the acute inflammatory process in the tonsils is also supported by several clinical observations:

- their recovery in tonsillar or retropharyngeal abscesses often without any aerobic bacteria;[51]
- their isolation from tonsils in Vincent's angina;[5]
- the recovery of encapsulated pigmented *Prevotella* and *Porphyromonas* spp. in acutely inflamed tonsils;
- the isolation of anaerobes from the core of recurrently inflamed non-GABHS tonsils;[52] and

¦ the response to antibiotics in patients who have non-GABHS tonsillitis. [53] [54]

Furthermore, immune response against *Prev. intermedia* can be detected in patients who have non-GABHS tonsillitis;[55] and against *Prev. intermedia* and *F. nucleatum* in patients who recovered from peritonsillar cellulitis or abscesses [56] and infectious mononucleosis.[57]

Metronidazole therapy alleviated the symptoms of tonsillar hypertrophy and shortened the duration of fever in patients who had infectious mononucleosis. [53] Because metronidazole has no antiviral or aerobic antibacterial efficacy, suppression of the oral anaerobic flora may contribute to diminishing the inflammation induced by the Epstein-Barr virus. This is supported by the increased recovery of *Prev. intermedia* and *F. nucleatum* during the acute phases of mononucleosis. [58]

Recurrent pharyngotonsillitis and failure to eradicate the GABHS with penicillin can be a serious clinical problem. One explanation for penicillin failure is that repeated administrations result in selection of BLPB.[24] ß-lactamase-producing strains of pigmented *Prevotella* and *Porphyromonas* spp., *B. fragilis*, *Fusobacterium* spp., *H. influenzae* and *Staph. aureus* were isolated from the tonsils of more than 75% of children with recurrent GABHS tonsillitis[24] [42] [59] [60] and from 40% of children with non-GABHS tonsillitis.[52] Similar organisms were recovered from patients who had adenoiditis and adenoid hypertrophy. [61]

The recovery of these bacteria in more than three-quarters of the patients who had recurrent GABHS tonsillitis,[24] [59] [60] the ability to measure ß-lactamase activity in the core of these tonsils[62] and the response of patients to antimicrobials effective against BLPB (i.e. clindamycin or amoxicillin plus clavulanic acid)[24] [63] [64] support the role of these aerobic as well as anaerobic organisms in the inability of penicillin to eradicate GABHS tonsillitis.

Pleuropulmonary infections

Aspiration of oropharyngeal secretions or gastric contents, and severe periodontal or gingival disease are the most prevalent risk factors for developing anaerobic pleuropulmonary secretion. The infection can progress from pneumonitis into necrotizing pneumonia and pulmonary abscess, with or without empyema.[65] The lesions tend to develop in the dependent pulmonary segments, in either of the superior segments of the lower lobes and in the posterior segments of the upper lobes. The infection is generally polymicrobial where the causative organisms of community-acquired infection (in 60–80% of cases) are aerobic and anaerobic members of oropharyngeal flora. The anaerobes isolated are *Prevotella*, *Porphyromonas*, *Fusobacterium* and *Peptostreptococcus* spp., and the aerobes are a-hemolytic streptococci and microaerophilic streptococci (Table 232.10).[66] Anaerobes can also be recovered in about one-third of patients who have nosocomial-acquired aspiration pneumonia and pneumonia associated with tracheostomy with and without mechanical ventilation,[67] where they are generally recovered mixed with Enterobacteriaceae, *Pseudomonas* spp. and *Staph. aureus*. Specimens for culture should be obtained in a manner that will avoid their contamination by the oral flora. They can be obtained using bronchoalveolar lavage, bronchoscopy via bronchial brush protected in a double-lumen plugged catheter (using quantitative cultures in the last two methods), percutaneous transtracheal aspiration, lung biopsy and thoracentesis (of empyema fluid). Management of these infections includes drainage of the pleural space, in the presence of empyema, and antimicrobials effective against the anaerobic and aerobic bacteria (see Chapter 36).

Intra-abdominal infections

Secondary peritonitis and intra-abdominal abscesses generally occur because of the entry of enteric micro-organisms into the peritoneal cavity through a defect in the wall of the intestine or other viscus as a result of obstruction, infarction or direct trauma. Perforated appendicitis, inflammatory bowel disease with perforation and gastrointestinal surgery are often associated with polymicrobial infections caused by aerobic and anaerobic bacteria, where the number of isolates can average 12 (two-thirds are generally anaerobes). Diverticulitis and its complications is also associated with such an infection.[68]

The initial infection that follows perforation is peritonitis. This is a synergistic infection in which more than one organism is involved. Characteristically, the more types of bacteria that can be isolated, the graver the morbidity. The specific micro-organisms involved in peritonitis are generally those of the gastrointestinal tract flora where anaerobes outnumber aerobes in the ratio 1:1000–10,000.[1] Of the more of the 400 bacterial species that constitute the gut flora, only the virulent ones survive in the peritoneum to cause the infection. The more distal the perforation in the gastrointestinal tract, the more numerous are the types and number of organisms that spill into the peritoneal cavity. An average of 11.6 organisms per specimen (8.5 anaerobes and 3.1 nonanaerobes) was recovered in a study of 71 patients with gangrenous and perforated appendicitis.[69] The predominant aerobic and facultatives are *Escherichia coli* and *Streptococcus* spp. (including *Enterococcus* spp.), and the most frequently encountered anaerobes are the *B. fragilis* group, and *Peptostreptococcus*, *Clostridium*, *Fusobacterium* and *Eubacterium* spp. (see Table 232.10).[3] [5]

Intra-abdominal infections are characteristically biphasic: in the initial stages a generalized peritonitis occurs, which is primarily associated with *E. coli* sepsis, and in the later stages, in which the infection is contained and intra-abdominal abscesses emerge, *B. fragilis* can be recovered.

The clinical manifestations of secondary peritonitis are a reflection of the underlying disease process. Fever, diffuse abdominal pain, nausea and vomiting are characteristic. Physical examination reveals signs of peritoneal inflammation, including rebound tenderness, abdominal wall rigidity and decrease in bowel sounds. These early findings may be followed by signs and symptoms of shock.

The manifestations of shock from a ruptured viscus merge with those of peritonitis and may be followed by toxemia, restlessness and irritability, a higher temperature, an increase in pulse rate, chills and convulsions. Biliary tract infection is caused by *E. coli*,

TABLE 232-10 -- Aerobic and anaerobic bacteria isolated in various types of infections.

AEROBIC AND ANAEROBIC BACTERIA ISOLATED IN VARIOUS INFECTIONS		
Type of infection	**Aerobic and facultative organisms**	**Anaerobic organism**
Pleuropulmonary	*Staphylococcus aureus*[*] viridans streptococci	Pigmented *Prevotella* spp. (*P. denticola*, *P. melaninogenica*, *P. intermedia*, *P. nigrescens*, *P. loeschii*)

		Clostridium spp.‡

* Recovered in hospital-acquired infection
† After exposure to oral flora
‡ After exposure to colonic flora

Klebsiella and *Enterococcus* spp. Anaerobes (mostly *B. fragilis* group, and rarely *C. perfringens*) can be recovered in complicated infections associated with carcinoma, recurrent infection, obstruction, bile tract surgery or manipulation.[70]

Laboratory studies reveal an elevated blood leukocyte count in excess of 12,000/mm^3 with a predominance of polymorphonuclear forms. Radiographs of the abdomen may reveal free air in the peritoneal cavity, evidence of ileus or obstruction and obliteration of the psoas shadow. Diagnostic ultrasound, gallium and CT scanning[71] may be useful in detecting appendiceal or other intra-abdominal abscesses. Postoperative wound infections can occur after appendectomy.

Appropriate management of mixed aerobic and anaerobic intra-abdominal infections requires the administration of antimicrobials that are effective against both aerobic and anaerobic components of the infection[2] [5] as well as surgical correction and drainage of pus.[72] Single and easily accessible abscesses can be drained percutaneously, thus avoiding a surgical procedure. The outcome of the infection depends on a variety of factors that include the general condition of the patient (as measured by the Apache score[73]), the site of perforation, the bacteriology of the infection and the antimicrobial chosen for therapy. The principle of using antimicrobial coverage effective against both the aerobic and anaerobic offenders has become the cornerstone of practice and its efficacy has been confirmed by numerous studies.[72]

The choice of therapy should cover Enterobacteriaceae and anaerobes (mainly *B. fragilis* group), and can be achieved by combination or single-agent therapy. Single-agent therapy provides the advantage of avoiding the ototoxicity and nephrotoxicity of aminoglycosides and may be less expensive. However, a single agent may not be effective against hospital-acquired resistant bacterial strains, and the use of a single agent is devoid of antibacterial synergy, which may be important in immunocompromised hosts. However, for otherwise healthy persons, when therapy is initiated without a long delay, single agents provide adequate therapy. An anti-Enterobacteriaceae agent, such as an aminoglycoside, a quinolone or a third-generation cephalosporin, plus an anti-anaerobic agent, such as clindamycin, metronidazole or cefoxitin, is used as combination therapy. Single agent therapy includes a carbapenem (i.e. imipenem, meropenem), or a penicillin plus a ß-lactamase inhibitor (i.e. ticarcillin-clavulanate). The need to add therapy directed at *Enterococcus* spp. is controversial and some authorities advocate

adding such a drug (i.e. amoxicillin or vancomycin). However, these organisms are isolated in only 10–20% of cases, and rarely in pure culture (see also Chapter 47).

Antimicrobial prophylaxis before colonic surgery includes either an oral preparation such as erythromycin plus neomycin, or a parenteral antimicrobial such as cefoxitin. Use of prophylaxis has reduced the rate of postsurgical wound infection (see also Chapter 190). [74]

Female genital tract infection

Female genital tract infections involving anaerobes are polymicrobial and include the following: bacterial vaginosis; soft-tissue perineal, vulvar and Bartholin gland abscesses; endometritis; pyometra; salpingitis; tubo-ovarian abscesses; adnexal abscess; pelvic inflammatory disease, which may include pelvic cellulitis and abscess; amnionitis; septic pelvic thrombophlebitis; intrauterine contraceptive device-associated infection; septic abortion; and postsurgical obstetric and gynecologic infections.[3] [5] Obtaining proper cultures is often difficult, and avoiding their contamination by the normal genital flora can be achieved by use of culdocentesis, laparoscopy or quantitative endometrial cultures of transcervical samples obtained with a telescoping catheter.

The predominant anaerobes include *Prev. bivia, Prev. disiens*, and *Peptostreptococcus, Porphyromonas* and *Clostridium* spp. *Bacteroides fragilis* group is less often isolated in these infections than in intra-abdominal infection. *Actinomyces* spp. and *Eubacterium nodatum* are commonly isolated in infections associated with intrauterine devices. *Mobiluncus* spp. may be involved with bacterial vaginosis.[3] [5] [75] The aerobic organisms also isolated mixed with these anaerobes include Enterobacteriaceae, *Streptococcus* spp. (including groups A and B), *Neisseria gonnorhoeae* and *Chlamydia* spp. (in sexually active females) and *Mycoplasma hominis* (see Table 232.10).

Clinical findings associated with the presence of anaerobes include gas in the tissues, abscess formation and foul-smelling discharge. Management of polymicrobial pelvic infection includes the use of antimicrobials effective against all potential aerobic and anaerobic pathogens. Additionally, coverage against sexually transmissible pathogens should be provided. The therapeutic regimens include

Figure 232-7 Infected diabetic ulcer.

Figure 232-8 Human bite wound.

doxycycline or a macrolide in combination with cefoxitin, cefotetan, clindamycin or metronidazole.

Skin and soft-tissue infections

Skin and soft-tissue infections that generally involve anaerobes include superficial infections, such as infected cutaneous ulcers, cellulitis, pyoderma, paronychia, hidradenitis suppurativa and a variety of secondary infected sites. These include secondary infected diaper rash, gastrostomy or tracheostomy site wounds, infected subcutaneous sebaceous or inclusion cysts, eczema, scabies or kerion infections, and postsurgical wound infection.[3] [5] [76] [77] [78]

Subcutaneous tissue infections that may also include skin involvement include cutaneous and subcutaneous abscesses, breast abscess, decubitus ulcers, infected diabetic (vascular or trophic) ulcers (Fig. 232.7), bite wound (Fig. 232.8), anaerobic cellulitis (Fig. 232.9) and gas gangrene, bacterial synergistic gangrene, infected pilonidal cyst or sinus, Meleney's ulcer and burn wound infection.[77] [78] Anaerobic soft-tissue infections that occur deeper are necrotizing fasciitis (Fig. 232.10), necrotizing synergistic cellulitis, gas gangrene and crepitus cellulitis.[79] These infections can involve the fascia and the muscle surrounded by the fascia, and can induce myositis (Fig. 232.11) and myonecrosis.

The organisms recovered from soft-tissue infections vary according to the type of infections. However, the location and the circumstances leading to the infection can

influence the type of the organisms involved in the infection. Cultures from lesions involving

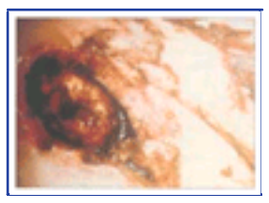

Figure 232-9 Polymicrobial necrotizing cellulitis. The initial lesion is a reddish-brown bled and is accompanied by local tenderness.

Figure 232-10 Necrotizing fasciitis caused by multiple aerobic and anaerobic bacteria. The fascia inspected through a surgical incision is swollen and dull in appearance, with areas of necrosis. A thin, brownish discharge exudes from the wound, with no pus.

Figure 232-11 Anaerobic streptococcal myositis involving muscle and fascial planes.

Figure 232-12 Distribution of organisms in subcutaneous abscesses, wounds, burns and decubitus ulcers.

anaerobes frequently contain bacterial species that are members of the 'normal flora' of the region of the infection (Fig. 232.12).

Aspirates from wounds and subcutaneous tissue infections and abscesses of the rectal area (decubitus ulcer, perirectal abscess) or those that originate from the gut flora (i.e. diabetic foot infection) tend to yield organisms found in the colonic flora.[3] [5] [77] [78] [79] These include *B. fragilis* group, *Clostridium* spp., Enterobacteriaceae and *Enterococcus* spp. In contrast, infections in and around the oropharynx, or those that originate from that site, generally contain members of the oral flora (i.e. paronychia, bites, breast abscess). These include pigmented *Prevotella* and *Porphyromonas, Fusobacterium* and *Peptostreptococcus* spp. Skin flora organisms such as *Staph. aureus* and *Streptococcus* spp., or nosocomially acquired organisms can be isolated at all body sites (see Table 232.10). In addition to oral flora, human bite infections often contain *Eikenella* spp. and animal bites harbor *Pasteurella multocida*.[80]

Infections involving anaerobes are generally polymicrobial, and in some (i.e. decubitus ulcers, diabetic foot ulcer) they are often complicated by osteomyelitis or bacteremia.[81] Deep tissue infections such as necrotizing cellulitis, fasciitis and myositis often involve *Clostridium* spp., *S. pyogenes* or a polymicrobic combination of aerobic and anaerobic bacteria. They often contain gas in the tissues and putrid-like pus with a gray thin quality, and are associated with a high rate of bacteremia and mortality.[79] [82]

Management of deep-seated soft-tissue infection includes surgical debridement, drainage and vigorous surgical management. Improvement of oxygenation of the involved tissues through enhancement of blood supply and administration of hyperbaric oxygen, especially in clostridial infection, may be helpful, although there is no formal evidence demonstrating the benefit of hyperbaric oxygen.

Osteomyelitis and septic arthritis

Osteomyelitis caused by anaerobic bacteria is often indistinguishable from infection caused by aerobic bacteria. Anaerobes are especially notable in oesteomyelitis of the long bones after trauma and fracture, osteomyelitis related to peripheral vascular disease, and decubitus ulcers and osteomyelitis of cranial and facial bones. [81] [83] Most of these infections are polymicrobial.

Anaerobic osteomyelitis of cranial and facial bones is generally caused by spread from a contiguous soft-tissue source or from sinus, ear or dental infection. The high number of anaerobes within the oral flora accounts for their improtance in cranial osteomyelitis. The predominance of intestinal anaerobes in pelvic osteomyelitis has been related to their spread from decubitus ulcers.[5] The anaerobes in osteomyelitis associated with peripheral vascular disease access the involved bone from adjacent soft-tissue ulcers. Osteomyelitis of long bones is generally caused by hematogenic spread, trauma or the presence of a prosthetic device.

Anaerobic streptococci and *Bacteroides* spp. are the most common organisms at all sites, including osteomyelitis associated with bites and cranial infection. Pigmented *Prevotella* and *Porphyromonas* spp. are especially prevalent in skull and bite infections, whereas members of the *B. fragilis* group are associated with vascular disease or neuropathy. Fusobacteria, which are members of the oral flora, are most frequently isolated from bites and from cranial and facial infections. Clostridia are most often found in long bones, especially in association with environmental wound contamination after trauma. Because clostridia colonize the lower gastrointestinal tract, they may contaminate compound fractures of the lower extremities.

Septic arthritis caused by anaerobic bacteria is uncommon, and is often associated with hematogenous and contiguous spread of infection, trauma and prosthetic joints.[81] [84] Most cases of septic arthritis caused by anaerobes are monomicrobial. The predominant isolated anaerobes are peptostreptococci and *Prop. acnes* (often in prosthetic joint infection), *B. fragilis* and fusobacteria (often in infections of hematogenic origin), and clostridia (associated with trauma).

Bacteremia

The incidence of anaerobes in bacteremia is 5–15%.[82] [85] The most prevalent blood culture isolates are *B. fragilis* group (over 75% of anaerobic isolates). Other common isolates include *Clostridium* spp. (10–20%), *Peptostreptococcus* spp. (10–15%), *Fusobacterium* spp. (10–15%) and *Prop. acnes* (2–5%).

The specific organisms involved in bacteremia largely depend on the portal of entry and underlying disease. Recovery of *B. fragilis* group and clostridia is mostly associated with a gastrointestinal source, pigmented *Prevotella* and *Porphyromonas* spp. and fusobacteria with oropharynx and pulmonary sources, fusobacteria with the female genital tract, *Prop. acnes* with foreign body, and peptostreptococci with all sources, but especially with oropharyngeal, pulmonary and female genital tract sources. The predominance of these isolates in conjunction with the specific sources is related to the origin of the primary infection and the endogenous flora at the infection site.

The predisposing factors to anaerobic bacterial bacteremia include malignant neoplasma; hematologic disorders; organ transplant; recent gastrointestinal, obstetric, or gynecologic surgery; intestinal obstruction; decubitus ulcers; dental extraction; the newborn; sickle cell disease; diabetes mellitus; postsplenectomy; and the use of cytotoxic agents or corticosteroids.[3] [5]

The clinical presentations of anaerobic bacteremia are similar to those seen with aerobic infection, except for the signs of infection at the portal of entry of infection. It commonly includes fever, chills, hypotension, leukocytosis, shock, disseminated intravascular coagulation and anemia. Features typical of anaerobic infection include metastatic lesions, hyperbilirubinemia, and suppurative thrombophlebitis. Mortality rate varies between 15 and 30% and is improved with early and appropriate

antimicrobial therapy and resolution, when present, of the primary infection.

MANAGEMENT

The recovery from an anaerobic infection depends on prompt and proper management. The principles of managing anaerobic infections include neutralizing toxins produced by anaerobes, preventing their local proliferation by changing the environment and hampering their spread into healthy tissues.

Toxin neutralization by specific antitoxins may be employed, especially in infections caused by *Clostridium* spp. (tetanus and botulism). Controlling the environment is achieved by debriding of necrotic tissue, draining the pus, improving circulation, alleviating the obstruction and increasing the tissue oxygenation. Certain types of adjunct therapy such as hyperbaric oxygen (HBO) may also be useful. The primary role of antimicrobials is in limiting the local and systemic spread of the organism.

Hyperbaric oxygen

There is controversy regarding whether HBO should be used in infection of spore-forming Gram-positive anaerobic rods. There are several uncontrolled reports that demonstrated efficacy in individual cases.[3] [5] [86] However, because no well-controlled studies are available, the efficacy of HBO is unproved. Using HBO in conjunction with other therapeutic measures is not contraindicated, except when it may delay the execution of other essential procedures. Topical application of oxygen-releasing compounds may be useful as an adjunct to other procedures.

Surgical therapy

In many cases surgical therapy is the most important and sometimes the only form of treatment required, whereas in others surgical therapy is an important adjunct to a pharmacologic approach. Surgery is important in draining abscesses, debriding necrotic tissues, decompressing closed space infections and relieving obstructions. When surgical drainage is not used, the infection may persist and serious complications can develop.

Antimicrobial therapy

Appropriate management of mixed aerobic and anaerobic infections requires the administration of antimicrobial drugs effective against both the aerobic and the anaerobic components. A number of factors should be considered when choosing appropriate antimicrobial agents. They should have efficacy against all target organisms, induce little or no resistance, achieve sufficient levels in the infected site, and have minimal toxicity and maximum stability.

Antimicrobials often fail to cure the infection. Among the reasons for this are the development of bacterial resistance, achievement of

Figure 232-13 Susceptibility of anaerobic bacteria to antimicrobial agents.

insufficient tissue levels, incompatible drug interaction and the development of an abscess. The environment of an abscess is detrimental to many antibiotics. The abscess capsule interferes with the penetration of drugs, and the low pH and the presence of binding proteins or inactivating enzymes (i.e. ß-lactamase) may impair their activity. The low pH and the anaerobic environment within the abscess are especially unfavorable for the aminoglycosides and quinolones. However, an acidic pH, high osmolarity and an anaerobic environment can also develop in the absence of an abscess.

When choosing antimicrobials for the therapy of mixed infections, their aerobic and anaerobic antibacterial spectrum (Fig. 232.13) and their availability in oral or parenteral form should be considered (Table 232.11). Some antimicrobials have a limited range of activity. For example, metronidazole is active only against anaerobes and therefore cannot be administered as a single agent for the therapy of mixed infections. Others (i.e. carbaepenems) have wide spectra of activity against Enterobacteriaceae and anaerobes.

The selection of antimicrobial agents is simplified when reliable culture results are available. However, this may be difficult to achieve in anaerobic infections because of the problems in obtaining appropriate specimens. For this reason, many patients are treated empirically on the basis of suspected, rather than established, pathogens. Fortunately, the types of organisms involved in many anaerobic infections and their antimicrobial susceptibility patterns tend to be predictable. However, the pattern of resistance to antimicrobials may vary in a particular hospital and resistance to antimicrobial agents may emerge while a patient is receiving therapy.

The susceptibility of the *B. fragilis* group to the frequently used antimicrobial drugs has been studied systemically over the past two decades. These surveys have failed to reveal strains resistant to chloramphenicol or metronidazole and minimal resistance (<1%) to imipenem or the combinations of a penicillin and ß-lactamase inhibitors, but resistance to other agents varies. The rate differs among various medical centers and generally increases with extensive use of some antimicrobial agents (penicillins, cephalosporins and clindamycin).[87]

Aside from susceptibility patterns, other factors influencing the choice of antimicrobial therapy include the pharmacologic characteristics of the various drugs, their toxicity, their effect on the normal flora and bactericidal activity. Although identification of the infecting organisms and their antimicrobial susceptibility may be needed for selection of optimal therapy, the clinical setting and Gram-stain preparation of the specimen may indicate the types of anaerobes present in the infection as well as the nature of the infectious process.

TABLE 232-11 -- Antimicrobial drugs recommended for the therapy of site-specific anaerobic infections.

ANTIMICROBIAL DRUGS RECOMMENDED FOR THE THERAPY OF SITE-SPECIFIC ANAEROBIC INFECTIONS			
	Surgical prophylaxis	**Parenteral**	**Oral**
Intracranial	Penicillin (vancomycin)	Metronidazole* (chloramphenicol)	Metronidazole* (chloramphenicol)
Dental	Penicillin (erythromycin)	Clindamycin (metronidazole* , chloramphenicol)	Clindamycin, amoxicillin + CA (metronidazole* chloramphenicol)
Upper respiratory tract	Cefoxitin (clindamycin)	Clindamycin (chloramphenicol, metronidazole*)	Clindamycin, amoxicillin + CA (chloramphenicol, metronidazole‡
Pulmonary	NA	Clindamycin* (chloramphenicol, a penicillin + BLI§ , a carbapenem)	Clindamycin* (chloramphenicol, metronidazole,‡ amoxicillin + CA)
Abdominal	Cefoxitin (clindamycin*)	Clindamycin* , cefoxitin* , metronidazole* (a carbapenem, a penicillin + BLI)	Clindamycin* , metronidazole* (chloramphenicol, amoxicillin + CA)
Pelvic	Cefoxitin (doxycycline)	Cefoxitin§ , clindamycin* (a penicillin + BLI§ metronidazole§)	Clindamycin§ (amoxicillin + CA§ , metronidazole§)
Skin	Cefazolin# (vancomycin)	Clindamycin, cefoxitin (metronidazole* + methicillin)	Clindamycin, amoxicillin + CA (metronidazole‡)
Bone and joint	Cefazolin# (vancomycin)	Clindamycin, a carbapenem (chloramphenicol, metronidazole* , a penicillin + BLI)	Clindamycin (chloramphenicol, metronidazole*)

Bacteremia with BLPB	NA	A carbapenem, metronidazole (cefoxitin, a penicillin + BLI)	Clindamycin, metronidazole (chloramphenicol, amoxicillin + CA)
Bacteremia with BLPB	NA	Penicillin (clindamycin, metronidazole, cefoxitin)	Penicillin (metronidazole, chloramphenicol, clindamycin)
Therapies are given as drug(s) of choice (alternative drugs). BLI, ß-lactamase inhibitor; BLPB, ß-lactamase-producing bacteria; CA, clavulanic acid; NA, not applicable.			

* Plus a penicillin
‡ Plus a macrolide (i.e. erythromycin)
* Plus an anti-aerobic bacilli agent (aminoglycoside)
§ Plus doxycycline
# In location proximal to the rectal and oral areas use cefoxitin

Antimicrobial agents

Some classes of agents have poor activity against anaerobic bacteria. These include the aminoglycosides, the monobactams and the currently available quinolones. Antimicrobial agents suitable for use in controlling aerobic infections are discussed in more detail below.[88] [89]

Penicillins

Penicillin G (benzypenicillin) is still the drug of choice against most non-BLPB. These include anaerobic streptococci, *Clostridium* spp. and nonsporolating anaerobic bacilli, and most non-ß-lactamase-producing Gram-negative anaerobic rods (i.e. *Bacteroides, Fusobacterium, Prevotella* and *Porphyromonas* spp.).[88] However, in addition to the *B. fragilis* group, which is known to resist the drug, many other anaerobic Gram-negative rods are showing increased resistance. These include *Fusobacterium* spp., pigmented *Prevotella* and *Porphyromonas* spp. (prevalent in orofacial infections), *Prev. bivia* and *Prev. disiens* (common in obstetric and gynecologic infections), and *Bilophila wadsworthia* and *Bacteroides splanchinus*. Resistance to penicillin of some *Clostridium* spp. through production of ß-lactamase has also been noted. These included *C. ramosum, C. clostridioforme* and *C. butyricum*.

The increase in the number of penicillin-resistant bacterial strains has important implications for antimicrobial therapy. Many penicillin-resistant bacteria can produce enzymes that degrade penicillins or cephalosporins by releasing the enzyme in the area of the infection. Therefore, these organisms may protect not only themselves but also penicillin-sensitive pathogens. Penicillin therapy directed against a susceptible pathogen might therefore be rendered ineffective by the presence of BLPB.[24]

The use of combinations of ß-lactamase inhibitors (such as clavulanic acid, sulbactam, or tazobactam) plus a ß-lactam antibiotic (ampicillin, amoxicillin, ticarcillin or piperacillin) can overcome this phenomenon in organisms that produce a ß-lactamase that can be bound by the inhibitor. However, if other mechanisms of resistance emerge, blockage of the enzyme ß-lactamase will not prevent resistance. Other mechanisms of resistance include alteration in the porin canal through which the antimicrobial penetrates into the bacteria and changes in the penicillin-binding protein that inhibit binding of the drug into the bacterial cell wall.

The semisynthetic penicillins, carbenicillin, ticarcillin, piperacillin and mezlocillin are generally administered in large quantities to achieve high serum concentrations. These drugs have good activity against Enterobacteriaceae and most anaerobes in these concentrations. However, they are not absolutely resistant to ß-lactamase produced by Gram-negative anaerobic bacilli.

Cephalosporins

The efficacy of cephalosporins varies against *Bacteroides* spp.[88] [89] The activity of the first-generation cephalosporins against anaerobes is similar to that of penicillin G, although on a weight basis they are less active. Most strains of the *B. fragilis* group and many *Prevotella* and *Porphyromonas* spp. are resistant by virtue of cephalosporinase production. The second-generation cephalosporin cefoxitin is relatively resistant to this enzyme and is therefore the most effective cephalosporin against the *B. fragilis* group. However, 5–15% of *B. fragilis* group may be resistant, reflecting hospital use pattern. Because of its wide antibacterial coverage, it is often used for the therapy and prophylaxis of mixed infections. Cefoxitin is relatively inactive against most species of *Clostridium* (including *C. difficile*); *C. perfringens* is an exception. Other second-generation cephalosporins, such as cefotetan and cefmetazole, have a longer half-life than cefoxitin. These two agents are as effective as cefoxitin against *B. fragilis*, but have poor efficacy against other members of the *B. fragilis* group (i.e. *B. thetaiotaomicron*). Third-generation cephalosporins have activity against *Bacteroides* spp. that is inferior to that of second-generation cephalosporins.

Carbapenems (imipenem, meropenem, ertapenem)

The ß-lactam carbapenems imipenem and meropenem have excellent activity against a broad spectrum of aerobic bacteria and anaerobic bacteria, including ß-lactamase-producing *Bacteroides* spp. and Enterobacteriaceae and *Pseudomonas* spp.[89] Resistance of *B. fragilis* group is very race (<1%). Ertapenem has similar efficacy, but is not active against *Pseudomonas* spp. and *Acinetobacter* spp.[90]

Chloramphenicol

Chloramphenicol shows excellent *in-vitro* activity against most anaerobic bacteria, and resistance is rare. The drug is also effective against many Enterobacteriaceae and Gram-positive cocci. However, the experience of using this drug in intra-abdominal sepsis was disappointing. The toxicity of chloramphenicol, the rare but fatal aplastic anemia and the dose-dependent leukopenia, limit its use, especially in neutropenic patients.

Clindamycin and lincomycin

Clindamycin and lincomycin are effective against anaerobes and have good activity against aerobic Gram-positive cocci.[88] Clindamycin has the broader coverage against anaerobes, including ß-lactamase-producing *Bacteroides* spp. Resistance of *B. fragilis* group is 5–10%, and some *Clostridium* spp. other than *C. perfringens* are resistant. Antibiotic-associated colitis caused by *C. difficile* was first described after clindamycin therapy. However, colitis has been associated with many other antimicrobial agents, including penicillins and cephalosporins.

Metronidazole

Metronidazole has excellent activity against anaerobes. However, its antibacterial efficacy is limited to anaerobic bacteria. Microaerophilic streptococci, *Prop. acnes* and *Actinomyces* spp. are often resistant. Concern was raised about the carcinogenic and mutagenic effects of this drug; however, these effects were shown only in one species of mice and were never substantiated in other animals or humans.[3] [5]

Macrolides (erythromycin, azithromycin, clarithromycin)

The macrolides erythromycin, azithromycin and clarithromycin have moderate-to-good *in-vitro* activity against anaerobic bacteria other than *B. fragilis* group and fusobacteria. They are active against *Prevotella* and *Porphyromonas* spp., microaerophilic and anaerobic streptococci, Gram-positive nonspore-forming anaerobic bacilli and certain clostridia. They show relatively good activity against *C. perfringens* and poor or inconsistent activity against Gramnegative anaerobic bacilli.

Glycopeptides (vancomycin, teicoplanin)

The glycopeptides are effective against all Gram-positive anaerobes (including *C. difficile*), but are inactive against Gram-negative bacilli.

Tetracyclines

Tetracycline is of limited use because of the development of resistance by all types of anaerobes, including *B. fragilis* group. The newer tetracycline analogs doxycycline and minocycline are more active than the parent compound. Because there is significant resistance to these drugs, they can be used if the organisms are susceptible or in less severe infections in which a therapeutic trial is feasible.

Quinolones

The first generation of fluoroquinolones such as ciprofloxacin and ofloxacin are inactive against most anaerobic bacteria. However, some broad-spectrum quinolones, which have recently become clinically available or are under active development, have significant anti-anaerobic activity. Quinolones with low activity against anaerobes include ciprofloxacin, ofloxacin, levofloxacin, fleroxacin, pefloxacin, enoxacin and lomefloxacin. Compounds with intermediate anti-anaerobic activity include sparfloxacin and grepafloxacin. Trovafloxacin, gatifloxacin and moxifloxacin yield low minimum inhibitory concentrations (MICs) against most groups of anaerobes. Quinolones with the greatest *in-vitro* activity against anaerobes include clinafloxacin and sitafloxacin.[91] The use of the quinolones is restricted in growing children and pregnancy because of their possible adverse effects on the cartilage.

Other agents

Bacitracin is active against pigmented *Prevotella* and *Porphyromonas* spp. but is inactive against *B. fragilis* and *Fusobacterium nucleatum*. [2] Quinupristin-dalfopristin shows antibacterial activity against anaerobic organisms tested, including *C. perfringens* and *Lactobacillus* and *Peptostreptococcus* spp.[92] Linezolid is active against *F. nucleatum*, other fusobacteria and *Porphyromonas, Prevotella* and *Peptostreptococcus* spp. [93] Little clinical experience has been, however, gained in the treatment of anaerobic bacteria using these agents.

Choice of antimicrobial agents

The parenteral antimicrobials that can be used in most infectious sites (Table 232.11 , Table 232.12) are clindamycin, metronidazole, chloramphenicol, cefoxitin, a penicillin (e.g. ticarcillin, ampicillin, piperacillin) and a ß-lactamase inhibitor (e.g. clavulanic acid, sulbactam, tazobactam), and a carbapenem (e.g. imipenem, meropenem, ertapenem).

An agent effective against Gram-negative enteric bacilli (e.g. aminoglycoside) or an antipseudomonal cephalosporin (e.g. cefepime) are generally added to clindamycin, metronidazole and, occasionally, cefoxitin, when treating intra-abdominal infections to provide coverage for these bacteria. Failure of therapy in intra-abdominal infections has been noticed more often with chloramphenicol and, therefore, this drug is not recommended.

Penicillin can be added to metronidazole in the therapy of intracranial, pulmonary and dental infections to cover for microaerophilic streptococci, and *Actinomyces* spp. A macrolide (i.e. erythromycin) is added to metronidazole in upper respiratory infections to treat *Staph. aureus* and aerobic streptococci. Penicillin is added to clindamycin to supplement its coverage against *Peptostreptococcus* spp. and other Gram-positive anaerobic organisms.

TABLE 232-12 -- Antimicrobial drugs of choice for anaerobic bacteria.

ANTIMICROBIAL DRUGS OF CHOICE FOR ANAEROBIC BACTERIA		
	First choice	**Alternative**
Peptostreptococcus spp.	Penicillin	Clindamycin, chloramphenicol, cephalosporins
Clostridium spp.	Penicillin	Metronidazole, chloramphenicol, cefoxitin, clindamycin
Clostridium difficile	Vancomycin	Metronidazole, bacitracin
Gram-negative bacilli (BL-)	Penicillin	Metronidazole, clindamycin, chloramphenicol
Gram-negative bacilli (BL+)	Metronidazole, a carbapenem, a penicillin and BL inhibitor, clindamycin	Cefoxitin, chloramphenicol, piperacillin
Gramnegative bacilli include *Bacteroides fragilis* group and *Prevotella*, *Porphyromonas* and *Fusobacterium* spp. BL, ß-lactamase.		

Doxycycline is added to most regimens in the treatment of pelvic infections to provide therapy for chlamydia and mycoplasma. Penicillin is still the drug of choice for bacteremia caused by non-BLPB. However, other agents should be used for the therapy of bacteremia caused by BLPB.

Because the duration of therapy for anaerobic infections, which are often chronic, is generally longer than for infections caused by aerobic and facultative anaerobes, oral therapy is often substituted for parenteral therapy. The agents available for oral therapy are limited and include clindamycin, amoxicillin plus clavulanic acid, chloramphenicol and metronidazole.

Clinical judgment, personal experience, safety and patient compliance should direct the physician in the choice of the appropriate antimicrobial agents. The duration of therapy generally ranges between 2 and 4 weeks, but should be individualized depending on the response. In some cases, such as lung abscesses, treatment may be required for as long as 6–8 weeks, but can often be shortened with proper surgical drainage.

Chapter 233 - Mycobacteria

Clark B Inderlied

INTRODUCTION

In his review article entitled 'The White Plague', MF Perutz recounted that Cardinal Richelieu (1585–1642), Heinrich Heine (1797–1856), Frédéric Chopin (1810–49), Anton Chekhov (1860–1904), Franz Kafka (1883–1924), George Orwell (1903–50) and Eleanor Roosevelt (1884–1962) all shared a common fate.[1] Each of these famous people died of tuberculosis. In some cases their disease was not understood or only poorly understood, while in other cases management of the disease was inadequate, often because of a lack of effective therapeutic agents. Indeed, while the virulence and transmissibility of *Mycobacterium tuberculosis* are critical factors, there are additional factors that influence the occurrence and spread of this disease.

Clearly, the presence of a concurrent disease (especially AIDS) as well as the overall state of person's health and host defense mechanisms are critical determinants of the morbidity and mortality rates of tuberculosis. However, even more complex factors strongly influence the incidence of tuberculosis including poverty, ignorance and indifference about the disease, and the lack of access to health care. Indeed, in the World Health Organization (WHO) 2002 report on global tuberculosis control, 22 countries were identified as having a 'high burden' of tuberculosis. For example, while 62% of the world's human population (estimated at 6.1 billion persons in 2000) live in these 22 countries, nearly 80% of cases of tuberculosis worldwide occur in these countries. Nevertheless, even within the 'high burden' countries the incidence of tuberculosis varies from a low of 68 cases to more than 584 cases per 100,000 population. The nearly 9-fold difference in the incidence of tuberculosis reflects the plethora and complexity of factors that influence the spread and incidence of tuberculosis.

The goals of the WHO global tuberculosis control program are to detect 70% of tuberculosis cases in the high burden countries and to successfully treat 85% of the identified cases. Although the WHO sponsored program is focused on tuberculosis, many of the principles of diagnosis, treatment and control of tuberculosis pertain to other nontuberculous infections. The laboratory diagnosis of tuberculosis and other mycobacterial diseases is an important element of the effective treatment and control of all of these diseases and is the focus of this chapter.

NATURE

Lehmann and Neumann first introduced the genus *Mycobacterium* into the scientific literature in 1896. The subsequent history of the genus in terms of our knowledge and understanding of these micro-organisms has been profoundly influenced by the fact that only one of the more than 40 currently recognized species has been a devastating cause of human disease and suffering for time immemorial: *M. tuberculosis*. Indeed, Wayne[2] noted in his discussion of mycobacterial speciation that taxonomic studies of the genus have been undoubtedly skewed because of the focus on the need for the detection and accurate identification of *M. tuberculosis*. Thus, studies of microbial physiology, structure, genetics and diagnostic tools have focused on *M. tuberculosis* and secondarily on *Mycobacterium leprae*. Nevertheless, during the past several years other species of mycobacteria, notably the rapidly growing mycobacteria and the *M. avium* complex, have been the subject of extensive investigations largely because of the increased incidence of human disease and increased awareness of disease caused by these mycobacteria.

All members of the genus *Mycobacterium* are aerobic, nonsporeforming, nonmotile single cell bacteria. In general, the size of mycobacteria are significantly smaller than other types of bacteria and cell shape varies from coccobacilli to elongated rods, but pleomorphic morphology is common. The most prominent feature of mycobacteria that is uniformly present and distinctive to the genus is the complex, lipid-rich cell envelope. Indeed, it is the complex cell envelope of mycobacteria that confers upon these bacteria the property of 'acid-fastness' (i.e. resistance to decolorization when stained with carbolfuchsin and decolorized with dilute hydrochloric acid). The mycobacterial cell envelope has been the subject of extensive investigations because of the chemical uniqueness of the structure, the importance of the envelope to the biology of the micro-organism, and the role of envelope antigens in immunobiology and diagnostics.

Mycobacteria are classified with the Gram-positive bacteria, but most mycobacteria do not stain well with Gram's stain. Mycobacteria possess a cell wall polysaccharide that resembles that of Gram-positive bacteria; however, the mycobacterial peptidoglycan contains lipids in place of proteins and polysaccharides.[3] Furthermore, the mycobacterial envelope contains a plasma membrane that is quite similar in structure and function to the plasma membrane of other bacteria except for the presence of lipoarabinomannan (LAM), lipomannan and phosphatidylinositol mannosides.[3] The cell wall component of the envelope confers size, shape, protection against osmotic pressure, and probably protects the plasma membrane from deleterious molecules in the environment of the cell. The peptidoglycan confers cell shape while the next layer of the envelope, arabinogalactan esterified to the mycolic acids (fatty acids), is largely believed to restrict permeability.

At the exterior surface of the cell envelope are the mycosides, a mixture of glycolipids. The mycosides confer the agglutination serotype of a strain and influence colony morphology and may influence virulence. The mycosides are 'in charge of public relations for mycobacteria' and in this capacity are analogous to the 'O' antigens of Gram-negative bacteria.[4] In 1947, Middlebrook first described growth of tubercule bacilli in the shape of serpentine cords ('cording'), and for many years cording was correlated with virulence and was considered to be a distinctive feature of *M. tuberculosis* (Fig. 233.1). However, it is now known that several species of mycobacteria display cording and the correlation with virulence, if any, is unclear. Cord factor appears to be a mixture of mycolate-containing molecules including the original cord factor associated with *M. tuberculosis*, trehalose 6,6'-dimycolate. Thus, the structure of the mycobacterial cell envelope (Fig. 233.2) includes a plasma membrane, a peptidoglycan layer, an arabinogalactan layer esterified to an uneven mycolate layer, and a glycolipid layer. Lipoarabinomannan and a

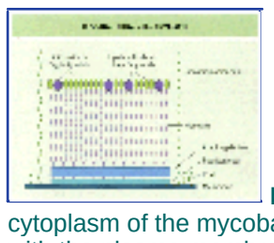

Figure 233-2 Mycobacterial cell envelope. This model displays the asymmetric array of the structural elements extending from the plasma membrane that surrounds the cytoplasm of the mycobacterial cell. The arabinogalactan is covalently linked to the peptidoglycan, which along with the lipoarabinomannan and phosphatidylinositol mannosides (PIM) are associated with the plasma membrane. The cell wall lipids are shown in a possible arrangement with the mycolates linked to the arabinogalactan. Two classes of polar lipids with medium and short chain fatty acids complement the varying hydrocarbon chains of the mycolates to create an even cell envelope. There is evidence for a small number of porins within the hydrophobic bilayer. *Adapted from Brennan and Draper.*[3]

small number of porins traverse the width of the mycobacterial envelope. As in other bacteria the mycobacterial porins provide a mechanism for the passage of low molecular weight molecules from the environment into the intracellular matrix.

Many species of mycobacteria are capable of producing carotenoids and this feature can be an important aid in the presumptive identification of an unknown mycobacterial isolate. The principal carotenoids produced by mycobacteria are carotenes and xanthophylls and it appears that all mycobacteria are at least capable of producing some carotenoids. However, the production of carotenoids is strongly influenced by the composition of the media and growth conditions. Light has a significant effect on pigment production for some species. Scotochromogens (e.g. *M. scrofulaceum*) produce pigment in the absence of light whereas

photochromogens (e.g. *M. kansasii*) produce pigment when stimulated by light (Fig. 233.3). Nonphotochromogens (e.g. *M. avium* complex and *M. tuberculosis*) may or may not produce carotenoids, but most strains usually do not. The

Figure 233-3 *Mycobacterium kansasii,* a photochromogenic mycobacterium, grown on Löwenstein-Jensen medium in light. *Courtesy of S Froman and A Gaytan.*

function of mycobacterial carotenoids is largely unknown, but some evidence suggests that carotenoids provide protection from phototoxic effects.

The genome of mycobacteria is large (3–5.5×10^9 Da) and like other prokaryotes is arranged as a closed circle. The nucleotide base composition of mycobacterial DNA is extraordinarily rich in guanine (G) and cytosine (C; i.e. 66–71 mol% GC). Most of the environmental species of mycobacteria, in particular *M. avium* complex, *M. scrofulaceum* and the rapid growers, contain plasmids. The size and number of plasmids vary; the function(s) of the plasmids are largely unknown, but may include resistance to heavy metals. There has been some evidence and considerable speculation that plasmids in mycobacteria include DNA sequences that encode a variety of virulence factors. However, plasmids would appear to have no role in antibiotic resistance or virulence in *M. tuberculosis*, since the majority of *M. tuberculosis* strains do not contain plasmids.

A phylogenetic tree, based on 16S rRNA sequence information of selected species of slowly growing mycobacteria is shown in Figure 233.4 .[6] The lack of separation of 'species' within the *M. tuberculosis*

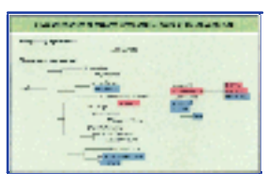

Figure 233-4 Phylogenetic tree of selected mycobacteria, based on 165 rRNA sequence information, including species whose genome sequence is completed (red) or is in progress (green). *Figure adapted from Brosch et al.*[6]

complex reflects that these mycobacteria should be viewed more as pathovars or subspecies. Overall, however, this analysis of genetic relatedness confirms the classical classification scheme based on pigmentation and growth rate. However, genome sequence information has already revealed interesting information about differences within the *M. tuberculosis* complex. For example, comparisons of *M. tuberculosis* H37Rv (a human isolate that is also virulent in mice) with bacille Calmette-Guérin (BCG) Pasteur revealed that 18 variable sequence regions are missing in BCG Pasteur. Perhaps even more intriguing is the presence of two large tandem duplications in BCG Pasteur, whereas other BCG strains lack one of these duplications and neither of the duplications are seen in H37Rv. Furthermore, the genome size of *M. bovis* is significantly smaller than that of *M. tuberculosis*, which seems at odds with the fact that *M. bovis* has a significantly wider host range than *M. tuberculosis*.[6] Indeed, sequence information has placed in doubt the longheld belief that *M. tuberculosis* evolved from an animal pathogen (i.e. *M. bovis*) and indicates that *M. tuberculosis* was always a human pathogen.[7]

EPIDEMIOLOGY

Tuberculosis

Tuberculosis is the leading cause of death worldwide that can be attributed to a single infectious disease agent.[8] [9] [10] The vast majority of tuberculosis cases are found in the developing world and disease occurs predominantly during the prime period of life from 15 to 59 years of age. The estimated incidence of tuberculosis worldwide in 2000 was 8.7 million cases, of which nearly 80% (6.9 million) were found in 22 high-burden countries (Fig. 233.5).[11] Conversely, less than 3% of the worldwide incidence of tuberculosis is found in the industrialized countries. [12] The mortality rate due to tuberculosis closely tracks the worldwide incidence with the highest mortality rate again in South East Asia and Africa. Overall, tuberculosis is estimated to cause over 25% of avoidable adult deaths in the developing world. Indeed, before the development of effective chemotherapy, the mortality rate for tuberculosis was 50–60%. However, following the discovery of isoniazid and then rifampin (rifampicin), the majority of pulmonary and extrapulmonary tuberculosis became treatable. Nevertheless, the treatment of tuberculosis remains problematic because of the lack of or intermittent access to therapy, poor adherence to therapy and the emergence of resistance.

Leprosy

Epidemiology of leprosy (Hansen's disease) is difficult to assess accurately because of the lack of a diagnostic skin test, inability to cultivate the leprosy bacillus in vitro and the nature of the geographic distribution of endemic disease. Leprosy appears to be primarily spread from human to human through nasal secretions. Skin contact is most likely an uncommon route of transmission.[13] Although there has been speculation that an insect vector may be responsible for the spread of some leprosy, this has not been demonstrated. It does appear that transmission by any route requires prolonged exposure to an infected individual. However, the transmission of leprosy is similar to tuberculosis in that, while prolonged exposure is the most common risk factor, a single exposure involving coincident but otherwise singly rare circumstances can result in the transmission of disease. Treatment appears to decrease infectiousness significantly. The global incidence of leprosy is estimated to be between 5.5 and 6.5 million patients.[4] The vast majority of patients are in the developing world, predominantly South East Asia and mostly in India. The care and treatment of leprosy have two equally difficult components. The first is treatment of active disease, especially in patients with physical deformities or at risk of developing deformities. The second is care of effectively treated patients, but with disabling or debilitating deformities due to the pathology associated with the various manifestations of this disease.

Mycobacterium avium complex

Mycobacterium avium complex (MAC) disease occurs as a disseminated disease usually, but not exclusively, in people with HIV infection. *Mycobacterium avium* complex also causes pulmonary disease in immunocompetent patients and cervical lymphadenitis in normal hosts, mostly children. It is ubiquitous in the environment, including and especially soil and water, but also in certain foods (e.g. hard cheese). Portals of infection are probably both gastrointestinal and pulmonary by ingestion of contaminated food or water and inhalation of aerosols. Disseminated MAC disease was rarely reported before the first reports of opportunistic infections and AIDS, published in the early 1980s. Based on complete follow-up information (even at the peak of the AIDS epidemic in the USA disseminated MAC was infrequently the AIDS-defining opportunistic infection) disseminated MAC disease occurs in 20–35% per year of people with HIV infection. [14] However, even this is an historic figure and MAC prophylaxis (rifabutin, azithromycin or clarithromycin) and the

Figure 233-5 Estimated tuberculosis incidence rates, 2000. *Data and map adapted from World Health Organization. Global tuberculosis control: surveillance, planning, financing. WHO Report 2002, Switzerland, WHO/CDS/TB/2002.295.*[11]

use of highly active antiretroviral therapy (HAART) has significantly decreased the incidence of MAC disease in people with HIV infection. The incidence of disseminated MAC disease in children with HIV infection is nearly the same as in adults and the manifestations of disseminated MAC disease in these patients are virtually identical to those in adults. *Mycobacterium avium* complex pulmonary disease is seen worldwide with an overall incidence of about 1/100,000 persons. The incidence of pulmonary disease appears to be increasing, but this may be due in part to increased surveillance and awareness by the medical community. Although

MAC pulmonary disease has been associated with a history of chronic lung infection including cystic fibrosis, many patients have no identifiable risk factors except age. *Mycobacterium avium* complex cervical lymphadenitis is mostly a pediatric disease and primarily seen in children under 5 years of age. There are several reports of disseminated MAC disease in children who do not have HIV infection, but it seems likely that these children have a very specific immunodeficiency that causes the patient to be at risk for MAC infection.

Rapid growers

Although there are over 30 species of rapidly growing mycobacteria, the vast majority (>90%) of disease that occurs in humans is caused by three species: *Mycobacterium fortuitum*, *Mycobacterium chelonae* and *Mycobacterium abscessus*. These species are important causes of cutaneous, pulmonary and postsurgical wound infections especially following catheter placement, augmentation mammaplasty and cardiac bypass surgery. Disseminated disease is rare and almost invariably occurs in immunocompromised patients, but disease is not common in people with HIV infection.

The distribution of rapidly growing mycobacteria appears to be worldwide. The three species associated with human disease have been isolated from drinking water as well as natural waters. In addition, these mycobacteria are commonly found in animal drinking water, waste water and soil. The ubiquitous nature of these micro-organisms, their resistance to disinfectants including relative resistance to chlorine, and their ability to grow on unusual substrates such as polyhalogenated phenols account for the fact that rapidly growing mycobacteria are found as contaminants of medical equipment, prosthetic valves and disinfectants.

The incidence of pulmonary disease caused by rapidly growing mycobacteria is unclear (80% by *M. abscessus*), but an increased awareness of these species as human pathogens is leading to greater insight into the true incidence of disease. Nevertheless, the isolation of rapidly growing mycobacteria from respiratory tract specimens must be interpreted with great caution because contamination and colonization are common. True infection is usually associated with chronic pulmonary disease such as cystic fibrosis, previous mycobacterial lung disease and bronchiectasis due to previous respiratory infection. Rapidly growing mycobacteria are intrinsically resistant to antituberculous agents including isoniazid, rifampin and pyrazinamide.

PATHOGENICITY

The pathogenicity of mycobacterial infections in the immunocompetent host has as much to do with the immune response of the host as with destructive virulence properties of the mycobacterial pathogen. Thus, the principal virulence factor of mycobacteria is the ability to invade and persist or replicate within macrophages. Tubercle bacilli are believed to attach to macrophages by binding to the mannose receptor on the macrophage via the mycobacterial cell envelope LAM. Alternatively tubercle bacilli can indirectly bind via CR1/CR3 complement receptors or Fc receptors.

The bacilli enter the macrophage by phagocytosis and once internalized the bacilli are surrounded by a membrane-bound vacuole to

form a nascent phagosome. With the maturation of the phagolysosome, bacilli are exposed to a variety of antimicrobial factors including reactive oxygen intermediates, hydrolytic activities and a highly acidic pH. Cytokine-activated macrophages may also produce reactive nitrogen intermediates, although this has been conclusively shown only in murine macrophages. Virulent mycobacteria obstruct the maturation of phagosomes, inhibiting acidification, and can escape from the phagolysosome into the cytoplasm. Other bacilli appear able to adapt to life within the phagolysosome.

Recent evidence indicates that the maturation of the phagolysosome varies depending on the bacterial pathogen and varies even between intracellular pathogens.[15] The composition of the phagosome membrane is determined in part by the infecting mycobacteria; for example, phagosomes containing *M. avium* do not contain the vacuolar H^+ -ATPase that is needed for acidification of the phagosome. Phagosomes containing either *M. tuberculosis* or *M. avium* bacilli are frequently incompetent for fusion with endocytic organelles, suggesting a mechanism for the block in phagolysosome fusion. Inhibition of acidification can occur as a consequence of the exclusion of a proton pump (as with *M. avium*) or fusion with a lysosome that does not contain a pump or perhaps by the release of an ammonia metabolizing enzyme such as glutamine synthetase. Once mycobacteria have modified or adapted to the intracellular environment the bacilli may proliferate, but the mechanism of intracellular replication of mycobacteria is poorly understood.

The immunopathogenesis of mycobacterial infections primarily involves a cell-mediated immune response. This response includes the activation of macrophages to identify and inhibit or kill mycobacteria and the detection and lysis of phagocytes in which mycobacteria are in a state of growth and replication (Fig. 233.6).

Mycobacterial antigens are presented by antigen-presenting cells (monocyte/macrophage lineage) resulting in secretion of interleukin (IL)-2 and clonal proliferation of $CD4^+$ and $CD8^+$ lymphocytes (a/ß T cells). Mycobacterial antigens arising from the phagosome are presented by major histocompatibility complex (MHC) class II molecules while antigens arising from the cytoplasm are presented by MHC class I molecules.[15] This difference determines, in part, the fate of the antigen-presenting cell, stimulation or destruction, because the presentation of antigen arising from the cytoplasm indicates that the cell has failed to control the mycobacteria. The release of interferon (IFN)-? by the clonally expanded CD4 cells, but also to a lesser extent by CD8 cells, natural killer (NK) cells and ?d cells, activates macrophages. This initiates a cascade of events including the hydrolysis of vitamin D that leads to further activation of macrophages and the release of tumor necrosis factor (TNF)-a by the activated macrophages. The sequence of cellular responses at the site of mycobacterial infection appears to be polymorphonuclear granulocytes (PNGs), NK cells, ?d cells and then a/ß T cells; however, with time the a/ß T cells become predominant in the cellular response. The sequence of recruitment is probably determined by the proximity of the cells to the site of infection; for example, ?d cells are likely to be one of the first cells recruited to the site of *M. tuberculosis* infection in the lung. The PNGs produce highly proteolytic enzymes that cause tissue liquefaction while each of the T-cell types possesses cytotoxic activity. Activated macrophages have an increased capacity for seeking out, engulfing and destroying mycobacteria, but the production of TNF-a by macrophages contributes to tissue necrosis and, therefore, to the immunopathology of the disease.

The activity of macrophages to resist mycobacterium multiplication, which determines in part host susceptibility or host resistance to tuberculosis, is determined by the presence of the gene *Bcg/Ity/Lsh* in mice with its human homolog *NRAMP1* (natural resistance-associated macrophage protein 1).[17] [18]

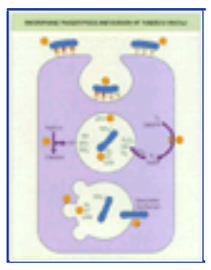

Figure 233-6 Macrophage phagocytosis and evasion of tubercle bacilli. The tubercle bacilli bind via lipoarabinomannan (LAM) (1) or complement receptors (2); phagocytosis occurs (3) with the activation of an oxidative burst (4); glycolipids (GL), sulfatides (ST) and LAM can downregulate the oxidative burst (5); reactive nitrogen intermediates may play a role in antimycobacterial activity (6), as does the acidic pH of the phagolysosome (7). Finally, the production of ammonia by tubercle bacilli may diminish the effect of reactive nitrogen intermediates (8) and contribute to the failure to form a phagolysosome fusion (9). Tubercule bacilli may evade the antimycobacterial activities of the phagolysosome by producing a hemolysin that releases the bacilli into the cytoplasm (10). NADP, nicotinamide adenine dinucleotide phosphate; NADPH, nicotinamide adenine dinucleotide phosphate, reduced form; SOD, superoxide dismutase. *Adapted from Chan and Kaufmann.* [16]

On the other hand, mycobacteria are equipped to resist oxidative killing by phagocytic cells. This resistance is controlled by the *katG* promoter in the micobacterial genome. The *katG* gene encodes an enzyme with catalase, peroxidase and peroxynitritase activities.[19]

Granulomas develop as a mycobacterial infection becomes more chronic. Granulomas are aggregates of activated macrophages that take on epithelial cell-like morphology (epithelioid cells), and typically lymphocytes are found at the periphery of the granuloma. Although the formation of a granuloma effectively contains the mycobacteria where they can be killed, bacilli can persist within giant cells (fused epithelioid cells) and the granuloma may never sterilize. With time a fibrotic wall (collagen) will encapsulate the granuloma and the center of the granuloma may become necrotic with a cheese-like appearance, which is the source of the descriptive word caseation. Hippocrates termed granulomas 'tubercles' because they were similar in morphology to the tubers of plants, hence the name tuberculosis.[4]

Finally, in immunocompetent hosts and to lesser degree immunocompromised hosts (e.g. people with HIV infection may be totally anergic), there is a delayed-type hypersensitivity (DTH) reaction to *M. tuberculosis* infection. In addition, a DTH reaction probably occurs in most mycobacterial infections, but certainly with *M.*

avium-intracellulare, *M. leprae* and *M. ulcerans*. The DTH that occurs in response to *M. tuberculosis* infection is the basis for the tuberculin skin test commonly referred to as the purified protein derivative (PPD) test.

DIAGNOSTIC MICROBIOLOGY

The detection and identification of mycobacteria in clinical specimens is largely still considered to be a subspecialty in clinical microbiology that requires considerable expertise, especially for the accurate identification and susceptibility testing of uncommon mycobacterial species. Nevertheless, the technology available to assist in the laboratory diagnosis of mycobacterial infections has improved remarkably. Semi-automated culture systems are available for the primary culture of clinical specimens. Nucleic acid amplification assays are commercially available for the direct detection of *M. tuberculosis* in clinical specimens and nucleic acid probes have been commercially available for several years for the rapid identification of *M. tuberculosis*, *M. avium* complex, *M. avium*, *M. intracellulare*, *M. kansasii* and *M. gordonae* from culture.

Susceptibility testing of *M. tuberculosis* is more standardized and several molecular assays have been described for the rapid detection of antimicrobial resistance, especially rifampin resistance in *M. tuberculosis*, but molecular methods for detecting resistance have yet to become routinely used in clinical mycobacteriology laboratories.[20] [21] [22]

In discussing diagnostic mycobacteriology it is important to emphasize two general principles of laboratory medicine. First, the quality of any clinical test is highly dependent on the quality of the specimen, including the time of collection in the course of the disease, the appropriateness and sufficiency of the specimen, and the prompt and proper transport of the specimen to the laboratory. Second, the intended purpose of the test, as it was designed and verified, must be understood by the physician who orders the test. Was the test designed to screen for disease, to provide a definitive diagnosis based on a clinical index of suspicion, to confirm another test, to monitor therapy (test of cure), or to provide epidemiologic information? Although any one test may have multiple purposes, most tests have been designed and evaluated for a limited purpose. Use of a test for a purpose for which it was not designed and evaluated could be misleading. For example, nucleic acid amplification assays for the direct detection of *M. tuberculosis* in clinical specimens were evaluated as diagnostic assays, not as tests of cure or for monitoring response to therapy.

Laboratory diagnosis

The laboratory diagnosis of mycobacterial infections often consists of five steps:

- first, mycobacteria can be directly detected in clinical specimens by microscopic examination and molecular assays;
- second, mycobacteria can be detected in clinical specimens by culture using a variety of liquid and solid media;
- third, the isolated mycobacteria can be identified using morphologic, biochemical and molecular tests;
- fourth, the activity of antimicrobial agents can be measured using in-vitro tests; and
- fifth, strains of mycobacteria can be characterized by molecular or other methods for epidemiologic and public health purposes.

The isolation of *M. tuberculosis* strains resistant to multiple antibiotics and the increase in the incidence of tuberculosis in the USA for a short time led to concerns about the length of time (commonly believed to be at least 4–8 weeks) necessary for a conventional laboratory diagnosis. Therefore, in providing laboratory services for the diagnosis of tuberculosis and other mycobacterial diseases, one must recognize the need for prompt as well as accurate information. Salfinger[23] led in designing and implementing 'fast-track' mycobacteriology services, initially in response to an acute need during an outbreak of multidrug resistant *M. tuberculosis* in New York City. However, even before the 'fast-track' era, it was possible to provide mycobacteriology services in a reliable and prompt manner. All that was required was the appropriate diligence and awareness of the laboratory, physicians and public health officials.

Specimen collection

The most critical step in the laboratory diagnosis of any infectious disease occurs before the specimen arrives at the laboratory. The quality, quantity, timing, transport and appropriateness of the specimen have a greater impact on the outcome of a laboratory test than almost any other factor (Table 233.1). Mycobacterial infections can be localized or disseminated, or disseminated with foci of infection that are more likely than other body sites to yield mycobacteria. Once a specimen has been collected it is important to transport the specimen in a container that is sterile, leak-proof and wax-free. The specimen must be accompanied by a request form or transmittal slip that includes the patient's name, medical record number, date and time collected, name of the laboratory, diagnosis, therapy, type of specimen, and test(s) requested. It is important that physicians notify the laboratory if they suspect an uncommon or fastidious mycobacterial infection such as *M. ulcerans*, *M. marinum* or *M. haemophilum*. These and other species of mycobacteria have growth requirements that are significantly different from the majority of other species of mycobacteria isolated from clinical specimens.

Sputum

Sputum is the best specimen for the diagnosis of pulmonary tuberculosis. Expectorated sputum specimen should be collected early in the morning on three occasions. Sputum should be collected directly into a wide-mouthed, sterile, plastic container (wax free) with a tight fitting cap. The specimen should be immediately transported to the laboratory or held at 32–39.2°F (0–4°C) until processed. Prompt processing of sputum is required because of the potential for overgrowth of normal respiratory tract microflora. Alternative respiratory tract specimens are induced sputum, endotracheal aspiration, bronchial washings or aspirates taken during bronchoscopy, laryngeal swabs (not a simple throat swab) and gastric lavage. Bronchoscopes must be carefully cleaned and decontaminated after collecting specimens from a patient with suspected tuberculosis.

Gastric lavage

Gastric lavage (for swallowed sputum) is useful for collecting specimens from patients who for a variety of reasons are unable to produce sputum by other means. Gastric lavage is frequently used to collect specimens from young children. In performing a gastric lavage it is common to suggest to patients that they sip water or swallow a small amount of ice to help pass the gastric tube into the stomach. However, *M. gordonae* is frequently found in many hospital water supplies and especially in ice machines, and use of such contaminated water during the collection of a gastric aspirate may result in a false-positive smear or culture. A gastric lavage must be promptly sent to the laboratory because it must be processed as soon as possible or neutralized with 10% sodium carbonate to avoid loss of mycobacteria due to gastric acidity. As with expectorated sputum specimens, gastric lavage specimens should be collected early in the morning, before eating, and on three separate occasions.

TABLE 233-1 -- Specimen types and requirements for the diagnosis of mycobacterial infections.

SPECIMEN TYPES AND REQUIREMENTS FOR DIAGNOSIS OF MYCOBACTERIAL INFECTIONS			
Specimen type	**Requirements**	**Collection device**	**Note**
Abscess fluid	10ml*	Syringe with cap	Dry swab unacceptable
Blood	10ml	SPS tube, Isolator, Bactec 13A	EDTA tube unacceptable, treat coagulated blood as tissue
Fluids (pleural, pericardial, peritoneal)	10–15ml*	Sterile container, syringe	
Bone	Bone chip	Sterile container, no fixative	Formalin fixed unacceptable
Bone marrow	100mg* 1–3ml aspirate	SPS tube, 1.5ml Isolator	Aspirate volumes >5ml may be primarily peripheral blood
Bronchoalveolar lavage or bronchial washing	=5ml	Sterile container	Avoid contamination of bronchoscope with tap water — possible false positive
CSF	10ml*	Sterile tube	Smear is STAT
Gastric lavage	5–10ml	Sterile container, collect in morning before arising and before eating	Neutralize with 10% carbonate, if delayed processing

Lymph node	Whole node or part, caseous part	Sterile container	Formalin fixed unacceptable
Skin biopsy	Sterile container, aspirate in syringe	Biopsy at periphery or aspirate from under margin of lesion	Note if suspect *M. ulcerans*, *M. haemophilum*, or *M. marinum* — need special culture conditions or extended incubation
Sputum	5–10ml	Sterile, wax-free container	Use sterile hypertonic saline for induced sputum, avoid exposure to tap water
Stool	=1g	Sterile, wax-free container	Do *not* freeze
Tissue bropsy	1g	Sterile container	Caseous portion, formalin fixed unacceptable
Transtracheal aspirate	10ml*	Syringe with cap	
Urine	50ml*	Sterile container, syringe with cap	24-hour urine, catheter urine are unacceptable
SPS, sodium polyanetholsulfonate.			

* As much as possible up to or in excess of the weight shown

Urine

Three early morning midstream urine specimens should be collected into a sterile plastic container (wax-free) with a leak-proof cap. Large volumes of urine can be concentrated by filtration, but 24-hour urine should not be used because of contamination and dilution of any mycobacteria present. True positive urine cultures for mycobacteria almost invariably indicate infection elsewhere in the patient.

Blood and bone marrow

Blood, bone marrow aspirates or cores are ideal specimens for the diagnosis of disseminated MAC, disseminated *M. tuberculosis*, and other disseminated mycobacterial infections. Blood should be processed using an agent that causes blood cell cytolysis and the cell-free mycobacteria collected by centrifugation using either an Isolator tube (Wampole, Cranbury, NJ) or a sodium polyanethol sulfonate (SPS) tube.[24] Blood collected in an SPS tube must be treated with a lytic agent such as desoxycholate and then concentrated by centrifugation before inoculating media. Alternatively, blood can be collected into an SPS tube and transferred directly to a Bactec460 TB 13A medium or other semi-automated systems (Table 233.2) for the detection of *M. avium* complex. Bone marrow aspirate can be collected in a pediatric Isolator tube, but bone marrow core should be processed as tissue. Bone marrow specimens should also be inoculated into a liquid medium such as Bactec460 TB 12B or Middlebrook 7H9. Blood and bone marrow for culture should not be collected in an EDTA tube; however, an albumin-citrate-dextrose (ACD) tube can be used if an SPS tube is not available.

Other fluids

Cerebrospinal fluid (CSF), pleural, pericardial, synovial and ascitic fluids as well as pus and bone marrow aspirates may be submitted for smear and culture. *Mycobacterium tuberculosis* meningitis is a medical emergency and CSF specimens should be collected, transported and processed in a manner that reflects the urgent nature of such a diagnosis. Aseptically collected sterile body site fluids should not be decontaminated, but these specimens can be concentrated. Fluids should be promptly processed and inoculated into a liquid growth medium as well as solid media.

Tissues

Tissue should be submitted for both histology and mycobacteriology. Tissue is preferred over necrotic material or pus for culture, therefore, it is important to have fresh tissue and not swabs submitted to the microbiology laboratory for smear and culture. Formalin-preserved tissue should be submitted for histologic studies. Although not suitable for culture, formalin-preserved and paraffin-embedded tissue can be submitted for polymerase chain reaction (PCR) analysis, especially if acid-fast bacilli are observed on microscopic examination of the tissue sections. [25] [26]

Feces

Feces are not a particularly useful specimen for the diagnosis of tuberculosis or other mycobacterial infections, with the exception of suspected gastrointestinal tract infection with MAC in HIV-positive patients. However, the recovery of MAC from feces is poor (low sensitivity) even in HIV-positive patients. If *M. avium* is isolated from the feces the positive predictive value of the culture is high, meaning that the patient is likely to develop disseminated disease.[27] In order to avoid overgrowth of normal gastrointestinal tract microflora, feces must be rather harshly decontaminated, but this is likely to also decrease the yield of mycobacteria.[28] The use of a selective medium such as Mitchison's selective medium may assist in the recovery of mycobacteria from feces.

TABLE 233-2 -- Semi-automated systems for the detection of *Mycobacterium tuberculosis* and other mycobacteria in clinical specimens.

SEMI-AUTOMATED SYSTEMS FOR THE DETECTION OF *MYCOBACTERIUM TUBERCULOSIS* AND OTHER MYCOBACTERIA IN CLINICAL SPECIMENS			
Instrument/medium	**Manufacturer**	**Detection system**	**SIRE/PZA susceptibility testing**
Bactec 9000MB MYCO/F medium + supplements (modified 7H9 broth)	Becton Dickinson Microbiology Systems, Sparks, MD, USA	Detects changes in O_2 concentration in the growth medium using an O_2 sensor based on fluorescence quenching	No/No
Bactec MGIT 960 (modified 7H9 broth)	Becton Dickinson Microbiology Systems, Sparks, MD, USA	O_2 sensor based on fluorescence quenching	Yes/Yes
ESP Culture System II/ESP Myco (modified 7H9 broth)	TREK Diagnostic Systems, Westlake, OH, USA	Detects production and consumption of gas by measuring changes in partial pressure of gas phase of culture medium	Yes/No
MB/BacT	BioMerieux, Durham, NC, USA	Detects changes in CO_2 concentration in gas phase of the growth medium using a colorimetric sensor and reflected light	Yes/No
Bactec 460/Bactec 12B and Bactec 13A (modified 7H9 broth)	Becton Dickinson Microbiology Systems, Sparks, MD, USA	Detection of radioactively labeled CO_2 released during the catabolism of ^{14}C-labeled palmitic acid in the growth medium	Yes/Yes
PZA, pyrazinamide; SIRE, streptomycin, isoniazid, rifampin and ethambutol.			

Processing contaminated specimens

Most respiratory tract specimens are expected to be contaminated with normal respiratory tract microflora. In addition, the mucin matrix of these specimens makes the specimens difficult to process and mucin both protects and traps micro-organisms. Such contaminated specimens must be treated to liquify the specimen and release any micro-organisms trapped in the mucin or cells. Then, the specimen is decontaminated to reduce or eliminate other micro-organisms that would be likely to overgrow the mycobacteria that might be present in the specimen. The most common mucolytic agents used to digest sputum are *N*-acetyl-L-cysteine (NALC) and dithiothreitol (DTT or sputolysin). Both NALC and DTT are unstable in air and must be prepared fresh; sodium citrate is usually added to NALC/DTT to chelate heavy metals that may inactivate these compounds. Both NALC and DTT have sulfhydryl groups that reduce the disulfide bridges of the glycoprotein that confers upon sputum its mucilaginous property. A combination of NALC and sodium hydroxide is most commonly used for digesting and decontaminating sputum. Other agents used

for digestion and decontamination are zephiran (benzalkonium chloride)-trisodium phosphate, oxalic acid, cetylpyridinium chloride (CPC)-sodium chloride, and sulfuric acid.

There is no ideal method for digesting and decontaminating sputum and other respiratory tract specimens and invariably mycobacteria are lost during decontamination. Indeed, it has been estimated that up to one-third of the mycobacteria present in a sputum specimen may be lost during decontamination. If *M. gordonae* is naturally found in the environment of the laboratory, one should expect about 5% of clinical specimens processed in the laboratory will be contaminated with this mycobacterium. If less than 5% *M. gordonae* contamination is observed, the decontamination procedure may be too harsh. Detailed descriptions of the various procedures for digesting and decontaminating sputum and other contaminated specimens have been well described elsewhere.[29] [30]

Processing uncontaminated specimens

Aseptically collected tissues and fluids from normally sterile body sites usually do not require processing before inoculation of cultures. Certain fluids such as pericardial or pleural fluid may require the addition of an anticoagulant to the collection container. The primary concern about specimens from sterile body sites is the quantity of specimen submitted for smear and culture. Swabs usually contain insufficient material for culture and 1g of tissue or 10ml of fluid are ideal. To improve recovery of mycobacteria, centrifugation or filtration should be used to concentrate large volumes of fluids.

Centrifugation

Although the chemical components of the digestion and decontamination procedure are critical to specimen processing and the successful recovery of mycobacteria, the concentration of mycobacteria by centrifugation is a frequently overlooked component of the procedure that may contribute to poor recovery if not performed properly. Two aspects of the centrifugation step are important:

- the sedimenting efficiency or relative centrifugal force (RCF); and
- the heat generated during centrifugation.

The sedimenting efficiency should be 95% and the RCF should be at least 3000G for 15–20 minutes. Higher RCF values can be used; however, the type of centrifuge tube used will also determine the maximum permissible RCF. Aerosols generated during centrifugation are a high-risk factor for transmission of tuberculosis to laboratory workers. Therefore, specimens must be placed in aerosol-free canisters or in an aerosol-free centrifuge. Manipulation of the supernatant must follow appropriate biohazard protection guidelines.

Culture

A variety of solid and liquid media are available for the culture of mycobacteria from clinical specimens. It is prudent to use several media to ensure recovery and provide good growth for subsequent identification and susceptibility testing. The macroscopic and microscopic growth of mycobacteria may vary with the type of media and these differences in morphology, rate of growth and pigmentation are valuable in making a presumptive identification (see Fig. 233.1).

Several semi-automated systems are designed to detect mycobacteria in clinical specimens (Table 233.2) in addition to the radio-respirometric system developed in the late 1970s by Middlebrook and commercially developed as the Bactec460 TB 460 system in the early 1980s by Becton Dickinson Co. In the various studies that were performed to evaluate these newer systems, comparisons were usually made with conventional culture (e.g. Löwenstein-Jensen medium) and the Bactec460 TB system. Indeed, the Bactec460 TB 460 system became a 'gold standard' for the rapid detection of mycobacteria in semi-automated systems. In the Bactec460 TB 460 the growth of mycobacteria is detected by measuring the release of $^{14}CO_2$ from ^{14}C-labeled palmitate, which is the primary carbon source in the Bactec460 TB 12B culture medium. The limitations of

the Bactec460 TB 460 system are that the medium includes a radioactive substrate, the media are expensive and the system is surprisingly labor intensive.

Information about the performance of the new semi-automated systems, the studies published to date indicate that these systems (Becton Dickinson's Bactec460 TB 9000MB and Bactec MGIT 960, Trek Diagnostic System's ESP II and bioMerieux's MB/BacT) perform well in comparison with conventional culture and the Bactec 460 system.[31] [32] [33] [34] [35] [36] [37] [38] [39] [40] [41] [42] [43] [44] The new systems are convenient, do not require the use of radioisotope, and are truly labor-saving. In comparison with the Bactec460 TB 460 system the newer systems are 5–10% less sensitive and the time to detection is the same or 1–5 days longer. It is important to emphasize that a liquid medium, of one of the types described here, as well as a solid medium must be included in the laboratory diagnosis of mycobacterial infections to ensure maximum recovery (sensitivity).

Additional manual culture systems used for the detection of mycobacteria are the Septi-Chek acid-fast bacillus (AFB) biphasic system, the MB Redox tube system and the Mycobacteria Growth Indicator Tube (MGIT). These are manual culture systems, although the MGIT system has been recently adapted to a semi-automated detection system. The Septi-Chek AFB system is a biphasic medium consisting of 30ml of Middlebrook 7H9 broth and a triangular-shaped plastic paddle with Middlebrook 7H11 agar on one side and Middlebrook 7H11 with NAP and chocolate agar on the remaining surfaces. Comparison studies with conventional culture and the Bactec460 TB 460 system indicated that the Septi-Chek AFB system is reliable and practical.[45] [46] MB Redox tubes contain 4ml of modified Kirchner medium (Kirchner base medium plus glucose, horse serum, a vitamin combination and OADC (oleic acid, albumin, dextrose and catalase)). In addition, the medium contains a mixture of antimicrobial agents (polymyxin B, amphotericin B, carbenicillin and trimethoprim) and a redox indicator (tetrazolium salt). Mycobacteria reduce the tetrazolium salt to a pink-, red- and violet-colored formazan. The accumulation of reduced dye on the surface of the bacilli results in the appearance of visible microcolonies. The MGIT culture is a highly enriched Middlebrook 7H9 broth that contains a disk of silicon rubber impregnated with ruthenium pentahydrate that acts as a fluorescence-quenching oxygen sensor. Growth is detected by exposing

TABLE 233-3 -- The *Mycobacterium tuberculosis* complex.†

THE *MYCOBACTERIUM TUBERCULOSIS COMPLEX*			
Species	**Geographic distribution**	**Taxonomic features**	**Identifying features**
M. tuberculosis	Widespread, humans are the definitive host		TCH-resistant, PZA-susceptible, nitrate reductase activity positive, aerobic
M. bovis	Widespread, broad host range including cattle, nonhuman primates, goats, cats, dogs, buffalo badgers, possums, deer and bison. Humans are viewed as a 'spillover' host	While probably more properly viewed as a subspecies of *M. tuberculosis*, epidemiologic and economic factors presently compel separation of species	TCH-susceptible, PZA-resistant, nitrate reductase activity negative, microaerophilic
M. bovis BCG	Nonvirulent vaccine strain	First reported in 1908 as a nonvirulent strain of *M. tuberculosis*; appears to be a regulatory mutant of *M. bovis*	TCH-susceptible, PZA-resistant, nitrate reductase activity negative, aerobic
M. africanum		Probably more properly viewed as a subspecies or biovar of *M. bovis*	TCH-susceptible, PZA-resistant, nitrate reductase activity negative, microaerophilic
M. microti	Usually considered strictly an animal pathogen (e.g. voles), severe human cases were reported in 1998*	Probably more properly viewed as a subspecies or pathovar of *M. tuberculosis*	
M. canetti	East Africa, but probably worldwide. Appears to have a very limited incidence	Taxonomic status is unclear, but PRA results suggest a distinct taxonomic cluster	Smooth colony variant of *M. tuberculosis*, PZA-resistant
PRA, PCR restriction analysis; PZA, pyrazinamide; TCH, thiophen-2-carboxylic acid hydrazide.

* From van Soolingen *et al.*[55]

an inoculated MGIT tube to ultraviolet light and examining for fluorescence, which is an indication of growth and oxygen consumption. The performance of these aforementioned manual systems varies in comparison with the Bactec 460 standard, but most investigators have concluded that each of these systems, in combination with conventional solid media, are a satisfactory substitute for the Bactec.[40] [47] [48] [49] [50] [51] Indeed, deciding factors are more likely to reflect differences in cost, convenience and safety, availability and workload.

Identification

In 1958, Ernest Runyon proposed that by dividing mycobacteria into four groups based on the rate of growth and pigmentation one could make a preliminary identification. Rapid growers were separated from slowly growing mycobacteria according to the time required to produce clearly visible colonies (=7 days for rapid growers). Slowly growing mycobacteria were separated based on pigment production: photochromogenic, scotochromogenic (Fr. Gk *skotos*, darkness) and nonphotochromogenic. Forty years later Dr Runyon's simple scheme, now the Runyon groups, remains a valuable guide for the initial identification of mycobacteria isolated by culture, and the logic of this classification has been corroborated by 16S rRNA sequence analysis. [52] Indeed, the correlation between an initial classification into a Runyon group and the final identification ranges from 87% (nonphotochromogens) to 97% (rapid growers).[53] The first challenge for the clinical mycobacteriology laboratory is to distinguish between an isolate that is in the *M. tuberculosis* complex (Table 233.3) and an isolate that is a nontuberculous mycobacterium, a taxonomically imprecise but clinically important distinction. In many ways clinical mycobacteriology remains an arcane field and experience is a critical factor in assuring the accurate identification of mycobacteria, especially the nontuberculous mycobacteria (Table 233.4).

Nature and appearance of cultures

The growth of *M. tuberculosis* on Middlebrook 7H10 or 7H11 agar at 95°F (35°C) is usually detected in 2–3 weeks. The colonies are beige-colored, rough, dry, corded, flat and with irregular borders (Fig. 233.7). On egg media such as Löwenstein-Jensen or Ogawa media the colonies are frequently warty and granular and with time heap into a cauliflower shape (Fig. 233.8). Although the growth of

TABLE 233-4 -- Nontuberculous mycobacteria.*

NONTUBERCULOUS MYCOBACTERIA							
Clinical disease/specimen/site	**Occurrence**	**Species**	**Growth rate**	**Recovered from environment**	**Geographic distribution**	**Risk factors**	**Microbiologic features/diagnostic tools**
Cutaneous, wound	Common	*M. chelonae*	Rapid	Yes	Widespread		
Cutaneous, wound	Common	*M. fortuitum*	Rapid	Yes	Widespread	Central catheter postsurgical wound	Rapid growth (<7 days, especially on subculture), not pigmented, growth in salt and MacConkey agar is temp dependent
Cutaneous, wound	Common	*M. haemophilum*	Slow	Yes?	Australia, Europe, North America	AIDS, organ transplant, lymphoma, children	Growth requires hemin or ferric ammonium citrate, growth at 86–89.6°F (30–32°C), growth stimulated by CO_2 , colony variants occur, may be missed
Cutaneous	Common	*M. marinum*	Rapid/slow	Yes	Widespread	Skin abrasion or trauma	Photochromogen, slow-to-rapid growth, initial culture =89.6°F (32°C), colony variants occur
Cutaneous, ulcers	Common	*M. ulcerans*	Slow	Yes	Ghana, Uganda, South East Asia, Tropics, Central and South America, Australia	Normal host, third most prevalent mycobacterium isolated from human specimens and continuing to emerge	Culture — slow growth at 77 and 98.6°F (25 and 37°C), HPLC, microaerophilic, mycolic acids similar to *M. marinum*
Cutaneous, wound	Uncommon	*M. abscessus*	Rapid	Yes			
Cutaneous, wound	Uncommon	*M. avium complex*	Slow	Yes			
Cutaneous	Uncommon	*M. kansasii*	Rapid	Yes			
Cutaneous	Uncommon	*M. smegmatis*	Rapid	Yes			
Cutaneous, wound	Unknown	*M. conspicuum*	Slow	No			Culture, HPLC, 16S rRNA
Cutaneous Urine Fluids (BAL, joint) Blood	Unknown	*M. immunogenicum*	Rapid	Yes	Unknown	Respiratory pseudo-outbreaks (contaminated bronchoscopy equipment). Newly described species	Culture 77–86°F (25–30°C), 16S rRNA or DNA hybridization, *M. abscessus-chelonae*-like
Cutaneous	Unknown	*M. novocastrense*	Rapid	Yes		Potential human pathogen	Culture, pigmented (yellow), HPLC, 16S rRNA, *M. marinum*-like
Disseminated		*M. xenopi*	Slow	Yes	Worldwide	AIDS	
Disseminated	Common	*M. avium complex*	Slow	Yes	Widespread	AIDS, hairy cell leukemia, congenital immunodeficiencies	Slow growth (>7 days), nonpigmented but pigmented colonies occur, colony variants isolated from blood, bone marrow, other biopsies
Disseminated	Common	*M. chelonae*	Rapid	Yes	Widespread		
Disseminated Blood or bone marrow	Common	*M. haemophilum*	Slow	Yes?	Australia, Europe, North America	Common and continuing to emerge	Culture (requires hemin), HPLC, GLC, TLC, 16S rRNA
Disseminated	Common	*M. kansasii*	Rapid	Yes	Europe, USA		
Disseminated	Uncommon	*M. abscessus*	Rapid	Yes			
Disseminated Blood, bone marrow, liver, spleen	Uncommon	*M. genavense*	Slow	Yes	Widespread, isolated from pet birds	Disease in humans established, especially in AIDS, malnourished	
Disseminated	Uncommon	*M. malmoense*	Very slow	Yes		AIDS	

Disseminated	Unknown	*M. celatum*	Slow	No	Europe, USA	Disease in humans established	Culture, nonphotochromagen, HPLC, TLC, cross-reacts with GenProbe Mtb probe, 16S rRNA
Disseminated, blood	Unknown	*M. conspicuum*	Slow	No			Culture, HPLC, 16S rRNA
Disseminated Spinal osteomyelitis Lymphadenitis	Unknown	*M. lentiflavin*	Slow	No		Disease in humans established, especially HIV and AIDS	Culture, 16S rRNA
Disseminated Lymph nodes, spinal fluid, pericardial and peritoneal fluids	Unknown	*M. triplex*	Slow	No	Unknown	Disease in humans established	Culture, HPLC, 16S rRNA, *M. simiae-avium*-like
Intestinal		*M. paratuberculosis*	Slow	Yes			Cause of Johne's disease in cattle
Lymphadenitis	Common	*M. avium* complex	Slow	Yes	Widespread	Children	
Lymphadenitis	Common	*M. malmoense*	Very slow	Yes	UK, Northern Europe, Scandinavia	Childhood	Slow growth (6 weeks), subculture growth is similarly slow, easily missed
Lymphadenitis	Common	*M. scrofulaceum*	Slow	Yes	Widespread	Children	
Lymphadenitis	Uncommon	*M. abscessus*	Rapid	Yes			
Lymphadenitis	Uncommon	*M. chelonae*	Rapid	Yes			
Lymphadenitis	Uncommon	*M. fortuitum*	Rapid	Yes			
Lymphadenitis	Uncommon	*M. haemophilum*	Slow	Yes?			
Lymphadenitis Soft tissue	Unknown	*M. bohemicum*	Slow	Yes	Unknown	Potential pathogen	Culture, GLC, 16S rRNA
Lymphadenitis	Unknown	*M. heidelbergense*	Slow	No	Germany, unknown?	Potential pathogen	Growth, HPLC, PRA
Lymphadenitis Pulmonary	Unknown	*M. tusciae*	Slow	Yes	Tuscany, unknown?	Potential pathogen	Culture, HPLC, 16S rRNA
Lymphadenitis Disseminated	Unknown	*M. interjectum*	Slow/rapid	No		Disease in humans established	HPLC, TLC, 16S rRNA
Pulmonary	Common	*M. abscessus*	Rapid	Yes	Widespread, predominantly USA		Rapid growth (<7 days), not pigmented
Pulmonary	Common	*M. avium complex*	Slow	Yes	Widespread	Chronic lung disease, cystic fibrosis	Slow growth (>7 days), usually not pigmented, colony variants
Pulmonary	Common	*M. kansasii*	Rapid	Yes	Localized USA, UK, Europe	Alcoholism, AIDS, chronic lung disease	Photochromogen, intensely pigmented, large, beaded, acid-fast, elongated bacilli
Pulmonary	Common	*M. malmoense*	Very slow	Yes	Localized UK, Northern Europe	Pneumoconiosis, silicosis, industrial dust disease. Common and continuing emerge	Slow growth (6 weeks), subculture growth is similarly slow, easily missed
Pulmonary	Common	*M. xenopi*	Slow	Yes	Localized UK, Europe, Canada	Underlying lung disease. Common and continuing to emerge	Culture, slow growth, pigmented, growth at 113°F (45°C), 'birds nest' colony
Pulmonary	Uncommon	*M. asiaticum*	Slow	Yes	Localized Australia, USA		
Pulmonary	Uncommon	*M. fortuitum*	Rapid	Yes			
Pulmonary	Uncommon	*M. gordonae*	Slow	Yes	Widespread	Chronic lung disease, but frequent contaminant and rare cause of disease	'Tap-water' scotochromogen
Pulmonary	Uncommon	*M. haemophilum*	Slow	Yes?	Unknown, seems localized		
Pulmonary	Uncommon	*M. shimoidae*	Slow		Australia, Japan		
Pulmonary	Uncommon	*M. simiae*	Slow	Yes	Israel, Thailand, France, USA, Australia	Underlying lung disease, pneumonia	Photochromogen, slow but good growth at 98.6°F (37°C), produces niacin
Pulmonary	Uncommon	*M. szulgai*	Slow	Yes?	Europe, Japan, USA	Underlying disease, alcoholism	Scotochromogen, slow growth at 77–98.6°F (25–37°C), no growth at 107.6°F (42°C)
Pulmonary, sputum	Unknown	*M. alvei*	Rapid	Yes	Unknown, first isolated and described in Spain	Potential human pathogen	GLC, DNA hybridization
Pulmonary	Unknown	*M. branderi*	Slow	No	Unknown	Potential pathogen	Culture, chromatography, 16S rRNA
Pulmonary	Unknown	*M. brumae*	Rapid	Yes	Unknown	Potential human pathogen	Culture, arylsulfatase-negative
Pulmonary	Unknown	*M. celatum*	Slow	No	Europe, USA		Culture, nonphotochromagen, HPLC, TLC, cross-reacts with GenProbe Mtb probe, 16S rRNA
Pulmonary, sputum	Unknown	*M. confluentis*	Rapid	No	Unknown	Potential human pathogen	Culture, brown pigment, chromatography, 16S rRNA
Pulmonary	Unknown	*M. conspicuum*	Slow	No	Europe	Disease in humans established	

Pulmonary	Unknown	*M. heckeshornense*	Slow	No	Unknown	Potential pathogen	Culture, GLC, TLC, HPLC, *M. xenopi*-like organism
Pulmonary	Unknown	*M. interjectum*	Slow/rapid	No		Disease in humans established	
Pulmonary	Unknown	*M. intermedium*	Slow/rapid	No	Unknown	Disease in humans established	Culture, photochromogen, GLC, TLC
Pulmonary	Unknown	*M. kubicae*	Slow		Unknown	Potential human pathogen	Culture, HPLC, 16S rRNA
Pulmonary, sputum?	Unknown	*M. mageritense*	Rapid	No	Spain, unknown	Potential human pathogen	DNA hybridization, 16S rRNA
Pulmonary, wounds	Unknown	*M. mucogenicum*	Rapid	Yes	Unknown	Newly described, occurrence unknown	Culture, HPLC, GLC, 16S rRNA
Pulmonary	Unknown	*M. triplex*	Slow	No	Unknown	Disease in humans established	Culture, HPLC, 16S rRNA, *M. avium* complex-like
Urine	Unknown	*M. hassiacum*	Rapid	Yes	Unknown	Nonpathogen?	Culture, scotochromagen, HPLC, PRA
Wound	Unknown	*M. branderi*	Slow	No	Unknown	Disease in humans established	Culture, HPLC, GLC, TLC, 16S rRNA
Wound, soft tissue, blood	Unknown	*M. fortuitum* 3rd biovariant	Rapid	Yes		Newly described, occurrence unknown	Culture, 16S rRNA, includes *M. septicum*
Wound, pulmonary	Unknown	*M. goodii*	Rapid	No	Unknown	Newly described, occurrence unknown, nosocomial?	Culture, pigmented/HPLC, 16S rRNA, *M. smegmatis*-like
Wound, osteomyelitis	Unknown	*M. wolinskyi*	Rapid	No	Unknown	Post-traumatic and postsurgical.	Culture, HPLC, 16S rRNA, *M. smegmatis*-like
						Newly described, occurrence unknown	
BAL, bronchoalveolar lavage; GLC, gas liquid chromatography; PRA, PCR restriction analysis; TLC, thin layer chromatography.							

** Information compiled and adapted from a variety of sources including Falkinham,[56] Grange,[4] Kiehn and White,[57] American Thoracic Society[58] and Brown-Elliot et al.[59]*

Figure 233-7 Primary isolate of *M. tuberculosis* grown from sputum on Löwenstein-Jensen medium displaying characteristic beige, rough and dry-appearing growth. *Courtesy of S Froman and A Gaytan.*

Figure 233-8 Primary isolate of *Mycobacterium tuberculosis* grown from sputum on Löwenstein-Jensen medium displaying 'cauliflower' or verrucose colonies. These are also characteristic of other mycobacteria including MAC and rapid growers, especially as a culture ages. *Courtesy of S Froman and A Gaytan.*

M. tuberculosis is quite distinct and it is not unreasonable for an experienced mycobacteriologist to make a presumptive report of *M. tuberculosis* isolated based on the rate and appearance of growth, the identification must always be confirmed by biochemical, chromatographic or nucleic acid probe tests.

Three species of mycobacteria have optimal growth temperatures less than 95–98.6°F (35–37°C): *M. ulcerans*, *M. marinum* and *M. haemophilum*. If these species are suspected the cultures should be incubated at 86°F (30°C). In addition, *M. haemophilum* requires hemin for growth and, therefore, specimens suspected to harbor this species should be inoculated onto chocolate agar, Middlebrook 7H10 agar with hemolyzed blood or 7H10 agar with a hemin-containing paper strip.

The most common clinically significant mycobacterium isolated in many clinical microbiology laboratories is MAC. *Mycobacterium avium* complex isolated from blood or sputum appears as non-pigmented colonies within 10–14 days after inoculation. When grown on Middlebrook 7H10 or 7H11 agar two colony variants are commonly observed. One variant is smooth, opaque and domed while the second variant is flat and transparent. The distinction between variant types diminishes with the age of the culture and eventually the colonies become verrucose and many develop pigment. The initial distinction between colony types is important because the transparent variants tend to be more resistant to antimicrobial agents and these colonies should be picked for susceptibility testing. The colony variant types are not observed when MAC is grown on egg-based media.

Growth rate

Mycobacteria are commonly separated into rapid growers and slowly growing based on whether growth appears before or after 7 days of incubation. It is important to note that the most accurate measure of growth rate is made with subcultures. Harsh digestion-decontamination of a specimen may significantly increase the time it takes for a rapid grower to appear on primary culture.

Acid-fast stain

An acid-fast stain remains the most rapid, convenient and least expensive method for directly detecting mycobacteria in clinical specimens. Although an acid-fast stain is not specific, the presence of acid-fast bacilli in a specimen from a patient with signs and symptoms of tuberculosis or another mycobacterial infection is an important guide to effective treatment and the initiation of public health measures. Furthermore, an acid-fast stain can be used to monitor the response to therapy and quickly assess patient infectiousness, and is used to confirm that a culture is acid-fast. The sensitivity of the acid-fast stain has been estimated to be 5000–10,000 bacilli/ml of sputum while culture is estimated to be 100- to 1000-fold more sensitive[53] (i.e. the sensitivity of an AFB stain may be only 22–78% compared with culture).[51] The threshold for the detection of MAC in bone marrow by either immunoperoxidase (Fig. 233.9) or Kinyoun staining is of a similar magnitude.[60] The importance of the acid-fast stain and the need for a prompt turnaround time cannot be over-emphasized. In laboratories that do not perform cultures, an acid-fast stain can be performed using a specimen treated for a short time with 5% sodium hypochlorite. If specimens are sent to a reference laboratory, insist that acid-fast stain results are reported within 24 hours of specimen collection.[61]

Acid-fastness is a distinctive feature of mycobacteria that is shared with only a few other bacteria such as *Nocardia* spp. and *Rhodococcus* spp., and parasites such as

Cryptosporidium spp. and *Isopora* spp. The three stains that are commonly used to detect acid-fast bacteria are Ziehl-Neelsen, Kinyoun and auramine-rhodamine fluorochrome stains. With each of these procedures, acid-fastness is defined as resistance to decolorizing with acid-alcohol (e.g. 3% hydrochloric acid in 95% ethanol). When mycobacteria are stained with Gram's crystal violet and safranin they often appear as beaded Gram-positive bacilli or fail to stain at all. It is important to note, however, that culture media, incubation conditions and the age of the culture influence the acid-fastness of mycobacteria. The critical role of the mycobacterial cell wall in acid-fastness is underscored by the observation that isoniazid causes a loss of 'acid-fastness' in susceptible strains of *M. tuberculosis*.

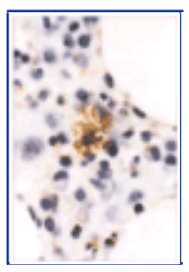

Figure 233-9 Immunoperoxidase stain of *Mycobacterium avium* complex in the bone marrow of a patient who has HIV infection and disseminated disease. The presence of mycobacteria in the bone marrow and blood of a patient is the microbiologic hallmark of disseminated MAC disease. The presence of mycobacteria in bone marrow sections using either an immunoperoxidase stain or a conventional acid-fast stain requires the presence of approximately 1.5×10^4 bacilli/g of bone marrow.

The preparation of the smear is the critical first step in performing an acid-fast stain. Using a glass slide cleaned with ethanol, make a smear of approximately 1×2cm of a single specimen or isolate. For CSF specimens previously concentrated by centrifugation, three drops of the concentrate are placed on a clean glass slide, one drop at a time. The drop is allowed to air dry before the next drop is added. The slide is heated at 149–167°F (65–75°C) for 2–24 hours or alternatively 176°F (80°C) for 15 minutes — it is important to note that heat fixing may not kill all the mycobacteria on the slide. Mycobacteria appear brightly fluorescent against a dark background in the auramine-rhodamine stain and the increased sensitivity of the fluorescence stain compared with the other stains is used to rapidly screen slides at a lower (250–450×) magnification. However, fluorescent objects must be examined at 800–1000× to confirm morphology and positive fluorescent smears should be confirmed with the Ziehl-Neelsen or Kinyoun stains. The Ziehl-Neelsen stain requires that the carbolfuchsin stain be heated for the stain to penetrate the mycobacterial cell. In contrast, heating is unnecessary with the Kinyoun stain because the concentration of basic fuchsin and phenol have been increased to ensure that the basic fuchsin penetrates the

mycobacterial cell wall. Using a 100× oil immersion lens, 100–300 fields of a properly prepared smear and stain should be examined. It should be remembered that examining even 100–300 fields, only 1–4% of a 1×2cm smear would be examined. Mycobacteria usually appear as slender rod-shaped bacilli; however, pleomorphic shapes are common and range from coccoid to long rods with curves or bends (Fig. 233.10 ; see Fig. 233.1).

Conventional biochemical tests

The salient biochemical features used in the conventional identification of mycobacteria are shown in Table 233.5 . Although many of these tests have been supplanted by other more convenient or rapid tests, the conventional biochemical tests represent a 'gold standard'. Details about the many biochemical tests used in the conventional identification of mycobacteria are described in a variety of sources and Wayne and Sramek[62] described a strategy for the use of these tests.

Although biochemical testing is a reliable and accurate approach to the identification of mycobacteria, alternative methods have largely supplanted biochemical tests for the identification of most

mycobacteria commonly isolated from clinical specimens. These alternative methods include high performance liquid chromatography (HPLC), the Bactec460 TB NAP test, nucleic acid probes and nucleic acid sequencing.

Developed in the late 1960s, HPLC is used in many sections of the clinical laboratory for a variety of analytes including the detection and quantitation of antimycobacterial agents.[63] In addition, HPLC has proven to be a useful and reliable technology for the rapid identification of mycobacteria.[64] Other applications of HPLC have been developed for the direct detection of mycobacteria in smear-positive clinical specimens or positive liquid cultures.[65] For the identification of mycobacteria, HPLC is used to analyze mycolic acids extracted from an unknown organism. The mycolic acids are extracted by saponification and then derivatives are prepared with either a phenyl ester or a fluorescent compound for detection by ultraviolet absorption or fluorescence spectroscopy. The HPLC pattern of an unknown is then compared with a library of known patterns usually facilitated by a decision analysis system.[66] The equipment cost and the expertise required to perform HPLC analyses has restricted use of this technology mostly to large hospital, and reference and public health laboratories. Alternative chromatographic methods that can be used in the identification of mycobacteria include thin-layer chromatography of lipids and capillary gas chromatography of mycobacterial fatty acids. Instrumentation and software for the identification of mycobacteria as well as other micro-organisms using whole cell fatty acid analysis is commercially available (e.g. Microbial Identification Systems, Newark, DL).

Nucleic acid probes

Nucleic acid probes are commercially available (AccuProbe, GenProbe, San Diego, CA) for the identification of five of the most common species of mycobacteria isolated from clinical specimens: *M. tuberculosis* complex, *M. avium*, *M. intracellulare*, MAC, *M. gordonae* and *M. kansasii*. The AccuProbe culture confirmation test is based on the use of DNA probes that are complementary to species-specific rRNA. The rRNA is released from the mycobacteria using a combination of a lysing reagent, sonication and heat. The rRNA-containing lysate is reacted with a species-specific DNA probe that is labeled with an acridinium ester. If a stable RNA-DNA

duplex forms, the acridinium label is protected from a selection reagent while free acridinium label is inactivated. Stable duplexes are detected by the addition of an alkaline hydrogen peroxide solution, which in combination with the bound acridinium ester generates chemiluminesence. The amount of light emitted is proportional to the amount of probe hybridized to the target rRNA. The amount of light produced is measured in a luminometer as relative light units (RLU). The AccuProbe test cannot be used for the direct detection of mycobacteria in clinical specimens; the test is for culture identification only. Ribosomal RNA from a rare number of MAC isolates (identified based on biochemical characteristics or 16S rDNA sequence analysis) will not hybridize to the MAC probe. These strains of *M. avium* may represent a third genospecies within the MAC.[67] *The M. tuberculosis* complex AccuProbe test does not differentiate between the species of the *M. tuberculosis* complex. The MAC AccuProbe test does not differentiate between *M. avium* and *M. intracellulare*. In general, the AccuProbe tests are considered to be highly reliable and simple to perform. In addition, the AccuProbe tests can be successfully combined with the semi-automated culture systems (Table 233.2).[68] [69] [70] [71]

Molecular methods

Molecular methods have been described and in many instances are commercially available for:

- detecting and identifying mycobacteria directly in clinical specimens;
- identifying culture isolates; and
- identifying strains of a mycobacterium for epidemiologic purposes.

Molecular methods have also been developed to detect antimicrobial resistance in mycobacteria based on a knowledge of the genetic basis of resistance.

Two molecular tests are commercially available in the USA for the direct detection of *M. tuberculosis* in clinical specimens:

- the Amplicor *M. tuberculosis* Test (Roche Diagnostic Systems, Inc.); and
- the Amplified *M. tuberculosis* Direct Test (MTD; GenProbe, Inc.).

Both these tests are based on a knowledge of prokaryotic 16S rDNA sequence information. 'Signature' sequences (unique rDNA or rRNA sequences that serve to distinguish one organism or group of organisms from another) have been determined for a majority of clinically relevant, slowly growing mycobacteria.[72] The Amplified *Mycobacterium tuberculosis* Direct (MTD) test detects viable and nonviable tubercle bacilli in a clinical specimen. The test uses transcription-mediated amplification and a hybridization protection assay to qualitatively detect all members of the *M. tuberculosis* complex. Mycobacterial rRNA is released by sonication from bacilli present in a clinical specimen, the rRNA is denatured with heat and transcribed into cDNA with a reverse transcriptase. One part of the oligonucleotide used in the reverse transcription step includes a promoter region for a high efficiency RNA polymerase (e.g. phage T7 polymerase); the other part of the oligonucleotide includes a 16S rRNA target-specific sequence. As a result of cycles of denaturation, reverse transcription and RNA synthesis there is an amplification of the mycobacterial rRNA. The repetitive cycles of denaturation and synthesis can be performed under isothermal conditions — 107.6°F (42°C) — because the RNase H activity associated with the reverse transcriptase used in the assay destabilizes RNA-DNA duplexes. *Mycobacterium tuberculosis* complex-specific amplified sequences are detected using the GenProbe hybridization protection assay. The probe in this assay is an acridinium ester-labeled single-stranded DNA molecule that is complementary to the amplified *M. tuberculosis* complex-specific rRNA sequences. Stable RNA-DNA duplexes protect the acridinium label (using a proprietary selection agent) and hybridized label is measured as chemiluminesence in a luminometer.

When initially approved by the US Food and Drug Administration, the assay was limited to use with AFB stain-positive specimens from untreated patients suspected of having tuberculosis. Furthermore, the patients must have received less than 7 days of therapy or, if previously treated, the patient must not have had therapy in the previous 12 months. However, in September 1999, an enhanced version of the GenProbe MTD test was approved for use with respiratory specimens, regardless of the AFB stain results. In several studies the negative predictive value for the enhanced MTD test was 99% or higher. Nevertheless, the MTD test should be performed in conjunction with a routine mycobacterial culture in order to:

- identify subspecies (e.g. *M. tuberculosis* vs *M. bovis*);
- detect mycobacteria other than *M. tuberculosis*; and
- provide growth for susceptibility testing.

The presence of large numbers of nontuberculous mycobacteria in a specimen may generate a weak false-positive reaction (low relative light units) with the MTD test. The MTD test should be performed only with sediments prepared using a standard NALC/NaOH procedure for decontamination and concentration. An acid-fast stain should always be performed on the same specimen at the time the MTD test is performed.

The Amplicor *M. tuberculosis* test is a PCR assay designed for the qualitative detection of *M. tuberculosis* complex DNA in concentrated sputum specimens, bronchial specimens, bronchial alveolar

---

aspirates or washes and endotracheal aspirates. The PCR assay targets a 584 base pair (bp) sequence within the 16S rDNA that is amplified with oligonucleotide primers conjugated to biotin. Amplified DNA is detected by capturing single-stranded forms of the PCR-amplified DNA with a species-specific probe bound to bovine serum albumin that is, in turn, bound to the wells of a microtiter plate. The DNA duplex of probe and amplified target DNA are detected with an avidin-horse radish peroxidase conjugate in a colorimetric enzyme assay. The result is measured as a 450nm optical density read in a microtiter plate spectrophotometer. The amplification reaction includes deoxyuridine in place of deoxythymidine along with the three other nucleotide triphosphates. In this manner the carryover of previously amplified target DNA can be eliminated because the PCR reaction mix includes uracil-N-glycosylase (UNG), an enzyme that degrades DNA that contains deoxyuridine. The UNG itself is denatured in the first cycle of amplification when the temperature reaches 131°F (55°C). Both the GenProbe MTD and Roche Amplicor assays perform extremely well (=95% sensitivity and specificity) with smear-positive specimens; however, only the GenProbe test has been approved for use with AFB stain-negative specimens. An algorithm for the use of these nucleic acid amplification tests is shown in Table 233.6 , which is based on the recommendations of the Centers for Disease Control and Prevention, USA. In considering the use of these tests it is important to realize that AFB-staining is itself only 40–60% sensitive and, of course, is not specific for *M. tuberculosis*. Furthermore, while culture is commonly accepted as the 'gold standard', in reality it too is an imperfect standard and is only 70–80% sensitive when compared with all other laboratory data, patient history and clinical observations.

Another important application of molecular methods has been for epidemiologic studies of *M. tuberculosis*, *M. avium* and other species of mycobacteria. Two methods were initially used:

- restriction endonuclease analysis (REA) using field inversion or pulse field electrophoresis to separate large DNA fragments generated by restriction enzymes with infrequent restriction sites; and
- fragment length polymorphism analysis of the number and pattern of certain insertion sequences (IS) or repetitive DNA elements present in a collection of potentially related strains.

TABLE 233-6 -- Algorithm for the use and interpretation of nucleic acid amplification tests for tuberculosis.*

ALGORITHM FOR THE USE AND INTERPRETATION OF NUCLEIC ACID AMPLIFICATION TESTS FOR TUBERCULOSIS				
	Specimen	**Smear**	**NAA**	**Interpretation/response**
?	1st	-	-	Repeat smear and culture, do not repeat NAA
	2nd	-	X	Repeat smear and culture, do not repeat NAA
	3rd	-	X	Presume patient to not have tuberculosis
?	1st, 2nd or 3rd	+	+	Presume patient to have tuberculosis. Unless NTM are a consideration, the NAA test adds little diagnostic value
?	1st	+	-	If inhibitors of NAA test not present, test 2nd specimen
	2nd	+	-	If inhibitors not present, patient presumed to have NTM
	1st	+	-	If inhibitors present, NAA test is of no diagnostic value NAA up to two additional specimens

?	1st	-	MTD+	Test 2nd specimen. Note Roche Amplicor test is *not* approved for testing smear-negative specimens.
	2nd	-	MTD+	Presume patient has tuberculosis
	2nd	-	MTD-	Test 3rd specimen
	3rd	-	MTD+	Presume patient has tuberculosis
	3rd	-	MTD-	Rely on clinical judgment
Respiratory specimens (e.g. sputum) should be collected on three different days for AFB smear and culture. The nucleic acid amplification (NAA) test (Roche Amplicor *Mycobacterium tuberculosis* Test or GenProbe Amplified *Mycobacterium Tuberculosis* Direct Test) should be performed on the first specimen, first smear-positive specimen, or as indicated in the table. MTD, *Mycobacterium tuberculosis* direct test; X, test not performed; NTM, nontuberculous mycobacteria.				

** Adapted from Centers for Disease Control and Prevention.*[73]

REA is cumbersome because the patterns generated are complex and sometimes difficult to reproduce. IS6110 analysis for the identification of strains of *M. tuberculosis* is based on differences in the copy number of this genetic element. IS6110 is a 1355bp insertion sequence that was first identified in 1990, and was found to be widely distributed in strains of *M. tuberculosis*. There are 0–20 copies of IS6110 in most strains of *M. tuberculosis*. In strains of *M. tuberculosis* with a small number of IS6110 sequences, the elements are uniformly distributed throughout the genome. This factor can limit the epidemiologic value of IS6110 analysis involving such strains because the resulting patterns often do not discriminate between strains. However, a majority of strains of *M. tuberculosis* carry several copies of IS6110 and the distribution of these IS elements within the genome appears to be stable over several months to years. Slight variations in the distribution of IS6110 elements can usually be tolerated in focused epidemiology studies.[74] Insertion sequence analysis is conceptually straightforward, but technically subject to operator error or variations in protocol. Therefore, standard methods of analysis and interpretation have been developed to ensure comparability of results.[75] Basically, the method involves extraction of genomic DNA, restriction of the DNA with an appropriate enzyme (e.g. *Pvu*II) and electrophoretic separation of the restriction fragments (RFLP analysis). The IS6110 pattern is revealed by Southern hybridization using a labeled fragment of the IS6110 sequence. A computer-based method of analysis of the IS6110 patterns was described by Heersma *et al.*[76] A drawback to this method is the relatively large amount (about 2µg) of genomic DNA that is required for analysis. Therefore, PCR-based typing methods were developed that have comparable discrimination and reproducibility to RFLP analysis. Spoligotyping uses primers to PCR amplify the 36bp direct repeats (DR) in the genomic DR region of *M. tuberculosis* DNA.[77] The resulting PCR products are hybridized to 43 different oligonucleotides fixed to a membrane. The 43 oligonucleotides were derived from the sequences of the spacer DNA between the DRs. However, in general spoligotyping is used as a screen for IS6110 analysis. Other methods of analysis include polymorphic GC-rich sequence (PGRS) RFLP typing, [78] genome sequence-based fluorescent-amplified fragment length polymorphism analysis (FAFLP)[79] [80] and PCR-based typing.[81]

ANTIMICROBIAL RESISTANCE AND SUSCEPTIBILITY TESTING

Resistance

Antimicrobial resistance in mycobacteria is fundamentally a reflection of the large populations of mycobacteria present in infected tissues and fluids and the frequencies of individual gene mutations that result in a resistant phenotype. In pulmonary tuberculosis there are 10^7 –10^9 bacilli in lung cavities, but only 10^2 –10^4 bacilli in hard caseous lesions. In disseminated *M. avium* disease the level of bacteremia ranges from 1 to 10^6 colony forming units (cfu) per milliliter of blood, but may be orders of magnitude higher in bone marrow and other tissues. Therefore, drug resistance is a more common occurrence in cavitary tuberculosis than noncavitary disease and resistance in disseminated *M. avium* complex infections develops rapidly when patients are given macrolide monotherapy. Antimicrobial resistance in *M. tuberculosis* is classically defined as a significant difference in the activity of an antimycobacterial between a wild-type strain and another strain. A wild-type strain is defined as a strain isolated from a patient before treatment and less than 1% of a population of that strain is resistant to any antimycobacterial agent. Resistance emerges as a consequence of individual mutations in mycobacterial genes that lead to a structural or functional change such that an antimycobacterial agent is no longer active against that strain. [16] For example, there is compelling evidence that resistance to isoniazid results from a mutation or a combination of

TABLE 233-7 -- Mycobacterial genes with mutations associated with antimicrobial resistance.*

MYCOBACTERIAL GENES WITH MUTATIONS ASSOCIATED WITH ANTIMICROBIAL RESISTANCE

					[99]
Fluoroquinolone	*M. tuberculosis*,	*gyrA*	75–94	DNA gyrase A subunit	[100]
	M. smeginatis				[101]
Azithromycin/clarithromycin	*M. avium*,	V domain 23S rRNA	95	235 rRNA	[102] [103] [104]
	M. intracellulare,				
	M. chelonae				
	M. abscessus				
Proportion of resistance represents the estimated percentage of resistance that can be accounted for by mutations in the respective genes; mutations in *katG*, *aphC*, *inhA* and/or *kasA* collectively probably account for 90% of isoniazid resistance.					

** Adapted from Musser. [22] Percentage figures taken in part from Alcaide and Telenti.[21]*

mutations in the *katG*, *ahpC*, *inhA* or the *kasA* genes of *M. tuberculosis* (Table 233.7).[82] [83]

Resistance to rifampin is a result of a mutation within an 81bp (27 amino acid) sequence of the core region of the *rpoB* gene (RNA polymerase ß subunit) and streptomycin resistance has been attributed to mutations in either the *rrs* gene (16S rRNA gene) or the *rpsL* gene (ribosomal protein S12). Quinolone resistance has been ascribed to mutations in the *gyrA* genes[100] and pyrazinamide resistance to mutations in the *pncA* gene that encodes pyrazinamidase/nicotinamidase activity.[97] [99] The targets for the major classes or types of antimycobacterial agents are shown in Figure 233.11 . Antibiotic resistance does not appear to transfer between strains of mycobacteria by either plasmid exchange or resistance transfer factors. The *M. tuberculosis* multidrug resistance phenotype (minimally resistant to isoniazid and rifampin) appears to be entirely the result of accumulation of individual mutations. Intrinsic resistance to antimicrobial agents is also common in both slowly and rapidly growing mycobacteria. In most instances this form of resistance appears to be the result of the impermeability of the mycobacterial cell envelope. For example, most MAC isolates are resistant to rifampin despite the fact that the isolate has a wild-type *rpoB* gene. However, *M. avium* resistance to isoniazid may reflect the lack of an effective antimicrobial activity rather than or in addition to a lack of permeability.[107] [108] Both *M. chelonae* and *M. abscessus* are intrinsically resistant to quinolones, while *M. fortuitum* is susceptible.

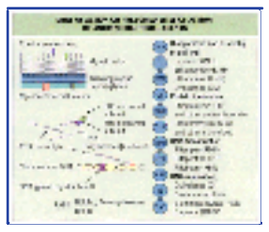

Figure 233-11 Sites of action or presumed sites of action of antimycobacterial agents. DHFR, dihydrofolate reductase; DHPS, dihydropteroate synthase; PABA, *p*-aminobenzoic acid; PAS, *p*-aminosalicylic acid. *Figure adapted from Parsons et al.*[105] *and Young.*[106]

TABLE 233-8 -- Antimycobacterial agents ranked by clinical use.

ANTIMYCOBACTERIAL AGENTS RANKED BY CLINICAL USE			
Species	**Primary or first choice**	**Secondary or second choice**	**Notes**
M. tuberculosis	INH, RMP, PZA, SM, EMB	Amikacin, ciprofloxacin, levofloxacin or sparfloxacin	Treatment plan varies depending on incidence of INH resistance in community, if MDR (INH plus RMP resistance), patient adherence (viz. DOT), other factors
M. bovis	INH, RMP, EMB		Uniformly PZA resistant, 9–12 months therapy recommended by some. Confirm identity of isolate, sometimes nontuberculous mycobacterium
M. leprae	Dapsone, RMP, clofazimine, clarithromycin	Ethionamide, prothionamide, minocycline, pefloxacin, sparfloxacin	Treatment plan varies depending on paucibacillary or multibacillary disease
M. avium	Azithromycin or clarithromycin, ethambutol, rifabutin	Amikacin, streptomycin, moxifloxacin	Isoniazid resistance is usual. Drugs and does vary depending on immunocompetency, disseminated or pulmonary or other, and treatment vs prophylaxis
M. intracellulare			
M. chelonae	Amikacin, cefoxitin, ciprofloxacin, clarithromycin, doxycycline or minocycline, sulfonamides	Imipenem, levofloxacin, tobramycin (*M. chelonae* only)	All resistant to INH, PZA, RMP, SM, EMB and clofazimine. EMB may be useful for treating *M. smegmatis.* Contamination with these species is common, confirm clinical significance
M. fortuitum			
M. abscessus			
M. kansasii	RMB, INH, EMB	Pyridoxine, clarithromycin, rifabutin, sulfamethoxazole	PZA resistance is uniform. Only test RMP; testing of INH and EMB can be misleading. Clarithromycin resistance occurs. Treatment for 12 or more months
M. scrofulaceum	Surgical excision without chemotherapy	Azithromycin, clarithromycin	INH and PZA resistant
M. ulcerans	Surgical excision, RMP, amikacin	EMB, trimethoprim-sulfamethoxazole, SM, ciprofloxacin, sparfloxacin	Chemotherapy rarely effective
M. marinum	Clarithromycin, minocycline, doxycycline, RMB, EMB, trimethoprim-sulfamethoxazole		INH and PZA resistant
M. haemophilum	Clarithromycin, rifabutin, ciprofloxacin. Surgical debridement		Limited clinical experience
M. simiae	Treat like *M. avium* complex		INH, RMP, EMB and PZA resistant
M. xenopi	Azithromycin, clarithromycin, RMP	Rifabutin, SM	
M. celatum	Clarithromycin		RMP resistant
M. genavense	EMB, RMP, rifabutin, clarithromycin	Amikacin, clofazimine	
M. gordonae	INH, RMP, EMB	Amikacin, ciprofloxacin	Common contaminate, confirm clinical significance
First-choice agents are expected to be active against wild-type isolates (i.e. from untreated patients); second-choice agents are less preferred, usually due to toxicity, expense or unclear efficacy. DOT, directly observed therapy; EMB, ethambutol; INH, isoniazid; MDR, multiple drug resistance; PZA, pyrazinamide; RMP, rifampin; SM streptomycin. (See also Chapter 202 .)			

Antimicrobial agents

There are a variety of antimicrobial agents available for the treatment of mycobacterial infections; however, until recently almost all clinical studies of these agents were focused on *M. tuberculosis* and to a lesser extent *M. leprae*. The emergence of MAC as an important opportunistic infection associated with HIV infection and increased recognition that rapidly growing mycobacteria are a significant cause of human disease led to an expansion in our knowledge about the activity of certain agents against these and other mycobacteria. Infections caused by rapidly growing mycobacteria must be treated with antimicrobial agents other than the primary antituberculous agents. *Mycobacterium avium* complex is resistant to isoniazid and only variably susceptible to rifampin, but MAC infections can be successfully treated with a macrolide and at least one other agent such as ethambutol. For most other species there is often only limited information about the effectiveness and efficacy of antimycobacterial agents, perhaps with the exception of *M. kansasii* and *M. marinum*. The antimicrobial agents recommended for the treatment of various mycobacterial infections are shown in Table 233.8 ; however, it is not always appropriate to perform susceptibility tests on all of the agents because of a lack of standardized procedures and well-established interpretive criteria (see also Chapter 202).

Susceptibility testing

The susceptibility testing of mycobacteria and the definition of antimicrobial resistance have been influenced by decades of focus on *M. tuberculosis*. Thus, there is more information about antimicrobial agents and the susceptibility testing of *M. tuberculosis* than for all other species of mycobacteria. Indeed, the susceptibility testing of many nontuberculous mycobacteria has been largely extrapolated from experience with *M. tuberculosis*, including adoption of the same interpretive criteria. In some instances this extrapolation has proven to provide useful and reliable information, but in other situations this practice can be misleading. Therefore, with the exception of the routine testing of *M. tuberculosis* isolates against the first-line antimycobacterial agents (isoniazid, rifampin, ethambutol, streptomycin and pyrazinamide), susceptibility testing of mycobacteria should be performed in laboratories with extensive experience in this aspect of clinical mycobacteriology. Although the laboratory can provide valuable guidance in the interpretation of results, the application of those results to the treatment of a patient with an uncommon mycobacterial infection is likely to require the involvement of a physician with experience in the management of such infections.

Critical concentrations

The most common method of susceptibility testing *M. tuberculosis* is based on the concept of 'critical concentrations' of antituberculosis agents and the percentage of resistant tubercle bacilli within a test population. Critical concentrations for antituberculosis agents were established on an empiric clinical basis. Therapeutic success was unlikely if the proportion of drug-resistant mutants within a population of *M. tuberculosis* isolated from a patient exceeded a threshold of 1% at a concentration of the antituberculosis agent that was known to be therapeutically effective against a 'wild-type' or fully susceptible strain. The susceptibility test method used to measure the percentage of resistance is, therefore, referred to as the 'proportion method'. The critical concentration may not be the same as the peak serum concentration of a drug and only recently has there been an interest in applying the use of minimum inhibitory concentration (MIC) testing to mycobacteria.[109] However, there are no standardized methods for MIC testing of mycobacteria and the testing of *M. tuberculosis* continues to follow the conventions of critical concentrations and the 1% growth inhibition threshold.

Test methods

Four methods are used for susceptibility testing of *M. tuberculosis*:

- agar proportion method,
- radiometric (Bactec460 TB) proportion method,
- absolute concentration method, and
- resistance ratio method.

The agar proportion and radiometric proportion methods are widely performed in the USA, UK and Western Europe and the following discussion will focus on these methods.

Agar proportion method

The proportion method can be applied as either a direct or an indirect test. In the direct test, a specimen that is positive for acid-fast bacilli by stain is used as the source of inoculum for the susceptibility test. The specimen is inoculated directly onto the test agar media with and without drugs. In the indirect test, a pure culture of acid-fast bacteria is used as the inoculum source for the susceptibility test. On average, the results of the direct test are available 3–4 weeks before the results of an indirect test. The results of a direct test should be confirmed with the indirect test. Inoculating several dilutions of a standardized suspension of mycobacteria onto Middlebrook 7H10 agar plates is the basis of the agar proportion method. The number of cfu that grow on the drug-containing plates or quadrants are compared with the number of cfu on a drug-free plate or quandrant. If the number of cfu that grow on drug-containing medium exceeds 1% of the total number of cfu on the drug-free medium, then the isolate is considered 'resistant' to that drug at that concentration. Some advocate the use of Middlebrook 7H11 agar because some drug-resistant strains of *M. tuberculosis* do not grow on the 7H10 medium.

Radiometric proportion method

The radiometric proportion method is simply an adaptation of the agar proportion method to the Bactec460 TB 12B medium and radiometric measurement of growth inhibition. The test isolate is inoculated into Bactec460 TB 12B medium with or without the addition of test drug. The concentration of mycobacteria inoculated into medium without drug is 100-fold less than the concentration inoculated into Bactec460 TB media with drug. If a drug inhibits the growth of the test strain such that the growth of the control (no drug with 100-fold fewer organisms) reaches a growth threshold before growth in the drug-containing medium reaches that same threshold, then the test isolate is considered susceptible to that drug at the concentration tested. Although partial inhibition of growth occurs, more commonly an isolate of *M. tuberculosis* is either fully susceptible (no growth) or fully resistant (growth exceeds the control). Nevertheless, the growth of resistant isolates may be particularly slow and a report that an isolate is susceptible to a drug should be made only after a full period of incubation. Resistance can be reported as soon as growth in the presence of a drug is detected and exceeds the growth of the control, but the report should be preliminary until the performance of the controls can be assured.

It is prudent to consider the limitations of the Bactec460 TB method. In some clinical situations the Bactec method might be best considered as a screening test because the method does not allow an estimate of the percent of resistant bacilli and is vulnerable to major errors (false susceptibility or resistance) due to mixed populations of mycobacterial species. Indeed, when a multiple drug resistance isolate of *M. tuberculosis* is detected for the first time using the Bactec460 TB method, the identity of the isolate should be confirmed and the presence of a contaminant or mixed culture should be ruled out before proceeding with the testing of secondary agents. Although the importance of promptly reporting a multiple drug resistant isolate of *M. tuberculosis* cannot be overstated, the consequences of a false report of multiple drug resistance must be recognized as well.

Pyrazinamide testing

Pyrazinamide is only active at an acidic pH, and therefore susceptibility tests for this drug must be performed in media with a pH of 5.5–6.0. Methods have been developed for testing pyrazinamide using either Middlebrook 7H10 agar or Bactec460 TB 12B media adjusted to pH 5.5 or 6.0, respectively. The Bactec460 TB method is more convenient and the higher pH is less toxic to *M. tuberculosis* isolates.[76] It should be noted that pyrazinamide monoresistance is rare in *M. tuberculosis* and virtually all *M. bovis* isolates are intrinsically resistant to pyrazinamide. Therefore, pyrazinamide testing of *M. tuberculosis* could be restricted to isolates that are known to be resistant to isoniazid or rifampin and the occurrence of pyrazinamide monoresistance is suggestive that the isolate is *M. bovis*.

Other methods

Three semi-automated mycobacteria culture systems have procedures for testing the primary antituberculosis agents (see Table 233.2), but only the MGIT system can be used to test PZA.[77] The absolute concentration method consists of inoculating media with and without antimycobacterial agents with a carefully controlled inoculum containing 2×10^3 -1×10^4 cfu of mycobacteria. Resistance is defined as growth that is greater than a certain number of cfu (usually 20) at a particular drug concentration and the drug

---

concentrations must be precisely confirmed for each batch of media. The resistance ratio method is similar to the absolute concentration method except that a second identical series of tubes are inoculated with the standard *M. tuberculosis* H37Rv strain. The susceptibility test results are expressed in terms of the ratio of the MIC of drug necessary to inhibit the growth of the test isolate of *M. tuberculosis* to that of the standard H37Rv strain. The advantage of this method is that small batch-to-batch variations in the test media can be disregarded because the results are normalized using the H37Rv strain.

Mycobacterium avium complex, *Mycobacterium kansasii* and other slowly growing mycobacteria

In-vitro susceptibility testing of MAC and most of the other nontuberculous mycobacteria, using the methods and interpretive criteria described for *M. tuberculosis*, has little value as a guide to antimicrobial treatment. One important exception is *M. kansasii*, for which in-vitro results based on the interpretive criteria used with *M. tuberculosis* correlate with clinical efficacy. Interpretive criteria have been proposed for clarithromycin and azithromycin, macrolides with proven efficacy in the

treatment of *M. avium* and other nontuberculous mycobacteria. For many uncommon nontuberculous mycobacteria (e.g. *M. simiae* and *M. szulgai*) there are few clinical cases, often initially confused with tuberculosis, to form a basis for interpretive criteria. Indeed, it is often difficult to distinguish between contamination, colonization, infection and disease with many of the nontuberculous mycobacteria, especially the rapidly growing mycobacteria.

In general, the in-vitro susceptibility testing of MAC has limited value primarily because of the lack of a correlation with clinical response and, therefore, the lack of interpretive criteria. The important exceptions are for azithromycin, clarithromycin and roxithromycin because these macrolides have proven clinical and microbiologic efficacy in the prophylaxis and treatment of MAC disease with interpretive criteria based, at least in part, on monotherapy trials in humans. Although wild-type MAC is uniformly susceptible to macrolides, macrolide resistance develops quickly with monotherapy. An analysis of these resistant isolates showed that over 95% of clinically significant macrolide resistance in MAC is a consequence of mutations in the V-domain of the 23S rRNA gene.[107] [108] Therefore, clinically significant macrolide resistance can be defined as a MIC for clarithromycin and azithromycin at pH 6.8 of =64µg/ml and =512µg/ml, respectively.[110]

Mycobacterium avium complex isolates from patients with breakthrough azithromycin, roxithromycin or clarithromycin prophylaxis can be tested against one macrolide. Testing one drug is sufficient, since all evidence indicates that resistance crosses between these macrolides. If a patient has not received macrolide prophylaxis, it is unnecessary to perform a susceptibility test on initial MAC isolates from blood or tissue to guide treatment. However, establishing baseline MIC values for a MAC isolate may prove valuable in interpreting susceptibility test results for a subsequent isolate from the same patient weeks or months later. Susceptibility testing is also warranted if a patient relapses, if the infection is intractable or if the clinical situation is desperate. Testing may assist in deciding to add drugs; however, macrolide treatment should probably be continued even in the face of resistance.

The interpretation of in-vitro test results for ethambutol should not be attempted at this time. Ethambutol is commonly used as a 'second' agent in the treatment of MAC to prevent macrolide resistance,[111] [112] but ethambutol has little or no therapeutic activity alone against MAC.[113] The drug does, however, increase the activity of other agents including macrolides and this may influence the mutation frequency.[114] The National Committee for Clinical Laboratory Standards (NCCLS) now recommends that MAC be tested using either a Bactec 460 or microtiter method.[115]

Mycobacterium marinum is predictably susceptible to rifampin and ethambutol; alternative agents are amikacin and kanamycin as well as tetracycline, doxycycline, minocycline, ciprofloxacin, clarithromycin and trimethoprim-sulfamethoxazole (co-trimoxazole). Routine susceptibility testing of *M. marinum* isolates using methods and interpretive criteria described for *M. tuberculosis* appears to be inappropriate and the methods and interpretive criteria for testing rapidly growing mycobacteria are more likely to provide clinically useful results. Wild-type isolates of *M. haemophilum* are susceptible to quinolones, rifamycins, clarithromycin and azithromycin, and resistant to pyrazinamide, ethambutol and are likely to be resistant to isoniazid and streptomycin.[116] *Mycobacterium simiae* is highly resistant to antimycobacterial agents; however, there are exceedingly few cases of disease to base any firm conclusions about susceptibility and clinical usefulness. Based on an animal test system, clarithromycin in combination with ethambutol and perhaps a quinolone such as ofloxacin is effective. [117] Testing *M. gordonae* isolates is usually inappropriate because actual disease is quite rare and contamination quite common. Before testing such isolates the following questions should be asked.

- Is the isolate a true *M. gordonae*?
- Is there convincing evidence that the isolate is playing a role in the disease?

Rapid growers

Although four methods have been described for measuring the invitro susceptibility of rapidly growing mycobacteria, the NCCLS now recommends only the broth microdilution method.[115] Broth microdilution provides a quantitative result and better supports the growth of *M. chelonae*. The broth microdilution method is essentially a modification of a standard method for nonmycobacteria that grow aerobically as described, for example, by Brown *et al.*[118] Commercially prepared broth microdilution panels can be used if the appropriate drugs are available at the necessary concentrations. Alternatively, broth microdilution panels can be prepared in house. The agents that should be tested are listed in Table 233.9 . The inoculum can be either a subculture in broth or prepared directly by picking colonies from a plate. Typically the plates are incubated for 3–5 days at 86°F (30°C) and longer periods of incubation should be avoided because of potential drug instability. The MIC is defined as the lowest concentration of antimicrobial agent that completely inhibits visible growth. The testing of rapidly growing mycobacteria should be restricted to laboratories with more extensive experience testing these mycobacteria.

MANAGEMENT AND PREVENTION

In general the treatment of mycobacterial infections requires the use of multiple antimicrobial agents administered over several months (e.g. 6–9 months). Patients with an underlying immunodeficiency or other complicating medical condition may require even longer periods of treatment, or in the case of people with HIV infection, some advocate lifelong treatment. Multiple agents are used to prevent the emergence of resistance,[119] but increasingly in the hope of achieving a synergistic effect and improved outcome. Disseminated and localized MAC infections can be successfully treated with a macrolide (clarithromycin) or an azalide (azithromycin), usually in combination with at least one additional agent such as ethambutol, but also rifabutin, amikacin or a quinolone. Indeed, clarithromycin and azithromycin have emerged as valuable chemotherapeutic agents for the treatment of several nontuberculous mycobacteria, if not as first-line agents, then as second-line agents.[58] For example, clarithromycin may be useful in the treatment of infections caused by

TABLE 233-9 -- Antimicrobial agents to test against selected mycobacteria as adapted from National Committee for Clinical Laboratory Standards (NCCLS). [115]

ANTIMICROBIAL AGENTS TO TEST AGAINST SELECTED MYCOBACTERIA		
Antimicrobial agent	**Susceptible (µg/ml)**	**Resistant (µg/ml)**
M. tuberculosis		
Primary agents		
INH	0.05–0.2	
RMP	0.5	
PZA	20	
EMB	1–5	
Secondary agents		
Streptomycin	8	
Capreomycin	1–50	
Kanamycin	5	
Cycloserine	5–20	
Ethionamide	0.6–2.5	
PAS	1	
Alternative agents		
Rifabutin	0.06–8	
Rifapentine		
Amikacin	1	
Ciprofloxacin	0.25–3	
Ofloxacin	0.5–2.5	
***M. avium* complex**		

Clarithromycin	=16	=64
Azithromycin	=128	=512
***M. kansasii* and selected other slowly growing mycobacteria**		
RMP	1–2	
Rifabutin	0.5–2	
Ethambutol	5	
Isoniazid	5	
Streptomycin	10	
Clarithromycin	32	
Amikacin	10	
Ciprofloxacin	2	
Trimethoprim-sulfamethoxazole	2/38	
Rapidly growing mycobacteria		
Amikacin	=16	=64
Cefoxitin	=16	=128
Ciprofloxacin	=1	=4
Clarithromycin	=2	=8
Doxycycline	=1	=16
Imipenem	=4	=16
Sulfamethoxazole	=32	=64
Tobramycin	=4	=16
Susceptible (µg/ml) for *M. tuberculosis* refers to the typical MIC for a susceptible isolate. Susceptible and resistant breakpoints for other mycobacteria refer to the NCCLS recommended breakpoints.		

M. chelonae, *M. abscessus*, *M. leprae*, *M. kansasii*, *M. marinum* and *M. malmoense*. Rapidly growing mycobacteria are resistant to the conventional antimycobacterial agents, but can be effectively treated with amikacin, cefoxitin, imipenem, ciprofloxacin, augmentin, sulfonamides and doxycycline as well as clarithromycin (see Chapter 38).

Prophylaxis with isoniazid for 6–12 months is recommended for people with significant exposure to drug-susceptible tuberculosis or following conversion of their skin test (see Chapter 37 and Chapter 202). In the latter situation, isoniazid is used more as preventive therapy than prophylaxis. Prophylaxis or preventive therapy is especially important in children, who are at greater risk than adults for extrapulmonary tuberculosis including meningitis. Clarithromycin, azithromycin and rifabutin are effective prophylactic agents for disseminated MAC infection in people with HIV infection with $CD4^+$ lymphocytes counts below 100 cells/mm^3 . The evidence now seems compelling that a restoration of $CD4^+$ cells to levels above this threshold, in response to treatment of HIV infection with highly active antiretroviral agents, is protective against disseminated MAC infection (see Chapter 129). [120]

CLINICAL MANIFESTATIONS

Tuberculosis in the most common form is a chronic pulmonary disease classified as either primary or post-primary disease. Post-primary disease can be a consequence of either reactivation (endogenous infection) or re-infection (exogenous infection). By far, the most common (95%) route of infection is inhalation of infectious droplet nuclei, but exposure to *M. tuberculosis* bacilli neither always lead to infection nor are all patients with disease infectious. Risk of infection is directly related to the number and distribution of tubercle bacilli in the inhaled and respired air, emphasizing the importance of infectious droplet nuclei to airborne transmission. Unless a patient receives prophylaxis, symptomatic disease eventually occurs in 5–10% of infected patients. The appearance and extent of disease varies with only one-half of infected patients developing disease within the first 2 years. Hematogenous spread of tubercle bacilli from the lung probably invariably occurs, but the bacteremia is usually occult and usually does not produce symptoms or disease. Nevertheless, hematogenous dissemination accounts for the occurrence of extrapulmonary involvement of lymph nodes, kidneys, reproductive organs, bones and gastrointestinal tract (see Chapter 37).

Leprosy is a chronic disease of the skin, nerves and mucous membranes. The immunologic response (e.g. hypersensitivity) becomes an important component of the pathogenesis of the disease. The clinical manifestations of leprosy have been separated into six categories according to the Ridley-Jopling classification scheme.[13] This classification system is both a clinical classification based on the nature and severity of symptoms and a histopathologic classification. The classification groups are:

- (1) polar tuberculoid,
- (2) borderline tuberculoid,
- (3) borderline,
- (4) borderline lepromatous,
- (5) lepromatous (subpolar), and
- (6) lepromatous polar.

Lepromatous leprosy is the most severe form of the disease with numerous skin lesions involving the face and nose. At one pole, lepromatous leprosy, acid-fast bacilli are numerous and present in immature macrophages while at the other pole, tuberculoid leprosy, macrophages have matured into epithelioid cells (see also Chapter 154).

Mycobacterium arium complex disease is frequently viewed as disease in two groups of patients, persons with and without underlying HIV infection. Although there are some similarities in the manifestation of MAC disease in both groups, the mortality rate, extent and pathologic manifestations of disease are frequently dissimilar.[121] Disseminated MAC disease in people with HIV infection is a progressive illness characterized by intermittent fever, sweats, weakness, anorexia and weight loss. Patients may have nausea, diarrhea and vomiting along with abdominal pain. The microbiologic hallmark of MAC disease is a positive blood or bone marrow culture; however, duodenal, rectal, spleen or liver biopsies may be diagnostic (Fig. 233.12). The level of the bacteremia ranges from intermittently culture positive to 10^6 cfu/ml. The level of infection of bone marrow may be orders of magnitude higher than in blood.[122]

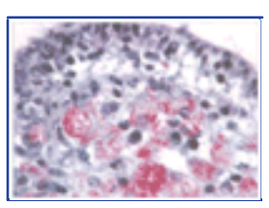

Figure 233-12 Acid-fast stain of a section of small intestine from a patient who has HIV infection and disseminated *Mycobacterium avium* disease. The photomicrograph shows many acid-fast bacilli within a villus tip of the intestinal tract biopsy. The cuboidal cells at the periphery of the tip are in disarray and appear abnormal with cell nuclei not evenly distributed at the base of the cells. There is no evidence of granuloma, but the overwhelming number of mycobacteria may be partially obscuring the host's cellular response. The histopathology is consistent with the symptoms of patients with MAC gastrointestinal tract infections, including abdominal pain, diarrhea and wasting. *Courtesy of LS Young.*

Disseminated MAC infection in people with HIV infection clearly decreases survival and treatment with a macrolide and another agent improves survival and the quality of life. MAC disease in people with HIV infection may be focal including pulmonary infection, peripheral lymphadenitis and cutaneous infection (see Chapter 129). The majority (=90%) of disseminated MAC disease is caused by *M. avium*; however, other species should be considered for symptomatic patients with negative cultures,

such as *M. triplex*, *M. genavense* and *M. conspicuum* or, for patients with cutaneous infections, *M. haemophilum* (see Table 233.4). In patients without underlying HIV infection, MAC can cause pulmonary disease, usually in patients with a history of chronic pulmonary disease, including patients with chronic obstructive pulmonary disease and cystic fibrosis. Symptoms are varied and non-specific, including chronic productive cough, dyspnea, sweats, malaise and fatigue (see Chapter 38).

Distinction between infection with MAC and transient colonization may be difficult. *Mycobacterium intracellulare* is isolated about as frequently as *M. avium*, but the isolation of *M. avium* has been associated with a poorer prognosis.

Mycobacterium arium complex lymphadenitis in immunocompetent children usually presents as an insidious, painless, unilateral process involving one or more lymph nodes. Mycobacteria isolated from infected lymph nodes are mostly (60–80%) MAC with the remainder being *M. scrofulaceum* and *M. tuberculosis* (see Chapter 39). *Mycobacterium arium* complex lymph node infection of children over 12 years of age is rarely simple lymphadenitis and may indicate disseminated disease and immunodeficiency. Disseminated MAC disease in HIV-negative patients is usually associated with congenital immunodeficiency, immunosuppression, malignancy or a specific immunodeficiency such as a deficiency in IFN-? production or IFN-? receptors. Disseminated MAC disease with visceral involvement has been associated with a high (82%) mortality rate in children without HIV infection.

Chapter 234 - Mycoplasma and Ureaplasma

Per-Anders Mårdh

INTRODUCTION

The first mycoplasma strain was isolated in 1936 from a female genital tract specimen and was most likely a strain of *Mycoplasma hominis*.[1] Since then a number of other *Mycoplasma* spp. have been recovered from the human genital tract and from other organ systems. They have been found in otherwise sterile samples such as blood, cerebrospinal fluid (CSF) and synovial fluid, as well as in pus from abscesses in a variety of organs.[2] [3]

The mycoplasmas and ureaplasmas taxonomically belong to the order Mycoplasmatales in class Mollicutes together with organisms of the families Acholeplasmataceae and Spiroplasmataceae. Apart from being human pathogens, some organisms of the order Mollicutes are economically important plant and animal pathogens.

The initial division of mycoplasmas into different species was based on inhibition of growth of the organisms on agar media by homologous antibodies. In later studies, sequencing of the genome of mycoplasmas has confirmed the relevance of the initial classification method.

The role of *Mycoplasma pneumoniae* in primary atypical pneumonia became established in the 1940s; earlier it was believed that the condition was caused by a virus, known as the 'Eaton agent'. Chanock and Hayflick succeeded in 1961 in isolating the organism on an agar medium.[4]

First recovered by Tully and Taylor-Robinson in 1981,[5] *Mycoplasma genitalium* is the most recently recognized human mycoplasma pathogen. It has been regarded as a urogenital pathogen, for example causing nongonococcal urethritis (NGU).[6] [7]

Ureaplasma urealyticum was first discovered in 1954 by Shepard.[8] It was isolated from the urethra of men who had signs of urethritis.[2] [3] Its role in NGU has, however, remained controversial and some studies indicate that *M. genitalium* may instead be the responsible agent in such cases.[6] *Ureaplasma urealyticum* is an otherwise common inhabitant of the genital tract of healthy people. Ureaplasmas have been associated with low-birth-weight infants and can cause neonatal meningoencephalitis.[9]

Apart from the species mentioned above, several other species of *Mycoplasma* occur in the human indigenous flora of the mouth and the genital tract (e.g. *Mycoplasma buccale, M. faucium, M. lipophilum, M. orale* and *M. salivarium*).

NATURE

Mycoplasma and ureaplasma measuring 400–500nm are the smallest organisms so far identified as being capable of reproducing in broth and on agar media; on the latter they form colonies barely visible to the naked eye.[10] They also have the smallest known genome of any 'free-living' organisms (i.e. 4.5 × 10^8 Da). The genome has been completely sequenced for some species.[11] The guanine and cytosine (GC) content is low (i.e. approximately 25% as compared with the approximately 80% found in eubacteria).

The organisms are regarded as so unique that they form their own taxonomic class (i.e. Mollicutes), which refers to their 'soft skin' (they lack the rigid cell wall found in eubacteria) and to their pleomorphic shape (Fig 234.1 and Fig 234.2). Thus, they differ from eubacteria by lacking peptidoglycan, which gives the latter a rigid shape and a strong osmotic stability. The mycoplasmas are surrounded by a 8–10nm thick protoplasma membrane. The absence of peptidoglycan and ß-lactam receptors (i.e. for penicillins and cephalosporins) explains their resistance to these antimicrobial agents interfering with cell wall integrity.

Interestingly, two of the human pathogens, namely *M. genitalium* and *M. pneumoniae*, have an adherence organ in contrast to the rest of the species of the family Mycoplasmataceae. [5]

Ureaplasma urealyticum derives its name from the fact that it processes the enzyme urease. Previously, the organism was called T-strain mycoplasma as it produced tiny (T) colonies in comparison to those of mycoplasmas. *Ureaplasma urealyticum* has remained the single species in the genus *Ureaplasma*, although there have been several proposals for a differentiation based, for example, on biochemical and serologic characteristics. Fourteen different serotypes of *U. urealyticum* have been described. One biovar of human ureaplasmas (biovar no. 1) has been called *Ureaplasma parvum*.[12]

EPIDEMIOLOGY

Mycoplasma hominis

This organism has been isolated from the fallopian tubes of women with laparoscopic signs of acute salpingitis (i.e. pelvic inflammatory disease (PID)), and in whom an antibody response to the organism could be demonstrated.[13] [14] The organism seems to be able to spread through the cervical canal via the uterine cavity as well as by the lymphatic vessels of the parametrium to the tubes (Fig. 234.3). The relative role of *M. hominis* and *M. genitalium* in endometritis and salpingitis is currently under investigation.

Mycoplasma hominis is a common finding in women who lack a lactobacilli-dominated vaginal flora and who present with a mixture of bacterial species in the vagina. Many of these species are strictly anaerobic, most of which normally occur in the intestinal flora. Up to 75% of all women with a flora change, such as that seen in bacterial vaginosis (BV), are carriers of *M. hominis*.[15] A role for *M. hominis* in both BV and non-specific vaginitis has been considered, but has been difficult to prove. One of the reasons is that *M. hominis* can also occur in the vagina of women with vaginal flora changes who do not fulfill the criteria for BV.[16] The recovery rates of *M. hominis* (and of *Mobiluncus* spp.) in women with BV, trichomoniasis, vulvovaginal candidosis and in a group of healthy women are shown in Table 234.1 .

Salpingitis can occur as secondary infections of the fallopian tubes in women in whom the tubes have been primarily damaged by sexually transmitted disease agents, such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.[17] *Mycoplasma hominis* may increase the risk for tubal occlusion and infertility, if infection has already damaged the tubes.

Mycoplasma hominis has been recovered from blood of women who have had a septic (febrile) abortion.[18] A significant change in

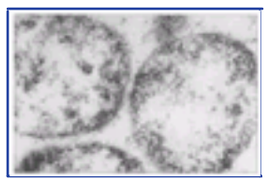

Figure 234-1 Electron micrograph of a mycoplasma organism. It has a diameter of approximately 300nm and lacks a rigid cell wall containing peptidoglycan.

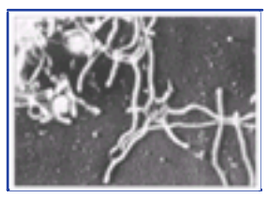

Figure 234-2 Electron micrograph of a mycoplasma organism producing filamentous structures in a broth culture. This gives the organism the appearance of a fungal mycelium. ('Myco' in mycoplasma refers to this feature.)

Figure 234-3 Modes of spread of *Mycoplasma hominis* to the upper genital tract. The canalicular spread to the tubes is indicated in the lower panel of the figure and the lymphatic spread to the parametria in the upper one.

the antibody titer to the organism has been found in such patients. *Mycoplasma hominis* has also been recovered from blood cultures of women with postpartum fever. These findings have been associated with a specific antibody response and a positive culture from the amniotic surface of placentas of such cases. A pure culture of

TABLE 234-1 -- Recovery of *Mycoplasma hominis, Mobiluncus mulieris* and *Mobiluncus curtisii.*

RECOVERY OF *MYCOPLASMA HOMINIS, MOBILUNCUS MULIERIS* AND *MOBILUNCUS CURTISII*				
Study group	**No. tested**	**No. of persons positive for**		
		M. hominis	***M. mulieris***	***M. curtisii***
Bacterial vaginosis	62	31	51	47
Trichomoniasis	13	3	0	0
Candidiasis	37	1	0	6
Healthy women	25	5	2	6
Partners to BV cases	47	8	1	5
Samples taken from women with bacterial vaginosis (BV), vulvovaginal candidiasis and trichomoniasis, and from healthy females and male partners of women with BV.				

M. hominis has been obtained from synovial fluid of a woman postpartum who had septic arthritis.

Mycoplasma hominis has also been recovered from the blood and CSF of newborns with signs of sepsis and meningoencephalitis.[15] [19] [20] There is a series of case reports in the literature of infants infected by *M. hominis* with malformation of the central nervous system, such as spina bifida, but also in cases without any malformation.[15] A significant antibody response to *M. hominis* has been detected in infants who have signs of pneumonia and from whom *M. hominis* has been isolated from the upper respiratory tract. In stillbirth, the organism has been recovered from lung and liver tissue.

There is no evidence that either *M. hominis* or *U. urealyticum* is the cause of bartholinitis as earlier believed.

Mycoplasma genitalium

Mycoplasma genitalium has been claimed to play an etiologic role in acute and possibly also in chronic cases of NGU.[6] Further studies have supported an independent role of *M. genitalium* and *Chlamydia trachomatis* in NGU in men.[7] Likewise, *M. genitalium* has been recovered from the urethra of HIV-infected men.[21] It can be found in urethral cultures from men with and without urethral discharge. There is no evidence of a role for the organism in chronic prostatitis.

In a recent study of women in the second and third trimesters of pregnancy, *M. genitalium* was recovered from vaginal lavage samples in 1.6% of the 500 women who had reached the second trimester. This percentage had increased in those who returned for repeated examination in the third trimester. The corresponding percentages for *M. hominis* were 10.8 and 22.3, respectively.[22]

Mycoplasma genitalium is likely a cause of cervicitis and endometritis[23] which may induce pre-term birth. Carriage of *M. genitalium* was associated with mucopurulent discharge, smoking, frequent vaginal douching and a history of miscarriage.[24] On the other hand, there seems to be no evidence of an association with bacterial vaginosis.

Mycoplasma genitalium antibodies were detected in 40% of women with PID, in whom microimmunofluorescence tests indicated a 4-fold or greater titer change within 1 month of clinical onset of upper genital tract infection.[25] Such antibodies were detected by immunoblotting in approximately half of the women with proven tubal factor infertility, and there was a correlation between the occurrence of specific anti-mycoplasma antibodies and tubal scarring.

Mycoplasma genitalium has also been associated with pneumonia and arthritic conditions.[26]

Mycoplasma pneumoniae

Mycoplasma pneumoniae infection is one of the most frequent causes of atypical pneumonia.[26] [27] [28] [29] Endemic infections occur on

a regular basis in between epidemic outbreaks which, at least for some decades, occurred in many countries every 3–5 years. However, this sequence pattern has become less distinct in many countries during recent decades.

Young adults are particularly affected by *M. pneumoniae*. The incubation period, as indicated by case-to-case transmission studies, is estimated at a mean of 20 days (range 11–25 days). The reported attack rates in closed communities, such as in families, have been 17–66%. [26] [30]

Ureaplasma urealyticum

The prevalence of *U. urealyticum* in the genital tract is associated with sexual experience.[2] Disappearance of the organism from the genital tract after long-term sexual abstinence has been documented.

There have been a large number of studies on the possible role of *U. urealyticum* in NGU, since it was first recovered from the urethra of US military men by Shepard.[8] One major problem in evaluating its possible role in nongonococcal, nonchlamydial urethritis has been to find suitable comparison groups as the organism is a very common member of the indigenous microbial flora of the male urethra. A quantitative approach in culture studies of *U. urealyticum* in NGU cases has been undertaken. If the organism establishes itself as a pathogen, it is likely to increase in number. However, such studies have not been consistent and are therefore difficult to interpret.

Furthermore, an extensive etiologic investigation is required to prove a role of *U. urealyticum* in NGU, including highly sensitive diagnostic tests for *Chlamydia trachomatis* and *M. genitalium*.[7] However, these organisms were not known at the time when many of the NGU studies were performed. Phenotyping and serotyping of ureaplasma isolates and antibody tests have not confirmed a pathogenic role for *U. urealyticum* in NGU. The difference in susceptibility of *U. urealyticum* and other possible causative agents of urethritis has been utilized in attempts to establish the role, if any, of *U. urealyticum* in NGU.[2] [3] However, none of the studies have yielded conclusive results.

Ureaplasma urealyticum often recolonizes the genital tract of individuals after attempts to eradicate it by antibiotic therapy. This may be seen as a criterion for the organism belonging to the indigenous human microbial flora, meaning that it does not represent an exogenous pathogen.

Like most organisms found in the urogenital tract of men, *U. urealyticum* has also been proposed to be a causative agent of nonbacterial prostatitis. Cultures of urethral secretion, voided urine as well as expressed prostatic fluid do not prove an etiologic role of ureaplasmas in prostatitis because of the risk of contamination of the samples from nonprostatic sites. Likewise, antibiotic therapeutic trials cannot easily prove such a role of the agent in nonbacterial prostatitis.

Ureaplasma urealyticum is found in the lower genital tract in up to 75% of all women of reproductive age. It may ascend to the fallopian tubes.[13] Treatment of infertile couples with tetracyclines has provided inconclusive support for a role for *U. urealyticum* as a cause of infertility.

The higher recovery rate of *U. urealyticum* from babies with low birth weight than from infants of normal weight has remained a puzzling observation. There is also a statistical correlation of carriage of *U. urealyticum* with pre-term birth. Several studies have shown that *U. urealyticum* is a comparatively common isolate, not only from the urethra [31] but also from amniotic fluid in women with adverse pregnancy outcome, such as premature birth.[24] The organism may be recovered from the respiratory tract of newborns. Respiratory distress syndrome, the need for assisted ventilation, severe respiratory insufficiency and death of newborns have been found to be more common in those colonized than not colonized by *U. urealyticum* in the nasopharynx or elsewhere in the upper respiratory tract. Studies have not proved an etiologic role of *U. urealyticum* in chronic lung disease in persons born pre-term.

It is an important observation that *U. urealyticum*, like *M. hominis*, can cause meningoencephalitis in newborns. Such infections should be considered as a differential diagnosis in any investigation of meningitis in newborns, particularly when the CSF glucose level is normal.[15] [20]

PATHOGENICITY

Pathogenetic mechanisms are not known for the vast majority of *Mycoplasma* spp. One obvious exception is *M. neurolyticum*, which produces a neurotoxin, explaining the course of infections by this animal pathogen.

Mycoplasmas are generally epiparasites, attaching to eukaryotic cell surfaces. However, the fact that *M. genitalium, M. fermentans* and *M. penetrans* can grow intracellularly means that the organisms can be protected from many host defense mechanism. For example, in experimentally infected vero cell cultures *M. genitalium* penetrated the cells. This capability may give the organism the ability to persist in AIDS patients, from whom the organisms have been recovered (see below).[21] [32] [33] [34] [35] [36] [37] [38]

Both *Mycoplasma pneumoniae* and *M. genitalium* have a flask-like appearance under the electron microscope.[5] They both have an adherence organ. These structures probably represent a pathogenic mechanism. The adherence structure has a 170kDa epitope, which is shared by *M. pneumoniae* and *M. genitalium*. A distinct binding site for *M. pneumoniae* on mononuclear cells has also been identified. *Mycoplasma pneumoniae* is motile and produces hydrogen oxide, which may contribute to its pathogenicity.

Both *M. hominis* and *M. genitalium* are able to cause salpingitis experimental infections in subhuman primates.[39] [40] Oviduct inoculation of *M. genitalium* in grivet monkeys and marmosets resulted in a moderate-to-severe endosalpingitis with consequent adhesions between the mucosal folds. The changes were similar to those found in experimental infections by *M. hominis* and *C. trachomatis* as well as being consistent with alterations seen in women naturally infected with these agents who had developed PID.

In tissue cell cultures of human fallopian tubes infected by *M. hominis*, a pathologic swelling or so-called 'ballooning' of the cilia has been seen (Fig. 234.4). Whether a similar phenomenon occurs in vivo in women who have contracted the organism is, however, not known.

In mice, estradiol predisposes animals to infection by *M. hominis*. Progesterone induces susceptibility to *M. genitalium* in the murine genital tract when the organism has been installed intravaginally. However, this does not account for experimental infection with *M. hominis* in this animal model.

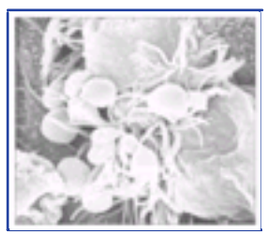

Figure 234-4 Swelling ('ballooning') of cilia in tissue cell cultures experimentally infected by *Mycoplasma hominis.*

Mycoplasma pneumoniae causes a polyclonal stimulation of both B and T lymphocytes and results in cytokine production. A marked increase in the total serum IgM is often seen in people infected by *M. pneumoniae*, often by as much as 100% or more.[30] [41]

Antibodies directed against the blood group antigen (i.e. cold agglutinins) may occur in *M. pneumoniae* infection and may, although very seldom, cause hemolytic anemia and intravascular coagulation, which may be fatal.[26] [27]

The development of antibodies to a number of tissue antigens (e.g. to brain[42] and kidney tissue epitopes) occurs as a transient autoimmune phenomenon in persons infected by *M. pneumoniae*, often without any obvious pathologic effects.

Ureaplasma urealyticum has the ability to split urea, which has been considered to be a mechanism by which the organism could cause stone formation in the urinary tract, including calculi formation in the kidney pelvices. Calculi formation has been seen in female rats experimentally infected by *U. urealyticum* after bladder installation of the organism. It is not clear, however, whether colonization by ureaplasmas occurs more easily in persons who have already developed stones in the urinary tract.

Ureaplasma urealyticum also expresses a specific immunoglobulin A1 protease that cleaves human immunoglobulin into Fab and Fc fragments, the clinical relevance of which is unknown.

Colonization with *U. urealyticum* in experimentally infected female mice is enhanced by estradiol therapy.

There have been several observations of a correlation between low birth weight and culture positivity for genital mycoplasmas and/or ureaplasmas from the nose and throat in newborns.[2] [3] The influence on pregnancy outcome has remained difficult to explain. Therapeutic trials in which the organisms have been eradicated from the lower genital tract of pregnant women resulting in an increased birth weight of their offspring is an even more puzzling observation. Confounding, unrecognized factors might have played a role.

Mycoplasmas and AIDS

It has been claimed that *M. fermentans* might play a role in AIDS.[33] [34] [36] When first recovered from AIDS patients, the isolates of *M. fermentans* were named *M. incognitus*. The organism has been detected in urine samples and antigen of the organism has been detected in blood samples of HIV-infected persons.

Mycoplasma genitalium has been recovered from genital samples of AIDS patients.[21] In contrast to many of the infections observed in untreated AIDS patients, no

relation between *M. genitalium* positivity on one hand and $CD4^+$ lymphocyte count, HIV p24 antigenemia and any opportunistic infections on the other has been demonstrated, and it is no longer believed that mycoplasma have any causative role.

PREVENTION

Prevention of mycoplasmal genital infections should follow the principles of any sexually transmitted infection, including partner notification and treatment of infected partners at the same time as the index case to prevent 'ping-pong' infections. However, there are no data proving the positive effect of such interventions.

As there is a markedly increased risk of tubal occlusion with each new episode of salpingitis and thereby a risk of infertility, eradication of *M. hominis* may be indicated in females who are vaginal carriers of the organism and who have a history of PID.

Treatment of pregnant women who are carriers of *M. hominis* and *U. urealyticum* to prevent obstetric and perinatal infections has been recommended, but there is no hard evidence for such a recommendation. It is unclear whether *M. genitalium* should be screened for and whether therapy should be given both to carriers and their sexual partners.

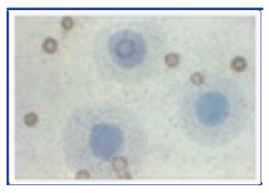

Figure 234-5 Colonies of *Mycoplasma hominis* on PPLO agar with 'fried egg' appearance.

Prevention of mycoplasmal (i.e. *M. pneumoniae*) respiratory tract infections is generally not feasible.

DIAGNOSTIC MICROBIOLOGY

Mycoplasmas can be recovered on special pleuropneumonia-like organism (PPLO) agar media, where they produce colonies with a characteristic 'fried egg' morphology (Fig. 234.5). Growth inhibition on agar media by species-specific antibodies (lysis of organisms) has been used for speciation of mycoplasmas. Growth inhibition in broth cultures by specific antisera (e.g. in tests for interference with arginine metabolism by growing mycoplasmas) has also been used for this purpose. The latter test, however, requires reading the result at an unpredictable time after initiating the test, making it impractical to use.[10]

The suitability of each batch of mycoplasma medium should be checked before use (e.g. serum components may be toxic to the mycoplasma organisms). A number of commercial media are available. Solid media should be incubated at 36°C or 96.8°F in an atmosphere of 5% carbon dioxide (for ureaplasmas the concentration may be as high as 15%) and 95% nitrogen.[10]

Polymerase chain reaction (PCR) has become more frequently used for diagnosing mycoplasma infections.[31] [43] Specific primers that assess not only the occurrence of the organism but also its species can be obtained. Anti-*M. pneumoniae* IgM antibodies are often not detected in pneumonia caused by the agent.[44] Also, secretory IgA antibodies to *M. pneumoniae* occur in cases with other types of respiratory tract infections and in healthy controls. Culture facilities are generally not available and, even if they are, cultures are often negative in cases where serologic tests indicate a current infection by the agent.

Mycoplasma pneumoniae

Attempts to diagnose *M. pneumoniae* infections by culture usually fail. If successful, it takes weeks before colonies (Fig. 234.6) can be detected when inspected under a microscope. *Mycoplasma pneumoniae* can be distinguished from other human *Mycoplasma* spp. by its

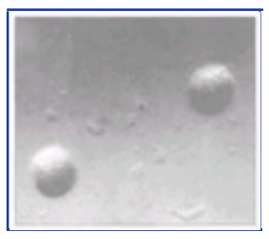

Figure 234-6 Colonies of *Mycoplasma pneumoniae* on PPLO agar with 'golf ball' appearance.

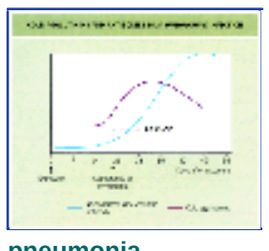

Figure 234-7 Kinetics of appearance of cold agglutinins and specific antibodies to *Mycoplasma pneumoniae* related to time after being taken ill with *M. pneumoniae* pneumonia.

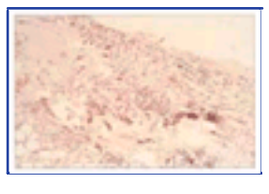

Figure 234-8 Section of parametrium from which *Mycoplasma hominis* was recovered. The patient had parametritis and developed an antibody response to the organism.

ability to adsorb red blood cells, resulting in a mulberry-like appearance of the colonies.

Serology and detection of cold agglutinins have played a more important role in diagnosis of *M. pneumoniae* than culture studies (Fig. 234.7). [26] Detection of IgM antibodies to *M. pneumoniae* has a limited diagnostic value for detecting current infection. Cold agglutinins occur before specific antibodies to *M. pneumoniae* appear (see Fig. 234.7). However, detection of cold agglutinins alone has low sensitivity and specificity in patients with community-acquired pneumonia. The possibility of diagnosing *M. pneumoniae* pneumonia by one seropositive sample plus a positive cold agglutinin test has been stressed.[27] At admission, an IgM antibody response to *M. pneumoniae* has been shown in 86% of patients with *M. pneumoniae* pneumonia. However, some have questioned the diagnostic value of such antibody tests in routine practice. Approximately 20% of patients with such pneumonia have not developed a specific antibody response to *M. pneumoniae* at their first visit. Antibodies to a number of tissue antigens develop during the course of a *M. pneumoniae* infection,[42] the clinical significance of which has remained unestablished.

Progress in the diagnosis of infections by *M. pneumoniae* has been achieved by the use of nucleic acid-based techniques [43] [45] (e.g. ^{125}I-labeled DNA probe), directed against sequences specific for *M. pneumoniae* rRNA (GenProbe) or probes. The test has the disadvantage of requiring metabolically active organisms but it has been claimed to be more sensitive than enzyme immunoassays. PCR tests can detect only 10^2 –10^3 organisms/ml, but adequate internal controls are necessary to avoid false-negative results. The usefulness of PCR tests is limited in the post-therapy situation, as dead *M. pneumoniae* organisms may be detected. Such organisms are shed for up to 1 month after finishing antibiotic therapy. A comparison of the outcome of cultures, PCR tests and serology in suspected *M. pneumoniae* cases showed that, in 21 cases in which cultures were performed, 19 were found to harbor the organism and 14 of the same 21 cases were seropositive for the organism. Only two of another 62 culture- and serology-negative cases were positive for *M. pneumoniae* in a study using a PCR assay. Both sputum and pharyngeal swabs may be tested by PCR to prove a mycoplasma etiology in pneumonia cases.

Mycoplasma pneumoniae DNA has also been detected in intestinal biopsy samples of persons with inflammatory bowel disease (e.g. in cases of Crohn's disease and

in those with ulcerative colitis as well as in healthy controls).[46]

Thus, there are obvious difficulties in diagnosing *M. pneumoniae* infections, even when laboratory support makes use of PCR assays. The use of more than one diagnostic test may be helpful. The clinical picture may also be misleading. For example, there may be difficulties in distinguishing between mycoplasmal and chlamydial infections.[47] The diagnostic difficulties have been stressed by the US Practice Guidelines for the Management of Community-acquired Pneumonia, which state that it is not possible to diagnose *M. pneumoniae* infection with any degree of accuracy in a routine health care situation.[28]

Mycoplasma hominis

Mycoplasma hominis is easy to isolate on agar media.[10] Isolates can be typed by homologous antisera, causing growth inhibition. The capacity of *M. hominis* to metabolize arginine can be tested by the production of ammonia as an end-product, the presence of which results in a pH increase that can be visualized by an indicator strip. Colonies of *M. hominis* produce pinpoint nonhemolytic colonies on blood agar plates. Polymerase chain reaction tests may also be used.[32]

Mycoplasma genitalium

Mycoplasma genitalium is difficult to grow on artificial media, which is why the introduction of PCR-based methods for its detection has been important. The organism is susceptible to thallium acetate. This may explain why it has been detected only recently, as thallium acetate has often been added to mycoplasma media to reduce any overgrowth of eubacteria and fungi. [7]

Ureaplasma urealyticum

Growth in a broth medium containing urea and an indicator causing a color change has been used to diagnose ureaplasmas.[10] This test is useful for detection of ureaplasmas in genital samples. Tests for the urea-splitting capability of ureaplasmas can also be carried out on agar media, where the color of colonies of *U. urealyticum* turns dark brown after adding the test substrate. Ureaplasmas do not grow in the presence of thallium acetate, which is often used in mycoplasma media to avoid overgrowth of other microbes. Using 16S rRNA gene-based PCR tests, *U. urealyticum* is more often detected in the lower female genital tract than by culture.[32]

CLINICAL MANIFESTATIONS

Women with *M. hominis* salpingitis may be afebrile and present with a malodorous vaginal discharge that is often characterized as 'having a smell of rotten fish'. They may have palpatory pain over the adnexa and pain at movement of the cervix during vaginal examination. However, as in PID of any etiology, mycoplasmal PID may be more or less asymptomatic.[13] *M. hominis* may cause parametritis (Fig. 234.8).

Figure 234-9 *Mycoplasma pneumoniae* pneumonia. There were few signs on auscultation.

Mycoplasma hominis sepsis may be suspected in women who have aborted and who develop fever, particularly in cases in which bacterial blood cultures are negative for bacterial pathogens.

Symptoms of *M. pneumoniae* infections are initially malaise, muscle pain, headache, fever, throat pain, chills and nonproductive cough. The latter occurs in up to 90% of cases.[26] [28] [29] [41] [48] The symptoms and signs of mycoplasma pneumonia are more like those of a viral than a bacterial pneumonia. However, cough and headache do occur more often, and rhinitis less often, in mycoplasmal than viral pneumonia cases. Later, often after 1–2 weeks, cough may become productive and, although less commonly, hemorrhagic. The expectorate is often sparse. Cough may continue during the convalescent period. Tracheitis, bronchitis and tracheobronchitis may occur, but less often than pneumonia. Severe deterioration of the general condition may occur with high body temperature, due to the development of generalized aveolitis.

Findings on auscultation are often sparse or even normal, even when there are obvious radiographic changes. The alterations are usually unilateral and found in a lower lobe (Fig. 234.9). Chest radiography usually shows multiple interstitial or alveolar consolidation in one of the lower lobes, often radiating from the hilum. A solid lobular consolidation may be seen and there may be pleuritis. The chest radiographic findings may be mistaken for a viral pneumonia. Symptoms of fatigue may last for many months, and in children this may result in poor performance at school.[49] (see Chapter 34)

In children, the clinical course of a *M. pneumoniae* infection usually runs a milder course than in adults.[28] The infection in children may even pass as a clinically silent or relatively asymptomatic upper respiratory infection that ones pay no attention to. In elderly persons, the infection may manifest itself as pharyngitis, laryngitis or bronchitis rather than pneumonia.

Truly asymptomatic *M. pneumoniae* infections are uncommon. Only a small percentage of such infections run a clinically silent course as evidenced from serologic findings. Transient carriage of *M. pneumoniae* may occur after repeated exposure in those who have developed a cellular immunity to *M. pneumoniae*.

Mycoplasma pneumoniae infection has been associated with a large number of other conditions (Table 234.2) although in many cases evidence to support an etiologic role for *Mycoplasma* is uncertain.[30] [41] [48] [50] [51] [52] [53]

Death in infections with *M. pneumoniae* is very unusual. In such cases, either intravascular coagulation or complications from the central nervous system have been diagnosed. At autopsies of

TABLE 234-2 -- Clinical manifestations of *Mycoplasma pneumoniae* infection.

CLINICAL MANIFESTATIONS OF *MYCOPLASMA PNEUMONIAE* INFECTION	
Respiratory tract	Pharyngitis, laryngitis, acute bronchitis, bronchopneumonia
Skin and mucosa	Maculopapular and vesicular exanthema, urticaria, purpura, erythema nodosum, erythema multiforme, Stevens-Johnson syndrome
Central nervous system	Meningitis, meningoencephalitis, acute psychosis, cerebellitis, Guillian-Barré syndrome?
Parenchymatous organs	Pancreatitis, diabetes mellitus, non-specific reactive hepatitis, subacute thyroiditis?
Miscellaneous	Hemorrhagic bullous myringitis, hemolytic anemia, pericarditis, thromboembolism?
Some associations remain uncertain.	

persons who died of *M. pneumoniae* infection, diffuse interstial pneumonia has been demonstrated. Other autopsy findings have included bronchial edema. Histology has revealed macrophage, lymphocyte and plasma cell infiltrates in bronchial tissue.

The broad spectrum of complications described in *M. pneumoniae* infections must be considered in the light of recent studies that have found that nucleic acid tests for *M. pneumoniae* may often be positive even in healthy individuals. That is, without serologic evidence of an ongoing acute infection, it is difficult to confirm any etiologic relationship to various conditions.

MANAGEMENT

Mycoplasmas are resistant to ß-lactam antibiotics as they lack a cell wall and penicillin-binding proteins. They are generally susceptible to tetracyclines. Tetracycline resistance in *M. hominis* is, however, common in certain areas[54] and is often due to decreased intracellular uptake of the drug.[55]

Children should not be given tetracylines. Erythromycin is the drug of choice for children, except for infections by *M. hominis*, which has natural resistance to this antibiotic. The reason for this diversity from all other species of *Mycoplasma* is unknown. Clindamycin is a suitable alternative for *M. hominis* infections in newborns.

Azithromycin and clarithromycin are alternative drugs for the treatment of *M. pneumoniae* infections in adults. Intravenous treatment of *M. pneumoniae* pneumonia has not proved to be superior to oral therapy (see Chapter 34).

Mycoplasma genitalium has an antibiotic susceptibility pattern similar to that of *M. pneumoniae* (i.e. being susceptible to macrolides and tetracyclines).[56] [57] Azithromycin has been recommended for therapy of *M. genitalium* infections.

Aminoglycosides and chloramphenicol are second- and third-line therapy alternatives. Chloramphenicol has, however, been used successfully to treat meningoencephalitis in newborns infected by tetracycline-resistant strains of *M. hominis*.

A number of antibiotics are less active against mycoplasmas than macrolides and tetracyclines (e.g. quinolones, such as cinoxacin, ciprofloxacin and norfloxacin). Sparfloxacin is the most active quinolone against *M. genitalium*.[57] Mycoplasmas, like ureaplasmas, are resistant to sulphonamides and trimethoprim-sulfamethoxazole.

Ureaplasmas are known to have a similar susceptibility pattern to mycoplasmas. However, they are usually susceptible to erythromycin, in contrast to *M. hominis*.

Mycoplasma pneumoniae pneumonia in adults can be treated with a macrolide or tetracycline.

For younger patients, apart from those infected by *M. hominis*, erythromycin can be given for 10–14 days with a dose adjusted to the weight of the infant or child under treatment.[28]

Chapter 235 - Rickettsia and Rickettsia-like Organisms

Peter R Mason
Patrick J Kelly

INTRODUCTION

The family Rickettsiaceae was established to accommodate fastidious, obligate intracellular, pleomorphic coccobacilli that could not survive for long outside the host cell and were transmitted to vertebrate hosts by arthropods. Members of the family usually stained weakly with Gram's stain but stained well with Giemsa or Gimenez stains. Cross-reactivity with antisera indicated that they shared common antigens, although this did not always lead to cross-protection against infection. Two organisms, *Rochalimaea* (now *Bartonella*), which was capable of growth in cell-free media, and *Coxiella*, which was able to survive outside a host cell for long periods of time, were regarded as rickettsias because of their morphologic similarity to other members of the family and because of their association with arthropod vectors. The family was further divided into three tribes, Rickettsiae, Ehrlichiae and Wolbachiae on the basis of pathogenicity for humans, pathogenicity for other vertebrate animals or exclusive association with insects, respectively. All human pathogens then known were classified in the tribe Rickettsiae.

Molecular techniques are now used to classify bacteria. Phylogenetic trees, constructed from 16S rRNA gene sequences, show three major groups of rickettsias, each belonging to a different subdivision of the Proteobacteria. The genera *Rickettsia*, *Ehrlichia* and *Anaplasma* belong to the a_1 subdivision, the genus *Bartonella* is found in the a_2 subdivision, and these two groups are themselves only distantly related to *Coxiella*, which belongs to the ? subdivision (Fig. 235.1).

Within the genus *Rickettsia*, three groups were originally recognized: the typhus group, the spotted fever group and the scrub typhus group. Molecular techniques show close affinity between the typhus and spotted fever groups, confirming their status as members of the same genus. On the basis of differences in ultrastructure and DNA composition the causative organism of scrub typhus, *Rickettsia tsutsugamushi*, has been reclassified into a new genus, *Orientia*. Some members of the genus *Ehrlichia* are now known to infect humans and cause diseases that were previously unrecognized. Finally, an increasing number of members of the genus *Bartonella* are being recognized as human pathogens and the cause of an expanding array of diseases. The field of rickettsiology is thus undergoing rapid change and expansion, with recognition of new organisms, of new relationships between rickettsias and other bacteria, and of new diseases.

The rickettsias are found on all continents, occupying many different ecologic niches and are associated with a variety of arthropod and vertebrate hosts. Human rickettsioses may be subclinical, may cause mild, self-limiting disease or may cause severe, life-threatening disease. In general, early treatment greatly decreases the severity of infection, with consequent reduction in the risk of mortality. Unfortunately, early diagnosis is seldom easy. Tick bites are often painless and go unnoticed. Rickettsioses are clinically non-specific, and isolation of organisms requires specialized techniques and carries a risk to laboratory staff. Serodiagnosis is simpler and safer, but the commonly used Weil-Felix agglutination test has low sensitivity and specificity. Even with more reliable serologic tests, false-negative results are common early in infection. A high index of suspicion is therefore critical in detecting rickettsioses. Fortunately, most infections respond rapidly to therapy with widely available antibiotics.

SPOTTED FEVER GROUP RICKETTSIAS

NATURE

The spotted fever group (SFG) rickettsias are intracellular coccobacilli, of 1µm × 0.3µm, that are found within the cytoplasm, and sometimes the nucleus, of the host eukaryotic cell. Ultrastructural studies show that the cell membrane has an inner leaflet that is thicker than the outer leaflet, a characteristic that distinguishes *Rickettsia* from related genera. The cell wall has a high content of lipopolysaccharides (LPS), which are highly immunogenic and are responsible for the serologic cross-reactivity of different SFG rickettsias. The LPS also confers cross-reactivity with *Proteus* and *Legionella*. High-molecular-weight proteins can be recognized in cell-wall preparations using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), and specific antigenic characteristics have been demonstrated by Western blot.[1]

The SFG rickettsias do not grow on cell-free media but will grow in animals, including guinea pigs and embryonated chicken eggs, and in tissue cultures. Members of the group are often distinguished using reactivity with homologous and heterologous murine antisera in the micro-immunofluorescence (MIF) test. The reliability of this is

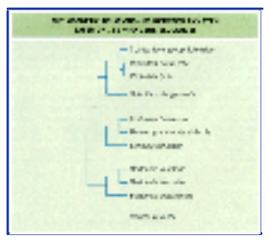

Figure 235-1 Phylogenetic relationships between rickettsias based on 16S rRNA gene sequences.

unclear, however. If molecular criteria were strictly applied, many of the currently recognized 'species' would have to be considered serotypic variants of *Rickettsia rickettsii*, despite the differences in epidemiologic, antigenic and pathogenic characteristics.

Before 1984, only six SFG rickettsioses were recognized: Rocky Mountain spotted fever, Mediterranean spotted fever, Siberian tick typhus, Queensland tick typhus, rickettsialpox and Israeli spotted fever. Another eight new tick-borne rickettsioses have been described in recent years: Japanese spotted fever, Chinese spotted fever, Flinders Island spotted fever, Astrakhan fever, African tick bite fever and three so far unnamed spotted fevers (caused by *Rickettsia mongolotimonae*, *Rickettsia helvetica* and *Rickettsia slovaca*). In addition, the ELB agent, transmitted by cat fleas, is now recognized as *Rickettsia felis*, and is the causative agent of flea typhus in southern USA and parts of Mexico.[2] The list will undoubtedly continue to enlarge as more investigations are completed.

Sequence analysis of genes coding for outer membrane proteins indicate that there are three main complexes within the SFG:[3]

- cluster I: *Rickettsia conorii* complex, including Malish, M1, Moroccan and Indian tick typhus strains as well agents of Astrakhan fever and Israeli tick typhus;
- cluster II: *Rickettsia africae*, *Rickettsia parkeri*, *Rickettsia sibirica* and *R. mongolotimonae*; and
- cluster III: *Rickettsia aeschlimannii*, *Rickettsia rhipicephali*, *Rickettsia japonica*, *Rickettsia massiliae* and *Rickettsia montanensis*.

Other rickettsias, including *Rickettsia rickettsiae*, *R. japonica*, *R. slovaca* and Thai tick typhus rickettsias, show greater divergence in gene sequences and do not fit within these groups.

EPIDEMIOLOGY

With the exception of *Rickettsia akari* (transmitted by mites) and *R. felis* (transmitted by fleas), ticks are the vectors of most SFG rickettsias. The prevalence of infected ticks may be high.[4] Ticks probably become infected when they feed on rickettsemic wild or domestic animals and the rickettsias then multiply rapidly in many organs of this host. Infection of the ovaries and oocytes of a female tick leads to transovarial transmission, with at least some eggs becoming infected. Thereafter infections are transmitted trans-stadially, probably to all stages of the tick, and each time the larvae, nymphs or adults feed they may transmit the infection to the vertebrate host. Because all of the stages may be infected with rickettsias, ticks are regarded as both reservoirs and vectors of SFG rickettsial infection. Tick bites usually occur during occupational or recreational activity, or following the introduction of infected ticks into the home by domestic animals. Transmission of infection, however, has also been reported during the manual removal of ticks from domestic animals.

Most of the SFG rickettsial diseases of humans have limited geographic distribution (which is reflected in the names used to describe them; Table 235.1) and different tick species may be important transmitters in these different regions (Fig. 235.2). Increasing international traffic, and possibly movement of vectors on hosts such as birds, has resulted in a number of apparently imported cases of SFG rickettsial infection.[5] Transmission through the use of contaminated needles is suggested by the finding that intravenous drug users may be at increased risk of *R. akari* infection.[6]

PATHOGENICITY

Ticks and mites inject organisms into the host with their saliva. At the site of the bite the rickettsias localize in contiguous endothelial cells. Entry into the cells appears to be by receptor-mediated attachment and phagocytosis. Organisms move out of the phagolysosome,

Figure 235-2 *Amblyomma hebraeum*, a typical tick vector of spotted fever group rickettsial infection.

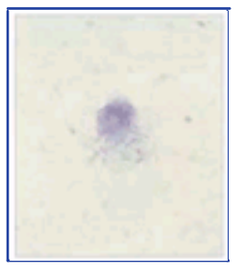

Figure 235-3 Gimenez stain of tissue culture cells infected with spotted fever group rickettsias.

probably by means of a phospholipase, into the cytoplasm and start to divide by binary fission (Fig. 235.3). Dilation of rough endoplasmic reticulum can be observed after about 48 hours. The bacteria can move between adjacent cells via cytoplasmic extrusions, and movement is associated with polymerization of actin molecules. The resulting vascular damage results in moderate to severe lymphohistiocytic vasculitis, increased vascular permeability leading to edema, and cutaneous necrosis. As an eschar forms at the bite site and organisms escape from infected cells and spread via lymphatics to endothelial cells in blood vessels throughout the body. The

resulting widespread cell death, vasculitis and increased vascular permeability result in the typical 'spotted fever' and 'tick typhus' diseases.

PREVENTION

Preventive measures include tick control programs for domestic and wild animals and the use of tick repellents on clothing and skin. Vaccines are effective in laboratory animals but have not been developed for use in humans. Antibiotic prophylaxis for people exposed to tick bites is not recommended as tetracyclines may be bacteriostatic and so only delay the onset of disease rather than prevent it.

TABLE 235-1 -- Global distribution of spotted fever group rickettsias.

GLOBAL DISTRIBUTION OF SPOTTED FEVER GROUP RICKETTSIAS			
Geographic distribution	**Human disease**	**Organism**	**Principal vector(s)**
Africa			
Mediterranean	'Mediterranean spotted fever'	*Rickettsia conorii*	*Rhipicephalus sanguineus*
	'Boutonneuse fever'		
Sub-Saharan Africa	'Kenyan tick typhus', 'South African tick-bite fever'	*Rickettsia conorii*	*Rhipicephalus simus*
			Haemaphysalis leachii
			Rhipicephalus mushamae
	'African tick bite fever'	*Rickettsia africae*	*Amblyomma hebraeum*
			Amblyomma variegatum
Morocco	None known	*Rickettsia aeschlimannii*	*Hyalomma marginatum*
Central African Republic	None known	*Rickettsia rhipicephali*	*Rhipicephalus* spp.

	Rhipicephalus turanicus		
Russia	Rickettsialpox	*Rickettsia akari*	*Allodermanyssus sanguineus*

DIAGNOSTIC MICROBIOLOGY

Early diagnosis is necessary for prompt and appropriate therapy, a factor that significantly reduces morbidity and mortality. A history of tick-bite, the presence of an eschar at the bite site, fever, headache and rash are the classic features of SFG rickettsioses, but these may occur together in only 50–75% of patients. Tick bites are usually painless and may go unnoticed, particularly if they occur in the anogenital region or among the hairs on the scalp. The lesion at the bite site may be confused with traumatic, parasitic, bacterial or viral skin lesions. Fever, headache and rash may be due to a variety of causes. There are, therefore, no clinical or epidemiologic findings that are reliable in diagnosis.

Spotted fever group rickettsias can be isolated from blood or from biopsies of the eschar, using rodents or embryonated chick eggs. Organisms may not, however, be detected for a week or more after inoculation, and special laboratory facilities are needed. Close attention to safety is required in order to prevent transmission to laboratory workers. The centrifugation-shell vial technique, where samples are centrifuged on to a cell monolayer, may reduce the time for detection to 3–4 days.

Rickettsial antigens can be detected in endothelial cells in dermal blood vessels by direct immunofluorescence staining of frozen skin sections from the eschar or sites affected by rash. Direct immunofluorescence may also be used to detect antigens in circulating endothelial cells isolated from whole blood. Even greater sensitivity may be achieved with polymerase chain reaction (PCR) assays, using various primers.[7] These technologies are, however, only rarely available in diagnostic laboratories.

The classic serologic test for rickettsial infection is the Weil-Felix test, which relies on the antigenic cross-reactivity between epitopes in the LPS of *Rickettsia* spp. and in particular strains of *Proteus* spp. Although very simple, and widely available, the test has low specificity and sensitivity and is regarded as unacceptable for accurate diagnosis. There are a number of other tests such as latex agglutination, hemagglutination, indirect fluorescent antibody (IFA) and the

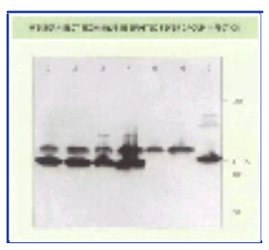

Figure 235-4 Western blot technique in spotted fever group infection. Western blot of pooled mouse antisera to *Rickettsia africae* — human isolate (lane 1), *Rickettsia africae* — tick isolate (lanes 2–4), *Rickettsia conorii* — Kenyan strain (lane 5), *Rickettsia conorii* — Moroccan strain (lane 6) and Israeli SFG rickettsia (lane 7). Molecular masses (in thousands) are shown.

enzyme-linked immunosorbent assay (ELISA).[7] The latter two show high sensitivity and can be adapted to detect different antibody isotypes, which may be useful in acute infections. There is extensive cross-reactivity of sera with the different species of SFG rickettsias, and so IFA or ELISA cannot be reliably used to make a specific diagnosis. Recently, dried blood spots have been shown to be effective for serologic testing.[8]

Demonstration of rising titers in paired sera is more reliable than examination of a single specimen, although this is seldom of benefit since treatment must be initiated as early as possible. Western blotting may detect significant antibody titers one day earlier than IFA or ELISA, but patients who present soon after the onset of symptoms may have antibody titers below the threshold of detection by any test (Fig. 235.4). Kinetic studies show that IgM and IgG antibodies appear 3–10 days after the appearance of symptoms, and peak titers are reached after 3–4 weeks. Titers then decline slowly, and IgM and IgG are still detectable after 1 and 4 years, respectively. Administration of therapy within 2 days of the onset of symptoms may abrogate antibody production.

CLINICAL MANIFESTATIONS

The SFG rickettsioses are usually named after the geographic region in which they are detected (e.g. 'Rocky Mountain spotted fever', 'Mediterranean spotted fever', 'African tick bite fever', 'Indian tick typhus', etc.). After an incubation period of 4–10 days, common clinical features in Rocky Mountain spotted fever include:[9]

- an eschar or '*tache noire*' at the site of tick attachment;
- regional lymphadenopathy;
- fever (100.4–104°F (38–40°C));
- severe headache;
- chills;
- joint and muscle pain;
- malaise; and
- general weakness.

Within 3–4 days of the onset of fever, a maculopapular rash may develop on the trunk and extremities, frequently but not consistently including the soles and the palms. If untreated, the fever persists for 6–12 days and the rash may still be visible for up to 3 weeks. In African tick bite fever, and other SFG infections, pyrexia, headache and lymphadenopathy may be common but a rash is seen infrequently. [10]

Many organs may become involved, with hepatomegaly and splenomegaly and gastrointestinal symptoms such as vomiting, diarrhea and abdominal discomfort. Nephritis and renal failure may occur, and cardiac and circulatory abnormalities such as dysrhythmia, myocarditis, pericarditis, heart failure, deep venous thrombosis and embolism have been described. Pulmonary disorders such as pneumonitis and pleuritis and neurologic signs including impaired consciousness, seizures and vertigo may occur. [11]

Hematologic abnormalities include anemia and thrombocytopenia, with neutropenia in the acute phase of the disease and leukocytosis in the later stages. Biochemical changes include decreased levels of protein, particularly albumin, sodium, potassium and chloride during the first 10 days of the disease. Alkaline phosphatase, alanine aminotransferase and aspartate aminotransferase are usually elevated. Creatinine phosphokinase and lactic dehydrogenase are also often raised in acute infection. Cytokine abnormalities may also be seen, with raised levels of macrophage colony stimulating factor, interleukin (IL)-1ß, IL-10, interferon-? and tumor necrosis factor-a.

Predisposing factors for the development of severe infections include initiation of treatment after the seventh day of illness, old age, diabetes, cardiac insufficiency, heavy smoking, alcoholism, chronic liver disease and glucose-6-phosphate dehydrogenase deficiency.

MANAGEMENT

Based on in-vitro susceptibility testing and in-vivo experience, doxycycline is the currently recommended drug of choice for the treatment of the SFG rickettsioses.[12] [13] The most commonly used regimen is 200mg daily for 2–5 days or until 24 hours after defervescence. Two single 200mg doses of doxycycline are also effective.

Ciprofloxacin has been shown to be at least as effective as doxycycline. Treatment for 5 days with the macrolide josamycin has been successful in children and pregnant women in whom quinolones are not considered safe. Other macrolides, such as clarithromycin, have been shown to have in-vitro activity against a number of rickettsias[14] and may be useful in treatment. Treatment failure has been reported with chloramphenicol. The aminoglycosides, ß lactams, erythromycin and trimethoprim-sulfamethoxazole are ineffective, and the latter is in fact contraindicated as it may stimulate bacterial growth and increase the severity of disease. Studies indicate there may be considerable heterogeneity in susceptibility to rifampin (rifampicin), and this may explain discrepancies in the outcome of treatment with this antibiotic.[12]

TYPHUS GROUP RICKETTSIAS

NATURE

Rickettsia typhi is the etiologic agent of endemic or murine typhus and *Rickettsia prowazekii* is the agent of epidemic typhus. They are both small, Gram-negative coccobacilli and, as with other members of the genus *Rickettsia*, their outer walls have an inner leaflet that is thicker than the outer. A polysaccharide slime layer may cover the outer leaflet, although its function is unknown and it is not associated with virulence.

There is considerable sharing of antigens by these two rickettsias and, while this gives cross-immunity, it creates problems in serologic surveys. The surface antigens include both high-molecular-weight proteins and low-molecular-weight LPS. The latter do not react with monoclonal antibodies to LPS of SFG rickettsia, suggesting structural differences. Combinations of immunofluorescence tests and Western blots can help to distinguish epidemic and endemic typhus in most cases. [15] Species specific epitopes occur on a 120kDa major surface protein, and monoclonal antibodies to these can distinguish *R. typhi* from *R. prowazekii*.

The complete genome sequence of *R. prowazekii* has been published, although less is known about *R. typhi*. [16]

EPIDEMIOLOGY

Endemic typhus, caused by *R. typhi*, is transmitted by the rat flea *Xenopsylla cheopsis* and is distributed throughout the world, but particularly in developing countries where there is close contact between humans and rodents. *Rickettsia prowazekii*, causing epidemic typhus, is transmitted in the feces of infected body lice, *Pediculus humanus* var. *corporis*, and occurs in epidemic foci where conditions are disrupted by poverty, famine, wars or natural disasters (Table 235.2). The historic association between epidemic typhus and war has been noted by many authors but, in recent years, the disease has been described mainly from disaster areas in Africa, such as Burundi,[17] and from outbreaks in Central and South America. Epidemic typhus occurs occasionally in developed countries and, while many such infections are probably imported, some appear to be locally acquired.[18] Older people, who may have had contact with epidemic typhus years before, may serve as a source of epidemics in areas in, for instance, eastern Europe, where conflict and political turmoil have disrupted normal living conditions.

TABLE 235-2 -- Comparison of features of endemic and epidemic typhus.

COMPARISON OF FEATURES OF ENDEMIC AND EPIDEMIC TYPHUS		
	Endemic typhus	**Epidemic typhus**
Causative agent	*Rickettsia typhi*	*Rickettsia prowazekii*
Vector	Rat flea	Human louse
Occurrence	Worldwide	Outbreaks associated with war, famine
Onset	Slow	Sudden
Eschar	Rare	Rare
Lymphadenopathy	Rare	Rare
Rash	Mascular, becoming papular	Macular, becoming petechial or necrotic
CNS symptoms	Rare, mild	Common, sereve
Duration	1–2 weeks	3–4 weeks
Mortality	<5%	Up to 60%
Recrudescence	Does not occur	Brill-Zinsser disease may occur
Diagnosis	Weil-Felix (OX 19), immunofluorescent assay, extensive cross-reactivity	

PATHOGENICITY

After multiplication at the injection site, there is hematogenous spread to endothelial cells of capillaries and small veins throughout the body. The rickettsias invade the cytoplasm of host cells but not the nucleus. Unlike SFG rickettsias, *R. prowazekii* grows to large numbers without causing significant injury until cell lysis. Polymerization of actin filaments is not a characteristic of typhus group infection, suggesting that these rickettsias do not migrate through the cytoplasm or move directly from one cell to another. Fibrin and platelet deposition in infected blood vessels leads to perivascular infiltration, and this may lead to local thrombosis, which affects many organs but particularly the heart, kidney and liver.

PREVENTION

Vector control with insecticides such as permethrin powder (1%) at doses of 30–50g for an adult and 15–25g for a child is the mainstay of protection. Insecticide should also be applied at 125–250mg/m^2 to kill lice in clothes and bedding. For endemic typhus both the normal murine host of the vector and the vector itself are the target of control measures. Insecticides can be used in buildings where rodents abound, and when the flea population has been reduced traps are used to limit the rodent population. Insecticide applied around the traps ensures control of fleas leaving the dead host. A recombinant 120kDa protein has been shown to confer protection against *R. prowazekii* in laboratory animals but there is little information on safety and efficacy in humans. Older vaccines, produced in yolk sacs, are protective but may induce non-specific reactions in recipients.

DIAGNOSTIC MICROBIOLOGY

A history of exposure to the vector is a crucial aid in the diagnosis of typhus. Isolated cases of epidemic typhus occur rarely,[19] [20] and usually there is a focus associated with war, famine or other disaster.[17] Organisms can be recovered from blood, using cell or animal cultures, and shell-vial assays using human embryonic lung fibroblasts may be useful. Organisms are highly infectious and safety facilities are essential.

Antibodies to typhus group rickettsias develop within 1–2 weeks of illness in the majority of patients. In the Weil-Felix test there is a rise in the agglutination titer with OX19 *Proteus vulgaris* antigen, but the low specificity of this test makes it unreliable. More sensitive and specific tests, such as IFA and ELISA, are available. There is extensive cross-reactivity between *R. typhi* and *R. prowazekii*, and infections can be distinguished by serology sometimes only with difficulty.[15] Cross-reactivity with some SFG rickettsial antigens may also occur, adding further to the difficulties of accurate serologic diagnosis. Detection of DNA sequences by PCR has been described[18] and has been used to detect *R. prowazekii* in cerebrospinal fluid.[19]

CLINICAL MANIFESTATIONS

The clinical features of endemic and epidemic typhus are similar, although the former is a milder disease. After an incubation period of 7–14 days, there is a high fever (>102°F (>39°C)), with headache, backache, chills, malaise and generalized pain. In epidemic typhus the onset is sudden but in endemic typhus signs of the infection develop over several days. Eschars, lymphadenopathy and splenomegaly are unusual features. A macular rash develops between day 5 and day 7 of the illness but it

may be absent in 50% of endemic typhus cases, especially in children. Unlike SFG rickettsial infections, the rash is more prominent on the trunk than on the limbs and rarely involves the face, palms or soles. In epidemic typhus, a pink macular rash usually spreads from axillary regions to the trunk and limbs.[20] The rash may become petechial or necrotic.

Invasion into the central nervous system is characteristic and confusion, coma, meningitis, delirium or manic symptoms develop toward the end of the first week, especially, although not exclusively, in epidemic typhus. Other features of infection include pulmonary (pneumonitis, bronchitis, bronchiolitis), cardiovascular (myocarditis, hypotension, tachycardia) and renal (oliguria) dysfunction. Similar but milder symptoms occur in endemic typhus.

If untreated, symptoms persist for 1–2 weeks (endemic typhus) or 3–4 weeks (epidemic typhus). In epidemic typhus the mortality can be over 40% but in endemic typhus mortality is low and is usually restricted to the elderly or immunocompromised. Recovery in epidemic typhus is slow, with convalescence lasting several months, while in endemic typhus defervescence and recovery occurs within 2–3 days of commencing therapy.

Recrudescent typhus (Brill-Zinsser disease) can occur years after patients show clinical recovery from epidemic typhus, usually at a time of immunodepression. Relapses present as a mild febrile illness, often without a rash, and diagnosis requires a history of previous rickettsial disease. The site and mechanism of survival of rickettsias within the body is not known, but they remain virulent and are transmissible to lice. Testing, contact tracing and the implementation of delousing programs may be needed to prevent outbreaks arising from recrudescent epidemic typhus.

MANAGEMENT

In-vitro antibiotic tests show both *R. typhi* and *R. prowazekii* are susceptible to tetracyclines, chloramphenicol and erythromycin. Resistance to erythromycin may emerge rapidly in vivo, and treatment failure has been reported in Brill-Zinsser disease with azithromycin. As with other rickettsial diseases, doxycycline is the recommended therapy in typhus infections, and quinolones may be suitable alternatives. Patients become afebrile within 3 days of starting treatment, but treatment should continue for 2–3 days longer to prevent relapse.

SCRUB TYPHUS

NATURE

Unlike true *Rickettsia* spp., the outer leaflet of the cell membrane of the agent of scrub typhus is thicker than the inner leaflet. This and other structural, immunologic and genotypic characteristics led to the reclassification of this agent as *Orientia tsutsugamushi*. [21]

Orientia tsutsugamushi is a weakly Gram-negative, obligate intracellular coccobacillus that can be cultured in fertilized eggs or in cell monolayers, where it forms plaques. In human cells, the bacteria are 1.2–1.6µm by 0.5–0.6µm, but in insect cells they may grow considerably longer (up to 4µm). Escape from the intracellular environment is via projections on the cell surface and is not necessarily related to cell damage.

Different strains can be recognized on the basis of serologic reactivities but they are not associated with a specific vector, geographic area or host species. Indeed, different serotypes of *O. tsutsugamushi* have been detected in the same host at the same time. An immunodominant 56kDa major outer membrane protein is found in all isolates, although there may be variation in amino acid sequences in this protein.

EPIDEMIOLOGY

Scrub typhus is a disease that occurs most frequently in South East Asia, but it has been reported from the Indian subcontinent, Australia and from Astrakhan in central Asia. Infections may be endemic or seasonal, depending to a large extent on the numbers of the vector, namely mites of the genus *Leptotrombidium*. These mites feed on vertebrates only in their larval stage, the nymphs and adults feeding on organic matter in the soil. The larva or 'chigger' takes only a single meal, and so can infect only one host. In the mite, rickettsias multiply in many organs, and are transmitted transovarially to the offspring. They do not, however, infect spermatogonal cells and so are not transmitted from male to female. Sex ratio distortions occur in some infected mite populations, with the almost complete absence of males. The mechanism for this is not known, but other related bacteria are associated with parthenogenesis and male-killing in insects.

In areas where ideal climatic conditions, vegetation and hosts are present, hyperendemic 'mite islands' may occur. In these areas transmission of scrub typhus is rapid and frequent.[22]

The usual vertebrate hosts for the mites are rats, mice and voles. In naturally infected rodents, rickettsemia may last several months. The significance of rickettsemia is unknown, however, since chiggers feed on tissue juices rather than blood, and the majority of mite infections are maintained by transovarian transmission rather than by infection from vertebrate reservoirs.

The recovery of viable *O. tsutsugamushi* from packed red cells has raised the possibility of transmission via blood transfusion from asymptomatic donors[23] and cell filtration or the use of psoralen photochemistry have been suggested as ways of preventing this.

PATHOGENESIS

Organisms are introduced into the skin by the bite of the mite, and adherence to cell surfaces is mediated by specific polypeptides of about 54–56kDa. Monoclonal antibodies directed against these can differentiate serotypes that may show differing degrees of virulence. *Orientia* induce host cell phagocytosis in order to enter cells and then escape to the cytoplasm, through which they migrate using microtubules.[24] Endothelial cells are the main targets of *O. tsutsugamushi*, and cell culture studies indicate that they induce apoptosis.[25]

Multiplication occurs in the endothelial cells of many organs, and organisms have been recovered from the heart, lung, brain, kidney, pancreas and skin. Spread is via the lymphatics and blood stream and, while initially regional, lymphadenopathy quickly becomes generalized. Proinflammatory cytokines such as IL-6 and IL-8 may be stimulated during infection.

PREVENTION

No vaccines are available for scrub typhus, and prevention is by use of insect repellents such as DEET (diethyl toluamide) or DEPA (diethyl phenyl acetamide) to reduce the risk of being bitten, and both of these compounds can be used on clothing. Rapid removal of mites is recommended since they do not feed until several hours after attachment.

DIAGNOSTIC MICROBIOLOGY

Scrub typhus should be suspected in patients from endemic areas who present with high fever and lymphadenopathy. Hematologic signs — a neutropenia and/or mononucleosis — are not specific, and most infections are diagnosed by serology. The Weil-Felix test detects cross-reacting antibodies that agglutinate the OXK strain of *Proteus*, probably through common epitopes on membrane LPS molecules. The test is rapid and simple but unreliable, with a sensitivity of less than 50%. The IFA is more specific but requires at least four antigenically distinct strains of *O. tsutsugamushi*, because responses may be serotype-specific.[26] Hemagglutination using recombinant 56kDa protein has been found to be sensitive and specific, and rapid testing for IgM and IgG antibodies by an immunochromatography flow assay has been described.[27] A PCR assay uses primers derived from the gene coding for the 56kDa protein, and can be used to detect bacteria in blood with high sensitivity.[23] [28]

CLINICAL MANIFESTATIONS

The presentation of scrub typhus depends on features of both host and pathogen and can vary from a mild, inapparent infection to a fulminant, rapidly fatal disease. After the bite of an infected mite, incubation takes 1–3 weeks. A vesicular lesion forms at the site of the bite in about 75% cases, particularly in visitors to infective areas, and develops into a necrotic eschar. Systemic disease is indicated by a sudden onset high fever (>102°F (>39°C)), with headache, myalgia and regional and generalized lymphadenopathy, the latter particularly in patients who do not develop an eschar. A maculopapular rash appears about 5–6 days after onset in up to 80% cases in some studies.[29] Purpuric or hemorrhagic lesions are rare and transient. In the absence of treatment, defervescence starts by the end of week 3.

Neurologic signs such as lethargy, asthenia, confusion and delirium may occur. Respiratory symptoms are reported frequently, and radiologic abnormalities may be common.[29] Retinal vein occlusion with retinal hemorrhage, gastrointestinal vasculitis, pericarditis, myocarditis, acute renal failure and encephalomyelitis have all been reported as serious complications of scrub typhus.

Recently it was shown that there was a significant reduction in HIV-1 viral load during acute *Orientia* infection. [30] Moreover, sera from HIV-1 negative patients who had scrub typhus had potent HIV-1 suppressive effects in vitro, indicating the release of HIV-1 suppressive agents during scrub typhus infection. These findings are under further investigation.

MANAGEMENT

As with other rickettsial infections, tetracycline antibiotics are the drugs of choice in treatment. With doxycycline defervescence usually occurs within 24 hours. Resistance may occur in some areas, such as northern Thailand. Rifampin or azithromycin may be useful alternatives, and chloramphenicol may be effective.

HUMAN EHRLICHIOSIS

NATURE

The tribe Ehrlichiae was originally established to include veterinary pathogens such as *Anaplasma marginale, Cowdria ruminantium, Ehrlichia canis* and *Ehrlichia phagocytophila.*. The first human infection with an *Ehrlichia* species, thought to be *E. canis*, was described in 1987 and, shortly after this, retrospective examination of sera from patients who had suspected SFG rickettsioses demonstrated many who had antibodies reactive with *E. canis* antigen. Prospective studies showed that human ehrlichiosis occurred frequently in some parts of the USA.[31] The application of tissue culture techniques led to the isolation of an *Ehrlichia* species from the blood of a febrile soldier at Fort Chaffee, Arkansas and its description as a new species, *Ehrlichia chaffeensis*.[32] The two species, *E. canis* and *E. chaffeensis*, share a number of antigens, and it is likely that at least some reports of *E. canis* infection in humans may be serologic cross-reactivity.

Sequence analysis of ehrlichial 16S rRNA and other genes suggests that there are three related genogroups: the *Ehrlichia*, the *Anaplasma* and the *Neorickettsia* (Table 235.3). Changes in nomenclature have been proposed to unify members of each of the genogroups into a single genus.[33] The agent of human granulocytic ehrlichiosis (HGE) is so similar to *E. phagocytophila* and *Ehrlichia equi* that all three are included in a single species, *Anaplasma phagocytophila*. It remains to be seen if this proposed classification becomes widely accepted.

It is now recognized that there are two etiologically and epidemiologically distinct forms of disease: human monocytic ehrlichiosis (HME) and HGE. *Ehrlichia chaffeensis* is the main agent of HME. While the other species that invade monocytes, such as *E. canis*, may be human pathogens, their role in HME is at best a minor one. The agent of HGE is a member of the *E. phagocytophila* group, and both this agent and *Ehrlichia ewingii* invade granulocytes.[34] Serologic evidence from Japan suggests that *Ehrlichia muris* may also occasionally infect humans, but no isolates have been made.

The characteristic structures of ehrlichias, visible by light microscopy, are the morulas that lie within vacuoles in host cells (Fig. 235.5). Electron microscopy has shown the morulas to be aggregates of bacteria with two distinct morphologic forms. Larger (1µm in diameter) reticulate forms have evenly dispersed nucleoid filaments and ribosomes, while smaller forms (0.6µm in diameter) have filaments and ribosomes that are condensed in a central mass. These small forms are often actively dividing by binary fission. The cell wall of members of the genus *Ehrlichia* has outer and inner leaflets of equal thickness.

EPIDEMIOLOGY

Both HME and HGE have been detected in clinical samples from the USA and Europe. While there is serologic evidence of these infections in Africa, South America and Israel, the organisms are closely related and cross-reactions occur within and between groups. Isolation of organisms and/or molecular identification of pathogens will be needed to confirm the distribution of these two infections. It is probable that many infections go unrecognized because of the lack of specific clinical features and the difficulty of diagnosis. A prospective surveillance study of hospitalized febrile patients in Georgia showed that the incidence of human ehrlichiosis was six times that of Rocky Mountain spotted fever.[31]

TABLE 235-3 -- Genogroups of ehrlichias.

GENOGROUPS OF EHRLICHIAS				
	Human infection	**Animal infection**	**Vector**	**Host cell**
Group I: ***Ehrlichia* group**				
Ehrlichia chaffeensis	Yes	Deer	*Amblyomma*	Monocyte/macrophage
Ehrlichia canis	Possibly	Dogs	*Rhipicephalus*	Monocyte/macrophage
Ehrlichia ewingii	Yes	Dogs	*Amblyomma*	Neutrophil
Ehrlichia muris	Possibly	Vole	?	Monocyte/macrophage
Ehrlichia ruminantium	No	Cattle, sheep, goats	*Amblyomma*	Endothelium
Group II: ***Anaplasma* group**				
Anaplasma bovis	No	Cattle	*Boophilus*	Erythrocyte
Anaplasma platys	No	Dogs	*Rhipicephalus*	Neutrophil
Anaplasma phagocytophila (incl. *Ehrlichia phagocytophila, E. equi* and 'HGE' agent)	Yes	Horses, cattle, sheep, deer	*Ixodes*	Neutrophil
Group III: ***Neorickettsia* group**				
Neorickettsia helminthoeca	No	Dogs	Fish	Macrophage
Neorickettsia sennetsu	Yes	No	Possibly fish	Monocyte/macrophage
Neorickettsia risticii	No	Horses	Trematode larvae	Monocyte/enterocyte

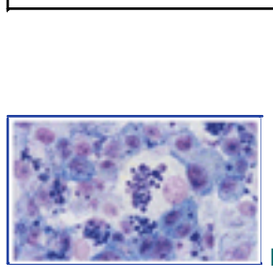

Figure 235-5 Multiple morulas of *Ehrlichia canis* in culture DH82 cells.

Surveys of tick populations using monoclonal antibodies or PCR have shown *Amblyomma americanum*, the 'lone star tick', to be the main vector of *E. chaffeensis* in the USA. The vectors of HGE are *Ixodes* ticks in both the USA and Europe. In some areas, both HGE and *Borrelia burgdorferi* may be found in the same tick at the same time.[35] Reservoirs of infection are found in many vertebrates, including deer, dogs and rodents. Ticks probably become infected in their larval and nymph stages, and the infection can be transmitted transstadially, so that both nymphs and adults can transmit the infection. There is no evidence for transovarian transmission of ehrlichias.

PATHOGENICITY

Both *E. chaffeensis* and the HGE agent are introduced into the skin by the bite of a tick. From there the organisms spread hematogenously to their respective target cells. *Ehrlichia chaffeensis* is taken into the phagosomes of macrophages and monocytes in the liver, spleen and lymph glands. Human granulocytic ehrlichiosis organisms are thought to primarily infect granulocyte precursor cells in the bone marrow rather than to invade mature peripheral neutrophils. The agent of HGE does, however, stimulate IL-8 production, inducing neutrophil migration to sites of infection.

Animal studies show that ehrlichiosis has an impact on immune function, with macrophage necrosis, inhibition of phagocytosis and killing, downregulation of

immunoglobulin production, and decreased lymphocytic responses to mitogens.[36] An immunopathologic basis for HGE has also been suggested in mouse models of infection. [37] Patients who are infected with *E. chaffeensis* show a lymphocytopenia with an abnormal predominance of ?dT cells in the peripheral circulation[38] and neutrophils infected with HGE show inhibited superoxide anion generation.[39] The mechanisms of these immunologic abnormalities and their clinical significance is not well understood, but autopsy studies of patients who had HGE have shown that many patients had opportunistic lung infections, suggesting that impaired host defenses are a primary feature of human ehrlichiosis.

PREVENTION

There are no vaccines for ehrlichiosis and prevention is based on avoiding areas where ticks are common or the use of tick repellents. Tick control programs in wild and domestic animals may be beneficial in reducing the risk of exposure. Daily removal of ticks may not be effective in preventing infection as transmission may occur within 24 hours of tick attachment.[40]

DIAGNOSTIC MICROBIOLOGY

Ehrlichiosis should be included in the differential diagnosis of patients who have acute febrile illness where there has been a history of exposure to ticks. Hematologic abnormalities, particularly a leukopenia and thrombocytopenia, would be consistent with this diagnosis but there are no pathognomonic signs. The presence of arthralgias and/or an elevated C-reactive protein may help differentiate ehrlichiosis from other infections such as tick-borne encephalitis. Careful examination of peripheral blood or buffy coat smears may show morulas in macrophages or neutrophils but in most cases such examinations are fruitless. The majority of cases of human ehrlichiosis have been diagnosed on the basis of serology, using IFA or ELISA, or detection of specific DNA sequences. Using IFA with *E. chaffeensis* antigen, antibody titers rise during the third week of illness, peak and then decline rapidly about a year later. Serology has been negative,

however, in a number of patients confirmed to have ehrlichiosis using PCR, and the sensitivity of IFA may be low. Cell-free recombinant antigens of *E. canis* have been described, and may become useful in serologic tests for HME.[41] Serologic tests for HGE using *E. equi* infected horse neutrophils or cultured human isolates also detect antibodies within 2 weeks after onset of symptoms, and peak titers are reached during the first month. Antibodies may still be detected in about 50% of patients after 1 year.[42] The *E. phagocytophila* group is, however, characterized by antigenic diversity, and this may lead to interlaboratory differences in interpretation of serology assays. Recombinant antigens, derived from *E. phagocytophila* or HGE isolates, have been used to develop rapid serologic assays, and these may give more consistent results. [43] Specific sequences for PCR, using primers from the 16S rRNA gene sequences, have been described for both *E. chaffeensis* and HGE, but diagnostic procedures continue to be revised. [44]

CLINICAL MANIFESTATIONS

Studies of seroconverters suggest that two-thirds of human ehrlichial infections are asymptomatic. In symptomatic cases, there is a moderate to severe illness, with the majority requiring hospitalization. There are no clinically distinct diagnostic features but fever, headache, myalgia, anorexia, vomiting and nausea are common. Skin rash, cough, pharyngitis, diarrhea, abdominal pain and confusion are reported from less than 25% of patients. Involvement of the central nervous system may lead to seizures and coma, and myocardial damage has been recorded. The symptoms are similar in both human monocytic and granulocytic ehrlichiosis, although rash is very rare in the latter. The mortality is probably less than 5% in HME, but may be higher in HGE.[45] In untreated patients, symptoms persist for 3–11 weeks before resolving, leaving a long lasting immunity to further infection.

Both leukopenia and thrombocytopenia are laboratory common findings, with an increase in band neutrophil counts in early infection. A reduced lymphocyte count may be the most significant hematologic finding in HGE culture positive cases. [46] A mildly elevated hepatic transaminase activity may occur.

MANAGEMENT

In-vitro studies have shown that *E. chaffeensis* is susceptible to doxycycline and rifampin but is resistant to quinolones, aminoglycosides, erythromycin and trimethoprim-sulfamethoxazole. Studies with *E. phagocytophila* show a similar picture, except that the organisms are

Figure 235-6 Colonies of *Bartonella henselae* on blood agar. *Courtesy of R. Birtles.*

susceptible to quinolones.[47] Administration of doxycycline leads to defervescence in 2–3 days in over 90% of patients and so this is the antibiotic of choice. With other antibiotics, the fever may persist for up to 7 days. Persistence of viable ehrlichias after treatment is known to occur in animal infections, even after 6 weeks of treatment, and has been reported from at least one human case. The significance of persistent ehrlichiosis in humans is not known. Rifampin has been successfully used to treat HGE in a pregnant woman.

BARTONELLOSIS

NATURE

The *Bartonella* are Gram-negative rods that belong in the a_2 subgroup of the class Proteobacteria. [48] They can be grown in tissue culture and also on cell-free media containing blood. Identification of *Bartonella* is based on genomic analysis, as the organisms are biochemically inert.

There are now 19 species in the genus, each with a mammalian reservoir host and each probably transmitted by an arthropod vector.[49] The principal human pathogens are *Bartonella quintana*, *Bartonella henselae* (Fig. 235.6) and *Bartonella bacilliformis*. Six other species have been implicated in human disease: *Bartonella elizabethae* and *Bartonella vinsonii* subsp. *berkhoffii* have been found to cause endocarditis, *B. vinsonii* subsp. *arupensis* was isolated from a febrile patient who had heart valve disease, *Bartonella grahamii* has been implicated in cases of neuroretinitis, *Bartonella clarridgeiae* has been implicated in cat scratch disease and *B. washoensis* has been identified as a cause of myocarditis (Table 235.4).

EPIDEMIOLOGY

Infections with *B. bacilliformis* have been reported only from valleys in the Andean regions of Peru and Ecuador, where sandfly vectors of the genus *Lutzomyia* occur. Infections with *B. quintana* and *B. henselae* have been reported from North America, Europe, the Middle East, Africa and Asia, and so are presumed to occur worldwide. Both the body louse *P. humanus* var. *corporis* and the head louse *P. humanus* var. *capitis* are experimentally capable of transmitting *B. quintana*, but epidemiologic evidence is that natural transmission is effected only by the body louse. In the louse, the organism is extracellular in the gut lumen and causes no pathology. They are, however, excreted in large numbers in louse feces. Humans are the only known natural animal host of *B. quintana*, and even under experimental conditions primates are the only susceptible animals. This contrasts with *B. henselae*, which has frequently been isolated from domestic cats. Cats can transmit the infection to humans in bites and scratches, and the presence of *B. henselae* in cat fleas indicates that these may also be a source of human infection. *Ixodes* ticks infected with *Bartonella* closely related to human pathogens have been described, and some infections may be transmitted this way.[50]

PATHOGENICITY

Microscopic examination of tissue infected with *Bartonella* frequently shows tumor-like capillary lobules indicating neovascular proliferation, and these lesions regress during antibiotic therapy. Experimental studies show that contact with a number of *Bartonella* species enhances proliferation of endothelial cell lines.[51] These observations suggest that *Bartonella* directly stimulates angiogenesis, possibly through secretion of one or more angiogenic factors, and there is some evidence that production of these is mediated through extrachromosomal elements. [52]

TABLE 235-4 -- *Bartonella* spp. associated with human disease.

***BARTONELLA* SPP. ASSOCIATED WITH HUMAN DISEASE**			
***Bartonella* sp.**	**Disease**	**Vector**	**Reservoir**
B. bacilliformis	Oroya fever	*Lutzomyia*	Human
	Verruga peruana		
B. quintana	Trench fever	*Pediculus humanus*	Human
	Bacteremia		
	Endocarditis		
	Bacillary angiomatosis		
B. henselae	Cat scratch disease	Cat flea	Cats
	Endocarditis		
	Bacteremia		
	Bacillary angiomatosis		
	Juvenile arthritis		
B. vinsonii subsp. *berkhoffii*	Endocarditis	Fleas and ticks	Dogs
B. vinsonii subsp. *arupensis*	Endocarditis	Not known	Rodents
B. elizabethae	Endocarditis	Fleas	Rodents
B. clarridgeiae	Cat scratch disease	Cat flea	Cats
B. grahamii	Neuroretinitis	Not known	Rodents
B. washoensis	Myocarditis	Not known	Rodents
Other species (e.g. *B. vinsonii* subsp. *vinsonii*, *B. tribocorum*, *B. weissii*, *B. alsatica*, *B. taylorii*, *B. doshiae*, *B. schoenbuchii*, *B. capreoli* and *B. koehlerae*) may be found in rodents, rabbits and ruminants but have not so far been associated with human infections.			

PREVENTION

Control of the arthropod vectors and avoidance of close contact with cats and cat fleas are the only preventive measures available.

DIAGNOSTIC MICROBIOLOGY

Recovery of *Bartonella* from blood requires prolonged incubation using highly enriched media and/or cultivation in endothelial cell lines. The timing of blood sampling may be important since the numbers of bacteria in the blood stream varies. Primary isolation may require a month or more of culture in a humid (80%), CO_2 -enriched (5%) atmosphere using media containing horse or rabbit blood. The addition of fetal calf serum and maintenance of hemin concentration within the range 50–250µg/ml improves growth. For *B. bacilliformis* an incubation temperature of 82.4°F (28°C) is preferred.

Primary isolates produce rough colonies deeply embedded in the agar. On subculture, growth is more rapid, with smooth, shiny colonies developing in 5 days or less. Organisms will also grow in liquid media, and acridine orange staining of culture samples is useful because of the slow growth and because little or no CO_2 is produced. Suspect isolates can be presumptively identified on the basis of slow growth, Gram stain appearance and lack of biochemical activity. Specific identification of isolates is usually based on molecular analysis[52] [53] or serologic typing.[54]

Serologic diagnosis can be made using hemagglutination, IFA and ELISA. There is little cross-reactivity with other rickettsias, but cross-reactions with *Coxiella* and *Chlamydia* spp. have been described. Removing LPS from antigen preparations improves the specificity. Serology is particularly useful in endocarditis, where culture may take several weeks.[55] Cross-reacting protein antigens are common to different species of *Bartonella*, and serologic tests cannot reliably distinguish between *B.*

quintana and *B. henselae* infections. Polyvalent murine antisera and monoclonal antibodies can, however, be used to differentiate *Bartonella* species isolated in the laboratory[56] .

Polymerase chain reaction assays, based on primers for the 16S rRNA gene, can be used to detect *Bartonella* in clinical specimens.

CLINICAL MANIFESTATIONS

A number of different clinical conditions have been associated with *Bartonella* infections.

Trench fever

A relapsing fever accompanied by severe pain in the legs became prominent as a disease among troops serving in the trenches during the First World War and the etiologic agent is now named *B. quintana*. Infection occurs by penetration of organisms in excreta of body lice into skin broken from scratching as a result of intense pruritus. The incubation period is usually 2–3 weeks, and infection leads to sudden onset of fever, retro-orbital headache, weakness, pain in the legs, shivering, intestinal disturbance and insomnia. The severity of symptoms increases over the first 2–3 days. There may be neck stiffness and the disease may resemble meningitis. Intense pain in the tibia is characteristic, and is exacerbated by cold and damp conditions. Pyrexia is often periodic, recurring about every 5 days (hence the name *quintana*), with each attack being less severe than the previous one. Laboratory findings are non-specific, with a polymorphonuclear leukocytosis, anemia and disturbance of liver function. The disease is usually not fatal, although it may persist for 4–6 weeks and is very debilitating. More recently, trench fever has been described in refugees in Burundi,[17] and also as so-called 'urban trench fever' among louse-infested homeless persons.[57]

Bacteremia and endocarditis

In a study of homeless, chronic alcoholics, bacteremia with *B. quintana* persisted for more than 10 days in 4/10 patients, and untreated bacteremia persisted for over 8 weeks.[58] Prolonged bacteremia with *B. henselae* is also common and, in HIV-infected patients, this may be asymptomatic or be associated with an insidiously developing, prolonged symptom complex of malaise, fatigue, weight loss and recurring fevers. Both *B. henselae* and, more frequently, *B. quintana* have been associated with endocarditis,[59] with extensive damage to heart valves, fibrosis and calcification suggestive of prolonged infection. Failure to detect more common pathogens from the blood of endocarditis patients should alert the physician to the possibility of *Bartonella*-induced endocarditis.

Cat scratch disease

Cat scrath disease, caused by *B. henselae* and perhaps other *Bartonella* spp., is now considered to be the most common cause of chronic, benign lymphadenopathy in children and young adults. Epidemiologic evidence suggests that transmission is through cat scratches, bites or contact with cat fleas and studies in the USA have shown that up to 40% of domestic cats have an asymptomatic *B. henselae* bacteremia, which may persist for more than 1 year. In humans the initial lesion develops as a nonpruritic vesicle, papule or pustule, usually on the head, neck or arms, 3–10 days after a scratch or bite. The lesion heals without scar formation within a week. Regional lymphadenopathy may persist for 2–4 months before resolving spontaneously. Transient mild systemic symptoms include fever, malaise, fatigue, headache, anorexia and weight loss. Atypical manifestations include conjunctivitis with pre-auricular lymphadenopathy, hemolytic anemia, hepatosplenomegaly, glomerulonephritis, pleural effusion and neurologic abnormalities and severe chest and pulmonary diseases have been reported.[60]

Arteriolar proliferation and widening of the arteriolar walls, reticulum cell hyperplasia, multiple microabscesses, frank abscess formation and tubercle-like granulomas may be seen on histology of affected lymph nodes. Organisms can be seen using Warthin-Starry stain in clumps or as filaments in the walls of vessels and epithelial cells and free in necrotic debris. Dissemination of organisms can result in the formation of granulomas, identical to those described in lymph nodes, in bone, liver, mesenteric lymph nodes and/or spleen.

Bacillary angiomatosis

Bacillary angiomatosis and epithelioid angiomatosis are vascular proliferative diseases that usually, but not exclusively, involve the skin and are associated with immunodeficiency (Fig. 235.7). Both *B. quintana* and *B. henselae* have been detected in patients in Europe and North America. A similar condition, verruga peruana, is caused by *B. bacilliformis*, but has a limited geographic distribution. Cutaneous lesions may be single or multiple red or purple papules that increase in size and become nodular and bleed profusely when punctured. They may be superficial, dermal or subcutaneous and sometimes involve the oral, anal, conjunctival or intestinal mucosa. While they may resemble lesions of Kaposi's sarcoma, there is no evidence that herpesvirus is involved in the vascular proliferation.[61] Other organs that may be affected include bone marrow, spleen, liver and lymph nodes. Severely immunocompromised patients, particularly those who have HIV, may develop peliosis hepatitis, characterized by cystic,

Figure 235-7 Skin lesions of bacillary angiomatosis. *Courtesy of P. Kelly.*

blood-filled spaces in the hepatic parenchyma. Histology shows masses of bacteria in dense clumps of granular material.

Concurrent lymphadenopathy is more frequent in *B. henselae* infected patients, while concurrent central nervous system disorders are more frequent in *B. quintana* infected patients. [62] [63] The main risk factor in *B. henselae* bacillary angiomatosis patients is contact with cats and fleas, while homelessness, poor socio-economic status and contact with lice are the main risk factors in *B. quintana* patients.

Carrion's disease

Carrion's disease, caused by the intra-erythrocytic organism *B. bacilliformis*, was first described in 1907. The disease is restricted geographically to the Andean regions of Peru and Ecuador, and occurs in two forms: a febrile anemia ('Oroya fever') and an angioprolific cutaneous disease ('verruga peruana') that resembles bacillary angiomatosis.

MANAGEMENT

Most *Bartonella* isolates are susceptible in vitro to ß-lactams (except oxacillin and cephalothin), rifampin, chloramphenicol, macrolides and tetracyclines but susceptibility to clindamycin, quinolones and trimethoprim-sulfamethoxazole is more variable. Clinical trial data are scarce, but most report a poor relationship between in-vitro susceptibility and in-vivo efficacy. Recommendations on treatment depend to a larger extent on clinical presentation rather than on etiology. In immunocompetent patients who have cat scrath disease there is no evidence that antibiotic therapy reduces the duration of symptoms. The use of antibiotics in immunosuppressed patients, however, is associated with rapid clinical improvement. *Bartonella quintana* bacteremia has been reported to respond well to doxycycline, ceftriaxone and macrolides.[57] The majority of patients who have bacillary angiomatosis respond initially to amoxicillin, aminoglycosides or trimethoprim-sulfamethoxazole but relapses occur frequently. The efficacy of tetracyclines and erythromycin appears to depend on the duration of therapy, with fewer relapses occurring in patients treated for more than 1 month. There are few data on treatment of *Bartonella* endocarditis but complex regimens using combinations of ß-lactams, aminoglycosides and rifampin have been used.[57] Valve replacement is almost always essential because of the extent of damage to the valves by the time a diagnosis is made.

Q FEVER

NATURE

'Query' or Q fever was first recognized as a disease of humans in abattoir workers in Queensland, Australia in the 1930s and it is now known to occur worldwide. The causative agent, *Coxiella burnetii*, is an obligate intracellular organism that requires the acidic environment within the phagolysosome of eukaryotic cells for its metabolism. While originally included within the Rickettsiaceae, *C. burnetii* has always been regarded as an unusual member of this family because of unique features of its life cycle and epidemiology. It is more closely related to organisms such as *Legionella* and *Francisella* than to *Rickettsia* spp.

Morphologically, *C. burnetii* is a Gram-negative, intracellular, pleomorphic coccobacillus 0.2–1.0µm in diameter. The organism may occur as a small-cell variant (SCV) or large-cell variant (LCV). The SCV is a compact, small rod with a very electron-dense center of condensed nucleoid filaments. The LCV is larger and less electrondense, and has a clear, periplasmic space between the outer and cytoplasmic membranes. A dense, endospore-like body 130–170nm in diameter might be found at one pole of some LCV. The SCV are

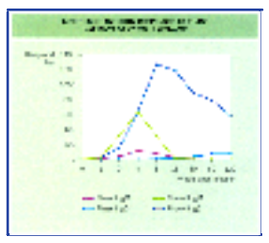

Figure 235-8 Kinetics of antibody responses to phase variants of *Coxiella burnetii*.

metabolically inactive and are the extracellular form of the organism. Once within a phagolysosome, the SCV is activated by the acidic environment and forms an LCV. The LCV is the metabolically active intracellular form of the bacterium, and undergoes sporogenic differentiation to produce resistant, spore-like forms of the bacterium. These develop to SCVs, which are released when the cells lyse.

In addition to this morphologic change, there is also phase variation, which is associated with changes in the LPS of the outer membrane. Phase I organisms can be readily isolated from acutely infected animals, and remain virulent, while phase II organisms, obtained after serial passage in eggs or tissue culture, are of low virulence. Phase II organisms revert to phase I following passage in a vertebrate host. There are no distinct morphologic changes associated with this phase variation, and SDS-PAGE studies show only minor changes in immunogenic protein profiles (Fig. 235.8).

EPIDEMIOLOGY

With the notable exception of New Zealand, *C. burnetii* infections occur worldwide. The ability of *C. burnetii* to survive extreme environmental conditions for many years, and the low infective dose, results in ready transmission of infection, probably in most cases by inhalation of infectious aerosol particles. While cattle, sheep and goats are the most important animal reservoirs, *C. burnetii* has also been detected in fish, birds, rodents, marsupials, snakes, tortoises and many domestic animals, and has been recovered from ticks and other arthropods. Naturally infected cattle, sheep or goats carry large numbers of bacteria in blood and tissues, and they excrete viable organisms in milk. In most cases these animal infections are asymptomatic. While abortion occurs only rarely, the placenta of an infected animal frequently contains large numbers of organisms. It is contamination of the environment from these sources that usually precedes transmission to humans.

Because the minimum infective dose is a single viable organism, [64] exposure need only be minimal. Most human cases of Q fever occur sporadically but outbreaks occur with high-risk occupations (farmers, hunters, workers in meat or milk processing plants, slaughterhouses, veterinary schools, etc.). Outbreaks have also been reported in such disparate groups such as inhabitants of a village through which infected sheep were herded, golf players on a course previously used as a sheep pasture, military personnel coming into contact with infected hay and poker players exposed to a parturient cat. Extracellular *C. burnetii* are extremely resistant to desiccation, low or high pH, disinfectants and ultraviolet light, and may remain infective in aerosols for up to 2 weeks and in the soil for as long as 5 months. Amebae may also be infected with *C. burnetii* and may be another reservoir for contamination of the environment. [65] Ticks are probably important only in maintaining infections in small rodents and lagomorphs. There is little evidence for direct tick transmission to humans, but organisms may be excreted in large numbers in tick feces, leading to environmental contamination.

In addition to inhalation of viable *C. burnetii* in aerosols, infection may also occur through ingestion of infected milk and meat products. Most such infections result in seroconversion without symptoms, however. *Coxiella burnetii* has been isolated from the human placenta and breast milk, and transmission may also be from mother to child. Sexual transmission of Q fever has recently been reported.[66]

PATHOGENICITY

Monocytes and macrophages are target cells for *C. burnetii*, and alveolar macrophages are the usual primary target. Attachment to the host cell is followed by passive entry into the phagolysosome, where production of a potent acid phosphatase protects the organism from enzyme attack.[67] Disturbance of cytokine regulatory processes, allowing survival and replication of *C. burnetii* within host cells, is also important in establishing infection.[68]

In animals, the great majority of infections produce no obvious pathology, apart from inflammation in the uterus and placenta, where there may be massive replication of *C. burnetii* during the final stages of pregnancy.

Monoclonal antibodies react specifically with epitopes on isolates associated with acute (Nine Mile strain) and chronic (Priscilla strain) infections. Plasmids that code for surface proteins may also be associated with virulence. For example the plasmid QpHI is found in isolates from acute infection, while the plasmid QpRS is found in isolates from patients who have endocarditis. Other studies suggest, however, that differences in host response are more important that genomic variation in determining the clinical outcome of infection.

PREVENTION

The extent to which Q fever organisms contaminate the environment, the ability of these organisms to survive harsh conditions and the low infective dose means that prevention through the use of environmental measures is difficult. Some measures, such as the avoidance of unpasteurized dairy products, may prevent some forms of transmission. Q fever can be prevented in animals using vaccines prepared from extracted subunits of phase I cells, and vaccines may also be useful for people at high risk when they can be identified.[69] Vaccines prepared from phase II organisms have been shown to prevent abortion in animals, but vaccinated animals may still transmit infection to humans.

DIAGNOSTIC MICROBIOLOGY

The suspicion of acute Q fever is not dependent on a specific history of exposure to animals, since organisms persist in the environment for many years. Symptoms are not pathognomonic and may readily be confused with influenza or with other rickettsial diseases. Because organisms are highly infectious, all specimens from patients who have suspected Q fever should be handled with extreme care. *Coxiella* can be recovered from blood, urine and other body fluids during acute infection, using mice or vero cell lines, although only laboratories with adequate safety facilities should attempt this. The shell vial assay may

improve recovery of organisms from patients who have endocarditis. A PCR assay, using primers derived from the *htpAB*-associated sequence, has been used to detect organisms in a variety of specimens, including heart valves and milk.[70] *Coxiella burnetii* plasmid DNA has also been identified in human serum specimens by PCR.[71]

Serologic diagnosis is more usual, and is especially useful in areas of high endemicity. While complement fixation and IFA have been used, ELISA is useful for epidemiologic screening and as a diagnostic test. The stage of the infection may be distinguished by using isotype-specific tests, and phase specific antigens. Immunoglobulin M antibodies reactive with phase II *C. burnetii* appear rapidly, reach high titers within 14 days and persist for 10–12 weeks. Immunoglobulin M antibodies reactive with phase I antigens are usually at a much lower titer during acute infection. Immunoglobulibn G antibodies reactive with phase II antigens reach peak titers about 8 weeks after the onset of symptoms, while those reactive with phase I antigens develop only very slowly and remain at lower titers than antibodies to phase II antigens, even after a year. In chronic Q fever, where there is persistence of organisms, the IgG titers to phase I and phase II antigens may both be high, and the presence of IgA antibody to phase I antigen is usually, although not exclusively, associated with chronic infection. Thus elevated levels of IgG (>1/200) and IgM (>1/25) to phase II but not phase I antigens indicates acute infection, while high titers of IgG (1/800) and IgA (>1/50) to phase I antigen is more predictive of chronic infection. An analysis of three isotype-specific assays (IgG, IgM and IgA) is therefore more useful than total antibody assays in laboratory investigations of suspected Q fever.[72] Moreover, patients who have increased levels of IgA2, rather than IgA1, to phase II antigens appear to be at high risk of developing endocarditis.[73]

CLINICAL MANIFESTATIONS

The incubation period depends on the route of exposure, the inoculum dose and the age of the patient, but is usually about 3–4 weeks. A variety of clinical manifestations may be recognized. The most frequent of these are mild fever (>99.5°F (>37.5°C)), headache, chills, sweating, cough, nausea and bradycardia relative to body temperature[69] . A maculopapular rash develops in about 20% of acute infections. The fever usually subsides gradually during week 1, with recovery by week 3 of the illness. There is an inverse relationship between severity of disease and age, and infections in children may go unnoticed. Other frequently occurring presentations include pneumonia and hepatitis, and the prevalence of these may vary geographically. Possible reasons for this geographical variation include strain characteristics, the source, the route and the dose of infection and a variety of host factors.

Clinical recovery usually occurs by the third week but *C. burnetii* organisms may persist in the tissues much longer, and can be recovered from tissues years or even decades after primary infection. A post-Q-fever fatigue syndrome, associated with cytokine dysregulation and presenting with fatigue, myalgia, arthralgia, night sweats, mood change and sleep disturbance, may occur in up to 20% of patients. Chronic Q fever may result in osteomyelitis or encephalitis but there is a high risk of endocarditis, particularly in patients who have pre-existing valvular disease. Q fever endocarditis has a poor prognosis despite therapy. Myocarditis, splenic rupture, meningoencephalitis and pericarditis are all rare manifestation of acute Q fever.[74]

Management

In-vitro studies have shown that rifampin, doxycycline and oxytetracycline and quinolones inhibit the growth of *C. burnetii*, although within the acidic environment of the phagolysosome other agents such as ceftriaxone and fusidic acid may be more effective. Prompt treatment of acute Q fever with doxycycline or tetracycline reduces the duration of fever, but it is not known whether this correlates with elimination of organisms. Combinations of doxycycline with either hydroxychloroquine, or ofloxacin taken daily for 18–36 months has been recommended for chronic infections and may prevent development of endocarditis. [75] The treatment of Q fever endocarditis is problematic. Prolonged regimens that include doxycycline and either rifampicin, trimethoprim-sulfamethoxazole or lincomycin have been reported to be effective but organisms can still be demonstrated in tissues months or even years later.

Chapter 236 - Chlamydia

Pekka Al Saikku

INTRODUCTION

The disease of trachoma was described for the first time some 3000 years ago. Chlamydial inclusions were first observed in patients with trachoma in 1908 by Halberstaedter and Prowazek[1] but the causative agent was isolated in chicken egg yolk sacs only in 1957.[2] Although the association was found before the First World War, it was not until the 1970s that the prominent role of the trachoma agent in sexually transmitted disease (STD) was realized and soon its importance in pelvic inflammatory disease (PID) was revealed.[3] [4]

The causative agent of psittacosis ('parrot fever'), transmitted by caged birds, was discovered in the 1930s. In several animal diseases, similar small bacteria that multiply in inclusions were found, and later it was realized that they were related to lymphogranuloma venereum and the trachoma agent. In the 1960s, these agents were finally classified on the basis of their multiplication cycle and the common group antigen as belonging to the genus *Chlamydia*, which was further divided, on the basis of glycogen content of inclusions, into two species: *C. trachomatis* (trachoma and human STD strains) and *C. psittaci* (which included all the other strains).[3]

Once serologic diagnosis of psittacosis was available, it became apparent that 'bird-transmitted pneumonia' could be transmitted without any apparent contact with birds. A chlamydial strain that had been isolated in 1965 as a result of trachoma studies in Taiwan was found to be responsible for the majority of chlamydial respiratory infections in humans. It represented a new chlamydial species, *C. pneumoniae*, and is in fact the most common chlamydial species infecting humans.[5]

The diseases seldom occur abruptly and they are not easily recognized; rather, chlamydial infections may run an insidious, chronic course, causing severe damage only after years of infection. Moreover, their obligatory intracellular growth makes normal bacteriologic analysis difficult.[6] The sequencing of whole genomes of several chlamydial species[7] has provided new possibilities for studying these organisms and our concepts of the nature of chlamydiae are changing accordingly.

NATURE

Current classification of chlamydial species is rapidly evolving and there are proposals to name new species and even new genera.[8] The genus *Chlamydia* includes *C. trachomatis* as a human pathogen with relatives found in the mouse (*C. muridarum*) and pig (*C. suis*). The genus *Chlamydophila* includes *C. pneumoniae* as a human pathogen with relatives reported in the horse and koala. *Chlamydophila psittaci* is a pathogen of birds, *C. abortus* and *C. pecorum* are pathogens of ruminants, *C. felis* is a pathogen of cats and *C. caviae* is found in guinea pigs. All except the last species also cause diseases in humans.

Two new families are proposed, Parachlamydiaceae and Simkaniaceae. Both currently contain a single species and *S. negevensis* seems to be common in humans. Its possible association to human diseases is still poorly understood.[9] The closest relatives of *Chlamydia* spp. are small aquatic bacteria that, like *Chlamydia* spp., do not use peptidoglycan as the structural component of the infective particle (Table 236.1).

Chlamydiae are small, Gram-negative bacteria that are obligatory intracellular parasites. They are not cultivable on synthetic media. They exist in nature in two forms: a non-replicating, infectious dense particle called the elementary body (EB); and a loose, larger, intracellular form, the reticulate body (RB), which is able to multiply by binary fission but is noninfectious (Fig. 236.1).[10] The EB is a spherical particle about 300nm in diameter; it can be stored at -94°F (-70°C) in sucrose-containing buffers and cultured in cell cultures.

Chlamydiae have a double layer membrane of Gram-negative bacteria with a periplasmic space. They are usually devoid of peptidoglycan, but seem to use it when dividing.[11] The circular genomes of *C. pneumoniae* and *C. trachomatis* contain 1,230,000 and 1,039,000 base pairs, respectively, with just over 1000 potential genes.[7] Species-specific plasmid is present in 10 copies in *C. trachomatis*,[12] but is not found in the human type of *C. pneumoniae*. The major outer membrane protein (MOMP) forms the outer membrane of the particle with some minor proteins, of which two are rich in cysteine. *Chlamydia trachomatis* has nine and *C. pneumoniae* 21 genes for putative membrane proteins (PMPs). Cysteine-rich proteins apparently have replaced the peptidoglycan with their S-S bridges in maintaining the rigidity of the chlamydial membrane. On electron microscopy, the surface can be seen to consist of a hexagonal pattern with substructures made up of a few rosettes with short spikes (Fig. 236.2).[13]

The MOMP of *C. trachomatis* contains four variable regions, which divide it into about 20 immunotypes denoted alphabetically. [14] The MOMP of *C. pneumoniae* is more homogeneous and the surface structure differs from that of *C. trachomatis*. Chlamydial lipopolysaccharide (LPS) is of rough type, weakly endotoxic and situated in the outer membrane.

The multiplication cycle is best known in the case of *C. trachomatis*. The EBs attach to the surface of susceptible cells and are passively engulfed by activity of the cell. *Chlamydia trachomatis* lymphogranuloma venereum biotype is wrapped by heparan sulfate that is taken from the cell by the chlamydial organism, which can then use heparin receptors on the cell surfaces;[15] *C. pneumoniae* and *C. psittaci* may also use heparin in the attachment. An oligosaccharide containing mannose residues that are covalently bound to MOMP may also participate in the attachment process.[16]

Chlamydiae can prevent the fusion of the endocytic vacuole with lysosomes and travels on microtubules joining to the exocytic pathway. The EB envelope changes, transforming the metabolically inactive inert EB into the metabolically active RB, which is 0.8–1µm in diameter. In the process, the disulfide bridges are reduced and MOMP acts as a porin. DNA, RNA and proteins are synthesized within the RB, which divides successively by binary fission. The endosomal walls intercept nearby trans-Golgi vesicles that incorporate sphingomyelin and glycerophospholipids into the swelling chlamydial inclusion (Fig. 236.3 and Fig. 236.4) Metabolically active RBs acquire

TABLE 236-1 -- General properties of *Chlamydia*.

GENERAL PROPERTIES OF *CHLAMYDIA*
• Obligatory intracellular Gram-negative parasites
• Elementary body-reticulate body cycle
• Lack of peptidoglycan
• Common group antigen (lipopolysaccharide)
• Tendency to persistent infections
• Immune defense participates in the development of lesions

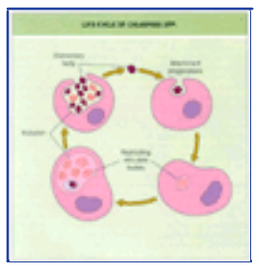

Figure 236-1 Life cycle of *Chlamydia* spp.

nutrients and metabolic building blocks, including nucleotides and ATP ('energy' parasites) from host cells.[17] Chlamydial LPS is present in RBs and seems to attach to host cell membranes.

Chlamydiae use their type III secretion system to gain control over the host cell. Apoptosis is prevented during the growth period but induced in nearby inflammatory cells.[18] Eventually, the inclusion body may contain several thousand chlamydial RBs. At the end of the replication cycle, chlamydiae start to condense into EBs and apoptosis and proteolysis are promoted in order to liberate the new infectious particles. Recently, the presence of a chlamydial cytotoxin has been demonstrated.[19] Sometimes the mature inclusion is expelled intact but usually the inclusion bursts open, releasing infective chlamydial particles and the cell dies. The whole cycle takes 2–3 days. Depletion of tryptophan or iron or the presence of penicillin or interferon-? in subinhibitory concentrations induces an aberrant, slowly metabolizing form of RB, which can persist for long periods. In chronic infections this may be the dominant form of chlamydia.[20] The microscopic appearance of chlamydial inclusion varies with different strains, and the inclusions of *C. trachomatis* contain glycogen.

EPIDEMIOLOGY

Chlamydia trachomatis is transmitted by direct contact and via vectors such as flies and contaminated towels in poor sanitary conditions in trachoma-endemic areas. Newborn infants contract the infection from their mother, sometimes before birth, and can infect their siblings via excretions. In industrialized countries, *C. trachomatis* is by far the most common bacterial STD. The incidence is greatest in young sexually active people and varies widely among different areas, from very low levels in Scandinavian countries to 15–20% in some urban areas of other developed countries (see Chapter 74).

Chlamydia pneumoniae is a common respiratory pathogen worldwide. In tropical countries, infections are common during the first

years of life, especially in urban slums. In industrialized countries, children begin to seroconvert at school age at the rate of 10% each year.[21] The rate seems to depend on population density, but at the age of 15 years 25–50% of populations have demonstrable antibodies against the agent. The antibody prevalence continues to rise; nearly all elderly people have measurable antibodies. Because antibodies are lost by a few years after an acute infection, this steady increase points to repeated infections during life and to possible chronic infections. Spread via droplets has been proposed. Asymptomatic carriers are found but their number is disputed and there is a possibility that only some people are effective transmitters of the agent. In sparsely inhabited areas in high latitudes, *C. pneumoniae* causes epidemics at intervals of 5–7 years. In lower latitudes, the interval between epidemics is shorter and an endemic situation can be found near the equator. In military garrisons with susceptible recruits, the epidemics are prolonged and can last 6 months.[22]

Avian *C. psittaci* is contagious in dried droppings of diseased birds for several days and is typically transmitted by the inhalation of dust. Patients are usually turkey or duck farmers, plant processors or persons who have contact with diseased caged or wild birds. Person-to-person transmission occasionally occurs. Infections caused by *C. psittaci* strains from mammals are less well known. Ovine abortion strains are known to cause septic abortions in pregnant women who are in contact with affected farm cattle. [23] Pet cats can be a source of *C. felis* infections. *C. psittaci* strains are well known for their capacity to cause severe laboratory infections.

C. pneumoniae, like *Legionella*, is able to multiply in amebae[24] but the significance of this property in epidemiology is so far not known.

PATHOGENICITY

Owing to their unique life cycle, in which they parasitize only living, metabolically active cells, chlamydiae are not harmless commensals.[3] [25] It is not known whether the pathogen stays dormant inside cells, protected from antibodies, for prolonged periods, only to be activated later by some signal, or whether there is a special form of chronically infecting *Chlamydia* spp.[26] In chronic persistent infections in vitro, it is possible that chlamydiae respond with morphologically abnormal forms,[27] in which internal proteins such as heat shock proteins (hsps) are produced and antigens of mature EBs are diminished.[20]

Chlamydiae are potent inducers of cytokines, such as interferon-? and interleukin-1, which prevent the multiplication of the agent in vitro.[17] In chronic infections such as trachoma, there are findings that point to diminished cell-mediated immunity and increased humoral immunity.[28] Chlamydial immunity is relatively short-lived and immunotype specific and reinfections are common. In repeated chlamydial infections,[29] there is a hypersensitivity component, apparently caused by common internal cross-reactive proteins. Chlamydial hsp60, a protein produced in chronic infections, has been blamed for the hypersensitivity reactions seen.[30] Moreover, it is related to the host's hsp60 and may initiate autoimmune reactions.[31]

In chronic chlamydial infections, chlamydia can persist in non-cultivable form and damage results partly from persistent inflammation.[25] Blinding trachoma[32] was thus named after *C. trachomatis* and long-term sequelae of lymphogranuloma venereum (rectal strictures, elephantiasis and esthiomena) have been known for some time,[33] but infertility and ectopic pregnancies caused by tubal occlusion have only recently been associated with chronic *C. trachomatis* infection. [4] *Chlamydia pneumoniae* (Fig. 236.5) is able to disseminate inside white blood cells in the circulation[34] [35] and multiply in vascular tissue.[36] Human hsp60 and chlamydial hsp60 co-localize in atherosclerotic plaques.[37] Chlamydial LPS induces cytokine and adhesin responses and formation of foam cells in macrophages.[38]

PREVENTION

Vaccines against *Chlamydia* spp. have been under development for 40 years without evident success. *Chlamydia trachomatis* has several immunotypes, making development of a vaccine complicated, and the protective antigens of *C. pneumoniae* are not known. Knowledge of the complete genome and progress in immunology may alter this situation in the future.[39]

Mass medication campaigns have been used against trachoma in Africa and there are local projects to eradicate the agent with generalized antibiotic courses for the whole population.[40] However, improvement in living standards would be a better long-term preventive measure. Washing the face every second day with clear water and wiping it with a towel that is not shared with other people is effective.[41] Dirty water and shared towels are effective disseminators of the infection from eye to eye. Latrine hygiene is effective in controlling flies that spread trachoma. Using an undamaged condom protects against genital chlamydial infection.

Active tracing and treatment have been effective against sexually transmitted *C. trachomatis*. The new nucleic acid-based tests have raised the question of general screening in order to eradicate *C. trachomatis* from populations. In the USA screening of sexually active women under 25 years of age is recommended (see Chapter 73).[42]

DIAGNOSTIC MICROBIOLOGY

The clinical features of chlamydial infections, such as their slow onset, the low numbers of infectious agents present and the cross-reactions seen in serology, make usual diagnostic methods difficult.[43] [44]

Culture

Culture was originally the gold standard in *C. trachomatis* diagnosis but it is an unsatisfactory standard for *C. trachomatis* and even more so for *C. pneumoniae*. Moreover, culture of *C. psittaci* is a well-known cause of laboratory infections.

Samples for culture should contain live cells from the diseased area and this can be problematic if the pathogen has invaded to deeper tissues. The sample is collected in a medium that contains sucrose, aminoglycosides, vancomycin and antifungal agents. McCoy cell lines and green monkey kidney cell lines are commonly used for *C. trachomatis* and Hep2 and HL cells are commonly used for *C. pneumoniae*. Centrifugation onto cells and the addition of cytostat

---

(usually cycloheximide) into the growth medium are needed for optimal growth. Multiwell plates are suitable for mass isolation attempts, but vials are better protected from cross-contamination. *Chlamydia trachomatis* can be stained by Lugol's iodine stain. Immunofluorescence staining gives a more clear-cut result and, when using LPS-specific monoclonal antibody, stains all *Chlamydia* spp. The culture result is available in 2–3 days, but blind passage can improve sensitivity.

Chlamydia trachomatis can be present in clinical samples in sufficient amounts to be toxic for cell cultures. The situation is quite different with *C. pneumoniae*, because as a rule only a few inclusions are found in primary isolations, pointing to the paucity of *C. pneumoniae* in throat epithelium collected by swabbing. Nasopharyngeal swabs for *C. pneumoniae* rather than throat swabs have been recommended in some studies.

Antigen detection

All enzyme immunoassay (EIA) kits for the diagnosis of *C. trachomatis* measure the common LPS group antigen that is present in all chlamydiae and produced in large amounts during the growth cycle. Several commercial kits, some fully automated, are available and widely used. Because massive microbial contamination can cause false-positive reactions, positive results should be confirmed. Confirmatory EIA tests are available, but in the case of *C. trachomatis*, EBs can be concentrated from the positive sample and visualized with direct fluorescent antibody (DFA) staining. Lipopolysaccharide-EIA kits can probably also be used for the detection of *C. pneumoniae* LPS from respiratory tract samples, but they have not been systematically tested.

Direct fluorescent antibody staining has been successfully used in *C. trachomatis* diagnosis. This test seems to be marginally more sensitive than EIA; moreover, the quality of the sample can be controlled in the stained smear. However, the interpretation demands expertise and is tiring to the reader, and therefore the test is often used only in the confirmation of EIA tests. In this circumstance, samples that are weakly positive (under the cut-off range) should be tested with DFA staining, which will reveal the true positives among the weakly positive samples. The test is insensitive in the demonstration of *C. pneumoniae* in throat swabs. The pharyngeal microbial flora is quite variable, and the search for very small numbers of EBs is difficult. *Chlamydophila psittaci* can also be seen in smears. The lack of species-specific monoclonal antibodies for *C. psittaci* necessitates the use of anti-LPS antibody, and the results can then be difficult to interpret, especially if the number of EBs is small.

Serology

In individual *C. trachomatis* infections, serologic tests are often of questionable value, although serology has been important in epidemiologic and disease association studies. The infection is often superficial without detectable seroconversion. Proper antibiotic therapy can also prevent antibody formation. Serology has been the method most commonly used for *C. psittaci* and *C. pneumoniae*. The need for paired samples considerably lessens the value of serology in acute situations.

The time-honored complement fixation (CF) test has traditionally been used for the diagnosis of chlamydial respiratory tract infections. The CF test is sensitive in psittacosis, but in *C. pneumoniae* infections it is sensitive only in primary infections of young adults.[22] The use of the CF test in *C. trachomatis* infections is limited to lymphogranuloma venereum.

Enzyme immunoassay tests based on chlamydial EBs or chlamydial LPS (group antigen) are commercially available but have not gained wide popularity. In acute infections, in most cases they demonstrate seroconversions satisfactorily. Synthetic peptides should enable EIA to be made species-specific in the future.

Microimmunofluorescence (MIF) testing, if properly done, can differentiate between species and even immunotypes. It is, however, demanding and can be performed in relatively few laboratories. Chlamydial antibodies are rare in young children, but at school age antibodies against *C. pneumoniae* begin to rise rapidly. *Chlamydia trachomatis* antibodies start to appear at the sexually active age and peak at about 30 years of age. They are more often found in females than in males; the opposite is seen with *C. pneumoniae* antibodies, where males predominate. Microimmunofluorescence testing seems, for the moment, to be the most convenient test for the serologic diagnosis of an acute *C. pneumoniae* infection.[44] In primary infections the diagnosis can be obtained from the first sample that contains IgM antibodies specific for *C. pneumoniae*. The possibility of a false-positive reaction due to IgM rheumatoid factor should always be kept in mind, especially in elderly patients. In elderly patients undergoing reinfections, the rapid response can be missed if the first serum sample is not collected early enough after the onset of disease. Apart from the situation in which strong group reaction interferes with the result, an experienced reader can interpret the reaction to differentiate not only the species but also the immunotype. In MIF testing, strains of *C. pneumoniae* react much more uniformly than do those of *C. trachomatis*. In *C. trachomatis* infections, MIF testing is usable in lymphogranuloma venereum, perihepatitis and infant pneumonitis, and it can give a clue to the triggering agent in reactive arthritis.

Detection of nucleic acids

The use of nuclei acid-based detection systems has altered the former concept of culture as the 'gold standard' of *C. trachomatis* diagnosis[42] and is replacing other diagnostic methods. Three methods have already appeared on the market, based on polymerase chain reactions (PCR), ligase chain reaction or transcription-mediated amplification. A great advantage is the possibility of using mailed morning void urine, tampons and self-collected samples for detection.

In the case of *C. pneumoniae* commercial PCR kits are not currently available and in-house PCR kits vary widely in their sensitivity. [43] In acute infections, they seem to be more sensitive than isolation. Upper respiratory tract samples can be negative and sputum is preferred. [44]

Diagnosis of chronic chlamydial infections

Diagnosing chronic chlamydial infections is problematic. The number of infective organisms can be small and the site of infection can be difficult to reach. Culture often remains negative, especially if the sample is from a peripheral site. Antibody responses can be quite variable or even lacking. Persistently elevated titers, especially of IgA, have been suggested as a marker, but their value in individual diagnosis is doubtful. Enzyme immunoassay tests have been inferior when compared to the MIF test. Antigen detection by immunohistochemistry is more sensitive and diagnostic but, like nucleic acid-based methods (e.g. amplification, in-situ hybridization), they are currently used in research laboratories only.[44] The value of demonstrating circulating immune complexes that contain chlamydial antigens in blood samples is under evaluation, as is the value of detecting nucleic acid in circulating white blood cells. Both markers, however, can also be found in healthy persons and are affected by age and season.[34] [45]

CLINICAL MANIFESTATIONS

The diseases associated with chlamydial infection are listed in Table 236.2 .

TABLE 236-2 -- Diseases associated with *Chlamydia spp.*, or in which a possible association has been proposed.

DISEASES ASSOCIATED WITH *CHLAMYDIA* SPP., OR IN WHICH A POSSIBLE ASSOCIATION HAS BEEN PROPOSED				
Species	**Infection**	**Distribution**	**Disease**	**Incidence**
Chlamydia trachomatis	Acute infections	Females	Cervicitis	About 30%
			Endometritis	Common
			PID	10–70%
			Perihepatitis, splenitis, appendicitis	Isolated case reports
			Bartholinitis	Rare
		Males	Urethritis	10–30%
			Epididymitis	In young males
		Both sexes	Conjunctivitis	Isolated case reports
			Reactive arthritis	Common cause
		Neonates	Conjunctivitis	<10%
			Infant pneumonitis	By definition
	Chronic infections		Trachoma	By definition
			Chronic PID	Common
Chlamydia pneumoniae	Acute infections		Pneumonia Endemic	10%
			Pneumonia Epidemic	up to 50%
			Acute bronchitis	5%
			Sinusitis	<5%
			Otitis media	Isolated case reports
			Upper respiratory tract infection	~10% of school children annually
			Carditis	Isolated case reports
			Vasculitis (erythema nodosum)	Isolated case reports
			Reactive arthritis	Isolated case reports
	Chronic infections		Chronic obstructive lung disease	10–50%
			Asthma	?
			Sarcoidosis	?
			Atherosclerosis	up to 50%
Chlamydia psittaci			Psittacosis-ornithosis	By definition
			Infectious abortion	Rare

Chlamydia trachomatis infections

Genital infections in females (see Chapter 74)

Chlamydia trachomatis is the most important cause of bacterial genital infections in women. Infected women often remain asymptomatic carriers and can thus transmit the disease. The prevalence of carriers varies widely depending on the population (2–20%). Immunotypes E–K and B are usually found in genital infections.

Vaginitis due to *C. trachomatis* is seen only in childhood and after the menopause. Women aged 15–25 years are particularly susceptible to *C. trachomatis* cervicitis, both for anatomic reasons and because of the slow development of immunity. It cannot be differentiated clinically from cervicitis caused by other agents, although mucopurulent discharge and hypertrophic follicular formations in an edematous and friable epithelium ('genital trachoma') are typical of the disease (Fig. 236.6).[46] One of the causes of 'aseptic', culture-negative cystitis in women is *C. trachomatis*. [47] *Chlamydia trachomatis* has been isolated as pure culture in cases of bartholinitis. It is much more common in patients with endometritis.[48] Plasma cell infiltration is the typical microscopic hallmark in the chronic form of this disease.

Pelvic inflammatory disease is the most important complication of female genital infection with *C. trachomatis*, and in areas where the prevalence of gonorrhea has decreased *C. trachomatis* is the most common cause of PID. Clinically, chlamydial PID cannot be differentiated from gonococcal PID, but in chlamydial PID the patients tend to be younger and the onset of the disease is slower with a less marked fever. Markers of acute infection, such as erythrocyte sedimentation

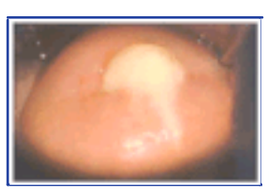

Figure 236-6 Mucopurulent cervicitis caused by *Chlamydia trachomatis*. *Courtesy of Dr J Paavonen.*

rate (ESR) and C-reactive protein, are clearly elevated. Infection can proceed to the abdominal cavity and cause 'sterile' peritonitis with ascites.

Typically, however, the symptoms come from more localized areas of infection. Acute perihepatitis (Fitz-Hugh-Curtis syndrome) is commonly caused by *C. trachomatis*

and this should be kept in mind when young female patients complain of right upper quadrant

abdominal pain. In perihepatitis, the capsule of the liver, not the liver tissue itself, is inflamed, typically leading to 'violin-string' adhesions. Periappendicitis and perisplenitis have also been reported.

Chlamydial PID often goes unrecognized. As a result, the patient is not treated, infection becomes chronic and over years can severely damage the fallopian tubes. Almost 50% of patients with tubal occlusions and elevated chlamydial antibody titers deny any episode of PID. Ectopic pregnancies and infertility problems are the most important complications of genital chlamydial infections in women.[49] Chronic chlamydial infection has been associated with fetal death, pre-term labor and late-onset puerperal fever.[50]

Genital infections in males

One-third of cases of nongonococcal urethritis are caused by *C. trachomatis*. The incubation period is 6–12 days, which is longer than for gonorrhea, and the course is milder than in gonorrhea. Asymptomatic carriers of *C. trachomatis* are also more common (up to 10% in some areas) than asymptomatic *N. gonorrhoea* carriers. Treatment aimed at gonococci does not affect *Chlamydia* spp. and the majority of postgonococcal urethritis cases are due to simultaneously acquired *C. trachomatis* infection.

The role of *Chlamydia* spp. in prostatitis is unclear. Cultures are negative but chlamydial nucleic acids and antigens have been demonstrated in prostatic tissue. It has not been proven that chlamydiae are a cause of azoospermia or infertility in men. However, epididymitis in young males is most commonly caused by *C. trachomatis*, and if the infection is bilateral this can cause infertility.

Infections in newborns

Chlamydial infection can be transmitted in utero and cause serious disease in the pre-term infant. Half the children born to a chronically infected mother are infected during birth. Topical prophylaxis is not effective and mothers should be treated before birth. Inclusion conjunctivitis of the newborn (ophthalmia neonatorum; Fig. 236.7) develops in 50% of the infants, usually after they have been discharged from hospital. The disease is milder than gonococcal ophthalmia neonatorum and there is no danger of perforation; only minute scarring can be seen. The disease is usually unilateral, but edema of both eyelids can be marked. *Chlamydia* spp. can also infect the nasopharynx, middle ears, lungs, intestine and vagina of the newborn.

Infant pneumonitis is a well-characterized complication.[51] The disease starts at 3–12 weeks of age with a stuffy nose, difficulty in breathing and a gradually worsening staccato cough. The infant is usually afebrile, but chest radiographs may show marked hyperexpansion and prominent striations in the lungs. Specific IgM levels

Figure 236-7 Ophthalmia neonatorum. *Courtesy of Dr M Puolakkainen.*

are elevated, as may those of eosinophils. Although the radiograph findings are often marked, the short-term prognosis is good and only rarely does the patient require intensive therapy. In the long term, however, the lungs seem to be damaged and these children are sensitive to repeated respiratory tract infections and often go on to develop asthma.[52] *Chlamydia trachomatis* is a rare cause of respiratory tract infections after 6 months of age. There are reports in the literature of pharyngeal carriage of *C. trachomatis* in adults, but the agent has not been clearly associated with pharyngitis.

Eye infections

Trachoma, which is due to *C. trachomatis*, is still a great scourge in developing countries, where it is the most common preventable cause of blindness.[32] About 500 million people are victims of this disease and 7 million are blind as a result of the chronic follicular conjunctivitis it causes. Although the pathogenesis of trachoma has been intensively studied, it is not known why only some of the children exposed to repeated inoculations by chlamydial agents (immunotypes A–C) develop chronic disease. The clinical features of the chronic disease include a pannus over the cornea and scarring of the lids by entrichiasis (eyelashes turn inwards and scrape the cornea). Trachoma occurs in poorly developed areas with a low standard of sanitation and lack of washing facilities.

Occasionally, genital *C. trachomatis* infection can lead to 'inclusion conjunctivitis', because of self-inoculation or oral sex with an infected partner. Follicular formation is seen, but corneal lesions are rare. Infection is usually unilateral and associated with palpebral edema. The disease is typically diagnosed only after topical treatments have failed. Although the first *C. pneumoniae* strains to be isolated were from eyes, conjunctivitis is rarely seen in *C. pneumoniae* infections.

Lymphogranuloma venereum

Chlamydia trachomatis immunotypes L_1 , L_2 and L_3 differ from other *C. trachomatis* strains in their invasive nature and in belonging to the lymphogranuloma venereum biovar. Instead of multiplying in epithelial cells, they multiply in the reticuloendothelial system. Inguinal lymph nodes are the target organs, but the agent spreads systemically and can affect various organs. Sequelae include strictures in pelvic lymphatic vessels, which may lead to elephantiasis, and rectal strictures. The disease is not common in industrialized countries, but it is important in some tropical areas (see Chapter 78). [33]

Chlamydophila pneumoniae and *Chlamydophila psittaci* infections

Chlamydophila pneumoniae and *C. psittaci* multiply in similar target cells. The patterns of disease they cause are identical except that the ovine abortion agent of *C. psittaci* can cause infectious abortion in pregnant women and acute infections due to *C. psittaci* tend to be more severe than those caused by *C. pneumoniae*.

Respiratory infections

In children the typical disease picture is a mild upper respiratory tract infection, but pneumonia has been reported, even in infants. This pneumonia should not be confused with *C. trachomatis* infant pneumonitis, in which the parents must be treated for their STD. Chlamydial pneumonias typically have an insidious onset, fulminant psittacosis being an exception. Epithelial cells and mononuclear phagocytes are target cells and the result is pneumonitis without purulent sputum. If the sputum turns purulent, there is likely to be an accompanying bacterial infection. Except for true psittacosis and in elderly patients with underlying predisposing disease, the prognosis is good, but convalescence can be prolonged by persisting fatigue. There is a tendency for relapses.[53]

C. pneumoniae can cause sinusitis and otitis, but dry cough with mild pharyngitis is often the most common manifestation. [22]

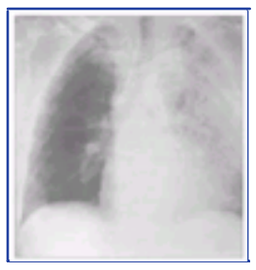

Figure 236-8 *Chlamydia pneumoniae* reinfection pneumonia in a 63-year-old male.

C. pneumoniae is the cause of acute bronchitis in 5% of cases.[5] Infection can be asymptomatic, especially in children, but the number of carriers is unknown.

In young adults, 10% of cases of *C. pneumoniae* infections are pneumonias, which often have an insidious-onset pharyngitis followed by a mild pneumonia. The throat is hoarse and there is a persistent dry cough and usually a low-grade fever. Erythrocyte sedimentation rate and C-reactive protein are elevated, but the white cell count is usually normal or only mildly elevated. Differential diagnosis from other causes of pneumonia is impossible on clinical grounds. Chlamydial pneumonia cannot be reliably differentiated from pneumococcal pneumonia on chest radiograph, because chlamydial pneumonia can have a lobar pattern as well as its more usual pattern of 'atypical' pneumonia (Fig. 236.8) (see Chapter 34).

Generalized* Chlamydophila pneumoniae *and* Chlamydophila psittaci *infections

Chlamydophila pneumoniae and *C. psittaci* are able to multiply in mononuclear phagocytes and this enables dissemination into the circulation. Headache and confusion are common in severe infections, and meningoencephalitis and Guillain-Barré syndrome have been described. In some patients liver enzymes are elevated and proteinuria is present. Endocarditis, myocarditis and pericarditis have been found.[54] All of these symptoms have been described in the absence of any preceding overt respiratory infection.

C. pneumoniae infection has a tendency to remain persistent and low levels of the agent have been demonstrated in the lungs of healthy young adults by immunohistochemistry.[55] *Chlamydophila*-specific IgA levels are elevated in serum and especially in the local secretions of patients with chronic obstructive lung disease.[56] Exacerbations associated with acute *C. pneumoniae* infections have been reported [57] but more often there seems to be chronic carriage without seroconversion; the agent is detected in pulmonary secretions by using PCR and is shown to be abundant in histologic samples by immunohistochemistry and electron microscopy.[55] [58] The extent to which this carriage participates in the inflammatory process is not known.

Recent studies have also suggested an association between *C. pneumoniae* and asthma, in both adults and children.[59] Favorable outcomes in therapeutic trials with antibiotics effective against *C. pneumoniae* have been claimed in adult-onset asthma,[60] where the presence of specific IgA antibodies again seems to be a better marker of chronic infection than IgG. The role of the agent in childhood asthma is uncertain, but carriage demonstrated by both culture and PCR has been reported, as has *C. pneumoniae*-specific IgE and local IgA antibodies. The first large intervention trial against *C. pneumoniae*-associated asthma in adults with antibiotics left the question open.[61]

One of the most unexpected findings in *Chlamydia* research has been the association of *C. pneumoniae* with atherosclerosis.[62] If proven, it will be of enormous significance.

Over 50 seroepidemiologic surveys have repeatedly demonstrated that the presence of elevated antibodies against *C. pneumoniae* is associated with an increased risk of having a cardiac event.[63] [64] The magnitude of the increased risk is dependent partly on the prevalence of antibodies in control population; it is greatest in young populations during periods between epidemics. The risk increases usually about 2-fold but higher risks have been reported. The antibody findings are further supported by the presence of circulating immune complexes containing *C. pneumoniae* antibodies and antigens, pointing to an access of chlamydial components into the circulation.[45] Final demonstration of the common presence of the agent in the atherosclerotic lesion has been obtained by electron microscopy, immunohistochemistry, nucleic acid demonstration by PCR, in-situ hybridization[65] and even isolation of the agent from lesions.[35] [66] [67]

The important question is does this presence have an effect on the atherosclerotic process? There is a possibility that *C. pneumoniae* is simply an innocent bystander in atherosclerotic lesions. However, it is a nonmotile intracellular pathogen, able to multiply in macrophages, endothelial cells and smooth muscle cells.[36] This multiplication is accompanied by induction of cytokines, adhesion molecules, proteases and oxidative substances as the host defense mechanisms against chlamydial infection. Infected macrophages tend to become foam cells, the characteristic pathologic feature of the atherosclerotic plaque.[38] Several well-known risk factors for coronary heart disease are also associated with a chronic *C. pneumoniae* infection, such as smoking, elevated cholesterol levels, lowered levels of high-density cholesterol[64] and elevated blood pressure.[68] Continuous induction of cytokines may be responsible for this association. Recent animal experiments point to the possibility that it could even initiate the process[69] and that this could be prevented with antibiotics. Recent preliminary human intervention trials with macrolides[70] [71] [72] [73] [74] [75] or doxycycline[76] have given partly contradictory results.

If chlamydial infection is a significant factor in the development of atherosclerosis, it would open new perspectives in the battle against this disease and even the prospect of the development of an 'anti-atherosclerosis vaccine' is possible.

Chlamydia-*associated arthritis*

Chlamydiae have long been known to trigger reactive arthritis which is typically seen after an episode of urethritis in males (Reiter's syndrome — a similar association is elusive in females) and in cases of *C. pneumoniae* and *C. psittaci* after a respiratory tract infection. Patients usually have HLA-B27 antigen and a complete Reiter's triad of urethritis, conjunctivitis and arthritis can occasionally be seen. Although chlamydial cultures are usually negative, recent studies have demonstrated chlamydial particles in synovial fluid and metabolically active chlamydia in synovial tissue, which is not the original concept of reactive arthritis. This could also explain why prolonged antibiotic treatment is effective in chlamydial arthritis[77] but not in enterobacterial reactive arthritis. *Chlamydia trachomatis* seems to be the most common cause of chlamydial arthritis. Whether this is a reflection of differing tissue tropism of the different *Chlamydia* spp. is not known.

Chlamydiae in cancer and chronic neurologic processes

By the 1930s, *C. trachomatis* lymphogranuloma venereum biovars had been associated with anorectal cancers and subsequently they were associated with cervical dysplasia and cancer. Recently, these observations have been repeated and there seems to be an

association between *C. trachomatis* infection and invasive squamous cell cervical carcinoma.[78] In smokers, *C. pneumoniae* has been associated with squamous cell carcinoma and small cell carcinoma in lungs.[79] The situation is analogous to the association between *Helicobacter pylori* and gastric cancer and it deserves further study. There are some claims that *C. pneumoniae* is associated with chronic neurologic processes such as multiple sclerosis and Alzheimer's disease, but this has remained unproven.[80]

MANAGEMENT (see Chapter 18 , Chapter 34 and Chapter 74)

Chlamydiae are sensitive to tetracyclines, macrolides, azalides and newer fluoroquinolones. An antimicrobial effect is also seen with rifampin (rifampicin), clindamycin and chloramphenicol. Chlamydiae are resistant to aminoglycosides, vancomycin and cephalosporins.

Chlamydiae contain penicillin-binding proteins and amoxicillin has been recommended for *C. trachomatis* cervicitis or carriage during pregnancy.[81] However, there is a danger of infection becoming chronic. Single-dose 1g azithromycin is replacing the traditional 7–10 days' tetracycline or macrolide treatment in uncomplicated genital chlamydial infections.[82] In complications such as PID, longer treatment periods of 2 weeks are recommended, and a possible polymicrobial origin must be considered. In *C. trachomatis* conjunctivitis, whether neonatal or adult, topical treatment is not sufficient. *C. pneumoniae* can be very resistant to therapy and in pneumonia 3-week macrolide or doxycycline courses have been recommended. In chronic chlamydial infections, prolonged treatment courses of 1–3 months have been used. Persistent forms seem to be very resistant to treatment and in intervention trials even 1-year courses have been tried.

Chapter 237 - Opportunistic Fungi

Andy IM Hoepelman

INTRODUCTION

Fungal infections have become increasingly important clinically because of the rising incidence of immunocompromised patients as a result of infection, malignancy (especially leukemia), chemotherapy and immunosuppressive therapy, especially in transplantation medicine and in critical care. Moreover, the use of current antimicrobial prophylactic strategies has likely contributed to the changing epidemiology of invasive mycoses. Table 237.1 gives a list of medically important fungi that can cause disseminated infection in humans. Table 237.2 shows the variables that likely account for the current trends in the epidemiology of opportunistic fungal infections.

CANDIDIASIS

NATURE

Candida spp. are yeast-like fungi that can form true hyphae as well as pseudohyphae. They are ubiquitous in soil and food and can be found as normal commensals on skin and mucosal membranes of the human gastrointestinal, genitourethral and respiratory tracts.

Candida spp. that under certain conditions are clinically important are *C. albicans, C. guilliermondii, C. krusei, C. parapsilosis, C. tropicalis, C. kefyr, C. lusitaniae, C. rugosa, C. dubliniensis* and *C. glabrata* (also called *Torulopsis glabrata*).

The fungal origin of these lesions was first proposed in 1839. [1]

EPIDEMIOLOGY

Since the introduction of antibiotics in the 1940s, there has been a sharp increase in the incidence of candidal infections. In a survey of 180 hospitals from 1980 to 1990, *Candida* spp. were the sixth most commonly isolated nosocomial pathogens, most frequently cultured from the urinary tract (46%).[2] *Candida* spp. were the fourth most common cause of bloodstream infection (BSI; 8%), and were associated with a mortality of 29% (compared with 17% for BSIs caused by nonfungal pathogens).[2] [3]

In addition, there is an increasing shift toward non-*albicans* spp. in candidemia. A surveillance program of BSIs in the USA, Canada, Latin America and Europe from 1997 through 1999 detected 1184 episodes of candidemia in 71 medical centers (32 in the USA, 23 in Europe, nine in Latin America and seven in Canada). Overall, 55% of the yeast BSIs were due to *C. albicans*, followed by *C. glabrata* (20%) and *C. parapsilosis* (15%), *C. tropicalis* (9%) and miscellaneous *Candida* spp. (6%).[4]

Changes in the frequency of invasive candidiasis are most notable in the following subgroups of patients: those hospitalized in critical care units, patients with hematologic malignancies, hematopoietic stem cell transplant recipients and organ transplant recipients.[5] In a recent review of 74 published studies,[6] [7] the most important risk factors for nosocomial colonization and infection with *Candida* spp. were as follows: underlying diseases (hematologic cancer (OR 1.7–45), renal failure (OR 1.4–22), hepatic failure (OR 7–42)); invasive procedures or devices (central venous or arterial catheter (OR 5.8–26), urinary catheter (OR 13)); interhospital transfer of a patient (OR 21); and prolonged use of antibiotics (OR 1.7–25), especially vancomycin (OR 275). In mice and humans, vancomycin has indeed been shown to enhance gastrointestinal colonization with *C. albicans*.[2]

Among hematopoietic stem cell transplant recipients, an overall decrease has been documented in the frequency of candidal infections, as well as a shift toward isolation of non-*albicans* species of *Candida*.[8] [9] It has been proposed that use of fluconazole as antifungal prophylaxis largely accounts for these trends.[8] Antifungal prophylaxis with fluconazole during neutropenia and acute graft-versus-host disease (until day 75 after transplantation) was associated with a significant reduction in the incidence of invasive candidiasis and improved survival rates.[9] However, although *C. albicans* was the most common colonizing isolate before transplantation, resistant species such as *C. krusei* and *C. glabrata* were isolated after transplantation and exposure to fluconazole.[9] In another study, fluconazole prophylaxis was the most important determinant for the relative increase in isolation of *C. krusei* (OR 27.07) and *C. glabrata* (OR 5).[8] A meta-analysis of 16 randomized controlled trials, however, showed that fluconazole prophylaxis in neutropenic non-bone marrow transplant patients did not decrease fungus-related mortality or systemic fungal infections.[10]

Among organ transplant recipients, invasive candidal infections are most relevant for liver and pancreas transplant recipients. An overall decline in the incidence of invasive candidiasis has been noted in liver transplant recipients, even in the absence of systemic antifungal prophylaxis; many centers now report incidences of under 10%.

Molecular typing has shown that, in the majority of cases, candidemia arises from an endogenous origin after previous colonization. This holds true for *C. albicans* and most non-*albicans* spp. except for infections with *C. parapsilosis*, which are thought to arise mainly from infected biomaterials, intravenous fluids or the hands of health care workers.[3] Also, human-to-human transmission (patient-to-patient, nurse-to-patient and between sexual partners) has become increasingly important.

Recurrence of oropharyngeal candidiasis in patients who have AIDS has been shown to be mostly due to recurrence of the same strain (relapse), although infection with a new strain also occurs.[3]

PATHOGENICITY

Intact barrier function is an essential feature of host defense against candidiasis. The virulence of the *Candida* spp. has been shown to correlate with their ability to adhere to epithelial cells (especially *C. albicans*) or plastic polymers such as intravascular or urethral catheters (*C. tropicalis*). The fungus is capable of secreting proteinases and lipases that can assist invasion, although the clinical importance of these enzymes is not clear.[11]

After candidal invasion of the dermis or bloodstream, neutrophils constitute the first line of defense, followed by monocytes and eosinophils, which can kill *Candida* spp. via oxidative and nonoxidative

TABLE 237-1 -- Fungi causing disseminated infection in humans.

FUNGI CAUSING DISSEMINATED INFECTION IN HUMANS	
Fungi	**Medically important species**
Penicillium	*Penicillium marneffei*
Candida	*C. albicans, C. guilliermondii, C. krusei, C. lusitaniae, C. parapsilosis, C. pseudotropicalis, C. rugosa, C. stellatoidea, C. tropicalis, Torulopsis (or Candida) glabrata*
Cryptococcus	*C. neoformans var. neoformans, C. neoformans var gattii*
Aspergillus	*A. fumigatus, A. flavus, A. niger, A. terreus, A. nidulans*
Mucorates	*Rhizopus oryzae, R. arrhizus, R. rhizopodiformis, Rhizomucor pusillus, Absidia oryzae, A. corymbifera, A. ramosa, Mucor circinelloides*
Histoplasma	*H. capsulatum*
Coccidioides	*C. immitis*
Blastomyces	*B. dermatitidis*
Sporothrix	*S. schenckii*
Fusarium	*F. solani, F. oxysporum, F. moniliforme, F. dimerum, F. chlamydosporum, F. anthophilum*
Trichosporon	*T. beigelii, T. capitatum*
Geotrichum	*G. candidum*
Rhodotorula	*R. rubra*

Dermatiaceous molds (phaeohyphomycetes)	*Pseudallescheria boydii* (scedosporium apiospermum), *Bipolaris*, *Alternaria*, Scedosporium prolificans

TABLE 237-2 -- Variables that likely account for the current trends in the epidemiology of opportunistic fungal infections.[5]

VARIABLES THAT LIKELY ACCOUNT FOR THE CURRENT TRENDS IN THE EPIDEMIOLOGY OF OPPORTUNISTIC FUNGAL INFECTIONS
Increasing number of susceptible hosts
Greater laboratory expertise in the detection and identification of fungi
Use of new transplantation modalities for hematopoietic stem cell transplantation (e.g. $CD34^+$ selected autografts and peripheral blood stem cell transplantation)
Evolution in organ transplantation practices
Advances in surgical technology
Use of corticosteroid-sparing regimens and an overall conservative approach to immunosuppression
Use of novel immunosuppressive agents
Use of antimicrobial prophylactic practices, e.g. use of fluconazole for antifungal prophylaxis, ganciclovir for cytomegalovirus prophylaxis, quinolones for Gram-negative bacterial prophylaxis

pathways. Patients who have neutropenia are particularly at risk of developing candidiasis, which underscores the importance of neutrophils in host defense against this fungus. The clinical outcome of infection is primarily determined by the host defense status. Clinical and experimental data suggest that:

- an impairment of acquired cellular immunity (e.g. in HIV infection) predisposes mainly to mucocutaneous candidiasis (gastrointestinal and vaginal); and
- impaired innate immunity, especially neutrophil function, with or without impaired T-cell function, is the major risk factor for the development of systemic candidiasis.

Figure 237-1 Colonies of *Candida albicans* on culture plate.

In the rare chronic mucocutaneous candidiasis syndrome, various combinations of defect in T cell response to *Candida* spp. have been described [12] (see Chapter 98).

The role of humoral acquired immunity in the body's defense against candidal infection remains to be determined.[11]

DIAGNOSTIC MICROBIOLOGY

In general, a diagnosis of candidiasis faces the dual problem of:

- differentiating between colonization and infection, and
- under-detection of deep-seated infection.

In culture, *Candida* spp. grow rapidly at 77–98.6°F (25–37°C) on simple media. On special culture media, hyphae or elongating pseudohyphae are formed.

Candida spp. grow in routine ventilated blood culture flasks and on agar plates as smooth creamy white colonies (Fig. 237.1). A differential culture medium (CHROMagar Candida) can distinguish between *C. albicans* and certain non-C. *albicans* spp.

The yield from blood cultures in disseminated disease using conventional methods is low (15–30%), but improved culture techniques such as biphasic cultures and lysis-centrifugation have greatly improved the diagnostic capacity.[13] [14] Recently developed new methods to detect fungi more rapidly in blood cultures are BACTEC and BacT/Alert (Table 237.3). Therefore, appropriate communication about any clinical suspicion of candidemia to the diagnostic laboratory is of paramount importance.

Specimens for microscopic evaluation give a better diagnostic yield after treatment with 10% potassium hydroxide, which lyses epithelial cells. The demonstration of blastoconidia (budding yeast), hyphae and pseudohyphae is highly suggestive but not diagnostic for tissue invasion.[13] Staining with calcofluor white (the preferred method) is a sensitive method for the detection of fungi, but requires a fluorescent microscope. Alternatives to the calcofluor white stain are Gram stain (fungal elements stain Gram positive) and the germ tube test, which enables identification of *C. albicans* (but not most non-*albicans* spp.) by showing the formation of hyphal elements within 90 minutes.[13]

Nonculture methods being developed and evaluated for mycotic infections include polymerase chain reaction (PCR), galactomannan (GM) antigenemia, Western blot (WB) to detect antibodies, and detection of the fungal metabolites D-arabinitol and (1,3)-ß-D-glucan. Sample preparation for PCR from blood specimens depends on fractionation of peripheral blood, its pre-incubation in blood culture broth or a total DNA method, which does not rely on fractionation or pre-incubation. Targets for PCR of fungi in the 18S or ITS2 subunits of the ribosomal RNA genes facilitated the design of *Aspergillus* and *Candida* genus and species probes.

TABLE 237-3 -- Detection of fungal infections.

DETECTION OF FUNGAL INFECTIONS			
Diagnostic technique	**Major features**	**Useful**	**Not useful**
Microscopy/histopathology	Rapid	Histopathologic identification of:	Cannot give a specific species classification for:
	Relies on distinctive appearance of organism	*Cryptococcus*	*Aspergillus*
		Blastomyces	*Candida*
		Histoplasma	
		Coccidioides	
Culture-based methods			
• Traditional culture	Inexpensive	*Cryptococcus* grows rapidly	Slow growth for most endemics
		Aspergillus — tissue sample	Poor sensitivity for *Candida* and *Aspergillus* blood samples
• Automated blood culture methods	Early detection of growth	*Candida* and BSIs	No value for *Aspergillus*
	Capital expense	*Cryptococcus* and *Histoplasma*	
Nonculture methods			

• Antigen	Sensitive and specific	*Cryptococcus* and *Histoplasma*	No reliable tests for other mycoses
		Aspergillus-galactomannan may be useful	
• Antibody	Moderately sensitive and specific	Endemic mycoses	No reliable tests for opportunistic fungi
• PCR	Still experimental	Potential use for *Candida* and *Aspergillus*	

TABLE 237-4 -- General patterns of susceptibility of *Candida* species[*]

GENERAL PATTERNS OF SUSCEPTIBILITY OF *CANDIDA* SPECIES						
***Candida* species**	**Fluconazole**	**Itraconazole**	**Flucytosine**	**Amphotericin B**	**Caspofungin**	**Voriconazole**
C. albicans	S	S	S	S	S	S
C. tropicalis	S	S	S	S	S	S-I
C. parapsilosis	S	S	S	S	S-R	S
C. glabrata	S-DD to R	S-DD to R	S	S-I	S	S
C. krusei	R	S-DD to R	I-R	S-I	S	S
C. lusitaniae	S	S	S	S to R	S	S

** (Adapted from Rex et al.[27])*

The measurement of anticandidal antibodies in the serum of patients does not allow a distinction between colonization and local infection from disseminated disease.[14] The diagnostic sensitivity and specificity reported in the literature of various enzyme immunoassays for cell wall mannan tested on a mixed patient population ranged from 53% to 100% and from 89% to 100%, respectively. [14] [15] [16] The diagnostic yield increases significantly with repeated sampling.

The performance of a rapid test based on the ratio of D/L-arabinitol in urine has been disappointing. Many patients were positive, positivity was shown late in infections and many infections due to *C. krusei* remained undetected due to nonproduction of arabinitol.

Molecular diagnosis by PCR appears very promising since fungal DNA can be detected in the blood of infected patients before conventional methods. Furthermore, a broad range of yeasts and molds can be identified to species level. Automation of sample preparation and use of real-time PCR systems will help standardize the procedure and reduce false-positive results due to contamination.[16] Candidal strain typing is mainly used in hospital infection control and for epidemiologic investigation.

Susceptibility testing and drug dosing

Intensive efforts to develop standardized, reproducible and clinically relevant susceptibility testing methods for the fungi have resulted in the development of the NCCLS M27-A methodology for susceptibility testing of yeasts.[17] Data-driven interpretive breakpoints using this method are available for testing the susceptibility of *Candida* spp. to the most important antifungals (Table 237.4). Several features of these breakpoints are important. First, these interpretive breakpoints should not be used with other methods without extensive testing. Second, these breakpoints place a strong emphasis on interpretation in the context of the delivered dose of the azole antifungal agent. The novel category S-DD (susceptible-dose/delivery dependent) indicates that optimizing dosage and bioavailability is critical to successful therapy. In the case of fluconazole, both human and animal data suggest that S-DD isolates may be treated successfully with 12mg/kg/day. In the case of itraconazole, oral absorption is somewhat unpredictable and achievement of blood levels of 0.5g/ml (as determined by high-performance liquid chromatography) appears important to successful therapy. Finally, these breakpoints have been developed on the basis of data from two groups of infected patients: patients with oropharyngeal and esophageal candidiasis and patients with invasive candidiasis (mostly non-neutropenic patients with candidemia).

Reliable and convincing interpretive breakpoints are not yet available for amphotericin B. The NCCLS M27-A methodology does not reliably identify amphotericin B-resistant isolates. Although these methods are as yet insufficiently standardized to permit routine use, several generalizations are becoming apparent. First, amphotericin B resistance appears uncommon among isolates of *C. albicans*, *C. tropicalis* and *C. parapsilosis*. Second, isolates of *C. lusitaniae* most often demonstrate readily detectable and clinically apparent amphotericin B resistance. However, the exact frequency of this event is uncertain and not all isolates are resistant. Third, a growing body of data suggests that a significant proportion of the isolates of *C. glabrata* and *C. krusei* may be resistant to amphotericin B. Importantly, delivery of additional amphotericin B by use of a lipid-based preparation may not always be adequate to overcome this resistance.

CLINICAL MANIFESTATIONS

Clinical manifestations of candidal infections are also discussed in Chapter 111 .

The clinical manifestations of candidal infection can be divided into mucocutaneous infections and deep-seated infections. Mucocutaneous infections include thrush, candidal esophagitis, nonesophageal gastrointestinal candidiasis, candidal vaginitis and cutaneous candidiasis syndromes. Deep-seated infections include chronic disseminated candidiasis (hepatosplenic candidiasis), candidemia and candidiasis of various organ systems.

Mucocutaneous candidiasis

The most common clinical manifestation of candidal infection is oral thrush (acute pseudomembranous candidiasis), which presents as curd-like plaques on examination. It is diagnosed by the demonstration of yeast hyphae and pseudohyphae in a Gram-stained direct smear, 10% potassium hydroxide preparation, calcofluor preparation or culture of scrapings. Oral thrush should alert the physician to the possibility of an underlying disease.

Candidal esophagitis (Fig. 237.2) is frequently associated with AIDS, lymphoma or leukemia, although it can occur in people who are not immunocompromised. In up to 30% of cases of esophagitis there are no oral lesions on examination.

Of women with vulvovaginal candidiasis 75% have no risk factors. Diagnosis is made on the basis of the combination of clinical symptoms, microscopy with 10% potassium hydroxide (include a wet preparation as well to exclude *Trichomonas vaginalis* and clue cells) and/or culture. The vaginal pH in candidiasis should be in the normal range (4.0–4.5); a pH higher than 4.7 indicates bacterial vaginosis, trichomoniasis or a mixed infection.

Chronic mucocutaneous candidiasis is a relatively rare disease characterized by protracted and persistent infections with *Candida* spp. of skin, mucosal membranes, hair and nails, and it is frequently associated with endocrinopathies or autoimmune disorders. Severe disease may prove fatal, usually due to bacterial sepsis. Disseminated candidiasis is a rare complication.[12]

Deep organ infection

Disseminated candidiasis and candidemia constitute major clinical and diagnostic problems. Overall, in more than 50% of cases, fungal blood cultures remain negative,[13] although increased blood volume,

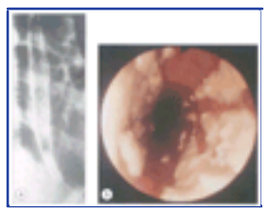

Figure 237-2 Candidal esophagitis. (a) Double-contrast radiography in candidal esophagitis. (b) Endoscopy of same patient.

ventilation of culture flasks and Isolator lysis-centrifugation cultivation have improved the diagnostic yield to 82%.[14] The value of surveillance cultures is controversial, although absence of *C. albicans* in surveillance cultures has a high predictive value for the absence of disseminated candidiasis in patients who have leukemia or lymphoma or in bone marrow transplantation patients.[2] [14] However, isolation of *C. tropicalis* in surveillance cultures is highly suggestive of disseminated infection because more than 50% of these patients will develop candidemia. Skin and eye lesions (Fig. 237.3) are present in only 10% of cases of disseminated candidiasis. In general, only 15–40% of cases are diagnosed early enough to initiate therapy.

For a detailed clinical discussion of disseminated candidiasis, candidemia and chronic disseminated or hepatosplenic candidiasis (Fig. 237.4), see Chapter 111 .

Virtually every organ can be infected by *Candida* spp.

Candidal meningitis and encephalitis usually occur as a complication of disseminated candidiasis. In disseminated candidiasis, 62% of cases developed candidal myocarditis,[13] with electrocardiographic changes mimicking infarction and supraventricular tachycardias.

Candida spp. are the major cause of fungal endocarditis, with up to 41% of cases caused by non-*albicans* spp. Blood cultures are positive in 54% of patients; additional means of diagnosis are culture of the cardiac vegetation (73% sensitivity) and histologic examinations.[18a]

Candidal pneumonia (Fig. 237.5) is usually associated with disseminated candidiasis. Primary candidal pneumonia is rare. Diagnosis is based on transbronchial biopsy.

In abdominal surgery, heavy growth of *Candida* spp. in the first culture (intraoperative or from abdominal drain) or an increasing

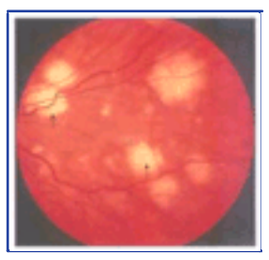

Figure 237-3 Retina of a patient who has lesions (arrows) due to disseminated candidiasis.

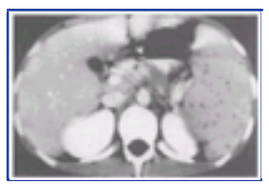

Figure 237-4 Hepatosplenic candidiasis. Multiple abscesses can be seen.

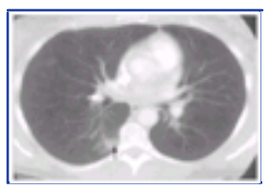

Figure 237-5 CT scan showing enlarged right hilar lymph node (top arrow) and a posterior infiltrate (bottom arrow) due to *Candida albicans.*

fungal load in serial cultures has been shown to be highly predictive of the development of candidiasis.

Infection of the urinary tract with *Candida* spp. is difficult to discriminate from colonization or from disseminated candidiasis. Microscopic urine analysis does not discriminate, unless renal casts containing yeasts are found, and quantitation of candiduria (such as is used for bacterial urinary infections) is not a reliable indicator of deep infection. Any patient who has persistent candiduria without a recent history of urinary tract instrumentation should be evaluated for diabetes mellitus, renal insufficiency or genitourinary tract abnormalities. [18]

'*Candida* hypersensitivity syndrome'

For many years, *C. albicans* has been mentioned as the cause of a chronic syndrome called *Candida* hypersensitivity syndrome, also known as chronic candidiasis, *Candida*-related complex and 'the yeast connection'.[19] Symptoms include general malaise, fatigue and non-specific gastrointestinal, genitourinary and neuropsychiatric complaints. The syndrome is said to be caused by intestinal and vaginal fungal overgrowth, inflammation, production of fungal toxins and invasion of mucous membranes. Therapy usually consists of a rigorous 'yeast elimination' diet and long-term antifungal treatment.

TABLE 237-5 -- Drugs approved for treatment of systemic fungal diseases.

DRUGS APPROVED FOR TREATMENT OF SYSTEMIC FUNGAL DISEASES				
Class	**Generic name**	**Brand name**	**Available formulation(s)**	**Year initially approved**
Polyene	Amphotericin B	Fungizone (Apothecon Products, Princeton, NJ)	Intravenous, oral solution	1958
Polyene	Amphotericin B lipid complex	Abelcet (Liposome, Princeton, NJ)	Intravenous	1995
Polyene	Amphotericin B cholesteryl sulfate	Amphotec (SEQUUS Pharmaceuticals, Menlo Park, CA)	Intravenous	1996
Polyene	Amphotericin B liposomal	AmBisome (Fujisawa Healthcare, Deerfield, IL)	Intravenous	1997
Pyrimidine	Flucytosine	Ancoban (ICN Pharmaceuticals, Costa Mesa, CA)	Oral tablet, intravenous	1972
Azole	Ketoconazole	Nizoral (Janssen Pharmaceutica, Titusville, NJ)	Oral tablet	1981
Azole	Fluconazole	Diflucan (Pfizer, New York, NY)	Intravenous, oral tablet, oral suspension	1990
Azole	Itraconazole	Sporanox (Janssen Pharmaceutica, Titusvilie, NJ)	Intravenous, oral capsule, oral solution	1992
Azole	Voriconazole	Vfend (Pfizer, New York, NY)	Intravenous, oral tablet	2002
Echinocandin	Caspofungin	Cancidas (MSD, Whitehouse Station, NJ)	Intravenous	2001

In an effort to characterize the disease, 100 individuals who had chronic fatigue syndrome were evaluated, including eight who had been given a diagnosis of 'yeast connection'. No differences in laboratory or physical findings, including candidal skin testing, could be detected between patients and control subjects. [20] A prospective randomized clinical trial comparing nystatin treatment with placebo failed to show an improvement in the systemic complaints [21] and analysis of the diet demonstrated nutritional imbalances that could lead to the development of nutritional deficiencies if the diet were followed over a prolonged period of time. The American Academy of Allergy and Immunology reviewed the literature and concluded that the *Candida* hypersensitivity syndrome is 'speculative and unproven'.[22]

MANAGEMENT

Recently the mycoses study group of the Infectious Diseases Society of America (IDSA) published practice guidelines for the treatment of fungal infections. [17] [23] These will be followed throughout this part of the chapter. The current drugs approved for treatment of systemic fungal diseases in the USA are listed in Table 237.5 . Their mechanism of action is shown in Fig. 237.6 .

Mucocutaneous candidiasis

Oropharyngeal candidiasis

Initial episodes can be treated with clotrimazole troches (one 10mg troche 5 times daily) or nystatin (available as a suspension of 100,000 U/ml (46ml 4 times daily) or as flavored 200,000 U pastilles (one or two 4–5 times daily) for 7–14 days). Oral fluconazole (100mg/day for 7–14 days orally) is as effective as and in some studies superior to topical therapy. Itraconazole solution (200mg/day for 7–14 days orally) is as efficacious as fluconazole. [24] Ketoconazole and itraconazole capsules are less effective than fluconazole because of variable absorption. Suppressive therapy is effective for the prevention of recurrent infections, but to reduce the likelihood of development of antifungal resistance it should be used only if the recurrences are frequent or disabling. Fluconazole-refractory oropharyngeal candidiasis will respond to itraconazole (200mg/day orally, preferably as the solution) approximately two-thirds of the time. Amphotericin B oral suspension (1ml 4 times daily of the 100mg/ml suspension) is sometimes effective in patients who do not respond to itraconazole. Intravenous amphotericin B (0.3mg/kg/day) is usually effective and may be used as a last resort in patients with refractory disease. Denture-related disease may require thorough disinfection of the denture for definitive cure.

Figure 237-6 Targets and mechanisms of action of antifungal drugs.

Esophageal candidiasis

Systemic therapy is required for effective treatment of esophageal candidiasis. Although symptoms of esophageal candidiasis may be mimicked by other pathogens, a diagnostic trial of antifungal therapy is often appropriate before endoscopy to search for other causes of esophagitis. A 14- to 21-day course of either fluconazole (100mg/day orally) or itraconazole solution (200mg/day orally) is highly effective. Suppressive therapy should be used occasionally in patients with disabling recurrent infections. Fluconazole-refractory esophageal candidiasis should be treated with itraconazole solution (200mg/day orally). Intravenous amphotericin B (0.3–0.7mg/kg/day as needed to produce a response) may be used in patients with otherwise refractory disease.

In mainly HIV-positive patients with esophageal and oropharyngeal candidiasis, the new antifungal agent caspofungin in a dosage of 35 or 50mg/day showed superior efficacy compared with low-dose amphotericin B (0.5mg/kg/day). This compound, representing the first clinically studied agent from a new class of antifungals inhibiting the synthesis of ß-(1,3)-D-glucan in the fungal cell wall, was extremely well tolerated.[25]

For *Candida*-associated denture stomatitis, the treatment of choice is fluconazole (50mg daily for 2 weeks) combined with chlorhexidine.[26]

Candidal vulvovaginitis

This may be classified into complicated (severe, resistant species, impaired host defenses) and uncomplicated forms. Uncomplicated vaginitis is seen in 90% of patients and responds readily to short-course oral or topical treatment with any of the therapies listed above, including the single-dose regimens. In contrast, the complicated vaginitis seen in 10% of patients requires antimycotic therapy for 7 days. Azole therapy is unreliable for non-*albicans* spp. of *Candida*. *Candida glabrata* and the other non-*albicans* infections frequently respond to topical boric acid 600mg/day for 14 days or topical flucytosine. Azole-resistant *C. albicans* infections are extremely rare.

Recurrent vaginitis is usually due to azole-susceptible *C. albicans*. After control of causal factors (e.g. uncontrolled diabetes), induction therapy with 2 weeks of a topical or oral azole should be followed by a maintenance regimen for 6 months. Suitable maintenance regimens include fluconazole (150mg orally every week), ketoconazole (100mg/day), itraconazole (100mg every other day) or daily therapy with any topical azole.

The persistent immunologic defect of chronic mucocutaneous candidiasis requires a long-term approach.[12] Systemic therapy is needed and all of the azole antifungal agents have been used successfully. The dosages required are similar to those used for other forms of mucocutaneous candidiasis. As with HIV-infected patients, development of resistance to these agents has also been described.

Systemic candidiasis

Candidemia and intravenous catheter-related candidal infections

Candida BSIs are frequently associated with clinical evidence of the sepsis syndrome and high associated attributable mortality. In addition, hematogenous seeding may compromise the function of one or more organs.

In the past, there was controversy regarding whether every candidemia should be treated. Currently, the consensus is that all patients with a positive blood culture should be treated, even if the sample is drawn from a catheter.[17] Additionally, indwelling intravascular catheters should be removed or changed, preferably without using a wire for replacement. The evidence for this recommendation is strongest in the non-neutropenic patient population. In neutropenic patients, the role of the gut as a source for disseminated candidiasis is evident from autopsy studies, but in an individual patient it is difficult to determine the relative contribution of gut versus catheter as the primary source of fungemia. An exception is made for fungemia due to *C. parapsilosis*, which is very frequently associated with catheters.

The standard treatment for candidemia was amphotericin B (0.7–1.5mg/kg/day) with or without 5-FC, but recent clinical trials have shown that for stable non-neutropenic and stable neutropenic patients who have not previously been exposed to azoles, fluconazole (at 400mg/day, not to exceed 6mg/kg intravenously for the first week) can be as effective as amphotericin B and is less toxic.[27] For neutropenic patients who have evidence of deep organ infection or for unstable patients, amphotericin B with or without 5-FC is advised. If fluconazole is used in these groups, a higher dose up to 800mg/day (12mg/kg) is preferable. Three lipid formulations of amphotericin B have been developed and approved for use in humans: amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion (ABCD) and liposomal amphotericin B (Ambisome). Only ABLC and liposomal amphotericin B have been approved for use in proven candidiasis. These approvals are for second-line therapy of patients who are intolerant of or refractory to therapy with conventional amphotericin B (defined in one study using ABLC as: failure of 500mg amphotericin B, initial renal insufficiency, creatinine clearance <25ml/min), a significant rise in creatinine (to 2.5mg/dl for adults or 1.5mg/dl for children) or severe acute administration-related toxicity. Open-label therapy of candidemia with ABCD at 26mg/kg/day has been successful. In a randomized trial, ABLC at 5mg/kg/day was found to be equivalent to 0.6–1.0mg/kg/day amphotericin B as therapy for nosocomial candidiasis (mostly candidemia). Trials with caspofungin and voriconazole in candidiasis are underway. A recent study showed that caspofungin is at least as effective as amphotericin B for the treatment of invasive candidiasis. [27A]

Antifungal treatment should be continued for at least 2 weeks after the last positive blood culture or after the clinical symptoms have subsided, and patients should be followed for 3–6 months to detect long-term sequelae due to hematogenous seeding.

An increased incidence of the less fluconazole-sensitive *C. krusei* and *C. glabrata* in neutropenic patients has been associated with frequent use of fluconazole as prophylaxis.[8] [9] This warrants caution in treating candidemia in immunocompromised patients with fluconazole before the *Candida* sp. has been identified (germ tube test), especially if there has been previous fluconazole exposure.

Data on the use of itraconazole in candidemia are limited. Unlike fluconazole, itraconazole also acts against *Aspergillus* spp., which is a theoretic advantage over fluconazole in neutropenic patients.

If 5-FC is added to amphotericin B, the dose (on average 100mg/kg/day) should be regularly adjusted according to peripheral blood cell counts, nomograms for renal functions or serum 5-FC levels (under 50–100µg/ml) to prevent bone marrow toxicity. Because of the rapid development of resistance, 5-FC should not be given as monotherapy.

Recommended treatment of candidal meningitis or encephalitis has been high-dose (0.7–1mg/kg) amphotericin B combined with flucytosine. The flucytosine dose should be adjusted to produce serum levels of 40–60µg/ml. The role of fluconazole remains to be determined. Data on the use of intrathecal amphotericin B or fluconazole are sporadic and this treatment should be reserved for severe therapy-refractory cases. Intracranial shunts should be removed. The occurrence of a brain abscess worsens the prognosis considerably. The indication for surgery remains to be determined but surgical drainage, if feasible, is probably advisable.[17]

Candidal endocarditis should be treated with combined antifungal treatment (amphotericin B plus 5-FC) and early valve replacement. Without surgical intervention, the mortality is high (90%); with combined surgical and medical treatment, the mortality has dropped to 45%.[17] Because of the high relapse rate of candidal endocarditis, continuation of amphotericin B plus 5-FC for at least 6–10 weeks (but possibly much longer) after surgery has been recommended. Because recurrences have occurred years later patients should be followed up for at least 2 years. Primary therapy with fluconazole has been successfully used on occasion, but fluconazole is more often employed as part of a long-term suppressive regimen.

In urinary candidiasis, the clinical circumstances dictate the management because candiduria can represent colonization, cystitis, pyelonephritis, disseminated candidemia or a fungus ball. If the candiduria is not catheter related and diabetes mellitus, neutropenia, urinary tract obstruction and urinary tract abnormalities have been ruled out and the patient is otherwise in good physical condition, observation is justified. Postcatheter candiduria in the stable patient usually resolves without treatment as well. In contrast, most patients who are neutropenic or who have had a recent renal transplant or have ureteric stents need systemic treatment with either amphotericin B or fluconazole (provided that *C. krusei* and *C. glabrata* have been ruled out). Treatment is not invariably indicated for catheter-related asymptomatic candiduria (eradication of candiduria in almost 40% of patients). Catheter-related candidal cystitis, where the catheter cannot be removed, can be treated with fluconazole 50–200mg/day for 2–3 days or a single intravenous dose of amphotericin B (0.3mg/kg). A recently completed placebo-controlled trial found that fluconazole at 200mg/day for 14 days hastened the time to a negative urine culture, but that 2 weeks after the end of therapy the frequency of a negative urine culture was the same in both treatment groups (60% for catheterized patients and 73% for non-catheterized patients).

Bladder irrigation with amphotericin B (50g/ml in sterile water or 5% glucose administered continuously over a three-way Foley catheter for 5–7 days) has been shown to clear the infection temporarily in over 80% and can be used as a diagnostic 'wash-out' test for systemic or renal candidiasis but is not recommended as definitive treatment. If there is a fungus ball in the urinary tract, then the treatment is surgical.

There are two major syndromes of peritoneal candidiasis. In disease related to peritoneal dialysis catheters, catheter removal is usually required for successful therapy. Both amphotericin B and fluconazole have been used successfully. Intraperitoneal amphotericin B has been associated with painful chemical peritonitis and should in general be avoided.

Candida peritonitis may also develop in association with surgical or traumatic injury to the gut wall. In this setting, *Candida* is usually part of a polymicrobial infection and case series suggest that therapy directed toward *Candida* is indicated, particularly when it is isolated as part of a complex infection or in an immunocompromised patient (as opposed to isolation in association with promptly repaired acute traumatic injury). The required duration of therapy for all forms of *Candida* peritonitis is not well defined and should be guided by the patient's response. In general, 2–3 weeks of therapy seems to be required. Surgical patients with recurrent gastrointestinal perforation are at increased risk for *Candida* peritonitis and may benefit from prophylactic antifungal therapy.

Chronic disseminated candidiasis (hepatosplenic candidiasis) is difficult to treat; this syndrome is not acutely life-threatening but does require prolonged therapy to produce a cure. Fluconazole at 6mg/kg/day is generally preferred in stable patients. Amphotericin B at 0.6–0.7mg/kg/day may be used in acutely ill patients or patients with refractory disease. Some but not all experts recommend an initial 1–2 week course of amphotericin B for all patients, followed by a prolonged course of fluconazole. Therapy should be continued until calcification or resolution of lesions, particularly in patients receiving continued chemotherapy or immunosuppression. Premature discontinuation of antifungal therapy may lead to recurrent infection.

Prophylaxis

Antifungal prophylaxis is highly controversial because the relationship between candidal colonization and dissemination is often not clear and azole prophylaxis may select for *Candida* spp. that are resistant to azoles.

Randomized, prospective, placebo-controlled trials have shown that systemically active antifungal agents can reduce the rate of development of invasive *Candida* infections in high-risk patients. The best data have compared fluconazole at 400mg/day with placebo in bone marrow transplant recipients.[9]

No consensus exists over the prophylactic use of azoles in other neutropenic patients.[17] Also, prophylaxis for high-risk (=2 risk factors such as retransplantation, creatinine <2mg/dl, choledochojejunostomy, intraoperative use of =40 units of blood products, fungal colonization within the first 3 days after transplantation) liver transplant recipients is advised.[17] The risk for candidiasis following pancreatic transplantation may be comparable to that following liver transplantation. The risk of invasive candidiasis following transplantation of other solid organs appears to be too low to warrant systemic prophylaxis.

Apart from pharmacologic prophylaxis, simple measures such as handwashing by medical personnel are of paramount importance, especially in preventing the spread of *C. parapsilosis*.[3]

ASPERGILLOSIS

NATURE

Aspergillus spp. can cause disease in humans by:

- colonization and subsequently allergic reactions,
- colonization of pre-existing cavities (fungus ball or aspergilloma), or
- tissue invasion.

Aspergilli are found ubiquitously in organic debris such as hay, decaying vegetation (compost piles), soil, potted plants, in pepper and spices and in construction sites. The genus *Aspergillus* contains over 250 species, although only a few are associated with disease.

EPIDEMIOLOGY

Worldwide, aspergillosis is the most common invasive mold infection. [28]

In a 10-year autopsy survey,[29] the overall incidence of invasive aspergillosis was 1.4%. In the subgroup of immunocompromised patients, however, the incidence was found to be 10.7% and was highest in liver transplant recipients and patients who have hematologic malignancies. Mini-outbreaks of aspergillosis in immunocompromised patients have been reported in association with local construction work.[30] The most common sites of infection are the lungs and the brain. In patients who have AIDS, invasive aspergillosis is often diagnosed at autopsy. Surveys of clinically diagnosed disease report an incidence of 0.9–8.6%,[31] all before the highly active antiretroviral therapy (HAART) era.

The reported prevalence of allergic bronchopulmonary aspergillosis (ABPA) in patients who have asthma varies from 6% to 28%. In cystic fibrosis, 6–25% of patients are reported to have ABPA.[32]

PATHOGENICITY

The main route of infection in aspergillosis is airborne, via inhalation of the 2.5–3.0µm conidia (spores), which settle in lungs, nose or paranasal sinuses. However, most studies suffer from a lack of correlation between air spore counts and the rate of infection. Very recently, the hospital water supply has been recognized as a source of infection.[33] Other routes of infection are traumatized skin, especially due to burns, insertion openings of indwelling intravenous catheters and intravenous drug use. No patient-to-patient spread has been described.

The main risk factors for invasive aspergillosis include prolonged profound granulocytopenia ($<0.5 \times 10^9$ /l), especially in bone marrow transplant recipients, high-dose corticosteroid therapy, broad-spectrum antibiotic therapy, chronic granulomatous disease, AIDS with a $CD4^+$ lymphocyte count below 50/l, and treatment with cytotoxic drugs such as ciclosporin. Less commonly encountered risk factors are diabetes mellitus, alcohol excess, influenza, prematurity and exposure to aspergilli in large quantities.[34]

In chronic granulomatous disease, phagocytes are unable to generate the respiratory burst to kill micro-organisms. The fact that these patients and patients who have neutropenia are at risk of developing aspergillosis underscores the importance of phagocytes in host defense. The role of T-cell-mediated immunity in aspergillosis is not clear. In the past, HIV infection was not considered to be an independent risk factor for aspergillosis, but this view has recently been challenged, even though patients who have late-stage HIV infection ($CD4^+$ lymphocyte count <50/l) frequently have other risk factors as well, such as neutropenia or treatment with glucocorticosteroids or broad-spectrum antibiotics.[34]

Alveolar macrophages and neutrophils play a major role in the defense against aspergilli.[35] Alveolar macrophages form the first line of defense by ingesting and killing conidia, even in the absence of opsonins. When conidia escape and germinate to form hyphae, granulocytes will adhere to and kill the fungus. The conidia that have not been cleared may germinate in the alveolar spaces and hyphal forms invade the pulmonary tissue and vasculature, leading to hematogenous dissemination to other organs (brain). However, blood cultures are rarely positive. Conidia that stay in the dormant state can survive for many days in the reticuloendothelial system. Killing of aspergilli by phagocytes is impaired by corticosteroids.

The role of humoral immunity is double-edged. In ABPA, aspergilli elicit an anti-aspergillus IgE antibody response, which evokes a type I immediate hypersensitivity reaction. Anti-aspergillus IgG antibodies have been demonstrated in ABPA, aspergilloma and in the convalescence phase of invasive aspergillosis. These antibodies do not seem to play a significant role in host defense.

The fungus secretes various metabolic products (gliotoxin) and enzymes, such as phospholipases, hemolysin and elastase, which may play a role in virulence.[34] However, the biologic significance of these agents is not clear, since molecular studies in which gene-deletion mutants have been constructed do not show diminished virulence.

DIAGNOSTIC MICROBIOLOGY

Aspergillus is a mold that grows with dichotomously branching septate hyphae (Fig. 237.7). Only pathogenic *Aspergillus* spp. are able to grow in temperatures between 95°F (35°C) and 98.6°F (38°C) and *A. fumigatus* can even grow at 127.4°F (53°C). *Aspergillus fumigatus* (80–90%) and *A. flavus* (5–10%) account for the majority of all *Aspergillus* infections. Other infections are caused by *A. niger* (1–2%), *A. terreus* (2–5%) and *A. nidulans* (<1%).

Aspergilli can be isolated from the sputum of 1–6% of healthy individuals. Also, *Aspergillus* colonization is found in patients who have chronic lung disease, cigarette smokers and those who have HIV infection. However, in immunocompromised patients who do not have AIDS, positive sputum cultures have a high positive predictive value for invasive aspergillosis, even without chest radiograph abnormalities. The positive predictive value may be as high as 80–90% in patients with leukemia or bone marrow transplants.

The negative predictive value of sputum cultures in these patients is low. Growth of aspergilli in cultures from nasal swabs of leukemic patients who have neutropenia has been shown to be predictive of invasive pulmonary aspergillosis.

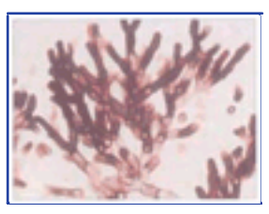

Figure 237-7 *Aspergillus* hyphae.

In invasive aspergillosis, positive blood cultures for aspergilli are rare. In neutropenia, *Aspergillus* spp. are responsible for 8% of all fungemias and there is an overall mortality of 56%. Patients who undergo cardiac surgery have a risk of developing fungemia and *Aspergillus* endocarditis, probably due to contamination of the operating room air.[34]

Even though *Aspergillus* spp. can grow on standard bacteriologic media, mycologic media will give a higher yield and are therefore recommended. A potential diagnostic and management problem is pseudofungemia (i.e. contamination of blood specimens of uninfected patients in the laboratory). For patients at risk, however, culture results have to be taken seriously until proven otherwise.[34]

Because of the ubiquitous nature of the organism, establishing a definitive diagnosis of disease caused by *Aspergillus* is difficult. The use of antibodies against *Aspergillus* to diagnose invasive aspergillosis has produced conflicting results. Patients in high-risk groups are too frequently falsely seronegative. With antibody or antigen testing, serial assays appear more valuable than isolated tests, but specific recommendations about frequency of testing have not been established. Several promising assays have been developed to detect *Aspergillus* galactomannan in urine, sera, cerebrospinal fluid and bronchoalveolar lavage specimens by EIA, ELISA and immunoblot. These appear more sensitive and reproducible than earlier latex agglutination methodology. Studies with an EIA system commercially available in Europe for detection of *Aspergillus* galactomannan reported positive predictive values of 54% and negative predictive values of 95%, largely among bone marrow transplant recipients in France.[36] [37] A problem in some studies with antigen testing was that case detection occurred too late to be useful, although early detection has been noted in some studies with ELISA methodology. In some studies, true positives were more frequent among the high titer results and false positives more common in children.

In addition, assays that use PCR have been reported to detect fragments within the 18S rRNA of *Aspergillus* spp., the 135-bp fragment in the mDNA of *Aspergillus* spp. and a 401-bp fragment in the rDNA complex of *A. fumigatus*, and PCR assays may prove more sensitive than antigen detection.[16] However, few of these PCR assays have been tested with body fluids in prospective trials of invasive aspergillosis, and reproducibility must be verified.

Therefore, a diagnosis of invasive aspergillosis is ideally based on a combination of culture results and histologic proof of tissue invasion.

CLINICAL MANIFESTATIONS

Clinical manifestations of aspergillus infections are also discussed in Chapter 111 .

Aspergillosis can manifest as either fungal colonization, which can cause allergic disease and saprophytic disease (aspergilloma), or invasive disease.

The spectrum of disease caused by *Aspergillus* spp. includes:

¦ noninvasive aspergillosis — sinotracheobronchial colonization, allergic (bronchopulmonary) aspergillosis, aspergilloma (i.e. secondary saprophytic colonization of pre-existing cavities) and obstructing bronchial aspergillosis (mainly in patients who have AIDS); and
¦ invasive aspergillosis with pulmonary involvement such as acute bronchopneumonia, cavitation or slowly progressive bronchopneumonia, or extrapulmonary involvement of paranasal sinuses, central nervous system (CNS), skin, bone and heart.

Allergic bronchopulmonary aspergillosis

Allergic aspergillosis can either manifest as an extrinsic allergic alveolitis, causing a hypersensitivity pneumonitis in nonatopic patients, or it can cause ABPA in atopic individuals.

For a diagnosis of ABPA, Rosenberg and Wang established seven criteria:[32]

¦ episodic bronchial obstruction (asthma),
¦ immediate cutaneous reactivity to *A. fumigatus*,
¦ elevated total serum IgE (<150IU/ml),
¦ precipitating antibodies to *Aspergillus* antigen,
¦ proximal bronchiectases,
¦ history of infiltrates on chest radiography, and
¦ peripheral blood eosinophilia at the same time as infiltrates on chest radiography.

The diagnosis of ABPA was felt likely if the first six diagnostic criteria were present, and the presence of all seven made the diagnosis certain. The presence of central bronchiectases in ABPA signifies more permanent lung damage. [32]

Aspergilloma

Aspergillomas are fungus balls that colonize pre-existing cavities in the lungs, and occasionally in the sinuses and the nose. They can cause massive hemoptysis, which is fatal in 10% of cases.[34] Other symptoms can include fever, malaise and weight loss. A pulmonary computerized tomography (CT) scan may show a cavitary mass surrounded by air. Microscopic and cultural identification of *Aspergillus* spp. in a sputum smear and high antibody titers to *Aspergillus* support the diagnosis. Over 95% of patients have detectable IgG antibodies to *Aspergillus*, and antibody levels usually decrease after successful surgical removal of the aspergilloma.

Invasive aspergillosis

Invasive aspergillosis is a life-threatening aggressive disease that affects immunocompromised patients and is described in detail in Chapter 111 .

If a pulmonary infiltrate (Fig. 237.8) occurs during granulocytopenia, it is more likely to be due to invasive aspergillosis than if an infiltrate develops during recovery from neutropenia, which is more

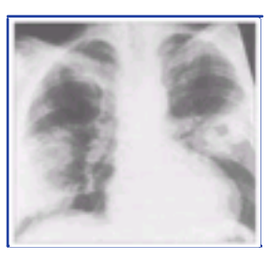

Figure 237-8 *Aspergillus* pneumonia.

likely to represent a resolving bacterial pneumonia.[38] If invasive pulmonary aspergillosis is suspected in an immunocompromised patient, then a chest CT scan or magnetic resonance imaging (MRI) should be performed, even if the chest radiograph shows no abnormalities. Typical abnormalities on CT scan in aspergillosis are a halo sign (low radiographic density around an area of infiltration), air crescent lesions or a cavitary lesion or consolidation combined with pneumothorax, although *Mucorales* can cause similar lesions.

A retrospective study of 300 immunocompromised patients, evaluating the diagnostic value of cytology from bronchoalveolar lavage (BAL) fluid for the diagnosis of invasive pulmonary aspergillosis, reported a sensitivity of 64%, a specificity of 99%, a positive predictive value of 84.2% and a negative predictive value of 97%. Compared with cytology, the positive and negative predictive values for culture from BAL fluid were slightly less favorable.[37] Colonization with aspergilli occurs, but an immunocompromised patient who has *Aspergillus* spp. in sputum or BAL fluid and fever or radiographic infiltrates that are not responding to antibiotic treatment warrants antifungal treatment.[37] [38]

For definite proof of invasive aspergillosis, additional biopsy results are important. Transbronchial biopsies are often negative in invasive aspergillosis due to sampling error, and so percutaneous or open lung biopsies may be required.

Recent studies published in abstract only show that a combination of HRCD scan of the thorax in combination with galactomannan detection in BAL has a high positive

predictive value.

Chronic invasive (necrotizing) aspergillosis

Chronic invasive aspergillosis is a more indolent form of pulmonary aspergillosis. This syndrome may be seen with aspergillomas, at the interface of the fungus ball and normal lung. Presumably, the slowly progressive nature of this infection is a function of the host immune response, which is enough to barely hold the organism in check, but not to completely kill it. CIA is usually seen in middle-aged and elderly patients with documented or suspected underlying lung diseases like COPD, inactive tuberculosis, previous lung resection, radiation therapy, pneumoconiosis, cystic fibrosis, lung infarction, or, rarely, sarcoidosis. It also has been described in patients with mild immunosuppression, including those with diabetes mellitus, those with poor nutrition, those undergoing low-dose corticosteroid therapy, and those with connective tissue diseases such as rheumatoid arthritis and ankylosing spondylitis Cough, hemoptysis, weight loss of 1 to 6 months' duration and low grade fever may be seen. The chest x-ray shows an infiltrative process in the upper lobes or the superior segments of the lower lobes. A fungal ball may be seen in nearly one half of the cases. Adjacent pleural thickening is a characteristic finding and may be an early indication of a locally invasive process. However, interpretation of radiologic studies may be complicated by the presence of concomitant lung disease, since this is the setting in which chronic invasive aspergillosis usually presents.

The diagnosis is confirmed by a histologic demonstration of tissue invasion by the fungus and the growth of Aspergillus species on a culture. However, the yield of transbronchial biopsy specimens or percutaneous aspirates is relatively poor, and a thoracoscopic or open-lung biopsy is rarely performed in these patients. So, a clinical diagnosis of CNA could be made using the following criteria:

- ¦ Clinical and radiologic features consistent with the diagnosis;
- ¦ Isolation of Aspergillus species by culture from sputum or from bronchoscopic or percutaneous samples; and
- ¦ Exclusion of other conditions with similar presentations, such as active tuberculosis, atypical mycobacterial infection, chronic cavitary histoplasmosis, or coccidioidomycosis.

Treatment with antifungal medications is indicated once the diagnosis is made.[38A] The response to antifungal therapy is generally favorable. Surgical resection is generally reserved for healthy young patients with focal disease and good pulmonary reserves, patients not tolerating antifungal therapy, and patients with residual localized but active disease despite adequate antifungal treatment. In the initial series by Binder et al,[38B] 90% of patients who underwent surgical resections had good responses. However, there were significant postoperative complications, and one patient died. The long-term prognosis for patients with CNA is not well-documented. In the original series, 73% of the patients were alive 1 to 2 years following therapy, and the majority of deaths were due to other causes.

Extrapulmonary aspergillosis

Extrapulmonary dissemination of pulmonary aspergillosis, especially to the brain, is common in the immunocompromised host. Meningitis due to *Aspergillus* spp. can occur, but it is rare. A multivariate discriminant analysis of autopsy-proven fungal infections of the CNS demonstrated that a combination of pulmonary infiltrates and focal neurologic disease in an immunocompromised patient is more likely to be caused by *Aspergillus* spp. than by either *Candida* spp. or *Cryptococcus neoformans*. Definite diagnosis is made by biopsy.[38]

Virtually any organ can be infected by *Aspergillus* spp. The fungus may cause local infection in the ear or eye (endophthalmitis, keratomycosis). Direct bony invasion can occur or hematogenous spread causing osteomyelitis. In the gastrointestinal tract, aspergillosis can lead to fatal perforation. Black necrotizing skin lesions can be a sign of disseminated aspergillosis.

As in candidiasis, aspergilli can form fungal balls in the urinary tract, which present as renal colic.

Fungal sinusitis

Fungal sinusitis (Fig. 237.9) should be considered in all patients who have chronic sinusitis. [39] Clinical features and predisposing conditions are listed in Table 237.6 . It is important to distinguish between noninvasive and invasive sinusitis because the latter can progress through invasion into soft tissue, cartilage and bone into the palate and nose or it can invade cerebral blood vessels, resulting in ischemic infarction and direct infection of the brain.

Chronic indolent invasive sinonasal infections occur in immunocompetent hosts in regions with high levels of environmental spores, such as the Sudan, Saudi Arabia, and other tropical or desert areas, and occasionally in patients with diabetes in other locales. *Aspergillus flavus* is the most common causative agent of these infections, in contrast to the frequent isolation of *A. fumigatus* from sites of infection in immunocompromised hosts. These infections have a progressive clinical course over months to years, with invasion of the surrounding tissues: the ethmoid sinuses, orbit and subsequent cranial bone osteomyelitis and intracranial extension.

Figure 237-9 *Aspergillus* sinusitis. Involvement of right maxillary sinus with extension to adjacent structures and the brain (arrows). Coronal section.

TABLE 237-6 -- Key clinical points in the diagnosis and treatment of fungal sinusitis.*

KEY CLINICAL POINTS IN THE DIAGNOSIS AND TREATMENT OF FUNGAL SINUSITIS				
Type	**Clinical clues**	**Most common causes**	**Diagnosis**	**Initial management**
Noninvasive fungal sinusitis	Immunocompetent patient: intractable symptoms despite adequate treatment for bacterial sinusitis; allergic rhinitis, asthma, nasal polyps. Calcifications in sinus on CT; proptosis in children	Hyaline molds; *Aspergillus* spp.; *Fusarium* spp.; dematiaceous molds; *Bipolaris* spp.; *Curvularia lunata; Pseudallescheria boydii*	Aspiration of sinus contents should be followed by silver impregnation staining and culture of aspirate; sinus contents often have the consistency of peanut butter or cottage cheese; in patients who have diabetes mellitus or other conditions involving immunocompromise, biopsy of healthy and diseased mucosa and bone should be considered to rule out tissue invasion	Surgery is necessary to establish drainage and to remove impacted mucus, polyps or fungus ball
Invasive fungal sinusitis	Fever, headache, epistaxis and cough in an immunocompromised patient; diabetes mellitus; hemochromatosis; protein-calorie malnutrition; leukemia; neutropenia. Nasal mucosal ulcer or eschar; calcifications in sinus on CT; orbital apex syndrome; proptosis in adults	Hyaline molds, zygomycetes; *Rhizopus oryzae; Cunninghamella bertholetiae; Aspergillus* spp.; *Fusarium* spp.; dematiaceous molds; *P. boydii*	Early endoscopic evaluation should be followed by biopsy of healthy and diseased mucosa and bone; sinus contents should be cultured; aspiration of sinus contents should be followed by silver impregnation staining and culture of aspirate; if the results of endoscopic evaluation are negative, open biopsy should be performed immediately	Emergency surgery is necessary to remove necrotic and devitalized tissue; treatment with amphotericin B should be initiated on demonstration of tissue invasion and before culture results become available; immunosuppression should be reversed, including discontinuation of corticosteroids and treatment of iatrogenic neutropenia

** Adapted from DeShazo et al.[39]*

Radiologic findings associated with fungal sinusitis are calcifications and loss of bony sinus margins, as well as features that are common in bacterial sinusitis, such as air-fluid levels of more than 8mm of mucoperiosteal thickening.

To distinguish between invasive and noninvasive fungal sinusitis, adequate tissue biopsies as described in Table 237.6 are necessary. The presence of hyphae excludes chronic bacterial sinusitis. In superficial fungal disease, hyphae are found only in mucopurulent material within the sinus. In invasive fungal infection, hyphae penetrate into the sinus submucosa, blood vessels or bone.

The main differential diagnosis is zygomycosis.

Aspergillosis and AIDS

Aspergillosis and AIDS is discussed in Chapter 126 .

MANAGEMENT

In ABPA, the treatment of choice is systemic corticosteroids. Generally, prednisone is advised, 0.5mg/kg for 2 weeks followed by gradual tapering, although no randomized studies have been performed. Parameters for monitoring the treatment response are pulmonary function, chest radiograph and serum IgE concentration.

Another approach to the treatment of ABPA is to eradicate *Aspergillus* spp. from the airways. A recently completed double-blind, randomized, placebo-controlled trial[40] for ABPA showed that itraconazole 200mg twice daily for 16 weeks resulted in statistically significant differences in ability to ameliorate disease, as assessed by the reduction in corticosteroid dose and IgE and the improvement in exercise tolerance and in pulmonary function. Itraconazole may be useful as a corticosteroid-sparing agent. Detailed therapeutic guidelines are provided by Stevens *et al.*[41]

For aspergillomas, the natural history is variable, and therapy must be individualized. A conservative approach is prudent. Surgical resection (or where available, selective radiologic embolization of the feeding vessels) is indicated for hemoptysis. Spontaneous resolution of pulmonary aspergillomas has been reported.

The medical treatment options for invasive pulmonary aspergillosis are listed in Table 237.7 . For neutropenic patients, the isolation of *Aspergillus* spp. from any site warrants immediate antifungal treatment. The same is true for any sudden intracranial event in this group, especially in the presence of pulmonary infiltrates, with or without fever.[38]

The largest therapeutic experience is with amphotericin B deoxycholate, which should be given at maximum tolerated doses (e.g. 1–1.5mg/kg/day) and should be continued, despite modest increases in serum creatinine levels. Lipid formulations of amphotericin are indicated for the patient who has impaired renal function or who develops nephrotoxicity while receiving deoxycholate amphotericin.

Itraconazole, the only triazole presently licensed for the treatment of aspergillosis, has recently become available for intravenous administration. In neutropenic patients with hematologic malignancies and refractory fever, intravenous itraconazole has shown at least equivalent efficacy (47% vs 38%) to D-AmB.[42] Not surprisingly, it was better tolerated (withdrawal due to toxicity 19% vs 38%) and showed less nephrotoxicity than D-AmB. Beyond that, about one-third of patients given intravenous itraconazole could be switched to the oral formulation after a median of 9 days of treatment.

Caspofungin has also shown significant efficacy as a salvage antifungal in 63 patients with documented invasive aspergillosis refractory or intolerant to conventional antifungals.[43] Based upon the clearly documented response to caspofungin in 41% of these patients, the drug was approved in early 2001 by the Food and Drug Administration (FDA) for the treatment of patients with aspergillosis refractory or intolerant to other licensed antifungals.

The US Mycoses Study Group and the Invasive Fungal Infections Co-operative Group of the European Organization for Research and Treatment of Cancer recently reported that in patients with proven or probable invasive aspergillosis, voriconazole is significantly superior to AmB with respect to response rates (53% vs 31%) and survival (71% vs 58%).[44] Walsh *et al.*[45] were able to show that voriconazole was as effective as L-AmB for empiric therapy in neutropenic patients with fever refractory to broad-spectrum antibiotics. The rate of breakthrough fungal infections was significantly lower in patients treated with voriconazole compared even with those receiving L-AmB (1.9% vs 5%). However, the response rates (defined as defervescence during neutropenia and absence of breakthrough

TABLE 237-7 -- First- and second-line therapy for invasive aspergillosis.*

FIRST- AND SECOND-LINE THERAPY FOR INVASIVE ASPERGILLOSIS		
Generic (trade) name	**Dosage**	**Comments**
Amphotericin B deoxycholate	0.8–1.25mg/kg/day iv	High doses in neutropenia; significant interaction with ciclosporin
Itraconazole	Intravenous form, recently available 200mg iv qd; 200mg q8h for 4 days, then 200mg q12h po (for cerebral disease 400mg q12h)	If patient can eat and does not take hepatic cytochrome P450-inducing co-medication; significant interaction with ciclosporin; measure itraconazole serum levels; new itraconazole cyclodextrin oral solution has better bioavailability; limited data on iv use >14 days
Voriconazole	Loading 6mg/kg twice daily, thereafter 3mg/kg twice daily or 200mg orally twice daily	At least as effective as liposomal amphotericin B for emperical antifungal therapy in febrile neutropenia[45] More effective than D-AmB for invasive aspergillosis[45]
Caspofungin	70mg iv on day 1	FDA approved for refractory aspergillosis
	50mg iv thereafter	
Lipid-formulations of amphotericin (all iv)		
Liposomal amphotericin (AmBisome)	1–5mg/kg/day	Less toxic than amphotericin B deoxycholate, but higher dosage needed to be equally effective
Amphotericin B colloidal dispersion (ABCD, Amphotec)	4–6mg/kg/day	Less toxic than amphotericin B deoxycholate, but higher dosage needed to be equally effective; expensive
Amphotericin B lipid complex (ABLC, Abelcet)	5mg/kg/day	Less toxic than amphotericin B but higher dosage needed to be equally effective; expensive

* *Adapted from Denning.*[28]

fungal infections and no withdrawal due to adverse events and survival) were disappointing in both groups (26% vs 31%). Two issues with voriconazole must be taken into account: the occurrence of transient visual disturbances in about 30% of patients, and the considerable number of drugs showing important interactions with voriconazole.[45]

The optimal duration of therapy is unknown and dependent on the extent of invasive aspergillosis, the response to therapy and the patient's underlying disease(s) or immune status. A reasonable course would be to continue therapy to treat microfoci, after clinical and radiographic abnormalities are resolving, cultures (if they can be readily obtained) are negative, and reversible underlying predispositions have abated. Duration of therapy should be guided by clinical response rather than any arbitrary total dose. Continuation of antifungal therapy through reinduction cancer chemotherapy, or resumption of antifungal therapy in patients with apparently resolved fungal infection who are about to receive reinduction chemotherapy, is worthy of consideration. The ultimate response of these patients to antifungal therapy is largely related to host factors, such as the resolution of neutropenia and the return of neutrophil function, lessening immunosuppression and the return of graft function

from a bone marrow or organ transplant, as well as the extent of aspergillosis when diagnosed.

PREVENTION

If untreated, the mortality of invasive aspergillosis reaches 100%.[28]

Patients who have cancer and who develop invasive aspergillosis during cytotoxic chemotherapy have been shown to have a 50% risk of recurrence during subsequent cytotoxic chemotherapy cycles. Therefore, empiric administration of amphotericin B or voriconazole at the onset of granulocytopenia with fever or even before the development of neutropenia has been advocated if the patient has a positive history of invasive aspergillosis or residual cavitary disease.

Preventive measures include reduction of environmental exposure of patients from sources of infection and antifungal prophylaxis. Specialized air-handling systems capable of excluding *Aspergillus* spores, such as high-efficiency particulate air (HEPA) filtration with or without laminar air flow ventilation, have proven to be very efficacious. Given recent data, the water systems should be evaluated in facilities with high-risk patients. Targeted antifungal prophylaxis for hematologic patients who are at high risk for developing invasive fungal infections is not currently recommended.

CRYPTOCOCCOSIS

NATURE

Cryptococcosis is a systemic infection caused by the encapsulated yeast-like fungus *Cryptococcus neoformans*. As early as 1894, Otto Busse described 'corpuscular' tumor-like lesions caused by 'coccidia species'. Since then *C. neoformans* has been known by a variety of names, including *Saccharomyces neoformans* and *Torula histolytica*. Of the existing cryptococcal species, only *neoformans* is known to be pathogenic.

According to the chemical structure of the cryptococcal polysaccharide capsule, four serotypes can be distinguished in three varieties:

- serotype A: *C. neoformans* var. *grubii*;
- serotype D: *C. neoformans* var. *neoformans*; and
- serotypes B and C: *C. neoformans* var. *gattii*.

The sexual form of *C. neoformans* is classified as *Filobasidiella neoformans*, and has two mating phenotypes: a- and *a*-mating type. In clinical isolates, the a-mating type is always predominant.[46]

Cryptococcus neoformans var. *neoformans* and *grubii* are ubiquitous. They are found year round, especially in aged pigeon droppings, and affect mainly the immunocompromised host.

Cryptococcus neoformans var. *gattii* has a tropical and subtropical distribution and is found mainly in Australia, South America, parts of Africa, South East Asia, southern Europe and southern California, where it is associated with the river red gum tree (*Eucalyptus camaldulensis*) and the forest red gum tree (*Eucalyptus tereticornis*). Recently, a Vancouver Island outbreak was detected. *Cryptococcus neoformans* var. *gattii* infects mainly healthy individuals. The peak incidence of disease coincides with the flowering season of the eucalyptus tree, namely November through February.

EPIDEMIOLOGY

Cryptococcal meningitis is the most common life-threatening fungal infection in people who have HIV infection.

The incidence of cryptococcosis in patients who have AIDS in the USA, western Europe and Australia has been estimated to be 6–10%, but a recent analysis of survival data of patients who have AIDS in the USA before the introduction of HAART demonstrated a decrease in the cryptococcosis-associated death rate from 7.7% in 1987 to 5% in 1992,[47] probably due to the widespread use of azoles for candidiasis. Since the introduction of HAART, a further decline in incidence of cryptococcosis has been seen.[48]

In sub-Saharan Africa, the estimated incidence of cryptococcosis in AIDS patients is 15–30%. In Zimbabwe, cryptococcosis constitutes the AIDS-defining illness in 88% of HIV-infected patients, where it currently represents the most important cause of meningitis in adults.[49] In people who have AIDS, almost 100% of cases are caused by *C. neoformans* var. *grubii*, even in areas where *C. neoformans* var. *gattii* is endemic.[50] In France, 21% of *C. neoformans* infections are caused by serotype D, which is associated with a higher incidence of skin lesions and a lower incidence of meningitis than serotype A.[51] In the immunocompetent host, 70–80% of cryptococcal infections are caused by *C. neoformans* var. *gattii*. [52]

For unknown reasons, the incidence of cryptococcal meningitis in children is much lower than statistically expected.[50]

Use of novel immunosuppressive agents may also have a role in the changing frequency, spectrum and clinical presentation of opportunistic mycoses. With the declining incidence of *C. neoformans* infection in HIV-infected patients treated with HAART, organ transplant recipients have re-emerged as one of the leading groups of immunocompromised patients at risk for cryptococcal infections.[3]

PATHOGENICITY

Cryptococcus neoformans is a facultative intracellular organism. Its pathogenicity depends upon the immune status of the host, virulence factors of the *C. neoformans* strain and the size of the inoculum.

Risk factors for cryptococcosis include (in decreasing order of frequency):

- HIV infection (especially with a low $CD4^+$ lymphocyte count),
- corticosteroid treatment,
- organ transplantation,
- chronic leukemia,
- lymphoma, and
- sarcoid, even without corticosteroid treatment.

The main fungal virulence factors consist of its:

- polysaccharide capsule,
- production of melanin and mannitol,
- alpha mating type, and
- mannoprotein-4.[53]

The polysaccharide capsule is known to interfere with phagocytosis, antigen presentation and leukocyte migration, and it can activate immunosuppressive T cells.[46] Most clinical cryptococcal strains develop large capsules during infection.[46] The cryptococcal metabolic products melanin and mannitol can function as antioxidants that can protect the yeast against oxidative attacks of phagocytes. It is not known why the alpha mating type of *C. neoformans* is correlated with enhanced virulence.[50] An interesting and still incompletely explained observation is that more than 95% of in vivo and in vitro isolates are of the alpha mating type. Moreover, studies in mice showed that this mating type was also more virulent.[50]

No direct animal-to-human cryptococcal transmission is known. Human-to-human transmission has only been described through infected corneal transplants. Laboratory technicians working with *C. neoformans* and pigeon breeders have a high incidence of positive skin tests, but active cryptococcal disease in these groups is extremely rare, except for a local cryptococcoma after accidental direct inoculation with yeasts. Infection with *C. neoformans* is thought to occur through inhalation of poorly encapsulated or acapsular organisms. Once the yeast is inhaled, it starts to regenerate its capsule. The first line of defense consists of alveolar macrophages, followed by infiltration of neutrophils and later T cells, natural killer cells and monocytes. Neutrophils can kill opsonized cryptococci in vitro. There is evidence that the capsular polysaccharide of *C. neoformans* plays an active role in interfering with neutrophil migration into the subarachnoid space during inflammation,[54] [55] despite the presence of the neutrophil attractant interleukin (IL)-8 in the cerebrospinal fluid (CSF).[56] Recently, we have identified mannoprotein-4 as a novel capsular antigen prematurely activating neutrophils and desensitizing them toward a chemoattractant challenge. [53]

However, the role of neutrophils in the host defense against *C. neoformans* is not clear because patients who have severe neutropenia are not at risk of developing cryptococcosis. Experimental data have shown that functional T cells are essential in restricting cryptococcal spread. With intact T-cell function, confinement of yeasts and granuloma formation has been observed. Occasionally, *C. neoformans* can be found in granulomatous pulmonary lesions and reactivates upon decreasing host

resistance and appears analogous to the primary complex in tuberculosis. [57]

The role of antibodies in the defense against *C. neoformans* is not clear, but passive immunization with anticapsular antibodies has been shown to prolong survival in mice infected with *C. neoformans*. Antibodies do play a role in opsonization and antibody-dependent cellular cytotoxicity, as well as clearance of deleterious levels of capsular polysaccharide.

A case-controlled study of the human antibody response to *C. neoformans*, comparing the serum antibody profiles of HIV-infected persons who did (HIV+/CM+) or did not (HIV-infected controls) develop cryptococcal meningitis (CM) and HIV-uninfected persons with samples obtained from the Multicenter AIDS Cohort Study, was performed. Compared with the HIV+/CM+ group, the HIV-infected control group had significantly lower levels of total IgM, IgA and antibodies expressing a certain VH3 determinant. The HIV-infected control group manifested an increase in immunoglobulin levels with a decrease in CD4 lymphocytes. The findings suggest a possible association between reduced expression of certain immunoglobulin subsets and HIV-associated CM.[58]

DIAGNOSTIC MICROBIOLOGY

Cryptococcus neoformans grows on routine laboratory media such as Sabouraud agar, producing white-to-cream colored mucoid colonies, which develop within 36–72 hours (Fig. 237.10). Unlike

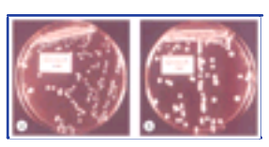

Figure 237-10 ***Cryptococcus neoformans.*** (a) Thinly encapsuiated. (b) With a thick capsule.

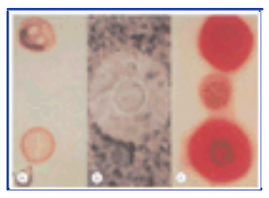

Figure 237-11 ***Cryptococcus neoformans.*** (a) Cytologic preparation of CSF, (b) India ink preparation, (c) Mayer's mucicarmine stain. *With permission from Jaster and Malecha. Copyright 1996 Massachusetts Medical Society. All rights reserved.*

nonpathogenic cryptococci, *C. neoformans* replicates at 98.6°F (37°C). For blood cultures, the lysis-centrifugation (Isolator) method has been recommended. Because *C. neoformans* is susceptible to cycloheximide, media containing cycloheximide should not be used. A rapid test to identify *C. neoformans* is the urease test because cryptococci produce large amounts of urease in the presence of urea (as do all basidiomycetous yeasts). To distinguish *C. gattii* from *C. neoformans* var. *neoformans*, glycine-L-canavanine-bromothymol blue agar can be used.

Microscopically, *C. neoformans* can be distinguished from other yeasts by its capsule, which is visualized by an India ink preparation (Fig. 237.11). The preparation is made by mixing equal volumes of sample fluid and ink, and ideally one should be barely able to read a newspaper through the preparation. The preparation typically shows budding yeast with a double refractive wall, distinctly outlined capsule and refractive inclusions in the cytoplasm. Occasionally, short hyphal yeast forms can be seen.

The laboratory diagnosis of cryptococcosis is rather straightforward compared with that of other fungal infections (see Table 237.3).

Latex agglutination tests (or ELISA) for cryptococcal antigen in body fluids are sensitive and specific and detect all serotypes. Due to differences between various commercial kits, absolute titer values are not interchangeable. In general, however, a positive test at a dilution of greater than 1:4 is highly suggestive of cryptococcal infection. False-positive results can be caused by rheumatoid factor or (rarely) through cross-reaction with other micro-organisms such as *Trichosporon beigelii* and the bacterium *Capnocytophaga canimorsus* or contamination of the specimen with agar or agarose in the laboratory. In CSF, false-negative results can be caused by either low or high antigen titers (prozone effect, especially in patients who have AIDS) or because of immune complex formation. Pronase pretreatment of the sample reduces both prozone reactions and rheumatoid factor interactions. Antigen testing in CSF is more sensitive than India ink preparation or culture. In patients who have pulmonary cryptococcosis without dissemination, serum samples may test negative for cryptococcal antigen. However, in these cases, *C. neoformans* antigen is likely to be positive in BAL fluid. Cryptococci are occasionally isolated from the sputum. In patients who are not immunocompromised it is safe to keep the patient under close observation without starting treatment. In all other cases, a careful search for infection of other sites should be made (including CSF examination), and there should be a low threshold for initiating therapy.

Antibodies to *C. neoformans* have no diagnostic value and are found in healthy people as well as in those with cryptococcosis. Presumably, antibodies have a favorable prognostic value when they become positive during convalescence in patients who do not have AIDS. In pulmonary cryptococcosis, antibodies may interfere with antigen testing due to the formation of complexes, necessitating pronase pretreatment of the samples.

For epidemiologic purposes, individual cryptococcal strains can be biotyped (e.g. AFLP or RAPD) or fingerprinted by restriction analysis or enzymatic methods.

CLINICAL MANIFESTATIONS

Clinical manifestations of cryptococcosis are also discussed in Chapter 111 and Chapter 126 .

Although *C. neoformans* usually enters the body through the lungs, the main site of infection is the CNS. However, any other organ can be involved, mainly skin, bone, prostate and eye.

The clinical picture of cryptococcosis in patients who have AIDS resembles that in severely immunocompromised patients who do not have HIV infection. In patients who have AIDS, the fungal burden is usually higher and they have a higher frequency of positive blood and urine cultures, more extraneural sites of infection and a higher relapse rate, and fewer CSF inflammatory cells.[56] In the rare cases where patients who have AIDS are infected with *C. neoformans* var. *gattii*, the clinical picture resembles that of *C. neoformans* var. *neoformans* or *grubii*.

In the immunocompetent host, disease is usually more focal, with cryptococcoma formation (especially with *C. neoformans* var. *gattii*) and disease is more often confined to the lungs.[52] Although survival is higher for infection with *C. neoformans* var. *gattii*, it causes more neurologic complications, residual disease and relapses than *C. neoformans* var. *neoformans* and *grubii*. [51] [52]

Pulmonary involvement

The clinical picture of pulmonary cryptococcosis depends upon the immune status of the host. In the immunocompetent host, one-third of patients are asymptomatic, and in some cases isolation of *C. neoformans* may represent colonization. The majority of patients present with pulmonary symptoms such as cough (54%), chest pain (46%) and sputum production (32%). If the cryptococcosis is confined to the lungs, cultures and antigen titers in CSF, blood and urine can be negative.

Compared with the immunocompetent host, cryptococcosis in the immunocompromised patient who does not have HIV infection has a more rapid course with early dissemination. In an analysis of 41 cases, 83% of patients presented with constitutional symptoms such as fever and malaise, and 44% presented with chest pain.[59]

Patients who have HIV infection and pulmonary cryptococcosis are almost invariably symptomatic, presenting with fever (84%), cough (63%), dyspnea (50%), weight loss (47%) and headache (41%). They have disseminated disease, as shown by positive cultures and antigen testing in CSF, blood and urine. Most patients have low $CD4^+$ lymphocyte counts, often less than 100,000/ml.

Pulmonary cryptococcosis is diagnosed through antigen detection or culture of expectorated sputum, BAL, transbronchial lung biopsy (Fig. 237.12) or needle

aspiration. In all cases, serum and CSF analysis for antigen and cryptococcal culture should be performed to assess dissemination.

Central nervous system involvement

If the CNS is involved in cryptococcosis, both the brain and the meninges are usually diffusely affected. In the immunocompromised patient, cryptococcomas and focal signs of disease are rare. Approximately 70–90% of patients present with signs of subacute meningitis

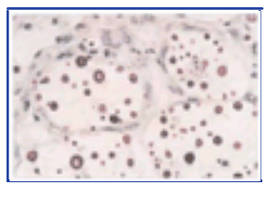

Figure 237-12 Histology of pulmonary cryptococcosis.

or meningoencephalitis: headache, fever, irritability, dizziness, memory loss, personality change, somnolence, confusion or obtundation. Classic signs of meningitis such as nuchal rigidity are often absent. Papilledema is seen in one-third and cranial nerve palsies in one-fifth of cases. Symptoms may wax and wane over weeks to months and are often non-specific.

Cryptococcal meningoencephalitis in immunocompromised patients who do not have HIV infection resembles the clinical picture in patients who do have HIV infection, with three exceptions:

- the duration of symptoms is usually shorter in patients who have AIDS, due to paucity of the inflammatory response and high fungal burden;
- patients who have AIDS present more often earlier in the disease with a second site of infection such as lungs, skin or blood; and
- concomitant illness such as infections (e.g. due to *Toxoplasma gondii*) or neoplasms is more likely.

Because focal neurologic symptoms due to cryptococcosis occur in only 10% of patients who have HIV infection, these symptoms should alert the physician to concomitant pathology. Patients who are successfully treated for cryptococcosis but who present with insidious mental impairment, ataxia or other neurologic signs should be evaluated for hydrocephalus by CT. Shunting is indicated for hydrocephalus.

Analysis of CSF in cryptococcal meningitis will typically yield the following findings:

- high opening pressure (reflecting raised intracranial pressure),
- CSF glucose level that may be either low or normal, and
- elevated or normal protein levels.

Usually, the CSF contains remarkably few cells with mononuclear predominance, especially in patients who have AIDS.[56] Cryptococci can be cultured or identified directly through staining with India ink (see above, under Diagnostic microbiology); cryptococcal antigen levels in CSF and serum are almost always positive.

Cerebral CT findings can be normal in 50% of patients who have cryptococcal meningitis, regardless of whether they have HIV infection. In patients who do not have AIDS, the CT may reveal hydrocephalus, gyral enhancement and/or multiple focal nodules with or without contrast enhancement. In patients who have AIDS, diffuse cortical atrophy is more common. Cerebral MRI appears to be more sensitive than CT in cryptococcal meningoencephalitis. The finding of pseudocysts and choroidal ependymal granulomas (cryptococcomas) is thought to be relatively specific for cryptococcosis. Lesions due to *C. neoformans* var. *gattii* tend to be fewer in number, bigger in size and surrounded by edema as compared with those caused by *C. neoformans* var. *neoformans* and *grubii*.

Other sites of infection

About 10–15% of patients will develop skin manifestations, which can present in many forms. For unknown reasons, serotype D (var. *neoformans*) is relatively more often associated with skin lesions than serotype A.[51] In patients who do not have AIDS, skin lesions can be the sole site of infection; however, in patients who have AIDS, cryptococcal skin lesions are almost always a sign of disseminated disease. A diagnosis of cryptococcal skin disease is confirmed by biopsy.

The eye is a frequent site of infection and any part of the eye may be involved. Visual loss is a distinct threat, especially in cases of endophthalmitis, although some patients have visual loss without signs of endophthalmitis, possibly due to optic neuritis or elevated intracranial pressure. Early diagnosis and rapid treatment are essential to preserve sight.[50]

From 5% to 10% of patients have bone lesions, which are mostly osteolytic and must be distinguished from cold abscesses (e.g. due to tuberculosis) or neoplasms.

Many other body sites can be affected by *C. neoformans*. In men, the prostate gland is thought to serve as an extraneural reservoir and source of relapse.

Interestingly, solid organ transplant recipients receiving tacrolimus were significantly less likely to have CNS involvement than were those receiving a different agent (ciclosporin or azathioprine), on the basis of immunosuppression (78% vs 11%, respectively). On the contrary, skin, soft tissue and/or osteoarticular involvement was significantly more likely in patients receiving tacrolimus (66%) than in patients receiving a different agent.[3]

MANAGEMENT

In isolated pulmonary cryptococcosis and other non-CNS disease in patients who do not have HIV infection, patients can be treated according to their risk and disease severity. In the immunocompetent asymptomatic patient who has minor lesions on the chest radiograph and no extrapulmonary dissemination, careful observation or fluconazole monotherapy (200–400mg/day for 3–6 months) is justified because many undergo spontaneous regression. Every patient who has symptomatic or disseminated disease or a compromised immune system should be treated with antifungal medication. In all cases, lumbar puncture should be performed to exclude meningeal involvement.

There is no consensus about the treatment schedule for pulmonary cryptococcosis and other non-CNS disease. For patients who have extensive lobar consolidation or mass lesions (more frequent with *C. neoformans* var. *gattii*), surgical resection of the lesions can be warranted.

All patients who have cryptococcal meningitis should be treated, regardless of their immune status, because 10–20% will either die or develop serious neurologic sequelae.

For patients who have cryptococcal meningitis and AIDS, the antifungal regimen of choice is high-dose amphotericin B (0.7mg/kg/day) plus 5-FC (100mg/kg/day) for 2 weeks, followed by consolidation therapy with fluconazole 400mg/day for 8–10 weeks, and subsequent lifelong maintenance therapy at 200mg/day. This regimen has been shown to reduce the mortality from about 15% to 6% in the first 2 weeks in a recently published double-blind randomized multicenter trial.[60] Combination therapy of amphotericin B and flucytosine will sterilize CSF within 2 weeks of treatment in 60–90% of patients.

The addition of flucytosine to amphotericin B was independently associated with earlier CSF sterilization, and 5-FC is thought to be important in preventing early relapse. Response rates are lower if CSF cultures at 2 weeks are still positive and these patients may require longer courses of induction therapy. For consolidation therapy, itraconazole (400mg/day) compared only slightly less

TABLE 237-8 -- Preferred treatment options for cryptococcal disease in HIV-negative patients.*

PREFERRED TREATMENT OPTIONS FOR CRYPTOCOCCAL DISEASE IN HIV-NEGATIVE PATIENTS
Pulmonary and other non-CNS disease
Mild-to-moderate symptoms or culture-positive specimen from this site
Fluconazole, 200–400mg/day for 6–12months
Itraconazole, 200–400mg/day for 6–12months
Amphotericin B, 0.5–1mg/kg/day (total 1000–2000mg)
Severe symptoms and immunocompromised hosts
Treat like CNS disease
CNS
Induction/consolidation: amphotericin B 0.7–1mg/kg/day plus flucytosine 100mg/kg/day for 2 wk, then fluconazole 400mg/day for minimum 10 wk
Amphotericin B 0.7–1 mg/kg/day plus flucytosine 100mg/kg/day for 6–10 wk
Amphotericin B 0.7–1mg/kg/day for 6–10 wk
Lipid formulation of amphotericin B 3–6mg/kg/day for 6–10 wk
The clinician must determine whether to follow lung therapeutic regimen or CNS (disseminated) regimen for treatment of infection in other body sites (e.g. skin). When other disseminated sites of infection are noted or the patient is at risk for disseminated infection. It is important to rule out CNS disease. Duration of therapy is based on resolution of disease.

** Adapted from Saag et al.[59]*

favorably to fluconazole, which makes it a reasonable alternative to fluconazole for maintenance therapy (at 10 weeks after diagnosis, fluconazole maintenance therapy resulted in 72% negative CSF cultures vs 60% with itraconazole[59]). Weekly intravenous amphotericin B has been shown to be inferior to fluconazole in preventing relapse of cryptococcal disease in patients who have AIDS.

It has been shown that maintenance therapy can be safely discontinued if the CD4 cell count is >200 for 3 months.[61]

For patients who have cryptococcal meningitis (Table 237.8), but who do not have AIDS, the regimen of choice is less well defined. Treatment with low-dose amphotericin B plus 5-FC has proved to be as effective and less toxic than amphotericin B alone in this group and it is likely that the above-mentioned regimen of 2 weeks of amphotericin with 5-FC intravenously followed by high doses of fluconazole for 8 weeks will also be effective in patients who do not have HIV infection. A total treatment duration of 4–6 weeks has been successful, but the relapse rate may be lower with longer treatment courses or azole consolidation therapy.

It is advisable to follow patients closely over the first 6–12 months because most relapses occur in the first year after treatment. In male patients who do not have AIDS, positive urine culture after prostatic massage can predict a high risk for recurrence and prolonged oral treatment is advisable in these cases.

For those who have pre-existing neutropenia, amphotericin B (0.7–1.0mg/kg/day) monotherapy can be given to avoid additional bone marrow toxicity. Fluconazole as monotherapy is associated with a higher mortality in the first 2 weeks, with a slower CSF clearing rate than with amphotericin B.

For patients with elevated baseline opening pressure, lumbar drainage should remove enough CSF to reduce the opening pressure by 50%. Patients should initially undergo daily lumbar punctures to maintain CSF opening pressure in the normal range. When the CSF pressure is normal for several days, the procedure can be suspended. Occasionally, patients who present with extremely high opening pressures (>400mmH_2 O) may require a lumbar drain, especially when frequent lumbar punctures are required to or fail to control symptoms of elevated intracranial pressure. In cases where repeated lumbar punctures or use of a lumbar drain fail to control elevated pressure symptoms, or when persistent or progressive neurologic deficits are present, a ventriculoperitoneal shunt is indicated. There are no data to support the routine use of direct intraventricular therapy (e.g. via an Ommaya reservoir).

Despite wide use of triazole (and other antifungal) drugs, drug resistance has not yet been a serious concern in cryptococcocal infections.

PROGNOSIS

For patients who do not have AIDS or cancer, the mortality rate due to cryptococcal infections is about 25–30%. After initial curative treatment, 20–25% of patients who do not have AIDS relapse. Among cured patients 40% have significant neurologic deficits such as visual loss, cranial nerve palsy, motor dysfunction, personality change and decreased mental function due to chronic increased intracranial pressure or hydrocephalus. Mortality in patients after solid organ transplantation is, given the current antifungal regimens, still high at 40%.[5]

For patients who have AIDS, the mortality rate during initial therapy has been 10–25%, and 30–60% of patients die within 12 months. The relapse rate without maintenance treatment is 50–60%. Currently, the prognosis is mainly determined by the response to HAART. The prognosis for patients who have a malignancy is worse than for patients who have AIDS, but this probably reflects the course of the underlying disease rather than the cryptococcosis.[50]

The most important prognostic predictor of early mortality in cryptococcal meningitis is the mental status of the patient at presentation.[62] Also, the prognosis is adversely affected by a high fungal burden and a poor inflammatory response.

Adverse prognostic clinical features in patients who do not have HIV infection are listed in Table 237.9 . [63] Other adverse clinical prognostic signs include altered mental status and blood pressure changes.

PREVENTION

Prospective controlled trials indicate that fluconazole and itraconazole can reduce the frequency of cryptococcal disease among

TABLE 237-9 -- Adverse prognostic clinical features in cryptococcal meningitis in patients who do not have HIV infection.

ADVERSE PROGNOSTIC CLINICAL FEATURES IN CRYPTOCOCCAL MENINGITIS
• Initial positive India ink examination of CSF
• High CSF opening pressure
• Low CSF glucose
• Low CSF leukocyte count (<20/µl)
• Cryptococci isolated from extraneural sites
• Initial CSF (or serum) antigen titer >32
• Corticosteroid treatment or lymphoreticular malignancy
Recurrent cryptococcal disease
• Abnormal CSF glucose concentration after =4 weeks of therapy
• Absence of anticryptococcal antibodies
• Post-treatment CSF (or serum) cryptococcal antigen titer of =8
• No decrease in antigen titers during therapy

• Daily corticosteroid treatment =20mg prednisone after completion of antifungal therapy
A retrospective study of patients who had AIDS demonstrated only a prognostic value of antigen levels in the CSF, not in serum. There is substantial variability in titers with the different antigen detection kits used.

patients who have advanced HIV disease. However, the majority of HIV specialists recommend that antifungal prophylaxis not be used routinely to prevent cryptococcosis because of the relative infrequency, the lack of survival benefits associated with prophylaxis, possibility of drug interactions, potential antifungal drug resistance and cost.[59]

MUCORMYCOSIS AND INFECTIONS BY OTHER ZYGOMYCETES

NATURE

Mucormycosis refers to disease caused by fungi belonging to the order Mucorales. Other names for the disease include phycomycosis and zygomycosis, the latter including diseases caused by Entomophthorales. Both Mucorales and Entomophthorales belong to the class Zygomycetes.

The major forms of zygomycosis include rhinocerebral, pulmonary, cutaneous, gastrointestinal and disseminated diseases. *Rhizopus, Mucor, Rhizomucor* and *Absidia* are the most common organisms that cause zygomycosis in humans.

EPIDEMIOLOGY

Although these organisms are ubiquitous and grow in decaying organic material, mucormycosis is a rare disease and occurs almost exclusively in patients who have an underlying disease, with the exception of *Apophysomyces elegans*, a newly described species, that has been reported as a causative agent of zygomycosis, especially in immunocompetent patients.

Risk factors for mucormycosis are listed in Table 237.10 . Diabetes mellitus and neutropenia are the most commonly encountered risk factors.

PATHOGENICITY

Infection with Mucorales usually occurs through inhalation of spores or deposition of spores in the nasal turbinates. In cutaneous mucormycosis, direct inoculation of abraded skin can result in disease with invasion of subcutaneous tissue.[64]

After pulmonary infection, the first line of defense is provided by alveolar macrophages. In animal studies, alveolar macrophages from healthy mice have been shown to inhibit germination of *Rhizopus oryzae* spores. In contrast, alveolar macrophages from corticosteroid-treated mice or diabetic mice fail to inhibit spore germination and the mice are rapidly killed by pulmonary and disseminated disease.

Neutrophils play an important role in the second line of host defense. It is not known how diabetes mellitus or corticosteroids interfere with elimination of the fungi. Normal human serum can

TABLE 237-10 -- Risk factors for mucormycosis.*

RISK FACTORS FOR MUCORMYCOSIS
• Diabetes mellitus, especially with ketoacidosis
• Immunosuppression, especially corticosteroid treatment
• Iron overload with or without deferoxamine treatment (e.g. hemodialysis, hemochromatosis)
• Hematologic disease, especially neutropenia
• Intravenous drug use (CNS mucomycosis)
• Sustained skin trauma (cutaneous mucormycosis)
• Kwashiorkor (gastrointestinal mucormycosis)

** From Sugar[64] and Yohai et al. [66]*

inhibit the growth of *Rhizopus* spp., unlike serum from patients who have diabetic ketoacidosis, which enhances fungal growth. The precise mechanism is unknown, although alteration in the availability of iron due to the decreased pH has been suggested.[66] Iron or iron bound to circulating deferoxamine (desferrioxamine) is used by Mucorales for replication. This is underscored by the clinical observation that patients who receive deferoxamine (e.g. in renal failure with hemodialysis or patients who have iron overload) are at risk of developing mucormycosis.[66]

As in aspergillosis, a hallmark of mucormycosis is angio-invasion, resulting in thrombosis and tissue necrosis. The fungus has a predilection for veins over arteries.[66]

DIAGNOSTIC MICROBIOLOGY

Mucorales grow at temperatures of 77–131°F (35–55°C) with an optimal temperature of 82.4–86°F (30°C). Clinical isolates will grow at 98.6°F in the laboratory 2–5 days after incubation under aerobic conditions.[64] Cycloheximide inhibits their growth, and so culture media containing cycloheximide should not be used.

On light microscopy (Fig. 237.13), Mucorales have irregularly shaped, nonseptate, broad (10–20mm in diameter) hyphae with right-angle branching, visualized with hematoxylin and eosin staining, periodic acid-Schiff reaction or Grocott-Gomori methenamine-silver nitrate stains. In tissue samples, Mucorales are often found near blood vessels and surrounded by a neutrophilic infiltrate.

CLINICAL MANIFESTATIONS

A detailed description is provided in Chapter 111 .

The clinical manifestations of mucormycosis can be divided into seven syndromes:

- rhinocerebral,
- pulmonary,
- cutaneous,
- gastrointestinal,
- CNS,
- disseminated, and
- miscellaneous (e.g. bones, kidney, heart or mediastinum).

The clinical manifestations depend upon the underlying disease. In patients who have diabetic ketoacidosis, rhinocerebral disease is the most common manifestation. Leukemic patients who have neutropenia are susceptible to rhinocerebral, pulmonary and disseminated disease. Children who have kwashiorkor (proteincalorie malnutrition) are especially at risk of developing gastrointestinal mucormycosis. Patients treated with deferoxamine because

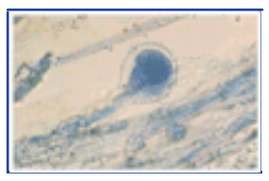

Figure 237-13 Lactophenol cotton blue preparation of *Absidia corymbifera.*

of iron or aluminum overload mainly present with disseminated mucormycosis.

In general, clues to the diagnosis of mucormycosis are signs of vasculitis with tissue necrosis, such as a black discharge or eschar on the skin, palate or nasal mucosa. Also, any radiographic imaging that reveals a lesion that surrounds vessels without a mass effect in an immunocompromised patient is suggestive of mucormycosis.

A biopsy with culture and microscopic evaluation is needed in order to discriminate between mucormycosis, aspergillosis and infection caused by Gram-negative bacteria such as *Pseudomonas* spp. The angio-invasion of the fungus causes an unusually low tendency to bleed during diagnostic surgery, which should alert surgeons to the diagnosis.[66]

If the organism is isolated by culture only, the clinician should differentiate between colonization, contamination and infection.

About 60% of rhinocerebral mucormycosis cases occur in diabetic patients and it is a rapidly fulminant disease, presenting with fever, nasal mucosal ulceration or necrosis, sinusitis (in 26% as an early sign), headache and facial pain or orbital involvement. Typically, when a ketoacidotic diabetic patient who has decreased consciousness does not wake up within 24–48 hours after correction of serum glucose and electrolytes, (rhino)cerebral mucormycosis should be considered and the palate should be inspected for a black necrotic eschar resulting from extension of the disease towards the oropharynx.

In rare cases, rhinocerebral disease may follow a chronic course. [66]

The pulmonary form of mucormycosis is the third most commonly occurring pulmonary opportunistic mycosis, especially in severely neutropenic hematologic patients or those who have diabetes mellitus. It presents with cough, fever, chest pain and dyspnea and progresses rapidly. In diabetics, a less fulminant form of pulmonary mucormycosis may occur.

A diagnosis of pulmonary mucormycosis is often made by bronchoscopy. Chest radiographs will underestimate the actual amount of tissue damage. The appearance of an air crescent sign on chest radiography or CT may herald a potentially fatal hemoptysis and warrants surgical and medical intervention.[67]

Cutaneous mucormycosis usually occurs in people who have sustained trauma (including indwelling postoperative catheters) or who have an underlying illness such as diabetes mellitus. Occasionally, cutaneous mucormycosis is a manifestation of systemic disease.

Gastrointestinal mucormycosis is primarily found in patients who have extreme malnutrition. All segments of the gastrointestinal tract can be involved. The clinical symptomatology mimics an intra-abdominal abscess.

Central nervous system mucormycosis is rare and occurs most frequently as a direct extension from the nose or paranasal sinuses, or is associated with intravenous drug use.

Cerebral lesions appear on CT scanning as low-density masses with variable peripheral enhancement. Gadolinium-contrast MRI can suggest cavernous sinus thrombosis and thrombosis of other vessels as indirect signs of infection, or ocular muscle involvement may be demonstrated.

MANAGEMENT

Mucormycosis is a rapidly progressive disease that warrants immediate aggressive combined surgical and medical treatment. All devitalized tissue should be removed, if necessary repeatedly, followed by reconstructive surgery in a later phase. Optimal treatment of the underlying disease is vital, including rapid correction of diabetic ketoacidosis. Intravenous amphotericin B in high (initial) doses of 1–1.5mg/kg/day is the treatment of choice, with a total dose around 2.5–3g. Several case histories report positive results with lipid formulations of amphotericin B.[68] A case report describes successful treatment of disseminated mucormycosis in a neutropenic patient with a combination of surgery, ABLC and G-CSF.[69]

Other less common treatment modalities reported in the literature with presumed but unproven effect include local irrigation with amphotericin B, addition of rifampin (rifampicin) or tetracycline to amphotericin treatment and hyperbaric oxygen. Despite occasional successful case reports, the currently registered azoles have no significant in-vitro activity against mucormycosis.

PROGNOSIS

The prognosis of mucormycosis depends largely upon the underlying disease, and in general the prognosis is better for those who have diabetes mellitus. The overall mortality has been over 50%, but with early aggressive surgery combined with medical treatment, this mortality has been reduced to less than 20%. Adverse prognostic factors in rhinocerebral disease include hemiparesis or hemiplegia, bilateral infections, nondiabetic co-morbidity and extensive facial necrosis (Fig. 237.14).[66] An overall mortality of 80% has been reported in pulmonary mucormycosis, but varies widely according to the underlying disease and extension of the infection.[70]

Gastrointestinal mucormycosis has a high mortality and is usually diagnosed at autopsy.

PENICILLIOSIS

NATURE

Penicilliosis is caused by the fungus *Penicillium marneffei*, a dimorphic mold with yeast-like growth in tissue.

The fungus is endemic in South East Asia and was originally isolated from the bamboo rat *Rhizomys sinensis*. It causes deep-seated infections in humans and rodents.

EPIDEMIOLOGY

Before the AIDS era, most patients in endemic regions (northern Thailand and rural south eastern China) affected with penicilliosis had no known underlying disease. Now, the infection mainly affects patients who have HIV infection and is recognized as an AIDS-defining opportunistic infection. In Thailand's Chiang Mai province it is the third most common HIV-related opportunistic infection (after tuberculosis and cryptococcosis).[71]

PATHOGENICITY

Penicillium marneffei is a facultative intracellular organism that can survive and replicate in macrophages. The route of infection is not known but it is assumed to be airborne or through ingestion, and

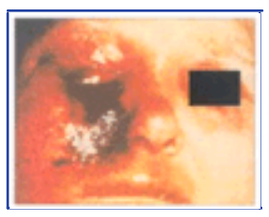

Figure 237-14 Patient with mucormycosis. Ocular invasion by Mucor in a patient with diabetes mellitus and ketoacidosis.

occasionally infection occurs through local inoculation. *Penicillium marneffei* evokes three patterns of tissue response:

- in the immunocompetent host, granuloma formation with central necrosis;
- suppurative abscesses are found in various organs; and
- in the immunocompromised host, an anergic necrotizing reaction in lung, liver and skin is seen, with diffuse infiltration of macrophages in tissues with proliferating yeast.

Antibody-mediated immunity does not seem to play a major role in host defense.[72]

Penicilliosis affects all ages and both sexes, although 90% of the cases reported in the English literature are male.[72] Although the fungus has been repeatedly isolated from the bamboo rat, human contact with or consumption of the rat does not appear to be a risk factor. In contrast, a recent history of exposure to soil is significantly associated with the acquisition of human penicilliosis, so a common reservoir of infection for rats and humans has been suggested.[73]

DIAGNOSTIC MICROBIOLOGY

In culture, *P. marneffei* is the only thermally dimorphic *Penicillium* spp. The fungus grows as a mold at 77°F (25°C) and looks grayish and downy. It produces a distinctive red diffusible pigment, which is visible on agar media. At 98.6°F (37°C) it grows as a yeast on Sabouraud glucose agar with cerebriform colonies that do not produce the red pigment.

On microscopic examination (Fig. 237.15), *Penicillium* spp. appear as short, septate, branching hyphae as well as sausage-shaped cells that divide by fission instead of budding, and may show a central septum, which distinguishes it from *Histoplasma capsulatum*. *Penicillium* spp. can be identified both inside macrophages and extracellularly when tissue preparations are stained with periodic acid-Schiff, Wright's or Giemsa stain. Recently, a monoclonal antibody has been developed that enables immunohistochemical identification of the fungus. [72]

CLINICAL MANIFESTATIONS

Clinical manifestations of penicilliosis are also discussed in Chapter 126 .

In patients who are not immunocompromised, the clinical picture may strongly resemble that of tuberculosis or histoplasmosis (e.g. suppurative lymphadenitis, fever, weight loss, anemia and a nonproductive cough). In patients who have HIV infection, the disease is usually disseminated, affecting skin, reticuloendothelial system, lung and gut. Other tissues that may be involved are liver and spleen, kidney, bone, joints and pericardium. In contrast to histoplasmosis and tuberculosis, adrenal involvement and CNS infections are rare. The molluscum contagiosum-like lesions of skin and mucosa indicate disseminated disease (Fig. 237.16).[72]

Chest radiographs show patchy infiltration and sometimes abscess formation. Abdominal CT scanning often demonstrates hepatomegaly or hepatosplenomegaly, but the diffuse microabscesses that cause the hepatomegaly are usually indistinguishable.

The diagnosis is made by culturing *P. marneffei* from blood, bone marrow, skin scrapings or liver biopsy specimen or by identifying the organism microscopically in a touch smear of a skin biopsy or bone marrow aspirate.

MANAGEMENT

The treatment of penicilliosis is amphotericin B (0.5–1.0mg/kg/day for 2 weeks), followed by itraconazole 200–400mg/day for 6 weeks for people who do not have HIV infection, and indefinitely for patients who have HIV infection. [69] [71] In in-vitro studies, fluconazole

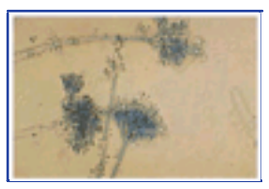

Figure 237-15 Lactophenol cotton blue preparation of *Penicillium brevi compactum.*

Figure 237-16 HIV-infected patient with *Penicillium marneffei* infection with molluscum contagiosum-like lesions.

appears to be less active. If treated appropriately, the reported response rate ranges between 59%[68] and 75%.[69]

Prevention with itraconazole in advanced HIV disease is successful, but does not provide survival benefit.

FUSARIOSIS

Fusarium spp. are found in soil with a worldwide distribution. Infections with *Fusarium* spp. (*Fusarium verticillioides* is, after *Fusarium solani*, the most common species) are rare and can lead to localized or disseminated disease. Examples of localized disease include keratomycosis, endophthalmitis, peritonitis due to implanted catheters for chronic ambulatory peritoneal dialysis, paronychia, invasive nasal infection and post-traumatic lesions of the bone, joint or skin.[73] Disseminated fusariosis has been described in a study of 97 patients.[74] These infections are supposedly airborne or inoculated through breakdown of the skin barrier. Most patients have prolonged and severe (<100 neutrophils/ml) neutropenia. The disease mimics aspergillosis and presents with an abrupt onset of fever, often combined with sinusitis, painful ecthyma gangrenosum-like skin lesions, pulmonary involvement and myalgia.

Histopathologic tissue examination with PAS or Gomori methenamine-silver staining reveals vascular invasion by hyphae

with infarction and necrosis. Contrary to aspergillosis, 50–70% of cases with disseminated fusariosis have positive blood cultures.[74] *Fusarium* spp. grow rapidly on agar media but growth is inhibited by cycloheximide. The response of *Fusarium* spp. to amphotericin B and itraconazole is limited. Newer treatment modalities such as lipid formulations of amphotericin B, voriconazole and the adjuvant use of growth factors (G-CSF and GM-CSF) may be promising.[74] Localized infection usually responds to treatment, but disseminated infection has a high mortality, especially if the underlying myelosuppression is not reversed. Moreover, successfully treated disseminated fusariosis tends to recur with repeated bone marrow suppression.

Chapter 238 - Systemic Fungi

Thomas G Mitchell

INTRODUCTION

Systemic mycoses are customarily acquired by inhaling exogenous fungi that may disseminate to other internal organs, as well as the skin. The etiological agents tend to be restricted to rather circumscribed geographical areas. Consequently, the prevalence and geographic distribution of these mycoses are highly delimited. The term systemic mycoses is not exclusive, as many opportunistic (Chapter 237) and subcutaneous (Chapter 239) mycoses may also exhibit systemic clinical manifestations. Although systemic mycoses may be caused by a number of exogenously acquired fungi, this chapter will focus on the four most common primary systemic mycoses: blastomycosis, coccidioidomycosis, histoplasmosis and paracoccidioidomycosis. All are caused by thermally dimorphic fungi. The fungi that cause coccidioidomycosis and histoplasmosis exist in nature, where they are associated with dry soil or soil mixed with guano. The agents of blastomycosis and paracoccidioidomycosis are presumed to exist in nature, but their habitats have not been clearly defined. Inhalation of any one of these fungi can lead to pulmonary infection, which may or may not be symptomatic. Dissemination may occur to other parts of the body. Except for a few extremely rare cases, there is no evidence of transmission among humans or animals. Table 238.1 compares some of the epidemiological features of these systemic mycoses.

Although most symptomatic cases of blastomycosis, coccidioidomycosis, histoplasmosis and paracoccidioidomycosis occur in patients without significant pre-existing and predisposing disease, individuals with defects of cell-mediated immunity have long been recognized to be at risk for these mycoses if they are exposed by residence or travel in the appropriate endemic areas. In recent years, the incidence of each of these mycoses as opportunistic mycoses in AIDS patients has sharply increased. Indeed, the AIDS pandemic has revealed a new endemic and systemic, dimorphic, opportunistic pathogen, *Penicillium marneffei*; both the agent and the disease are confined to Asia (see Chapter 126).

Blastomycosis, coccidioidomycosis, histoplasmosis and paracoccidioidomycosis are caused respectively by the following dimorphic fungi: *Blastomyces dermatitidis, Coccidioides immitis* (or *Coccidioides posadasii*), *Histoplasma capsulatum* and *Paracoccidioides brasiliensis*. Each species grows as a mold in nature or the laboratory at temperatures below 98.6°F (37°C). On routine fungal culture media at 77–86°F (25–30°C), they produce mycelial colonies that vary in texture, pigment and growth rate, but may be indistinguishable from each other or many saprophytic molds. The ecology and geographic distribution of these fungi are summarized in Table 238.2 . Microscopically, the hyphae are uniform in width, hyaline (not pigmented), branched, septate and similar in appearance except for the production of asexual spores or conidia, which are helpful aids to their identification. In the host or under the appropriate growth conditions *in vitro*, they convert to a distinctive form of growth that is found in tissue: *B. dermatitidis, H. capsulatum* and *P. brasiliensis* produce characteristic budding yeast cells and *C. immitis* and *C. posadasii* produce spherules.

BLASTOMYCOSIS

Blastomycosis is a chronic infection characterized by granulomatous and suppurative lesions but the clinical manifestations may be protean. The disease is undoubtedly initiated by inhalation of air-borne conidia of the etiologic agent, *Blastomyces dermatitidis*. From the lung, dissemination may occur to any organ, but preferentially to the skin and bones. The disease has been called North American blastomycosis because many early cases were confined to the United States, Canada and Central America. Although the prevalence continues to be highest on the North American continent, autochthonous cases of blastomycosis have been documented in Africa, South America and Asia. In some parts of the United States it is even endemic for humans and dogs.

Blastomycosis was first described in its chronic cutaneous form in the 1890s by Gilchrist.[1] Many early case descriptions were undoubtedly confused with coccidioidomycosis, cryptococcosis (European blastomycosis) and paracoccidioidomycosis (South American blastomycosis) until Benham established the etiology of blastomycosis in 1934.[2] Eventually, Schwarz & Baum gathered histopathologic evidence to confirm that both cutaneous and systemic manifestations originate in the lung.[3] Primary cutaneous infection has been demonstrated only rarely. Thus, blastomycosis is primarily a pulmonary infection characterized by secondary spread to the skin and other parts of the body. However, the respiratory episode may be completely asymptomatic.

NATURE

Cultural characteristics

Blastomycosis is caused by a single dimorphic species, *B. dermatitidis*. The sexual or teleomorphic form is *Ajellomyces dermatitidis*. At temperatures below 95°F (35°C), *B. dermatitidis* grows as a mold, producing a colony of uniform, hyaline, septate hyphae and conidia. On Sabouraud's glucose agar at 77°F (25°C), different isolates of *B. dermatitidis* vary in their rate of growth, colony appearance and degree and type of conidiation. Colonies usually require at least 2 weeks to reach full development. Many strains produce a white, cottony mycelium that becomes tan to brown with age (Table 238.2). On enriched media at 98.6°F (37°C), *B. dermatitidis* converts to growth in the yeast form and produces colonies that are folded, pasty and moist.

Microscopic appearance

The mycelial form produces abundant conidia from short lateral conidiophores on the aerial hyphae (Fig. 238.1). The conidia are spherical, ovoid or pyriform in shape, smooth walled and up to 10µm in diameter. Thick-walled chlamydospores, 7–18µm in diameter, may also be observed. Because the colony and conidia of *B. dermatitidis* may be confused with many other fungi, identification must be confirmed by conversion to the characteristic yeast form. This conversion can be accomplished by *in vitro* cultivation on rich

TABLE 238-2 -- Summary of systemic mycoses.

SUMMARY OF SYSTEMIC MYCOSES					
Mycosis	**Etiology**	**Ecology**	**Geographic distribution**	**Mycelial form***	**Tissue form**
Blastomycosis	*Blastomyces dermatitidis*	Unknown (riverbanks?)	Endemic along Mississippi, Ohio & St Lawrence River valleys & south-eastern USA	Slow to moderate growth rate. Colonies are white to tan, flat, velvety or cottony. Hyaline septate hyphae and short conidiophores bearing single globose to pyriform conidia, 2–10µm	Thick-walled yeasts with broad-based, usually single, buds, 8–15µm
Coccidioidomycosis	*Coccidioides immitis* and *C. posadasii*	Soil	Semiarid regions of southwestern USA, Mexico, Central & South America	Moderate to rapid growth rate. Colonies are white to brown, flat to wooly. Hyaline s eptate hyphae and arthroconidia, 3 × 6µm.	Spherules, 10–80µm or larger, containing endospores, 2–4µm
Histoplasmosis	*Histoplasma capsulatum* var. *capsulatum* and *H. capsulatum* var. *duboisii*	Bat & avian habitats (guano); alkaline soil	Global; endemic in Ohio, Missouri & Mississippi River valleys; central Africa (var. *duboisii*)	Slow growth rate. Colonies are white to brown, powdery to wooly. Hyaline septate hyphae, tuberculate macroconidia, 8–16µm, and small oval microconidia, 3–5µm	Oval yeasts, 2 × 4µm, intracellular in macrophages
Paracoccidioidomycosis	*Paracoccidioides brasiliensis*	Unknown (soil?)	Central & South America	Slow growth rate. Colonies are flat to velvety, white to brown. Hyaline, septate hyphae and rare globose conidia and chlamydospores	Large, multiple budding yeasts, 15–30µm or larger

* Colony descriptions are for typical isolates grown at 77°F on Sabouraud's glucose agar.

medium (e.g. brain-heart infusion, chocolate agar or Kelly's medium) at 98.6°F (37°C) or by animal inoculation. Under these conditions, *B. dermatitidis* grows as a thick-walled spherical yeast that usually produces single buds (Fig. 238.2). The bud and parent yeast have a characteristically wide base of attachment and the bud often enlarges to a size equal to that of the parent cell before it separates. Yeast cells are multinucleated and normally range in size from 8 to 15µm, although some cells reach a diameter of 30µm.

Sexual reproduction

The teleomorphic state (i.e. the sexual or perfect form) of *B. dermatitidis* was discovered by McDonough and Lewis.[4] Based on its sexual apparatus and resultant ascospores, *B. dermatitidis* was renamed *Ajellomyces dermatitidis*; it has been placed in the same genus as the teleomorph of *H. capsulatum*. Both species, as well as the sexual forms of the dermatophytes, are closely related and classified in the ascomycetous family Gymnoascaceae. *Ajellomyces dermatitidis* is heterothallic and requires two compatible (opposite) mating types for sexual reproduction. Although the two mating types possess different antigens, they are similar in many other respects, including pathogenicity. Mating compatibility has been used to confirm that a single species is responsible for blastomycosis among dogs and humans and probably also for cases in North America and Africa.

EPIDEMIOLOGY

Ecology

The natural habitat of *B. dermatitidis* has not been resolved. Assuming that most cases of blastomycosis are acquired by inhalation of exogenous, infectious particles, *B. dermatitidis* must reproduce in nature and generate air-borne cells. However, there have been too few isolations of *B. dermatitidis* from the environment to establish its ecological niche. Over the years, *B. dermatitidis* has been isolated, but never repeatedly, from soil samples collected in rural environments, including a chicken house, a cattle crossing and

Figure 238-1 *Blastomyces dermatitidis,* mycelial form in culture at 86°F. This shows hyaline, septate, branching hyphae and short conidiophores bearing solitary oval-to-piriform conidia.

Figure 238-2 *Blastomyces dermatitidis,* yeast form in hematoxylin and eosin-stained section of microabscess from a cutaneous lesion. This shows large spherical yeasts characterized by thick, highly refractile cell walls, single budding and a broad attachment between the parent yeast cell and bud.

several river banks. Positive samples were collected in Wisconsin from a beaver dam associated with a large outbreak of blastomycosis and at another outbreak from a fishing site. Several clusters of cases, with or without recovery of *B. dermatitidis* from environmental samples, have been associated with river banks, which suggests an association with fresh water and soil.[5] [6] [7] [8] However, a recent study showed that the genotypes of environmental isolates proximal to outbreaks were not prevalent among the case isolates.[9]

Dogs are commonly infected and numerous reports have documented isolated cases in other animal species, but there is no evidence that an animal reservoir exists to perpetuate *B. dermatitidis*. It probably resides in nature in a protected and dormant condition during most of the year, until it is stimulated by a suitable climatic or other specific but transient event to propagate and produce conidia that become air borne and infectious.

Geographic distribution

Because *B. dermatitidis* is not readily recoverable from nature and an adequate skin test antigen is not available for conducting population surveys of exposure, the geographic distribution of blastomycosis has been estimated from reports of human and canine cases. The endemic area extends broadly eastward from states that border the Mississippi River. Blastomycosis is endemic in southern Canada east of Manitoba and, in the United States, in Illinois, Wisconsin, Minnesota, Ohio, the Atlantic coastal states and the south-eastern states, with the exception of Florida. Blastomycosis is rare in the New England and western states. The highest incidence occurs in Arkansas, Kentucky, Illinois, Louisiana, Mississippi, North Carolina, Tennessee and Wisconsin. Within these areas, local pockets of high endemicity have been identified. Canine cases exhibit the same endemic pattern as those of humans. Indeed, blastomycosis may occur more frequently in dogs than in humans.[5] [10]

Clinical reports have also documented autochthonous cases in both northern and southern Africa, as well as India, Israel, Mexico and Venezuela. Reports of the infection occurring elsewhere are dubious because the diagnosis was questionable or the patients had a history of travel to an endemic area.

At least 11 outbreaks of blastomycosis have been documented.[5] [6] [7] [8] [11] [12] Each outbreak consisted of a cluster of cases that occurred at approximately the same place and time. All but one area was rural. Seven outbreaks occurred during the fall and winter, and four in the summer. These outbreaks have provided helpful insights regarding the ecology of *B. dermatitidis* and natural history of blastomycosis.

Incidence

The data from large, clinical reviews indicate that blastomycosis occurs more frequently during middle age and in males. Although the disease can occur at any age, 60% of patients were between the ages of 30 and 60 years. Among the hundreds of cases compiled in several reviews, less than 4% of the patients were under 20 years of age and blastomycosis was rarely reported in children. However, in more recent studies, especially involving outbreaks, blastomycosis occurred equally in both sexes, and two-thirds of the patients associated with outbreaks have been children (<16 years old).

The male-to-female ratios reported in several surveys involving hundreds of patients vary from 6:1 to 15:1, but lower ratios have been reported in smaller studies and the overall sex ratio of outbreak cases is approximately 1. Perhaps both sexes are equally susceptible to acute blastomycosis, but males are more inclined to develop chronic or disseminated disease. The other systemic mycoses caused by exogenous fungi also occur more often in males (Table 238.1) and male animals are more susceptible (or less resistant) than females to challenge with *B. dermatitidis*. Blastomycosis may be similar to histoplasmosis in that children are equally susceptible to infection and disease, but the sex-related differences are manifested after puberty.

Genetic or racial differences in attack rates have not been confirmed. Socio-economic and occupational data have associated blastomycosis with poverty, malnutrition, manual labor, agriculture, construction work and exposure to dust and wood. The incidence of blastomycosis among immunocompromised patients, including patients with AIDS, is relatively low but apparently rising.[13] [14]

PATHOGENICITY

Strains of *B. dermatitidis* vary in their virulence for experimental animals, but the explanation for these differences has not been resolved.[15] Among cell wall components, evidence has linked experimental virulence of strains of *B. dermatitidis* with the amount of

a-1,3-glucan in the cell walls. This polysaccharide has been shown to vary in strains of *H. capsulatum* and *P. brasiliensis* that differ in virulence.[16]

The best characterized virulence factor is the WI-1 (also called BAD1) cell wall adhesin and immunodominant antigen. This protein contains multiple copies of a

25-amino acid tandem repeat, which binds to CR3 complement receptors and elicits both antibodies and cell-mediated immune responses.[17] [18] [19] Compared with less virulent mutants, the wild type contains less surface-bound WI-1. Although the mechanisms whereby WI-1, as well as a-1,3-glucan, contribute to virulence have not been fully elucidated, Klein and associates have postulated that shedding of WI-1 by virulent strains may neutralize macrophage defenses by occupying receptors, diminishing their ability to bind yeast cells.[17] [18] [20] Many strains of *B. dermatitidis* from Africa lack WI-1 and are less virulent than New World isolates.[19]

Pathogenesis

Almost all cases of blastomycosis originate in the lung. In the alveoli, *B. dermatitidis* induces an inflammatory response characterized by the infiltration of both macrophages and neutrophils and leading to the subsequent formation of granulomata. Both conidia and yeast cells are susceptible to the killing mechanisms of neutrophils and macrophages.[21] The accumulation of neutrophils presents a suppurative component that is uncharacteristic of most mycoses and other chronic diseases. Neutrophils and cell-mediated immunity combine to marshal effective resistance to blastomycosis. Unlike coccidioidomycosis and histoplasmosis, blastomycosis is relatively rare in patients with cellular immunodeficiencies.

If the pathogenesis of blastomycosis resembles that of histoplasmosis and coccidioidomycosis, most infections may be subclinical and resolve spontaneously. However, because specific and sensitive skin test antigens are lacking, the extent of exposure to *B. dermatitidis* in the general population has not been determined. In addition, calcification is uncommon and there is little radiologic or histopathologic evidence of residual blastomycotic lesions. The best evidence for the existence of subclinical blastomycosis derives from the reported outbreaks, where specific serological and skin test reactions documented exposure to *B. dermatitidis* in the absence of symptoms.[22]

Alternatively, based on the apparent scarcity of *B. dermatitidis* in nature and the limited evidence for subclinical infections, blastomycosis may be a rare and usually serious disease.[23] This hypothesis is supported by some of the studies of experimental canine blastomycosis. In humans, the primary pulmonary lesion may be inapparent to severe. If inapparent, dissemination to the skin and bones may follow. If the pulmonary episode is severe, the generalized systemic disease may develop, with the potential involvement of multiple organs.

PREVENTION

There are no clear guidelines for the prevention of blastomycosis. However, the WI-1 antigen may be an excellent vaccine candidate for future study.

DIAGNOSTIC MICROBIOLOGY

Blastomycosis is best diagnosed by direct examination or positive culture of sputa, skin lesions or other specimens. On most routine culture media, *B. dermatitidis* produces a mold with variable macroscopic features and conidia. Its identification is confirmed by growth on a rich medium at 98.6°F (37°C) and conversion to the characteristic yeast form. Alternatively, the identity of a culture may be established by an immunodiffusion test to detect a *B. dermatitidis*-specific

TABLE 238-3 -- Species-specific exoantigens for the identification of systemic dimorphic fungal pathogens.[1] [21]

SPECIES-SPECIFIC EXOANTIGENS FOR THE IDENTIFICATION OF SYSTEMIC DIMORPHIC FUNGAL PATHOGENS	
Fungus	**Exoantigens**
Coccidioides immitis	HS, F, HL
Histoplasma capsulatum	h, m
Blastomyces dermatitidis	A
Paracoccidioides brasiliensis	1, 2, 3
Exoantigens are detected by precipitin lines of identity in immunodiffusion tests of concentrated culture supernatant fluids versus reference antigens and antisera.[25] [120]	

antigen (antigen A) in a concentrated overnight, aqueous extract of the colony on solid medium or in the supernatant fluid of a short-term broth culture of the isolate. The formation of a precipitin line of identity with reference antisera and control antigen identifies the specific exoantigen extracted from the isolate. This method is rapid and applicable to nonsporulating cultures. As indicated in Table 238.3 , the technique has also been expanded to identify other dimorphic pathogens. In addition, a DNA probe is commercially available to identify cultures of *B. dermatitidis*, as well as other agents of systemic mycoses.[24]

In culture at 98.6°F (37°C) or in tissue, *B. dermatitidis* forms large single-budding yeast cells with highly refractory cell walls and a broad attachment between the bud and parent yeast cell. As noted below, in fresh specimens or histopathological sections, the yeasts can be readily observed and identified.

Since the tests for complement fixing antibodies and delayed-type skin reactivity lack specificity and sensitivity, they are not helpful unless the patient is negative to heterologous fungal antigens; even then, positive, monospecific serological tests to *B. dermatitidis* may not indicate active infection. Serological tests for antibodies to the specific antigen A, which can be detected by the immunodiffusion test or an enzyme immunoassay, are more suggestive of infection, but negative tests do not exclude blastomycosis. Table 238.4 summarizes the conventional serological tests for antibodies to *B. dermatitidis* and other systemic fungi.

Microscopic examination

In calcofluor white or KOH preparations of pus, exudate, sputum, bronchial lavage fluid or other specimens, a diagnosis can be established by detecting the characteristic yeast cells of *B. dermatitidis*. The yeasts are large (8–15µm in diameter) and typically thick walled. The cell wall is highly refractile and often resembles a double wall. Budding usually occurs singly. The bud is attached to the parent cell by a broad base and enlarges to the size of the parent yeast before it is detached. These features, as depicted in Figure 238.1 and Figure 238.2 , are pathognomonic for blastomycosis. Unsuspected cases of blastomycosis are occasionally diagnosed from respiratory specimens submitted for routine cytology. In tissue stained with hematoxylin and eosin, the yeast cytoplasm stains darkly and the cell wall appears colorless. The yeasts are multinucleated. They are often abundant in cutaneous lesions and these specimens are usually positive on direct examination. If the yeasts are sparse, fungal cell wall stains, such as periodic acid-Schiff or methenamine silver, are helpful.

Rarely, small forms are seen in tissue. These cells are typical of *B. dermatitidis* in shape and budding but only 2–5µm in diameter. Their multinucleation may help to differentiate them from *Cryptococcus neoformans* and *H. capsulatum* var. *duboisii*.

TABLE 238-4 -- Summary of serologic tests for antibodies to systemic dimorphic fungal pathogens in patients without AIDS.

SUMMARY OF SEROLOGIC TESTS FOR ANTIBODIES TO SYSTEMIC DIMORPHIC FUNGAL PATHOGENS IN PATIENTS WITHOUT AIDS					
Mycosis	**Test**	**Antigen**	**Sensitivity and value**		**Limitation/specificity**
			Diagnosis	**Prognosis**	
Blastomycosis	CF	By	Less than 50% of cases positive; reaction to homologous antigen only is diagnostic	Fourfold change in titer	Highly cross-reactive
	ID	Bcf	Up to 80% of cases positive, i.e. A band	Loss of A band	More specific than CF test
	EIA	A	Up to 90% of cases positive (titer =1:16)	Change in titer	92% specificity

Coccidioidomycosis	TP	C	Early primary infection; 90% cases positive	None	None
	CF	C	Titer =1:32 = secondary disease	Titer reflects severity (except in meningeal disease)	Rarely cross-reactive with H
	ID	C	More than 90% cases positive, i.e. F and/or HL band		More specific than CF test
Histoplasmosis	CF	H	Up to 83% of cases positive (titer =1:8)	Fourfold change in titer	Cross-reactions in patients with blastomycosis, coccidioidomycosis, cryptococcosis, aspergillosis; titer may be boosted by skin test with H
		Y	Up to 94% of cases positive (titer =1:8)	Fourfold change in titer	Less cross-reactivity than with H
	ID	H(10X)	Up to 85% of cases positive, i.e. m or m and h bands	Loss of h	Skin test with H may boost m band; more specific than CF test
Paracoccidioidomycosis	CF	P	80–95% of cases positive (titer =1:8)	Fourfold change in titer	Some cross-reactions at low titer with aspergillosis and candidiasis sera
	ID	P	98% of cases positive (bands 1, 2 and/or 3)	Loss of bands	Band 3 and band m (to H) are identical

A, antigen A of *B. dermatitidis*; Bcf, culture filtrate of *B. dermatitidis* yeast phase; By, yeast phase of *B. dermatitidis*; C, coccidioidin; CF, complement fixation; EIA, enzyme immunoassay; H, histoplasmin; ID, immunodiffusion; P, culture filtrate of *P. brasiliensis* yeast phase; TP, tube precipitin; Y, yeast phase of *H. capsulatum*. [27] [102] [103]

Culture

Clinical specimens are cultured on any of several fungal media. Sabouraud's agar, the standard medium used for morphologic descriptions of pathogenic fungi, is composed of 4% glucose, 1% neopeptone and agar. A modified Sabouraud's agar, containing 2% glucose, is a more effective isolation medium. Inhibitory mold agar is a complex medium designed for optimal recovery of pathogenic fungi. For the culture of nonsterile specimens, such as sputum, skin or urine, antibiotics are included in the media, usually cycloheximide and chloramphenicol or gentamicin, to inhibit saprophytic fungi and bacterial contaminants. Inhibitory mold agar contains all three additives. Cultures should be incubated at 86°F (30°C) or room temperature for at least 4 weeks. Primary colonies are white to brown, variably textured molds, and they produce potentially infectious conidia. The identification of *B. dermatitidis* is confirmed by detecting the A exoantigen (Table 238.3), by subculturing on an enriched medium, such as brain-heart infusion blood agar or Kelly's medium at 98.6°F (37°C), for subsequent conversion to the yeast form (Fig. 238.2) or by hybridization with a specific DNA probe.[25]

Some laboratories employ direct animal inoculation as a method of rapidly isolating and identifying *B. dermatitidis*. Mice are injected intraperitoneally with the clinical specimen and their peritoneums are examined for typical yeast cells 1–2 weeks later.

Skin test

Delayed-type hypersensitivity to *B. dermatitidis* has been detected by skin tests with both whole cell and culture filtrate antigens (blastomycin). However, the commercial blastomycin was abandoned because it lacked specificity and sensitivity. More promising antigen preparations have been developed, but they are not available for routine human skin testing.

Serology

The most useful serologic procedure is an enzyme immunoassay (EIA) for antibodies to antigen A. With titers >1:16, the sensitivity and specificity of this test were shown to be >77% and >92%, respectively,[26] [27] and EIA titers reflected the severity of disease (Table 238.4). More recent evaluation of a commercial EIA reported sensitivity of 83% and false-positive results with sera from patients with histoplasmosis, but only rarely with sera from patients with other mycoses.[28] In this study, the EIA was much more sensitive than the immunodiffusion test. Using reference reagents, precipitins to antigen A can also be detected by an immunodiffusion (ID) test, as indicated in Table 238.4 . Measurement of CF antibodies to various antigen preparations of *B. dermatitidis* has not proved reliable.

CLINICAL MANIFESTATIONS

Two classic forms of blastomycosis are recognized: pulmonary, often with dissemination, and chronic cutaneous blastomycosis. A wide variety of symptoms, pathology and radiographic appearances may be observed in blastomycosis. The most common symptoms include cough, weight loss, chest pain, skin lesions, fever, hemoptysis and localized swelling. After the lung, the most frequently involved organs are the skin, bones and genitourinary tract, followed by the central nervous system, liver or spleen. Less often, the lymph nodes, thyroid, heart, adrenal, omentum, gastrointestinal tract, muscles and pancreas may become infected.[14] [29] [30] [31] [32] [33]

Pulmonary blastomycosis

Primary pulmonary blastomycosis may be asymptomatic or present as acute or subacute pneumonia, ranging from mild to severe. Cases associated with outbreaks have confirmed that spontaneous recovery can follow primary blastomycosis. [32] [34] However, the possibility of subsequent reactivation cannot be excluded. Even if nonapparent, dissemination may spread to the skin, bones or other sites. If the pulmonary episode is severe, the generalized systemic disease may develop and may involve multiple organs. Cases associated with outbreaks have indicated that the incubation period is 3–12 weeks and that spontaneous recovery can follow primary blastomycosis. Overall, most cases occur in adults and in males, but in pediatric blastomycosis, children of both sexes are equally susceptible. Most pediatric cases are recognized as acute pulmonary blastomycosis.[5] [30]

Patients with symptomatic, primary pulmonary infection may present with symptoms of mild respiratory infection, including cough, chest pain and high fever, as well as numerous other complaints. The primary pulmonary infection may persist locally, spread to other organ(s), or both. Alternatively, the pulmonary lesion may heal by fibrosis and absorption, leaving no residual evidence of infection. In patients whose pulmonary lesions have resolved, dissemination, generally to the skin, may already have occurred. If the pulmonary focus becomes more severe, an acute to chronic lung infection may develop. Patients with chronic pulmonary blastomycosis usually present with cough, low-grade fever, loss of weight, night sweats and other problems. The most common forms of pulmonary involvement are infiltration, cavitation, pneumonia or nodules.[22] [35] A variety of pulmonary manifestations may be observed and none of the radiographic presentations are consistent enough to be diagnostic of blastomycosis.

Chronic cutaneous blastomycosis

In chronic cutaneous blastomycosis, the initial skin lesion presents as one or more subcutaneous nodules that eventually ulcerate. Lesions are most common on exposed skin surfaces, such as the face, hands, wrist and lower leg. Spread may occur by extension to the trunk or other areas and may require weeks or months for the ulcerative process to evolve. If untreated, elevated, granulomatous lesions with advancing borders will develop in time. The yeast cells can be found in microabscesses near the dermis. Extensive, often verrucous, epithelial hyperplasia overlying the abscesses may develop and resemble carcinoma. These extensive cutaneous lesions are characteristically discolored and crusty and they tend to heal and scar in the central, older areas. The active microabscesses found at the leading edge of the lesion can be aspirated or biopsied and the typical yeast cells of *B. dermatitidis* can be observed on direct microscopic examination (Fig. 238.3).

Disseminated blastomycosis

Dissemination may be widespread in blastomycosis. The most frequently involved extrapulmonary sites are the skin, bones, genitourinary tract, central nervous system and spleen. Less frequently, the liver, lymph nodes, heart and other viscera are infected. The progressive systemic form of blastomycosis develops in patients with

unresolving pulmonary infection, but the degree of pulmonary involvement is not related to the extent of dissemination. This infection may be chronic, with few organisms present, or multiple pulmonary foci may be demonstrable at the time generalized systemic disease develops.

From the lungs, the yeasts disseminate with a characteristic predilection for the skin and bones. Skin lesions may be more severe than those in chronic cutaneous blastomycosis and are seen in about 75% of the cases. Overall, skeletal involvement is observed in approximately a third of patients. Osteomyelitis and, in some cases,

Figure 238-3 Initial cutaneous lesion of blastomycosis.

draining sinuses to the skin develop and should be examined for the presence of characteristic yeast cells. Because of the frequency of bone involvement and because almost any bone can be affected, whenever blastomycosis is diagnosed, a complete radiographic examination is advisable. Arthritis may develop by extension from infected bone or by direct dissemination from the lung without bone infection. In up to 22% of patients, the urogenital tract is involved, especially the prostate, male genitalia, kidney and adrenals. Metastasis to the central nervous system, resulting in meningitis or brain abscess, occurs in up to 10% of patients.

Primary cutaneous blastomycosis

This form of blastomycosis is initiated by traumatic autoinoculation or contamination of an open wound with the infectious material. The pathogenesis differs considerably from the other forms of blastomycosis. The lymphatics and regional lymph nodes are involved, but the infection remains localized and often resolves without treatment. Several cases of accidental cutaneous inoculation have occurred in veterinarians who were examining or performing autopsies on diseased dogs. Traumatic inoculation leading to primary, subcutaneous disease can occur, albeit rarely, with any of the systemic fungi discussed in this chapter. The natural history and pathology are similar to subcutaneous mycoses (see Chapter 239) and systemic dissemination is rare in the immunocompetent host.

Blastomycosis and AIDS

Despite the consistent prevalence of blastomycosis in its endemic area, patients with HIV infection are not commonly infected. Because of the presumed rural reservoir of *B. dermatitidis* or its low census in nature, patients with AIDS may be exposed less often than similar patients in the endemic areas for coccidioidomycosis or histoplasmosis. Alternatively, the host defenses against *B. dermatitidis* may be less dependent upon cell-mediated immunity. The cases of blastomycosis and AIDS that have been reported include the presentation of acute miliary disease in the lungs and a relatively higher frequency of CNS disease.[36] [37] Blastomycosis in compromised patients is being seen more frequently and has a much poorer prognosis.[13] [37]

MANAGEMENT

As demonstrated by several outbreak cases, primary blastomycosis in immunocompetent individuals may not require therapy. Nevertheless, such patients with a confirmed diagnosis of primary pulmonary infection that is mild and resolves spontaneously without treatment must be closely observed for at least 2 years following the primary infection because of the possibility of reactivation blastomycosis. Patients with

protracted, severe or progressive primary infection, chronic pulmonary or disseminated blastomycosis require treatment.[30] [38] Depending upon the manifestations of disease and the integrity of the underlying host defenses, chemotherapeutic success rates with amphotericin B, ketoconazole or itraconazole currently vary between 70% and 95%. Survival in patients with AIDS and other immunocompromising conditions is about half this figure.[37] [39] Recent guidelines recommend itraconazole for mild to moderate blastomycosis and amphotericin B for life-threatening disease and/or patients with AIDS.[39]

Ketoconazole

Ketoconazole was the first azole recommended for immunocompetent patients with mild to moderately severe disease (e.g. blastomycosis that is neither life threatening nor involving the central nervous system). An oral dose of 400–800mg per day for at least 6 months is effective in most adult patients, but patients must be closely followed because relapses have occurred on ketoconazole.[39] Successful treatment of blastomycosis has been achieved in 80–90% of adult patients. The adverse effects of ketoconazole include liver toxicity and reversible hormonal imbalances (e.g. gynecomastia), as well as nausea, pruritus, dizziness or headache. Itraconazole has supplanted ketoconazole because it offers improved absorption. tolerance and efficacy.[39]

Itraconazole

Recent trials have confirmed the efficacy of itraconazole for the treatment of mild to moderate, nonmeningeal, nonlife-threatening blastomycosis. When such adult patients were given oral dosages of 200–400mg/day for at least 6 months, the rate of cure or improvement was 95%. Itraconazole should be taken with meals and patients are treated for approximately 6 months with follow-up for 1 year or longer. Toxicity from itraconazole occurs in less than one-third of patients, is usually mild and rarely necessitates cessation of therapy. The most common side-effects are gastrointestinal symptoms, usually nausea, vomiting or diarrhea. Minor reactions include weakness, dizziness, headache, chills, fever, tinnitus, skin rash, pruritus, paresthesia and, rarely, transient, modest elevation of transaminase. Any relapse may be amenable to a second course of itraconazole.

Compared with ketoconazole, itraconazole is equally or more effective and better tolerated. For example, gastrointestinal symptoms were more than twice as frequent among patients receiving ketoconazole than itraconazole, although these symptoms occur more often in association with higher doses. Several treatment failures with ketoconazole have been successfully managed with itraconazole. The recommended pediatric regimen of itraconazole is 5–7mg/kg/day.[30] [39]

Fluconazole

Fluconazole, at 400 or 800mg/day for at least 6 months, is an effective alternative for the treatment of nonlife-threatening cases of blastomycosis, especially in patients who may not have responded to another drug.[40] Its only advantage over itraconazole may be in patients with involvement of the CNS, which is penetrated well by fluconazole.

Amphotericin B

Blastomyces dermatitidis is quite susceptible to amphotericin B (AMB), which is the recommended treatment for patients with life-threatening or severe disease (e.g. involvement of multiple organs), those with meningitis, or blastomycosis in immunocompromised patients, as well as patients who do not respond to an azole.[39] A total dose of 2–2.5g is required to eradicate all the organisms, as the relapse rate is significant if <1.5g is administered. The protocol for administration of AMB and monitoring renal function are the same as its application for other mycoses (see Chapter 208). An initial test dose of 1 or 5mg in adults is administered intravenously in a solution of 5% glucose, deoxycholate and buffer. The dose is gradually increased by 5–10mg/day to a maximal daily administration of 0.5–1.5mg/kg body weight.

Most patients experience adverse side effects, including renal dysfunction, fever, anorexia, phlebitis, hypokalemia, nausea, chills, headache and anemia. Administration is interrupted when blood levels of urea nitrogen reach 40–50mg/dl or 3.0–3.5mg/dl of creatinine.

Lipid emulsions of AMB have the advantage of delivering higher doses with diminished toxicity. Adult respiratory distress syndrome due to overwhelming pulmonary blastomycosis requires aggressive treatment with AMB. Blastomycosis in patients with AIDS may require suppressive therapy, following the initial course of treatment with AMB, similar to the management of cryptococcosis and histoplasmosis in patients with AIDS. Suppressive treatment in AIDS patients would be 200–400mg/day itraconazole, or possibly 800mg/day fluconazole for CNS disease.[39]

For children, the test dose of 0.1mg/kg (maximum dose 1mg) should be followed by 0.25mg/kg at 4 hours later and 0.5mg/kg after 24 hours. Beyond 48 hours, 1mg/kg/day is administered to reach a total dose of >30mg/kg. Pediatric, as adult patients, must be closely monitored for adverse reactions.

Blastomycosis has been reported in pregnant women, and the infection may or may not be transmitted to the infant. Pregnant patients have been treated with AMB without congenital or toxic effects in the fetus. Systemic treatment with azoles must be avoided in pregnant women because of their teratogenic potential. In the endemic area, blastomycosis should be considered in any neonate with a reticulonodular lesion on chest film or whose mother has evidence of blastomycosis.

Surgery

Corrective surgery may be necessary as an adjunct to antibiotic treatment. Because of the occurrence of relapse or reactivation blastomycosis, patients should be observed for years after treatment and resolution of disease.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is caused by either of two indistinguishable species, *Coccidioides immitis* or *Coccidioides posadasii*, dimorphic fungi that normally live in well-defined geographic areas. Both the agents and coccidioidomycosis are almost entirely limited to these endemic regions. *Coccidioides immitis* was first described in 1892 by an Argentinian pathologist. Alejandro Posadas, who examined tissue from a fatal case and named the orgnaism *Coccidioides*, meaning '*Coccidia*-like', because of the spherules found in tissue.[41] [42] The species name, 'immitis,' means not mild. Indeed, most early cases were diagnosed at autopsy and until 1930, the disease was erroneously thought to be invariably severe and disseminated.

It was recognized quite early that coccidioidomycosis is confined to the south-western United States, contiguous regions of northern Mexico and specific areas of Central and South America. The natural reservoir was established by isolating *C. immitis* from soil samples collected throughout the endemic areas, and the environmental conditions under which the fungus was propagated were described. From mycelial culture filtrates, the skin test antigen coccidioidin was developed and used to detect exposure to *C. immitis* or *C. posadasii* and to conduct population surveys of skin reactivity. The more common primary form is a mild, respiratory ailment, also called valley fever or San Joaquin Valley fever.

NATURE

Etiology and dimorphism

The new species, *C. posadasii*, was recently recognized by Fisher *et al.*[43] They compared the genotypes of isolates of *C. immitis* from different geographical regions and, based on their phylogenetic analyses of these populations, determined that the majority of isolates outside California belong to a different species, which they named *C. posadasii* to honor Dr Posadas. Since *C. posadasii* has a broader geographical distribution, it is the more likely cause of the majority of cases of coccidioidomycosis. Although these species differ in their geographical distribution and genotype, any differences in their phenotypes or pathogenicity have yet to be delineated. Because the two species cannot be distinguished by simple laboratory tests, the more familiar name, *C. immitis*, will continue to be used.

The life cycle of *C. immitis* (or *C. posadasii*) encompasses at least four distinct morphologic structures that are produced under different conditions. In nature and in the laboratory, either species grows as a mold, producing hyaline, branching, septate hyphae. As the culture ages, characteristic arthroconidia are formed, usually, but not invariably, in alternate hyphal cells (Fig. 238.4). With time, the arthroconidial chains fragment to release the unicellular, barrel-shaped arthroconidia, the ends of which often retain remnants of cell wall material from the disintegrated adjacent cells. Arthroconidia are approximately 3 × 6µm in size, easily air borne and small enough to be inhaled into the alveoli. They are highly resistant to desiccation, temperature extremes and deprivation of nutrients and may remain viable for years. Under appropriate growth conditions, the arthroconidia will germinate to recycle the saprophytic mycelial form (Fig. 238.4).

Following their inhalation, the arthroconidia become spherical. In the infected host, *C. immitis* exists as spherules — spherical thick-walled structures, 15–80µm in diameter that are filled with a few to several hundred endospores (Fig. 238.5). As a spherule enlarges, the nuclei undergo mitosis, the cytoplasm condenses around these nuclei and a cell wall forms around each developing endospore. At maturation, the spherule ruptures to release its endospores. The endospores are 2–5µm in size and may, in turn, enlarge to form mature spherules. Hyphae as well as spherules may form in the tissues and appear in sputum of patients with coccidioidal cavities of the lungs.

Cultural characteristics

On routine mycological media, such as inhibitory mold or Sabouraud's agar, at the usual incubation temperature of 77–86°F (25–30°C), different isolates of *C. immitis* produce a wide variety of colony types. Colonies may be white, gray or brownish in color, with a powdery, wooly or cottony texture. Because numerous infectious arthroconidia are produced in culture and can be readily aerosolized in the dry state, cultures of *C. immitis* must be handled with extreme caution to prevent accidental exposure. Tubes or plates should be opened only under a safety cabinet that protects both the laboratory worker and the environment.

Spherules can be produced in the laboratory on a complex medium at 104°F (40°C) under 20% CO_2 . However, *in vitro* growth of the tissue phase even under optimal conditions is seldom extensive.

EPIDEMIOLOGY

In the USA, the geographic areas endemic for coccidioidomycosis and from which *C. immitis* can be isolated from the soil correspond to the Lower Sonoran life zone. These areas are characterized by a semi-arid climate, alkaline soil and characteristic indigenous desert plants and rodents. The endemic foci in Mexico, Argentina and other scattered areas of Central and South America are associated with

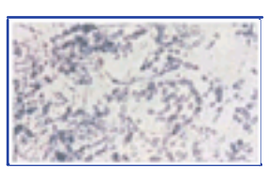

Figure 238-4 *Coccidioides immitis,* mycelial form in culture at 86°F. This shows hyaline, septate, branching hyphae and chains of arthroconidia, often in alternating cells.

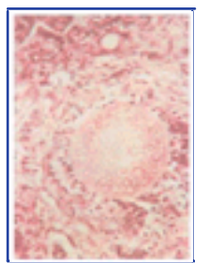

Figure 238-5 *Coccidioides immitis,* spherule in hematoxylin- and eosin-stained section of lung lesion. This shows refractile cell wall and internal endospores.

ecologically similar environments. Although *C. immitis* grows in the laboratory over a wide range of temperature, pH and salt concentration and requires only glucose and ammonium salts to grow, it has never become established in soils outside the endemic area, despite being transmitted to other locations by infected animals and fomites. Although *C. immitis* is inhibited by other micro-organisms, cultivated soil or treatment with various chemicals, none of these factors fully explains its restricted habitation. The mycelia, which can be found several inches beneath the soil surface, are recovered at the surface after the spring rains. As the weather becomes hot and dry, the mycelia convert to infectious arthroconidia and this accounts for the peak infection rate during the summer. In the endemic area, natural infections also occur among indigenous fauna, such as desert rodents, dogs and cattle.

Inhalation of the arthroconidia of *C. immitis* leads to infection and acquisition of a positive delayed-type hypersensitivity response to coccidioidin. More than half of these infections are benign and most of the others are symptomatic but self-limited (see Table 238.1). Approximately 1% of these cases will develop progressive pulmonary disease, dissemination or both. Some individuals

have an increased risk of developing disseminated disease following primary infection (Table 238.5). These include persons in certain ethnic groups: Filipinos, African

Americans, Latin Americans, and Native Americans. This ethnic predilection for severe disease clearly indicates the importance of the genetic background of the host in mounting an effective immune response to infection.[44] In addition to ethnicity, males, women in the third trimester of pregnancy, persons with a cellular immunodeficiency (including AIDS), and individuals at the age extremes are more susceptible to severe disease (see Table 238.5).

The areas of endemicity defined by case reports and by isolation of *C. immitis* from soil have been confirmed by skin test surveys with coccidioidin. Within the endemic areas, which include portions of the south-western USA (California, Arizona, New Mexico, Nevada, Utah and Texas) and north-western Mexico, the percent reactivity varies; some of the highest rates are found in Phoenix and Tucson, Arizona, and Kern County, California. Isolated cases of coccidioidomycosis occurring outside the established areas of endemicity have been attributed to fomite transmission of the arthroconidia or to patient travel through the endemic area.

Numerous outbreaks of primary infection have been reported among individuals simultaneously exposed to a heavy aerosol of arthroconidia. Coccidioidomycosis is therefore considered an occupational hazard for construction workers, archeology students and others who work the soil in the endemic areas. In a similar manner, many cases of acute disease developed subsequent to a severe wind storm in California in 1977, when contaminated soil was blown from the San Joaquin Valley far north and west, exposing large populations of unsensitized individuals. A similar epidemic of coccidioidomycosis produced a marked increase in Kern County in 1991–92. [45] The explanation for this increase has baffled investigators, but it may have been caused by concurrent earthquakes and high winds. Risks for severe pulmonary disease include diabetes, cigarette smoking, low income and old age.[46] Recently an outbreak was described among Navy SEALs who trained for 6 weeks in Coalinga, California. Forty-five percent (10 out of 22) had serologic and radiographic evidence of acute coccidiodomycosis, and all were symptomatic.[121]

PATHOGENICITY

Using reverse genetics, Cole and his colleagues have identified antigens and potential virulence factors that are elaborated by *C. immitis*. The cell wall of the infectious particle, the arthroconidium, has three distinct layers.[47] *In vivo*, potent cell wall antigens are released when the arthroconidia develop into spherules.[48] Although arthroconidia and endospores are readily engulfed by alveolar macrophages, killing is enhanced by activation of

TABLE 238-5 -- Risk factors for disseminated coccidioidomycosis.

RISK FACTORS FOR DISSEMINATED COCCIDIOIDOMYCOSIS
Age Infants and elderly
Sex Male
Genetics Filipino > African-American > Native American > Hispanic > Asian
Serum CF antibody titer >1:32
Pregnancy Late pregnancy and postpartum
Delayed-type hypersensitivity skin test Negative
Depressed cell-mediated immunity Malignancy, chemotherapy, steroid treatment, HIV infection

macrophages with the appropriate T cells or cytokines.[49] When stimulated by spherules, leukocytes from both patients and skin test-positive subjects secrete potentially protective cytokines, such as interferon-? and IL-12.[50] [51]

Investigators have identified several potential virulence factors. For example, *C. immitis* produces a serine proteinase with broad specificity for host substrates, such as elastin, collagen, IgG and IgA. [52] [53] Other proteinases have also been detected.[16] [54] These proteinases are thought to contribute to the development of spherules and release of endospores.

Many of the patients who develop disseminated coccidioidomycosis have depressed cell-mediated immunity. There is a marked inverse relationship between the antibody titer (see below) and specific cell-mediated immunity, as measured by skin test and, *in vitro*, by the numbers of $CD4^+$ and $CD8^+$ T cells, the responsiveness of T cells to mitogens or antigens, and the production of cytokines. In severe coccidioidomycosis, patients have elevated antibody titers and circulating immune complexes and depressed cellular immunity. This condition has been related to increased antigen burden, populations of suppressor cells, immune complexes and impaired lymphocyte circulation.[55] Immune complexes are detected in serum of patients with coccidioidomycosis and correlate with the severity of disease.[56] In the mouse model of experimental coccidioidomycosis, specific anergy is correlated with the amount of coccidioidal antigen present.[57] Recovery often leads to restoration of immune functions. However, the impaired cellular immune responses are likely governed by whether Th1 or Th2 responses predominate early in infection.[55] [58] [59] In strains of mice that differ in susceptibility to *C. immitis*, protective responses are correlated with the secretion of interferon-?, which is a Th1-associated cytokine and potent activator of macrophages.[60] Conversely, much of the immunopathology may be attributable to excess production of TNF-a. Perhaps the ethnic predisposition to disseminated coccidioidomycosis (Table 238.5) is related to genetic control of the T cell response to *C. immitis*.

PREVENTION

Coccidioides immitis cannot be eliminated from the soil, but public health efforts to reduce the dust associated with dispersion of the arthroconidia are helpful in areas of high endemicity.[61] Another approach has focused on the development of a vaccine for persons at risk. In mice and humans, cell-mediated immunity to *C. immitis* confers excellent protection against disease. Spherule-derived vaccines in the past were not successful, but several new approaches to identify specific candidate epitopes are currently under investigation.[58] [62]

DIAGNOSTIC MICROBIOLOGY

Direct examination

A definitive diagnosis of coccidioidomycosis requires the finding of spherules of *C. immitis* in sputum, draining sinuses or tissue specimens (Fig. 238.5). Clinical exudates should be examined directly in 10% or 20% potassium hydroxide, with or without calcofluor white, and tissue obtained from biopsy can be stained with hematoxylin and eosin or special fungal stains, such as Gomori methenamine silver or the periodic acid-Schiff stain, which stain fungal cell walls black or reddish, respectively. Direct microscopic examination of cutaneous or deep tissue specimens, either in calcofluor/KOH preparations or histologic sections, yields positive results in approximately 85% of proven cases. However, sputum specimens are positive by direct examination or culture in less than half of the cases.

Culture

Clinical specimens are cultured on inhibitory mold, Sabouraud's agar or other routine fungal medium, as described above under Blastomycosis. Colonies of *C. immitis* develop within 1 or 2 weeks and are examined microscopically for the production of characteristic arthroconidia. Microscopic preparations of mycelia should always be prepared under a biosafety hood. The identification of *C. immitis* may be confirmed by the production of spherules *in vitro* by incubation in a complex medium at 104°F (40°C) with 20% CO_2 or by animal inoculation (e.g. intraperitoneal injection or mice or intratesticular inoculation of guinea-pigs). An easier method of confirmation involves the exoantigen test described in the discussion of Blastomycosis. Production of exoantigen F confirms the identity as *C. immitis* (see Table 238.3). This rapid method can be used with young, nonsporulating cultures.[25] [63] [64] Alternatively, DNA-based identification is available with a commercial system.[24] [63]

With the exception of tissue scrapings, biopsies and surgical specimens, cultures are more often positive than microscopic examinations of clinical material. However, use of both procedures will optimize the opportunity to establish a diagnosis. Between 25% and 50% of sputa, bronchial washes, spinal fluids and urine specimens yield positive cultures. Positive blood cultures are infrequent but significantly associated with acute, disseminated coccidioidomycosis and high mortality.

Skin tests

As noted above, coccidioidin, which is a crude but standardized toluene extract of a mycelial culture filtrate, is used for skin testing. A delayed-type hypersensitivity reaction is elicited, and a positive test is defined as induration exceeding 5mm in diameter. Another *C. immitis* antigen, prepared from cultured spherules and termed spherulin, is more sensitive but less specific than coccidioidin. Skin testing with either antigen does not induce or boost an immune response. The skin test becomes positive within 2 weeks after the onset of symptoms and before the appearance of antibodies and often remains positive indefinitely. A positive reaction has no

diagnostic significance without a history of conversion, but a negative test can be used to exclude coccidioidomycosis, except in patients with severe disseminated coccidioidomycosis who may have become anergic. Indeed, a negative skin test in confirmed cases is associated with a grave prognosis. Conversely, a positive skin test in healthy subjects implies immunity to symptomatic reinfection.

Serologic tests

As indicated in Table 238.3 , tube precipitins or latex agglutinins measure specific IgM antibodies. They are produced early and assist in the diagnosis of primary infections. They are detected by a sensitive tube test that becomes positive in 90% of patients within 2 weeks after the appearance of symptoms and disappears in most cases by 4 months. Therefore, a positive tube precipitin (TP) test indicates active primary (or reactivation) coccidioidomycosis. Results obtained with the original TP method correlate quite well with those obtained with the more rapid and convenient latex particle agglutination test; the latter procedure is more sensitive but less specific than the TP test. The TP antigen, a component of coccidioidin, is heat stable at 140°F (60°C), whereas the antigen detected in the complement fixation (CF) test is heat labile.

The CF test, which measures IgG antibodies to coccidioidin, is a powerful diagnostic and prognostic tool. Because the CF test becomes positive more slowly and persists longer, the presence of CF antibodies may reflect either active infection or the recovery stage. The CF titer correlates with the severity of disease. Most patients with secondary coccidioidomycosis develop a titer of 1:16 or higher, whereas in nondisseminated cases, the titer is almost

Figure 238-6 Coccidioidomycosis, showing hilar lymphadenopathy and a cavity in the left lung.

invariably lower. Therefore, a critical titer of 1:32 or higher reflects active, disseminated disease. However, a lower titer does not exclude disseminated disease because many patients, such as those with single extrapulmonary lesions, notably coccidioidal meningitis, do not develop high titers.

Multiple serum specimens are most helpful because a change in the CF titer reflects the prognosis: the CF titer declines with recovery and eventually disappears. A rising titer indicates active, uncontrolled infection and a poor prognosis. A stable or fluctuating titer often indicates the presence of a recalcitrant or stabilized lesion. An exceptional situation is coccidioidal meningitis, in which only half of the patients have a titer of 1:32 or higher. However, most of these patients will have a positive CF test in their spinal fluid, which is equally valuable.

The immunodiffusion (ID) method can be used to detect both TP and CF antibodies by using reference antisera and heated (TP only) and unheated antigen. Antibodies to two specific heat-labile antigens, termed F (or CF) and HL, may be detected. The CF antigen has been determined to be a chitinase.[65]

CLINICAL MANIFESTATIONS

Primary coccidioidomycosis

Following inhalation of arthroconidia, the primary infection in most individuals is asymptomatic. Others may develop flu-like symptoms: fever, chest pain, cough or weight loss. Radiographic examination often reveals discrete nodules in the lower lobes. Primary pulmonary coccidioidomycosis has an incubation period of 10–16 days and usually resolves without complication in 3 weeks to 3 months. A small percentage of patients retain cavities (Fig. 238.6), nodules or calcifications, but endogenous reactivation of residual pulmonary lesions is rare in immunocompetent individuals.

Up to 20% of patients with primary coccidioidomycosis manifest allergic reactions, usually erythema nodosum (Fig. 238.7) or erythema multiforme, which appear with the primary symptoms, are very painful and persist for approximately 1 week. These allergic manifestations are associated with strong immunity and a good prognosis.

Secondary coccidioidomycosis

Disseminated or secondary coccidioidomycosis usually develops within a few months as a complication of the primary form. The numerous manifestations of secondary coccidioidomycosis include chronic and

Figure 238-7 Allergic manifestations of infection with *Coccidioides immitis.* Erythema nodosum on the lower legs.

progressive pulmonary disease, single or multiple extrapulmonary dissemination or generalized systemic infection. Chronic pulmonary coccidioidomycosis usually involves a single, thin-walled cavity, but patients may develop enlarging or multiplying nodules or cavities.

Dissemination may be fulminant or chronic, with periods of remission and exacerbation. Extrapulmonary lesions most frequently involve the meninges, skin or bone. Chronic cutaneous coccidioidomycosis develops from initial lesions that usually appear on the face or neck and that, over a period of years, evolve into thick, raised, verrucous lesions with extensive epithelial hyperplasia.[66] Bone involvement may accompany generalized systemic disease. Both osteomyelitis of long bones, vertebrae and other bones and arthritis may develop.[67] Draining sinus tracts may evolve from subcutaneous and osseous lesions.

Coccidioidomycosis and AIDS

Coccidioidomycosis is the AIDS-defining illness for many patients, who commonly present with fever and chills, weight loss and night sweats.[68] [69] After pulmonary disease, coccidioidal meningitis is a frequent complication. Serologies are often negative in AIDS patients and the mortality rate is high. Diffuse pulmonary disease and low $CD4^+$ lymphocyte count (<50/μl) carry a poor prognosis.[68]

MANAGEMENT

Symptomatic treatment is usually adequate for the patient with primary coccidioidomycosis, although ketoconazole may reduce the symptoms. However, if the primary infection is persistent or severe, or if there is evidence of dissemination, ketoconazole or itraconazole should be administered at 400mg/day for 2–6 months.

The chronicity of the disseminated disease usually requires prolonged therapy, which may increase the chances of undesirable side effects. Successful treatment with ketoconazole may require continuous administration for more than a year. Chronic coccidioidal meningitis is often treated with fluconazole, which has excellent penetration across the blood-brain barrier. Some cases may require the intrathecal administration of chemotherapy. Grave disease is treated with amphotericin B in the usual formulation or as a lipid preparation to provide a higher dosage with reduced toxicity. For patients with AIDS, the total dose of amphotericin B (1.0–1.5mg/kg/day) should be at least 1.0g, after which a maintenance regimen of itraconazole or fluconazole may be started. Patients treated with amphotericin B or azoles are more likely to relapse if the delayed skin test becomes negative and the CF antibody titers equal or exceed 1:256.[70]

HISTOPLASMOSIS

Histoplasmosis, the most prevalent cause of pulmonary fungal disease in humans and animals, is caused by the thermally dimorphic fungus, *Histoplasma capsulatum*. The infection occurs worldwide and is initiated by inhalation of *H. capsulatum*. The incidence varies considerably, being negligible in many parts of the world but pronounced in local regions wherein most of the native population have been infected. Ninety-five percent of the infections are inapparent and are detected only by the manifestation of residual lung calcification(s), delayed hypersensitivity to *H. capsulatum*, or both. As one of the more common primary mycoses, throughout history, its existence has been inferred on the basis of descriptions of the pathogenesis and natural history of disease.

Around the turn of the last century, when histoplasmosis was discovered, the appearance of the organism within macrophages in histopathologic sections of infected tissue resembled encapsulated protozoa, hence the name, *Histoplasma capsulatum*.[71] The fungal etiology of histoplasmosis was subsequently confirmed and even though *H. capsulatum* is neither a parasite nor encapsulated, the name, by precedence and taxonomic custom, remains. With the discovery of a sexual reproduction cycle in *H. capsulatum*, it was transferred to the family Gymnoascaceae within the subdivision Ascomycotina. Because of the similarity between the sexual reproductive structures of the teleomorphs of *H. capsulatum* and *Blastomyces dermatitidis*, whose teleomorph, *Ajellomyces dermatitidis*, had been discovered earlier, *H. capsulatum* was transferred to that genus as *Ajellomyces capsulatus*.[72] [73] The name *H. capsulatum* is retained by common usage and remains appropriate as the fungus is clinically isolated in its asexual or anamorphic state. The close relationship between *H. capsulatum* and *B. dermatitidis* has been confirmed by molecular evolutionary studies comparing ribosomal DNA sequences.[74] Of three closely related varieties of *H. capsulatum*, most human cases are caused by *H. capsulatum* var. *capsulatum*, while *H. capsulatum* var. *duboisii* is found in Africa (see below), and *H. capsulatum* var. *farciminosum* causes infection in horses.

The extent of unapparent infection was not appreciated until the 1940s. During extensive skin test surveys for tuberculosis in student nurses from various parts of the country, radiologists observed small calcifications in the lungs of many apparently healthy individuals who were nonreactive to old tuberculin.[75] [76] Subsequent skin testing with histoplasmin, an antigen from *H. capsulatum* analogous to old tuberculin, revealed a high correlation between delayed skin test reactivity and pulmonary calcifications in tuberculin-negative individuals. The availability of skin test antigens for histoplasmosis has provided a very useful epidemiologic tool.

NATURE

Histoplasma capsulatum is a thermally dimorphic fungus. At temperatures below 95°F (35°C), it grows as a mold, often white or brown in color, and at 98.6°F (37°C), it grows as a yeast with small, heaped and pasty colonies. *Histoplasma capsulatum* characteristically grows slowly. Under optimal conditions, the mold colony develops after 1 or 2 weeks and conidia are produced shortly thereafter. However, cultures of clinical specimens sometimes require incubation periods of 8–12 weeks before there is detectable growth. Primary isolates are often brown and become white with prolonged cultivation.[25]

Both microconidia and macroconidia are produced at temperatures below 95°F (35°C). The microconidia are borne singly on short conidiophores, globose and 1–5µm in diameter. Upon dehydration, the conidia are easily dislodged by air currents and aerosolized. Their small size enables the microconidia to transmit the infection. The

macroconidia, or tuberculate chlamydospores, are very distinctive. Mature forms are large, 8–16µm in diameter, spherical thick-walled structures with projections radiating from the cell wall (Fig. 238.8). Young macroconidia are smooth walled and the echinulations develop as the conidia mature.

At 98.6°F (37°C), the mold converts to growth as a small, budding yeast. Conversion is often difficult to effect *in vitro* but is enhanced by a rich, complex medium, such as brain-heart infusion agar. Hyphal cells may form buds directly or develop enlarged, transitional cells, which subsequently produce buds. Microconidia may also convert to budding yeast cells. The yeast cells are small, ellipsoidal, approximately 1–3µm by 3–5µm in size, and virtually identical to the yeasts observed *in vivo* within phagocytes (Fig. 238.9).

Biochemical studies of the yeast and mycelial forms of *H. capsulatum* have detected significant differences in the relative amounts of chitin, a-glucan and ß-glucan of the cell walls. The three RNA polymerases in each growth form are also different. Morphogenesis in *H. capsulatum* involves a protein, histin, isolated from the cytoplasm of mycelial form. Histin inhibits RNA polymerase and may help to regulate the temperature-dependent control of transcription. An inhibitor, such as histin, may be operative in the mycelia, because protein synthesis is considerably reduced during mycelial growth.

In *in vitro* studies of the crucial mycelium-to-yeast conversion at 98.6°F (37°C), Maresca *et al.* confirmed the importance of cysteine.[77] [78] This conversion proceeds in three stages:

1. during the first 40 hours at 98.6°F (37°C), respiration gradually decreases and the intracellular amino acid pools become almost depleted;
2. the cells remain dormant for 4–6 days;
3. then concentrations of intracellular cysteine and other amino acids increase and respiration is restored.

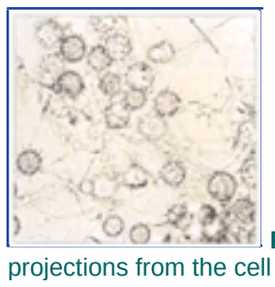

Figure 238-8 *Histoplasma capsulatum,* mycelial form in culture at 86°F. This shows hyaline septate branching hyphae, microconidia and large spherical macroconidia, with projections from the cell walls.

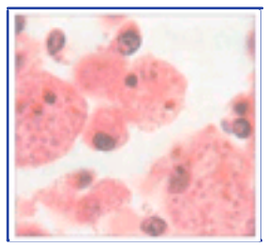

Figure 238-9 *Histoplasma capsulatum.* Small yeast cells packed inside macrophages in a Giemsa-stained smear of bone marrow aspirate.

Cysteine and cystine are essential for the transition to yeast cells. These compounds and other reducing agents appear to stimulate the mitochondrial electron transport chain, probably via a unique cysteine oxidase. This mycelium-to-yeast conversion is inhibited by elevated cyclic AMP, which may also be regulated intracellularly by the action of sulfhydryl agents.[77] Recent research from several laboratories has identified yeast form-specific genes that may be involved in the regulation of dimorphism and consequently virulence.[79] [80] [81] [82] [83]

In studies of virulent strains, the sulfhydryl blocking agent, *p*-chloromercuriphenylsulfonic acid (PCMS), irreversibly inhibited the conversion of mycelium to yeast at 98.6°F (37°C), but mycelial growth continued at 98.6°F (37°C).[84] PCMS-treated mycelia also failed to infect mice. Therefore, mycelium-to-yeast transformation appeared necessary for pathogenicity but not for growth at 98.6°F (37°C). PCMS-treated mycelia may provide a vaccine for histoplasmosis and indicate the essential changes for transformation.[84]

Sexual reproduction

As noted above, discovery of its sexual reproductive cycle led to reclassification of the teleomorph *A. capsulatus*, which closely resembles the teleomorph of *B.*

dermatitidis. [72] Being heterothallic, *A. capsulatus* requires strains of two opposite (compatible) mating types for sexual reproduction. Although the mating types, designated '+' and '-', are equally prevalent among soil isolates, many more infections are caused by the '-' type, which suggests a linkage of this allele with pathogenicity.[85]

Biotypes

Biotyping may facilitate epidemiological studies and several DNA-based methods have been developed to identify and compare strains of *H. capsulatum* from different sources and with different phenotypes. Isolates that differ in virulence for animals have been compared with strains from the environment and with isolates from patients with and without AIDS.[86] [87] [88] In addition, phylogenetic analyses have identified major subpopulations of *H. capsulatum* that correspond with geographic groups.[89]

EPIDEMIOLOGY

Ecology

In nature, *H. capsulatum* lives in soil with a high nitrogen content and is associated with bat and avian habitats. *H. capsulatum* has been isolated many times from bird roosts, chicken houses, bat caves and similar environments. Conidia, when dry, are easily air borne and spread by wind currents, as well as by birds and bats. *H. capsulatum* is most prevalent in the environment where the infection is most endemic, namely in the Ohio-Mississippi Valley — in Missouri, Kentucky, Tennessee, Indiana, Ohio and southern Illinois. This region also has the highest population of starlings, which tend to congregate in large numbers. The excrement from these birds provides an ideal medium for the enrichment of *H. capsulatum*. In South America, the chief reservoir appears to be chicken coops and bat caves.

In cases of histoplasmosis from Africa, both *H. capsulatum* and a stable variant, *H. capsulatum* var. *duboisii*, have been isolated. Infections elsewhere are due to the global variety, *H. capsulatum* var. *capsulatum, H. capsulatum* var. *duboisii* causes African histoplasmosis, which is distinguished from the usual infection by:

- a greater frequency of skin and bone lesions;
- diminished pulmonary involvement;
- pronounced giant cell formation; and
- larger, thick-walled yeast cells in tissue.

Although these clinical features are characteristic and reproducible, *H. capsulatum* var. *duboisii* cannot be reliably differentiated *in vitro* from the type species on the basis of morphology, physiology

and antigenic composition. Indeed, both forms of histoplasmosis are the same species, as *H. capsulatum* var. *duboisii* mates with *H. capsulatum* var. *capsulatum*, and its sexual form is identical to *A. capsulatus*.

Another variety, *H. capsulatum* var. *farciminosum*, is associated with cutaneous, subcutaneous and lymphangitic lesions in horses.[90]

Histoplasmin skin test

The antigen, histoplasmin, is produced by growing the mycelial phase of *H. capsulatum* in a specialized broth medium. The filtrate from the culture is dialyzed, the concentration is standardized and 0.1ml of the appropriate dilution is injected intradermally. A positive reaction is indicated by induration of >5mm diameter after 48 hours.

A positive test, if specific, denotes previous sensitization to *H. capsulatum*. Without a history of prior negativity, the positive test has no diagnostic significance. Histoplasmin is a crude, polyvalent mixture of antigens, only some of which are specific for *H. capsulatum*. Because some antigenic determinants are shared by other pathogenic fungi, cross-reactions can occur. For example, some individuals sensitive to *B. dermatitidis* or *C. immitis* will give a false-positive reaction to histoplasmin. Therefore, along with histoplasmin, it is routine to administer coccidioidin in the USA or coccidioidin and paracoccidioidin in South America. A reaction to a single antigen is generally considered specific. Reactions to two antigens may be caused by sensitization to one or both, although the larger reaction is often considered more specific.

Incidence

Much of the knowledge concerning the prevalence of histoplasmosis has been derived from extensive skin test surveys conducted since the 1950s all over the world. The region with the highest level of reactivity is the central USA, along the river valleys of the Ohio, Mississippi, St Lawrence and Rio Grande rivers, where in some locales 80–90% of the population may be skin test positive by the age of 20 years. Foci of high reactivity exist elsewhere in the world, such as southern Mexico, Indonesia, the Philippines and Turkey. In the USA alone, projections based on skin test surveys have led to estimations that more than 40 million people have been exposed with 500,000 new infections every year. Of these, perhaps 55,000 to 200,000 cases will be symptomatic, 1500–4000 will require hospitalization annually and 25–100 deaths will occur. These projections were made prior to 1980 and do not reflect the increasing incidence of opportunistic histoplasmosis in patients with AIDS.

Outbreaks

Outbreaks or epidemics of acute respiratory histoplasmosis result from the simultaneous exposure of a large number of people. These epidemics are not caused by direct spread among humans or animals. The experience of youths on Earth Day, 1970, in Delaware, Ohio, is more ironic than most, but otherwise typical of these epidemic outbreaks.[122] The young people gathered to reclaim an abandoned park and, in so doing, overturned several truckloads of soil, which was enriched with starling feces and contaminated with an enormous quantity of *H. capsulatum* conidia. Several cases of acute respiratory histoplasmosis followed inhalation of this heavy inocula of aerosolized microconidia. Many similar episodes have been documented: the sudden release leads to multiple exposure of a heavy inoculum that has accumulated in a dormant environment. Silos, air-conditioning units contaminated with bird droppings and accumulations of guano in caves, attics or parks have all been implicated as reservoirs for *H. capsulatum* in outbreaks of this type. Perhaps the largest outbreak occurred in Indianapolis between the fall of 1978 and 1979.[91] It is estimated that more than 100,000 persons were infected during this time, resulting in over 300 hospitalized cases and at least 15 deaths. The incidence of disseminated histoplasmosis and the fatality rate were unusually high. The environmental source of the fungus was not determined. Indeed, *H. capsulatum* was not recovered from any of the soil samples collected at the most likely site, where an abandoned amusement park had been recently dismantled.

Males develop symptomatic histoplasmosis more often than females, and approximately 75% of cases occur in males. Before puberty, the attack rate for males and females is identical and the percentage of positive skin test reactors is the same for both sexes at all ages. These epidemiologic data suggest that either adult males are inherently more susceptible to the disease or females are more resistant. Severity of disease and mortality are greater at the age extremes, in infancy and after the age of 50.

In addition to humans, many wild and domestic animals are susceptible to histoplasmosis. Some animals, including the bat, may act as vectors to disseminate the organism in nature.

PATHOGENICITY

All clinical forms are believed to evolve from the same natural history. Microconidia are inhaled from an exogenous source and penetrate to the alveoli, where they convert to small, budding yeast cells. This temperature-dependent morphogenesis is related to the virulence of strains of *H. capsulatum*. [92] [93] The yeasts are readily phagocytized by alveolar macrophages. At this stage, the yeast-laden macrophages may be cleared through the upper respiratory tract. They may disseminate through the circulation, spreading the yeasts to other reticuloendothelial organs, and/or they may invoke a tissue response *in situ*. The tissue reaction may involve an early influx of neutrophils and lymphocytes, but the pyogenic inflammatory response gives way to epithelioid cell tubercle formation. In the course of these various possible reactions, the intracellular yeasts may or may not be inactivated by the phagocytes (see below).

The conversion of *H. capsulatum* to the yeast form at 98.6°F (37°C) appears to be essential for pathogenicity. As noted above, treatment of the mycelial form with PCMS blocks morphogenesis and reduces virulence, but does not inhibit survival at 98.6°F (37°C).[84] The expression of yeast-specific genes has been correlated with

virulence and thermal tolerance.[80] [83] [92] [94]

Pathogenesis

After being phagocytized, the yeast cells of *H. capsulatum* survive intracellularly by a calcium-dependent process, block acidification within the phagolysosome and multiply within macrophages.[83] [95] However, macrophages from immunized animals, as well as normal macrophages activated by immune lymphocytes or cytokines, restrict the growth of intracellular yeasts.[96] [97] In experimental, self-limited murine histoplasmosis, various parameters of cell-mediated immunity are depressed during the height of antigen (yeast) burden, suppressor T cells and macrophage-like suppressor cells are detected and production of IL-1 and IL-2 is impaired.[98] [99] Concomitant with resolution of the infection, the number of suppressor cells in the spleen diminishes and T helper cells increases. These correlations of competent cell-mediated immune responses with resistance to infection are supported by the clinical data. Similar to coccidioidomycosis, there is an inverse relationship between the magnitude of the cell-mediated immune response, as measured by delayed-type hypersensitivity or *in vitro* lymphoblastogenesis, and high levels of specific antibody, which correlate with the severity of the disease. Additional evidence suggests that TNF-a may be crucial in the induction of protective T-cell responses.[55] [100]

DIAGNOSTIC MICROBIOLOGY

Microscopic examination

Histoplasmosis can be diagnosed on finding the yeast cells in clinical material. Suitable specimens include sputa, tissue from biopsy or surgical specimens, spinal fluid and blood. The buffy coat of a blood specimen may reveal yeast-filled macrophages. Bone marrow obtained when patients are febrile may contain yeast cells. Smears of infected sputum, blood, marrow or tissue that have been fixed with methanol and stained with the Wright or Giemsa stain will reveal the characteristically small, ellipsoidal yeast cells (approximately 2 × 4µm) inside macrophages. With either stain, the larger end of the yeast cell contains an eccentric, red-staining mass (see Fig. 238.9).

Culture

Sputum specimens should be collected early in the morning and purulent or sanguineous portions should be selected for culture. A bronchial wash is even more likely to be positive. Nonsterile specimens (e.g. sputum, skin or urine) should be cultured on a blood-enriched medium and inhibitory mold or Sabouraud's agar with antibiotics (cycloheximide and chloramphenicol or gentamicin) and incubated for at least 4 weeks at 77°F (25°C) or 86°F (30°C). Because *H. capsulatum* may grow very slowly, cultures should be incubated for up to 12 weeks, if possible, before discarding as negative. If a sporulating mold develops, *H. capsulatum* can be identified by the presence of its characteristic macroconidia (see Fig. 238.8) and by conversion to the yeast from by growth on an enriched medium at 98.6°F (37°C). Alternatively, conversion to the yeast may be effected by growth in tissue cultures, such as HeLa cells, or by animal inoculation, such as the intraperitoneal injection into mice. Occasional isolates of *H. capsulatum* will not produce conidia, but it should be possible to identify these variants by conversion to the yeast form, by the detection of *H. capsulatum*-specific exoantigens (see Table 238.3) or by using a specific DNA probe.[24]

In endemic areas or in cases where histoplasmosis is suspected, specimens should be inoculated on multiple media, such as Sabouraud's agar without antibiotics at 77–86°F (25–30°C), Sabouraud's agar with antibiotics (cycloheximide and chloramphenicol, gentamicin or penicillin and streptomycin) at 77–86°F (25–30°C), brain-heart infusion agar with 5% sheep blood and antibiotics at 77–86°F (25–30°C), and brain-heart infusion agar with 5% sheep blood without cycloheximide at 98.6°F (37°C). The pH of these media should be near neutrality, since *H. capsulatum* is inhibited below pH 6.

In disseminated cases, the lysis-centrifugation method is recommended for culturing blood, although transient fungemia may be observed in patients with acute pulmonary histoplasmosis. Blood volumes of 10ml are added to a tube containing a mixture of anticoagulants and reagents to lyse the blood cells; the tubes are then centrifuged and the pellet, which contains any yeast cells in the blood, is inoculated onto plates of inhibitory mold agar and other media. Lysis-centrifugation is the most sensitive and rapid method to recover fungi from blood, especially *H. capsulatum*.[101]

Skin test

The skin test antigen, histoplasmin, is a valuable epidemiologic tool. Within weeks after infection, most persons develop a positive skin test and this reactivity usually persists for many years. The diagnostic value of the skin test is minimal. With most patients, only a history of conversion from negative to positive is diagnostic. A negative reaction can be used to rule out active histoplasmosis in the immunocompetent subject, but patients with anergy may be falsely negative. Without a prior history of a negative skin test, a positive reaction is meaningless except in infants, in whom a positive test can be presumed to result from recent or current infection. Because of its limited diagnostic value and the possibility that the skin test may confound the antibody titration (see below), skin testing with histoplasmin should be avoided in most patients.

Serology

Specific antibodies to *H. capsulatum* antigens can be detected during infection. Two serologic tests are now widely accepted because of their convenience, availability and utility: the measurement antibodies by complement fixation (CF) and the immunodiffusion (ID) test for precipitins. Both tests may be helpful in the diagnosis and prognosis of histoplasmosis, provided the results are properly interpreted (see Table 238.4).

The CF test is routinely performed under standard conditions for measuring fixation of complement by the classic pathway.[102] [103] CF tests are performed to detect antibodies to two antigens of *H. capsulatum*: histoplasmin and a standardized suspension of killed yeast cells. Because of the possibility of cross-reactivity, patient sera are tested concomitantly against other fungal antigens, such as coccidioidin, spherulin, *B. dermatitidis* or *Paracoccidioides brasiliensis*. Serum antibodies specific for *H. capsulatum* antigens can be detected by the CF test 2–4 weeks following exposure. Most laboratories perform the CF test on twofold dilutions of patient serum, beginning with a dilution of 1:8. With resolution of the infection, the antibody titer gradually declines and disappears (i.e. titer <1:8), in most cases by 9 months. The CF test with either *H. capsulatum* yeast or mycelial (histoplasmin) antigen is very sensitive and 90% of patients are positive (i.e. titer >1:8).[91] A titer of 1:32 that persists or rises over the course of several weeks indicates active disease in patients with an established diagnosis of histoplasmosis. Unfortunately, in sensitive patients, the skin test antigen may boost the CF antibody titer to histoplasmin and the elevated titer may remain for as long as 3 months. Therefore, the CF test, which can deliver results as rapidly as the skin test, is preferable for diagnostic purposes. However, a positive CF test, even in high titer, is not by itself diagnostic, as the results can be caused by cross-reacting antibodies. If a patient's serum is reactive to more than one fungous antigen or if it is anticomplementary, the ID test should be conducted.

Precipitins can be detected by immunodiffusion (ID) of serum and antigen in agarose. The antigen is histoplasmin in 10-fold the concentration used for the CF test. The ID test becomes positive in up to 80% of patients with histoplasmosis by the third or fourth week of infection. This test, while less sensitive and requiring a longer time to become positive, is more specific than the CF test. Precipitin lines or bands specific for *H. capsulatum* are detected by the formation of lines of identity with reference serum. There are two specific precipitin bands, m and h. The m line, which is observed more frequently, appears soon after infection and may persist in the serum for up to 3 years following recovery. The h band, which forms closer to the serum wells, is more transient. Because it disappears soon after the disease, the presence of serum antibodies to the h antigen is better correlated with active infection. As with the CF titer, the m band may be boosted by the administration of the histoplasmin skin test, and the boosting effect may last up to 3 months.

An excellent radioimmunoassay (RIA) test for antigenemia and antigenuria has been developed by Wheat and colleagues.[104] [105] Tests for polysaccharide antigen in the serum have been detected in 79% of patients with disseminated histoplasmosis and 97% had a positive test for antigen in the urine. After treatment with AMB, serum titers dropped in all the patients and urine titers dropped in 91% of patients. Testing either serum and urine had prognostic value, detecting relapses in AIDS patients. [104] This RIA is commercially available from the Histoplasmosis Reference Laboratory (Indianapolis, IN 46202). The antigen can also be measured in CSF or bronchoalveolar lavage fluid specimens. However, the test lacks optimal specificity

---

because patients with other systemic mycoses have been shown to yield positive tests for the antigen in urine.[106]

CLINICAL MANIFESTATIONS

The manifestations of infection with *H. capsulatum* are numerous. The initial pulmonary episode may be acute or chronic or dissemination may occur by hematogenous

or lymphatic spread from the lungs to other organs. Several clinical classifications have been devised, but none is completely satisfactory. Most normal individuals are able to contain the infection. The granulomata that form may undergo fibrosis, and residual scars may remain in the lungs or spleen. Resolution appears to confer some immunity to reinfection. This process occurs without symptoms in 95% of all persons with acute, primary histoplasmosis, whether disseminated or confined to the lung.

Acute pulmonary histoplasmosis

Patients with acute pulmonary histoplasmosis manifest symptoms ranging from a mild influenza-like illness that clears spontaneously to a moderate or severe disease. In healthy hosts, the degree of involvement and symptomatology seems to correlate with the size of the inoculum inhaled. In the previously sensitized individual, such reinfection exposure results in a shorter and milder infection with minimal histopathology. The incubation period varies from one to several weeks. A moderate disease is characterized by cough, chest pain, dyspnea and hoarseness. In more severe cases, patients have fever, night sweats and weight loss. Occasionally, yeast cells may be observed in the sputum. Radiologic examination may reveal multiple lesions scattered throughout the lungs and in patients with active disease, hilar lymphadenopathy is usually present (Fig. 238.10). Pulmonary lesions due to *H. capsulatum* resolve slowly. Healing may be complete or with fibrosis but, typically, calcification occurs.

The differential diagnosis includes other systemic mycoses, tuberculosis, bacterial bronchiectasis and lymphoblastoma. An experienced radiologist can differentiate between the calcifications of histoplasmosis and tuberculosis. Calcifications produced by *H. capsulatum* are more regular, with halos, and may be found in the liver and spleen as well as in the lungs. Miliary calcifications may also occur. Calcifications are produced more rapidly in children than adults. Single, solitary, uncalcified coin lesions are also produced and are similar to those seen in tuberculosis. These resemble neoplastic lesions and are often removed surgically. Another tuberculosis-like pulmonary manifestation usually found in the adult lung is a histoplasmoma, which may be 2–3cm in diameter and contains a central necrotic area encased in a fibrotic capsule. Calcification begins in the center of the lesion and is followed by the development of concentric rings of fibrosis and calcification.

Chronic pulmonary histoplasmosis

This form is seen most often in adult males. It is considered to be an opportunistic complication of underlying chronic obstructive lung disease with emphysema and abnormal pulmonary spaces. With small emphysematous air spaces, transient pneumonitis develops and infection of large bullous spaces may result in cavitary histoplasmosis. Symptoms of the latter may be indistinguishable from those of chronic cavitary tuberculosis. The chronic form is secondary to the underlying pulmonary disease. It may develop immediately after primary inhalation or after years of apparent quiescence. Pathologic and immunologic evidence suggests that the late onset results from reactivation of an old lesion rather than exogenous reinfection. Chronic pulmonary histoplasmosis is usually apical. Patients experience a low-grade fever, productive cough, progressive weakness and fatigue. Chest films show centrilobular or bullous emphysema. Prognosis depends upon control of the underlying disease as much as on treatment for histoplasmosis.

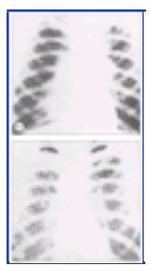

Figure 238-10 Histoplasmosis. (a) Acute pulmonary histoplasmosis showing hilar lymphadenopathy and diffuse infiltrates. (b) Hilar lymphadenopathy and miliary calcifications throughout both lungs.

Disseminated histoplasmosis

The gamut of clinical forms and pathology observed in pulmonary histoplasmosis can also occur in any other part of the body. The yeast cells are probably disseminated throughout the body while inside macrophages. The most common sites of involvement, after the lung, are the reticuloendothelial tissues of the spleen, liver, lymph nodes and bone marrow. However, lesions have been documented in almost every organ. Dissemination may be completely benign and unapparent except for the presence of calcified lesions, usually in organs of the reticuloendothelial system.

Alternatively, disseminated histoplasmosis may be acute and progressive. In such cases, the pulmonary symptoms are insignificant and patients may have splenomegaly and hepatomegaly, weight loss, anemia and leukopenia. Granulomatous lesions and macrophages packed with yeast cells can be observed throughout the liver, spleen, marrow and, quite often, the adrenals. Acute progressive histoplasmosis is often fulminant and rapidly fatal — ultimately every organ can become diseased. This form of histoplasmosis is an opportunistic disease associated with compromised cell-mediated immunity, such as in patients with AIDS or those receiving immunosuppressive drugs and those with underlying lymphomatous neoplasia. In most cases, the compromising condition serves to reactivate a quiescent lesion that was originally acquired years earlier. Within the endemic area, infants with histiocytosis may develop disseminated histoplasmosis that is characteristically fulminant. Chronic disseminated histoplasmosis may evolve from protraction of the acute disease. This form is progressive, with eventual involvement of every organ, especially the mucocutaneous areas around the eye, tongue and anus.

Histoplasmosis and AIDS

In a recent prospective study in the endemic area, the annual incidence of subclinical and asymptomatic histoplasmosis among

patients with AIDS was 4.7%. Three-quarters of the cases were symptomatic and histoplasmosis was the initial AIDS-defining condition in most of them.[107] The survival time for patients with AIDS was significantly shorter for those with disseminated histoplasmosis. Significant risk factors were identified for the development of histoplasmosis in AIDS patients: environmental exposure to likely sources of *H. capsulatum* (chicken coops), positive CF antibodies to histoplasmin, chronic medical condition(s), herpes simplex infection and a $CD4^+$ lymphocyte count of <150,000/ml.[107] [108]

Other forms

Very rarely, chronic disseminated histoplasmosis develops following primary inoculation of the skin or mucocutaneous tissue. The lungs are not involved in these cases, as the organisms are typically introduced following the contamination of a traumatic wound. Such infections may be anatomically localized, as with some ocular cases, or they may chronically progress with involvement along the draining lymphatics.

Another clinical condition, probably unrelated to *H. capsulatum*, is 'presumed ocular histoplasmosis syndrome' or POHS. Patients with POHS exhibit characteristic choroidal lesions, macular subretinal membranes and peripapillary atrophy.[109] Although POHS is usually associated with a positive histoplasmin skin test, its cause is unknown. Patients with histoplasmosis may develop ocular lesions, but POHS is not seen in patients with active histoplasmosis.

MANAGEMENT

Most primary pulmonary infections with *H. capsulatum* go undetected and require no treatment. Symptomatic cases in immunocompetent persons are alleviated with itraconazole or ketoconazole. With progressive pulmonary or disseminated disease, the treatment of choice for mild to moderate or stable disease is itraconazole.[110] Severe cases of any form are treated initially with AMB followed by itraconazole. The regimen of AMB is similar to that applied to other systemic mycoses and a total dose of 1.5g AMB is recommended. Recovery following treatment with AMB is generally faster and fewer relapses occur than are experienced with blastomycosis and coccidioidomycosis. Arrested pulmonary lesions are often removed surgically. Less severe cases in nonimmunocompromised patients may be treated with itraconazole. AIDS patients with histoplasmosis may be placed on maintenance therapy with itraconazole at 200mg twice per day.[110] [111] Cases of meningitis due to *H. capsulatum* are treated with amphotericin B followed by fluconazole.

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis (South American blastomycosis) is an infection caused by the thermally dimorphic fungus, *Paracoccidioides brasiliensis*. The infection is restricted to endemic areas of Central and South America. It is a chronic, granulomatous disease that begins with a primary, pulmonary, usually unapparent infection that disseminates to produce ulcerative granulomata in the mucosal surfaces of the nose, mouth and gastrointestinal tract. In addition to the skin and lymph nodes, the infection may spread to the internal organs.

NATURE

Colonies of *P. brasiliensis* grow very slowly, requiring 2 or 3 weeks of incubation to reach a diameter of 1–2cm. The macroscopic features of the mold colony are variable and nonspecific. Various asexual reproductive structures are produced by *P. brasiliensis*, including chlamydospores, arthroconidia and singly borne conidia. In the absence of conidia, which may not be produced for 10 weeks

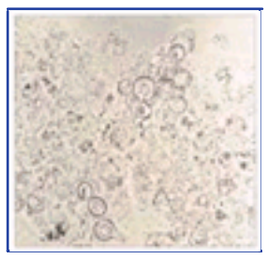

Figure 238-11 ***Paracoccidioides brasiliensis.*** Large multiply budding yeast cells in a potassium hydroxide preparation of a scraping of cutaneous paracoccidioidomycosis.

in culture, the mycelia and colony may be indistinguishable from *B. dermatitidis* or many saprophytes.

The yeast form can be induced by cultivation on a rich medium at 95–98.6°F (35–37°C). The yeasts are readily identified by their unique appearance. As shown in Figure 238.11 , the yeasts produce multiple buds and each is attached to the parent yeast by a narrow base. The yeast cells are large, up to 30µm in diameter, and have thinner walls than the yeasts of *B. dermatitidis*. These forms have been described as 'pilot wheels'.

EPIDEMIOLOGY

The natural habitat of *P. brasiliensis* has not been proven, but is presumed to be soil. The organism has been recovered only sporadically and not repeatedly from soil in Venezuela and Argentina. Like *B. dermatitidis*, its natural existence and life cycle in nature are unknown. There is no evidence of an animal vector or transmission of the infection. Natural disease does not occur in either wild or domestic animals, although experimental infections can be established in mice and bats after inhalation of an infectious inoculum. Human infections are presumed to follow exposure to the organisms from an exogenous source. Most patients are males (>90%), agricultural workers, often malnourished, and usually 30–60 years of age.

Thousands of cases of paracoccidioidomycosis have been reported from Brazil, Venezuela, Colombia and lesser numbers from Argentina, Ecuador and other South and Central American countries, with the exception of Chile and the Caribbean nations.[112] Discrete endemic foci exist within this broad area of geographic distribution. However, all cases are isolated and outbreaks have not been observed. The endemic zones are associated with moderate temperatures 57–86°F (14–30°C) and rainfall, elevation of 500 to 6500 feet, subtropical forests and river valleys, but not all areas fitting this description have paracoccidioidomycosis.

Skin test surveys have been conducted with various antigens derived from *P. brasiliensis*. These paracoccidioidins exhibit cross-reactivity with histoplasmin and it is difficult to interpret double reactions of equal size in the same individual. As with the skin test antigens of the other dimorphic, systemic pathogens, paracoccidioidin elicits a delayed, indurative reaction that indicates previous exposure. The percentage of reactivity in the endemic areas varies up to 75% and occurs equally in both men and women. Significant risk factors for infection (i.e. positive skin test) include agricultural occupations, association with certain aquatic environments and contact with bats.[113]

Many patients with paracoccidioidomycosis are malnourished and exhibit depressed cell-mediated immune responses.

PATHOGENICITY

P. brasiliensis, like the other systemic fungi, causes disease in males more frequently than females (Table 238.1), although skin test surveys have revealed comparable reactivity between the sexes, implying equal exposure. Sex-linked differences may be associated with the generally more potent cellular immunity of females. Limited studies indicate that physiological concentrations of sex hormones do not directly inhibit these fungi. However, a protein from the mycelial cytosol of *P. brasiliensis* has been shown to bind estrogen but not testosterone or other hormones. Binding blocks conversion of the mycelium to yeast at 98.6°F (37°C) and may explain the resistance of females to paracoccidioidomycosis.[114]

Once yeast cells of *P. brasiliensis* have developed in the lung, yeast cell wall polysaccharides, such as a-glucan, are associated with virulence and the ability to stimulate granulomata.

DIAGNOSTIC MICROBIOLOGY

Microscopic examination and culture

Sputum, tissue or scrapings of mucocutaneous lesions may reveal the multiply budding yeast cells that are pathognomonic for *P. brasiliensis* (Fig. 238.11). Specimens should be cultured at 77–86°F (25–30°C) on inhibitory mold agar, Sabouraud's agar with antibiotics, Sabouraud's agar without cycloheximide and on brain-heart infusion blood agar at 95–98.6°F (35–37°C). The yeast form often grows better at 95°F (35°C) or 96.8°F (36°C) than 98.6°F (37°C).

Serologic tests

A number of antigens and serological procedures have been evaluated. [115] The ID test is extremely useful. As indicated in Table 238.4 , nearly 100% of patients have at least one of three specific precipitin lines (designated 1, 2 and 3) detected by identity with reference serum. The ID test also has prognostic value, as the bands disappear with clearing of the infection and the number of bands is somewhat correlated with the severity of the disease.[116] The CF test is quantitative and useful for assessing prognosis, but cross-reactions occur with other fungi.

CLINICAL MANIFESTATIONS

The initial contact with *P. brasiliensis* occurs by inhalation. This episode is unapparent and the organism becomes quiescent for an indefinite period, which may be several decades in some individuals, or the lesion may resolve, perhaps with scarring. This asymptomatic infection results in the acquisition of a positive delayed skin test reaction to paracoccidioidin. The eventual development of symptomatic disease depends upon the host-fungal interaction, namely, the integrity of the cell-mediated immunity of the individual, environmental conditions (e.g. temperature, nutrients), host conditions (e.g. age, sex, state of nutrition), and the virulence of the strain of *P. brasiliensis*.

Acute or subacute disease

Patients under 30 years of age may develop an acute, progressive infection characterized by lymphonodular lesions in the lung.[117] This juvenile form is rare. The yeasts may disseminate to the reticuloendothelial

Figure 238-12 Cutaneous and mucocutaneous paracoccidiodomycosis.

tissue, lymph nodes, liver, spleen, skin, bone, joints or other organs. The severity and duration of the illness depend upon the extent of organ involvement, but it may be fatal within a period of several weeks or months.

Chronic disease

More than 90% of cases are of this 'adult' type and develop from the latent form, usually after several years. Lesions may be localized in the lung or metastasis may occur from the lung to other organs, particularly the skin and mucocutaneous tissue, lymph nodes, spleen, liver, adrenals and combinations thereof. Mucocutaneous, often petechial, lesions frequently develop on the corners of the mouth, lips, gingiva or tongue (Fig. 238.12). Pulmonary lesions are granulomatous nodules that may cavitate but rarely calcify.[118]

MANAGEMENT

Patients should be assessed for malnourishment, alcoholism and extensive tobacco use, all of which exacerbate the disease. Since many of the antifungal drugs are effective against *P. brasiliensis*, the initial treatment choice may reflect the expense and local availability of antifungal agents.[119] Sulfonamide derivatives are among the earliest but less effective drugs. Trimethoprim-sulfamethoxazole (TMP-SMX) is the currently recommended formulation of this type. The azoles are much more effective. Some of the initial clinical trials with ketoconazole demonstrated its efficacy against paracoccidioidomycosis. Itraconazole is currently the drug of choice; a clinical cure rate approaching 100% is achievable with a daily dose of 100mg for 6 months. Relapses are rare. Fluconazole has also been shown to be effective, producing cures in about 90% of patients who received 200–400mg/day for 6 months. Although AMB is highly effective against paracoccidioidomycosis, it should be reserved for patients who fail to respond or cannot tolerate one of the azoles. The total dose usually required is 2g or less. After initiating therapy, serologies are checked every few months to monitor the effectiveness of treatment. Some clinicians recommend a maintenance regimen of sulfa-doxin, TMP-SMX or ketoconazole (200mg/day) for up to 1 year after serological tests become negative.[119]

Chapter 239 - Subcutaneous Mycoses

Malcolm D Richardson

Although subcutaneous fungal infections exhibit extraordinary heterogeneity, they have certain features in common — infection is usually acquired from nature and not from infected humans or animals, and the endemic areas are delineated by an ecosystem that consists of altitude, temperature, rainfall, type of soil and type of vegetation. Most patients belong to low socioeconomic groups or live in rural areas. Subcutaneous mycoses arise from inoculation of soil or vegetation into the skin by minor trauma, and most patients have an occupation connected either with agriculture or an outdoor activity and do not use appropriate footwear.

The group of fungi that cause the majority of subcutaneous infections in humans are termed black molds.[1] Black molds are a heterogeneous group of darkly pigmented (dematiaceous) fungi, widely distributed in the environment, that occasionally cause infection in humans. The taxonomy and terminology of dematiaceous fungal infections is baffling. The term chromoblastomycosis was introduced in 1922 and was later modified in 1935 to a broader term 'chromomycosis'. More recently, the term 'phaeohyphomycosis' was proposed to cover 'all infections of cutaneous, subcutaneous and systemic nature caused by hyphomycetous fungi that develop in the host tissues in the form of dark walled dematiaceous septate mycelial elements'. In 1981, the term was further expanded to include deuteromycota and ascomycota whose tissue forms are filamentous and dematiaceous. This certainly excludes infections by fungi that produce thick-walled 'sclerotic bodies' in the tissues and are classically labeled as chromoblastomycosis. The line of demarcation is, however, only histopathologic and very thin because some of the fungi (e.g. *Exophiala dermatidis*), in addition to mycelial forms, produce rounded structures closely resembling sclerotic bodies. Thus, there has been plenty of overlap in the nomenclature of these cases, especially during the 1970s and 1980s.

The clinical spectrum of infection includes mycetomas, chromoblastomycosis, sinusitis and superficial, cutaneous, subcutaneous and systemic phaeohyphomycosis. During the past few years, there have been reports of infections caused by black molds in previously healthy individuals and in immunocompromised patients. Molecular studies have contributed to our understanding of the epidemiology of these infections. In addition, data on antifungal susceptibility tests have become available. Surgical excision and antifungal therapy (usually itraconazole) remain the standard treatment for these infections.

Many standard texts contain excellent reviews of all the infections described here.[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] Specific references and reviews are cited here where new information, particularly concerning diagnosis and therapy, supercedes that found in the general texts.

NATURE

Chromoblastomycosis

Chromoblastomycosis (or chromomycosis) is a chronic localized infection of the skin and subcutaneous tissue, most often involving the limbs. It is characterized by raised crusted lesions. It may be caused by a number of brown-pigmented (dematiaceous) fungi.

Entomophthoramycosis

Rhinofacial conidiobolomycosis is a chronic mycosis affecting the subcutaneous tissues. It originates in the nasal sinuses and spreads to the adjacent subcutaneous tissue of the face, causing disfigurement. Basidiobolomycosis is a chronic subcutaneous infection of the trunk and limbs. For an exhaustive review of entomophthoramycosis refer to Ribes *et al.*[12]

Lobomycosis

Lobomycosis is characterized by slowly developing variably sized cutaneous nodules after a traumatic event. The dermal nodules manifest as either smooth, verrucose, or ulcerated surfaces that can attain the size of a small cauliflower-like keloid. The onset of the disease is generally insidious. The increase in size or number of lesions is a slow process, progressing over a period of 40–50 years. The lesions are composed of granulomatous inflammatory tissue containing numerous globose or subglobose to lemon-shaped, yeast-like fungal cells singly or in simple and branched chains.

Mycetoma

Mycetoma is a chronic suppurative infection of the skin, subcutaneous tissue and bone. It usually affects the hand or foot and may be caused by various fungi (eumycetoma) or actinomycetes (actinomycetoma). The micro-organisms are inoculated into subcutaneous tissue by minor trauma. A characteristic feature of mycetoma is the production of grains in the infected tissue; these grains are compact masses of fungal or actinomycete elements, and they discharge to the outside through sinus tracts.

Phaeohyphomycosis

Phaeohyphomycosis is a rare infection caused by dematiaceous fungi, involving the skin and subcutis, paranasal sinuses or central nervous system (CNS). Phaeohyphomycosis refers to subcutaneous and deep-seated infections caused by brown-pigmented (dematiaceous) molds that adopt a septate mycelial form in tissue. This term was also created to separate various clinical infections caused by dematiaceous molds from the distinct subcutaneous infection known as chromoblastomycosis. Unlike mycetoma and chromoblastomycosis, phaeohyphomycosis is not limited to the skin or subcutaneous tissues, and elicits a wider variety of inflammatory responses.

Phaeohyphomycosis is characterized by a nodule, cyst, or pyogranuloma. Histopathologically, the lesions show brown-walled hyphae in the dermis, subcutis, or sometimes in the epidermis.

Rhinosporidiosis

Rhinosporidiosis is a chronic granulomatous infection of the mucous membranes, especially the nasal mucosa, caused by *Rhinosporidium seeberi*.

Sporotrichosis

Sporotrichosis is a subacute or chronic infection caused by the dimorphic fungus *Sporothrix schenckii*.[13] [14] [15] [16] After implantation, this organism can cause cutaneous or subcutaneous infection, which

commonly shows lymphatic spread. Occasionally, widespread disseminated infection also occurs.

EPIDEMIOLOGY

Chromoblastomycosis

Chromoblastomycosis is encountered mainly in arid parts of tropical and subtropical regions. Most cases occur in Central and South America, but chromoblastomycosis has also been reported in South Africa, Asia and Australia. Another major focus appears to be Madagascar.[17]

Chromoblastomycosis is caused by various dematiaceous fungi, to which a number of names have been given. There is therefore a great deal of confusion in the nomenclature used by various authors. The most frequently involved etiologic agents, beginning with the most common, are *Phialophora verrucosa*, *Fonsecaea pedrosoi*, *Fonsecaea compacta*, *Cladosporium carrionii* and *Rhinocladiella aquaspersa* (*Ramichloridium cerophilum*). Sporadic cases of chromoblastomycosis can also be caused by other dematiaceous molds. These organisms form characteristic thick-walled, dark brown muriform sclerotic cells in tissue.

The etiologic agents of chromoblastomycosis are widespread in the environment, being found in soil, wood and decomposing plant matter. Human infection usually follows the traumatic inoculation of the fungus into the skin. Minor trauma, such as cuts or wounds due to thorns or wood splinters, is often sufficient. The disease is most prevalent in rural parts of warmer climates where people go barefoot. There is no human-to-human transmission.

Chromoblastomycosis is unusual in children and adolescents. Except in Japan, men contract the disease much more frequently than women, reflecting the importance of occupational exposure. Men have a greater opportunity for soil contact and predisposition to injury while working in the fields. The majority are aged 30–50 years. The rarity of the disease in children exposed to the same environmental conditions as adults suggests a long period of latency.

A number of collections of case reports have been published.[18] [19] [20] An illustrative example is a study of 51 cases of chromoblastomycosis detected in a 17-year period, all of which were clinically and mycologically proven by direct examinations, cultures and biopsies. Most cases were males (36 of 51; 70%), the mean age was 35 years and farmers predominated (74%); the most frequent lesions were in the lower limbs (54%). Major clinical presentations were nodular (41%) and verrucous (26%). The principal etiologic agent isolated was *F. pedrosoi* (90%). Overall results of the various treatments were as follows: 31% were cured, 57% improved and 12% failed. The best results were obtained with cryosurgery for small lesions, with itraconazole for large ones, and in some cases the combination of both treatments.

Another case series reviews the clinical features and response to therapy in patients with chromoblastomycosis in the state of Rio Grande do Sul, Brazil.[19] Case records of 100 patients with skin lesions caused by chromoblastomycosis, who were treated between 1963 and 1998, were reviewed. The cases were confirmed by histopathology and culture. There was a predominance of male patients (4:1) and of white farmers whose ages ranged from 50 to 59 years, with lesions on their lower limbs. Most of them were from the northern regions of the state. The average time between the appearance of the disease and medical diagnosis was 14 years. The verrucous type proved to be the most frequently reported lesion (53%). Thorn wounds were associated with the disease in 16% of the cases. Lesions uncommon to some parts of the body were also reported. In two of the cases, cutaneous lesions caused by paracoccidioidomycosis and chromoblastomycosis were found in the same patient. Epidermoid carcinoma was found in the same parts of the body affected by chromoblastomycosis. Eumycotic mycetoma and chromoblastomycosis were associated. *Fonsecaea pedrosoi* was found in 96% of the cases and *P. verrucosa* in 4% of the cases. Severe cases of chromoblastomycosis with intense skin

involvement (e.g. lesions with carcinoma) were observed. Statistical analysis showed recrudescence of the disease in 43% of cases despite the treatment used.

Entomophthoramycosis

Entomophthoramycosis occurs mainly in the tropical rain forests of East and West Africa, South and Central America, and South East Asia.

Conidiobolus coronatus (*Entomophthora coronata*), the causative organism of rhinofacial conidiobolomycosis, lives as a saprophyte in soil and on decomposing plant matter in moist, warm climates. It can also parasitize certain insects.

The most widely held view is that *Basidiobolus ranarum* is the sole agent causing basidiobolomycosis, and that *B. meristosporus* and *B. haptosporus* are synonyms of the former; not all authors are of this opinion, however. *Basidiobolus ranarum* has been recovered from soil and decaying vegetation; it has also been isolated from the gut of frogs, toads and lizards that had apparently swallowed infected insects. It is still uncertain how the disease is acquired and what is the length of incubation. Inoculation through a thorn prick or an insect bite has been suggested, as has contamination of a wound or other abrasion. The infection is most common in children. More detailed aspects of entomophthoramycosis caused by *B. ranarum* can be found in the review by Gugnani. [21]

For an exhaustive review of the epidemiology of entophthoramycosis refer to Ribes *et al.*[12]

Lobomycosis

In lobomycosis, the onset of the disease is generally insidious and difficult to document. The increase in size and number of lesions is a slow process; it can take 40–50 years. This latency period often makes it important to note the patient's history of travel or stay in areas of endemicity to arrive at a proper diagnosis. The history often reveals the cause being a trauma, for example an arthropod sting, a snake bite, a cut from an instrument, or a wound acquired while cutting vegetation. The causal agent of lobomycosis appears to be saprobic in aquatic environments, which probably plays an extremely significant part in its life cycle.

The human disease is endemic in the tropical zone of the New World and has been reported in central and western Brazil, Bolivia, Colombia, Costa Rica, Ecuador, Guyana, French Guiana, Mexico, Panama, Peru, Surinam and Venezuela. There have been isolated cases reported in Holland and a doubtful case in Bangladesh. Identification of the disease in dolphins widened the geographic distribution of the disease. Seven cases of lobomycosis involving two species of dolphins, namely marine dolphins (*Tursiops truncatus*) and marine freshwater dolphins (*Sotalia fluviatilis*), have been reported in Florida, the Texas coast, the Spanish-French coast, the South Brazilian coast and the Surinam River estuary. Although lobomycosis in dolphins has been reported in the USA, only one human case has been reported from the USA.[22]

All attempts to isolate the fungus from lesions of infected people have failed. In the dermis it appears as spheric or elliptic budding cells. Although it is accepted that the infection is exogenous in origin, the natural habitat of the causal fungus remains unknown.

The organism gains entry through the skin; it develops in situ for an unspecified period (several years) and then reaches the subcutaneous tissue. The disease is most prevalent in men aged 30–40 years; it is much less common in women and children.

Mycetoma

Mycetomas are most common in arid tropical and subtropical regions of Africa and Central America, particularly those areas bordering the great deserts. However, sporadic cases have been reported from many parts of the world. The countries surrounding the Saharan and Arabian deserts form the most important endemic area, not only because of the number of new cases occurring each year, but also because of the diversity of causal organisms. Mycetoma is also endemic in certain regions of India and in Central and South America.

Mycetomas are caused by various actinomycetes and fungi that occur as saprophytes in the soil or on vegetation. Individual species of fungi or actinomycetes are often associated with particular geographic areas. About six species of fungi are common causes of eumycetoma and five aerobic actinomycetes are common etiologic agents of actinomycetoma. The geographic distribution of these environmental organisms is influenced by climate.

In the arid regions of the tropics and subtropics, the most frequent etiologic agents are *Madurella mycetomatis*, *Actinomadura madurae*, *Actinomadura pelletieri* and *Streptomyces somaliensis*. These organisms are encountered in the great deserts of Africa and Asia and on their fringes, as well as in south-eastern Europe. In the relatively humid mountain regions of Latin America, *Nocardia brasiliensis* is the predominant organism while *Madurella grisea* is a less prominent cause of infection.

In the occasional cases of mycetoma that occur in temperate regions, the principal isolates have been *Pseudallescheria boydii*, *A. madurae* and *M. mycetomatis*. Other organisms that have occasionally been implicated as causes of mycetoma include *Leptosphaeria senegalensis*, *Neotestudina rosatii*, *Pyrenochaeta romeroi*, *Exophiala jeanselmei*, *Acremonium* spp., *Aspergillus nidulans*, *Nocardia asteroides* and *Nocardia caviae*.

Mycetomas occur more frequently in men than in women. Adults aged between 20 and 50 years are the most commonly affected, although cases in children have also been reported. Most patients come from rural districts in the tropics and subtropics, but cases often occur in some countries with a temperate climate, such as Romania.

Trauma is a critical factor in acquisition of the infection. The organisms may be implanted at the time of injury, or later as a result of secondary contamination of the wound. Traumas are often due to vegetable matter (grasses, wisps of straw, hay). In the tropics and subtropics thorny trees such as the acacia are abundant and are often used for fuel. Wounds caused by the thorns may facilitate the entry of soil organisms, or the causative agents may grow on the thorns and be implanted directly into the subcutaneous tissue. It is not surprising, therefore, that mycetomas affect mainly the feet of country-dwellers who walk barefoot.

The vast majority of organisms causing mycetomas are saprophytes of the external environment; *Nocardia* spp. exist in the soil; other species are encountered not only in the soil, but also on living and dead plants. However, little is known about their behavior outside the human host. A recent study of 264 cases of mycetoma in West Bengal illustrates the epidemiology of the causative organisms.[23] Between 1981 and 2000, 264 cases of mycetoma were diagnosed clinically and microbiologically at the Calcutta School of Tropical Medicine. Retrospective analysis of the records revealed that the ratio of actinomycetomas and eumycetomas was 197:67; the male to female ratio was 183:81. Ninety-four cases occurred in the 1980s and 170 in 1990s, with significantly more infections of *Actinomadura* spp. and fewer with *N. caviae* during the last decade. Pricking was the most common injury associated with eumycetomas. A total of 196 infections were in exposed body parts and 68 in covered areas. The localization of mycetomas differed significantly according to sex, incidence of actinomycetomas or eumycetomas, and obvious history of trauma. Exposed area cases were more common among agricultural workers, while covered area mycetomas were almost always actinomycetomas with a remarkably lower incidence of *N. caviae*, *A. madurae* and *M. grisea* infections. The peak age of onset was between 16 and 25 years. The delay of diagnosis for the 80th percentile of cases was around 6 years for cases caused by *N. brasiliensis* and *Streptomyces* spp.; 8 years for *N. caviae* and *N. asteroides*; and 10 years for *M. grisea* and *Actinomadura* spp. From the history of trauma in 130 patients, the 80th percentile incubation period was calculated for *N. brasiliensis, N. caviae* and *N. asteroides* as 3 years; for *Actinomadura* spp. 7 years; and for *M. grisea* 9 years. The minimum incubation period for all organisms was around 3 months.

Phaeohyphomycosis

Black molds are widely encountered in soil and wood. In addition, some organisms can produce yeast-like synanamorphs that adapt to aqueous environments. Typically, the infection is acquired by the inoculation of the fungus through a penetrating injury. In addition, other possible portals of entry have been suggested, including the inhalation of spores with lung or sinus invasion, the ingestion of contaminated food or water with subsequent penetration through the gastrointestinal tract, contamination of the skin at the insertion of a vascular catheter, and contamination of the catheter itself. Some cases of systemic infection have no apparent portal of entry.

Phaeohyphomycosis has a worldwide distribution, but subcutaneous infection is most often seen in the rural population of tropical parts of Central and South America. Most cases of cerebral or paranasal sinus infection have been reported from USA. There is little information on the incidence of phaeohyphomycosis. In a population-based surveillance conducted over 2 years in the San Francisco Bay area, the incidence of infection due to black molds was one case per million per year.[24]

The number of organisms implicated as etiologic agents of phaeohyphomycosis is increasing. More than 80 different molds, classified in 40 different genera, have been

incriminated. These fungi have often been given different names at different times, and there is therefore a great deal of confusion in the nomenclature used in different reports.

Among the more important etiologic agents, *Alternaria*, *Bipolaris*, *Curvularia*, *Exophiala*, *Exserohilum* and *Phialophora* spp. and *Xylohypha bantiana* can be included. Many of these organisms are found in soil or decomposing plant debris; others are plant pathogens. The most important predisposing factor for cutaneous and subcutaneous infection is exposure to contaminated material present in the environment (decaying wood, plants).

Human infection follows inhalation or traumatic implantation of the fungus. In addition to these agents of phaeohyphomycosis, others are being reported. For example, *Colletotrichum* spp., which are common plant pathogens, have been reported as a cause of subcutaneous phaeohyphomycosis in patients undergoing chemotherapy for hematologic malignancies and may cause life-threatening phaeohyphomycosis in immunosuppressed patients.[25]

Rhinosporidiosis

Rhinosporidiosis is endemic in India[26] and Sri Lanka, as well as in South America and Africa. Occasional cases have been reported from the USA, South East Asia and other parts of the world. The etiologic agent is an endosporulating organism, *Rhinosporidium seeberi*. So far, all attempts to isolate this fungus from lesions have failed. In tissue, large, thick-walled sporangia (spherules) are formed. Large numbers of spores are produced within the sporangia and, when the spores are mature, they are released through a pore in the wall. Each spore may develop to form a new sporangium. Little is known about the natural habitat of *R. seeberi*, but it

is believed that stagnant pools of water may be the source of human infection.

The disease is most prevalent in rural districts, particularly among people working or bathing in stagnant water (such as rice fields). Men are more commonly affected than women.

Sporotrichosis

Sporotrichosis is worldwide in distribution, but occurs most frequently in temperate humid climatic regions. At present, the largest number of reported cases comes from the North American continent.[27] Other regions where the infection is endemic include South America,[28] South Africa and South East Asia.

The causative agent is a dimorphic fungus, *Sporothrix schenckii*, which is found in the soil and on plants and sphagnum moss. It grows in nature as a mycelium, but in tissue it forms small, budding cells.

Infection usually follows the traumatic introduction of the fungus into the skin. Minor trauma, such as abrasions or wounds from thorns or wood splinters, may be sufficient. In occasional cases, infection follows spore inhalation.

It is not clear whether the infection is more common among men than women. Incidence in the different age groups is also variously assessed, but children are less often affected than adults.

Sporotrichosis is most prevalent among people who handle soil or plant materials, such as gardeners, florists, mineworkers and carpenters. For this reason sporotrichosis has been regarded as an occupational disease. Sporotrichosis is not transferred from human to human, and the multiple cases that sometimes occur in families or closed communities are usually due to common exposure to the same exogenous source of contamination.

PATHOGENICITY

Chromoblastomycosis

The causative fungi require implantation through the skin into subcutaneous tissue. The lesion appears at the site of skin trauma or puncture wound. However, the inoculation may have occurred so long before that no history of injury can be elicited. In general, the disease remains localized to the area surrounding the initial infection. In rare cases, hematogenous spread to the brain, lymph nodes, liver, lungs and other organs is observed.[9]

Entomophthoramycosis

Pathogenicity of the causal organisms is a reflection of inoculum size and frequency of exposure in endemic areas. For an exhaustive review of the pathogenicity of the agents causing entomophthoramycosis refer to Ribes *et al.*[12]

Lobomycosis

Lobomycosis develops following trauma to the skin, but in most clinical histories the event is so minimal that it is not remembered. The disease runs an extremely slow course and years may elapse before the patient seeks medical advice.

Mycetoma and phaeohyphomycosis

The organisms causing these conditions are not regarded as being pathogenic. Typically, the infection is acquired by the inoculation of the fungus through a penetrating injury

Rhinosporidiosis

Studies on the virulence of *R. seeberi* have not been carried out. Nothing is known about the mode of infection. It is most likely that trauma is an essential factor in the initiation of disease. Spores of *R. seeberi* are not able to penetrate intact epithelium. Because the nose and eyes are the most common sites of the disease it is suggested that the organisms are transmitted in dust and water.

Sporotrichosis

Sporothrix schenckii usually enters the body through traumatic implantation, but occasionally the fungus is introduced through inhalation of the conidia. Because the infection can also be hematogenously disseminated, it may be that the yeast cells are able to resist phagocytosis and intracellular killing by host effector cells, although in-vitro data suggest that the yeast cells are readily killed in the presence of human serum. Host defense mechanisms in response to *S. schenckii* have not been extensively studied.

PREVENTION

Avoidance of skin penetration is the best means of preventing chromoblastomycosis, entomophthoramycosis and phaeohyphomycosis. Suitable footwear will help to prevent chromoblastomycosis.

Very little is known about the ecology of *Loboa loboi* so it is difficult to recommend specific methods of contact and prevention for lobomycosis.

The causative agents of mycetoma normally live as saprophytes in the soil. Because the most common site for mycetoma is the foot it is reasonable to assume that the wearing of appropriate footwear would prevent infection. Avoidance of trauma to the hands and other areas is difficult to encourage because most infections seem to be related to outdoor activities.

Rhinosporidiosis can be prevented by avoiding eye and nose contact with contaminated dust and water.

Occupations that predispose persons to sporotrichosis include gardening, farming, masonry, floral work, outdoor labor and other activities involving exposure to contaminated soil or vegetation such as sphagnum moss or roses. Wearing gloves and protective clothing while carrying out these activities may therefore prevent traumatic implantation of the fungus through the skin.

DIAGNOSTIC MICROBIOLOGY

Chromoblastomycosis

Microscopic examination of wet preparations of pus, scrapings, or crusts from lesions can permit the diagnosis of chromoblastomycosis if clusters of the characteristic small, round, thick-walled, brown-pigmented sclerotic cells are seen (Fig. 239.1). These cells are often divided by longitudinal and transverse septa.[6]

The definitive diagnosis of chromoblastomycosis depends on the isolation of the etiologic agent in culture. Identifiable olive-green or brownish-black mycelial colonies can be obtained after incubation at

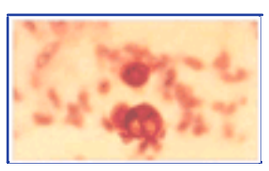

Figure 239-1 Chromoblastomycosis. Thick-walled, septate, dematiaceous muriform cells. *With permission from Richardson MD, et al. Slide atlas of fungal infection: subcutaneous and unusual fungal infections, Oxford: Blackwell, 1995.*

77–86°F (25–30°C) for 1–2 weeks, but cultures should be retained for 4 weeks before being discarded. Identification of the individual etiologic agents is difficult. Serologic techniques have been shown to detect cases of chromoblastomycosis caused by *C. carrionii*.[29]

Entomophthoramycosis

Microscopic examination of smears or tissue from the nasal mucosa will reveal broad, nonseptate, thin-walled mycelial filaments.

The culture of causal organisms of entomophthoramycosis is difficult. To optimize the recovery of fungus from clinical material, specimens must be inoculated on the largest possible number of media; they should be incubated at 77–95°F (25–35°C).

For an exhaustive review of the diagnosis of entomophthoramycosis refer to Ribes *et al.*[12]

Lobomycosis

The etiologic agent of lobomycosis is an obligate pathogen of humans and lower mammals that has yet to be isolated and grown in vitro; therefore, nothing is known of its basic cultural characteristics and growth. Diagnosis is based on demonstrating the presence of globose, thick-walled, yeast-like cells ranging from 5 to 12µm in diameter in lesion exudate or tissue sections. The organism multiplies by budding, and thus mother cells with single buds are often observed. However, characteristic sequential budding leads to the production of chains of cells that are linked to each other by a tubular connection, or isthmus. Budding may occur at more than one point on a cell, giving rise to branched or radiating chains of cells. These thick-walled, hyaline, spherical cells with chains of cells interconnected by tubular connections are the basis on which a diagnosis of lobomycosis rests. The thick-walled, budding hyaline cells with catenate chains of conidia can be readily observed in tissue smears or exudates mounted in 10% potassium hydroxide or in Calcofluor white preparations.

Microscopic examination of specimens of pathologic material will reveal numerous hyaline, round or ovoid cells with an average diameter of 9µm (Fig. 239.2). These cells closely resemble the yeast forms of *Paracoccidioides brasiliensis* or *Histoplasma duboisii*. The cells are enclosed in a double-contoured membrane and are capable of budding. They often form chains and appear to be joined together by bridge-like structures within the chain. If the individual elements show multiple budding, the chains are divided into branches.

The epidermis is irregular in thickness, with parakeratotic zones and sometimes ulcerations and crusts. The dermis underlying it shows hypertrophic and partly hyalinized bundles of connective tissue. Between these bundles are granulomatous infiltrates that contain numerous yeasts, which are either located extracellularly or phagocytosed by mononuclear and polynuclear cells. Intracytoplasmic

Figure 239-2 Lobomycosis. Yeast cells are attached to each other in short chains. Nonbudding and single-budding cells are also present.

asteroid bodies have been observed in some giant cells. Their nature is unknown and they have been confused with the asteroid bodies seen in sporotrichosis. They are, however, different and unrelated structures.[30]

A case report describing the first case of lobomycosis diagnosed in the USA illustrates further the histopathologic features of this disease.[22] The patient had traveled to the Angel Falls in Venezuela 7 years earlier where he had been exposed to the high pressures of the falls. This resulted in a pustule and surrounding erythema on the skin of his right chest wall. The lesion gradually increased in size and had the appearance of a keloid. After an uncomplicated excision the patient recovered completely. Examination of the tissue sections showed a nodular inflammatory infiltrate of foamy histiocytes, multinucleated giant cells and scattered lymphocytes. Throughout the infiltrate were numerous globose or subglobose, lemon-shaped cells that measured 5.0–11.0µm in diameter. Many cells showed thick refractile walls and reproduced by single and multiple budding. The buds were attached to the mother cell by narrow tubular connections, giving a beaded appearance. There were many chains of cells showing narrow tubular connections characteristic of *L. loboi*.

Loboa loboi has never been successfully cultured. This distinguishes it from *P. brasiliensis*, which it closely resembles morphologically. The globose and subglobose budding cells of *L. loboi* resemble budding cells of *P. brasiliensis* in tissue. However, the central mother cells of *P. brasiliensis* become large and thick-walled compared to the daughter cells, which remain smaller. In contrast, yeast cells of *L. loboi* remain consistent in diameter, giving rise to branching chains of blastoconidia. In addition, the cell wall of *L. loboi* contains constitutive melanin,[31] which can be detected by the use of the Fontana-Masson histologic stain. The walls of cells of *P. brasiliensis* are not known to contain melanin. *Loboa loboi* has never been cultured in vitro. On the other hand, *P. brasiliensis* can be grown in artificial culture and is known to be a dimorphic pathogen.

Molecular methods have been used in an attempt to characterize the causative agent of lobomycosis.[32] Fungal-specific primers targeted for highly conserved genomic nucleic acid sequences were used in a polymerase chain reaction (PCR) to amplify DNA from lobomycosis lesions in a bottlenose dolphin. Sequence alignments of this DNA possessed high homology to fungal ribosomal DNA sequences found in the genus *Cladosporium*. When used for in-situ hybridization, the riboprobe transcribed from a cloned PCR-generated fragment bound to *L. loboi* cells. These results support the hypothesis that *L. loboi* in dolphin tissue is a fungus.

A new monotypic genus, *Lacazia*, with *Lacazia loboi* as the type species, was recently proposed by Taborda *et al.*,[31] to accommodate the obligate etiologic agent of lobomycosis in mammals. The continued placement of *L. loboi* in the genus *Paracoccidioides* as *Paracoccidioides loboi* O.M. Fonseca et Lacaz was found to be taxonomically inappropriate. The older name *Loboa loboi* Ciferri *et al.* was considered to be a synonym of *P. brasiliensis*.

Mycetoma

The diagnosis of mycetoma depends on the identification of grains. These should, if possible, be obtained by puncture from a softened, but not ulcerated, nodule with a syringe. Failing this, grains can be obtained with a dissecting needle or by aspiration from the secretion flowing from a sinus.[33] If there is no pus flowing from the

lesion, small fragments of tissue should be removed. If possible, between 20 and 30 grains should be obtained; these should be rinsed in sterile saline before being cultured.

Gross examination of the grains may give a clue to the etiologic diagnosis. Black grains suggest a fungal infection; minute white

Figure 239-3 Granule of *Madurella mycetomatis.* The granules have a deeply pigmented periphery of compact hyphae. Randomly oriented, poorly pigmented fungal elements in the interior of the granule are less compact.

grains often indicate a *Nocardia* infection; and larger white grains the size of a pinhead may be of either fungal or actinomycotic origin. Small, red grains are specific to *A. pelletieri*, but yellowish-white grains may be actinomycotic or fungal in origin. Their shape, consistency and structure must be carefully determined.

Direct microscopic examination will confirm the diagnosis of mycetoma, and will also reveal whether the causative organism is a fungus or an actinomycete. [33] Actinomycotic grains contain very fine filaments (<1µm diameter), whereas fungal grains contain short hyphae (2–4µm diameter), which are sometimes swollen. This can be seen by direct microscopic examination of crushed grains in potassium hydroxide, but it is much more readily observed in stained histologic sections (Fig. 239.3).

Although the identification of the causal agents of mycetoma can often be deduced from the morphologic characteristics of the grains, it is also important to isolate the organism in culture. Agar plates should be inoculated with several grains (or with secretion or tissue fragments) and incubated at 77–86°F (25–30°C) and at 98.6°F (37°C). The most commonly used agar medium is Sabouraud's agar, without antibiotics but with cycloheximide for isolation of actinomycetes, and with antibiotics but without cycloheximide for fungal agents. Alternative media for isolation of actinomycetes include brain-heart infusion or blood agar.

Cultures should be retained for up to 6 weeks before being discarded. The actinomycetes grow much more slowly than the fungi.

Madurella mycetomatis is the commonest cause of eumycetoma in Sudan and other countries in tropical Africa. Currently, the early diagnosis of mycetoma is difficult. In attempting to improve the identification of *M. mycetomatis* and, consequently, the diagnosis of mycetoma, a specific oligonucleotide primer based on the sequence of the internal transcribed spacer (ITS) regions spacing the genes encoding the fungal ribosomal RNAs has been described.[34] The ITS regions were amplified with universal primers and sequenced, and then two sets of species-specific primers were designed that specifically amplify parts of the ITS and the 5.8S ribosomal DNA gene. The new primers were tested for specificity with DNA isolated from human mycetoma lesions and DNA extracted from cultures of *M. mycetomatis* reference strains and related fungi as well as human DNA. To study the genetic variability of the ITS regions of *M. mycetomatis*, ITS amplicons were obtained from 25 different clinical isolates and subjected to restriction

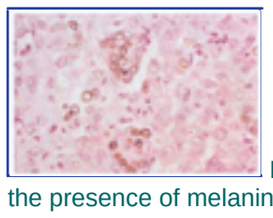

Figure 239-4 Subcutaneous phaeohyphomycosis caused by *Bipolaris spicifera.* The fungal elements are stained with Fontana-Masson, which accentuates and confirms the presence of melanin or melanin-like pigment in the fungal cell walls.

fragment length polymorphism (RFLP) analysis with *Cfo*I, *Hae*III, *Msp*I, *Sau*3AI, *Rsa*I and *Spe*I restriction enzymes. Restriction fragment length polymorphism analysis of the ITS region did not reveal even a single difference, indicating the homogeneity of the isolates analyzed during the study.

Phaeohyphomycosis

One common factor among these fungi is their melanin formation in the cell wall in culture and, in most cases, in human tissue. Microscopic examination of stained histopathologic sections or wet preparations of clinical material, such as pus or skin scrapings, can permit the diagnosis of phaeohyphomycosis if brown-pigmented septate mycelium with occasional branching is seen (Fig. 239.4).

Identification of the etiologic agent is essential for correct management, and this depends on its isolation in culture. Identifiable mycelial colonies can be obtained after incubation at 86°F (30°C) for 1–3 weeks. No serologic tests are available.

Rhinosporidiosis

Microscopy of clinical material reveals round or ovoid organisms that, depending on age, vary in diameter with a prominent wall.[35] [36] [37] These mature forms are known as sporangia. Sporangia measure up to 350µm in diameter and have a cell wall measuring about 5µm. The sporangia may be filled with endospores (Fig. 239.5). The immature forms of the organism are known as trophocytes; they are smaller than sporangia, have a relatively thinner wall and do not contain endospores. Trophocytes mature into sporangia. Endospores develop within sporangia. Endospores are released upon maturity and thereafter develop into trophocytes.

Rhinosporidium seeberi has traditionally been classified as a fungus on the basis of morphologic and histochemical characteristics. Recent molecular studies have generated conflicting results. The organism may be either a cyanobacterium or a protist. Using consensus PCR, a portion of the *R. seeberi* 18S rRNA gene directly from infected tissue has been amplified. [38] Analysis of the aligned sequence and inference of phylogenetic relationships showed that *R. seeberi* is a protist from a novel clade of parasites that infect fish and amphibians. Fluorescence in-situ hybridization and *R. seeberi*-specific PCR showed that this unique 18S rRNA sequence is also present in other tissues infected with *R. seeberi*. These data support the *R. seeberi* phylogeny recently suggested by others. *Rhinosporidium seeberi* is not a classic fungus, but rather the first known

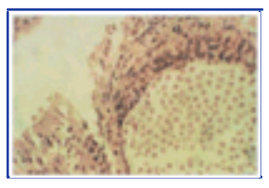

Figure 239-5 Rhinosporidiosis.

human pathogen on the basis of a previously aligned dataset of the DRIPs clade (named after the organisms *Dermocystidium*, the rosette agent, *Ichthyophonus* and *Psorospermium*), a novel clade of aquatic protistan parasites (*Ichthyosporea*).

Immunologic methods have been used to identify the causal agent of rhinosporidiosis in situ where the immunolocalization of *R. seeberi* antigens using sera from individuals infected with *R. seeberi* and tissue from Sri Lankan patients with rhinosporidiosis was investigated.[39] The tissues were fixed and evaluated by transmission electron microscopy for the presence of *R. seeberi* sporangia. The tissue samples were reacted with the patients's sera and then labeled with protein A colloidal gold (PACG) for immunolocalization. It was found that the PACG had fixed to antibodies that specifically recognized an internal electron lucent layer situated immediately under the mature sporangium's wall. The endospores and the juvenile and intermediate sporangia did not undergo PACG labeling. This study found that the expression of this antigen occurs only in the final developmental stages of *R. seeberi* mature sporangia. The data may explain why circulating antibodies to *R. seeberi* were not detected before in studies that used endospores as antigen in immunoassays. This appears to be the first report in which an antigenic material with a potential role in

the immunology of rhinosporidiosis has been described.

Sporotrichosis

Direct examination of clinical material, such as pus or tissue, is often disappointing because the organism is seldom abundant. However, it can be of value if conducted with painstaking care. The detection of typical ovoid or cigar-shaped cells or asteroid bodies of *S. schenckii* will confirm the diagnosis (Fig. 239.6).

The definitive diagnosis of sporotrichosis depends on the isolation of the etiologic agent in culture. Clinical material should be inoculated onto several media, including Sabouraud's agar, and incubated at 72–77°F (22–25°C). Identifiable mycelial colonies will appear in 2–5 days. The color usually changes from cream or light brown to dark brown or black with age. Confirmation of the identification depends on the morphologic characteristics of the mycelial form and its conversion to the yeast form on blood agar at 98.6°F (37°C).

At present, serologic tests do not have a significant role in the diagnosis of sporotrichosis. Tube agglutination and latex particle agglutination tests can be used to detect antibodies to *S. schenckii*, but are more helpful in diagnosing the unusual extracutaneous forms of sporotrichosis than in detecting cutaneous infection.

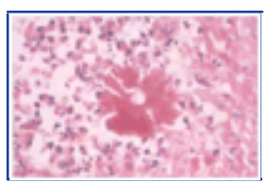

Figure 239-6 Asteroid body in cutaneous sporotrichosis. A yeast-like cell of *Sporothrix schenckii* with faintly basophilic, retracted cytoplasm is intimately surrounded by elongated spicules of Splendore-Hoeppli material.

Figure 239-7 Chromoblastomycosis lesions on the foot and ankle. The typical raised, crusted, verrucous lesions seen on the foot and ankle.

CLINICAL MANIFESTATIONS

Chromoblastomycosis

The lesions of chromoblastomycosis are usually unilateral and occur mainly on the exposed parts of the body, particularly the feet and lower legs (Fig. 239.7).[20] Other less common sites include the hands, arms, shoulders and neck (Fig. 239.8). The initial lesion is a painless papule or nodule on an erythematous and occasionally verrucous base. The condition may also present as an abscess surrounded by infiltration or as a psoriasiform lesion with erythema and scaling. As the disease develops, the affected limb becomes enlarged. Small satellite nodules may occur at the edge of the original lesion. Itching often occurs and it may be severe.

The primary lesion develops very slowly, its diameter increasing by only 1–2mm per year. It is firm and elastic in consistency and colored red or violet verging on gray. There is a warty, papillomatous margin surrounding a center that may be flat, smooth, or scaly, with areas of scarring.

Later in the disease, the lesion may become pedunculated or ulcerated (if bacterial superinfection occurs). However, the lesions usually retain a warty, dry character.

Figure 239-8 Chromoblastomycosis lesions on the ear. A crusty lesion on the lower part of the external ear.

Secondary lesions may appear, especially along the lymphatics draining the site of infection; here again, development is slow and symptoms are few. The lymph nodes are only involved if there is superimposed bacterial infection.

In some cases the skin lesions may spread and involve an entire limb. In other cases there is spontaneous resolution, leaving behind scars that are atrophic and abnormally pigmented or, by contrast, hypertrophic and contracting.

Cutaneous dissemination is rare, but may follow autoinoculation from scratching. Lymphatic or hematogenous spread may also occur. In elderly patients the lesions may spread to involve the skin of the trunk, whereas the scalp is rarely involved. The nails may also be damaged as a result of infection of the matrix and nailbed.

Rare complications of chromoblastomycosis include carcinomatous transformation. Metastatic lesions may occur in the oral mucosa, lymph nodes, bones and other tissues.

Usually lesions on the upper limbs are erythematosquamous, psoriasiform and of low relief, whereas those on the lower limbs are more exuberant. The latter may be associated with sclerosing inflammation of the subcutaneous tissue and result in elephantiasis.

In endemic areas the unilateral development of vegetative, atrophic and scarred lesions on a lower limb is suggestive of chromoblastomycosis. The condition must be distinguished from a number of other fungal infections including blastomycosis, lobomycosis, paracoccidioidomycosis, phaeohyphomycosis, rhinosporidiosis and sporotrichosis. It must also be differentiated from protothecosis, leishmaniasis, verrucous tuberculosis, certain leprous lesions and syphilis. On the upper limbs the erythematosquamous lesions can be confused with psoriasis or subacute or discoid lupus erythematosus. Mycologic and histologic investigations are indispensable for confirmation of the diagnosis.

Entomophthoramycosis

Entomophthoramycosis is a chronic subcutaneous infection of the trunk and limbs. The subcutaneous swelling that characterizes this disease is usually localized to the buttock and thighs, but may also be found on the arm, leg or shoulder.

The initial swelling may be rapid or slow in onset and is hard and painless. The spread is slow but relentless, and a large mass is formed that is attached to the skin but not to the underlying tissue (unlike *Conidiobolus* infection). This is a disfiguring infection, but the skin covering the lesions does not ulcerate. Lymphatic obstruction may occur and can result in massive lymphedema. There is no functional

Figure 239-9 Rhinofacial conidiobolomycosis. *With permission from Richardson MD, et al. Slide atlas of fungal infection: subcutaneous and unusual fungal infections, Oxford: Blackwell, 1995.*

impairment as long as the joints are not blocked by the volume of the swellings. The underlying bone and joints are not affected by the disease.

The disease is most common among adult males, particularly those living or working in tropical rain forests. Infection is acquired through inhalation of spores, or their introduction into the nasal cavities by soiled hands.

Very rarely, *B. ranarum* can cause gastrointestinal basidiobolomycosis.[40]

Conidiobolus infection generally begins with unilateral involvement of the nasal mucosa. The most common nasal symptom is obstruction, but frequent nose bleeding can occur and is evidence of the development of a nasal polyp in the anterior region of the inferior turbinate. Subcutaneous nodules then develop in the nasal and perinasal regions and may be associated with epidermal lesions.

The spread of the infection is slow but relentless. It is usually confined to the face, and the development of gross facial swelling involving the forehead, periorbital region and upper lip is very distinctive (Fig. 239.9). As a rule, the lesions are firmly attached to the underlying tissue, although the bone is spared. The skin remains intact. Spread to the lymph nodes has been reported. Even if, in advanced cases, the diagnosis is obvious from the appearance, mycologic and histologic examinations are essential for its confirmation.

The disease can be diagnosed with confidence on the basis of appearance and the results of the mycologic and (in particular) the histologic examination. Specimens must be taken from the subcutaneous tissue where the infection develops.

For an exhaustive review of the clinical manifestations of entomophthoramycosis refer to Ribes *et al.*[12]

Lobomycosis

Lobomycosis is an indolent infection that first manifests as a papule or small nodule of normal pink skin color or with a grayish tinge. The nodule then proliferates and, by partial or total coalescence, may form extensive multilobar lesions. The disease spreads by peripheral extension or autoinoculation from scratching, or it may follow the draining lymphatics, especially in elderly people.

The lesions are located in the dermis and subcutis and may form massive tumors, which are firm and resistant to pressure at the outset, but which later become hard and fibrous and resemble a keloid. If there is ulceration, depressed scars may remain; their surface is smooth and shiny in places, owing to atrophy of the underlying epidermis, and wrinkled and fissured elsewhere.

The disease may be symptomless or cause itching and burning, and trauma to the affected area may be especially painful. The most common sites of infection are the coolest parts of the body — the

limbs, face, ears and buttocks. The lesions may cover a whole limb. If the head is involved, the patient may be so grossly disfigured as to be completely excluded from social life. With a few exceptions there are no adenopathies.

Lesions may be keloid scars or irregular fibrous changes of the skin without secretion. Leprosy, leishmaniasis and chromoblastomycosis can produce similar lesions. Mycologic and histologic examination will confirm the diagnosis.

Mycetoma

Mycetoma is a chronic, suppurative infection of the subcutaneous tissue and contiguous bones. The lesion appears to begin at a site of minor trauma and continues to spread locally over the ensuing months and years.

The clinical features of the disease are fairly uniform, regardless of the type of organism causing it. Eumycetoma follows a slower and generally less destructive course than actinomycetoma. Spread to the internal organs and involvement of the regional lymph nodes is rare, occurring in no more than 2–5% of cases.

The feet are by far the most common site of involvement and account for two-thirds or more of cases (Fig. 239.10). Other sites include the lower legs, hands, head, neck, chest, shoulder, arms and abdomen.

In most cases, the first sign of the disease is a small, hard, usually painless, subcutaneous nodule that is not attached to the underlying tissue. It is covered by taut thinned skin, which is reddish-violet in color. A number of small nodules may coalesce to form a larger and frequently multilobar nodule.

Over the ensuing months the nodule begins to soften on the surface, caves in, ulcerates and partly empties, discharging a viscous, purulent fluid containing grains. If there is little fluid, the grains may not escape. The lesion then broadens out at the surface and also spreads inward to infect muscles and bones. The lesions, which are covered with depigmented and scarred skin, present as swellings, which are often covered with a crust. Later, the lesions develop sinus tracts that discharge pus and blood containing the characteristic grains.

The infection slowly spreads to adjacent tissue, including bone; this often causes considerable deformity. Mycetomas of the feet make the arches convex, thus preventing the toes from touching the ground. However, the general health of the patient is not affected. Pain, burning and pruritus may occur but are usually mild. Depending on the location and size of the lesion, and also on whether there is any bone involvement, limb function may be impaired.

Radiologic examination is useful in determining the extent of bone destruction. Abnormalities include periosteal reactions, sclerosis,

Figure 239-10 Mycetoma of the foot.

endosteal reactions, cortical erosions and joint destruction. Computerized tomography scanning is also helpful in delineating the extent of lesions.

Bacterial superinfection is not uncommon and is largely responsible for adenopathies and impairment of the general health. Visceral and especially cerebral metastases are the most serious complications; they cause cachexia and are often fatal. Fortunately, they are rare.

In most cases, the diagnosis of mycetoma of the feet presents no problems, but it may be difficult if other body sites are involved, particularly in regions where the disease is not endemic and if no grains have been discharged at the time of examination.

The characteristic feature of mycetoma is the presence in a fistulated swelling of grains that are found to contain actinomycotic or fungal filaments. This finding

distinguishes mycetoma from chromoblastomycosis, cutaneous tuberculosis, certain syphilitic or leprous lesions, botryomycosis and other conditions.

Phaeohyphomycosis

Phaeohyphomycosis can be divided into a number of distinct clinical forms, including subcutaneous infection, paranasal sinus infection, cerebral infection and invasive and systemic disease.[1] [41] The disease spectrum of noncutaneous phaeohyphomycosis includes sinusitis, pulmonary disease, CNS infection, ocular disease, arthritis, osteomyelitis, fungemia, endocarditis, peritonitis and gastrointestinal disease.

Subcutaneous phaeohyphomycosis

Subcutaneous phaeohyphomycosis usually follows the traumatic implantation of the fungus into the subcutaneous tissue. Minor trauma, such as cuts or wounds from thorns or wood splinters, is often sufficient. The principal etiologic agents include *E. jeanselmei*, *Exophiala spinifera*, *Exophiala dermatitidis* (*Wangiella dermatitidis*), *Phialophora richardsiae* and *Phialophora parasitica*.

The lesions occur mainly on the arms and legs. Other less common sites include the buttocks, neck and face. The initial lesion is a firm, sometimes tender, subcutaneous nodule that may enlarge slowly to form a painless cystic abscess. Lesions are attached to the skin but not to the underlying tissue or bone. Unless the cyst ruptures, the overlying skin remains unaffected. In immunosuppressed patients with subcutaneous phaeohyphomycosis, the lesions are more likely to drain through sinuses.

Phaeohyphomycosis in transplant recipients

Infection of subcutaneous tissue by black fungi has only been reported in six transplant patients, all of whom were solid organ recipients.[42] These patients presented with indolent, localized infections at least 1 year after transplant, while on maintenance immunosuppressive regimens. They were cured by surgical resection, either alone or in conjunction with antifungal agents. A further case report illustrates the features of subcutaneous phaeohyphomycosis, occurring in a bone marrow transplant recipient receiving high doses of immunosuppressive agents, in whom widespread subcutaneous infection due to *E. jeanselmei* was not eradicated by repeated resections and therapy with amphotericin B and flucytosine. [42] The infection was eventually cured after addition of itraconazole to the therapeutic regimen. Results of in-vitro testing of the isolate for susceptibility to a combination of amphotericin B, flucytosine and itraconazole confirmed the potential role of combination antifungal therapy in the setting of refractory infection.

Local recurrence of subcutaneous phaeohyphomycosis in transplant recipients after medication or surgical treatment is also seen. An illustrative case is a 42-year-old woman who had undergone a bilateral lung transplant who developed pheohyphomycotic cysts with local recurrence and then was successfully treated by local

excision with pre- and postsurgery oral itraconazole treatment.[43] Simple excision or excision with postsurgery oral itraconazole resulted in local recurrence in this patient. Local excision with pre- and postsurgery oral itraconazole was effective in preventing the local recurrence. The authors conclude that local excision with pre- and postsurgery oral itraconazole can be used to treat these patients with recurrent phaeohyphomycosis.

Paranasal sinus infection

This form of phaeohyphomycosis is becoming more common. The principal etiologic agents include *Alternaria* spp., *Bipolaris spicifera*, *Bipolaris hawaiiensis*, *Curvularia lunata* and *Exserohilum rostratum*.

It is a slowly progressive condition that may remain confined to the sinuses or spread to contiguous structures. Affected people usually complain of longstanding symptoms of allergic rhinitis, nasal polyps or intermittent sinus pain. Patients present with nasal obstruction and facial pain, with or without proptosis. The sinuses are filled with a thick, dark, tenacious, inspissated mucus.

Computerized tomography scanning is the best method for evaluating the extent of the infection. The typical finding is a large mass filling one or more of the sinuses.

Alternaria and *Curvularia* spp. occasionally cause necrotic lesions of the nasal septum in patients with leukemia or AIDS.

Cerebral phaeohyphomycosis

This form of phaeohyphomycosis may follow hematogenous dissemination of infection from the lungs, or it may result from direct spread from the nasal sinuses. Involvement of the CNS carries a poor prognosis. The routes of infection have not been clearly established, but the most likely port of entry seems to be the respiratory tract, although direct inoculation into the brain and extension from the sinuses, ear and pulmonary infections have also been reported. Most cases are due to *X. bantiana* (*Cladosporium trichoides*). Other etiologic agents include *Bipolaris* spp. and *E. dermatitidis*. Many cases of cerebral infection with *X. bantiana* have occurred in people with no obvious predisposing factors.

The symptoms of cerebral phaeohyphomycosis are gradual in onset. Persistent headache is the most common presenting symptom. The most frequent clinical findings include focal neurologic signs, hemiparesis and fits. Fever is minimal or absent. Chest radiographs are normal.

Computerized tomography scans of the head will often reveal a unilateral, well-circumscribed lesion, with the frontal lobes of the brain being the most common location. Cerebrospinal fluid (CSF) findings are varied. The opening pressure may be raised, the protein concentration may be increased, the glucose concentration may be reduced, and pleocytosis may be present. It is most unusual to recover the fungus from the CSF. The diagnosis is seldom established until neurologic resection is performed.

Cutaneous infection

Alternaria spp. have been seen in and isolated from crusted, ulcerated or scaling skin lesions. Many of these infections have followed traumatic implantation and a substantial proportion have occurred in leukemic patients or transplant recipients. The arms and legs are the more common sites of infection.

Other forms of phaeohyphomycosis

Dematiaceous molds have caused endocarditis after valve insertion or replacement, and peritonitis in patients on continuous peritoneal dialysis.[40] Post-traumatic osteomyelitis and arthritis have also been reported. Fungemia due to black fungi is unusual.[40] Fever without a clear source of infection is the most frequent presentation. In a series of 23 cases occurring in a tertiary hospital, fever was the most frequent clinical manifestation, and only one patient developed signs of deep-seated infection, with a clinical picture of necrotizing pneumonia similar to that caused by *Aspergillus* spp.[40]

The lesions of subcutaneous phaeohyphomycosis can be confused with the small initial lesions of chromoblastomycosis, sporotrichosis, blastomycosis, coccidioidomycosis and paracoccidioidomycosis, as well as with cutaneous leishmaniasis. Lymphangitic spread of sporotrichosis and the development of verrucous lesions in the other conditions makes the distinction easier.

In people who are not immunosuppressed, the clinical presentation of phaeohyphomycosis of the paranasal sinuses cannot be distinguished from that of *Aspergillus* infection. In immunosuppressed patients, *Aspergillus* sinusitis is a fulminant and often lethal condition, unlike pheohyphomycotic sinusitis. However, both groups of organisms can cause black necrotic lesions of the nasal septum.

Bacterial brain abscess is the most common initial diagnosis in patients with cerebral phaeohyphomycosis. In occasional patients, the diagnosis of cryptococcosis, histoplasmosis, coccidioidomycosis or sporotrichosis must be excluded.

Rhinosporidiosis

Rhinosporidium seeberi causes the production of large polyps or wart-like lesions that occur predominantly on the mucous membranes. The nasal mucosa is affected in more than 70% of cases. The onset of the disease in the nose is insidious and the patient remains unaware of its presence until symptoms of obstruction develop. In some cases, the patient complains of itching and unilateral coryza. Rhinoscopic examination will reveal papular or nodular smooth-surfaced lesions that gradually become pedunculated and acquire a papillomatous or proliferative appearance. They are pink, red, or violet in color. The polyps may obstruct the nasal passages, particularly in the event of even slight trauma. If located low in the nostril, they may protrude and hang onto the upper lips. If they are sited in the posterior part of the fossa, they may partially obstruct the pharynx or larynx and cause dysphagia or dysphonia and dysphonia and dyspnea.

In some cases the eyes are affected, the lesions being located on the conjunctiva. Initially these are small, flat granulations that may grow to form multilobed polyps of a pale pink color. At the same time there is diffuse vascular dilatation, photophobia and lacrimation, which is often due to involvement of the lacrimal sac and duct.

The ears may also become involved; depending on their size and location, these polyps may impair hearing.

Lesions may also develop on the male genital organs (the penis and, in exceptional cases, the urethra) and on the vulva and vagina in women. They may resemble flat or acuminate condylomas; lesions in the anus present as polyps and may sometimes be mistaken for hemorrhoids.

Cutaneous rhinosporidiosis, which is very rare, is generally due to spread from a neighboring mucosal lesion. It presents initially as minute papillomas; these gradually become larger and pedunculated. The surface is irregular, verrucous and polypous.

Cutaneous lesions are usually asymptomatic, but depending on their location (especially if they are on the sole of the foot) or their size they may cause pain. The surface of ulcerated rhinosporidiosis lesions is dotted with white spots, which are more readily discerned when depressed with a glass spatula; on microscopy these are seen to be sporangia.

Dissemination to the internal organs or bones is rare. In most cases the general health of the patient is unimpaired.

The appearance of pedunculated or unpedunculated polyps or nodules covered with white dots on the nasal mucosa or the conjunctiva should suggest the diagnosis of rhinosporidiosis. The condition must be distinguished from cryptococcosis, cutaneous tuberculosis, leprous lesions, leishmaniasis and treponematoses.

Figure 239-11 Localized lesion in sporotrichosis. The most common clinical presentation is a localized cutaneous or subcutaneous lesion, which develops at the site of implantation of the etiologic agent, *Sporothrix schenckii*.

Figure 239-12 Lymphagitic spread of sporotrichosis. The spread is from a primary digital lesion up the dorsal surface of the forearm.

Sporotrichosis

The clinical manifestations of sporotrichosis are rather variable, which helps to explain the large number of different classification schemes that have been proposed.[14] [16] The most common clinical presentation is a localized cutaneous or subcutaneous lesion (Fig. 239.11). Lymphatic spread may then lead to the development of further cutaneous lesions (Fig. 239.12). Much less commonly, the fungus may cause infection of the lungs, joints, bones, eyes and meninges. Widespread disseminated infection has been reported in patients with diabetes, alcoholics, drug abusers and patients with AIDS (Fig. 239.13).

Cutaneous sporotrichosis

Cutaneous sporotrichosis tends to affect exposed sites, mainly the limbs and especially the hands and fingers. The right hand is affected more frequently than the left. The initial lesion develops at the site of implantation of the fungus. It is a painless nodule that is movable at first but that later becomes attached to the neighboring tissue. The skin turns red then violaceous, and the nodule breaks down to form an ulcer, which discharges a serous or purulent fluid. The edge of the ulcer is often irregular and it may become edematous, vegetative and crusted.

After a period of a few days to several weeks, the primary lesion may become surrounded by satellite lesions, or further nodules

Figure 239-13 Multiple lesions in sporotrichosis. These skin lesions are a result of hematogenous spread.

along the course of the draining lymphatics may develop. These soon become palpable and ulcerate through to the skin. In most cases, however, the lymphangitis heals or remains static for a long time without ulcers forming. In most cases the regional lymph nodes are not involved. However, this is not an invariable rule. Any involvement of these lymph nodes is evidence of a superimposed bacterial infection and they may ulcerate in turn.

Apart from these very typical lesions, sporotrichosis may present a different clinical picture. Extension over large areas of skin, often described as the disseminated cutaneous form, may occur. Flat, infiltrated or papulopustular or nodulopustular lesions may develop. Whether oozing, proliferative, papillomatous or verrucous, the lesions of sporotrichosis are generally painless but often pruritic. Several ulcers may be interconnected by subcutaneous fistular passages. Confluent lesions may form a purulent and warty plaque with a continually expanding margin, whereas the center becomes atrophied, smooth and shiny.

Primary cutaneous lesions may heal spontaneously, leaving behind unsightly and even disfiguring scars, which may be a functional impediment. However, secondary lesions may persist for several years.

Extracutaneous sporotrichosis

Pulmonary sporotrichosis is a rare but well-recognized condition. It may be primary, following the inhalation of spores, and may be accompanied by enlargement of the hilar or tracheobronchial lymph nodes. It may, however, also be of a secondary character, caused by hematogenous dissemination. The symptoms are non-specific and include a productive cough, fever and weight loss. Hemoptysis may occur and can be massive and fatal. The course may be chronic. The typical radiologic finding is a single, nodular upper lobe lesion, which may or may not cavitate. The natural course of the lung lesion is gradual progression to death.

Most patients with osteoarticular sporotrichosis also have preceding cutaneous lesions. This condition presents as stiffness and pain in a large joint. The onset is indolent. In almost all cases of arthritis, the knee, elbow, ankle or wrist is involved. Osteomyelitis seldom occurs without arthritis; the lesions are usually confined to the long bones nearby affected joints.

Endophthalmitis, although very rare, may result in blindness; chorioretinitis has also been reported. Cases of meningitis have also been seen.

The development of a cutaneous lesion on the limbs following trauma is suggestive of sporotrichosis, particularly if the patient is resident in an endemic region. The development of multiple ulcers along lymphatics is also suspicious. At a later stage of development sporotrichosis must be distinguished from mycoses such as blastomycosis, chromoblastomycosis and paracoccidioidomycosis, and from leishmaniasis, verrucous tuberculosis and tertiary syphilis. The diagnosis ultimately depends on mycologic and histologic examination.

MANAGEMENT

There are no trials comparing different strategies for the treatment of infection caused by black fungi. Treatment depends on the clinical form of the disease and is reviewed by Silveira and Nucci.[1] Cutaneous and subcutaneous phaeohyphomycosis are usually treated with complete surgical excision of the lesion, resulting in complete cure in the majority of cases. In addition, various antifungal agents have been used. Itraconazole is considered the drug of choice, and the dose has ranged from 200 to 600mg daily. The duration of treatment is not established. Although unusual, progression or recurrence of disease, even with adequate itraconazole serum levels, has been observed Whenever possible, surgical resection is also recommended for lesions in other organs, in association with an antifungal agent.

A number of reviews expanding many of the guidelines given here have been published.[1] [44] [45]

Chromoblastomycosis

Chromoblastomycosis is a difficult condition to treat.[46] Surgical excision should be reserved for small lesions;[47] it carries a high risk of local dissemination and should only be attempted in conjunction with antifungal treatment.

There is no ideal antifungal treatment for chromoblastomycosis. The most commonly used drug is flucytosine (150–200mg/kg per day given as four divided doses), but resistance is a frequent problem during long-term treatment. Amphotericin B is not effective as monotherapy but appears to be effective in combination with 5-fluorocytosine (5FC). Ketoconazole is effective in combination with 5FC. Fluconazole is reported to be successful.[48] [49] [50]

Much better results have been obtained when 5FC (4g/day given as four divided doses) is combined with oral thiabendazole (1g/day given as two divided doses). Treatment should be continued for at least 1 month after clinical cure is obtained. Itraconazole (400mg/day) has given promising results in a few patients. Itraconazole is particularly effective when combined with liquid nitrogen cryotherapy. [51] [52] Recent trials have shown terbinafine (50mg/day) to be effective, even in chronic cases. [17] The local application of heat to the lesions may be beneficial.

Entomophthoramycosis

Rhinofacial conidiobolomycosis

Treatment has so far been disappointing. Surgical resection of infected tissue is seldom successful and it may hasten the spread of infection. The condition can be treated with saturated potassium iodide solution (up to 10ml q8h as tolerated) or amphotericin B. Long-term results are poor.

Patients with rhinofacial conidiobolomycosis treated with fluconazole (200mg/day for 4 months) have been completely cured or have exhibited considerable improvement. Some patients have responded to combination treatment with amphotericin B and terbinafine,[53] or a combination of itraconazole and fluconazole.[54]

Basidiobolomycosis

The therapy of choice still appears to be saturated potassium iodide solution (30mg/kg per day) which should be given for 6–12 months. Oral ketoconazole (400mg/day) has sometimes been successful, but amphotericin B has seldom been helpful. Surgical resection is not curative.

Ribes *et al.*[12] provides an exhaustive review of the treatment of entomophthoramycosis.

Lobomycosis

Antifungal drugs are ineffective. Amphotericin B, griseofulvin, sulfonamides and ketoconazole have been employed without adequate clinical responses.

Cure can only be achieved by surgical excision, the extent of the lesions permitting. Care must be taken during surgery of lobomycosis to avoid contaminating healthy tissue. Cryosurgery has also been used. Unfortunately, however, recurrence after excision is common. In advanced cases, the extensive excision required to remove the lesion may not be justified if the infection is not life-threatening. In cases involving larger areas of infection, treatment with clofazimine is recommended. At present, the disease does not have a satisfactory medical treatment. The course of the disease is slow and chronic and the prognosis is poor. Lobomycosis never heals spontaneously and is never fatal, but it may be a very serious impediment.

Mycetoma

Early actinomycetomas (and some late and advanced cases) respond well to treatment.[47] The drug of choice is streptomycin sulfate (1000mg/day intramuscularly). This should be combined with trimethoprim-sulfamethoxazole (co-trimoxazole) 960mg q12h in cases caused by *S. somaliensis*, *A. pelletieri* or *N. brasiliensis*. Other regimens include trimethoprim-sulfamethoxazole and amikacin, and streptomycin combined with either dapsone or trimethoprim-sulfamethoxazole. If no response is seen after 3 weeks of treatment, other regimens can be substituted. These include streptomcyin and rifampin (rifampicin), or streptomycin and sulfadoxine plus pyrimethamine. Therapy must be continued for months or even years. In favorable cases, edema and tenderness regress, discharge of secretion and grains diminishes, and sinuses dry up and close.

Even after symptoms and clinical signs have disappeared, the disease has become clinically silent and laboratory tests have become normal, it is recommended that treatment be continued for the same period of time as was required to achieve these results.

The response of eumycetoma to antifungal treatment is disappointing. *Madurella mycetomatis* and *P. boydii* infections have been known to respond to ketoconazole (400mg/day), but it is essential to test liver function before starting and during treatment with this drug. Long-term treatment with itraconazole has resulted in improvement in *M. grisea* mycetoma. The fungal agents causing mycetoma are resistant to amphotericin B and 5FC. Terbinafine has been successful in the treatment of maduromycetoma.

Mycetoma due to *Acremonium* spp. and *P. boydii* appear to respond to fluconazole (200mg daily for 10–12 weeks).

Surgical excision is the method of choice if the eumycotic lesions are small enough for total removal to be possible. Amputation is often required in advanced cases with bone involvement, particularly when there is no response to drug treatment. Prostheses and rehabilitation are indispensable in every case of mutilating surgery.

Phaeohyphomycosis

Subcutaneous phaeohyphomycosis

Incision and drainage of subcutaneous lesions is seldom successful. Surgical resection is required. Treatment with amphotericin B has

cured or improved unresectable lesions, but later relapse has been common. Itraconazole and terbinafine have been successful in the treatment of phaeohyphomycosis.

Paranasal sinus infection

Complete surgical debridement combined with amphotericin B treatment is essential to halt the progression of this form of phaeohyphomycosis. Even so, it is not uncommon for the condition to recur. The need for repeated debridement is most evident in patients with disabling symptoms or erosion of the bone separating the paranasal sinus from the brain.

Oral treatment with itraconazole (100–400mg/day) appears promising, although the optimum dosage and duration of treatment has not been defined.

Necrotic nasal septum lesions due to *Alternaria* spp. or *Curvularia* spp. have been cured after surgical excision.

Cerebral phaeohyphomycosis

In no case has a patient survived without surgical resection of the lesion. Treatment with amphotericin B on its own is ineffective. Lesions that have not been completely removed have usually proved fatal. A single case of cerebral phaeohyphomycosis due to *Cladosporium* spp. responded partially to fluconazole (300mg daily for 5 weeks).

Cutaneous infection

Surgical debridement of cutaneous lesions combined with parenteral amphotericin B is the most effective method of treatment. Topical antifungal treatment is seldom helpful.

Other forms of phaeohyphomycosis

Too few patients have been treated for firm recommendations to be possible. However, the response to amphotericin B has been partial at best. Surgical resection of lesions or oral treatment with itraconazole should be considered.

In in-vitro tests the new azole antifungals, including voriconazole, appear to be as active as itraconazole against a number of agents of phaeohyphomycosis.

Rhinosporidiosis

The treatment of choice is surgical excision. No drug treatment has proved effective. If left untreated, the polyps will continue to enlarge slowly. In very rare cases, widely disseminated or deep-seated visceral lesions may develop. Spontaneous remission is unusual.

Sporotrichosis

Saturated potassium iodide solution remains the treatment of choice for patients in developing countries who contract cutaneous sporotrichosis, owing to its ease of administration and low cost.[55] [56] The starting dose is 1ml q8h, and this is increased to 4–6ml q8h. Treatment should be continued for at least 1 month after clinical cure is obtained, which may take 2–4 months. Intolerance (iodism) is frequent and consequently therapy is often stopped.

If the patient cannot tolerate potassium iodide, oral itraconazole (100–200mg/day) can be used.[57] [58] Treatment should be continued for up to 6 months. The most appropriate therapeutic regimen appears to be 200mg/day during the entire treatment period, or 200mg/day at the beginning of treatment, reduced to 100mg/day after improvement. Many cases treated in this way are cured relatively quickly. Cutaneous sporotrichosis has also been successfully treated with terbinafine (125mg/day).[59] Oral ketoconazole has given poor results.

Local heat, on its own or in combination with drug treatment, has been shown to improve cutaneous lesions. Besides thermotherapy, the simple warming of diseased limbs in winter months has proved helpful.

Amphotericin B has cured some patients with extracutaneous forms of sporotrichosis, but failures are common. In cases of arthritis or osteomyelitis, better results have been obtained when the drug has been combined with surgical debridement.

Itraconazole (400mg/day) has given good results in patients with extracutaneous infection, especially in those who have not responded to fluconazole. [60] The Mycoses Study Group of the Infectious Diseases Society of America has recently reviewed the treatment options for sporotrichosis and published detailed practice guidelines.[61] Their recommendations were derived primarily from multicenter, nonrandomized treatment trials, small retrospective series and case reports. The treatment of choice for fixed cutaneous or lymphocutaneous sporotrichosis is itraconazole 100–200mg/day for 3–6 months.

Chapter 240 - Superficial Fungal Pathogens

Richard C Summerbell
Aditya K Gupta

The majority of superficial fungal infections are caused by three groups of fungi: dermatophytes, *Candida albicans* and *Malassezia* spp.[1] Dermatophytes, the agents of dermatophytosis (ringworm, athlete's foot) are members of the phylum Ascomycota. Within that phylum, they are related to the order Onygenales, along with systemic pathogens such as *Histoplasma* and *Coccidioides*. In conventional biologic classification they are related to the genus *Arthroderma*; in the unique dual nomenclature of fungal anamorphs (asexual states), they are members of the genera *Trichophyton, Microsporum* and *Epidermophyton* (Fig. 240.1).

NATURE

Candida albicans, the principal agent of candidiasis, is an anamorphic (asexual) yeast also related to the Ascomycota. It and some related *Candida* spp. are mammalian commensals (normally harmless colonizers) related to the class Endomycetes, which also contains the bread yeast *Saccharomyces*.

Malassezia spp. are yeast anamorphs related to the phylum Basidiomycota, but not closely related to other human pathogens in this phylum such as *Cryptococcus* and *Trichosporon* spp. They are lipophilic (lipid-requiring) body surface commensals and agents of the skin disease tinea versicolor (pityriasis versicolor). In addition, they may be causal in the allergically mediated condition seborrheic dermatitis.

Other fungi cause less common types of superficial disease. Yeasts in the genus *Trichosporon* may cause white piedra, superficial colonizations of the scalp, and axillary and public hair shafts. The melanized yeast-like organism *Hortaea werneckii* (also known by several older names all ending in '*werneckii*') causes the dark skin lesions of tinea nigra. The rare hair shaft colonization black piedra is caused by the ascomycete *Piedraia hortae*. Finally, approximately 35 nondermatophytic filamentous fungi and a few yeasts have been authenticated as causing onychomycosis (i.e. fungal nail disease). Most prominent among these are members of the genera *Scytalidium, Aspergillus, Scopulariopsis, Fusarium* and *Onychocola*.

EPIDEMIOLOGY

Dermatophytosis is among the most common of all communicable diseases. Because many cases are never brought to medical attention, fully reliable incidence figures do not exist. Onychomycosis, in which the great majority of cases are dermatophytic, [2] may account for 10–30% of all superficial mycoses.[3] [4] In the USA Medicare insurance for seniors (=65 years old) in 1 year paid for consultations involving 662,000 patients, or 2.7% of the senior population, at a cost of over US$43,000,000. Less than 10% of those aged under 30 years and more than 20% of those aged over 75 years had tinea unguium (dermatophytic onychomycosis; Table 240.1) in population studies.[5] Tinea capitis in children is common in some areas. In an urban center in the USA up to 4% of children presenting with non-dermatologic complaints at a clinic were infected by *Trichophyton tonsurans*, whereas up to 30% of asymptomatic adults accompanying infected children were carriers.[6] A study of 224 children in a Philadelphia school reported 3% symptomatic and 14% asymptomatic, infected children. [7] Tinea pedis has been found to affect 1.5% of pediatric patients, 5.9% of 11–15 year olds[6] and up to 45% of adult marathon runners.[8] There is a significant age-dependent association between sporting activities and pedal dermatophytosis.[9] Many of the most prevalent dermatophytes are cosmopolitan, but certain species, especially agents of tinea capitis, have defined endemic regions (see Table 240.1).

Cutaneous candidiasis is particularly common in infants, at least 10% of whom have candidal skin colonizations. Fifty per cent of this colonized group go on to become symptomatic, usually with candidal diaper dermatitis.[6] Many adults harbor an indigenous strain of *C. albicans*; up to 30% of healthy women, for example, are culture positive for this species in vaginal swab samples, at least when pregnant or taking oral contraceptives.[1] The lower gut may serve as a reservoir when other body sites are free of *C. albicans*. Normal skin only rarely yields *C. albicans* but the yeast may rapidly colonize chronically moist or damaged skin, including moist dermatophyte lesions.

Malassezia spp. have been found as skin commensals in over 90% of humans surveyed.[1] In the temperate zone they only occasionally proliferate to the point of causing the finely scaly maculae of tinea versicolor, but in the tropics the prevalence may reach 50% of the population.[1] *Malassezia* spp. in patients who have HIV and other immunocompromised patients may cause pustular hair follicle inflammations referred to as *Malassezia* folliculitis, and may be associated with an increased prevalence of seborrheic dermatitis. [10] In atopic individuals, *Malassezia* spp. growing commensally on skin may serve as a triggering allergen in atopic dermatitis. [11] A possible association between *Malassezia* and neonatal acne or cephalic pustulosis is under investigation.

White piedra is found worldwide, but is now uncommon because of modern hygiene. Black piedra is native to South East Asia, the Pacific and South America, and affects other primates in addition to humans. It is uncommon when discouraged but is cultivated in some cultures.[1] Tinea nigra is of tropical or subtropical origin; about 150 indigenous US cases were reported between 1950 and 1988, in addition to many more cases acquired by travelers, mostly in the Caribbean.[1] *Scytalidium* infections of nails, soles or palms are usually acquired in the tropics. *Scytalidium dimidiatum*, the most common infectious species, has rapidly growing pantropical forms as well as a distinctive slow-growing Indian subcontinent form that may be transmitted among family members in the Indian Diaspora. Most other agents of nondermatophytic onychomycosis are cosmopolitan saprobic molds and, despite their opportunistic potential, are more frequently seen as insignificant contaminants of body surfaces than as etiologic agents.[12]

PATHOGENICITY

Dermatophytes normally infect only the keratinized stratum corneum of the epithelial skin layers. They degrade keratin and other skin

Figure 240-1 *Trichophyton rubrum* (heavily conidial Afro-Asiatic variant). Typical micromorphology of a dermatophyte in pure culture, showing micro- and macroaleurioconidia.

proteins.[13] They are restricted to the stratum corneum by cellular immune components, and by the iron limitation and other effects mediated by transferrin.[14] A 2-fold higher prevalence in males than females may reflect inhibition by progesterone. Development of one type of dermatophytosis, tinea imbricata, requires homozygosity for

TABLE 240-1 -- Definition and distribution of dermatophytoses.

DEFINITION AND DISTRIBUTION OF DERMATOPHYTOSES			
Area of infection	**Disease name**	**Prevalent agents**	**Geographic area**
Scalp	Tinea capitis	*Trichophyton tonsurans*	Cosmopolitan, especially urban Americas, Latin America
		Microsporum canis	Cosmopolitan; predominant dermatophyte in parts of south and east Europe
		Trichophyton violaceum	Endemic to Middle East, North Africa
		Trichophyton soudanense	Endemic to sub-Saharan Africa
Beard area	Tinea barbae	*Trichophyton rubrum, Trichophyton verrucosum*	Cosmopolitan
Glabrous skin (trunk, limbs, face)	Tinea corporis	*Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes* complex, *Microsporum canis, Epidermophyton floccosum*	Cosmopolitan
		Trichophyton megninii	Endemic to Portugal, Sardinia
Scalp, glabrous skin	Favus	*Trichophyton schoenleinii*	Relict in rural Africa, central Asia; formerly widespread
Palms	Tinea manuum	*Trichophyton rubrum, Trichophyton mentagrophytes* complex	Cosmopolitan

Groin	Tinea cruris	*Trichophyton rubrum, Trichophyton mentagrophytes* complex, *Epidermophyton floccosum*	Cosmopolitan
Soles, toe webs	Tinea pedis	*Trichophyton rubrum, Trichophyton mentagrophytes* complex, *Epidermophyton floccosum*	Cosmopolitan
Nails	Tinea unguium (dermatophytic onychomycosis)	*Trichophyton rubrum, Trichophyton mentagrophytes* complex	Cosmopolitan

an otherwise uncharacterized recessive allele;[1] involvement of an autosomal dominant susceptibility allele has been proposed in the common chronic form of *Trichophyton rubrum* infection. [15] An indication of the relative importance of lymphocytes in host defense is seen in HIV infection, in which helper T-cell counts below 100 cells/ml correlate with a marked increase in onychomycosis,[16] including the unusual 'proximal white' form. Chronic dermatophytosis in normal patients may be mediated by locally immunosuppressive fungal carbohydrates as well as incapacitation of local cellular immunity by an immediate hypersensitivity response[17] and activation of a Th2 pattern of immune response.[18]

Dermatophytes differ in their host interactions. Anthropophilic dermatophytes (Table 240.2), specific to human disease, are distinguished from zoophilic dermatophytes, which have specific animal associations but may be transmitted to humans, and from geophilic dermatophytes, which are occasionally pathogenic to humans or animals but primarily grow on decaying keratinous material. The *Trichophyton mentagrophytes* complex (Fig. 240.2), containing four sibling-species distinguishable by molecular study, has both anthropophilic and zoophilic variants. Infection of humans by zoophilic dermatophytes usually elicits a pronounced inflammatory response.[14] Such inflamed lesions may resolve spontaneously, unlike the often chronic lesions of anthropophilic dermatophytoses.

The common anthropophilic dermatophytes include lower body dermatophytes associated with sites other than the scalp, and dermatophytes

TABLE 240-2 -- Common and formerly common dermatophytes and their infectivity.

COMMON AND FORMERLY COMMON DERMATOPHYTES AND THEIR INFECTIVITY		
Anthropophiles (type of scalp infection if characteristic)	**Zoophiles (type of human scalp infection) [principal hosts]**	**Geophiles (type of human scalp infection)**
Epidermophyton floccosum	*Microsporum canis* (ectothrix) [cat, dog]	*Microsporum gypseum* (ectothrix)
Microsporum audouinii (ectothrix)	*Microsporum gallinae* [fowl]	*Microsporum praecox*
Microsporum ferrugineum (ectothrix)	*Microsporum nanum* [swine]	*Microsporum racemosum*
Trichophyton concentricum	*Microsporum persicolor* [vole]	*Microsporum vanbreuseghemii*
Trichophyton megninii (ectothrix)	*Trichophyton equinum* [horse]	The listing of geophiles does not include species that have not been well substantiated to cause human disease. These species are not properly considered dermatophytes according to Ajello[19]
Trichophyton mentagrophytes complex (phylogenetic species *Trichophyton interdigitale*)	*Trichophyton mentagrophytes* complex (phylogenetic species *Trichophyton interdigitale, Trichophyton mentagrophytes, Trichophyton erinacei*) [rodents, rabbits, hedgehogs]	
Trichophyton rubrum	*Trichophyton simii* [monkey]	
Trichophyton schoenleinii (favus)	*Trichophyton verrucosum* [cattle]	
Trichophyton soudanense (endothrix)		
Trichophyton tonsurans (endothrix)		
Trichophyton violaceum (endothrix)		

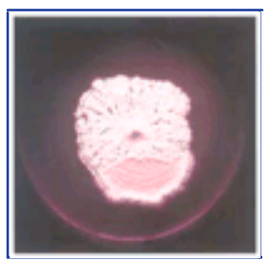

Figure 240-2 *Trichophyton mentagrophytes* complex: a zoophilic (animal-associated) isolate showing the 'granular' colonial morphology typical of such isolates. The strain depicted has been shown through mating to belong to the phylogenetic species *Trichophyton interdigitale* (sexual state called *Arthroderma vanbreuseghemii*), one of several genetic sibling species now known to make up the *T. mentagrophytes* complex.

matophytes strongly adapted for tinea capitis, less commonly causing other tineas. *Trichophyton rubrum, T. mentagrophytes* complex and *Epidermophyton floccosum* are the common lower body species. Tinea capitis dermatophytes consist of two major groups distinguished by their colonization of hair (see Table 240.2). In the 'ectothrix' group, hair shafts are externally ensheathed with masses of arthroconidia (spores). In the 'endothrix' group, the hair shafts are heavily invested internally by arthroconidia. An anomalous scalp infection, favus, caused by the now rare *Trichophyton schoenleinii*, is distinguished by the presence of follicles transformed into scutula, that is, pits lined with fungal mycelium.

Tinea capitis agents primarily cause new infections in children, and may cause dramatic outbreaks. *Microsporum audouinii* infections spontaneously resolve at 15–19 years of age, but most endothrix agents cause lifelong asymptomatic infections in some adult carriers[7] and occasionally cause new tinea corporis or other infections in adults. New anthropophilic tinea capitis infections are usually acquired via shared headgear, bedding or grooming and haircutting instruments. Adults who acquire new infections caused by endothrix species usually have intimate contact with infected children. Anthropophilic lower body dermatophytoses are often acquired via the feet, either from family members or in communal aquatic or exercise facilities. After infecting the feet, these fungi may go on to infect other body sites.

Zoophilic dermatophytes (see Table 240.2) usually cause tinea corporis or tinea capitis in humans. They may be transmitted directly from infected animals or from fomites, such as fence posts in cattle yards. *Microsporum canis* may cause limited outbreaks among humans before virulence is attenuated.[20]

Candida albicans is often acquired in the birth canal or in infancy from care givers. Generally, an individual harbors only one or two strains. Cutaneous candidiasis is predisposed to by warm, moist conditions with abrasion, especially in the diaper rash of infancy but also in adult occupations that involve wet hands. In the latter cases, paronychia or interdigital erosion frequently results. Intertriginous candidiasis occurs in moist body folds and is exacerbated by diabetes mellitus or obesity. Chronic mucocutaneous candidiasis (CMCC), in which skin and mucosa are extensively colonized by *C. albicans*, results from inherited defects in cellular immunity.[21] Particular associated conditions include congenital thymus dysplasias, poly-endocrine deficiencies and leukocyte dysfunctions such as chronic granulomatous disease.[1] In this latter disease, the impaired production of toxic oxygen species prevents killing of *Candida* spp. within phagocytes.

Malassezia spp. are also generally acquired as commensal surface flora in early infancy. They primarily use fatty acids secreted by the skin. Corticosteroid use, Cushing's disease, malnutrition and immunosuppression may contribute to an increased frequency of tinea versicolor; HIV infection and miscellaneous

immunosuppressions predispose to folliculitis.

Nondermatophytic onychomycosis caused by genera other than *Scytalidium* is strongly predisposed to by advanced age.[22]

PREVENTION

Prevention of infections caused by anthropophilic dermatophytes adapted for tinea capitis can be achieved by a combination of sanitation and detection of asymptomatic carriers. In *Microsporum* spp. outbreaks, a Wood's light can be used to screen potentially infected individuals rapidly; lesions usually fluoresce yellow-green. The same technique can also be used to detect animal carriers when the zoophilic *M. canis* is involved. Subclinical cases are more difficult to detect in nonfluorescent *Trichophyton* outbreaks; conventional microscopy and culture analysis of slightly scaly areas in individuals likely to be infected are required. In all cases in which tinea capitis fungi are involved, infected individuals must be treated promptly and their contacts must be educated not to share materials that contact the scalp. Fomites may endure on surfaces in contaminated rooms for months and belatedly cause new infections unless adequate disinfection is performed. Strategies for dealing with institutional outbreaks have been summarized.[14]

Lower body anthropophilic dermatophytosis, for example *T. mentagrophytes* complex tinea pedis, may be prevented to some extent by minimizing barefoot walking in public showers, swimming pool and hot tub peripheries, gymnasia, barracks and similar localities. However, familial genetic susceptibility and organism carriage may outweigh exposure in public places as a risk factor in the most common lower body dermatophytoses, *T. rubrum* tinea pedis and onychomycosis.[15]

Occupational animal handlers may reduce the risk of zoophilic dermatophytosis by wearing protective gloves.

Prevention of the more severe forms of epidermal candidiasis is linked to prevention of immunodepression and will not be dealt with here. Persons whose occupations involve frequent wetting of hands should wear protective gloves. Good hygiene and prompt change of diapers may aid in preventing candidal diaper rash.

Good hygiene is instrumental in the prevention of white piedra and may also help to prevent tinea versicolor.

DIAGNOSTIC MICROBIOLOGY

Superficial mycotic infections are best tested by the combination of direct microscopy for fungal elements in hydroxide (KOH, NaOH) slides, and fungal culture. Direct microscopy may be facilitated by the use of fluorescent fungal cell wall dyes such as calcofluor or Congo red. Histopathology performed with fungal stains has been suggested as an alternative to 'KOH and culture' for onychomycosis, but the ability of this technique to distinguish dermatophyte from nondermatophyte infections has received only preliminary investigation.

Dermatophytes in direct microscopy show cylindrical fungal filaments that may include chains of rounded arthroconidia. At times filaments may be converted entirely into arthroconidia, such as within or around hair shafts in tinea capitis. In superficial white onychomycosis caused by *T. mentagrophytes* complex members, microscopy may may show 'frondose branching', an appressed, palmate spreading of fungal hyphae between keratin lamellae. In nails, soles and palms, all morphologies of dermatophyte filaments overlap with those of other potentially infectious fungi, especially *Scytalidium* spp.

Generally, dermatophyte filaments from the growing fronts of infection, such as the peripheral 'ring' in classic ringworm and adjacent to the nailbed in tinea unguium, will be alive and will stain with vital stains such as neutral red. [23] Those from prior growth fronts, such as centers of ringworm lesions or extruded, distal nail, tend to be senescent and will not yield a culture. For this reason, sampling tinea at its extending margin, and subungual onychomycosis at the juncture of nail and nailbed, is recommended. Tinea corporis is sampled by using a scalpel to remove skin scale from the advancing lesion margin after light disinfection with an ethanol swab. In subungual onychomycosis, heavily contaminated debris is scraped from the undersurface of the nail and discarded; then, after swabbing with ethanol, friable material is scraped from the nail undersurface as close as possible to the nailbed. Clippings may also be taken. In superficial white onychomycosis, white, opaque areas on the upper nail surface are scraped. As with subungual onychomycosis, superficial debris is scraped and discarded before sample collection. In tinea pedis of the sole and tinea manuum, in which growth fronts may not be apparent, the affected area should be scraped broadly so that the whole is represented in the sample.

Even with expert sampling approximately 10–25% of nail samples positive for fungal filaments in direct microscopy fail to yield a culture.[23] That such a finding accurately reflects the active infection can be confirmed by vital staining,[20] and should not be mistaken for a technical 'false-negative' culture result. Also, approximately 45–50% of toenails and 60% of fingernails clinically suggestive of onychomycosis fail to yield any evidence of fungal infection.[24] Dermatophyte colonization in very degraded nails may be partially supplanted by secondary invaders such as *Pseudomonas* bacteria and *Scopulariopsis* mold (the latter may also appear as a sole agent of onychomycosis or as a contaminant), and the original etiologic agent may be difficult to trace.

Hair from tinea capitis or barbae is plucked so that the hair root, the best source of inoculum, is included. In 'black dot' tinea capitis, in which hairs are fragile, a few hair roots may be extracted with the tip of a scalpel and included along with surface scrapings of the lesion. *Microsporum* scalp lesions typically show strong yellow-green fluorescence under a Wood's light and can be presumptively diagnosed in this manner. In zoophilic tinea corporis and other lesions with vesicles or bullae, the apices of these may be clipped and included in the sample. Moist, suppurating lesions may be sampled with a swab. Swab samples may make direct microscopy difficult and are best evaluated by culturing.

For culture, scrapings or fragments from clippings are usually planted on Sabouraud agar supplemented with antibacterials and the selective antifungal cycloheximide. Common commercial equivalents include Mycosel, Dermasel and Mycobiotic. Dermatophytes and *C. albicans* are among the small minority of fungi able to grow well on these media. Potato glucose or potato flake agar with cycloheximide is preferred by some laboratories because the distinctive pigmentation of some species is enhanced. A cycloheximide-free medium is generally used for nails, and also be isolated from at least some of these sites. The most common of such media are plain Sabouraud agar supplemented with antibacterials only, and two restrictive media: Littman oxgall agar and inhibitory mold agar. These media, unlike plain Sabouraud agar, inhibit fast-growing contaminant molds from overgrowing the slower growing etiologic agents.

The characteristics and criteria used in identifying dermatophytes have been summarized.[25] [26] [27] Since most dermatophyte species are susceptible to similar therapies (duration of therapy may vary, e.g. between *Microsporum* spp. and the more rapidly inhibited endothrix

Trichophyton spp. in tinea capitis), species identification is salient primarily to recognize situations in which animal hosts or familial or institutional carriers constitute potential sources of re-infection and continuation of outbreaks. Zoophilic dermatophyte species and the endothrix tinea capitis agents are most notorious in these situations, but unusual outbreaks of anthropophilic lower body dermatophytoses may also be detected and controlled through species identification.

Candidiasis in skin and nails is recognized in direct microscopy by the presence of budding yeast cells and candidal-type filaments; the yeast cells bud through a narrow constriction, unlike *Malassezia* yeasts, and the filaments give rise to budding cells on side branches, unlike dermatophyte filaments. Although filaments indicate an invasive condition in cutaneous candidiasis, and are usually found in any genuine case of infection, masses of budding cells alone may be seen in some nail specimens. In fingernails, this often indicates nearby paronychia that was not sampled directly. In some cases, however, especially with toenails, yeast cells merely indicate harmless growth of *Candida* spp. (other than *C. albicans*) of the normal skin flora in crevices in onychomycotic or traumatized nails. *Candida albicans* should normally be identified when isolated from skin; there are a number of inexpensive, specific, rapid tests for this species such as rice-tween, cornmeal-tween or oxgall medium tests for formation of chlamydospores under a cover slip. *Candida* spp. other than *C. albicans* need not be identified to species level from superficial sites except in rare cases in which they are isolated from material with conclusive evidence of invasive yeast infection (e.g. formation of filaments with lateral budding cells) in direct microscopy. Because *C. albicans* commonly contaminates moist dermatophyte lesions without significantly exacerbating symptoms, and because normal flora yeasts may proliferate harmlessly in nail crevices, the laboratory gold standard for any diagnosis of cutaneous yeast infection is the specific presence of yeast-type filamentous elements within cutaneous tissue in direct microscopy.

Tinea versicolor is recognized in direct microscopy by the rounded yeast cells and short hyphal fragments ('spaghetti and meat balls') of *Malassezia* spp. Culture is normally unnecessary and may be problematic when attempted. Although there is considerable research interest in quantitative cultural analysis of *Malassezia* spp. in seborrheic dermatitis, clinical diagnosis based on symptoms remains the gold standard.

Other purely microscopic diagnoses not requiring culture include black and white piedra. Tinea nigra evinces distinctive dark filaments in direct microscopy (Fig. 240.3), but is also readily cultured to yield the etiologic agent, *H. werneckii*. No other organism shows melanized, two-celled yeasts budding from annellidic apertures heavily fringed with collarette remnants. Mycology laboratories

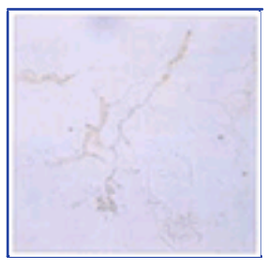

Figure 240-3 Direct microscopy (NaOH slide) of palm skin showing distinctive dark fungal filaments of *Hortaea werneckii*, causal agent of tinea nigra.

must also recognize the microscopically distinctive corynebacterial and actinomycetous elements found in erythrasma, trichomycosis axillaris and pitted keratolysis.[1] All intertriginous skin samples should be stained with methylene blue preparations to detect erythrasma. In specimens from this infection, methylene blue deeply stains delicate branching filaments less than 1µm in diameter, often seen breaking up into smaller bacillary or coccoid forms. The poorly understood '*Dermatophilus*-like' agent of pitted keratolysis[1] also stains in methylene blue, and shows a mixture of coccoid cells and short filaments, at least some of which appear tapered and, in broader regions, subdivide to give rise to a second or third longitudinal series of cells. In trichomycosis axillaris, hair is heavily ensheathed in corynebacterial cells (Gram-positive rod and coccus forms less than 1µm in diameter). These may be readily distinguished in crushed preparation in hydroxide from the over 2µm in diameter arthroconidia and yeast cells seen in the macroscopically similar white piedra.

The correct diagnosis of onychomycosis caused by nondermatophyte molds can be especially challenging. These nondermatophyte filamentous fungi can easily be ascertained as causing onychomycosis if distinctive morphologic elements such as conidiophores are seen in addition to filaments in direct microscopy of nail specimen, or if a fungus from warm latitudes, such as a *Scytalidium*, is isolated in an area in which only such fungi occur in infected patients. Most cases are more ambiguous. A fungal species such as *Aspergillus sydowii* may be isolated either as a contaminant or as an etiologic agent, and filaments seen in direct microscopy may be either nonviable dermatophyte elements or genuine nondermatophyte elements. Therefore, even exclusive and heavy isolation of such a nondermatophyte from a specimen positive for fungal filaments does not guarantee that the nail is infected by the same nondermatophyte.[12] The current gold standard, which may not be easy to attain in practice, is:

- first to demonstrate fungal elements in direct microscopy compatible with the suspected agent; and
- second, in culture, to show, through correlating the results of two nail samples collected at least 1 week apart, that the nondermatophyte in question consistently grows from the diseased nail.

True mixed infection by a dermatophyte and a nondermatophyte may occur, but again can only be demonstrated scientifically by showing a consistent presence of the latter in more than one serial sample.

CLINICAL MANIFESTATIONS

Tinea capitis

The organisms that cause the 'noninflammatory type' of tinea capitis (Fig. 240.4) include *T. tonsurans, M. canis, M. audouinii* and

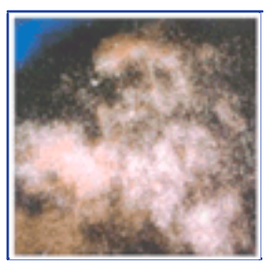

Figure 240-4 Tinea capitis, noninflammatory type. *Courtesy of Dr Natalie Roholt.*

Microsporum ferrugineum. There may be variable erythema with scaling that may be minimal or clinically significant, such that scale is consistently present. One or more well-demarcated patches may be present.

The inflammatory type of tinea capitis is often caused by zoophilic or geophilic species (see Table 240.2). The inflammatory changes range from a pustular folliculitis to multiple follicular abscesses, or even a kerion. A kerion may be fluctuant with a boggy feel to it. Pus may discharge from one or more points. Within the kerion there may be patchy or complete hair loss. In some instances the kerion resolves with scarring alopecia. A patient who has a kerion may have a tender, full neck as a result of cervical lymphadenopathy. Other symptoms and signs may include fever, neck ache and pruritus of the scalp.

Tinea capitis may also manifest as 'black dot' disease, which is usually caused by endothrix organisms, such as *T. tonsurans* and *Trichophyton violaceum*. The hair is brittle and breaks off at the scalp surface with the free end of the in-situ portion of the hair manifesting as a 'black dot'. There may be a variable amount of inflammation and scale present.

The favus type of tinea capitis is caused by *T. schoenleinii*; less commonly *T. violaceum* or *Microsporum gypseum* may cause a similar presentation. Within the scalp there are typically yellow crusts and scale, known as scutula. The condition may progress to involve large portions of the scalp, with yellow, adherent scale and crusting, and cicatricial alopecia.

Tinea barbae

Three types of tinea barbae exist: inflammatory, superficial and circinate. In the inflammatory type the lesions may be pustular, boggy or nodular, with alopecia. The superficial type can manifest as a folliculitis with papules and pustules. In the circinate variety there may be an active border with vesicles and pustules, and central scaling.

Tinea faciei (tinea corporis of the face)

Typically there is an annular lesion with erythema and scaling, with central clearing. The lesion may be pruritic and the patient may give a history of the lesion worsening after exposure to the sun.

Tinea corporis

Generally the lesions are annular with central clearing. The margin is typically erythematous with scaling, and sometimes with papules, pustules or vesicles. Pigmentary change may be seen with hypopigmentation or hyperpigmentation of the lesion. The inflammatory change may be more pronounced when the infecting organism is zoophilic. Sometimes the dermatophytes infect the hair follicle, with the formation of inflammatory perifollicular nodules or pustules, also known as Majocchi's granuloma. Infrequently, nodular granulomatous changes or subcutaneous spread may occur.

Tinea cruris

The eruption can be symmetric or asymmetric, unilateral or bilateral. The patient may complain of pruritus. The lesion may demonstrate an active border with erythema, scaling, papules and vesicles. When the causal organism is *T. rubrum* there may be a reservoir of infection, such as the nails or soles of feet. With *E. floccosum* infection there is no reservoir. When infection is caused by *Candida* spp. satellite pustules are less likely to be present in adults than in children.

Tinea pedis

The three major clinical presentations are the interdigital, the 'moccasin' or chronic hyperkeratotic, and the vesiculobullous (Fig. 240.5). Interdigital tinea pedis is the most common presentation, usually with involvement of the web space between the fourth and fifth toes or the third and fourth toes. The clinical presentation may vary from

Figure 240-5 Tinea pedis, vesiculobullous variety. *Courtesy of Dr Natalie Roholt.*

Figure 240-6 Tinea versicolor. *Courtesy of Dr Natalie Roholt.*

relatively asymptomatic mild scaling to maceration, erythema and exudative changes. In the plantar, moccasin-type tinea pedis there may be scaling, hyperkeratosis and a variable degree of erythema. Sometimes the fungal infection manifests as vesicles or bullae that may be seen on the instep of the foot or the mid-anterior plantar surface.

Tinea nigra

This superficial fungal infection caused by *H. werneckii* may appear as a scaly, asymptomatic, brown-black hyperpigmentation of the palms or soles of the feet. The palm and sole or both soles may be involved. The main differential diagnosis is benign and malignant melanocytic lesions.

Piedra

In black piedra, hard black nodules of varying sizes firmly adhere to hair. Generally scalp hair is involved, although hair at any site may be affected. In white piedra, soft white nodules are of varying sizes and are less adherent to the hair shaft. The infection is present within and on the exterior of the shaft, resulting in weakening of the hair. There is no fluorescence under Wood's light. In immunocompromised individuals disseminated infection may occur with skin lesions.

Tinea versicolor (pityriasis versicolor)

The lesions are macular, with fine scale and varying degrees of erythema. There may be hypo- or hyperpigmentation (Fig. 240.6). The usual site of involvement is the upper trunk and upper extremities. The eruption may occur at other sites, including the face, scalp, neck, palms and in areas of occlusion. In inverse tinea versicolor the flexural area may be involved.

Lesions of *Malassezia* folliculitis are generally seen on the trunk and upper extremities. The lesions are typically perifollicular, inflammatory papules and pustules that are often pruritic.

Candidiasis

The cutaneous and mucosal manifestations of candidiasis are varied and include oral candidiasis, balanitis and vulvovaginal candidiasis. Cutaneous candidiasis may colonize occluded areas or folds of the skin producing infection in flexural sites (*Candida* intertrigo), diaper dermatitis, inframammary dermatitis and infection in fingerweb areas (erosio interdigitalis blastomycetica). Clinical manifestations include erythema, scaling, maceration, and satellite vesicles and pustules. Candida miliaria may occur on the trunk of febrile patients after sweating.[28] Pustules or vesicles develop from which the organism may be recovered. A folliculitis may also occur, for example, in the perioral area.

Candida spp., particularly *C. albicans*, may be associated with nail infection. *Candida* paronychia is more common when there is frequent contact with water. Typically there is erythema, swelling and tenderness of the paronychial area. The cuticle may be separated from the surface of the nailplate. Application of gentle pressure on the paronychial surface can result in the expression of pus from underneath the proximal nailfold. Concomitant bacterial infection may be present. For example, with *Pseudomonas aeruginosa* infection a greenish discoloration of the nail can be expected. Uncommonly, distal and lateral subungual onychomycosis may be caused by *Candida* spp., particularly involving the fingernails. Congenital CMCC tends to feature both severe cutaneous candidiasis, including paronychia, and oral candidiasis, with manifestations usually seen in infancy or early childhood. *Candida* granulomas may be present. The nails may be thickened and dystrophic, with the entire nailplate being involved.

Onychomycosis

Onychomycosis is a fungal infection of the nailbed with secondary involvement of the nailplate. The five main types of onychomycosis are:

- distal and lateral subungual onychomycosis (DLSO; Fig. 240.7),
- superficial white onychomycosis (SWO),
- proximal subungual onychomycosis (PSO),
- endonyx onychomycosis (EO), and
- *Candida* onychomycosis (CO).

In DLSO the distal portion of the nail is infected initially with subungual hyperkeratosis and onychomycosis. In lateral onychomycosis the infection initially involves the lateral portion of the nailbed and nailplate. In DLSO the most common causative organism is *T. rubrum*. As DLSO has a similar clinical presentation whether caused by dermatophytes or nondermatophytes it is important to obtain a nail sample for mycologic examination so that the causative organism can be identified. In SWO the infection involves the superficial portion of the nailplate, the most common organisms being members of the *T. mentagrophytes* complex and *Aspergillus, Fusarium* and *Acremonium* spp. In PSO the infection initially involves the proximal

Figure 240-7 Onychomycosis (tinea unguium), distal and lateral subungual type. *Courtesy of Dr Natalie Roholt.*

nailbed and nailplate, with *T. rubrum* being the most common causative organism. Endonix onychomycosis, involving the nailplate but not the nailbed, is mainly caused by *Trichophyton soudanense*. [29] It gives affected nails a milky appearance without hyperkeratosis. Proximal white superficial onychomycosis is characteristically seen in patients who are immunocompromised, for example, those who have AIDS. *Candida* onychomycosis is typically found in patients who have CMCC. It may also occur in individuals who spend time with their hands in water, for example, bar-tenders or home-makers.

MANAGEMENT

In tinea capitis the causative organism should be identified whenever possible. If it is a zoophilic organism then the animal source should be treated. When the organism is anthropophilic, close contacts should be examined. Griseofulvin has been widely used to treat tinea capitis. The dose is 15–20mg/kg/day given for 6–8 weeks. In some countries a liquid formulation is available. Ketoconazole may have an efficacy similar to that of griseofulvin and has been used in patients who have responded poorly to griseofulvin. More recently terbinafine and itraconazole have been reported to be effective and safe. It may be possible to shorten the duration of therapy with the newer antifungal agents. Adjunctive measures may include cutting scalp hair short and using a shampoo such as ketoconazole or 2.5% selenium sulfide. If possible, old items of headgear should be discarded, the practice of sharing items such as caps and helmets discouraged and old combs thrown away or boiled in water, as appropriate.

With tinea barbae, tinea faciei, tinea corporis, tinea cruris and tinea pedis the source of infection should be identified and treated, whenever possible. In many instances the use of a topical antifungal agent such as an imidazole or an allylamine may suffice. Possible choices include ketoconazole, ciclopirox olamine or terbinafine creams. Some of the topical antifungal agents also have antibacterial and anti-inflammatory properties. Other topical antifungal agents, for example, tolnaftate and haloprogin, have a limited spectrum of activity. Generally, the topical antifungal agent should be applied over a small area beyond the active infection.

In instances in which the eruption involves a large area, when there is poor response (and the diagnosis has been confirmed to be a fungal infection), or if the infection involves the hair follicles and deeper cutaneous structures, then an oral agent should be considered. The traditional antifungal agent has been griseofulvin. In adults, ultramicrosize griseofulvin 330mg/day may be given for 2–4 weeks to treat tinea corporis and for 4–8 weeks in tinea pedis. In tinea pedis the dose may have to be increased to 330mg q12h. The newer antifungal agents itraconazole, terbinafine and fluconazole have also been reported to be effective. Itraconazole is a triazole that may be used as pulse therapy, 200mg/day for 1 week, to treat tinea corporis and tinea cruris. For tinea pedis the dosage of itraconazole pulse therapy is 200mg q12h for 1 week. Itraconazole may also be given as continuous therapy, 200mg/day for 2 weeks to treat tinea corporis and tinea cruris and for 4 weeks to treat tinea pedis. Terbinafine is an allylamine that is also effective in the treatment of tinea infections. The dosage regimen is 250mg/day given for 2–4 weeks to treat tinea corporis and tinea cruris and for 2–6 weeks when tinea pedis is present. In some instances a shorter duration of therapy may suffice. Reports of fluconazole used for the treatment of tinea infection suggest that a dose of 150mg once a week for 2–4 weeks may be beneficial.

For the management of onychomycosis, any co-existing tinea pedis should be identified and treated. The patient should be asked to cut the diseased nail as far back as possible, keep feet dry and clean, and wear socks made of absorbent material and, when possible, wear footwear that allows the feet to 'breathe'. The patient should use foot

---

powders judiciously and be encouraged to use appropriate footwear when walking on communal areas that may harbor a high density of fungal inoculum, for example swimming pools, gymnasium floors or health spas. Griseofulvin is a narrow-spectrum agent that is ineffective against *Candida* spp. and nondermatophyte molds. When griseofulvin is used to treat dermatophytes, cure rates have been low (3–30%) and relapse rates high (40–60%). Therapy for fingernail and toenail onychomycosis lasts for 6–9 months and 9–18 months, respectively. With the newer antifungal agents terbinafine, itraconazole and fluconazole the response rates are higher and treatment is given for a shorter duration. These agents have a favorable adverse effects profile. The recommended dosage for terbinafine is 250mg/day given for 6 and 12 weeks for fingernail and toenail onychomycoses, respectively. With itraconazole the dosage schedule is 200mg/day given as continuous dosing for 6 and 12 weeks for fingernail and toenail onychomycoses, respectively. When itraconazole is given as pulse dosing the treatment regimen is 200mg q12h for 1 week per month given for two and three pulses for fingernail and toenail onychomycoses, respectively. Fluconazole has been given as 150mg once a week for 7–12 months to treat toenail onychomycosis. Topical agents have recently received renewed attention as alternatives in the treatment of minimal-to-moderate onychomycosis. Traditional topical therapies produced less than desirable results in onychomycosis treatment; this may, in part, have been due to the method of application because creams, gels, powders and water- or oil-based lotions can easily be wiped, rubbed and washed off. Recently, with the development of nail lacquers such as amorolfine and ciclopirox, topical agents have shown increased efficacy rates and patient compliance. Amorolfine is available in many countries for the treatment of onychomycosis, but is not approved in the USA. Ciclopirox nail lacquer 8% is approved in the USA for the treatment of mild-to-moderate onychomycosis without lunula involvement. Surgical interventions such as nail avulsion may be considered as part of a combination therapy with antifungal drugs when a single nail is diseased; however, such procedures are used infrequently, particularly with the advent of the newer, more effective oral antifungal agents.

In tinea nigra, therapy includes topical azoles. Griseofulvin is ineffective. The management of piedra includes shaving the infected hair. Spontaneous remission may occur. Topical antifungal agents have been reported to be beneficial. The management of tinea versicolor includes topical products such as 2.5% selenium sulfide shampoo, ketoconazole shampoo, other topical azoles or terbinafine, and keratolytic agents. Griseofulvin and oral terbinafine are ineffective. Short-term therapies with ketoconazole and itraconazole may be effective. The management of candidiasis depends upon the particular clinical form and is covered in detail elsewhere (see Chapter 62 , and Chapter 111 and Chapter 126). [30]

Chapter 241 - Pneumocystis

Gunnar I Andriesse
Dana Milatovic

NATURE

Pneumocystis carinii was first described by Chagas, who misidentified the organism as the sexual state of *Trypanosoma cruzi*.[1] For years it was classified as a protozoon. However, detailed ultrastructural analysis and molecular analysis of 16S-like rRNA[2] and mitochondrial DNA from the organism revealed that it is phylogenetically closely related to the Ascomycetes and Basidiomycetes and thus is now classified as a fungus.

However, *Pneumocystis carinii* has features that are atypical for a fungus. It has the morphologic appearance of a protozoon: thick-walled cysts and amoeboid trophozoites. Furthermore, it contains only two copies of the rRNA gene, whereas most fungi contain hundreds of copies. It is resistant to antifungal agents affecting the outer sterol membranes of fungi (e.g. amphotericin or azole drugs) because it lacks ergosterol and contains cholesterol instead. Nevertheless, its similarity to fungi may ultimately prove therapeutically exploitable. In fact, the echinocandins that inhibit ß-glucan synthase of fungi are very effective in a rat model of *Pneumocystis* pneumonia.

It has become apparent that there is considerable genotypic and antigenic variation among *P. carinii* isolated from different host species and among *P. carinii* found in the same host species.[3] However, controversy remains as to whether these differences establish that multiple species of *P. carinii* exist. At present, the different variants of *P. carinii* are referred to as 'special forms'. Using a trinomial nomenclature system, human *P. carinii* is now known as *P. carinii* special form *hominis* (*P. carinii* sp. f. *hominis*). Until now, molecular epidemiologic studies have identified more than 50 genotypes of human-derived *P. carinii*.

The lack of an effective culture system for *P. carinii* has hampered efforts to study the antigenic composition of the organism. However, two antigen complexes have been identified that appear to be important in pathogenesis. The highly immunogenic major surface glycoprotein (MSG, also known as glycoprotein A or gp120) is encoded by a multicopy gene family. Expression of the MSG genes is regulated by a single expression site: the upstream conserved sequence (UCS). As a result the MSG shows considerable antigenic variation. This may be the mechanism enabling the organism to evade the host immune system. In fact, analysis of pulmonary samples of patients who had *Pneumocystis carinii* pneumonia (PCP) demonstrated that multiple MSG genes were expressed in a given host and that different patterns of MSG expression were seen among different patients.[4] Another glycoprotein that migrates in a 35–45kDa band appears to be important in eliciting humoral response to *P. carinii* in humans.[5]

EPIDEMIOLOGY

Serologic studies have shown that nearly 85% of all children undergo a *P. carinii* infection early in life, often being accompanied by mild respiratory symptoms.[6] [7] Up to now no environmental reservoir has been identified. Therefore it seems that humans are the only reservoir for *P. carinii* sp. f. *hominis*. As a result, for years the most accepted hypothesis for pathogenesis has been that the organisms remain latent within the lung until the host becomes severely immunocompromised and reactivation of *P. carinii* occurs. However, recent epidemiologic studies suggest that re-infection with *P. carinii* may also play a role.

The 'latency theory' is supported by several observations:

- *P. carinii* is carried in apparently healthy immunocompetent animals;
- refractoriness to grow in culture media suggests that it cannot grow outside of the mammalian host;
- host specificity implies co-evolution during long-term carriage; and
- *P. carinii* continuously changes its antigenic composition, which is consistent with the capacity for long-term carriage in an immunocompetent host.[3]

Although several studies using polymerase chain reaction (PCR) have demonstrated asymptomatic carriage of *P. carinii* in non-immunocompromised individuals,[7] [8] this does not necessarily prove long-term colonization.[9] Other data suggest that exposure to *P. carinii* can result either in direct clearance of the micro-organism from the airways, temporary latency or, depending on the immune status, in PCP. In the laboratory, immunosuppressed rodents acquire infection shortly after inhalation of *P. carinii*. Electrophoretic karyotyping identifies *P. carinii* in the lungs of naive animals as the same as those in chronically infected animals, from which infections are acquired.[10] When immunosuppression is withdrawn, these rats appear capable of clearing the organism completely from their lungs. Analysis of internal transcribed spacer (ITS) and mitochondrial large-subunit genes of *P. carinii* isolates in bronchoalveolar lavage (BAL) fluid from HIV patients during several episodes of pneumonia revealed that recurrence could also be attributed to de-novo infections.[11] [12] In approximately 50% of patients who had recurrent episodes of PCP, the sequence types observed at the second episode were different from those of the first, suggesting the occurrence of both reactivation of a previously acquired infection and re-infection from an exogenous source.[13] [14]

A finding complicating epidemiologic studies is that latency and infection are not monoclonal. Analysis using PCR of BAL specimens from 212 patients who had PCP revealed that 23% were infected with a single *P. carinii* genotype, 50% with two and 27% with more types.[15] [16] Moreover, the number of genotypes found in respiratory samples does not represent the number of genotypes found in autopsy lungs. These results suggest that there is heterogeneity and compartmentalization of *P. carinii* genotypes within the lungs.[17] [18]

The organism is probably not acquired from zoonotic sources because of host restriction based on distinct (anti)genetic subgroups.[19] Although *P. carinii* DNA has been found in samples of outdoor air, no environmental reservoir for *P. carinii* has been identified. Geographic studies of HIV-associated PCP cases have shown residential areas with significantly lower risks of PCP versus clustering of cases, suggesting an environmental factor.[20]

Studies using molecular techniques support person-to-person spread, which was suggested by earlier reports on clusters and

outbreaks of PCP among oncology and transplant patients.[21] *Pneumocystis carinii* DNA was detected in respiratory samples of health care workers and those with the closest occupational contact with patients who had PCP were more likely to have detectable *P. carinii* DNA.[22] Furthermore, analysis of air filters in hospitals suggests that transmission is airborne; corresponding genotypes were found in BAL specimens from PCP patients and air filters from their rooms.[23] [24] Currently available information justifies the isolation of patients who have PCP from individuals who are at increased risk of acquiring the infection.

PATHOGENICITY

In-vivo studies indicate that *P. carinii* is acquired by the airborne route. Once inhaled, the organism adheres to the type I alveolar cell of the lung and interacts with alveolar macrophages through the extracellular proteins fibronectin, vitronectin and surfactant protein D, which bind the MSG of *P. carinii* (Fig. 241.1). After several weeks of cortisone treatment, small clusters of *P. carinii* can be detected in alveolar spaces throughout the lungs of previously uninfected rats. Later, the alveoli become completely filled with organisms, suggesting that replication is slow but proliferation in the lung is extensive.

Two distinct morphologic forms of the organism are detected during infection. One is a small pleomorphic trophozoite that constitutes the majority of micro-organisms in

the lung and the other is a

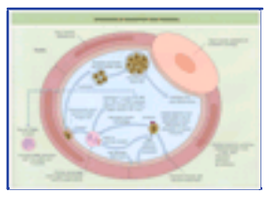

Figure 241-1 Pathogenesis of *Pneumocystis carinii* pneumonia. IFN, interferon; NO, nitric oxide; PMN, polymorph nuclear cell; SpA, surfactant protein A.

more mature, larger, thick-walled cyst that contains up to eight intra-cystic bodies. Examination of infected lung by light microscopy typically shows foamy alveolar exudate consisting of degenerative cell membranes, surfactant and host proteins (Fig. 241.2). A modest number of alveolar macrophages are present. As infection progresses, septal hypertrophy occurs and there is an accumulation of interstitial edema and mononuclear cell infiltration.[25] Pathophysiologic features have also been detected by electron microscopy and include subepithelial bleb formation resulting from increased alveolar-capillary permeability, degenerative changes in type-I alveolar cells and effacement of the basement membrane. Consequently, serum, fibrin and other proteins diffuse into the alveoli.[26]

Surfactant plays a major role in the pathogenesis of PCP; intra-tracheal instillation of surfactant improves oxygenation and pulmonary architecture in immunosuppressed laboratory animals with PCP. Furthermore, during experimental infection, there are alterations in phospholipid content of the surfactant (diminished phosphatidylcholine and increased sphingomyelin). This can be explained by the observation that the organism has uptake and catabolism of lipids[27] and that the surfactant protein A level, which regulates secretion and absorption of surfactant phospholipids, is increased. The exact relation of these changes to lung injury is unknown, although deficiency of surfactant phospholipids likely results in abnormalities in alveolar surface tension, lung distensibility and ventilation-perfusion matching. Surfactant protein A plays another role; it binds to the

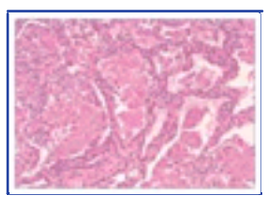

Figure 241-2 Hematoxylin and eosin stained section of lung tissue. Characteristic intra-alveolar foamy exudates can be seen in this patient, who has *P. carinii* pneumonia. *Courtesy of Michael Koss.*

mannose residue the MSG[28] and thereby enhances attachment of the organism to type I pneumocytes, interfering with the phagocytosis of *P. carinii* by alveolar macrophages.[29]

The physiologic consequences of these pathologic abnormalities include the early impairment of gas exchange because of increased alveolar-capillary permeability, which is measured by decreased membrane diffusing capacity of carbon monoxide and ultimately decreased compliance, total lung capacity and vital capacity. Lung function may be further impaired by the host inflammatory response. In severe combined immunodeficiency (SCID) mice with PCP, reconstitution of the immune system by bone marrow transplantation or infusion of $CD4^+$ lymphocytes resulted in clearance of *P. carinii* from the lungs[30] but also in early deaths from a hyperinflammatory local response. That the inflammatory response can be deleterious is also found in humans; a decrease in oxygenation occurs often soon after initiation of specific anti-*P. carinii* therapy that is blunted by adjunctive corticosteroids. Similarly, an increased number of neutrophils in BAL in patients is associated with a poor outcome.

Multiple studies have supported an important role for inflammatory mediators in the pathogenesis of PCP.[31] [32] [33] Production of interleukin (IL)-1, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor (TNF)-a, leukotriene B_4 and phospholipase A_2 are all increased in AIDS patients who have PCP. In individuals who have PCP, IL-8 is elevated in BAL fluid and correlates with BAL fluid neutrophilia, $P(A\text{-}a)O_2$ and severity of illness; therapy with corticosteroids resulted in a reduction in IL-8 levels.[34] Conversely, although TNF-a expression by alveolar macrophages is also decreased by corticosteroid administration, TNF-a appears to be essential in the host defense against *P. carinii*.[35]

Macrophages play an important role in clearing *P. carinii* from the lungs and preventing the development of PCP. *Pneumocystis carinii* is phagocytosed by the alveolar macrophages either after it is opsonized by specific antibodies (Fc-receptor mediated) or after binding by the mannose receptor (MR) to the MSG of *P. carinii*. Recent studies have demonstrated[36] [37] that alveolar macrophage MR activity is downregulated in HIV patients and that functional MR is shed from the macrophage cell surface. This soluble MR was detected in cell-free alveolar fluid from patients who had PCP, but not in alveolar fluid from healthy controls. When purified *P. carinii* organisms were incubated with soluble MR-containing supernatants, they were phagocytosed less readily by alveolar macrophages than were control organisms.[38] This suggests that *P. carinii* enhances the shedding of MR from the macrophage cell surface and binds to the 'free' MR, resulting in inhibition of phagocytosis.

In nude mice, SCID mice and medically immunosuppressed rodents, the common immunologic deficit predisposing these animals to PCP is severe depletion in T-cell function. Adoptive transfer of spleen T cells from phenotypically normal mice into *P. carinii* infected nude mice reduced lung cysts and resolved PCP.[39] Other adoptive transfer experiments established that helper L3T4 lymphocytes (equivalent to human $CD4^+$ lymphocytes) were necessary to reconstitute delayed-type hypersensitivity for *P. carinii* but suppressor lymphocytes were necessary for complete expression of resistance to the organism. Administration of monoclonal antibody to $CD4^+$ lymphocytes to conventional BALB/c mice and reconstituted SCID mice inoculated with *P. carinii* resulted in PCP and inability to eradicate the infection, respectively. These experiments all provide inferential evidence that depletion of $CD4^+$ lymphocytes is necessary for the development of PCP.

In humans who do not have HIV infection, PCP frequently occurs in association with lymphoreticular malignancies, certain congenital disorders and chemotherapy with ciclosporin or corticosteroids that have in common variable defects in T-cell function. By contrast, adults who have pure agammaglobulinemia rarely develop PCP. Most AIDS patients have $CD4^+$ lymphocyte counts in the range of 50–75/mm^3 at the time of their first episode of PCP, and more than 90% of episodes occur when counts are below 200/mm^3 . If patients who have less than 200 $CD4^+$ lymphocytes/mm^3 are not given prophylaxis, the risk of developing PCP is 8.4% at 6 months, 18.4% at 12 months and 33.3% at 36 months. Thus, diminished T cell function and/or numbers is most likely the critical immune deficit necessary for this opportunistic infection to occur.

Recent studies suggest that antibodies may also be important components of host defense to *P. carinii*.[40] In adoptive transfer of T cells and spleen cells from immunocompetent donors into SCID mice, B cells were necessary, in addition to T cells, for recipient mice to resolve pre-existing PCP. Both in mice and humans, intense reactivity of monoclonal antibodies from tracheobronchial lymph node B-cells[41] and a serum antibody response were found[5] following recovery from PCP. In HIV-infected patients both local antibodies (IgA) and the serum antibody levels were lower and the ability to mount an antibody response to the *P. carinii* infection was impaired, suggesting that the poor antibody response may contribute to the tendency of HIV-infected patients to have PCP.[42] [43] Thus, although T-cell-mediated immunity may be the central component of the host response to *P. carinii*, humoral immunity may also have an important role in certain aspects of protection against infection.

CLINICAL MANIFESTATIONS

The clinical manifestations of PCP in patients who do not have AIDS are similar to those in AIDS patients (covered in detail in Chapter 124). Although there can be great variability, non-AIDS patients typically present more acutely, often within days of their initial symptoms.[44] Up to 20% of patients who have corticosteroid-associated PCP present during stable dosing with corticosteroids, but severe symptoms typically appear abruptly upon rapid tapering of corticosteroid therapy. These events probably represent activation of immune mechanisms that had been inhibited by the high doses of corticosteroids.

The cardinal symptoms are fever, cough and shortness of breath. [44] [45] Early in the course of the disease, dyspnea may occur only on exertion and careful questioning is required to elicit a recent decrease in exercise tolerance. Cough is typically nonproductive, but small amounts of clear sputum are common, whereas purulent sputum and hemoptysis are rare in the absence of concurrent infection. Chest tightness and a dull retrosternal ache that is worse with inspiration may also occur.

Physical examination may be completely normal, particularly in individuals who have mild disease. Tachypnea, tachycardia and respiratory distress tend to signify advanced disease and a poorer prognosis.

Chest radiographs typically demonstrate fine, bilateral interstitial infiltrates extending from the hilum, but this appearance may be seen with many other pneumonias.

Normal or minimally abnormal radiographs may occur early in disease or in lung transplant recipients.[46] Atypical radiographic abnormalities have been frequently reported in

AIDS patients but also occur in non-AIDS patients and include localized or unilateral infiltrates, cavitary, cystic or honeycomb lesions, hilar enlargement with lymphadenopathy, spontaneous pneumothorax, predominant upper lobe disease, solitary nodules, small pleural effusions and linear opacities.[47] Dissemination to brain, kidney, adrenal and thyroid glands, liver, intestines, spleen and eye have been reported and require biopsy for definitive diagnosis. A high index of suspicion and appropriate stains of any involved organ will yield the diagnosis.

No single routine laboratory test either excludes or is pathognomonic for PCP. Elevated serum lactic dehydrogenase (LDH) and eosinophilia[48] are frequently found, particularly during severe episodes, but these tests are non-specific and there are multiple other causes for eosinophilia or raised LDH levels in immunocompromised individuals. Impaired oxygenation is frequently present and, when arterial blood gases are normal, diffusing capacity for carbon monoxide, arterial oxygen saturation during exercise and gallium scintigraphy are potentially helpful tests but are non-specific. The diagnosis ultimately depends on demonstration of the organism in respiratory secretions or lung tissue (see Diagnostic microbiology, below). Patients who have very low $CD4^+$ counts (<100 cells/mm^3) and/or BAL neutrophilia have a poorer prognosis. The overall mortality of PCP in both HIV and non-HIV patients is approximately 40%.[49]

DIAGNOSTIC MICROBIOLOGY

Bronchoscopy with BAL is the diagnostic procedure for obtaining pulmonary secretions with which all other tests are compared. Bronchoalveolar lavage involves wedging the bronchoscope into a peripheral nondependent airway (usually the right middle lobe), instilling 100–250ml non-bacteriostatic saline as 20–30ml aliquots and aspirating fluid after each aliquot is instilled. When approximately 50ml of fluid has been recovered, the specimen is centrifuged and the pellet is stained for *P. carinii*. In 86–97% of patients, *P. carinii* organisms are detected by this procedure.

Several approaches may improve yield. Bilateral BAL resulted in a diagnosis in 31 (94%) out of 33 patients compared with 51 (84%) out of 61 historical control patients undergoing BAL only on one side.[50] Similarly, the combination of multiple-lobe, site-directed BAL plus monoclonal antibody staining increased diagnostic yield from 80% to 98%.[51] In patients who had focal infiltrates, the combination of site-directed BAL and transbronchial biopsy led to a diagnosis in 90% of patients who had a prior nondiagnostic BAL.[52]

In contrast to BAL, induced sputum specimens are easily obtained by ultrasonic nebulization of hypertonic saline, although care must be taken because many patients experience arterial oxygen desaturation during the procedure. When the sediment is appropriately stained and slides are reviewed by experts, the procedure has a sensitivity of 15–94% with corresponding negative predictive values that have also varied widely (39–96%). The procedure is laborious for respiratory therapists, but positive results usually obviate the need for bronchoscopy. Fluorescent staining with monoclonal antibodies for *P. carinii* (Fig. 241.3) may increase the yield to over 90%.[53] With the use of PCR techniques, the sensitivity of induced sputum examination may approach that of BAL (see below).

As for BAL, the yield of induced sputum may be lower for patients receiving aerosol pentamidine because the numbers of organisms may be reduced. In one study of 54 patients, the diagnosis was confirmed by induced sputum in 64% of those receiving aerosol pentamidine compared with 92% of those not receiving the aerosol (p <0.02).[54] By contrast, the respective yields were 63% compared with 64% in another trial. [55]

When transbronchial biopsies are obtained without crush artefact and contain at least 25 alveoli, the diagnostic yield is similar to that

Figure 241-3 Monoclonal immunofluorescent stain. Monoclonal immunofluorescent stain of a BAL specimen (Merifluor stain) demonstrating *P. carinii* cysts that stain with a characteristic apple-green fluorescence. *With permission from Meridian Diagnostics.*

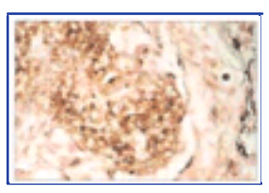

Figure 241-4 Gomori's methenamine silver stain of lung tissue. Gomori-stained section of lung tissue showing characteristic *P. carinii* cysts.

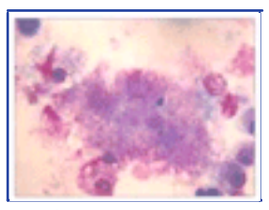

Figure 241-5 Wright-Giemsa stain of sputum. Wright-Giemsa stained specimen of an induced sputum specimen showing clusters of *P. carinii* organisms. *Courtesy of Maria Appleman.*

of BAL. If both BAL and transbronchial biopsies are obtained, the diagnostic sensitivity is additive and approaches 100%. However, pneumothoraces or bleeding may occur in up to 10% of patients undergoing bronchoscopic biopsy. Thus, many pulmonologists prefer to perform only BAL with the initial bronchoscopy. If the first procedure is nondiagnostic, BAL is repeated and transbronchial biopsies are obtained if coagulation indices permit. However, one study using monoclonal antibody staining suggests that biopsy does not increase the yield of BAL and may only increase the chance of complications. [50]

Open lung biopsy can also lead to the diagnosis of PCP but is rarely needed because of the high yield with sputum induction and BAL. It is usually reserved for patients in whom bronchoscopy has been non-diagnostic because of technical problems with the procedure or where transbronchial biopsies are contraindicated because of bleeding disorders or concurrent management with mechanical ventilation.

Traditionally Gomori's methenamine silver stain is used to identify *P. carinii* cysts in patient samples (Fig. 241.4). Its diagnostic sensitivity and specificity both generally exceed 95%. However, up to 10% false negatives may occur. The procedure requires 4–6 hours but modifications have reduced processing time to 1–2 hours. The cyst wall can also be stained by toluidine blue, with the advantage that it is more rapid than standard silver stains.

Wright-Giemsa (Fig. 241.5) and Diff-Quik stains have been used to stain trophozoites, nuclei of cysts and intermediate forms and can be

completed within 30 minutes. However, organisms will be missed in 10–15% of cases. The methodology also allows polymorphonuclear neutrophils to be identified in BAL fluid, a finding associated with more severe impairment in pulmonary physiology and lower survival.

Direct and indirect immunofluorescent staining using monoclonal antibodies (Fig. 241.3) are highly sensitive, with yields in excess of 90% for BAL specimens,[51] [53] and are more sensitive for sputum samples than silver or Wright-Giemsa stains. Although false positives occasionally occur, this has become the diagnostic procedure of choice in many clinical laboratories.

The development of the PCR has increased the sensitivity of detection of *P. carinii* in patient samples substantially. Consequently, the PCR can also yield a positive result in asymptomatic individuals who are colonized by *P. carinii*. In several studies analysis of respiratory samples by PCR (single and nested) revealed higher

numbers of false-positive results and lower positive-predictive values than microscopy for non-HIV immunocompromised and immunocompetent patients. Even with HIV patients, in whom the differences between the diagnostic results of microscopy and single and nested PCRs were quite marginal, microscopy and single PCR performed better than nested PCR with regard to specificity and positive predictive value.[56] [57] [58] [59] Although the PCR technique has no additional value in analysis of BAL fluid, it can improve diagnostic sensitivity of induced sputum and oral washes up to the same level as that of BAL specimens.[60] [61] [62] At present, it appears reasonable to reserve PCR for epidemiologic research and diagnosis in induced sputum and oral wash specimens that prove negative by immunofluorescence.

PREVENTION

The indications for primary and secondary chemoprophylaxis of PCP in HIV-infected patients are well known and are covered in Chapter 123 and Chapter 124 . In HIV-negative immunocompromised patients no general guidelines for PCP prophylaxis exist and the decision to administer prophylaxis depends on the degree and duration of the immunosuppression and on local institutional trends in PCP incidence. Patients at risk for PCP for whom chemoprophylaxis should be considered include:

- those who have primary immunodeficiency;
- those who have severe malnutrition;
- after organ transplantation;
- those who have persistent $CD4^+$ counts of below $200/mm^3$; and
- in cytotoxic or immunosuppressive treatment of cancer, connective tissue disorders and other diseases.[63] [64]

The incidence of PCP is highest during the first year after solid organ transplantation, except for patients who have lung transplants, who continue to have higher risks more than a year after transplantation.[65] The risk of PCP in transplant patients is also increased in cases of invasive cytomegalovirus disease, during intensive immunosuppression for allograft rejection (corticosteroids) and during periods of neutropenia.[66] [67] Prophylaxis should also be considered for more than 1 year after bone marrow transplantation for patients receiving corticosteroids as well as in those who have hematologic relapse or extensive chronic graft-versus-host disease.[68] Corticosteroids are recognized as an independent risk factor if given for longer than 4 weeks at a level equivalent to 20mg of prednisone (prednisolone) daily.[69] In non-HIV patients, determination of $CD4^+$ lymphocyte counts can help to identify patients who are at risk for PCP; 91% of patients have fewer than 300 $CD4^+$ lymphocytes/mm^3 at the time of diagnosis of PCP.[70] [71]

First choice of prophylaxis consists of one double-strength (960mg) tablet of trimethoprim-sulphamethoxazole (TMP-SMX) per day.[72] [73] One single-strength tablet (480mg) daily or one double-strength tablet three times per week is also effective. For pediatric patients who have acute lymphoblastic leukemia, TMP-SMX (150mg/m^2 TMP plus 750mg/m^2 SMX, to a maximum of 160mg TMP and 800mg SMX) given q12h for three consecutive days per week has similar efficacy to daily administration.[74] Regimens of TMP-SMX would also be expected to provide some protection against toxoplasmosis, *Nocardia asteroides, Listeria monocytogenes*, bacterial pneumonia and urinary tract infections. Some patients have to discontinue TMP-SMX prophylaxis because of adverse reactions (mostly gastrointestinal symptoms and skin rashes). For these individuals dapsone (100mg/day) alone, or dapsone (50mg/day) in combination with pyrimethamine (50mg/week) and leucovorin (25mg/week) could be an alternative.[75] [76] Aerosolized pentamidine (300mg once per month) may also be effective, but is more expensive.[72] [72] [77] Atovaquone suspension (1500mg or 750mg daily) has also proven effective after bone marrow and liver transplantation respectively.[78] [79] Other drug regimens have been considered but there is insufficient evidence to recommend their use.

Furthermore, judging from the current state of knowledge about the epidemiology and transmission of *P. carinii*, direct contact of PCP patients with other immunocompromised patients should be avoided.

MANAGEMENT

The management of patients who have AIDS-associated PCP is covered in detail in Chapter 124 . In HIV-negative patients, management should consist of TMP-SMX in a dosage of 15–20mg/kg/day TMP and 75–100mg/kg/day SMX in three or four divided doses (orally or intravenously). Initially, therapy should be given intravenously until clinical improvement ensues and the patient is able to tolerate oral intake well. Therapy should be continued for 21 days; shorter courses of therapy (i.e. 14–17 days) should be reserved for patients who have mild disease or who respond rapidly. Adverse events are considerably less common in non-AIDS patients[44] and include rash, fever, nausea and vomiting, leukopenia and hepatitis.

Sulfamethoxazole inhibits dihydropteroate synthase (DHPS) in the folic acid synthesis pathway. Although mutations in the DHPS genes are found more in patients who are taking sulfa or sulfone prophylaxis,[80] [81] [82] they are not invariably associated with failure of treatment or prophylaxis. Likewise, the majority of patients who have mutations respond well to sulfa or sulfone therapy. [82] [83]

Intravenous pentamidine is the primary alternative agent for non-AIDS patients who are intolerant of TMP-SMX. The standard dosage is 4mg/kg q24h. Because of problems with pain and sterile abscesses, the intramuscular route should not be used. Adverse events are common and occasionally life-threatening. They include hypotension, nausea and vomiting, ventricular dysrhythmias, renal failure, pancreatitis, hypoglycemia, hyperglycemia/diabetes mellitus (which can be permanent and require chronic insulin therapy), leukopenia, thrombocytopenia and hypocalcemia.

Trimethoprim-dapsone, clindamycin-primaquine, atovaquone and trimetrexate are proven alternatives for the treatment of PCP in AIDS patients but have not been studied in non-AIDS patients. Similarly, the role of adjunctive corticosteroids for non-AIDS PCP has not undergone controlled prospective investigation. As the pathogenic mechanisms are likely to be similar for HIV and non-HIV patients, it would be reasonable to consider use of prednisone (40mg q12h for 5 days, 40mg q24h for 5 days, then 20mg q24h for the remainder of the duration of PCP therapy) for any severely ill patient (PO_2 <70mmHg or (P(A-a)DO_2 >35mmHg).[84] For indivi-duals who develop symptomatic PCP upon tapering of ongoing corticosteroid therapy, a resumption of the previous dose of corticosteroids should be considered during their initial antimicrobial therapy, with subsequent tapering after clinical improvement occurs.

Development of future treatments may include artificial surfactant, deferoxamine or echinocandins.

Chapter 242 - Protozoa: Intestinal and Urogenital Amebae, Flagellates and Ciliates

Lynne S Garcia

This chapter discusses the amebae, flagellates and ciliates that parasitize the intestinal and urogenital systems of humans (Table 242.1). With the exception of *Trichomonas vaginalis*, all of the organisms live in the intestinal tract. Intestinal protozoa vary in pathogenicity and prevalence but, with rare exceptions, all have a worldwide distribution.

NATURE

Amebae, flagellates and ciliates are single-celled eukaryotic organisms belonging to the subkingdom or phylum Protozoa. In general, the organisms related to human infection change their form and function from the active, feeding trophozoites to the resting cyst form. All protozoa contain a nucleus, often with a karyosome near its center. The cytoplasm is composed of the endoplasm, which immediately surrounds the nucleus, and the ectoplasm, which functions as the locomotion apparatus. Reproduction is relatively simple and is accomplished through repeated asexual multiplication by binary fission. Currently, it is not completely clear whether *Blastocystis hominis* should be classified with the protozoa or is actually a fungus-like organism within the stramenopile group; however, it will be discussed in this chapter. [1]

EPIDEMIOLOGY

Intestinal amebae, flagellates and ciliates are transmitted through fecally contaminated food, water or other materials. Prevalence is correlated with socio-economic conditions and higher infection rates occur in people who have poor personal hygiene or who live in areas with poor sanitation. Contaminated water supplies are a particular problem because the usual levels of chlorination may not kill cysts. Filtration is required. Endemic and epidemic disease has been traced to water supplies that use surface water which either is not filtered or has improperly functioning filters.

These organisms generally have a cystic stage that develops when conditions in the environment are unfavorable for continued multiplication. The cyst wall is thicker than the trophozoite membrane and thus provides protection. Once these cysts have been transferred to a new host, usually by fecal-oral contamination from person to person, the organisms excyst. Excystation factors include osmotic changes in the environment, enzymatic action of the enclosed organism on the inner surface of the cyst wall and, among the parasitic protozoa, favorable pH and enzymatic action of the host tissues. Transmission of those protozoa with no identified cyst stage has not been totally explained.

Entamoeba histolytica

Infections with *E. histolytica* are seen worldwide and are more prevalent in the tropics. In 1997, over 500 million people were estimated to be infected with *E. histolytica*, 50 million had extensive symptoms, including colitis or extraintestinal abscesses, and there were 100,000 deaths.[2] For every case of invasive disease diagnosed, there are at least 10–20 asymptomatic individuals excreting infective cysts. Population groups with a higher incidence of amebiasis include people from the developing world or recent immigrants from there to the developed nations.

Social changes seen in the late 1960s — open expression of homosexuality, increased sexual contacts, increased frequency of sexual activities and anonymity of sexual partners — contributed to dramatic increases in sexually transmitted organisms, including *E. histolytica*. A number of clinical syndromes have been recognized and referred to as 'the gay bowel syndrome'. Published reports confirm that *E. histolytica* is one of the major pathogens in the gay bowel syndrome. However, some feel that this term 'gay bowel syndrome' is neither gay specific, confined to the bowel, nor a syndrome.[3] Clinical presentations within the homosexual community often differ from those seen in the heterosexual population and almost 50% of all homosexual men found to be infected with *E. histolytica* are asymptomatic. Studies have confirmed the lack of correlation between symptoms and the presence of *E. histolytica* in this risk group.[4] However, it is an accepted fact that the ameba morphologically identified as *E. histolytica* is actually two separate and distinct species. *E. histolytica* is the pathogenic species and is considered the etiologic agent of amebic colitis and extraintestinal amebiasis, while *E. dispar* is the nonpathogenic species and does not invade tissue or cause intestinal symptoms. This may explain the lack of correlation between symptoms and the presence of the morphological identification of *E. histolytica* in the group of homosexual men studied. Therefore, in epidemiologic studies prior to the development of specific reagents for the identification of true *E. histolytica*, those organisms identified as *E. histolytica* were actually *E. histolytica/E. dispar*.

Epidemiologic evidence of sexual transmission of *E. histolytica* has grown significantly since the early 1970s, particularly in New York City and San Francisco. In San Francisco, the incidence of reported symptomatic intestinal amebiasis increased by over 1000% from 1978 to 1988 among homosexual men between 20 and 39 years of age.[4] It appears that approximately 30% of urban homosexual men may be infected with *E. histolytica* (*E. histolytica/E. dispar*), a sharp increase over the estimated rate of less than 5% seen in the general population within the USA. Direct oral-anal contact (anilingus) leads to fecal exposure and oral contact with a variety of intestinal pathogens. Although anilingus has been listed as a key risk factor in potential exposure, transmission can also occur during oral-genital sex after anal intercourse has occurred. Active heterosexuals can acquire infection with *E. histolytica* through sexual activities that provide an opportunity for fecal-oral contamination. The key factor is not necessarily homosexuality, but the frequency of sexual activity and potential for fecal-oral contact. In a more recent study from Japan, symptomatic amebiasis in the east-south east area of Tokyo is a disease that predominantly afflicts males and the high rates of patients who engaged in male homosexual or bisexual practices suggest that amebiasis is likely to be a sexually transmitted disease in homosexual or bisexual men. These infections were confirmed to be true *E. histolytica*, primarily zymodeme II.[5]

TABLE 242-1 -- Amebae, flagellates and ciliate that parasitize the intestinal and urogenital systems of humans.

AMEBAE, FLAGELLATES AND CILIATE THAT PARASITIZE THE INTESTINAL AND UROGENITAL SYSTEMS OF HUMANS		
Type	**Species**	**Pathogenicity***
Amebae	*Entamoeba histolytica*	+

	Retortamonas intestinalis	-
Ciliate	*Balantidium coli*	+

* Pathogenic = +; nonpathogenic = -; ± = pathogenicity controversial
† Body site: mouth
‡ Body site: urogenital system

With the advent of AIDS and the subsequent modifications in sexual practices within homosexual communities, the incidence of *E. histolytica* infection has decreased. In recent years, the increased incidence of disease caused by coccidian parasites, *Isospora belli* and *Cryptosporidium parvum* and the microsporidia, *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* has become much more of a problem in patients who have AIDS.

In certain urban areas (Mexico City, Mexico; Medellin, Colombia; and Durban, South Africa), the incidence of invasive disease is considerably higher than in the rest of the world. Contributing factors may include poor nutrition, tropical climate, decreased immunologic competence of the host, stress, altered bacterial flora in the colon, traumatic injuries to the colonic mucosa, alcoholism and genetic factors.

The human is the reservoir host for *E. histolytica/E. dispar* and can transmit the infection to other humans, primates, dogs, cats and possibly pigs. The cyst stages are very resistant to environmental conditions and remain viable in the soil for days. The asymptomatic cyst passer who is a food handler is thought to play the most important role in transmission.

It has been postulated that a colonization-blocking vaccine could eliminate *E. histolytica* as a cause of human disease, particularly as humans serve as the only significant reservoir host, and a number of potential protective antigens are being investigated.[6] [7] [8]

Blastocystis hominis

Blastocystis hominis is probably transmitted via the fecal-oral route through contaminated food or water; the cysts survive in water for up to 19 days at normal temperatures.[9] [10] Although other modes of transmission are not defined, the incidence and apparent worldwide distribution suggest the traditional route of infection. Prevention would involve improved personal hygiene and sanitary conditions.

Giardia lamblia (intestinalis)

Although some authorities have changed or are considering a species name change to *G. intestinalis*, we have decided to maintain *G. lamblia* for this chapter. Transmission is by ingestion of viable cysts, and contaminated food and drink are the usual sources. This infection is found most frequently in children or in groups that live in close quarters.[11] [12] Also there may be outbreaks caused by poor sanitation facilities or breakdowns; travelers and campers often experience such outbreaks.[13] [14] There is also an increase in the prevalence of giardiasis in the male homosexual population, probably as a result of anal and/or oral sexual practices.[15]

Decreased gastric acid production may predispose people to infection with *G. lamblia*. Normal gastric acidity may act as a barrier to infection; patients who have had a gastrectomy are prone to infection with *G. lamblia*. Reduction in gastric acid also occurs as a result of malnutrition and both factors may, as a group, increase susceptibility to infection with this organism. Impairment of the host's immune system may also play a role.

Lower incidence of giardiasis in infants up to 6 months of age may be associated with breast-feeding and some protection against infection via secretary IgA; however, lower incidence may also be related to a decreased exposure to *G. lamblia* in breast-fed infants.

Giardiasis is one of the common causes of travelers' diarrhea and is worldwide in distribution. Visitors in areas endemic for *Giardia* spp. are more likely to become symptomatic than the inhabitants of that area; this is probably because the latter have developed immunity from previous, and possibly continued, exposure to the organism. A number of outbreaks in the USA have been attributed to resort or municipal water supplies, such as Oregon, Colorado, Utah, Washington, New Hampshire and New York.[16] [17] [18] High infection rates were also reported from hikers and campers who drank stream water. Because some of these areas were remote from human habitation, infected wild animals, especially the beaver, were suspected of being the source.[13] [17] [19] [20] [21] Surveys show human infection rates of 2–15% in various parts of the world.

Because of potential wild animal reservoirs and possible domestic animal reservoir hosts, measures in addition to personal hygiene and improved sanitation have to be considered.[22] [23] Iodine is recommended as an effective disinfectant for drinking water, but it must be used according to directions.[24] [25] Filtration systems have also been recommended, although they have certain drawbacks, such as clogging.

Isoenzyme studies, used for parasite identification and classification, have provided information related to organism pathogenicity, possible implication in water-borne outbreaks and the potential cause of human disease. The examination of isoenzyme patterns of *G. duodenalis* (*G. lamblia*) obtained from humans and animals showed no obvious correlation between clinical symptoms and isoenzyme patterns. These studies also demonstrated significant differences between isolates from within a single region and those from other distant geographic locations.[26] [27]

Dientamoeba fragilis

Dientamoeba fragilis infection is commonly associated with enterobiasis and it has been suggested that *D. fragilis* may infect *Enterobius* spp. eggs and thus bypass gastric acidity. Although clinical infections with *D. fragilis* occur, they are not often reported. This is probably because the infection is self-limiting, stool examination is not requested and laboratory identification is difficult. The incubation period for clinical disease is not clearly defined.

Trichomonas vaginalis

Infection with *T. vaginalis* is acquired primarily through sexual intercourse; asymptomatic men therefore need to be diagnosed and treated. The organism can survive for some time in a moist environment such as damp towels and underclothes; however, this mode of transmission is thought to be very rare.

Balantidium coli

Domestic pigs are probably the most important reservoir host for human infection with *B. coli*. In areas in which pigs are the main domestic animal, the incidence of human infection can be quite high (e.g. New Guinea). Human infection is fairly rare in temperate areas, although once the infection is established, it can develop into an epidemic, particularly when environmental sanitation and personal hygiene are poor. This situation has been seen in mental hospitals in the USA. Preventive measures involve increased attention to personal hygiene and sanitation, as the mode of transmission is ingestion of infective cysts through contaminated food or water.

PREVENTION

Transmission of the majority of the intestinal protozoa occurs through ingestion of infective cysts, which can be acquired from food, water and person to person by the fecal-oral route. These infections tend to be found more frequently in groups that live in close quarters or in certain population groups. There may be outbreaks due to poor sanitation facilities or breakdowns as evidenced by infections in travelers and campers; certainly this has been found for giardiasis. Although amebiasis is usually associated with poor sanitation and underdeveloped areas of the world, sexual transmission has also been documented, mainly among urban homosexual men. Prevention in this group is directly related to limiting sexual practices that provide an opportunity for fecal-oral contamination. The single most effective practice that prevents the spread of infections with intestinal protozoa, particularly in the childcare setting, is thorough handwashing by the children, staff and visitors. In the case of *D. fragilis*, it has been suggested that the trophozoites may infect *Enterobius* spp. eggs, thus allowing protection from gastric acidity; however, under most circumstances, total prevention of enterobiasis and/or infection with *D. fragilis* is neither realistic nor possible. *T. vaginalis* is acquired primarily though sexual intercourse, hence the need to diagnose and treat asymptomatic males. The organism can also survive for some time in a moist environment such as damp towels and underclothes; however, this manner of transmission is considered rare.

Although incomplete epidemiologic investigation and reporting make it difficult to determine the significance of the water-borne transmission of giardiasis accurately, the water-borne route seems to be more important for this protozoan than for other more commonly recognized water-borne pathogens, with the possible exception of *Cryptosporidium parvum*. Iodine has been recommended as an effective disinfectant for drinking water, but it must be used according to directions. Because of the potential for wild animal and possibly domestic animal reservoir hosts related to *Giardia* spp., measures in addition to personal hygiene and improved sanitary measures have to be considered and implemented. If appropriate procedures are followed, conventional water filtration should trap most protozoan parasites, including *Giardia*. One should avoid swallowing water when in lakes, rivers, pools or hot tubs; also do not drink directly from lakes, rivers, streams or springs. Filtration devices

for hikers and campers are also available; however, one should look for 'reverse osmosis', 'absolute 1 micron', 'Standard 53', and the words 'cyst reduction' or 'cyst removal'. Boiling water, at a rolling boil, for 1 minute is sufficient to kill organisms, including *Giardia* spp. and *Cryptosporidium* spp. It is also important to thoroughly wash all fruits and vegetables if eating uncooked, use safe water for washing food, peel fruit and avoid unpasteurized milk or dairy products.

PATHOGENICITY

Some of the intestinal protozoa are nonpathogenic and produce no disease; however, microscopists must be able to distinguish pathogenic from nonpathogenic species. The presence of nonpathogenic species indicates that the person has been exposed to fecal contamination. Several species can cause mild to severe gastrointestinal symptoms, and *E. histolytica* may produce extraintestinal lesions. However, pathogenic or potentially pathogenic protozoa do not always produce symptoms or they may remain after symptoms have resolved. Asymptomatic individuals may serve as reservoirs for the infection. Detection of a potentially pathogenic protozoan does not necessarily prove that the organism is causing the illness. Patients may have diarrhea caused by other organisms such as *Salmonella* spp., *Shigella* spp., *Escherichia coli* or rotavirus. The pathogenicity of some species (e.g. *B. hominis*) has been questioned and *E. histolytica* is now considered to be two separate organisms, one pathogenic (*E. histolytica*) and one nonpathogenic (*E. dispar*). *Trichomonas vaginalis*, a urogenital flagellate, is also considered pathogenic and may cause mild to severe vaginitis and other urogenital problems.

Entamoeba histolytica

Although many people worldwide are infected with *E. histolytica*, only a small percentage develops clinical symptoms. Morbidity and mortality caused by *E. histolytica* vary, depending on geographic area, organism species (*E. histolytica* vs *E. dispar*) and the immune status of the patient.

In 1961, with the development of successful axenic culture methods requiring no bacterial co-culture, sufficient numbers of organisms could be obtained for additional studies. Approximately 15 years later, reports indicated that *E. histolytica* clinical isolates could be classified into groups using starch gel electrophoresis and review of banding patterns related to specific isoenzymes. [28] The four isoenzymes are glucophosphate isomerase (GPI), phosphoglucomutases (PGM), malate dehydrogenase (ME) and hexokinase (HK), indicating that there are pathogenic and nonpathogenic strains (zymodemes) of *E. histolytica*. On the basis of analysis of thousands of clinical isolates, the zymodeme patterns were thought to be genetic rather than phenotypic.

During the 1980s and 1990s several publications reviewed the issues regarding pathogenic *E. histolytica* versus nonpathogenic *E. dispar*. On the basis of current knowledge, pathogenic *E. histolytica* is considered to be the etiologic agent of amebic colitis and extraintestinal disease, whereas nonpathogenic *E. dispar* produces no intestinal symptoms and is not invasive in humans. [29] [30] [31] Diamond & Clark[32] redescribed the two species as *E. histolytica* (Schaudinn 1903), which is the invasive human pathogen, and *E. dispar* (Brumpt 1925), which is noninvasive and does not cause disease.

Blastocystis hominis

In spite of the published literature, the true role of this organism in terms of colonization or disease and the relevance of organism numbers are still somewhat controversial. In one recent study of patients with irritable bowel syndrome, there was a set of patients in whom the presence of *B. hominis* did not appear to be incidental.[33] The first report of a possible relationship between intestinal obstruction and a concomitant *B. hominis* infection has also been published recently. [34] In patients with other underlying conditions, the symptoms may be more pronounced.[35] There is evidence to indicate there are several ribodeme types and there may be a relationship between ribodeme type and pathogenicity, only some of which will be responsible for increased intestinal permeability and symptoms.[36] [37]

Giardia lamblia (intestinalis)

The majority of individuals infected with *G. lamblia* are asymptomatic. Preliminary studies indicate that there may be two different strains of *G. lamblia*, group A and group B, associated with different degrees of virulence. Group A appears to be more pathogenic and is associated with symptomatic infection. Isoenzyme and molecular studies also support the differences between these two groups.[38] [39] [40]

Dientamoeba fragilis

Although its pathogenic status is still not well defined, *D. fragilis* has been associated with a wide range of symptoms. This uncertainty could be due in part to the existence of pathogenic and nonpathogenic variants. Evidence for two genetically distinct forms has been obtained using PCR-restriction fragment length polymorphism analysis of ribosomal genes.[41] [42]

Trichomonas vaginalis

T. vaginalis is site specific and usually cannot survive outside the urogenital system. After introduction, proliferation begins, with resulting inflammation and large numbers of trophozoites in the tissues and the secretions. Nutrient acquisition and cytoadherence, immune system evasion and regulation of virulence genes are virulence factors associated with pathogenesis. [43] It appears that interference with trichomonads, mucin receptors and proteinases may form a strategy to prevent colonization with this pathogenic flagellate.[44]

DIAGNOSTIC MICROBIOLOGY

Because intestinal symptoms are non-specific, diagnosis requires laboratory identification of the organisms present. Immunodiagnostic methods for antibody detection are useful for the diagnosis of extraintestinal amebiasis, but their utility is limited for intestinal disease.

Organism morphology varies and species characteristics often overlap. For reliable identification, microscopists must be able to differentiate all species regardless of their potential for causing disease. Special attention will be given to the clinically significant intestinal pathogens, especially *E. histolytica*, *B. hominis*, *G. lamblia*, *D. fragilis* and *B. coli*.

Identification of amebae in fecal specimens

Trophozoites and cysts are diagnostic stages of the amebae and either or both stages can be detected in feces. Microscopists must be able to distinguish trophozoites and cysts from epithelial cells, polymorphonuclear leukocytes and macrophages, as well as from pus cells, yeasts, pollen, moulds, and vegetable and crystalline artefacts.

Trophozoite motility in physiologic saline mounts of fresh material and cytoplasmic inclusions, such as erythrocytes in trophozoites and chromatoid bodies in cysts, can be observed. Iodine solutions are used for temporary cyst stains of fresh or fixed specimens. Cyst characteristics are less variable than those of trophozoites and species of cysts can often be identified in iodine-stained wet mounts. However, examination of permanent stained smears using oil immersion (×1000) is recommended for definitive identification of trophozoites and cysts. Size is not a reliable feature for species differentiation of either trophozoites or cysts except when separating *E. histolytica/E. dispar* from *E. hartmanni*.

The microscopist must observe the cytoplasmic and the nuclear characteristics of several organisms before making a final identification. Although cysts are more easily identified than trophozoites, several cysts (particularly if they are immature) should be observed to ensure that the identification is reliable. If two species are identified, there should be distinct populations of each.

Sometimes, although amebic organisms are seen, species cannot be identified. In these instances, the laboratory should report 'unidentified ameba trophozoites (or cysts)'. If the genus can be determined but the species cannot, 'unidentified *Entamoeba* trophozoites or cysts' should be reported and another specimen should be requested.

Entamoeba histolytica

Intestinal infection is usually diagnosed by the microscopic identification of organisms in feces or in sigmoidoscopic material from ulcerations (Fig. 241.1). Nonpathogenic amebae can be confused with pathogens (Fig 242.2 , Fig 242.3 , Fig 242.4 , Fig 242.5). Only trophozoites are found in tissue lesions, but both

trophozoites and cysts may be found in the intestinal

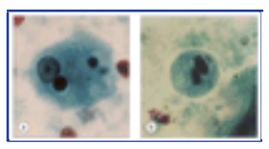

Figure 242-1 *Entamoeba histolytica.* (a) Trophozoite containing ingested red blood cells (the presence of red blood cells confirms the organism is the true pathogen, *E. histolytica*). (b) ***Entamoeba histolytica/E. dispar***, cyst containing four nuclei and chromatoidal bars with smooth, rounded edges (trichrome stain). Note: from the cyst morphology, it is not possible to differentiate pathogenic *E. histolytica* from nonpathogenic *E. dispar*.

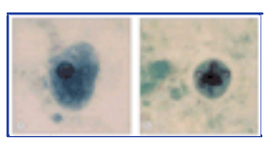

Figure 242-2 *Entamoeba hartmanni.* (a) Trophozoite. (b) Cyst containing up to four nuclei and chromatoidal bars with smooth, rounded edges (trichrome stain). Note: *E. hartmanni* measures less than *E. histolytica/E. dispar*, the trophozoite is <12µm and the cyst is <10µm.

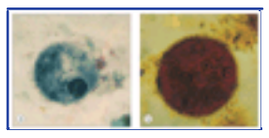

Figure 242-3 *Entamoeba coli.* (a) Trophozoite containing a single nucleus in which the karyosome is eccentric (tends to be centrally located in *E. histolytica/E. dispar*). (b) Cyst contains more than five nuclei (d'Antoni's iodine).

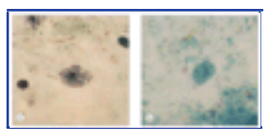

Figure 242-4 *Endolimax nana.* (a) Trophozoite containing a single nucleus with no peripheral chromatin (large karyosome only) and vacuolated cytoplasm. (b) Cyst containing four nuclei (three easily visible) (trichrome stain).

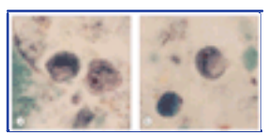

Figure 242-5 *Iodamoeba bütschlii.* (a) Trophozoite containing a single nucleus with a large karyosome and cyst containing a single nucleus and a large glycogen vacuole. (b) Cyst containing a single nucleus and a large glycogen vacuole — note the size of the karyosome (trichome stain). There is also a *Blastocystis hominis* central body form present at the lower left of the image.

lumen. Some patients who have invasive disease may have only trophozoites in fecal specimens and examination of permanent stained smears may be required to establish the diagnosis.

Suspected amebic abscesses are often diagnosed by positive serologic tests. Aspirates of abscesses or intestinal lesions may contain amebic trophozoites, sometimes with ingested erythrocytes seen in direct wet mounts or in permanent stains such as trichrome or iron-hematoxylin stains.[45] [46] Other species of intestinal amebae are not pathogenic but must be differentiated from *E. histolytica*. *Entamoeba polecki* is seen occasionally in refugees from South East Asia and may be confused with *E. histolytica*. [45] *Entamoeba gingivalis* is a common inhabitant of the oral cavity, particularly in patients who have poor oral hygiene. It resembles *E. histolytica* but has no known cyst stage. As a result, trophozoites of *E. gingivalis* may lead to the misdiagnosis of amebic lung abscess by morphologic examination of pulmonary material, especially sputum.

Currently, there are several immunoassays that can be used to identify organisms in the genus *Entamoeba* (*E. histolytica/E. dispar* group) and other reagents that can differentiate pathogenic *E. histolytica* from nonpathogenic *E. dispar*. The antigen detection enzyme-linked immunosorbent assay (ELISA) kits are based on specific amebic adhesin molecules found in the feces of people infected by either *E. histolytica* or *E. dispar*. The second ELISA reagent is able to detect the adhesin produced by *E. histolytica* in

feces. Another immunoassay product is available for the detection of *E. histolytica* and *E. dispar* in fecal specimens; however, this kit does not differentiate between the two organisms, but is specific for the *E. histolytica/E. dispar* group.[47] These procedures are simple, sensitive and specific. It is important to remember that these kits require fresh stool specimens; specimens preserved in any of the routine stool collection fixatives are not acceptable. Polymerase chain reaction methods are also being developed for the differentiation of *E. histolytica* from *E. dispar*.[48]

Serologic testing for intestinal disease is not recommended unless the patient has true dysentery; even in these patients, the titer (e.g. indirect hemagglutination) may be low and difficult to interpret. The definitive diagnosis of intestinal amebiasis should not be made without demonstrating the organisms. When extraintestinal disease is suspected, serologic tests are much more relevant. Indirect hemagglutination and indirect fluorescent antibody tests (FAs) have been reported positive with titers of =1:256 and =1:200, respectively, in almost 100% of cases of amebic liver abscess.[49] Positive serologic results, in addition to clinical findings, make the diagnosis highly probable. In the absence of rapid serologic tests for amebiasis (tests with very rapid turnaround times for results), the decision as to causative agent often must be made on clinical grounds and on results of other diagnostic tests such as scans.

Histologic diagnosis of amebiasis can be made when trophozoites within the tissue are identified and differentiated from host cells, particularly histiocytes and ganglion cells. Periodic acid-Schiff staining is often used; the organisms will appear bright pink with a green-blue background (depending on the counterstain used). Hematoxylin and eosin staining will also allow typical morphology to be seen. As a result of sectioning, some organisms will exhibit the evenly arranged nuclear chromatin with the central karyosome and some will no longer contain the nucleus.

Blastocystis hominis

The characteristic form of *B. hominis* that is usually seen in human fecal specimens varies in size from 6 to 40µm and contains a large central body resembling a vacuole, which may be involved with carbohydrate and lipid storage. The amebic form can occasionally be seen in diarrheal fluid but may be difficult to recognize. Generally, *B. hominis* will be identified on the basis of the typical round form containing the central body.[45] Routine stool examinations are very effective in recovering and identifying *B. hominis* (Fig. 242.6), although the permanent stained smear is the procedure of choice because the examination of wet preparations may not easily reveal the organism. The organisms should be quantitated on the report form, that is, as rare, few, moderate or many. It is also important to remember that other possible pathogens should be adequately ruled out before a patient is treated for *B. hominis*.

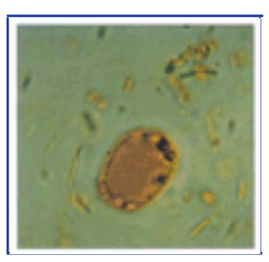

Figure 242-6 *Blastocystis hominis.* (a) Central body form with large 'empty' area (appears like a vacuole) with multiple nuclei around the edges (d'Antoni's iodine). (b) Three central body forms with the large empty area surrounded by nuclei (trichrome stain).

Identification of flagellates in fecal specimens

The flagellates are a more diverse group than the amebae. The type of motility, shape, number of nuclei and other characteristics, such as an undulating membrane, sucking disk, cytostome, spiral groove, and the number and location of flagellae, are important characteristics used to identify flagellate trophozoites. The organism shape and size, number and position of nuclei, and absence or arrangement of fibrils are used to identify flagellate cysts.

In some cases, species can be determined by the examination of either direct or concentrated wet mounts. Species of cysts may be identified in iodine-stained mounts. However, permanent stains are always recommended for every stool specimen submitted; organisms identified in wet preparations may not represent all types of organisms present.

Giardia lamblia (intestinalis)

Diagnosis is usually established by the demonstration of cysts or, occasionally, trophozoites in feces (Fig. 242.7). Nonpathogenic flagellates can be seen in Figure 242.8 . Because of the variable shedding of organisms, several stool specimens should be examined before the infection is ruled out. In some cases, a series of stools can be examined and be negative and yet the patient still has giardiasis. It is important for the laboratory and the clinician to recognize this fact. Permanent stains are recommended for the definitive diagnosis of this infection.

When *G. lamblia* organisms are not found in stool specimens, duodenal aspirates, string test mucus or biopsied mucosal tissue can be examined. The string test[45] is used to collect mucus from the duodenal area and its use may be less traumatic for the patient than other methods. Materials obtained by drainage, aspiration or the string test can be examined by simple, direct wet mounts. Biopsy tissue may be processed and stained by the usual histopathologic methods; however, before preservation, a fresh imprint smear of the mucosal surface on a slide can be made and stained with trichrome or Giemsa stain.

Immunoassay methods (enzyme immunoassay, FA, immunochromatographic assay) are available and may be appropriate in test ordering situations.[49A] [49B] Education of the medical staff will be mandatory to ensure that tests are appropriately ordered and that there is complete understanding of the limits of the information generated (test results limited to absence or presence of *G. lamblia*). Recently, industrial companies and municipalities have shown a great deal of interest in these reagents. This is particularly relevant when the water sources are used for drinking and/or recreational purposes. [45]

Dientamoeba fragilis

Permanent stains are required to diagnose this infection and multiple specimens may be required because shedding varies from day to day.

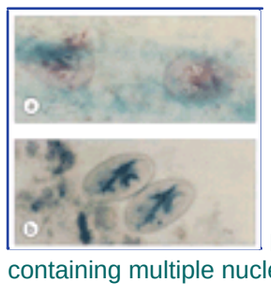

Figure 242-7 *Giardia lamblia.* (a) Trophozoites in mucus — note the sucking disk area, linear axonemes, curved median bodies and two nuclei (trichrome stain). (b) Cysts containing multiple nuclei, linear axonemes and curved median bodies (iron-hematoxylin stain).

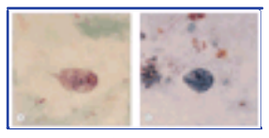

Figure 242-8 *Chilomastix mesnili.* (a) Trophozoite with single nucleus and clear feeding groove/cytostome. (b) Cyst containing single nucleus and curved fibril called the 'shepherd's crook' (trichrome stain).

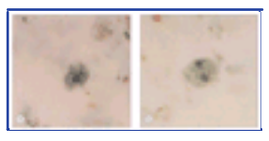

Figure 242-9 *Dientamoeba fragilis.* (a) Trophozoite with single nucleus fragmented into a 'tetrad' configuration. (b) Trophozoite containing two nuclei, each showing fragmented chromatin (trichrome stain). There is no known cyst form for this organism.

The delicately staining trophozoites are usually binucleate, although the nuclei may be in different planes of focus (Fig. 242.9). The nuclei tend to be fragmented and can often be seen in a 'tetrad' formation. They must be differentiated from the trophozoites of *Endolimax nana*, *Iodamoeba bütschlii* and *Entamoeba hartmanni*. Nuclear characteristics, the presence of binucleate forms, tremendous size variation, and the absence of cysts aid in identification of this organism.

A permanent stained smear should be examined for every stool specimen submitted to the laboratory for an ova and parasite examination.[45] [46] If this approach is not used, then many infections with this organism can be missed. If a laboratory periodically finds and identifies *G. lamblia* but never sees *D. fragilis*, then collection and diagnostic methods should be reviewed.

Identification of flagellates in urogenital specimens

Trichomonas vaginalis

Infections with *T. vaginalis* are usually detected by finding the motile trophozoites in wet mounts of vaginal fluid, prostatic fluid or sediments of freshly passed urine. In wet mounts, the trophozoites move with a jerky motion and possess an undulating membrane, which extends only one-half the length of the organism (Fig. 242.10). In old urine specimens, the organisms may be dead or badly distorted and thus cannot be identified or may be confused with host cells.

Specimens include vaginal fluid, scrapings or washings. They may be examined in a saline wet mount or as a stained smear, or the material can be cultured. Although some consider that wet mount examinations are as efficient as cultures in revealing infections, current evidence suggests that cultivation methods are superior.[50] [51] Immunofluorescent and ELISA methods have also been described. Organisms

Figure 242-10 *Trichomonas vaginalis.* Trophozoites showing axostyle, flagella and part of the undulating membrane (smaller organism) (Giemsa stain). There is no known cyst form for this organism.

may be difficult to recognize in permanent stains; however, if a dry smear is submitted to the laboratory, Giemsa or Papanicolaou stain can be used. Chronic *T. vaginalis* infections may cause atypical cellular changes that can be misinterpreted, particularly on the Papanicolaou smear. Organisms are routinely missed on Gram stains. The number of false-positive and false-negative results reported on the basis of stained smears strongly suggests that identification should be confirmed by observation of motile organisms, either from the direct wet mount or from appropriate culture media.

For culture, it is mandatory that the specimen be collected correctly, immediately inoculated into the proper medium and properly

incubated. Excellent methods are available using plastic envelopes containing appropriate media. This envelope approach allows both immediate examination and culture in one self-contained envelope. These systems are commercially available and serve as the specimen transport container, the growth chamber during incubation and the 'slide' during microscopy.[45] [50] [51] [52]

Monoclonal antibodies and DNA probe procedures for the detection of *T. vaginalis* have been reported as being very effective.[53] [54] An enzyme immunoassay has been developed for the detection of the *T. vaginalis* antigen from vaginal swabs.[55] [56] The predictive value of a positive test was 82% and that of a negative test was 99.3%. Commercial products based on these methodologies should be very helpful in diagnosing this infection. Serologic tests have been tried; however, none are commercially available.

Identification of ciliates in fecal specimens

Balantidium coli

In human feces, *B. coli* trophozoites are readily recognized by their large size, their shape and their rapid, rotating motion. Cysts are less easily identified, but they usually cause few diagnostic problems. The morphology of trophozoites and cysts is seen in Figure 242.11 .

Examination of direct saline mounts is the most practical method of detecting these protozoa. Cysts can be recovered by concentration, but in human infections trophozoites are usually more numerous than cysts. Iodine-stained mounts and permanent stains are of little value because the organisms tend to overstain and may resemble helminth eggs and/or debris.

CLINICAL MANIFESTATIONS (see Chapter 46)

In the descriptions of diseases, the clinical manifestations noted refer to findings in patients who have symptomatic disease and do not necessarily refer to findings in every person infected with the parasite species.

Amebae

Eight species of intestinal amebae may live in the cecum and colon of humans: *E. histolytica*, *E. dispar*, *E. hartmanni*, *E. polecki*, *E. coli*, *E. nana*, *I. bütschlii* and *B. hominis*. However, of these, only *E. histolytica* and *B. hominis* are thought to cause symptoms.

Entamoeba histolytica

Infections with the true pathogen, *E. histolytica*, are classified as amebiasis irrespective of whether the person exhibits symptoms. Outbreaks have occurred in the USA, usually from contaminated food or water. *Entamoeba* spp. isolated from patients who have clinical

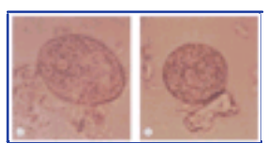

Figure 242-11 *Balantidium coli.* (a) Trophozoite — note the cilia around the edges ('fuzzy football'). (b) Cyst — note the cilia are difficult to see within the cyst wall (d'Antoni's iodine — light preparation, pale color).

disease have been shown by isoenzyme analysis to differ from nonpathogenic organisms and *E. histolytica* will be used to designate pathogens, whereas *E. dispar* will designate those that are nonpathogenic. The incubation is variable, from days to weeks or even months.

Asymptomatic infection

Individuals harboring *E. histolytica/E. dispar* may have either a negative or weak antibody titer and negative stools for occult blood and may be passing cysts that can be detected if a routine ova and parasite examination is performed. Although trophozoites may also be found, they will not contain any phagocytized red blood cells. Isoenzyme analyses of organisms isolated from asymptomatic individuals generally indicate that the isolates belong to nonpathogenic zymodemes (*E. dispar*).[28] Generally, asymptomatic patients never become symptomatic and may excrete cysts for a short period. This same pattern is found for patients who have either nonpathogenic or pathogenic zymodemes.

Intestinal disease

Although the exact mode of mucosal penetration is not known, studies suggest that amebae have enzymes that lyse host tissue, possibly from lysosomes on the surface of the amebae or from ruptured organisms. Cysteine proteinases and activation of host cell protein tyrosine phosphatases (PTPases) and dephosphorylation also play a critical role in the pathogenesis of invasive amebiasis caused by *E. histolytica*.[57] [58] [59] Amebic ulcers usually develop in the cecum, appendix or adjacent portion of the ascending colon and can also be found in the sigmoidorectal area. From these primary sites, other lesions may occur. Ulcers are usually raised, with a small opening on the mucosal surface and a larger area of destruction below the surface, thus described as 'flask shaped'. The mucosal lining may appear normal between ulcers. The incubation period may vary from 1 to 4 months and in an endemic area it is impossible to determine exactly when the exposure took place. Symptoms may range from none to those mimicking ulcerative colitis. Patients who have colicky abdominal pain, frequent bowel movements and tenesmus may present with a gradual onset of disease. With the onset of dysentery, bowel movements characterized by blood-tinged mucus are frequent (up to 10/day). Although dysentery may last for months, it usually varies from severe to mild over that time and may lead to weight loss and prostration. In severe cases, symptoms may begin very suddenly and include profuse diarrhea (over 10 stools/day), fever, dehydration and electrolyte imbalances. Acute illness may mimic appendicitis, cholecystitis, intestinal obstruction or diverticulitis. In some people, an increased frequency of bowel movements with or

without blood and mucus may occur. A chronic form, amebic colitis, produces symptoms similar to those of ulcerative colitis or other forms of inflammatory bowel disease, with diarrhea, sometimes bloody, occurring over months to years, sometimes alternating with periods of constipation or normal bowel function. Some patients who have amebiasis have been misdiagnosed as having ulcerative colitis. Another, less common form of intestinal disease, ameboma, is produced by the growth of granulomatous tissue in response to the infecting amebae, resulting in a large local lesion of the bowel that radiologically resembles a carcinoma.

Other than trophozoites containing ingested red blood cells, we have no way of differentiating pathogenic *E. histolytica* from nonpathogenic *E. dispar* based on morphologic differences, so our approach to reporting and therapy may not change in the near future. Any *E. histolytica* organisms should be reported to the physician and, providing the trophozoites do not contain ingested red blood cells, should be reported as *E. histolytica/E. dispar*. There are molecular-based diagnostic reagents that can confirm the group *E. histolytica/E. dispar* and other reagents that can indicate the species identification (*E. histolytica* or *E. dispar*). Although these reagents are relatively expensive, they may become more widely used in the next few years.[60]

Hepatic disease

Infections with *E. histolytica*, with or without a history of gastrointestinal symptoms, may result in hematogenous spread of the organisms from the submucosa to the liver via the portal system, resulting in amebic abscesses of the liver. This occurs in up to 5% of patients who have symptomatic intestinal amebiasis. Approximately 40% of patients who have amebic liver abscess do not have a history of prior bowel symptoms and in some patients *E. histolytica* may not be present in stool at the time liver disease becomes manifest. Onset of symptoms may be gradual or sudden; upper right abdominal pain with fever from 100° to 102°F (38–39°C) is the most

consistent finding. Weakness, weight loss, cough and sweating are less common. There is hepatomegaly with tenderness; however, liver function tests may be normal or slightly abnormal, with jaundice being very rare. There may be changes at the base of the right lung caused by the elevated diaphragm. The abscess can be visualized radiologically, sonically or by radionuclear scan and the majority of patients have a single abscess in the right lobe of the liver. The most common complication is rupture of the abscess into the pleural space. An abscess can also extend into the peritoneum and through the skin. Hematogenous spread to the brain, as well as to lung, pericardium and other sites, is possible.

Entamoeba histolytica cysts and trophozoites are found in the stools of only a few patients who have liver abscess. Usually 60% of these patients have no intestinal symptoms or any previous history of dysentery.

Blastocystis hominis

When *B. hominis* is present in large numbers in the absence of other parasites, bacteria or viruses, it may be the cause of diarrhea, cramps, nausea, fever, vomiting and abdominal pain and may require therapy. In patients who have other underlying conditions, the symptoms may be more pronounced. Incidence of this organism is found in a higher percentage of stools submitted for parasite examination than expected, especially when compared with percent positive stools for other intestinal protozoa. In symptomatic patients in whom no other etiologic agent has been identified, *B. hominis* should be considered a possible pathogen. When organisms number more than five per high-power field (×400), they should be quantitated and reported.[61] However, in one study, there did not appear to be any specific symptoms associated with *B. hominis* infection and the presence of larger numbers in the stool was not associated with more severe symptoms.[62] Other studies suggest that when a symptomatic *B. hominis* infection responds to therapy, the improvement probably represents elimination of some other undetected pathogenic organism (*E. histolytica*, *G. lamblia*, *D. fragilis*). [63] Data from other geographic areas indicate that although it is commonly seen in stool samples, *B. hominis* is thought to be nonpathogenic.[62] *Blastocystis hominis* inhabits the large intestine and organisms are passed in feces. Three morphologic forms have been described: amebic, granular and vacuolated.[64] The vacuolated ('central body') form is most commonly seen in fecal specimens.

Although *B. hominis* may be found in up to 25% of stool specimens examined, only occasional patients have clinical symptoms and the issue of pathogenicity may be explained by the confirmation of various ribodeme types. Different patient presentations can thus be explained, based on the evidence that there are several ribodeme types, only some of which will be responsible for increased intestinal permeability and symptoms.[36] [37] *Blastocystis hominis* may be suspected as the etiologic agent when the complete battery of parasitologic, bacterial and viral tests on stools has failed to disclose any agent other than *B. hominis*. Although most of these patients have numerous *B. hominis* organisms in the stool, organism numbers are not always elevated in symptomatic patients. The predominant and virtually only symptom has been persistent, mild diarrhea.

Infection is diagnosed by finding the familiar spherical or ovoid form with a large central vacuole with nuclei and various other organelles arranged around the periphery (see Fig. 242.6). *Blastocystis hominis* organisms can be demonstrated by any of the methods used for the diagnosis of intestinal parasite infections; however, the permanent stained smear is recommended.

Although we normally do not quantitate protozoa on the report form, this organism should be reported and semiquantitated (rare, few, moderate or many) from the examination of the permanent stained smear. As the published literature is somewhat controversial on the relationship between organism numbers and patient symptoms, quantitation may be helpful for the clinician. The percentage of people who harbor this parasite can range from about 10% to over 50% in some areas of the world.

Flagellates

Two species, *G. lamblia* and *D. fragilis*, cause clinically significant intestinal disease, and *T. vaginalis* is a frequent cause of vaginitis.

Giardia lamblia (intestinalis)

Because the acute stage usually lasts only a few days, giardiasis may not be recognized as the cause and the condition may mimic acute viral enteritis, bacillary dysentery, bacterial or other food poisonings, acute intestinal amebiasis or travelers' diarrhea (toxigenic *E. coli*). However, the type of diarrhea plus the lack of blood, mucus and cellular exudate is consistent with giardiasis.

Although organism numbers in the crypts of the duodenal mucosa may reach very high densities, they may not cause any pathology. Organisms have been seen in biopsy material inside the intestinal mucosa, whereas others have been seen only attached to the epithelium. In symptomatic cases, there may be irritation of the mucosal lining, increased mucus secretion and dehydration.

In the compromised patient, conditions and genetic factors associated with *G. lamblia* infection may include hypogammaglobulinemia, protein or caloric malnutrition, previous gastrectomy, histocompatibility antigen HLA-B12, gastric achlorhydria, blood group A, differences in mucolytic proteins, immunoglobulin deficiencies and reduced secretory IgA levels in the gut. Trophozoites infect the upper small intestine but do not invade the tissues to produce ulcers. Infection may elicit a variety of symptoms or may be

asymptomatic. The incubation period is variable, ranging from a few days to several weeks, with an average of about 9 days. In acute giardiasis, symptoms include nausea, upper intestinal cramping or pain, and malaise. There is often explosive, watery diarrhea, characterized by foul-smelling stools. These symptoms are accompanied by flatulence and abdominal distention. The acute stage of clinical giardiasis may be followed by a chronic stage or the chronic type of infection may be the first indication of infection. In such infections there is flatulence and abdominal distention. Patients may also exhibit belching, nausea, anorexia, vomiting and symptoms of heartburn. Fever and chills may be present, but to a lesser degree. Chronic disease must be differentiated from amebiasis and other intestinal parasite infections with *D. fragilis*, *C. parvum*, *Cyclospora cayetanensis*, *I. belli*, the microsporidia and *Strongyloides stercoralis* and from inflammatory bowel disease and irritable colon. On the basis of symptoms such as upper intestinal discomfort, heartburn and belching, giardiasis must also be differentiated from duodenal ulcer, hiatal hernia and gallbladder and pancreatic disease.

In some patients, the cysts may be excreted in stools in a variable pattern, although the reasons for this are not clear. This variable shedding of cysts may occur even when there are classic symptoms of disease and numerous trophozoites in the upper small intestine.

Dientamoeba fragilis

Symptoms have been reported more frequently in children than in adults and are predominantly diarrhea and abdominal distention. Outbreaks in daycare centers have been described. Nausea, vomiting and weight loss have been recorded in from one-third to one-fifth of the cases reported in the literature.[65]

Trichomonas vaginalis

The infection in men is generally asymptomatic, but 25–50% of infected women exhibit symptoms, which include dysuria, vaginal itching and burning and, in severe infections, a foamy, yellowish-green discharge with a foul odor. In many women the infection becomes symptomatic and chronic, with periods of relief in response to therapy. Recurrences of infection and disease may be caused by reinfection from an asymptomatic sexual partner or by failure of the drug metronidazole to eliminate the parasite completely. Symptomatic infections in men are rarely reported but include prostatitis, urethritis, epididymitis and urethral stricture. Rarely, *T. vaginalis* infections occur in ectopic sites and parasites may be recovered from areas of the body other than the urogenital system. *Trichomonas* spp. have been reported in pulmonary infections, presumably from oral trichomonads.

Ciliate

Balantidium coli

The symptoms of infection with *B. coli* are similar to those of amebiasis: lower abdominal pain, nausea, vomiting and tenesmus. Chronic infections may manifest with cramps, frequent episodes of watery, mucoid diarrhea and rarely with bloody diarrhea. Chronic infections have been known to last for several months. In tropical areas in which the parasite is endemic, the infection often is severe in patients who may also have other parasitic, bacterial or viral infections or who are undernourished.

Balantidium coli causes colonic ulcers similar to those caused by *E. histolytica*, but it does not spread to other organs.

MANAGEMENT

Entamoeba histolytica

Although carriers usually harbor amebae with nonpathogenic isoenzyme patterns (*E. dispar*), pathogenic patterns also may be found in these individuals. At present, test methodologies that differentiate between *E. histolytica* and *E. dispar* are not used routinely by all diagnostic laboratories. The diagnosis of *E. histolytica/E. dispar* infection is most often based on organism morphology. For this reason, in general, patients in the USA who harbor this organism are treated, regardless of the presence or absence of symptoms.

There are two classes of drugs used in the treatment of amebic infections: luminal amebicides, such as iodoquinol, paromomycin or diloxanide furoate, and tissue amebicides, such as metronidazole, chloroquine or dehydroemetine. Because there are differences in each drug's efficacy, it is important that the laboratory report for the physician indicates whether cysts, trophozoites or both are present in the stool specimen.

Asymptomatic patients

Patients found to have confirmed *E. histolytica* in the intestinal tract, even if they are asymptomatic, should be treated to eliminate the organisms. Both diloxanide furoate and iodoquinol (650 mg 3 times a day for 20 days; pediatric dose, 30–40 mg/kg/day (max 2g) in 3 doses for 20 days) or paromomycin (25–35 mg/kg/day in 3 doses for 7 days; pediatric dose, 25–35 mg/kg/day in 3 doses for 7 days) are available for treatment of patients who have cysts in the lumen of the gut. A study involving 14 years' experience in the USA using diloxanide furoate for treating asymptomatic cyst passers indicated that the drug is safe and effective and may be particularly well tolerated in children.[66] However, diloxanide furoate is generally not available commercially, but can be compounded by several pharmacies (500mg 3 times a day for 10 days; pediatric dose, 20mg/kg/day in 3 doses for 10 days).[67] In general, these treatments are ineffective against extraintestinal disease. If the patient is passing trophozoites and cysts, the recommended treatment is metronidazole (500–750mg 3 times a day for 7–10 days; pediatric dose, 35–50mg/kg/day in 3 doses for 7–10 days) or tinidazole (not marketed in the USA; 2g per day in 3 divided doses per day for 3 days; pediatric dose, 50mg/kg (max 2g) per day for 3 days).[67] [68]

Mild to moderate disease

In mild to moderate disease, metronidazole (Flagyl) should be given as indicated above when tissue invasion occurs, regardless of the tissue involved. Drugs directed against the lumen organisms should also be used in these cases (as indicated for iodoquinol or paromomycin above).

Severe intestinal disease

Metronidazole (750mg 3 times a day for 7–10 days; pediatric dose, 35–50 mg/kg per day in 3 doses for 7–10 days) or tinidazole (not marketed in the USA; 800mg 3 times a day for 5 days; pediatric dose, 60mg/kg per day (max 2g) for 5 days) should be used for therapy.[67] Some also recommend the use of a luminal drug (see iodoquinol or paromomycin above).

Hepatic disease

Metronidazole plus one of the luminal drugs should be used to treat hepatic disease. There are also other combinations that can be used; some physicians use emetine, in which case the patient must be monitored very carefully for possible cardiotoxicity. The importance of using both luminal and tissue amebicides was emphasized in a study that reviewed the enteric phase of 50 patients who had amebic liver abscess.[66] The prevalence of asymptomatic colonization was 72% (36 out of 50); however, isoenzyme analysis indicated that all of these isolates were pathogenic. In patients treated with metronidazole (tissue amebicide), the clinical response of the hepatic lesions was 100%; failure to eliminate the organism from the bowel in 20 out of 36 patients led to second bouts, with invasive disease and intestinal colonization. Also, these carriers constituted a public health hazard.[67]

Blastocystis hominis

Although there is not a great deal of clinical evidence, there have been studies on the *in vitro* susceptibility of *B. hominis* to numerous drugs.[64] At present, metronidazole appears to be the most appropriate drug. Di-iodohydroxyquin (Yodoxin) has also been effective, and dosage schedules for these two drugs are as recommended for other intestinal protozoa. Another option would be trimethoprim-sulfamethoxazole. The development of a new drug sensitivity assay may improve our ability to evaluate the activities of various drugs against this organism scientifically.[68]

Giardia lamblia (intestinalis)

If giardiasis is diagnosed, the patient should be treated. In the majority of patients, metronidazole is the drug of choice. Metronidazole is not recommended for pregnant women; although not absorbed and not highly effective, paromomycin may be used to treat giardiasis in pregnancy. Tinidazole has proved more effective than metronidazole as a single dose.[69] Furazolidone is another option, but has been reported to be mutagenic and carcinogenic.

Dientamoeba fragilis

Clinical improvement has been observed in adults receiving tetracycline; symptomatic relief was reported in children receiving di-iodohydroxyquin, metronidazole or tetracycline. Current recommendations include iodoquinol, paromomycin or tetracycline. As symptomatic relief has been observed to follow appropriate therapy, *D. fragilis* is probably pathogenic in infected individuals who are symptomatic.

Trichomonas vaginalis

Metronidazole is recommended for urogenital trichomoniasis, although resistance to this and to other 5-nitroimidazoles has been reported.[70] Sexual partners should be treated to avoid immediate reinfection.

Balantidium coli

Tetracycline is the drug of choice, although it is considered investigational. Iodoquinol or metronidazole may be used as alternatives.

Chapter 243 - Protozoa: Intestinal Coccidia and Microsporidia

Rainer Weber

Intestinal coccidia and microsporidia have increasingly gained attention as etiologic agents of HIV-associated diarrhea. These organisms, however, are not only opportunistic pathogens, but are also the cause of common, worldwide intestinal infections in immunocompetent children and adults. Also, newly described microsporidia are recognized as causing disseminated infections in immunocompromised patients.

NATURE

Intestinal coccidia

The intestinal coccidia are obligate intracellular protozoal parasites that belong to the phylum Apicomplexa, suphylum Sporozoa, and infect small intestinal enterocytes. Species of four genera (*Cryptosporidium*, *Cyclospora*, *Isospora*, *Sarcocystis*) are pathogenic in humans.[1] [2] [3]

The most frequent agents of human cryptosporidiosis are the human and the bovine genotype of *Cryptosporidium parvum*, although *C. meleagridis*, *C. felis*, and the canine genotype of *C. parvum* have also been identified in stools of patients with HIV infection and in HIV-seronegative Peruvian children.[1] [4] *Isospora belli* has been identified as the only accepted cause of human isosporiasis.[3] Intestinal organisms that were previously termed blue green algae, cyanobacterium-like bodies, or coccidia-like bodies were recently characterized as belonging to the coccidians, and are now named *Cyclospora cayetanensis*.[2]

Microsporidia

The term 'microsporidia' is a nontaxonomic designation commonly used to describe a group of obligate intracellular protozoa belonging to the phylum Microsporidia. More than 140 microsporidial genera and almost 1200 species have been identified that are parasitic in every major animal group. To date, seven genera (*Enterocytozoon*, *Encephalitozoon*, *Nosema*, *Pleistophora*, *Vittaforma*, *Trachipleistophora* and *Brachiola*) and unclassified microsporidia (referred to collectively as *Microsporidium*) have been implicated in human infections.[5] [6] [7] [8]

EPIDEMIOLOGY

Cryptosporidium species

Cryptosporidial infections have been detected on all continents. Cumulative prevalence rates are between 1 and 3% in industrialized nations and between 5 and 10% in developing countries.[9] [10] Children, particularly those less than 2 years of age, have a higher prevalence of infection than adults. Seroepidemiologic studies indicate that cryptosporidiosis may be more common than is estimated based upon surveys of fecal oocyst shedding. Seroprevalence rates in developed countries range between 25 and 35%, and in developing countries they are up to 65%. In severely immunodeficient patients with HIV infection, cryptosporidiosis is among the most important causes of chronic diarrhea, accounting for 10–20% of diarrheal episodes.[11]

Cryptosporidial oocysts are transmitted by the fecal-oral route and infection may be acquired from contaminated surfaces, ground and recreational water, pets and farm animals (particularly cattle and sheep), contaminated foods and person-to-person contact, including transmission between household members, sexual partners, children in day care centers and nosocomial infections involving both medical care staff and patients. An increasing number of outbreaks of cryptosporidial infections attributed to drinking water have been reported, including an outbreak in Milwaukee, USA in 1993 that affected over 400,000 persons. Ingestion of as few as ten oocysts may cause diarrhea.[12]

Cyclospora species

Cyclospora spp. have been identified worldwide in stool specimens of immunocompetent and immunocompromised patients, but appears to be most common in tropical and subtropical areas. The parasite is transmitted by the fecal-oral route and infection is most probably acquired from contaminated water or food.[13] It is not known whether animals can be infected and serve as sources for human infection. Direct person-to-person transmission is unlikely because excreted oocysts require days to weeks to become infectious. Warm temperatures and high humidity facilitate sporulation.

Isospora species

Isospora belli is endemic in many parts of Africa, Asia and South America, and is particularly common in patients from developing countries who have AIDS and chronic diarrhea; for example, it occurs in 10–20% of such patients in Haiti or Africa. Modes of transmission are not known but it is assumed that they comprise water and/or food that contains oocysts.

Microsporidia

Reported human infections are globally dispersed. Although microsporidiosis appears to occur most frequently in persons infected with HIV, it is emerging as an infection in otherwise immunocompromised hosts and in immunocompetent individuals. [5]

The sources of microsporidia infecting humans and modes of transmission are uncertain. Because microsporidial spores are released into the environment via stool, urine and respiratory secretions, possible sources of infection may be persons or animals infected with microsporidia. Ingestion of microsporidial spores is the most probable mode of transmission. Transmission by the aerosol route has also been considered because spores have been found in respiratory specimens of patients who have *Encephalitozoon* spp. infection.[14] Epidemiologic and experimental studies in mammals suggest that *Encephalitozoon* spp. can be transmitted transplacentally from mother to offspring, but no congenitally acquired human infections have been reported.

PATHOGENICITY

Cryptosporidium species

Cryptosporidium spp. develop intracellularly at the microvillous border of enterocytes (Fig. 243.1). Infected cells lack microvilli at

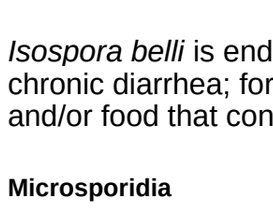

Figure 243-1 Intestinal cryptosporidial infection. Transmission electron micrograph of duodenal tissue of a patient with HIV infection showing two different developmental stages of *Cryptosporidium* spp. on the brush border of the mucosal surface: mature schizont with merozoites (right), undifferentiated zygote (left). *Cryptosporidium* spp. develop intracellularly just under the plasma membrane of the host cell. *Courtesy of MA Spycher.*

the site of parasite attachment and the mucosal surface appears disrupted. In immunocompetent individuals, infection is usually limited to the intestine. In immunocompromised patients, organisms are found throughout the entire gastrointestinal tract and within epithelial cells of the biliary tree, the pancreatic ducts and the airways. In the intestines, cryptosporidial infection induces atrophy, blunting or loss of villi, crypt hyperplasia, and infiltration of lymphocytes, neutrophils, plasma cells, and macrophages into the lamina propria. Cryptosporidial infection has been associated with marked reduction in the brush border enzyme activities, including sucrase, lactase, and maltase deficiency, with impaired absorption of vitamin B12 and D-xylose, and with increased permeability of the intestinal epithelium to organic molecules. Malabsorption and intestinal injury appear to correlate with the number of organisms infecting the intestine.[15] No specific virulence determinants of the parasite have been clearly linked to direct or indirect damage of intestinal host tissues. Putative virulence factors include molecules that are involved in parasite attachment to host cells and host cell membrane disruption. [16]

The immune responses to cryptosporidial infection are poorly understood, but probably include humoral and cellular processes. Persistent cryptosporidiosis has been observed in patients who have hypo- or agammaglobulinemias and those with T-cell deficiencies. Animal studies and epidemiologic data strongly indicate the

importance of the systemic cellular immunity, particularly $CD4^+$ lymphocytes, in modulating cryptosporidial infection.[1]

Isospora species

Isospora belli develops within parasitophorous vacuoles deep in the cytoplasm of the enterocyte. Histologic abnormalities associated with isosporiasis range from minimal changes of the small intestinal architecture to marked villous atrophy, crypt hyperplasia, and inflammatory infiltrates in the lamina propria consisting of eosinophils, neutrophils, lymphocytes and plasma cells. The mechanisms by which these changes occur are unknown. As a result of the intestinal injury, malabsorption and steatorrhea have been documented.[3]

Cyclospora species

Cyclosporiasis is associated with villous atrophy, crypt hyperplasia, and inflammatory infiltrates. The mechanisms that lead to the clinical features are unknown.

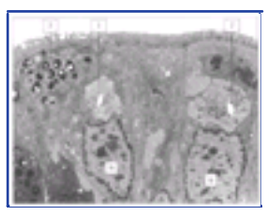

Figure 243-2 Intestinal *Enterocytozoon bieneusi* infection. Transmission electron micrograph showing duodenal epithelium of a patient with HIV infection who has *Enterocytozoon bieneusi* infection. The different developmental stages between the enterocyte nuclei (N) and the microvillous border include: (1) a proliferative plasmodium; (2) late sporogonial plasmodia; and (3) mature spores. *Courtesy of MA Spycher.*

Microsporidia

Microsporidiosis has been associated with abnormalities in structure and function of infected organs but how the different microsporidial species cause disease is not sufficiently understood.[5]

Enterocytozoon bieneusi

Enterocytozoon bieneusi infection generally appears to be limited to intestinal enterocytes (Fig. 243.2) and biliary epithelium. Patients who have severe cellular immunodeficiency appear at highest risk of developing microsporidial disease but little is known about immunity to *E. bieneusi* infection. It is not understood whether microsporidial infection in these patients is primarily a reactivation of latent infection acquired before the state of suppressed immunity or whether microsporidial disease is caused by recently acquired infection.

Encephalitozoon species

Encephalitozoon cuniculi and *E. hellem* infect a variety of cells including epithelial and endothelial cells, fibroblasts, kidney tubule cells, macrophages and possibly other cell types in numerous mammalian hosts, for example rabbits, rodents, carnivores, monkeys and humans.[17] In mammals, they usually cause latent asymptomatic or chronic mildly symptomatic infection, but interstitial nephritis and severe neurologic disease caused by central nervous system vasculitis and granulomatous encephalitis may occur. The parasites are able to persist in their animal hosts despite an active immune response. Microsporidial infection activates antibody production, although antibodies alone do not appear to yield protection. The role of a competent cellular immune response in suppressing microsporidial multiplication has been established experimentally. The pathogenesis of human *Encephalitozoon* infection has yet to be defined. Rare histologic and clinical investigations in immunodeficient patients have indicated that *E. cuniculi* and *E. hellem* usually cause disseminated infection in this patient group.[14] [17]

PREVENTION

Cryptosporidiosis

Cryptosporidial oocysts are remarkably resistant to many common disinfectants, including chlorine-based compounds. Adequate filter

systems are required to guarantee the complete removal of cryptosporidia from water supplies. A water disinfection device delivering germicidal ultraviolet (UV) light for *Cryptosporidium* oocyst inactivation yielded promising results.[18]

Cyclosporiasis, isosporiasis

Avoiding food or water that may be contaminated with feces may prevent cyclosporiasis and isosporiasis, but details of the sources of infection and the modes of transmission are unknown.

Microsporidiosis

Laboratory experiments indicate that the thick-walled spores may survive in the environment for months or years depending on the temperature and humidity. Exposure to recommended working concentrations of most disinfectants, boiling and autoclaving seems to kill *Encephalitozoon* spp. spores but no data are available for *Enterocytozoon* spp.

DIAGNOSTIC MICROBIOLOGY

Stool examination by light microscopy is the most important test to diagnose intestinal coccidia and intestinal microsporidia. In many laboratories, tests for *Cryptosporidium* spp., *Isospora* spp., *Cyclospora* spp. and microsporidia must be specifically requested because the general request of 'stool for O & P' (ova and parasites) often does not mean that the specific methods to detect these organisms are applied. Microsporidial species that cause systemic infection are best detected in urine sediments.

Cryptosporidium species

Examination of stool specimens by light microscopy

To visualize the *Cryptosporidium* spp. oocysts in fecal smears, acid-fast staining (e.g. modified cold Kinyoun technique; Fig. 243.3) and the immunofluorescence (IF) technique are among the most sensitive, specific and widely used methods. The IF detection procedure is more sensitive than the acid-fast staining but the difference in sensitivity may not be of clinical relevance when watery stools of patients with HIV infection are examined. These patients usually excrete an amount of oocysts that can easily be detected using acid-fast staining. The oocysts should be measured in order to distinguish *Cryptosporidium* spp. (4–6µm in diameter) from *Cyclospora* spp. (8–10µm). Enhanced sensitivity of stool examination can be obtained by concentrating oocysts, preferably with the formalin-ethyl acetate (FEA) technique.

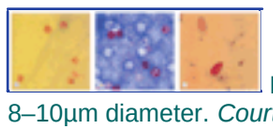

Figure 243-3 Acid-fast stained smears of fecal specimens showing intestinal coccidia. (a) *Cryptosporidium* spp., round, 4–6µm diameter. (b) *Cyclospora* spp., round, 8–10µm diameter. *Courtesy of EG Long.* (c) *Isospora belli*, elliptical, 23–33µm long and 10–19µm wide. Modified Kinyoun stain.

The exact sensitivity of the coprodiagnostic techniques is not known but some data raise questions about the widely held belief that these techniques are sufficient to meet the needs of clinicians and epidemiologists.[19] The minimum number of oocysts in human stool specimens that can be detected by the FEA stool concentration technique and the IF staining procedure was found to be unexpectedly high: 5000–10,000 oocysts per gram of stool in watery stool specimens and 10,000–50,000

oocysts per gram of stool in formed stool. Examination of multiple specimens may be necessary, because clinical studies have shown that examination of single stool specimens may have an insufficient diagnostic yield. Furthermore, in a prospective analyses of jejunal biopsies in patients who have AIDS, *Cryptosporidium* spp. were present in more than 10% of patients whose stool examinations were negative. These results, however, were in contrast to another study that only identified organisms on biopsy in one-third of patients shedding *Cryptosporidium* spp. in their feces.

Stool antigen detection techniques have been developed but the sensitivity of currently available tests is not better than microscopic techniques. Molecular diagnostic methods have improved diagnostic yields but currently are not ready to use in routine laboratories.[20] [21]

Cytologic diagnosis

Aspiration of duodenal fluid or small intestinal brushing can be used for diagnosis when upper endoscopy is performed. Examination of centrifuged duodenal aspirates under the microscope may be the most sensitive diagnostic procedure.

Histologic examinations

Cryptosporidium spp. appear basophilic by examination under the light microscope of small intestinal tissue sections stained with hematoxylin and eosin. The intracellular organisms seem to project into the intestinal lumen because of their apical extracytoplasmic localization. Under electron microscopy the unique ultrastructural features of different developmental stages of the parasite can be seen (see Fig. 243.1), but this is rarely necessary for diagnostic purposes.

Serology

Specific IgM or IgG antibodies to *Cryptosporidium* spp. can be detected within 2 weeks of onset of symptoms in most patients. In the majority of patients IgG titers may persist for long periods. Serologic testing is mainly used as an epidemiologic tool and has no diagnostic application, particularly because antibody persistence limits its use in the diagnosis of acute infection.

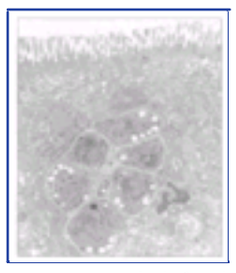

Figure 243-4 Intestinal *Cyclospora* infection. Transmission electron micrograph of duodenal epithelium obtained from a patient with HIV infection who has *Cyclospora cayetanensis* infection. A mature schizont filled with numerous merozoites is shown. *Courtesy of AM Deloul and FP Chatelet.*

Cyclospora species

Diagnosis of *Cyclospora* spp. is dependent on detection by light microscopy of the refractile oocysts, 8–10µm in diameter, in wet mounts of fresh stool specimens or in acid-fast stained smears prepared from stool concentrated by the FEA sedimentation.[22] Acid-fast stained oocysts vary in appearance from faint pink to deep red, and with many organisms remain as unstained spheres (see Fig. 243.3). The sensitivity of the coprodiagnostic techniques is unknown. In many patients' specimens, however, the number of oocysts detected per slide is low, indicating that not all symptomatic patients excrete a large enough number of oocysts for laboratory detection to be assured. Examination of small intestinal tissue of patients who have *Cyclospora* infection often did not reveal any parasites. The presence of intracellular parasites has rarely been documented in aspirated duodenal or jejunal fluid and on duodenal and jejunal biopsy (Fig. 243.4).

Isospora species

Diagnosis of *I. belli* is usually achieved by detection under the light microscope of the parasite oocysts in wet preparations or acid-fast stained smears of concentrated stool specimens (see Fig. 243.3). Repetitive stool examinations may be necessary because the parasite may be excreted intermittently or in low numbers. Histologic examination of small intestinal tissue sections may reveal the parasite within enterocytes.

Microsporidia

Diagnosis of microsporidial infection is dependent on morphologic demonstration of the organisms themselves. This can be difficult because of the organisms' small size and staining properties hamper visualization of the spores and developing stages using routine staining techniques. The spores, the stages by which microsporidia are usually identified, are small, ranging in size from 1 to 3.5µm in diameter.

Evaluation of patients who have suspected microsporidiosis should begin with examination of body fluids by light microscopy using special staining techniques. Definitive species identification of microsporidia is made using electron microscopy, antigenic analysis, and molecular analysis. Collection of fresh material (without fixative) may be useful for cell culture and for future molecular analysis. [5] [23]

Examination of stool specimens

In patients who have suspected enteric microsporidiosis, examination of stool specimens by light microscopy is the first step. It is at

Figure 243-5 Detection of microsporidia in stool samples. Smear of a formalin-fixed, unconcentrated stool specimen of a patient who has AIDS and chronic diarrhea, showing pinkish-red-stained spores of *Enterocytozoon bieneusi*. Chromotrope staining (oil immersion).

least as sensitive as examination of biopsy specimens. Detection of microsporidial spores requires adequate illumination and magnification [i.e. ×630 or ×1000 magnification (oil immersion)], and special staining methods. The two most commonly used stains are the chromotrope stain, which appears to be the most specific (Fig. 243.5),[24] and chemofluorescent agents, which might be more sensitive but may produce false-positive results.[25] An epidemiologic comparison of these techniques resulted in the recommendation to screen specimens with chemofluorescent agents and to confirm the results with the chromotrope stain.

The differences in spore size between *Enterocytozoon* (1–1.5µm in diameter) and *Encephalitozoon* spp. (2–3µm in diameter) often permit a tentative diagnosis of the genus from examination of stool under the light microscope. The microsporidian should be identified to the level of genus by electron microscopy or molecular analysis because *Encephalitozoon* spp. have a propensity for dissemination, and have a different drug sensitivity pattern compared with *Enterocytozoon bieneusi*.

Immunofluorescent procedures for diagnosis of *Encephalitozoon*-like microsporidial spores are promising but not widely available. Diagnostic application of polyclonal antibodies in fecal samples has been hampered by background staining, cross-reactions with yeast and bacteria, and low sensitivity. A few monoclonal antibodies against *Encephalitozoon* spp.[26] and one against spores of *Enterocytozoon bieneusi* have been generated.[27]

Histologic examination

Among patients with HIV infection who suffered from chronic diarrhea, stool examinations proved as sensitive as endoscopic evaluation for all pathogens except cytomegalovirus and *Leishmania*.[11] Examination of duodenal and terminal ileal tissue has resulted in detection of microsporidia but the parasites are rarely found in colonic tissue sections.

Only highly experienced pathologists have reliably and consistently identified microsporidia in tissue sections using routine techniques such as hematoxylin and eosin stain. Ultra-thin plastic sections stained with methylene blue-azure II-basic fuchsin or with toluidine blue may facilitate detection but these techniques are not routinely used. In our experience, tissue Gram stains such as Brown-Brenn or Brown-Hopps have proved to be the most useful for the rapid and reliable identification of HIV-associated microsporidia in routine paraffin-embedded tissue sections (Fig. 243.6). Others prefer a silver stain (Warthin-Starry stain) or the chromotrope-based staining technique.

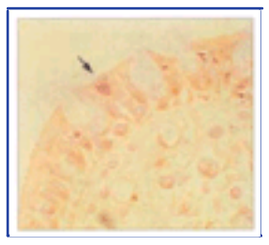

Figure 243-6 Intestinal *Enterocytozoon bieneusi* infection. Terminal ileal tissue obtained by ileocolonoscopy in a patient who has AIDS and chronic diarrhea caused by *Enterocytozoon bieneusi* infection. Gram-positive or Gram-labile microsporidial spores (arrow) are found in supranuclear location within small intestinal enterocytes. Brown-Brenn stain.

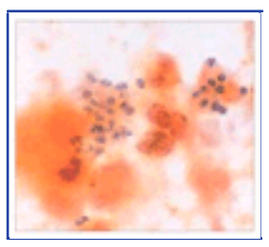

Figure 243-7 Detection of microsporidia in urine sediment. Urine sediment from a patient who has AIDS and disseminated *Encephalitozoon hellem* infection, showing Gram-labile intracellular and extracellular microsporidial spores. Gram stain (oil immersion).

Cytologic diagnosis

Microsporidial spores have been detected in sediments of duodenal aspirate, bile or biliary aspirates, urine (Fig. 243.7), bronchoalveolar lavage fluid, cerebrospinal fluid (CSF) and in smears of conjunctival swabs, sputum and nasal discharge.[5] Microscopic examination of centrifuged duodenal aspirate obtained during endoscopy appears to be the most sensitive technique for diagnosis of intestinal microsporidiosis. Because microsporidial infection often involves multiple organs, detection of microsporidia in virtually any tissue or bodily fluid should prompt a thorough search of other sites. In particular, urine specimens of patients suspected of having disseminated microsporidiosis should be examined.

Electron microscopy

Microsporidial ultrastructure is unique and pathognomonic for the phylum and, with rare exceptions, ultrastructural features can distinguish between most genera of microsporidia (Fig. 243.8 ; see Fig. 243.2).

Serology

Serologic assays (including carbon immunoassay, indirect IF test, enzyme-linked immunosorbent assay and Western blot immunodetection) have been useful in detecting antibodies to *E. cuniculi* in several species of animals, but reliable serologic tests for diagnosis of human microsporidiosis are lacking. This lack of availability is partly because *Enterocytozoon* spp. have not been continuously propagated in cell culture or laboratory animals.

Cell culture

Encephalitozoon spp., *Nosema* spp., *Trachipleistophora hominis*, *Vittaforma corneae* and *Brachiola algerae* have been isolated using cell culture systems, but these tests are fastidious and costly, and the

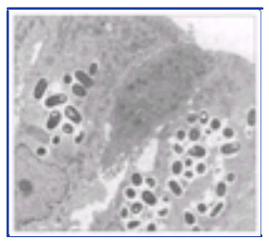

Figure 243-8 *Encephalitozoon intestinalis* (formerly *Septata intestinalis*): developing spores within enterocytes separated by a fibrillar matrix. *Encephalitozoon intestinalis* develop within parasitophorous vacuoles, unlike *E. bieneusi*, which develops in direct contact with enterocyte cytoplasm. *Courtesy of MA Spycher.*

most common human species, *E. bieneusi*, has not been continuously propagated.

Molecular techniques

Universal panmicrosporidian and species-specific primer pairs that amplify the short regions of the small subunit rRNA gene have been developed, [17] [28] but, at present, these techniques are confined to research laboratories. Diagnosis and identification of *Enterocytozoon bieneusi* and the different *Encephalitozoon* spp. have been successfully performed with fresh stool specimens, formalin-fixed stool specimens, intestinal tissue obtained by endoscopic biopsy, urine specimens and other body fluids.[17] [29] *In-situ* hybridization to visualize *E. bieneusi* in tissue sections has been developed.

CLINICAL MANIFESTATIONS

Cryptosporidiosis

For cryptosporidiosis the mean incubation period between infection and onset of symptoms is approximately 7–14 days (range 5–28 days). The severity and duration of illness varies depending on the immune status of the hosts. Children, the elderly and individuals with nutritional deficiencies may suffer from a more severe and prolonged disease, as is observed in immunodeficient patients. Whether cryptosporidiosis in immunocompromised patients is mainly a reactivation of latent infection or whether clinical illness is caused by recently acquired infection is not known.

Immunocompetent patients

In immunocompetent patients, cryptosporidia cause a self-limiting, usually watery, diarrhea lasting 10–14 days (range 2–28 days), but the clinical presentation varies from asymptomatic shedding of oocysts to severe disease that may last up to 3 months.[12] Patients often complain of abdominal pain, flatulence, loss of appetite, nausea and vomiting, and may suffer from low-grade fever, anorexia, malaise, weakness, fatigue, myalgias and headaches. The diarrhea and abdominal pain are often made worse by eating. Cough appears significantly more frequent in children with cryptosporidiosis than in children with diarrhea of another etiology, but the parasite has rarely been documented in the airways of immunocompetent individuals. Single case reports of pancreatitis associated with cryptosporidiosis and reactive arthritis have been described. Poorly understood lasting adverse effects of infection in children in developing children may include deficits of linear growth, even if

cryptosporidial infections is otherwise symptomless.[30]

Immunocompromised patients **(see Chapter 127)**

In immunocompromised patients, particularly individuals with HIV infection, cryptosporidiosis is a more severe, often chronic and

incurable illness that can be life-threatening. The main clinical presentation is watery diarrhea that can lead to severe dehydration, electrolyte depletion, malnutrition and weight loss. In addition, infection of the biliary tract and the gallbladder, resulting in acalculous cholecystitis, sclerosing cholangitis ('AIDS cholangiopathy') and stenosis of the papilla of Vater, frequently occurs. Infection of the epithelial cells of the respiratory tract, including sinuses, is increasingly described, but it is not clear whether this finding is of clinical relevance because most of these patients have a concomitant respiratory infection. Systemic cryptosporidiosis has not been described.

The clinical course of HIV-associated cryptosporidiosis is highly variable. Four clinical patterns of disease have been identified:

- asymptomatic shedding of oocysts;
- transient diarrhea with transient or chronic shedding of oocysts;
- chronic diarrhea; and
- fulminant disease that leads to cachexia and death within months.

Most patients who have severe illness have $CD4^+$ lymphocyte counts below 50 cells/mm^3 . Spontaneous clinical recovery may occur and is mainly correlated with higher $CD4^+$ lymphocyte counts, but a benign course of the diarrhea may also occur in severely immunodeficient patient. Clinical observations suggest that cryptosporidial disease is more severe if co-infections caused by other enteropathogens are present. Concurrent dual or multiple intestinal infection is found in up to 50% of patients who have HIV-associated cryptosporidiosis.

Cyclosporiasis

The spectrum of *Cyclospora*-associated illness is not yet fully defined but it may range from asymptomatic carriage of the organism to severe and prolonged diarrhea in immunocompetent and immunocompromised patients. Patients who have AIDS tend to have a more prolonged and severe illness, and *Cyclospora*-associated cholangiopathy has been described in this group.

The incubation period between infection and onset of symptoms ranges between 2 and 11 days and is usually about 7 days. In symptomatic infections the main clinical manifestation is mild to severe watery diarrhea, accompanied by abdominal cramps, bloating, increased flatus, nausea, anorexia, substantial weight loss and fatigue. Vomiting is less common and about 25% of the patients report fever and myalgias.

If not treated, diarrhea is self-limiting but may last for 1 month or longer (range 2–107 days), and remissions and relapses may occur during gradual resolution of the illness. *Cyclospora* infection does not appear to provide lasting immunity.

Isosporiasis

In immunocompetent persons, *I. belli* infection causes self-limited watery diarrhea accompanied by malaise, anorexia, cramping abdominal pain, weight loss and, less frequently, low-grade fever. In immunocompromised patients, the illness is more severe and prolonged, or chronic if untreated. Also, acalculous cholecystitis and two single cases of disseminated extraintestinal isosporiasis in patients with AIDS have been reported.

Microsporidiosis in immunocompromised patients

The spectrum of clinically manifest microsporidial infection is diverse and includes intestinal, ocular, muscular, cerebral, respiratory and urinary tract disease (Table 243.1). [5] The most prevalent microsporidial disease is HIV-associated chronic diarrhea.[11] Disseminated microsporidial infections are being increasingly recognized in patients who have AIDS.

Diarrhea, cholangitis, acalculous cholecystitis

Two microsporidial species — *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* — cause chronic diarrhea and wasting, cholangiopathy

TABLE 243-1 -- Microsporidial species pathogenic in humans, and clinical manifestations.

MICROSPORIDIAL SPECIES PATHOGENIC IN HUMANS, AND CLINICAL MANIFESTATIONS	
Microsporidial species	**Clinical manifestations**
Enterocytozoon bieneusi	Diarrhea, wasting syndrome
	Cholangiopathy, cholangitis, acalculous cholecystitis
	Sinusitis, bronchitis, pneumonitis
Encephalitozoon intestinalis (formerly *Septata intestinalis*)	Diarrhea
	Cholangiopathy, cholangitis, acalculous cholecystitis
	Sinusitis, bronchitis, pneumonitis
	Urinary tract infection, nephritis
	Bone lesions; nodular cutaneous lesions
Encephalitozoon cuniculi	Disseminated infection
	Keratoconjunctivitis
	Sinusitis, pneumonitis
	Urinary tract infection, nephritis
	Hepatitis
	Peritonitis
	Symptomatic and asymptomatic intestinal infections
	Seizures, encephalitis
Encephalitozoon hellem	Disseminated infection
	Keratoconjunctivitis
	Sinusitis, bronchitis, pneumonia
	Nephritis, ureteritis, cystitis, prostatitis, urethritis
Pleistophora spp.	Myositis
Trachipleistophora hominis	Myositis, keratoconjunctivitis, sinusitis
Trachipleistophora anthropophthera	Disseminated infection including brain, heart, kidneys

Brachiola connori (formerly *Nosema connori*)	Disseminated infection
Brachiola vesicularum	Myositis
Brachiola algerae (formerly *Nosema algerae*)	Keratitis
Vittaforma corneae (formerly: *Nosema corneum*)	Keratitis
	Disseminated infection
Nosema ocularum	Keratitis
Microsporidium ceylonensis	Corneal ulcer
Microsporidium africanum	Corneal ulcer

and acalculous cholecystitis in patients who have HIV infection or who are otherwise immunodeficient, particularly when $CD4^+$ lymphocyte counts drop below 50–100/µl.

Enterocytozoon bieneusi is estimated to be one of the most important HIV-associated intestinal pathogens, present in 5–30% of those with otherwise unexplained diarrhea. The main symptoms are chronic nonbloody diarrhea, anorexia, weight loss and bloating. Some patients experience intermittent diarrhea and a few excrete microsporidial spores without having diarrhea. The stool is watery or soft, and diarrhea seems to be worsened by most foods. Some of the patients report

abdominal pain or nausea and vomiting. Laboratory evidence for intestinal malabsorption is common. *E. bieneusi* itself is not immediately life-threatening, but diarrhea is debilitating, and weight loss may lead to cachexia, which is a significant cause or cofactor in the deaths of many patients. Up to one-third of patients who have intestinal microsporidiosis have dual or multiple co-infection with other intestinal pathogens. The parasite has also been detected in the biliary tree and/or gallbladder of patients who have cholangitis and acalculous cholecystitis. Imaging procedures often reveal dilatation of both intrahepatic and common bile ducts, irregularities of the bile duct wall and gallbladder abnormalities such as wall thickening, distention or the presence of sludge.[5] [11]

Encephalitozoon intestinalis primarily causes diarrhea, and the parasite may also spread into the biliary tract and gallbladder, causing cholangitis and cholecystitis. In contrast to *Enterocytozoon bieneusi*, systemic dissemination to kidneys and other sites may occur. [31]

Systemic microsporidiosis

There are three microsporidial genera, *Encephalitozoon* spp., *Trachipleistophora* spp. and *Vittaforma corneae*, which have been found to disseminate in severely immunodeficient patients who have HIV infection.[6] [17] [32] [33] Disseminated infection caused by *Brachiola connori* (formerly *Nosema connori*) was found at autopsy in a 4-month-old athymic boy reported in 1973.

Encephalitozoon spp. was initially identified in patients who had AIDS and keratoconjunctivitis.[34] Subsequently the spectrum of recognized *Encephalitozoon*-associated disease has expanded to include keratoconjunctivitis, bronchiolitis, sinusitis, pneumonitis, nephritis, ureteritis, cystitis, prostatitis, hepatitis, peritonitis, diarrhea and encephalitis.[14] [17] Clinical manifestations may vary substantially, ranging from an asymptomatic carrier state to organ failure.

Trachipleistophora anthropophthera was identified at autopsy in cerebral, cardiac, renal, pancreatic, thyroid, hepatic, splenic, lymphoid and bone marrow tissue of two patients who had AIDS and initially presented with seizures.[32]

Urinary tract infection

Predominant genitourinary signs and symptoms caused by *Encephalitozoon* infections have been observed. Clinical manifestations included asymptomatic microhematuria, urethritis, prostatitis, acute cystitis and interstitial nephritis associated with dysuria, gross hematuria and progressive renal insufficiency.[14]

Respiratory tract infection

In most patients who have respiratory tract microsporidial infection, including bronchiolitis, pneumonia and progressive respiratory failure, intestinal or systemic microsporidiosis was also present. Single cases of patients have been reported in whom sinusitis causing nasal obstruction and persistent mucopurulent nasal discharge caused by *E. bieneusi* or *Encephalitozoon* spp. was a predominant manifestation of systemic microsporidiosis.

Keratoconjunctivitis

HIV-associated ocular microsporidiosis caused by *Encephalitozoon* spp. is restricted to the superficial epithelium of the cornea and conjunctiva. Most patients exhibit bilateral coarse punctate epithelial keratopathy (Fig. 243.9), conjunctival inflammation resulting in redness and foreign body sensation, decreased visual acuity and photophobia. In patients who initially present with symptomatic keratoconjunctival microsporidiosis, dissemination of the parasite may be common, but clinical manifestations other than keratoconjunctivitis may be mild or absent.[35]

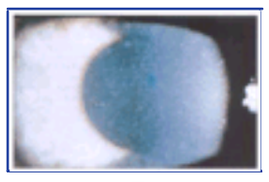

Figure 243-9 Keratopathy caused by *Encephalitozoon hellem.* Slit-lamp demonstration of punctate epithelial keratopathy in a patient who has AIDS and keratoconjunctivitis caused by *Encephalitozoon hellem*. Ocular microsporidiosis can often be diagnosed by examination under the light microscope of a smear obtained by a nontraumatic conjunctival swab. *Courtesy of M Diesenhouse and DA Schwartz.*

Figure 243-10 Cerebral microsporidiosis caused by *Encephalitozoon cuniculi* in a patient with HIV infection. The MRI shows multiple small contrast-enhancing, mostly ring-like, partly micronodular, lesions in hippocampal, mesencephal and intracortical regions (arrows), partly accompanied by slight edema, and congestion of the right ethmoid sinus. *Encephalitozoon cuniculi* was isolated from CSF. *From Weber et al.,[36] with permission from Massachusetts Medical Society.*

Cerebral microsporidiosis

Microsporidia was first accepted as the etiologic agent of a neurologic disorder in two children, reported in 1959 and 1984. Both presented with seizures and might have had impaired immune responses. *Encephalitozoon cuniculi* and *Trachipleistophora anthropophthera* were detected in CSF or brain tissue of patients with HIV infection who presented with fever and somnolence or seizures and mental decline. Magnetic resonance imaging disclosed multiple small, contrast-enhancing, mostly ring-like lesions localized to the hippocampus, mesencephalon and cerebral cortex (Fig. 243.10).[32] [36]

Myositis

Myositis caused by *Pleistophora* spp. has been described in an HIV-seronegative patient and in a patient with HIV infection, both of whom had severe cellular immunodeficiency. Newly characterized microsporidia, *Trachipleistophora hominis* and *Brachiola vesicularum*, were detected in muscle biopsies of patients who had

AIDS and presented with myositis.[6] [8]

Microsporidiosis in immunocompetent persons

Enterocytozoon bieneusi and *Encephalitozoon* spp. are associated with self-limiting watery diarrhea in immunocompetent adults as well as in children, particularly among persons who reside or have traveled in tropical countries.[37] An unexpectedly high prevalence (17%) of intestinal microsporidiosis due to *Enterocytozoon bieneusi* was found in HIV-seronegative elderly patients in Spain.[38]

Deep stromal infections of the cornea caused by different microsporidial species have been described in otherwise seemingly healthy persons who presented with severe keratitis or a corneal ulcer (see Table 243.1).

MANAGEMENT

Cryptosporidiosis

Among immunocompetent patients, cryptosporidiosis is usually self-limiting. In patients who have AIDS, case series and a randomized, controlled trial indicate that treatment with oral paromomycin (500mg q6h for at least 4 weeks) may result in decreased oocyst shedding and improved intestinal function and morphology,[39] but other investigators have not found any clinical benefit.[40] Case observations in patients who have AIDS suggest that maintenance therapy with paromomycin (1000–2000mg/day) may prevent relapses or improve the clinical course but controlled data are not available.

Randomized, double-blind trials found beneficial effects of nitazoxanide: At doses of 1–2g daily for 2 weeks, parasitologic cure was reported in 65% of Mexican patients who had AIDS.[41] Age-dependent doses of 100–500mg twice daily reduced the duration of diarrhea and oocyst shedding in HIV-seronegative children and in adults in Egypt.[42] *In-vitro* studies have indicated that nitazoxanide activity may be enhanced by the co-administration of azithromycin or rifabutin,[43] but clinical experience of such combinations is lacking. Hyperimmune bovine colostrum has been found in *in-vitro* experiments, in animal studies and in single patients to reduce or eradicate cryptosporidia, but these results could not be reproduced in larger human studies. Symptomatic treatment of diarrhea may include drugs that affect gut motility such as loperamide, diphenoxylate, opiates, somatostatin and octreotide. Immune reconstitution following initiation of potent antiretroviral therapy of patients who have HIV infection results in cessation of oocyst shedding and diarrhea, but cryptosporidial infection is controlled rather than cured because failure of antiretroviral therapy often results in relapse of cryptosporidiosis.[44]

Cyclosporiasis

A placebo-controlled trial showed that trimethoprim-sulfamethoxazole [TMP-SMX (co-trimoxazole); double-strength TMP 160/SMX 800mg q12h for 7 days] was clinically successful and shortened oocyst shedding in immunocompetent patients who have cyclosporiasis.[45] In this study, 3 days of treatment with TMP-SMX was not sufficient to eradicate cyclospora. Trimethoprim 160/SMX 800mg q6h for 10 days cured HIV-associated cyclosporiasis but the relapse rate was high (43%). Maintenance therapy with double-strength TMP-SMX three times per week did prevent relapses in these patients. There are no known alternatives to TMP-SMX.

Isosporiasis

Immunocompetent and immunocompromised patients respond promptly to therapy with TMP-SMX (double-strength TMP 160/SMX 800mg q6h for 10 days).[46] Alternatively, pyrimethamine 75mg/day plus folinic acid 10mg/day may be successful. To prevent the high rate of relapses in patients who have AIDS, maintenance therapy with double-strength TMP-SMX, three times per week, or pyrimethamine 25mg/day plus folinic acid 5mg/day, is recommended.

Microsporidiosis

Albendazole, fumagillin, its analog TNP-470, and nikkomycin Z have been found to inhibit completely or partially the replication or spore germination of *Encephalitozoon* spp. and *Vittaforma corneae* propagated in cell cultures, but did not destroy mature microsporidial spores, so that these may sustain infection.[47] [48] [49] Numerous other antiprotozoal drugs and antibiotics have been tested *in vitro*, with negative findings. *In-vitro* systems to investigate *Enterocytozoon bieneusi* are not available.

Little information on clinical experience in the therapy of human microsporidiosis is available, and only two controlled treatment trials have been conducted,[49] [50] confirming previous case observations which indicated that albendazole can result in clinical cure of HIV-associated encephalitozoonosis in parallel with the cessation of spore excretion. In contrast, albendazole is not effective for the treatment of *Enterocytozoon bieneusi* infection and does not reduce the parasite load although previous observations had suggested that clinical improvement may occur in some patients. Oral purified fumagillin was recently used in a pilot study and subsequently in a small randomized trial to treat HIV-associated diarrhea due to *E. bieneusi*. Fumagillin appeared to eradicate the parasite transiently in many patients but serious adverse events and parasitic relapse were observed.[49] [51] Recent experience with the antitumor necrosis factor-a agent thalidomide or potent antiretroviral treatment strategies in persons with HIV infection indicate that a modulation or improvement of the local or systemic immune function may lead to parasite clearance in this patient group.[44]

Chapter 244 - Protozoa: Free-living Amebae

Govinda S Visvesvara
Augusto Julio Martinez

NATURE

The concept that small free-living amebae, particularly *Acanthamoeba* spp. have the potential to cause disease in humans was developed by CG Culbertson of the Indiana University School of Medicine and the Eli Lilly Laboratories in 1958. The basis of this observation was a chance discovery of an ameba growing in a batch of monkey kidney cell cultures that were to be used for growing polio virus for the development of polio vaccine. This ameba, described as *Acanthamoeba* sp. (Lilly A-1), was found to produce, on intracerebral, intraspinal and intranasal inoculations, meningoencephalitis in cortisone-treated monkeys and mice.[1] [2] [3] This isolate is now called *Acanthamoeba culbertsoni*.

The first case of amebic meningoencephalitis in humans, attributed initially to *Acanthamoeba* although later the causative organism was identified as a species of *Naegleria*, was described in Australia in 1962. It is now known that besides *Acanthamoeba* spp., two other free-living amebae, *Naegleria fowleri* and *Balamuthia mandrillaris*, also cause central nervous system (CNS) disease in humans and other animals.[1] [2] [3] [4] Recently, however, *Sappinia diploidea*, a saprophytic ameba that has been previously isolated from the fecal specimens of lizards, elks and bisons, was identified in a brain biopsy specimen of a previously healthy 38-year-old man who developed visual disturbances, headache and a seizure.[5] This suggests that there are cases of human infections caused by free-living amebae other than *Acanthamoeba*, *Balamuthia* and *Naegleria* spp. that may have been either misdiagnosed or unrecognized.

Taxonomy

The free-living amebae are classified under the subphylum Sarcodina and superclass Rhizopodea.[2] The sarcodinian rhizopods are a heterogeneous group of amebae that include the free-living *Acanthamoeba, Naegleria, Balamuthia, Hartmannella* and *Vahlkampfia* spp. and others such as the parasitic amebae (e.g. *Entamoeba histolytica*) that move by producing cytoplasmic bulges, the lobopodia, from the surface of the body. In contrast to *E. histolytica*, which is a mitochondria-lacking ameba that causes gastrointestinal disease, *Naegleria, Acanthamoeba* and *Balamuthia* are mitochondria-bearing amebae that cause diseases of the CNS of humans and animals, which almost always lead to death. The term amphizoic amebae indicates the ability of these amebae to exist as free-living in nature and as parasites within host tissue; this differentiates them from the truly parasitic *E. histolytica*.[6]

Although several species of *Naegleria* have been described, so far only one species, *N. fowleri* (*Naegleria aerobia* and *Naegleria invadens* are non-valid synonyms), is known to infect the human CNS. Several of the more than 20 species of *Acanthamoeba* that have been described so far cause not only a chronic granulomatous CNS disease in humans and other animals, but also infect the cornea (*Acanthamoeba* keratitis), the skin, the nasal sinuses and pulmonary tissues. The disease caused by *Acanthamoeba* spp. has been described as granulomatous amebic encephalitis (GAE). *Balamuthia mandrillaris*, the only known species of *Balamuthia,* causes GAE and skin infections in humans and other animals.[1] [2] [3] [4] [7]

Naegleria fowleri

Naegleria fowleri is also described as an ameboflagellate because it has a transient flagellate stage in its life cycle in addition to a feeding and dividing form, the trophozoite, and a resistant cyst stage (Fig. 244.1). The trophozoite, measuring 10–25µm, normally feeds on bacteria and multiplies by binary fission. However, it is able to differentiate into a pear-shaped biflagellate stage in response to sudden changes in the ionic concentration of its environment. When the conditions become unfavorable the trophozoite differentiates into a resistant cyst stage. The trophozoite is usually uninucleate; the nucleus is spherical and contains a large, centrally placed, dense nucleolus. Additionally, numerous dumbbell-shaped mitochondria, vacuoles, lysosomes and ribosomes are present within the cytoplasm. Cysts are round and contain a single nucleus with a central dense nucleolus; the dense cyst walls are plugged with one or more flat pores. The cysts are 7–14µm in diameter, with a mean of 10µm.[2] [6]

Acanthamoeba spp.

In 1930 Aldo Castellani isolated an ameba from a yeast culture; it was later named as *Acanthamoeba castellanii*.[1] Currently more than 20 species of *Acanthamoeba* have been described.[8] The acanthamebae are also called opportunistic amebae because they produce disease principally in immunodeficient individuals.

The life cycle of *Acanthamoeba* spp. consists of two stages: a feeding and reproducing trophozoite stage and a resistant cyst stage (Fig. 244.2). The trophozoites feed on bacteria and detritus present in the milieu and multiply by binary fission. They are uninucleate and are 15–45µm in size. The nucleus has a centrally placed, large, densely staining nucleolus. The cytoplasm is finely granular and contains numerous mitochondria, ribosomes and lysosomes. Cysts are 10–25µm in size and are double walled. The outer wall or the ectocyst is wrinkled and contains protein and the inner wall, the endocyst, is usually stellate, polygonal, oval or spherical and contains cellulose. Pores covered by opercula are present at the point of contact between the ectocyst and the endocyst. Cysts are uninucleate and possess a centrally placed dense nucleolus.[6] [8]

Balamuthia mandrillaris

Balamuthia mandrillaris, previously called leptomyxid ameba, has two stages in its life cycle (Fig. 244.3). The trophozoite is irregular in shape and measures from 12 to 60µm with a mean size of about 30µm. It is usually uninucleate, but binucleate forms are occasionally seen. The nucleus contains a large centrally placed nucleolus. Occasionally, in infected human tissues, trophic stages containing a large nucleus with two or three nucleolar bodies have been observed. Cysts are also uninucleate, more or less spherical, and range in size from 12 to 30µm with a mean of 15µm. Cysts appear to be double walled with a wavy ectocyst and a spherical endocyst when viewed under the light microscope. However, ultrastructurally

Figure 244-1 ***Naegleria fowleri.*** The trophozoite can be differentiated from the cyst by its characteristic lobopodial locomotion; both are taken from culture. Differential interference contrast.

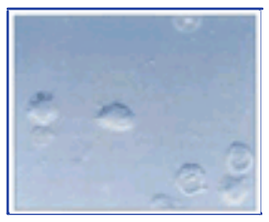

Figure 244-2 ***Acanthamoeba castellanii.*** The trophozoite has spiny acanthopodia whereas the cyst has an outer wrinkled ectocyst and a stellate endocyst; both are taken from culture. Differential interference contrast.

Figure 244-3 ***Balamuthia mandrillaris.*** The trophozoite is irregularly shaped whereas the cyst is spherical; both are taken from culture. Differential interference contrast.

the cysts are tripartite with an outer thin and irregular ectocyst, an inner thick endocyst and a middle amorphous fibrillar mesocyst.[4] [7]

Cultivation

Acanthamoeba spp. and *N. fowleri*, but not *B. mandrillaris*, can be cultivated on non-nutrient agar plates coated with a suitable Gram-negative bacteria such as *Escherichia coli* or *Enterobacter aerogenes*. The amebae will feed on the bacteria, multiply and differentiate into cysts within a few days. They can be easily subcultured by transplanting a small piece of agar containing trophozoites and/or cysts onto a fresh agar plate coated with bacteria as before. *Naegleria fowleri* and *Acanthamoeba* spp. can also be grown successfully on mammalian cell cultures. *Balamuthia mandrillaris* will not grow on bacteria-coated agar plates. However, it can be isolated from infected human or animal tissue by inoculating monkey kidney or human lung fibroblasts with the triturated tissue and from which a continuous culture can be established by periodic transfers.

Naegleria fowleri and *Acanthamoeba* spp. can be grown axenically (bacteria free) in a complex chemical medium. Although several different formulations are available, in our laboratory we use a modified version of Nelson's medium that contains a 0.5% solution of liver digest, 0.5% glucose and a low osmolarity buffered salt solution supplemented with 3–5% fetal bovine serum. *Acanthamoeba* spp. can also be easily grown in a medium composed of 2% proteose peptone, 0.5% yeast extract and 0.1% glucose made up in a low osmotic buffered salt solution with or without serum. Additionally, *N. fowleri* and several species of *Acanthamoeba* have also been grown in a chemically defined medium consisting of several different amino acids, vitamins, hemin and salts.[1] [2] *Balamuthia mandrillaris* has also been grown in an axenic medium, and this has facilitated the screening of various pharmaceutical agents. [9]

EPIDEMIOLOGY

Naegleria fowleri is widely distributed throughout the world and has been isolated from fresh water, thermal discharges of power plants, heated swimming pools, hot springs, aquariums, soil, dust in air, sewage and even from nasal passages of children. *Naegleria fowleri* is thermophilic and grows well, even at temperatures of up to 113°F (45°C). It is therefore not surprising that primary amebic meningoencephalitis (PAM) cases have occurred in the hot summer months when many people engage in aquatic activities in lakes, ponds and swimming pools that may harbor these amebae in large numbers. In colder climates these amebae will probably encyst and remain dormant in the sediments of fresh water lakes, ponds, rivers and swimming pools.[1] [2] [3] [10]

Acanthamoeba spp. have been isolated from soil, sewage, fresh, brackish and sea water, bottled mineral water, cooling towers of electric and nuclear power plants, physiotherapy pools, jacuzzis, heating and ventilating and air conditioning units, eye wash stations, dialysis machines, dust in the air, bacterial, fungal and mammalian cell cultures, contact lens paraphernalia, the nose and throat of patients who have respiratory complaints and healthy individuals, and biopsy or autopsy specimens of cornea, lungs, nasal sinus, skin and CNS tissue of humans and animals. *Acanthamoeba* spp. have been known to be hosts for *Legionella* spp., *Mycobacteria* spp. and echoviruses, which signifies the importance of these amebae to public health. [1] [2] [3]

Cases of GAE may occur at any time of the year and therefore transmission has no relation to climatologic changes.

Balamuthia mandrillaris has not as yet been isolated from the environment; it is, however, believed to have the same habitat as *Acanthamoeba* spp. and *N. fowleri*. *Balamuthia mandrillaris* has been isolated from biopsy and autopsy specimens of humans and other animals.[4] [7]

PATHOGENICITY

Naegleria fowleri

Primary amebic meningoencephalitis occurs in active healthy children and young adults with no known history of immune disorder. Most patients who have PAM have a history of swimming, diving or playing under water; the ameba enters through the nasal passages and the nasal mucosa is the initial site of the primary lesions. The route of invasion into the brain is through the fila olfactoria of the olfactory nerves. The trophozoites cross the cribriform plate and reach the subarachnoid space, which is richly vascularized and bathed in the cerebrospinal fluid (CSF), thus constituting an ideal medium for their proliferation and subsequent dissemination into the brain parenchyma and other areas of the brain.[1] [2] [3] [11]

Naegleria fowleri is a highly pathogenic and virulent ameba. However, the minimum number of amebae required to cause infection

and death in humans is not known. Experiments with infection have shown that mice, when just a few amebae are instilled intranasally, die of PAM in a similar fashion to humans. However, different isolates of *N. fowleri* vary in their degree of virulence: some are highly virulent whereas other isolates are only moderately virulent. Furthermore, any isolate can become avirulent on prolonged cultivation in an axenic medium. It is believed that the probability of infection in nature may depend upon the number and virulence of the amebae, the temperature and the type and source of the nutrient available to the amebae in the environment. [2]

The trophozoite of *N. fowleri* is highly phagocytic and induces necrosis of the CNS tissue. It is believed to ingest human tissue directly by producing a food cup or amebostome and by producing lysosomal hydrolases and phospholipases that degrade myelin. It has also been shown experimentally that the amebae exert a contact-dependent cytolysis mediated possibly by a multicomponent system that consists of a heat-stable hemolytic protein, heat-labile cytolysin and/or phospholipase A enzyme.[1] [2] [12]

The incubation period of PAM varies from 2 to 15 days depending on the size of the inoculum and the virulence of the amebae. In experimental infections with a mildly virulent *N. fowleri*, the incubation period has been as long as 3–4 weeks.[2]

Acanthamoeba spp.

Granulomatous amebic encephalitis, whether caused by *Acanthamoeba* spp. or *B. mandrillaris*, usually occurs in chronically ill, debilitated individuals, in immunosuppressed patients, those who have received broad-spectrum antibiotics or chemotherapeutic medications and those who have AIDS. [1] [11] [13] The pathogenesis of GAE is complex and poorly understood. It is believed that the immunity is predominantly T-cell mediated and therefore depletion of $CD4^+$ and T-helper lymphocytes permits the growth and development of the amebae. The incubation period is unknown and several weeks or months may elapse before the disease becomes apparent. The respiratory tract or the skin may act as the portal of entry. One hypothesis is that ulceration of the skin may enable the amebae to enter.[1] The route of invasion to the brain must be via the bloodstream because there are no lymphatic channels within the brain.[1] [13] Furthermore, trophozoites and cysts are often seen around blood vessels and within necrotic CNS tissue. The acanthamoebae are known to secrete enzymes such as lysosomal hydrolases, aminopeptidases and phospholipases, which may contribute to CNS damage. [1] [2]

Acanthamoeba *keratitis*

Acanthamoeba keratitis (AK) is the inflammation of the cornea caused by ocular trauma or by contact lens wear and the use of non-sterile homemade saline solution that has been contaminated with bacteria and fungi, which support the growth and multiplication of *Acanthamoeba* spp. The latter may secrete proteolytic and collagenolytic enzymes that may damage the corneal epithelium and thus contribute to the pathogenesis of AK. If proper treatment is not provided, AK may lead to a vascularized scar within a thin cornea, causing impaired vision or perforation of the cornea and loss of the eye.[14] [15]

PREVENTION

Primary amebic meningoencephalitis

The trophic and the cyst forms of *N. fowleri* are susceptible to chlorine and are killed at 1mg/l, provided the water temperature is 78.8°F (26°C) or below. If, however, the water temperature is above 78.8°F the chlorine concentration may need to be increased to 2mg/l. It is therefore important for swimming pools to be maintained properly with adequate chlorination at all times. As it is not possible to disinfect natural bodies of waters such as lakes and ponds in which *N. fowleri* may be found, appropriate warnings should be posted, particularly during the hot summer months.[1] [2]

Granulomatous amebic encephalitis

New and creative preventive measures need to be formulated because GAE produced by *Acanthamoeba* spp. and *B. mandrillaris* occurs principally in immunocompromised individuals. As *Acanthamoeba* spp. can grow and colonize hot water tanks, jacuzzis, filters used in heating, ventilating and air conditioning units, and in-line filters used for purifying portable water supplies and eye wash stations, periodic inspection of these systems is recommended.[1] [2] [3]

Acanthamoeba keratitis

It is recommended that eye care professionals educate patients about the proper care and use of contact lenses. Contact lenses and contact lens paraphernalia, particularly the solutions, should be kept meticulously clean. Contact lens wearers should follow the directions and recommendations of the manufacturers and eye care professionals. Additionally, contact lenses should not be used during swimming or other water sports.[14]

DIAGNOSTIC MICROBIOLOGY

Primary amebic meningoencephalitis

In individuals who have PAM, the CSF is characterized by pleocytosis, with a predominance of polymorphonuclear leukocytes but without bacteria. The CSF pressure is elevated (100–600mmHg). Glucose concentration may be slightly reduced or normal, but the protein content is elevated, ranging from 100mg/100ml to 1000mg/100ml. Computed tomography scans show obliteration of the cisterns around the midbrain and the subarachnoid space over the cerebral hemispheres. Differential diagnosis of PAM from acute pyogenic or bacterial meningoencephalitis is dependent upon the detection of the ameba in the CSF *in situ* under a microscope. Smears of CSF should also be stained with Giemsa or trichrome stains for the delineation of the characteristic nuclear morphology. Gram stain is not useful. Care must be taken to differentiate amebic trophozoites from macrophages. Many cases have been diagnosed retrospectively based on examination of hematoxylin and eosin-stained sections or immunofluorescent tests.[1] [2] [3] [11] Serologic tests are of no value in the diagnosis of PAM because most patients die too early (within 5–7 days) in the disease process to mount a detectable immune response.

Granulomatous amebic encephalitis

Examination of the CSF in patients who have GAE reveals lymphocytic pleocytosis with mild elevation of proteins and normal levels of glucose. Visual detection of *Acanthamoeba* spp. trophozoites in the CSF has rarely been reported. However, *Acanthamoeba* spp. have been identified in brain biopsies from several patients. Computed tomography scans and magnetic resonance imaging are nonspecific and of limited value in the diagnosis. Single or multiple heterogeneous, hypodense, non-enhancing, space-occupying lesions that involve the basal ganglia, cerebral cortex, subcortical white matter, cerebellum and pons may be encountered, suggesting a brain abscess, brain tumor or intracerebral hematoma. Brain and skin biopsies are important diagnostic procedures. *Acanthamoeba* spp. can be easily cultured from the brain, skin, lung and corneal tissue by placing a portion of the tissue that has been minced on non-nutrient agar plates coated with a layer of Gram-negative bacteria. Specimens for culture should be processed as quickly as possible. The incubation temperature depends upon the source of the samples. The agar plate should be incubated at 86°F (30°C), if the

specimens originate from cornea or skin, but at 98.6°F (37°C) if the specimens are from the brain, the lung or any other internal organ. Amebae, if present in the samples, will feed on bacteria and multiply by binary fission. If the plates are examined under the light microscope, distinctive track marks with an ameba at the end of each track may be seen. The amebae will differentiate into cysts after a few days of incubation. Amebae can be identified to the level of genus on the basis of the characteristic morphology of trophozoites and cysts. Additionally, *Naegleria* spp. can be identified if flagellates appear within 2–4 hours of a loopful of amebae from the agar plate being suspended in distilled water. Identification to the species level, however, is difficult on the basis of morphology alone; non-morphologic methods such as serology, isoenzyme analysis or DNA profiles therefore need to be used.[2] [6] [16] [17] [18]

Balamuthia mandrillaris will not grow on bacterized agar plates. However, *B. mandrillaris* can be isolated from the CNS by inoculating monkey kidney cell culture with brain extract[4] [7] and subsequently growing the amebae in an axenic medium.[9]

Acanthamoeba keratitis

For the diagnosis of AK, deep corneal scraping and biopsy is recommended. Unfixed specimens should be processed for culture. Smears should also be prepared and fixed with methanol, Schaudinn's fixative or a spray-on fixative, and stained with Giemsa-Wright or Hemacolor, or with Wheatly's or Masson's trichrome stain. Hemacolor staining is quick and stains the distinctive cyst wall pinkish-red. The trichrome stains the nucleolus of the trophozoite reddish-pink and the cytoplasm greenish-purple and is therefore useful in differentiating trophozoites of *Acanthamoeba* spp. from the host cells.[11] Confocal microscopy has also been used recently to diagnose AK.[19]

CLINICAL MANIFESTATIONS

Primary amebic meningoencephalitis

The first case of PAM was reported in 1965.[1] [2] [3] Although at that time the case was thought to be caused by *Acanthamoeba* sp., it is now considered to be caused by *N. fowleri*. It is believed that more than 200 cases of PAM have occurred worldwide as of March 2002. Further, as many as 100 cases have been reported in the USA alone. Primary amebic meningoencephalitis has also been described in a South American tapir and cattle.[1]

Primary amebic meningoencephalitis is an acute, fulminating and usually fatal CNS disease that occurs mainly in healthy young adults and children with a recent history of watersport activities. Primary amebic meningoencephalitis has a rapid onset and a short incubation period that lasts from 3 to 7 days. It is characterized by the sudden onset of bifrontal or bitemporal headaches, fever, nausea, vomiting and stiff neck. Nuchal rigidity usually occurs with positive Kernig's and Brudzinski's signs. Abnormalities in taste or smell and cerebellar ataxia may be seen early but photophobia occurs late in the clinical course. An increase in intracranial pressure has been reported in most patients. Generalized seizures leading to lethargy, confusion, coma and death within 48–72 hours have been reported in a number of patients.[1] [11] Focal myocardial necrosis has also been reported.

Pathologic features

At autopsy the cerebral hemispheres are swollen and edematous. The olfactory bulbs and the orbitofrontal cortices are necrotic and hemorrhagic. Because of increased intracranial pressure, uncal and cerebellar tonsillar herniations are usually seen. The arachnoid membrane is severely congested with scant purulent

exudate. Amebic trophozoites are usually seen within the Virchow-Robin spaces with minimal or no inflammatory reaction (Fig. 244.4). Cysts are not seen

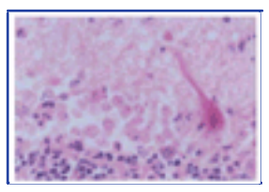

Figure 244-4 CNS section demonstrating numerous trophozoites of *Naegleria fowleri.* Note the absence of cysts. (H & E.)

within the CNS lesions. Necrotizing angiitis may occasionally be seen.[1] [2] [11]

Granulomatous amebic encephalitis produced by *Acanthamoeba* spp. and *Balamuthia mandrillaris*

Granulomatous amebic encephalitis caused by *Acanthamoeba* spp. occurs principally in individuals who are immunosuppressed (either iatrogenically or because of AIDS) and GAE caused by *B. mandrillaris* occurs in either the very young or very old and in individuals who have AIDS. As of 1 April 2002, more than 200 cases (114 caused by *Acanthamoeba* spp. and 93 caused by *B. mandrillaris*) of GAE had occurred worldwide. In the USA as many as 82 cases attributable to *Acanthamoeba* spp. (60 in people with AIDS) and 44 attributable to *B. mandrillaris* had occurred. Additionally, several cases of GAE caused by *Acanthamoeba* spp. and *B. mandrillaris* have been described in gorillas, a baboon, monkeys, dogs, sheep and cows.[1] [3] [20]

The clinical manifestations and pathologic features of GAE are similar regardless of which of these two organisms is the cause. It is an insidious disease and has a long and protracted clinical course. Clinical signs include personality changes, headache, low-grade fever, nausea, vomiting, lethargy, hemiparesis, seizures, depressed levels of consciousness and coma. Third and sixth cranial nerve palsies may be seen in some patients. Clinically, GAE may mimic bacterial leptomeningitis, tuberculous or viral meningitis, or single or multiple space-occupying lesions. Cerebellar ataxia and diplopia have been described in some patients. Pneumonitis with the presence of trophozoites and cysts within pulmonary alveoli has also been described.[1] [11] In most cases of GAE, however, final diagnosis is made at autopsy.

Pathologic features

The cerebral hemispheres are edematous. Encephalomalacia with multifocal areas of cortical softening and hemorrhagic necrosis may be seen. Multifocal necrotic lesions may also be seen in the posterior fossa structures, midbrain, thalamus, brainstem and cerebellum. Trophozoites and cysts of the infecting organisms are seen, most often in the necrotic lesions in basal ganglia, midbrain, brainstem and cerebral hemispheres (Fig. 244.5). Microglial nodules may be seen within the necrotic tissues. Occasionally, angiitis may be seen with perivascular cuffing by inflammatory cells, chiefly lymphocytes, a few plasma cells and macrophages. In patients who have advanced AIDS there is very little inflammation. Trophozoites and cysts can easily be identified by light microscopic examination of the tissue

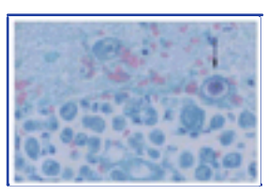

Figure 244-5 Brain section showing numerous trophozoites and a cyst (arrow) with typical features of *Acanthamoeba culbertsoni.* (Masson's trichrome.)

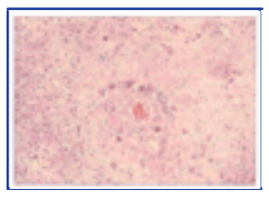

Figure 244-6 Trophozoites and cysts of *Acanthamoeba* sp. surrounding a blood vessel in a skin biopsy of a patient who has AIDS. A diffuse but modest inflammatory reaction is seen.

sections. Also in patients who have AIDS, multiple ulcerations of the skin with acute and chronic inflammation may be seen and the ulcers may contain trophozoites and cysts of the infecting ameba (Fig. 244.6). The kidneys, prostate gland, adrenal glands, lungs and liver may also be involved, suggesting hematogenous dissemination. The ulcerated skin may serve as a portal of entry for the amebae in some patients. Several cases of skin infection without dissemination into the CNS have also been reported.[1] [21] [22]

In general, the trophic and cyst stages of *Acanthamoeba* spp. and *B. mandrillaris* look similar in formalin-fixed and hematoxylin and eosin stained sections under the light microscope. In some patients, however, differential identification of *B. mandrillaris* can be made if the nuclei of the amebae in the sections possess two or three nucleolar elements because these are not seen in *Acanthamoeba* spp. (Fig. 244.7). A definitive identification may be arrived at by carrying out immunofluorescence analysis of the tissue sections using rabbit anti-*Acanthamoeba* spp. or anti-*B. mandrillaris* sera. The cyst wall of *B. mandrillaris* is characteristically tripartite and hence can be identified definitively by electron microscopy analysis of brain sections.[1] [4] [7]

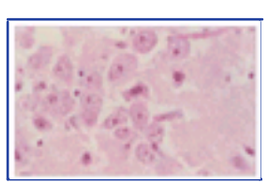

Figure 244-7 CNS section showing many trophozoites of *Balamuthia mandrillaris.* More than one nucleoli can be seen within the nuclei of the trophozoite.

Acanthamoeba keratitis

Acanthamoeba keratitis is a sight-threatening chronic inflammation of the cornea. It is associated with contact lens wear and the use of homemade nonsterile saline solution, corneal abrasion or trauma. Although the first case of AK in the USA was reported in a farmer from south Texas with ocular trauma of the right eye,[3] [14] wearing contact lenses and using nonsterile homemade saline was found to be a risk factor for AK in 1985 because most of the 24 patients reported in the previous 2 years were contact lens wearers.[3] [14] By December 1996, more than 700 cases of AK were estimated to have occurred worldwide.

The hallmark of AK is severe ocular pain, photophobia, a central or paracentral 360° stromal ring infiltrate (Fig. 244.8), recurrent breakdown of corneal epithelium with a waxing and waning clinical course and a corneal lesion refractory to the usual antibacterial, antiviral and antimycotic medications.[14] [15]

When examined under the light microscope, corneal scrapings and/or sections of biopsied corneal tissue reveal trophozoites and cysts of *Acanthamoeba* spp. infiltrated between the lamellae of the cornea (Fig. 244.9). Polymorphonuclear leukocytes, eosinophils, lymphocytes, macrophages and plasma cells, have also been seen occasionally. Ulceration, descemetocele formation and perforation are often seen in the later stages of AK.[11] [14] [15]

MANAGEMENT

Primary amebic meningoencephalitis

Primary amebic meningoencephalitis has almost always resulted in death. A few patients, however, have survived, probably because of

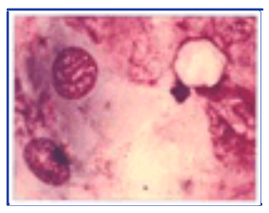

Figure 244-9 Characteristic star-shaped morphology of the cyst of *Acanthamoeba* sp. demonstrated by a corneal scraping stained with Hemacolor. *Courtesy of Dr Theodore.*

early diagnosis and aggressive treatment with amphotericin B, miconazole and rifampin (rifampicin).[23] Amphotericin B and miconazole can be administered intrathecally or intravenously, alone or in combination, and rifampin can be given orally. A 9-year-old girl from California, one of the patients who survived this disease in the USA, was treated as follows: intravenous amphotericin B 1.5mg/kg body weight per day in two divided doses for 3 days and then 1mg/kg for 3 days; intrathecal amphotericin B 1.5mg/day for 2 days followed by 1mg/day for 8 days; intravenous miconazole 350mg/m^2 body surface area per day in three divided doses for 9 days; intrathecal miconazole 10mg/day for 1 day followed by 10mg every other day for 8 days; and oral rifampin 10mg/kg per day in three divided doses for 9 days. The patient was also given sulfisoxazole (sulphafurazole) q6h for 3 days, but this was discontinued once *N. fowleri* was identified as the cause of the disease. Dexamethasone and phenytoin were given to lower the intracranial pressure and seizure activity, respectively. Amebae disappeared from the CSF after 3 days of treatment. Although cell counts and biochemistry of the CSF were abnormal for several months afterwards, the patient recovered completely without any neurologic sequelae.[23] It has also been reported that a boy from Texas, USA, recovered from PAM after intravenous amphotericin B and treatment in a hyperbaric chamber.[24]

Granulomatous amebic encephalitis

There is as yet no effective treatment for GAE and therefore the prognosis is poor.[1] [3] [25] [26] [27] The disease has been identified in only a very few patients before death. Three such patients who were diagnosed, however, have reportedly recovered from this disease. *Acanthamoeba rhysodes* was isolated from the CSF of a Nigerian patient with neurologic disease who showed clinical improvement after treatment with sulfamethazine. He was discharged from the hospital but was lost to follow-up.[2] [3]

Acanthamoeba culbertsoni was isolated from the CSF of an Indian patient with CNS impairment who recovered after treatment with chloramphenicol.[2] [3]

A 7-year-old girl from Barbados with a 'brain tumor' recovered without any neurologic sequelae after surgical excision. *Acanthamoeba healyi* was isolated from the 'tumor' and also demonstrated in the hematoxylin and eosin-stained, formalin-fixed sections. The patient also received oral ketoconazole treatment for 8 months postoperatively.[28] [29] It is known from *in-vitro* experiments that several drugs, including pentamidine, propamidine, dibromopropamidine, miconazole, paromomycin, neomycin, ketoconazole and 5-fluorocytosine, have inhibitory effects on several isolates of *Acanthamoeba*.[3] [30] According to one study a combination of pentamidine and azithromycin may be effective in treating GAE.[9] Prognosis of patients who have disseminated skin infections without CNS involvement is, however, good. In an immunocompromised (without HIV/AIDS) patient with *A. rhysodes* skin infection, skin ulcers healed after the following treatment regimen: cleansing of skin ulcers twice daily with chlorhexidine gluconate solution followed by the application of 2% ketoconazole cream. The patient was also given 4mg/kg intravenous pentamidine isethionate for 1 day. Because of pentamidine toxicity the dosage was cut to 2700mg and given over a 4-week period. Thereafter, he was given itraconazole orally at a dose of 200mg daily for 8 months, resulting in the total healing of the skin lesions.[21]

***Acanthamoeba* keratitis**

Treatment of AK with topical application of polyhexamethylene biguanide or chlorhexidine gluconate in combination with propamidine isethionate appears to be the treatment of choice, as several patients have been treated successfully in this way.[31] [32] Many patients have also been treated with topical application of propamidine isethionate 0.1% and dibromopropamidine, in conjunction with neosporin. Ketoconazole and clotrimazole appears to be effective *in vitro* and *in vivo*. Other reports of successful treatment with 0.1% hexamidine di-isethionate eye drops have been reported. Some patients have also been treated successfully with combinations of topical propamidine and miconazole and systemic ketoconazole, or topical clotrimazole or oral itraconazole with topical miconazole.[33] [34] Debridement of the cornea, penetrating keratoplasty and corneal grafting have also been performed with good results in some patients. Recurrence of AK has been reported after corneal transplantation, probably caused by cysts of *Acanthamoeba* spp. still present in the corneal stroma.

Chapter 245 - Blood and Tissue Protozoa

Pablo Martín-Rabadá
Emilio Bouza

Organisms of the genera *Plasmodium, Babesia, Toxoplasma, Leishmania* and *Trypanosoma* are the most prevalent protozoa able to invade blood and human tissues. They cause diseases of immense socioeconomic impact, most of them having a limited (although extensive) geographic distribution.[1]

MALARIA

Malaria means bad air in Italian, reflecting its association with marshy areas. It is caused by intraerythrocytic parasites first recognized by Laveran in 1880.

NATURE

Human malaria is caused by four species of *Plasmodium* parasites: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale* and *Plasmodium malariae*.

The life cycle of *Plasmodium* spp. in humans is shown in Figure 245.1 . The sporozoite form of the parasite is cleared from the circulation in less than 1 hour and infects hepatocytes (intrahepatic cycle). Because the number of infected liver cells is low, there are no symptoms or signs of disease at this stage. The parasite cells multiply in the infected hepatocytes (liver schizonts), and after an average incubation period of 5–20 days the liver schizonts rupture. The young parasite cells liberated into the circulation invade red cells where they grow (trophozoites) and divide (schizonts). Parasites of the species *P. vivax* and *P. ovale* may persist for months or even a few years as intrahepatocytic schizonts in a 'dormant' state (hypnozoites) before a new intraerythrocytic cycle begins. The earliest parasitic stage in the erythrocyte is the trophozoite (*trophos*, nourishment), a growing ring of cytoplasm with a nucleus on one side. As the parasite grows, a brownish-green pigment (hemozoin) accumulates in the red cell. In the schizont stage (*schizo*, to split), the nucleus of the plasmodium cell divides repeatedly giving rise to 8–24 daughter cells called merozoites (*mero*, separated part). The red cell disintegrates, releasing the merozoites into plasma where they invade new erythrocytes, to repeat the intraerythrocytic asexual cycle. After a few intraerythrocytic cycles, some trophozoites, instead of becoming schizonts, undergo sexual differentiation and develop into large uninucleate female gametocytes (macrogametocytes) and male gametocytes (microgametocytes). The gametocytes undergo no further development in humans, and eventually degenerate or are destroyed unless a susceptible mosquito feeds on them. Sexual reproduction takes place in the stomach of the mosquito (sporogonic cycle), and as a result infective sporozoites accumulate in the salivary gland of the mosquito from where they are injected into humans in the next blood meal.

EPIDEMIOLOGY

Malaria incidence is estimated to be 500 million cases/year and malaria causes at least 2 million deaths (4% of all deaths). Children account for more than 1 million of these deaths, and malaria causes 15–25% of all deaths in children under 5 years of age. About 80% of cases occur in sub-Saharan Africa, and up to 30,000 travelers from Europe and North America contract the disease each year.

Malaria transmission occurs when an infected *Anopheles* mosquito bites a susceptible individual. Infections are more likely to be acquired during the wet season in the tropics or spring and autumn in temperate climates. Figure 245.2 shows the geographic distribution of the disease.

In highly endemic areas, the disease is acquired in early childhood and the whole population is re-infected periodically throughout life.

PATHOGENICITY

The production of disease by *Plasmodium* spp. is complex and not fully understood, but essentially consists of hemolytic anemia and an impaired microcirculation (see also Chapter 166).

The anemia in malaria is due to the rupture of parasitized erythrocytes, removal of parasitized and unparasitized erythrocytes by the spleen, capillary sequestration and bone marrow dyserythropoiesis. Bleeding and, in some cases, disseminated intravascular coagulation (DIC) may contribute to the pathogenesis.

The pathogenesis of microvascular flow impairment is controversial. It is characterized by the 'packing' of red blood cells containing mature forms of the parasite in the capillaries and venules. Hemozoin or, more recently, phospholipids have been proposed as the 'toxins' that trigger the interleukin (IL) cascade and subsequent febrile reaction. Antibodies to these phospholipids and tumor necrosis factor (TNF)-a levels are elevated in malaria and correlate with the prognosis in *P. falciparum* malaria.

Several genetic and immunologic factors offer protection against malaria or against the more severe forms of the disease. The absence of Duffy antigen in red blood cells, a trait that predominates in West Africans and derived populations, prevents *P. vivax* malaria.

In patients with hereditary elliptocytosis, in those with glycophorin C deficiency (Leach phenotype) as well as in those who are heterozygous for sickle cell disease, it has been observed that the incidence of malaria is lower than expected for the general population of a given area. Other hemoglobinopathies such as thalassaemias or glucose-6-phosphate dehydrogenase (G6PD) deficiency may offer a less clinically evident level of protection.

Untreated infected patients eventually develop curative immunity against the parasitizing strain. As several strains usually circulate in any given area, re-infection is extremely common. When the patient has successive infections from a number of strains, a certain degree of immunity to the infection develops. This partial immunity prevents severe disease, conferring tolerance to high parasitemias. The immune protection reached after repeated infections eventually disappears if re-infections do not occur for years. Iron deficiency, which is very common in holoendemic areas, seems to protect against severe disease.

PREVENTION

The prevention of disease can be approached individually or as a wider disease control program. Complete eradication of the disease

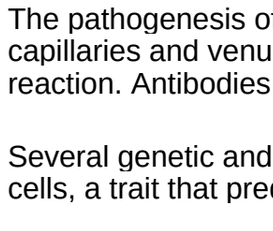

Figure 245-1 *Plasmodium vivax* life cycle. The life cycle starts when an infected mosquito feeds, inoculating the sporozoite form of the parasite, which infects the hepatocytes. The parasite cells then multiply (liver schizonts) and are liberated into the circulation to invade red cells where they grow (trophozoites) and divide (schizonts). Some trophozoites differentiate into gametocytes infective for mosquitoes.

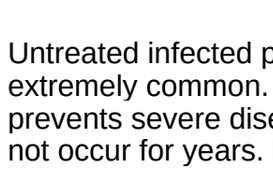

Figure 245-2 World distribution of malaria and areas of drug resistance, 2001.

is now considered to be unfeasible. The development of a vaccine has been attempted for decades with little success.

Personal preventive measures depend upon the estimated risk of infection based on itinerary, duration of stay, type of activities, accessibility to medical facilities, age and health. Counseling may then include protection from mosquito bites and appropriate chemoprophylaxis. The traveler must understand the importance of adherence

to preventive methods, but be aware that no method provides absolute protection and that symptoms may appear weeks or months after leaving the endemic area. Individuals at risk of developing severe disease such as infants, pregnant women or patients who have serious diseases should be discouraged from going to endemic areas. Appropriate protection against biting insects is strongly recommended.

In the few remaining areas of chloroquine-sensitive malaria, chloroquine prophylaxis is recommended. In chloroquine-resistant areas mefloquine, chloroquine-proguanil, atovaquone-proguanil or doxycycline may be recommended. The frequency of central nervous system (CNS) events with mefloquine prophylaxis is a matter of concern. Mefloquine prophylaxis usually should be taken for 1 week before entering a malarious area, while in the malarious area and for 4 weeks after leaving the area. Long-term (several months or years) prophylaxis is considered safe for chloroquine and mefloquine, and probably for doxycycline.[2] In areas of chloroquine resistance, strict personal antimosquito measures and chloroquine with proguanil is usually recommended to pregnant women. Mefloquine prophylaxis, which provides better protection, can be given after week 20 of pregnancy and is well tolerated. [3] Pregnancy must be avoided while on doxycycline prophylaxis. In areas of mefloquine resistance (parts of Thailand, Cambodia and Myanmar) doxycycline can be recommended for prophylaxis (Table 245.1).

Standby treatment is an alternative for selected patients. The standby treatment of choice for most areas would be atovaquone-proguanil. After leaving the endemic area, primaquine (15mg of base/day for 14 days) can be administered to eliminate any potential hypnozoites if exposure to *P. vivax* or to *P. ovale* infection has been intense.

Updated information on malaria risks and prophylaxis can be obtained from the US Centers for Disease Control and Prevention (CDC)[4] on a 24-hour toll-free telephone service (tel: (1) 877 FYI TRIP; fax: (1) 88 232 3299), or UK Travel Clinic, Hospital for Tropical Disease (tel: +44 171 388 9600), or through the internet (http://www.cdc.gov/travel/). The World Health Organization (WHO) also provides useful on-line information (http://www.who.int/ith).

TABLE 245-1 -- Malaria chemoprophylactic drug dosage.

MALARIA CHEMOPROPHYLACTIC DRUG DOSAGE		
Drug	**Adults**	**Pediatric**
Chloroquine phosphate	300mg base weekly (=500mg product)	5mg/kg base weekly
Mefloquine	250mg salt weekly	5mg/kg salt weekly
Doxycycline	100mg/day	2mg/kg/day Not for those under 8 years old
Proguanil	200mg daily	4mg/kg daily
Atovaquone ± proguanil	Atovaquone 250mg and proguanil 100mg daily	Atovaquone 62.5mg and proguanil 25mg. 11–20kg: 1 pediatric tablet daily (one extra tablet for each extra 10kg increase). Not for those under 11kg body weight
The maximum pediatric dosage is the adult recommended dose.		

DIAGNOSTIC MICROBIOLOGY

Laboratory confirmation of malaria is still based on microscopic examination of Giemsa-stained blood smears (see Chapter 166). The detection limit is around 50–500 parasites/µl of blood depending on the skill of the microscopist. Alternatively, visualization of plasmodia can be accomplished by fluorescent microscopy of capillary-tube centrifuged blood stained with acridine orange — quantitative buffy coat (QBC) — a slightly more sensitive method than thick films.[5]

If malaria is suspected and the first smear is negative, examinations should be repeated three times at 12-hour intervals, because in synchronous falciparum malaria the mature forms are sequestered from the circulation.

Parasitologic differential diagnosis should be made between the four *Plasmodium* spp. and *Babesia* spp. If a *Plasmodium* parasite cannot be identified to species level, it should be treated immediately as *P. falciparum*. The slides should then be sent to a reference laboratory and G6PD testing should be requested. The decision on treatment of possible intrahepatic hypnozoites using primaquine can be delayed until those results arrive.

Polymerase chain reaction (PCR) is highly specific and sensitive, detecting up to 0.3 parasites/µl of blood.[6] It has been found clinically useful in the detection of low parasitemia (as in the malarial hyper-reactive syndrome) and multiple-species infections.[7]

Antibody detection may be useful in the diagnosis of hyper-reactive malarial syndrome and for retrospective diagnosis. Recently developed immunochromatographic dipstick assays permit a rapid nonmicroscopic diagnosis of most cases of malaria. Their performance varies depending on the detected antigen, the level of parasitemia and the infecting *Plasmodium* spp. Compared with PCR tests devices that detect *P. falciparum* histidine-rich protein-2 have a sensitivity of 88% and a specificity of 97%. The test may persist positive weeks after successful therapy. The detection of aldolase or parasite lactate dehydrogenase permit the detection of high parasitemias of nonfalciparum malaria. In this device mixed infections would key out as *P. falciparum*. [8]

Serial parasite counts are recommended to monitor therapy;[9] 48 hours after the initiation of treatment, parasite counts are expected to be lower than 25% of initial counts. Quinine-related

TABLE 245-2 -- Features associated with a poor prognosis in *falciparum* malaria.*

FEATURES ASSOCIATED WITH POOR PROGNOSIS IN *FALCIPARUM* MALARIA		
Clinical	**Serum biochemistry**	**Hematology**
Agitation	? Glucose	Leukocytosis
Hyperventilation	? Bicarbonate	Severe anemia (PCV <15%)
Sustained body temperature	? Lactate	Platelets <50 × 10^6 /ml
>102.2°F(39°C)	? Creatinine	Fibrinogen <200mg/dl
Hypothermia	? Total billrubin	Prothrombin time >3 seconds
Bleeding	? AST 3×	Partial thromboplastin time ?
Coma	? ALT 3×	Parasitemia > 10^5 /ml
Convulsions	? 5-nucleotidase	Pigment-containing parasites >20%
Anuria	? CPK	Pigment-containing neutrophils >5%
Jaundice	? Myoglobin	
Shock	? Urate	
In patients who have premunition the parasitemia level has less prognostic value. CPK, creatine phosphokinase; PCV, packed cell volume; sAST, serum aspartate aminotransferase; sALT, serum alanine aminotransferase; 3×, three times normal.		

* *Adapted from White.*[11]

antimalarials do not kill gametocytes and so their presence in blood does not mean treatment failure. Recently, it has been shown that parasite lactate dehydrogenase is useful for monitoring patient progress.[10] Common laboratory findings are progressive anemia, moderate-to-severe thrombocytopenia and a normal white blood cell

count. Metabolic lactic or ketotic acidosis and other biochemical findings can be observed in severe disease (Table 245.2). Reaginic tests for syphilis may become positive.

CLINICAL MANIFESTATIONS

Malaria must be suspected in any febrile patient who has been in an endemic area in the previous 3 years. Occasionally, autochthonous cases are produced in nonendemic areas through transfusion of blood or blood products, sharing needles, maternal-fetal transmission or infection from an aircraft-transported infective *Anopheles* mosquito.

Before the onset of fever, non-specific symptoms such as malaise, headache, myalgia, fatigue, abdominal discomfort, dry cough, nausea, vomiting and diarrhea can occur, misleading the diagnosis.

Fever, the hallmark of malaria, usually develops 2 weeks after the infective bite, and in 95% of cases within the first 6 weeks and occasionally may follow the classic paroxysmal patterns:

- quartan pattern (peaks on days 1, 4, 7, etc.) — characteristic of *P. malariae;* or
- the tertian pattern of fever (peaks on day 1, 3, 5, etc.) — characteristic of all other species.

The absence of a typical fever pattern should not be a reason for disregarding malaria.

Physical examination may reveal tachycardia, splenomegaly, liver enlargement and jaundice. Malaria does not cause lymph node enlargement. In uncomplicated malaria, discrete hemolytic anemia, leukopenia and thrombocytopenia and other minor abnormalities of routine laboratory tests are usual.[11]

COMPLICATIONS

Patients infected with *Plasmodium* spp. other than *P. falciparum* rarely die of the infection in the developed world. The fatalities caused by 'benign' malaria are usually related to severe chronic anemia or rupture of an enlarged spleen. Patients infected with *P. malariae* may develop nephrotic syndrome.

On the other hand, *P. falciparum* infection must always be considered a life-threatening condition. The definition of severe malaria and complicated malaria is, however, controversial. On practical grounds, in developed countries where malaria is not endemic it is our practice to treat every patient who has *P. falciparum* malaria as an inpatient. Intravenous treatment is prescribed if the patient is seriously ill, regardless of strict fulfillment of the WHO definition of severe malaria.[12]

The most important complication of acute falciparum malaria is CNS involvement. Cerebral malaria is defined strictly as unrousable coma. Less severe neurologic manifestations are common, and high fever alone can cause confusion and delirium and, in children, seizures. In cerebral malaria, focal signs are uncommon and physical examination shows symmetric encephalopathy. Cerebrospinal fluid (CSF) is usually unrevealing. Untreated cerebral malaria is uniformly fatal. If adequately treated, the mortality ranges from 15 to 25%. There are persistent neurologic sequelae in 10% of children and 3% of adults.[13] A rare complication called postmalaria neurologic syndrome has been defined in patients recently recovered from *Plasmodium falciparum* malaria who have negative blood films at the time of onset of neurological or neuropsychiatric symptoms. Clinical manifestations emerge a few days or weeks after recovery from malaria and can be confused with mefloquine neurotoxicity.

Non-neurologic complications of malaria include renal failure, heart failure, acute pulmonary edema, adult respiratory distress syndrome, shock, coagulation disorders, severe anemia, hypoglycemia, metabolic acidosis, drug-related toxicity, malaria relapses and malarial hyper-reactive syndrome.

Relapse is defined as the reappearance of malaria originating from dormant liver schizonts, whereas recrudescence is the reappearance of disease after a partially effective treatment. Relapses can be expected in 50% of patients who have *P. vivax* or *P. ovale* infection who do not receive primaquine.

A condition called tropical splenomegaly or hyper-reactive malarial syndrome is occasionally seen in countries where malaria is endemic. It is defined as the presence of an enlarged spleen (often massive), raised IgM levels and high levels of antiplasmodium antibodies in patients who have negative smears for *Plasmodium* spp. and for whom no other cause of splenomegaly can be elicited.[14]

MANAGEMENT

Antimalarial therapy must be started in most cases without delay. The selection of treatment depends upon the parasite species and the expected resistance for that area. Details of drug regimens can be found in Chapter 166 .

Oral chloroquine is the treatment of choice for uncomplicated *P. falciparum* infections from chloroquine-sensitive areas, and for most *P. malariae*, *P. vivax* and *P. ovale* infections. Malaria due to the latter two species should also be treated with primaquine to eliminate hypnozoites. If the patient is pregnant or has G6PD deficiency, primaquine should not be used and any eventual relapses should be treated with chloroquine.

Occasionally, infections due to *P. vivax* are not cured by standard treatment. Chloroquine-resistant *P. vivax* and primaquine failure have been reported in areas of Asia and in Colombia.[15] It should be suspected if adequately treated *P. vivax* infection reappears within 1 month of treatment. In such a case mefloquine should be administered. If parasitemia reappears more than 1 month after the initial treatment, then primaquine failure should be suspected and more primaquine (22.5mg/day to a total cumulative dose of 6mg/kg) should be administered after chloroquine retreatment.

Uncomplicated *P. falciparum* infection from chloroquine-resistant areas can be treated with mefloquine taken with abundant water. The main side-effects are neuropsychiatric and cardiac. Intravenous physostigmine may reverse the severe neuropsychiatric side-effects of mefloquine.[16] Vomiting and diarrhea are associated with treatment failure. An acceptable alternative is 1 week of treatment with oral quinine, but lack of compliance may be a problem. When quinine is given combined with doxycycline, 3 days of treatment are equally effective. Pyrimethamine-sulfadoxine is a simple well-tolerated alternative, but parasite resistance has been reported from most endemic regions. Chloroquine plus clindamycin is also effective. Halofantrine is similar to mefloquine, but its cardiac toxicity is considered unacceptable if other alternatives are available. Atovaquone plus proguanil has proved efficacious for the treatment of uncomplicated, multidrug-resistant falciparum malaria.[17]

In some areas of Thailand, Myanmar and Cambodia, *P. falciparum* strains that have a higher level of resistance are common. Chloroquine or mefloquine does not prevent infections by these strains and their response to quinine, mefloquine and halofantrine is poor, unless these drugs are combined with other drugs. In these areas artemisin derivatives, such as artesunate, artemether or arteether, have been used extensively with remarkable success. Artesunate followed by mefloquine is the recommended treatment for malaria acquired in these areas. An alternative therapy is quinine plus doxycycline (clindamycin may be substituted for doxycycline in children

under 8 years of age and in pregnant women). In severe malaria, intramuscular artemether is as effective as quinine and less toxic.[18] [19] In severe *P. falciparum* infections, antimalarial treatment should be started parenterally because shock, vomiting and impaired swallowing may interfere with absorption. Therapy can be switched to oral administration after initial recovery,

Hyper-reactive malaria syndrome is treated with standard doses of antimalarials expected to be effective for the area of acquisition, followed by chemoprophylaxis while in the endemic area. Splenectomy is indicated if severe hypersplenism persists after months of continuous prophylaxis.

Supportive treatment is an essential part of the management of severe malaria. Seizures must be promptly treated or prevented in children and in adults with severe disease. Corticosteroids are not recommended for cerebral malaria. [20]

BABESIOSIS

Human babesiosis is an uncommon tick-borne parasitic zoonotic disease that was first described by Babes in Rumanian cattle in 1888. It was not reported as a human disease until 1957.

NATURE

The genus *Babesia* belongs to the family Piroplasmida and comprises over 70 species that parasitize mammals and birds. Infection in cattle is widespread and it is an economically important disease. Four species are the main potential human parasites:

- *Babesia bovis* and *Babesia divergens* in Europe;
- *Babesia microti* in the USA; and
- a *Babesia*-like piroplasm, designated WA1, that has been recently described in a patient from Washington State and might be the cause of the cases acquired on the west coast of the USA.[21]

EPIDEMIOLOGY AND PATHOGENICITY

Babesiosis in humans occurs predominantly in the USA, although a few cases have occurred in Europe and in other areas. It is highly endemic in the coastal areas of Massachusetts, Connecticut and New York State, where seroprevalence rates reach 4–6%, indicating that subclinical infections are common. In these areas rodents are the main reservoir and humans are usually infected by the bite of an infected nymph or *Ixodes dammini* tick. Transfusions of blood or blood products have caused a few cases. In Europe recent data indicate that most infections are not detected.[22]

PREVENTION

General recommendations include avoidance of known endemic areas, especially in the warm months of the year. Clothes should be sprayed with tick repellents before going on outdoor activities and on return the skin should be thoroughly examined for the presence of ticks.

DIAGNOSTIC MICROBIOLOGY

Babesia spp. are intraerythrocytic parasites that may resemble plasmodium trophozoites, but the hemozoin pigment is never present in babesiosis. Schizonts and gametocytes are not formed. Multiple erythrocyte parasitization is common and organisms are occasionally arranged in a characteristic Maltese cross shape (Fig. 245.3).

Parasitemia usually persists, demonstrable by light microscopy, for 3–12 weeks.

Serologic diagnosis can be made using indirect immunofluorescent antibody (IFA) assay. A serum titer of at least 1/256 is diagnostic of

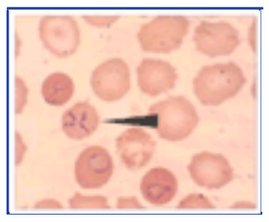

Figure 245-3 *Babesia* spp. Single and multiple intraerythrocytic parasites can be seen. The arrow marks a typical Maltese cross.

recent *B. microti* infection. Within a few weeks, most patients who have active infection have serum titers equal to or higher than 1/1024, falling over a few months to levels under 1/256.[23] Due to the lack of cross-reactivity, individuals exposed to the infection on the West coast of the USA should be tested also for antibodies to the *Babesia WA1* species.

PCR tests are more sensitive than microscopy but are not commonly available.

CLINICAL MANIFESTATIONS

The clinical forms of babesiosis vary widely depending upon the immune status of the host and the species of *Babesia* involved.

In the American Northeast, the symptoms of *B. microti* infection (Nantucket fever) range from a non-specific flu-like self-limited febrile illness to severe hemolytic anemia. It is most severe in those who are older or asplenic. The usual incubation period is 1–3 weeks. The onset is gradual with non-specific symptoms such as malaise, fatigue, anorexia, headache, emotional lability, myalgias and arthralgias. Blood leukocytes are not elevated and platelets are usually decreased. There may be a hemolytic anemia. The mortality rate is less than 10% of symptomatic cases.

The European cases typically occur in asplenic patients who present with a high fever and severe hemolytic anemia, and the infection is usually fatal. [24]

MANAGEMENT

Early treatment is recommended for all diagnosed cases to prevent long-term sequelae and potential transmission through blood donation.

The standard treatment is clindamycin, 600mg q8h plus 650mg of quinine q8h; both drugs are given for 7–10 days. Combination of atovaquone (750mg q12h) and azithromycin (500mg on day 1 and 250mg/day thereafter) for 7 days is also effective and is associated with fewer adverse reactions.[25] Chloroquine is not recommended. Blood transfusion and general supportive treatment may be needed for severe disease. Exchange transfusion has been used in an attempt to decrease parasite load, but its usefulness has not been demonstrated. It is recommended that co-infection by other tick-transmitted micro-organisms be ruled out.

TOXOPLASMOSIS

Toxoplasmosis is a widespread zoonosis, caused by the coccidian parasite *Toxoplasma gondii*, first recognized in 1908. *Toxoplasma* (from the Greek, meaning 'shaped as a bow') is a one-species genus.

Humans are usually infected orally, developing few, if any, symptoms of infection. The infection persists for life without signs of disease. However, during immunosuppression, quiescent parasites multiply, resulting in neurologic disease or, more rarely, other organ manifestations. Congenital transmission is a cause of major concern because it is frequently associated with severe disease in the newborn (see Chapter 65).

NATURE

Toxoplasma gondii is a parasite of many species of mammals and birds. The main forms of the parasite life cycle are oocysts, tachyzoites and bradyzoites.

The oocysts result from the sexual multiplication that takes place exclusively in the intestinal epithelium of cats and other felines. They are present in feline feces, and after maturing in the environment become the source of infection for noncarnivorous animals.

In the secondary host (all hosts but felines) *T. gondii* cells have two forms:

- rapidly multiplying tachyzoites (*tachy*, rapid), and
- 'dormant' bradyzoites (*brady*, slow).

When the host is infected by oocysts, tachyzoites or bradyzoites, a disseminated infection by tachyzoite forms takes place. Tachyzoites multiply inside the host cells, which rupture when 8–32 tachyzoites are produced. The tachyzoites released infect new cells. When the immune response controls the infection, some surviving parasites persist for many years in tissue cysts, which are sacs containing hundreds or thousands of *T. gondii* bradyzoites. They represent the parasite reservoir present in secondary hosts. Tissue cysts can be found in any tissue, but are most common in muscle and brain.

Cats become infected from eating birds, small rodents or other sources of raw meat. Humans and other animals become infected from either oocysts in soil and contaminated food or tissue cysts in raw meat. When acute infection occurs during pregnancy, tachyzoites are able to infect the placenta and, in a second step, the fetus.

EPIDEMIOLOGY

Toxoplasma gondii cysts are present in 5–92% of lamb meat and in a lower percentage of beef and pork meat. The prevalence of oocyst-shedding cats has been estimated at 1%. Infection rates in humans are very variable and depend upon eating habits and environmental factors. The prevalence increases progressively with age. In the 1990s the seroprevalence in women of child-bearing age with no obstetric history ranged between 37 and 58% in central Europe, Northern Africa and Australia, while in America and sub-Saharan Africa the range was 51–77%, and in India, South East Asia and China it was 4–39%.[26]

Human disease caused by *T. gondii* is much more restricted than the infection itself, and is generally a consequence of either intrauterine acquisition or immunocompromise.

PATHOGENICITY AND IMMUNITY

Toxoplasma gondii tachyzoites invade cells from nearly every organ, where they survive inside parasitophorous vacuoles. Resistance to the infection has been found to be enhanced by interferon (IFN)-? and diminished by IL-6. Extracellular tachyzoites are lysed by complement combined to specific antibody, and $CD4^+$ and $CD8^+$ T cells, lymphokine-activated killer and natural killer cells play a major role in infection control.

PREVENTION

Toxoplasmosis can be prevented at three different levels:

- prevention of primary infection;
- prevention of vertical transmission and congenital disease; and
- prevention of disease in infected immunocompromised individuals.

To prevent primary infection, the exposure to parasite can be reduced by health education (Table 245.3). No vaccine is presently available. Maternal immunity due to toxoplasmosis passed before conception protects the fetus from the infection. Immunodeficient patients receiving trimethoprim-sulfamethoxazole (co-trimoxazole)

TABLE 245-3 -- Recommendations to prevent toxoplasmosis.

RECOMMENDATIONS TO PREVENT TOXOPLASMOSIS
Do not eat raw or undercooked meat or eggs
Cured or smoked meat and sausages are considered safe. Freeze at -4°F (-20°C) for 1 or more days as an additional precaution
While handling raw meat, avoid touching the mouth or contaminating other food; normal hygienic washing of hands and utensils will suffice
Consume only pasteurized or ultra-heat-treated sterilized milk and dairy products
Wash or peel fruits and vegetables to be eaten uncooked
Control insect pests and their access to foodstuffs
Use gloves for gardening or handling sand where cats usually defecate
Avoid living with cats; if unfeasible, clean cat litter trays with nearly boiling water daily
Infection in cats can be reduced if they do not use raw meat, birds and rodents as a source of food

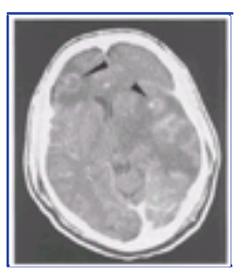

Figure 245-4 Toxoplasmic encephalitis in person who has AIDS. A cranial CT scan shows bilateral contrast-enhanced ring lesions with peripheral edema and mass effect.

as prophylaxis for *Pneumocystis* infection are substantially protected from toxoplasmosis.

Toxoplasma gondii IgG serology should be included in the initial work-up of pre-transplant patients, and transplantation of a solid organ from a seropositive donor to a seronegative recipient should be avoided if possible. If such a transplant is performed, then the recipient should have anti-*T. gondii* treatment for at least 2 months.

Individuals who have HIV infection and are seronegative for *T. gondii* should avoid being exposed to the parasite (Fig. 245.4), and should be periodically screened for seroconversion. For those patients who have HIV infection and are seropositive for *T. gondii*, further serologic tests do not provide useful information.

Maternal screening is controversial.[27] [28] Serologic screening is aimed at detecting acute maternal infection. It is, however, sometimes difficult to establish an early and reliable diagnosis of acute maternal or fetal infection. When acute infection is diagnosed in a pregnant woman, anti-*T. gondii* treatment, further assessment of fetal infection and abortion are offered.

DIAGNOSTIC MICROBIOLOGY

The diagnosis of *T. gondii* infection is usually made by serologic methods alone. The parasite can also be demonstrated by PCR, examination of stained tissue or fluid smears, cultivation in tissue cultures [29] and experimental animal inoculation.

Immunoglobulin G serology is widely used to screen for past infection. Immunoglobulin M appears earlier than IgG, declines faster and is a marker of relatively recent infection. In cases of toxoplasmic lymphadenopathy, 90% were IgM positive when tested within the first 4 months after the onset of lymphadenopathy and 22% remained positive when tested more than 12 months after the onset. In some cases, reactive IgM was undetectable.[30] [31] As the functional affinity of specific IgG antibodies is initially low and increases during subsequent weeks, the measurement of high-avidity antibodies helps to discriminate between recent (less than 3 months) and past infection. To diagnose a suspected case of acute toxoplasmosis IgG and IgM serology should be ordered in paired serum samples 3–4 weeks apart. If no antibodies are detected or if there is no seroconversion, acute toxoplasmosis can reasonably be ruled out. Avidity tests should be ordered if results are equivocal or IgM is positive.

CLINICAL MANIFESTATIONS

There are three different forms of toxoplasmosis: congenital infection, acute extrauterine infection and toxoplasmosis of the immunocompromised host.

Congenital toxoplasmosis

Toxoplasmosis acquired in utero can be asymptomatic or may produce signs of disease that can be present at birth.

The risk of congenital toxoplasmosis depends upon the time of acquisition of acute maternal infection.[32] Vertical transmission of *T. gondii* increases with gestation age (15–25% in the first trimester of pregnancy, 30–54% in the second and 60–65% in the third). Conversely, the severity of congenital disease is increased when infection occurs in early pregnancy. Signs of infection at delivery are present in 21–28% of those infected in the second trimester and up to 11% of those infected in the third trimester. Overall, 10% are born with severe disease.

Clinical manifestations of congenital toxoplasmosis include strabismus, chorioretinitis, encephalitis, microcephaly, hydrocephalus, psychomotor retardation and convulsions, as well as non-specific manifestations such as anemia, jaundice, hypothermia, thrombocytopenia, diarrhea and pneumonitis. The characteristic triad of hydrocephalus, cerebral calcifications and chorioretinitis resulting in

Figure 245-5 Fundoscopic image of toxoplasmic chorioretinitis. Most cases presenting in adults represent a late manifestation of a congenitally acquired toxoplasmosis.

mental retardation, epilepsy and impaired vision is the most severe and extreme form of the disease. Cerebral lesions may calcify, providing retrospective evidence of congenital toxoplasmosis.

Toxoplasma gondii chorioretinitis in immunocompetent patients is frequently secondary to congenitally acquired infection. The proportion of congenitally infected asymptomatic individuals who develop chorioretinitis later in life (usually in the first four decades) is unknown, but may well be over two-thirds (Fig. 245.5). Up to 30% of patients relapse after treatment.

Acquired toxoplasmosis

In 90% of cases, no clinical symptoms are apparent during acute infection. Most symptomatic patients present with enlarged lymph nodes that are located mainly in the head or neck area. Malaise and low-grade fever are present in less than 50% of symptomatic cases. Although *T. gondii* organisms are not usually seen, the histologic picture of acute *T. gondii* lymphadenopathy is usually diagnostic (Piringer-Kuchinka lymphadenitis). Occasionally, the lymph node histopathology can be mistaken for that of cat-scratch disease, other infections and lymphoma.[33]

Rare manifestations of acute infection include chorioretinitis, myositis and heart, lung, liver or CNS symptomatic involvement.

Toxoplasmosis in the immunocompromised host

Toxoplasmosis is a serious disease in patients who have profound immunosuppression such as those who have received a transplant or who have AIDS (see Chapter 127).

In transplant patients, the incidence and severity of the disease depends upon previous exposure to the parasite of donor and recipient, the type of organ transplanted and the degree of immunosuppression induced. The disease can be due to reactivation of a chronic silent infection or an acute primary infection acquired from the transplanted organ. The risk of developing toxoplasmosis for seronegative recipients of an organ from a seropositive donor is 57% for heart, 20% for kidney and minimal for liver transplants, reflecting the organ tropism of tissue cysts. [34] The disease manifests as a systemic disease with diverse degrees of multiorgan involvement including pneumonitis, carditis, hepatitis, myositis and encephalitis. In cardiac transplant recipients signs of myocarditis and pericarditis predominate.[35]

In patients who have AIDS, the clinical manifestations are usually related to CNS dysfunction or ocular lesions. Myocarditis is frequently found at autopsy, but is rarely clinically apparent. Infections of lung and other organs have also been reported.

Patients who become infected with *T. gondii* risk developing toxoplasmosis when their $CD4^+$ T cell count is less than 100 cells/mm^3 . The onset of *T. gondii* encephalitis is usually subacute. Fever and malaise usually precede the first neurologic symptoms. Headache, confusion, neuropsychiatric manifestations, seizures or other focal signs strongly suggest the diagnosis. Diagnosis is based upon clinical

data, neuro-radiology — magnetic resonance imaging (MRI) is the procedure of choice — and response to therapy. PCR testing of cerebrospinal fluid may be diagnostic too. *Toxoplasma gondii* encephalitis in patients who have AIDS usually presents as multiple abscesses in the basal ganglia or the gray-white matter junction with a contrast-enhanced ring (see Fig. 245.4). Diffuse *T. gondii* encephalitis is an uncommon rapidly fatal form.

In people who have HIV infection there is no good serologic marker of active toxoplasmosis. The presence of anti-*T. gondii* antibody means previous exposure and therefore present infection, but not necessarily disease. The absence of specific antibodies makes toxoplasmosis unlikely.

MANAGEMENT

Congenital toxoplasmosis

In gestational toxoplasmosis, the drug therapy may be intended to treat the mother, the fetus or the newborn (Fig. 245.6).[36] Spiramycin (not available in the UK) is a macrolide antibiotic that concentrates in the placenta, reducing placental infection by 60%.[37] It does not pass consistently through the placental barrier and it is used to decrease vertical transmission. Spiramycin 3g/day q8h should be given to pregnant women who have an acute infection from diagnosis to delivery unless fetal infection is proved. In such a case, the maternal regimen must be switched to sulfadiazine 4g plus pyrimethamine 25mg and folinic acid 15mg a day until delivery.[38] The risk of serious disease in early infections outweighs any consideration of potential teratogenic effects of antifolates used in the first trimester of pregnancy. All infected newborns should have anti-*T. gondii* treatment (sulfadiazine 50mg/kg q12h plus pyrimethamine 1mg/kg/day and folinic acid 5mg/kg/day for at least 6 months). No treatment regimen seems to decrease the rate of chorioretinitis

To confirm fetal infection, ultrasound fetal examination and sampling the amniotic fluid for *T. gondii* PCR and culture are recommended.[39] Fetal blood sampling obtained by cordocentesis has been commonly used to detect fetal antibodies and for *T. gondii* culture. Cordocentesis had an inherent risk of fetal loss of 2–3% and has been replaced by PCR testing of amniotic fluid.

Termination of pregnancy is commonly offered to women who seroconvert in the first 8 weeks of pregnancy and to those infected in the first 22 weeks of pregnancy when fetal infection is confirmed. A more conservative approach recommends abortion only if there is ultrasonographic evidence of hydrocephalus, although a small percentage of cases with neurologic disease will then be born.[36] [40]

Toxoplasmosis complicating a previous pregnancy is not an indication for prophylaxis during a subsequent pregnancy. Women may be reassured that they are not at greater risk of toxoplasmosis affecting the new pregnancy.

Acquired toxoplasmosis

Symptomatic *T. gondii* infection in nonpregnant immunocompetent individuals does not need to be treated unless there is visceral involvement or the patient has been infected in a laboratory accident.

Toxoplasmosis in the immunocompromised host

Standard anti-*T. gondii* treatment is sulfadiazine 4g/day q6h plus pyrimethamine as a first 100mg loading dose followed by 50mg/day and folinic acid 15mg/day for 6–8 weeks. If brain edema is of relevance corticosteroids should be given, but the clinical response to anti-*T. gondii* therapy would be masked by the unspecific improvement due to the reduction of edema. If the patient has not improved in the first 2 weeks of therapy a control computerized tomography (CT) or MRI scan should be repeated to review the empiric diagnosis. A repeat scan should be carried out after completing treatment. With

Figure 245-6 Toxoplasmosis risk management in pregnancy.

this regimen 80% of patients survive, although 50% of the survivors will have neurologic sequelae. Serious adverse effects to the medication can be expected in 40% of patients. In cases of intolerance to sulfadiazine, 75–100mg/day of pyrimethamine alone or with clindamycin has been used (see also Chapter 113 and Chapter 127).

Secondary prevention

Approximately 80% of AIDS patients relapse after an initial episode of toxoplasmosis. Daily treatment with pyrimethamine 50mg plus sulfadiazine 1g and folinic acid 10–15mg should be given to reduce the relapse rate to 5–10%. Current US Public Health Service (USPHS)/Infectious Diseases Society of America (IDSA) guidelines (http://www.hivatis.org) recommend that secondary prophylaxis may be discontinued in patients with sustained (>6 month) increase in CD4T cells (>200 cells/mm^3) (see Chapter 123 and Chapter 127).

LEISHMANIASIS

Leishmaniasis is the term used to describe a group of chronic parasitic diseases caused by a number of species of the genus *Leishmania*. The infection can be localized in the skin or mucous membranes or disseminated in the reticuloendothelial system. It is usually a zoonosis transmitted by Phlebotominae sandflies, which are endemic in areas of Southern Europe, Asia, Africa and the Americas.

NATURE

The genus *Leishmania*, along with the genus *Trypanosoma*, belongs to the order Kinetoplastida, which comprises flagellated protozoa that possess a characteristic extranuclear DNA mass called the kinetoplast.

Leishmania parasites are classified into two broad groups:

- New World *Leishmania* spp.; and
- Old World *Leishmania* spp.

Closely related species are grouped into complexes (Table 245.4). Members of *Leishmania braziliensis* complex have been renamed *Leishmania* subgenus *viannia*.

Sandflies are small (3–4mm), hairy mosquito-like insects, and transmit the disease. Old World sandflies belong to the genus *Phlebotomus*; New World species belong to the genera *Lutzomyia* and *Psychodopygus*.[41]

Sandflies become infected when taking a blood meal containing infected macrophages, which are present in blood or skin. Leishmania live in the digestive tract of the insect as flagellated parasites (the promastigote form). The parasites divide in the midgut of the insect except for the *viannia* group, which multiply in the hindgut. The highly motile promastigotes migrate to the buccal cavity of the insect, which regurgitates them on biting, thereby infecting a vertebrate host. Promastigotes rapidly penetrate macrophages and transform into an aflagellated oval body measuring 2–3.5mm across and called an amastigote (literally, without whip). Amastigotes live as obligate intracellular parasites inside the macrophages, where they multiply and are phagocytosed by other mononuclear cells when the host cell ruptures. The infection may disseminate to internal organs, spread locally to mucous membranes or persist as a chronic skin lesion.

TABLE 245-4 -- Summary of the epidemiology of leishmaniasis.

EPIDEMIOLOGY OF LEISHMANIASIS				
Complex	**Main species**	**Reservoir**	**Geographic distribution**	**Clinical disease**
Leishmania donovani	*L. donovani*	Humans	India, Bangladesh, Burma, Sudan, Kenya, Somalia	VL, PKDL, CL
	L. infantum	Dogs	A belt from Portugal to China	VL, CL
	L. chagasi (infantum)	Foxes, dogs, opossums	South of Mexico to northern South America	VL, CL
Not included in a complex	*L. major*	Rodents	Arid areas north of the Sahara, Arabia and Central Asia, sub-Saharan savanna	CL, LR
	L. tropica	Humans	Towns in East Mediterranean countries, Middle East and Central Asia	CL, LR
	L. aethiopica	Hyraxes	Highlands of Ethiopia and Kenya	CL, DCL, MCL
Leishmania mexicana	*L. mexicana*	Forest rodents	Tropical forests of Southern Mexico, Belize and Guatemala	CL (chiclero ulcer)
	L. amazonensis	Forest rodents	Tropical forests of South America	CL, DCL
	L. venezuelensis, L. garnhami, L. pifanoi	Unknown	Venezuela	CL
Leishmania braziliensis	*L. braziliensis*	Forest rodents, domestic animals	Tropical forests of South and Central America	CL, MCL, VL
	L. guyanensis	Sloths, arboreal ant-eaters	Guyana, Surinam, areas of Brazil	CL (forest pian), MCL
	L. panamensis	Sloths	Panama, Costa Rica, Colombia	CL (bejuco ulcer), MCL
	L. peruviana	Dogs	Areas of Peru and Argentina	CL (uta)
CL, cutaneous leishmaniasis; DCL, diffuse cutaneous leishmaniasis; LR, leishmaniasis recidivans; MCL, mucocutaneous leishmaniasis; PKDL, post-kala-azar dermal leishmaniasis; VL, visceral leishmaniasis. Common names are in parentheses. Currently, there is no firm concensus on the species classification.				

EPIDEMIOLOGY

Leishmaniasis is endemic in 88 countries (Fig. 245.7). The world prevalence and annual incidence have been estimated to be 12 and 2 million people, respectively. The incidence of all forms of the disease is steadily increasing.

The vast majority of patients are infected by sandflies, but rare cases in which infection is transmitted by blood transfusion have been reported. Transmission by sharing needles among intravenous drug abusers has been proposed. [42]

PATHOGENICITY

The internalization of leishmania in the macrophage results from the interaction of complement CR3 and fucose-mannose receptors with the parasite major surface protein (Gp63) cysteine proteinases, and membrane lipophosphoglycan. Parasite survival inside the parasitophorous vacuole is facilitated by iron superoxide dismutase and acidic phosphatase secreted by the parasite. In vitro the parasite inhibits inducible nitric oxide synthase activity and nitric oxide production by macrophages. In animal models, susceptibility to infection is mediated by two subsets of $CD4^+$ T cells, named T-helper (Th)1 and Th2:

- Th1 lymphocytes produce IFN-?, which activates macrophage destruction of parasites; and
- Th2 lymphocytes produce lymphokines, which inhibit Th1 activity and activate an ineffective humoral response.

The $CD8^+$ T cells also play a major protective role. The host's immune system, parasite species and strain-dependent factors interact to create the full spectrum of clinical disease (see Chapter 172).

Figure 245-7 Geographic distribution of leishmaniasis. Visceral leishmaniasis (VL): 90% of cases occur in India, Bangladesh, Sudan and Brazil. Mucocutaneous leishmaniasis (MCL): 90% of cases occur in Bolivia, Brazil and Peru. Cutaneous leishmaniasis (CL): 90% of cases occur in Afghanistan, Brazil, Iran, Peru, Saudi Arabia and Syria.

DIAGNOSTIC MICROBIOLOGY

The laboratory diagnosis can be made by demonstrating *Leishmania* by microscopy or culture, detecting parasite DNA by PCR techniques or demonstrating immune response by serology or leishmanin cutaneous tests.

To study skin lesions, smears can be prepared from the tissue juice of the raised edge of an ulcer. The sample can be aspirated with a needle or scraped with a blade. Parasites can be detected by microscopy or culture in only 30% of cases of leishmaniasis recidivans, 50% of cases of mucocutaneous leishmaniasis (MCL) and 70% of cases of cutaneous leishmaniasis (CL).

In cases of visceral leishmaniasis (VL) sternal bone marrow aspirate is the sample of choice for parasitologic diagnosis (62–100% sensitivity). Splenic fluid aspirate has a higher diagnostic rate (95–100%), but splenic rupture may complicate the procedure. Other samples such as blood, lymph nodes or liver tissue may be of value. To increase positive yield, samples should be routinely cultivated in special media. Species and strain identification can be accomplished by monoclonal antibody staining, PCR and isoenzyme typing.[43]

Serologic testing is useful in the diagnosis of VL and can be of value in cutaneous forms of leishmaniasis. The indirect fluorescent antibody test (IFAT) is sensitive and group specific and its sensitivity is 80–100% in VL patients who do not have HIV infection and 77–89% in MCL. In CL, low titers can occasionally be found. Latex and direct agglutination tests are useful for low-technical testing on field working conditions. Serologic cross-reactivity has been found in the sera of patients who have leprosy, tuberculosis, Chagas' disease, African trypanosomiasis, malaria and schistosomiasis. Refined enzyme-linked immunosorbent assay (ELISA) tests have shown promising results in VL and CL.[44] A proportion of individuals who have HIV infection and VL have persistently negative serology. The IFAT is positive in 22–57% of cases, whereas ELISA combined with IFAT is positive in 55–71% and the Western blot *Leishmania* test is positive in 83% of cases.[45] Polymerase chain reaction testing is superior to bone marrow culture and microscopy.[46] The detection of parasite antigens, that do not depend on serologic response, may eventually prove very useful.

Leishmanin tests (Montenegro reaction) assess cutaneous reactivity against a phenolized promastigote suspension. It is a useful epidemiologic marker of past infection. The test is almost invariably negative in patients who have VL, and in 80% becomes positive 6 months after successful treatment.[47] In localized cutaneous forms the test becomes positive within 3 months of appearance of the lesion and remains positive for life. In diffuse cutaneous leishmaniasis (DCL), this test is universally negative.

CLINICAL MANIFESTATIONS

Most cases of leishmanial infection are probably subclinical. The disease produced can be classified in two groups: VL (also called kala-azar) and CL. Cutaneous disease can be divided into Old World CL, New World CL and MCL. Less frequent forms include DCL, cutaneous recidivans leishmaniasis and post-kala-azar dermal leishmaniasis (PKDL) (see also Chapter 172).

Visceral leishmaniasis

The population at risk includes children under 5 years of age, immunocompromised patients and those who are malnourished. The incubation period is usually 2–8 months. Most patients do not recall having a suggestive skin lesion during the previous months. The onset is usually as an insidious febrile illness, but can be sudden with a high fever and chills. An enlarged spleen and moderately enlarged liver and lymph nodes can be detected on physical examination. As the disease progresses, signs of anemia, ecchymoses and abdominal discomfort become apparent. Anemia is due to splenic sequestration, hemodilution, bone marrow infiltration, hemolysis and bleeding. Thrombocytopenia and leukopenia are also common. In advanced disease, massive spleen enlargement, emaciation, ascites, subcutaneous edema, diarrhea, bleeding and severe anemia develop.

The mortality rate of untreated disease is 85–95%. Intercurrent infections are the cause of death in most cases.

Visceral leishmaniasis in immunocompromised patients

Patients who have HIV infection and immunosuppressed transplant recipients have an increased risk of developing leishmaniasis. In Southern Europe, the prevalence of leishmaniasis among AIDS patients is 2–9%. This represents 10,000 times the rate in the general population.[48] Several years may elapse from exposure to development of the disease. Immunodepressed patients may develop VL when infected with strains that in immunocompetent individuals cause only CL. Atypical manifestations of VL encountered in these patients include localized lesions on bony prominences (Fig. 245.8), tongue, larynx, intestinal tract and lung, and Kaposi's sarcoma. Most of these atypical manifestations have also been recognized in non-AIDS patients who have advanced disease. In immunocompromised patients the disease almost invariably relapses after treatment.[49]

Old World cutaneous leishmaniasis

There are four forms of CL with distinctive clinical and immunologic features.

Oriental sore or localized CL appears on the site of the sandfly bite after approximately 2–4 weeks. The lesion begins as an asymptomatic papule, which enlarges and forms a well-circumscribed ulcer with a raised violaceous border. The lesion spontaneously resolves over a period of months, leaving a depressed scar. Three species produce most cases: *Leishmania tropica*, *Leishmania major* and *Leishmania aethiopica*.

Leishmaniasis recidivans presents as a chronic skin lesion that appears on the skin areas where an oriental sore has been. It has also been called 'chronic relapsing CL' and 'chronic lupoid leishmaniasis' because it closely resembles lupus vulgaris both clinically and histologically.[50]

Figure 245-8 Cutaneous manifestation of kala-azar in AIDS.

Figure 245-9 New World cutaneous leishmaniasis.

Diffuse cutaneous leishmaniasis is a rare form of diffuse skin infection characterized by heavy parasitization of skin macrophages and absence of an effective cellular response. The lesions do not ulcerate.

Post-kala-azar dermal leishmaniasis consists of symmetric macules or nodules on the face and sometimes on the trunk and extremities of patients who have had VL.

New World cutaneous leishmaniasis

Cutaneous leishmaniasis and MCL in the Americas take several clinical forms. The most notorious are chiclero ulcer, uta, cutaneous diseases caused by *Leishmania (Viannia) braziliensis* and MCL.

Chiclero ulcer caused by *Leishmania mexicana* was originally seen in latex (chicle) collectors who entered the forest. The lesion appears as a destructive ulcer of the pinna of the ear or the face and progresses over months (Fig. 245.9).

In uta, a disease of young children caused by *Leishmania peruviana*, the skin ulcer heals in 3–6 months leaving a disfiguring scar, usually on the face.

The cutaneous diseases caused by *Leishmania (viannia) braziliensis* complex consists usually of multiple shallow ulcers that have a tendency to metastasize along the lymphatic vessels. They evolve to mucocutaneous disease in 5% of cases. Untreated, such diseases persist for years. Relapses after treatment are common.

Mucocutaneous leishmaniasis, a markedly disfiguring, life-threatening disease, is typically caused by *L. braziliensis* and appears during the first 10 years after resolution of cutaneous disease. It consists of a pseudotumoral destructive lesion. It usually starts in the nasal mucosa and spreads to oronasopharyngeal mucosa, larynx and skin of the lips and nose. Death may be due to pneumonia, laryngeal obstruction, secondary sepsis or starvation. Spontaneous cure is rare and response to therapy is poor. Differential diagnoses include carcinoma, syphilis, yaws, rhinoscleroma and rhinosporidiasis.

MANAGEMENT

Treatment schemes can be divided in two groups — those applied to localized CL and those for extensive disease (VL, MCL and DCL).

Most cutaneous sores will slowly resolve spontaneously providing lifelong immunity. Indications for treatment are infection by *L. braziliensis* complex and sores in potentially disabling sites. Surgical excision and cryotherapy are suitable for small lesions. Heating at 131°F (55°C) for 5 minutes using infrared radiation cured 90% of cases of oriental sores.[51] Infiltration of the sore with antimonials is also effective: 0.5–1.5ml of parenteral solution is carefully injected into the edges and base of the ulcer and three doses are given 3 days apart. Systemic treatment is recommended for all forms of *L. v. braziliensis* complex infections (see Chapter 172).

Alternative treatments include topical aminosidine (paromomycin) ointment (once daily for 1 month), ketoconazole (600mg/day for 4 weeks), dapsone (200mg/day for 4 weeks) and oral allopurinol (5mg/kg q6h) plus probenecid (500mg q6h) for 1 month. Some immune enhancing methods have also been found to be effective. [52]

For VL pentavalent antimonials have been the first choice of treatment for years. There are two commercial preparations with similar efficacy and toxicity:

- meglumine antimoniate, and
- stibogluconate sodium.

The recommended dosage of antimony is 20mg/kg/day. The duration of treatment is 1 month for VL and 2–3 months for DCL and PKDL. If the patient is not thrombocytopenic, intramuscular administration is recommended. Intravenous drug should be infused over 2 hours to prevent cardiac arrhythmia. If higher doses are used, cardiac monitoring is needed. Serum amylase concentration should be periodically measured because pancreatitis is frequently seen in patients who have HIV infection. Other common side-effects are arthralgia, myalgia, an exfoliative rash and abdominal cramps. In Bihar state (India) antimonial resistance is now widespread. The membrane of leishmania amastigotes contains ergosterol. For this reason, antifungals that interfere with the ergosterol pathway can be used in leishmaniasis. Amphotericin B deoxycholate, and meglumine have similar rates of initial cure, and relapse-free intervals differing in the type of toxicity.[53]

New lipid-associated amphotericin compounds are theoretically targeted against leishmania because the amphotericin B-lipid complexes are cleared from blood by the monocellular/macrophagic system where the parasite persists. None of these preparations has been tested against conventional amphotericin B, but as the treatment is of shorter duration and toxicity is diminished, it will probably be preferred where costs are not a major factor.[54] [55] Present recommended cumulated dosage of liposomal amphotericin B is at least 18mg/kg (3mg/kg per day for 5 days, followed by 3mg/kg on day 10).[56]

Parenteral administration of aminosidine, a toxic aminoglycoside with parasiticidal activity has been used combined with antimonials for antimonial-resistant strains after amphotericin failure. Miltephosin (an alkyl phospholipid derivative developed as a treatment for breast cancer) is a new promising oral treatment.[57]

Continuous suppressive treatment with one dose of antimonials every 2–4 weeks is indicated for patients who have HIV infection and leishmaniasis after a full course of treatment.[58] Amphotericin every 2–4 weeks has also been used. Pentamidine might prevent relapses when used as prophylaxis against *Pneumocystis carinii* infection. When suppressive therapy was discontinued after successful antiretroviral therapy relapses were observed only in patients with CD4 counts under 350 cells/mm^3 . [59]

TRYPANOSOMIASIS

Trypanosomes produce two clinically and epidemiologically different diseases that are presented separately:

- American trypanosomiasis or Chagas' disease, and
- African trypanosomiasis or sleeping sickness.

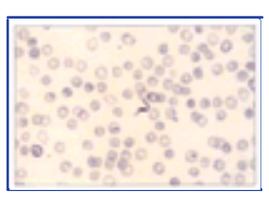

Figure 245-10 ***Trypanosoma brucei.*** Note the central nucleon, an undulating membrane and a clump of mitochondrial DNA called kinetoplast.

TABLE 245-5 -- Features of different types of human trypanosomiasis.

FEATURES OF HUMAN TRYPANOSOMIASIS			
	Trypanosoma brucei gambiense, Trypanosoma brucei rhodesiense	***Trypanosoma cruzi***	***Trypanosoma rangeli***
Geographic distribution	Africa	Central and South America	
Name of disease produced	Sleeping sickness	Chagas' disease	Nonpathogenic
Main affected organ	Brain	Heart, colon, esophagus	None
Vector (common name)	*Glossina* spp. (tsetse fly)	Reduviidae (kissing bugs)	
Mode of transmission	Bite (insect saliva)	Insect feces	Bite (insect saliva)
Multiplying form in humans	Trypomastigote	Amastigote	Trypomastigote

When a human host is infected the organisms multiply in the inoculation area, then pass into the blood, and in a third phase they localize in some internal organs causing chronic disease.

Trypanosomes pass through the morphologic stages of amastigote and trypomastigote (Fig. 245.10). The differences between the species that can be found in humans are summarized in Table 245.5 .

CHAGAS' DISEASE (AMERICAN TRYPANOSOMIASIS)

Chagas' disease is named after Carlos Chagas, who discovered *Trypanosoma cruzi* and described its life cycle and the clinical features of the disease.

The disease starts as an acute febrile illness followed by a long asymptomatic period and a chronic symptomatic stage characterized by distention and abnormal function of the heart and gastrointestinal tract.

Epidemiology

Chagas' disease is endemic in most Latin American countries. Low-income families of rural areas are most frequently affected and up to 20% of the population have the infection in the most affected regions. The WHO estimates that there are 16–18 million people who currently have the infection and that 2–3 million of them have chronic disease. It causes more than 45,000 deaths/year (see Chapter 173).

Pathogenicity

Hemipterous insects of the Reduviidae family (kissing bugs) are responsible for transmission. The parasite has a sylvatic cycle maintained by reduviids that feed on opossums and other wild animals, and which occasionally bite humans. It may also persist in a domestic cycle maintained by reduviids that live in the cracks of mud huts, feeding on humans, house rodents and domestic animals. In some areas, these two cycles overlap. As asymptomatic individuals may harbor a low number of parasites in their blood for many years, transmission by blood product transfusion is a major cause for concern. Oral transmission through breast milk or contaminated food and transplacental transmission are less common routes of infection.

Triatomid bugs infect when taking a blood meal from a host infected by *T. cruzi*. The parasite develops in the gut of the insect and infective trypomastigotes are released with insect feces. *Triatoma* spp. bugs bite humans at night and defecate soon after they are engorged, contaminating the skin with trypomastigotes that penetrate through skin erosions or mucosal surfaces (typically the conjunctiva). The parasite multiplies inside cells as amastigotes. Some amastigotes differentiate into trypomastigotes, which disseminate through the circulation and may eventually be eaten by a reduviid bug.

Although the histopathology of Chagas' disease is characteristic, the pathophysiologic mechanism that leads to these changes is not clearly understood. As a result of an inflammatory process (and perhaps a neurotoxin) the conducting system of the heart and the myenteric plexus are damaged. The mononuclear cell response gradually controls the infection, but does not usually eradicate it. In the late stages of the disease, only small numbers of parasites are found in cardiac muscle and the gastrointestinal tract, and autoimmune phenomena are probably responsible for the continuous progression of heart muscle damage. Neuronal depletion of the myenteric plexus leads to asynchronous peristaltic movement and, in the most severe cases, the esophagus, colon and other internal ducts dilate to enormous size.

Prevention

General improvement in housing standards or at least the use of noncracking plaster and the regular use of residual insecticides is recommended to eliminate domestic vectors. In endemic countries, blood donations should be serologically screened for trypanosome infection. Where this is not feasible, the addition of gentian violet to a bag of blood will 'trypanosome-sterilize' it.[60]

Diagnostic microbiology

Direct parasitologic diagnosis can be obtained by visualizing the parasite in blood or tissue, demonstrating it in culture or by xenodiagnosis. Conventional serology and PCR are especially useful for patients who have undetectable parasitemia.

Parasitemia is usually detectable in the acute phase of disease by staining the buffy coat. Needle aspiration or slit-skin smear of cutaneous inoculation lesions may be positive. The parasite can also be grown in leishmanial culture media.

Xenodiagnosis is the most sensitive method of parasite demonstration. [61] Fasted, laboratory-reared, triatomid bugs are placed in a box with a gauze on one side. The box is briefly applied to the forearm of the subject to let the bugs feed. After 10–30 days, the parasite can be found in the intestinal contents of the bugs. In acute

disease xenodiagnosis is nearly always positive, but in the chronic stage of disease it is positive in only half of the patients tested.

Serology is a reliable and sensitive method of diagnosis. It usually becomes positive 1 month after infection and remains positive for life.[62] The presence of antibodies that bind to the epitopes of living trypomastigotes (called lytic antibodies) is indicative of persisting infection. Cross-reactivity exists with leishmaniasis, malaria, toxoplasmosis, pemphigus foliaceus, infectious mononucleosis and *Trypanosoma rangeli* and mycobacterial infections.

Newly developed PCR techniques may be especially useful in defining parasitologic cure, diagnosing indeterminate-stage patients and assessing suspected cross-reacting serology or combined infections.[63]

Clinical manifestations

The disease evolves through three different clinical stages: acute infection, asymptomatic period and chronic disease (see Chapter 173).

Acute infection is symptomatic in only one-third of those infected. The severity and intensity of signs are greatest in younger patients, but the prevalence of infection increases with age. Symptomatic patients may develop an inflammatory nodule at the site of inoculation and an enlarged satellite lymph node. A characteristic feature is the presence of periocular edema due to conjunctival inoculation of *T. cruzi* (Romaña's sign). Manifestations of acute disease are fever, generalized lymphadenopathy, moderate hepatosplenomegaly, erythematous rash and myocarditis. Most patients survive the acute stage and gradually become asymptomatic within a few months. Congenitally infected newborns present with myocarditis or meningoencephalitis and usually die within days.

The indeterminate form is the asymptomatic period during which the infection can only be detected by serologic methods, although some degree of esophageal dysfunction or cardiac disease may be found when appropriate diagnostic methods are used.

The chronic symptomatic stage is characterized by the chagasic megasyndromes that develop in one-third of those infected, usually 5–15 years after infection (Fig. 245.11 and Fig. 245.12). Chronic cardiomyopathy is eventually present in 27%, digestive manifestations in 6% and neurologic disorders in 3% of infected individuals.

Congestive heart failure, arrhythmias and embolic disease characterize chagasic cardiomyopathy,[64] which is the most common cause of death in Chagas' disease. The presence of any of these conditions with suggestive epidemiologic data strongly suggest *T. cruzi* infection.

Esophageal disorders include achalasia, cardiospasm and enlargement. Megacolon results in constipation and abdominal pain. Associated complications include esophagitis, esophageal hemorrhage, esophageal cancer, volvulus and obstructive intestinal disease.

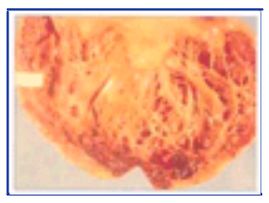

Figure 245-11 A dilated heart from a fatal case of chagasic cardiomyopathy. Chronic heart disease is the commonest cause of death in Chagas' disease. *Courtesy of Dr J Cohen, Cordoba, Argentina.*

Figure 245-12 Chagasic megacolon at autopsy. Grossly enlarged colon as shown here or other duct dilatation is characteristic of chronic Chagas' disease. *Courtesy of Dr J Cohen, Cordoba, Argentina.*

Latent disease reactivates in immunocompromised patients. In one series of AIDS patients who had Chagas' disease, 87% developed encephalitis and 21% acute myocarditis.[65]

Management

Antiparasitic therapy is clearly recommended only for the acute forms and parasitemic immunocompromised patients. Nifurtimox and benznidazole are the only two parasiticidal drugs used against *T. cruzi* (see Chapter 173).

Nifurtimox is seldom available. Benznidazole dosage is 7.5mg/kg up to 5g/day q12-24h given for 2 months. Some preliminary data suggest that the use of benznidazole in the early chronic stages and the use of allopurinol (600–900mg/day for 2 months) in chagasic heat disease may be beneficial.[66] Chagas' disease has traditionally been considered to be a contraindication for heart transplantation, but with the use of a low ciclosporin dosage, 80% survival at 24 months has been achieved.[67] Esophageal disease is treated with cardiac dilatation in early cases. Surgery is reserved for severe esophageal or colonic dilatation.

INFECTION BY *TRYPANOSOMA RANGELI*

Trypanosoma rangeli is an American parasite transmitted by triatomids. In some areas of Central America, human parasitization by *T. rangeli* is six times more frequent than that by *T. cruzi*. Although regarded as nonpathogenic to humans, it is medically important as a source of misdiagnosis of Chagas' disease.

AFRICAN TRYPANOSOMIASIS

Two African trypanosomes of the *T. brucei* complex infect humans:

- *Trypanosoma brucei gambiense*, which usually produces chronic infections; and
- *Trypanosoma brucei rhodesiense*, which tends to produce a more acute disease.

After an initial stage of parasitization restricted to the bloodstream, some individuals develop encephalitis. One of its most striking symptoms is a somnolence/insomnia disorder after which the disease was named 'sleeping sickness' (see Chapter 157).

Epidemiology

The vector of *T. brucei* subspecies is a fly of the genus *Glossina* (tsetse fly), which is geographically confined to tropical Africa. The incidence of the disease is unknown, but may be around 200,000 cases/year.

Several *Trypanosoma* spp. infect wild and domestic animals and the infection is an important economic problem.

Trypanosoma b. rhodesiense is transmitted by *Glossina morsitans*. This fly lives in the dry savannas of East Africa, feeding mainly on the wild ungulates, which represent the main reservoir. *Trypanosoma b. gambiense* is endemic in West Africa. Humans are considered to be the main reservoir. Transmission usually occurs in the shaded riverine areas where *Glossina palpalis* and *Glossina tachinoides* live and breed.

Trypanosoma brucei brucei is an animal pathogen that is unable to infect humans.

Nature

The vector fly is infected when taking a blood meal containing trypanosomes. The ingested parasites transform and multiply in the insect midgut and migrate to the salivary glands from where new hosts are infected by biting. In the human host the parasite multiplies asexually in the interstitial space and spreads through the lymphatic vessels to the lymph nodes and blood.

On human blood smears, two different morphologies can be observed:

- a short, stumpy form that is infective for *Glossina* spp; and
- a slender, actively multiplying, flagellated form.

Amastigote forms are not usually seen.

Pathogenicity

The parasite can produce hundreds of antigenically different surface glycoproteins serially. This process enables it to elude the host immune response, resulting in a characteristic fluctuating parasitemia pattern throughout the course of infection. After a variable period, the parasite reaches the CNS, causing meningitis and choroid plexus breakdown. Large amounts of IgM are produced in the serum and CSF. Characteristic plasmacytic morular cells can be seen in tissues, blood, bone marrow and CSF. Autoimmune phenomena, circulating immune complex deposition and increased vessel permeability play an important role in pathogenesis (see Chapter 157).

Prevention

Massive clearance of *Glossina* spp. habitats, insecticide spraying, destruction of wild game, periodic mass treatment and enforced relocation of entire populations were successfully used in the past. A more recent development for control is the use of *Glossina* spp.-attracting traps. Active surveillance is recommended periodically in areas of *T. b. gambiense* and during epidemics in *T. b. rhodesiense* areas. Travelers visiting endemic areas should be warned of the type of activities that may increase the chances of being bitten by tsetse flies and report any possible exposure. Mosquito repellents may be useful.

Diagnostic microbiology

The diagnosis of the disease essentially depends upon the careful microscopic examination of blood or CSF samples. Given the fluctuating nature of parasitemia, daily samples should be taken for 2 weeks to rule out parasitemia. Lymph node and bone marrow aspiration may be positive in cases with a low parasitemia. In-vitro culture and miniature anion exchange column test are also feasible. Serologic tests to detect antibodies against invariant surface antigens or against the most prevalent variant surface glycoproteins and PCR testing are available in some reference laboratories.

Clinical manifestations

In African trypanosomiasis, the disease develops in two stages:

- a hemolymphatic stage that spares the nervous system; and
- a second stage defined by CNS involvement.

The disease produced by *T. b. gambiense* usually develops chronically whereas in *T. b. rhodesiense* infection the disease tend to be more acute, without a clear distinction between stages.

An infective bite by a *Glossina* spp. fly may produce an inoculation chancre. Within days or weeks, the parasite disseminates to the blood. In the Gambian form of the disease, an enlarged neck lymph node may be present (Winterbottom's sign) and the patient may remain asymptomatic for years. In the hemolymphatic stage, the symptoms may be few and non-specific: undulant fever, headache, malaise, weight loss, anemia, edema, arthralgia, diarrhea and pruritus.

On physical examination there may be erythematous circinate papules on the trunk, disproportionate pain to soft tissue pressure (Kerandel's sign) and discrete enlargement of lymph nodes, liver and spleen. Pancarditis is common in the more acute forms, when it constitutes a major cause of death. Some degree of anemia, thrombocytopenia, leukocytosis, hypogonadism, renal disease and thymus atrophy may be seen.

The CNS manifestation that gave the disease its name is the disappearance of the circadian distribution of sleep and wakefulness, which are therefore fragmented throughout the day and night.[68] Other CNS manifestations include altered reflexes, paresthesiae, pareses, dyskinesia, choreoathetosis, epilepsy, slurred speech, mood changes, lethargy, delirium and psychosis. Without treatment, nearly all patients will develop neural involvement and die (see also Chapter 157).

Management

The choice of antiparasitic drug will depend upon whether the CNS is infected. Pentamidine or suramin can be used when the CNS is spared from infection. Melarsoprol and eflornithine are effective for both hemolymphatic and neural stages. Suramin dosage is 20mg/kg/day (maximum 1500mg), one intravenous injection every 5 days for 25 days. *Onchocerca volvulus* co-infection should be ruled out or treated before treatment of trypanosomiasis. Pentamidine dosage is 4mg/kg/day, one dose every second day for 20 days. *Trypanosoma b. rhodesiense* and some strains of *T. b. gambiense* do not respond to pentamidine.

Melarsoprol, a toxic trivalent arsenical derivative, has been the treatment of choice for patients who have CNS involvement for five decades. A number of empiric, dosing schemes have been used.[69] Relapse after treatment occurs in up to 6% of cases. Arsenic-related encephalopathy occurs in 10% of cases and prednisone treatment may reduce its incidence. The mortality rate of this side-effect largely depends upon the supportive treatment available, but is generally above 50%.[70]

Eflornithine (a-difluoromethylornithine) is an inhibitor of polyamine biosynthesis. Adult dosage is 400mg/kg/day in four divided doses for 1–4 weeks. Although it is less toxic than melarsoprol, drug shortages, high costs and the lack of comparative studies have relegated its use to a second-choice therapy.

General supportive treatment, anticonvulsant preventive therapy, and early recognition and treatment of associated parasitic and bacterial infections are essential.

With adequate treatment, most extraneural disease is cured. In the presence of CNS infection, cure rates are above 80%. All treated patients should be carefully followed up twice yearly for at least 3 years.

Chapter 246 - Helminths

John H Cross

Helminths are the most common parasites infecting humans. The world population is over six billion and there are probably a similar number of helminthic infections occurring in humans. They are transmitted to humans by food, water, soil and arthropod and molluscan vectors. Once established, they can be found in all organs, particularly intestines but also in liver, lungs, blood and occasionally in brain and other organs. This chapter describes some of these worms, their biology, epidemiology, pathogenicity, clinical aspects, diagnosis, management and prevention.

NATURE

The word helminth comes from the Greek meaning worm and refers to all types of worms, both free-living and parasitic. The major parasitic worms are found primarily in two major phyla:

- the Nematoda or roundworms; and
- the Platyhelminthes or flatworms, which are divided into the Trematoda or flukes and the Cestoda or tapeworms (Table 246.1).

Structurally the helminths have an outer covering called a cuticle or tegument. It may be tough or delicate and essentially protects the organism, especially from digestion, while in the host intestinal tract. This structure may also possess spines, hooks, cutting plates and stylets used for attachment or to aid in penetration. There are also suckers or acetabula used by the flatworms for attachment. Some species have lytic glands near the mouth and the secretions digest host tissue for food or lyse tissues during migration.

The helminths have digestive systems of various types, excretory systems and massive reproductive systems. Most of the trematodes are hermaphroditic, one worm possessing both male and female reproductive organs; the schistosomes, on the other hand, have separate sexes. Each segment of a tapeworm has both male and female sex organs, whereas the nematodes have separate sexes. Some worms produce larvae, but most produce eggs, which pass in the host's excrement. Worms in the circulatory system produce larvae, which are carried in the blood, are ingested by blood-sucking arthropods and are then transmitted to the next host via the bite. The life cycles of the parasites are highly variable, from simple direct egg transmission to complex cycles involving one or more intermediate hosts (Fig 246.1 , Fig 246.2 , Fig 246.3 , Fig 246.4). The classification of the worms is based upon internal and external structures, and reproductive stages of eggs, larvae and adults.

EPIDEMIOLOGY

Helminthic infections are the most common parasites of humans. The highest prevalence occur in tropical countries with poor or inadequate food supplies, and where insect, molluscan and other invertebrate vectors abound and sanitary conditions are poor.

Nematodes

Intestinal nematodes

Over one billion people, primarily children, are infected with *Ascaris lumbricoides*. In some areas of Indonesia infection rates are as high as 90%.[1] Nearly one billion people are infected with hookworm, *Necator americanus, Ancylostoma duodenale* or both. The former has a worldwide distribution, whereas the latter is found in certain parts of Africa, China, India and Japan. Hookworm prevalences are highly variable, being 35% in the Philippines and 90% in Indonesia, with infection rates highest in adult males.[1] Up to 800 million people are infected with *Trichuris trichiura*; both sexes and all age groups are infected and in the Cameroons 3.1–97.3% of 22,000 children were found to be infected.[2]

Strongyloides stercoralis, like other soil-transmitted helminths, is endemic in areas with high humidity, warm temperatures and poor sanitation. The prevalence of this parasite varies from 10% to 20% in areas of Africa, South America and Asia. In surveys conducted in Indonesia and the Philippines using the Harada-Mori filter paper test-tube technique on single-stool specimens the prevalence rates were usually less than 1%.[1] [3] There are reports, however, of rates as high as 25% in areas with concomitant high prevalence of human T-lymphocyte leukemia/lymphoma virus-1 virus infections.[4]

Pinworm or *Enterobius vermicularis* is a common nematode in temperate regions with an estimated 200 million infections worldwide. It is a parasite that most individuals acquire in childhood, but it is not uncommon in adults in a family with infected children. It is a common nematode infection in the USA. A high prevalence of pinworm is also reported in male homosexuals. [5]

Tissue nematodes

Larva migrans is a syndrome caused primarily by larvae of nematode parasites of lower animals. Larvae of dog hookworms such as *Ancylostoma braziliensis* and *A. caninum* penetrate human skin and migrate through this tissue causing a creeping eruption or cutaneous larva migrans. This occurs worldwide, but mostly in areas with warm, moist climates. *Ancylostoma caninum* can also cause an enteritis in humans, especially in Australia.[6] The larvae of dog and cat ascarids or *Toxocara* spp. cause visceral larva migrans in children when embryonated eggs are ingested. The larvae provoke granuloma formation, often in the central nervous system (CNS) and eye. Seroprevalence rates for *Toxocara* antibodies are high in England and France.

Although there are now seven recognized species of *Trichinella*, the only species that is important to humans is *T. spiralis*. This species has a worldwide distribution in the temperate regions,[7] whereas the other species are reported from animals in Africa (*T. nelsoni*), Arctic regions (*T. nativa*) and Palearctic and Nearctic regions (*T. pseudospiralis, T. britovi, T. murrelli*) and the Australian region (*T. papuae*). *Trichinella* spp. are ubiquitous and found in a wide variety of animal life. Transmission occurs among animals by the ingestion of *Trichinella*-infected meat. All types of carnivous mammals and birds are susceptible to infections. Most human infections are obtained by eating infected pigs, boars and other wild animals. Reports of trichinosis are sporadic, usually among groups who have participated in a communal meal. An epidemic in France reported several thousand with some deaths after the consumption of 'steak tartare' prepared from imported horse meat.[8]

TABLE 246-1 -- The major parasitic worms.*

THE MAJOR PARASITIC WORMS

Nematodes (roundworms)	Intestinal		
	Ascaris lumbricoides	*Necator americanus*	*Trichuris trichiura*
	Enterobius vermicularis	*Strongyloides stercoralis*	*Capillaria philippinensis*
	Ancylostoma duodenale	*Trichostrongylus* spp.	
	Tissue		
	Trichinella spiralis	*Angiostrongylus cantonensis*	*Phocanema* spp. (larvae from saltwater fish)
	Visceral larva migrans (*Toxocara canis or Toxocara cati*)	*Angiostrongylus costaricensis*	*Contracaecum* spp. (larvae from saltwater fish)
	Ocular larva migrans (*Toxocara canis or Toxocara cati*)	*Gnathostoma spinigerum*	*Capillaria hepatica*
	Cutaneous larva migrans (*Ancylostoma braziliensis or Ancylostoma caninum)*	*Anisakis* spp. (larvae from saltwater fish)	*Thelazia* spp.
	Dracunculus medinensis		
	Blood and tissues (filarial worms)		
	Wuchereria bancrofti	*Onchocerca volvulus*	*Dirofilaria immitis* (usually lung lesion; in dogs, heartworm)
	Brugia malayi	*Mansonella ozzardi*	
	Brugia timori	*Mansonella streptocerca*	*Dirofilaria* spp. (may be found in subcutaneous nodules)
	Loa loa	*Mansonella perstans*	
Platyhelminthes (flatworms)	Intestinal		
	Diphyllobothrium latum	*Hymenolepis nana*	*Taenia solium*
Cestodes (tapeworms)	*Dipylidium caninum*	*Hymenolepis diminuta*	*Taenia saginata*
	Tissue (larval forms)		
	Taenia solium	*Echinococcus multilocularis*	*Spirometra mansonoides*
	Echinococcus granulosus	*Multiceps multiceps*	*Diphyllobothrium* spp.
Trematodes (flukes)	Intestinal		
	Fasciolopsis buski	*Heterophyes heterophyes*	
	Echinostoma ilocanum	*Metagonimus yokogawai*	
	Liver/lung		
	Clonorchis (opisthorchis) sinensis	*Paragonimus westermani*	*Paragonimus skrjabini*
	Opisthorchis viverrini	*Paragonimus mexicanus*	*Paragonimus* spp.
	Fasciola hepatica	*Paragonimus heterotremus*	
	Blood		
	Schistosoma mansoni	*Schistosoma japonicum*	*Schistosoma mekongi*
	Schistosoma haematobium	*Schistosoma intercalatum*	

** Adapted from Garcia LS. Classification of human parasites. Clin Infect Dis 1997;25:21–3.*

The 'firey serpent of Medina' or *Dracunculus medinensis* (also known as the guinea worm) is reported from 17 African countries, Yemen, Saudi Arabia, India and Pakistan. Ten million people may be infected, and in some areas 50% of a population may have the infection every year. Sex prevalences are variable, but most infection occurs in those aged 15–40 years. Transmission is seasonal and closely related to rainfall, when the population of the major copepod vectors (*Cyclops* spp.) are abundant.

Angiostrongyliasis, or parastrongyliasis, is caused by the molluscan-borne nematodes *Angiostrongylus cantonensis* and *A. costaricensis*. The former is endemic in Asia, the Pacific Islands, Australia, India, Africa, the Caribbean and Louisiana in the USA. *Angiostrongylus costaricensis* is reported in Latin America and Texas, but most human infections are reported from Costa Rica. Human infection with *A. cantonensis* is reported primarily from Taiwan and Thailand with infection acquired from eating the snails *Achatina fulica* in Taiwan and *Pila ampullacae* in Thailand. In Taiwan most infections are in children of both sexes while in Thailand the parasitosis is seen mostly in adult males.[9] One human infection has been reported in a young boy in Louisiana.[10] *Angiostrongylus costaricensis* is usually seen in children who accidently ingest the slug *Vaginulus plebeius* on vegetation. Rats (*Rattus* spp.), cotton rats (*Sigmodon* spp.) and rice rats (*Oryzomys* spp.) are natural hosts for *A. costaricensis*.

Anisakiasis is caused by third-stage larvae of *Anisakis simplex* and *Pseudoterranova decipiens*, which are acquired by eating species of raw marine fish and squid. The adult worms, related to *Ascaris*, are found in marine mammals worldwide, but most infections in humans have occurred in Japan and other countries where people eat uncooked marine fish and squid.

Several *Gnathostoma* spp. larvae can invade human tissue and most infections are reported from Thailand and Japan, and occasionally Mexico. *Gnathostoma spinigerum* is the most common species in Thailand. *Gnathostoma hispidium* has also been found in humans, although there are fewer infections. Dogs and cats are the natural hosts for adult worms. Copepods serve as the first intermediate host, and fish, frogs, snakes and chicken are the second intermediate hosts. Infections are more common in adults of both sexes.

Blood and tissue nematodes

The filarids are a group of nematodes located in the lymphatics, subcutaneous and cutaneous tissues. There are eight major filarids of humans transmitted by arthropods in tropical and subtropical parts of the world.

Wuchereria bancrofti is the most widespread, being endemic in Asia, Africa, Central and South America and the Pacific Islands. Prevalence rates are highly variable depending upon the vector mosquito population, temperature, humidity, a susceptible human population and environmental sanitation. An estimated 115 million people may be infected worldwide, with 50 million in Africa, 62 million in Asia, 2 million in the Pacific Islands and less than 1 million in Latin

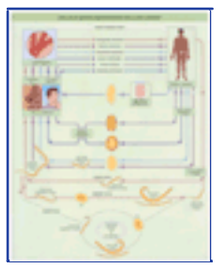

Figure 246-1 Life cycles of important human roundworms: adults living in the intestines.

America.[11] There are different vectors in different endemic areas; the most extensive is *Culex quinquefasciatus*, whereas *Aedes polynesiensis* is the important vector in the Pacific Islands. There is a nocturnal periodicity associated with the feeding habits of the mosquitoes, except in the Pacific where there is a diurnal periodicity and the mosquito vector feeds in the daytime. Although a limited number of monkeys have been experimentally infected with *W. bancrofti* [12] no naturally infected animal reservoirs have been documented.

Brugia malayi is found only in rural Asia and infects approximately 13 million[11] people. Many of the islands of Indonesia are endemic, with prevalence rates from less than 1% to over 30%.[13] The major mosquito vectors are *Mansonia, Anopheles* and *Aedes* spp. and cats and *Macaca* and *Presbytis* monkeys are known reservoir hosts. Most strains of brugian filariasis are periodic, but some microfilariae exhibit subperiodic periodicity.

Brugia timori is found only in the Lesser Sunda Islands of Indonesia. A prevalence rate of 25% was reported in a population on the island of Flores.[14] *Anopheles barbirostris* is a major mosquito vector and, although no naturally infected reservoirs have been found, cats and Mongolian gerbils have been experimentally infected. [15]

Onchocerca volvulus is endemic in 26 countries in Africa and six in Central and South America. Approximately 18 million people are infected and as a result 270,000 are blind and 500,000 severely disabled.[19] Infections are more common in males than females, reflecting male occupations and their higher exposure to vector flies. Prevalences are also higher in areas close to running water where the blackfly *Simulium damnosum* and related species breed. In the Americas infections are more common in the highlands 1000–4000 feet above sea level, whereas in Africa infection is common below 1000 feet. Infections decrease with distance from the rivers and streams. There are no animal reservoirs and there is no microfilarial periodicity.

Loa loa, the African eye worm, is endemic in West and Central Africa where *Chrysops* spp. are present. Prevalence rates vary from 8% to 40%, with infections increasing with age; 20–30 million people live in endemic areas. Transmission by the day-biting female deerflies is highest during wet seasons. Monkeys serve as reservoir hosts. The microfilariae are diurnal.

Three *Mansonella* spp. are found in humans:

- *M. streptocerca* is found in Africa;
- *M. perstans* in West Africa and parts of South America; and
- *M. ozzardi* in Latin America.

Culicoides spp. serve as vectors for all three species and *Simulium* spp. also transmit *M. ozzardi*. Monkeys in Africa serve as reservoir hosts. Infections are highest in adult males and some areas report prevalence rates as high as 80%. There is no microfilarial periodicity.

Trematodes (see Chapter 168)

Over 40 million people worldwide are infected with food-borne trematodes; the most important occur in the liver, lungs, blood and intestines.

Liver/lung trematodes

The opisthorchid liver flukes are reported from Asia and Europe. The Chinese liver fluke, *Clonorchis sinensis*, is reported from China, Japan, Korea, Taiwan and Vietnam. Infections are highest in older males and females and there is a tendency toward familial aggregations. An estimated 7 million people are infected, with prevalence rates in China of 15–24.6%, in Korea 11.7–30.8% and in Japan 2.9%. Infections are highest in the snail and fish intermediate hosts in the warmer months. Snails in the families Hydrobiida, Melaniidae, Assimineidae and Thiaridae are first intermediate hosts, and fish, primarily of the family Cyprinidae, are second

intermediate hosts. *Opisthorchis viverrini* is endemic in Thailand, Laos and Vietnam.

The infection is found in an estimated 10 million people in all age groups increasing from childhood to adulthood, and in both sexes. Prevalences vary from 7.3% to 53.2% in Thailand. *Bithynia* spp. are important snail hosts and *Cyclocheilichthys* spp. of freshwater fish are important second intermediate hosts. Dogs, cats and other fish-eating mammals are reservoir hosts.[17]

Fasciola hepatica, the sheep liver fluke, is endemic in most sheep-raising areas of the world. Human infections are increasing and are most common in parts of Europe, South America and the Middle East. Approximately 2.4 million people are infected. Sheep, goats and cattle are the natural hosts, with infection rates varying from 25% to 92% in countries such as Bolivia. The prevalence in humans reaches 65% in Bolivia, 24–53% in Ecuador, 10% in Peru and 2–17% in Egypt.[20] Infections are more common in adults who usually acquire infection from eating watercress in salads.

Although over 40 species of *Paragonimus* are described, only a few infect humans and only one, the Oriental lung fluke, *Paragonimus westermani*, is responsible for the most serious disease. It is reported from China, Taiwan, Japan, Korea, the Philippines and Thailand. Other species occur in China, Thailand, Mexico, Ecuador, Peru and parts of Africa. The parasitosis is acquired by eating metacercariae-laden crustaceans: crabs and crayfish. In some areas the juice from crabs is used for seasoning and traditional medicine. The juice may contain metacercariae. There are 20 million suspected infections in the Chinese, and over 600,000 elsewhere.[20] There are many snail hosts, with *Semisulcospira* spp. being major vectors in China and Korea. The crabs *Eriocheir* and *Potamon* spp. and the crayfish *Cambaroides* spp. are important second intermediate hosts. Dogs, cats and other carnivorous mammals are reservoir hosts. Children often obtain the infection by eating crabs on the way home from school.

Intestinal trematodes

There is a very large number (about 70) of intestinal flukes and they are reported mostly in Asians who acquire infections because of eating raw food. *Fasciolopsis buski*, the giant intestinal fluke, is reported from China, Taiwan, Thailand, Indonesia, Bangladesh and India and occasionally from Indonesia. Over 200,000 infections have been reported in China and 10,000 in Thailand.[20] Pigs are the reservoir host, and snails such as *Segmentina, Hippeutis* and *Gyraulus* spp. are important vectors. Cercariae from snails encyst on water plants such as water caltrop, watercress, water bamboo and water chestnut. These are eaten uncooked and infections occur most often in children.

Other important intestinal flukes include *Echinostoma, Heterophyes* and *Metagonimus* spp. There are an estimated 150,000 cases of echinostomiasis, 240,000 cases of heterophyiasis and 650,000 cases of metagonimiasis, most in China, Korea and Japan. Echinostome metacercariae are acquired from snails, fish and other aquatic animals, whereas *Heterophyes* and *Metagonimus* infective stages occur in fish. All ages and both sexes are infected as a result of eating the second intermediate hosts uncooked.

Blood trematodes

Schistosomiasis is endemic to many tropical areas of the world:

- *Schistosoma japonicum* is found in Asia;
- *S. haematobium* and *S. mansoni* in Africa and the Middle East; and
- *S. mansoni* in South America and some islands in the Caribbean (see Chapter 167).

Other species of less importance are *S. mekongi* and *S. intercalatum*, which are focally located in South East Asia and Africa, respectively.

It is estimated that there are over 200 million infections, with the prevalence and intensity of infections being highest in children

aged 5–15 years. Infection rates depend upon water contact in endemic areas. Despite the widespread distribution of snails and frequent opportunities for water contact, high transmission only occurs at a few sites. It is important to identify these sites.[21] Snail vectors are members of the genera *Bulinus* spp. for *S. haematobium*, *Biomphalaria* spp. for *S. mansoni* and *Oncomelania* spp. for *S. japonicum*. *Bulinus* and *Biomphalaria* spp. are strictly aquatic whereas the *Oncomelania* are amphibious snails. There are some animal hosts for *S. mansoni*, but humans are the most important source of infection. Humans are also the most important host for *S. haematobium*, whereas many domestic and wild animals are a reservoir host for *S. japonicum*. Although *S. japonicum* is endemic on Taiwan, the strain of parasite on the island will not infect humans. It is considered to be a zoophilic strain.[22]

Cestodes

Cestode or tapeworm infections are acquired by ingestion of intermediate hosts containing the infective larval stages:

- the beef tapeworm *Taenia saginata* and pork tapeworm *T. solium* are acquired by ingesting the cysticercus stage in beef or pork;
- the fish tapeworm *Diphyllobothrium latum* is acquired by eating raw fish infected with the plerocercoid or sparganum stage; and
- *Hymenolepis nana* and *H. diminuta* are rodent tapeworms that use fleas and beetles as intermediate hosts (see Chapter 168).

Taenia saginata is reported worldwide, with high infection rates in Africa and Asia. Most infections occur in adults. The cysticercus is found only in bovids; however, in parts of Asia, especially in Taiwan, pigs are a recognized source of infection for a strain of the parasite, namely *T. saginata (asiatica)*.[23]

Taenia solium is found sporadically in pigs worldwide, with many human cases reported from Mexico and Central and South America, South West Asia and Africa. Human cysticercosis is also present in these areas. Certain areas of Irian Jaya in Indonesia report many cases of cysticercosis because of the habit of eating uncooked pork.

Hymenolepis nana is the most common tapeworm in North America and is particularly reported in children worldwide. *Hymenolepis diminuta* is not common but reported occasionally in South East Asia.

There is a high prevalence of *D. latum* in humans in Scandinavia, Finland, Alaska, Canada and Northern USA. Other species of *Diphyllobothrium* are reported from Japan and South America.

Sparganosis or infections with the larval stage of *Spirometra* spp. is reported occasionally from many parts of the world. Infection is acquired by ingesting copepods or second intermediate host (frogs, toads or other aquatic animals). Infections in southern Asia are attributed to the use of fresh animal tissues as poultices.

Echinococcus granulosus and *E. multilocularis* are associated with human hydatid disease, whereas *E. vogeli* and *E. oligarthrus* rarely cause disease in humans. *Echinococcus granulosus* is the most important and found primarily in sheep-raising areas. Strains of the parasite are also found in goats, swine, cattle, horses and camels.

The parasitoses are found worldwide, with canines serving as the definitive host and animals such as sheep as intermediate hosts. Humans acquire infection by ingesting eggs from dogs, whereas dogs acquire the infection by eating sheep liver and other organs containing cysts with large numbers of scolices. Infections usually occur in the young and the cysts develop over a period of years.

Echinococcus multilocularis has a limited distribution in dogs, foxes, wolves and cats as the reservoir hosts and larval stages in wild rodents, especially voles. The parasite, however, is reported to be moving southward in the USA. Rare human infections are acquired by the ingestion of eggs passed by the canines. Infection with any of the *Echinococcus* spp., however, is related to poor sanitary conditions in populations with a low level of education and in people closely associated with canine reservoir hosts.

PATHOGENICITY

Helminths seem to live in peaceful coexistence with their hosts and usually cause few problems. However, if there are many worms, there may be severe disease and

symptoms. The parasites, especially in the intestines, can cause obstruction and possibly perforation. The worms also secrete or excrete toxic substances, which affect the tissues. Lytic substances, such as those secreted by hookworms to obtain blood, can induce inflammation and there may be changes due to malabsorption and competition for nutrients. Larval stages may be more pathogenic, secreting antigenic substances that cause hypersensitivity, while the antigens promote antibody production and cellular immune responses. The most serious aspect of helminthic infection is that the worms end up in ectopic locations. Worms in the wrong place can be highly pathogenic.

Helminths have intricate life cycles and disease is usually associated with the larval migratory pathways and the final habitat of adult worms in the host. The amount of pathology and disease varies with the parasitosis.

Nematodes living in the intestine

Enterobius vermicularis

The life cycle of *Enterobius vermicularis* is presented in Figure 246.1 . Pinworm resides in the large bowel, where mating occurs. Gravid females migrate out of the anus and deposit eggs on the perianal skin. The adult males die after copulation and the females usually after depositing eggs. The perianal region becomes itchy and scratching can lead to excoriation and weeping. Eggs under the fingernails in children lead to reinfection when the fingers are placed in the mouth. Eggs can be released onto the bedsheets and become disseminated throughout the household when the sheets are shaken. The eggs will survive for 2 weeks in a humid and cool environment. When eggs are ingested they hatch in the intestine and the larvae migrate to the large intestine to mature in 6 weeks. Adults may migrate into the vagina, cervix, uterus and fallopian tubes and peritoneal cavity. Granulomas caused by the adult worms are reported in the abdominal cavity. Young girls may experience urinary tract infection and vulvovaginitis caused by wandering female worms or the presence of eggs on the vulva.

Ascaris lumbricoides

Infection with *Ascaris lumbricoides* can occasionally be highly pathogenic. The life cycle is presented in Figure 246.1 . The adult male worm may measure 15–31cm by 2–4mm and the female 20–35cm by 3–6mm. The female can live for a year or more and produce 240,000 eggs/day. The eggs pass in the feces and embryonate in the soil in 10–14 days. Upon ingestion the egg hatches in the intestine and the liberated larva penetrates the mucosa and passes to the liver via the portal vessels and then to the lungs. After a few weeks the larva penetrates the alveolar air sac, passes up the pulmonary tree, is coughed up and swallowed. The worms become sexually mature in the small intestines and produce eggs in 60–75 days.

Migrating larvae in a previously infected sensitized person can cause inflammatory lesions in the liver. Large numbers of larvae can cause an intense tissue reaction, including inflammation and the development of granulomatous lesions involving eosinophils, epithelioid cells and macrophages. This is referred to as *Ascaris* pneumonitis.

Adult worms in the intestines cause little disease unless in large numbers or if the worms become erratic and migrate into vital organs or exit from one of the orifices. Heavy infections can also cause intestinal obstruction, intussusception, volvulus, blockage of the bile ducts and cholangitis and intestinal perforation.

Trichuris trichiuria

Trichuris trichiuria has a direct life cycle (see Fig. 246.1). Adult females in the large intestine deposit eggs in the fecal stream and after a few weeks in the soil they become embryonated. When eggs are swallowed they hatch in the intestine and the larva moves down the bowel to the colon. The worms bury their narrow anterior end into the mucosa with the wider posterior end extended freely into the lumen of the colon. The females lay eggs after 3 months and produce 3000–10,000/day. The worm's longer, thinner, anterior end contains rows of cells (stichocytes) surrounding the esophogeal tube. The females measure 35–55mm and the males 30–45mm. The males have a curved tail with copulatory spicules.

Heavy infections can cause local irritation, diarrhea, cramps, edema and blood loss; the worms suck blood and there is seepage at the attachment sites. A prolapsed rectum is not uncommon, especially in children. There may be eosinophilia along with nutritional and weight loss.

Hookworms

A number of hookworm species can enter the human body, but most are natural parasites of animals other than humans (i.e. zoonotic parasites). The species from lower animals usually cause a creeping eruption or cutaneous larva migrans. Only two hookworms are considered to be important human species:

- *Necator americanus*; and
- *Ancylostoma duodenale*.

Both species measure about 10–13mm for females and 6–11mm for males and can be 0.4–0.6mm in width. The anterior mouths have cutting plates or teeth and the males have bell-shaped bursal rays at the posterior end that are used for holding females during copulation. The vulva is mid-central and eggs pass from the females into the fecal stream and out with host feces onto the soil. Female worms pass 5000–10,000 (*N. americanus*) and 10,000–20,000 (*A. duodenale*) eggs/day. In warm, moist climates the eggs embryonate in the soil and rhabditform larvae are released. Within a few days the larvae molt and develop into filariform larvae or the infective stage. The larvae climb to the top of the soil or grass, cling together and wait for a human host to come by. They usually penetrate the skin between the toes or other body surfaces. Some *A. duodenale* larvae may be ingested in water and enter the oral mucosa. The larvae are carried by the blood to the heart and then the lungs where they remain for a period, break out into the alveoli, pass up the pulmonary tree and are swallowed. The parasite matures in the small intestine, copulates and produces eggs in about 5 weeks (see Fig. 246.1).

The infections can remain active for as long as 13 years. Penetration of larvae into the skin causes ground itch and at times a secondary, bacterial infection may develop. Ground itch is caused when hookworm or other larvae enter the skin by contact with the ground, which results in irritation, erythema, edema and papulovascular eruption. Larvae in the lungs also produce minute focal hemorrhage and pneumonitis. The attachment of adult worms can cause small erosive lesions, hemorrhage, tissue cytolysis and neutrophilic infiltration. The worms change attachment sites regularly, leaving old sites oozing blood and plasma. Iron deficiency anemia and blood loss result from long-term infection with a large number of worms.

Pathologic changes occur in the bone marrow due to blood loss. Liver function may change as a result of anemia, as well as reduced capacity for albumen synthesis. Fatty deterioration of heart, liver and kidney may also occur. Hookworm disease with iron deficiency anemia, hypoproteinemia and hepatosplenomegaly may contribute to thousands of deaths each year.

Strongyloides stercoralis

Strongyloides stercoralis is a unique nematode having a parasitic life cycle as well as a free-living cycle, with males and females present in the free-living cycle (see Fig. 246.1). Only females are present in the parasitic life cycle, however. The parasitic females measure 1.5–2.5mm, and have a long cylindric esophagus. The vulva is in the posterior third of the body and the paired uteri contain thin-shelled eggs.

The eggs are deposited in the small intestinal epithelium and hatch soon after release. The first-stage or rhabditiform larva passes in the feces and develops into a second-stage and then a third or infective-stage filariform larva after a few days. The third-stage larvae penetrate the skin and migrate through the body and via the blood to the lungs; after several days they migrate up the respiratory tree and are swallowed. The larvae enter the intestinal mucosa and mature, and the female worms produce eggs parthenogenetically. Some larvae transform into infective forms in the bowel, penetrate the mucosa, migrate and develop into adults. This is internal autoinfection and can lead to hyperinfection in the immunocompromised host. Some rhabditiform larvae transform into rhabditoid free-living male and female adults in the soil and reproduce. The eggs hatch, releasing rhabditiform larvae, which develop into filariform larvae that can enter the skin of a host.

Cellular immunity is responsible for keeping infections under control, but when immunity is affected by disease or immunosuppression, the parasite multiplies unabated and this leads to hyperinfection and dissemination. Larvae entering the skin can cause inflammation with lymphocytic and eosinophilic infiltration. Larvae in the lungs cause eosinophilic infiltration and hypersensitivity reactions.

Pneumonia and hemorrhage result from hyperinfection. The intestinal mucosa is edematous and covered with mucus in cases of chronic strongyloidiasis. A cellular infiltration with eosinophils and monocytes and reactions around the worms may be seen in the lamina propria. Mucosal atrophy and flattening of villi as well as fibrotic changes with ulcerative enteritis may result from long-term infections. In disseminated infections the parasite is found in many organs, with secondary bacterial infection when bacteria are carried by the larvae from the intestines.

Capillaria philippinensis

Intestinal capillariasis is a disease in which the parasite can multiply in the digestive tract. *Capillaria philippinensis* is a tiny worm; females measure 2.5–5.3mm and males 1.3–3.9mm. The anterior body is narrow and consists of an esophagus surrounded by rows of cells or stichocytes forming the stichosome. The posterior is slightly wider and contains reproductive organs and digestive tract. The females deposit eggs, which must reach water where they embryonate. When these are eaten by small freshwater fish the eggs hatch and the larvae develop into infective stages in 3 weeks. When humans eat the fish the larvae mature in 2 weeks. After mating the females first produce larvae that will mature in the gut, whereas the second-generation worms produce thick-shelled eggs, which pass out in the feces. The parasites can multiply rapidly, producing thousands of progeny.[24] If the patient is not treated the disease is usually fatal. Over 200,000 worms were recovered from 1 liter of bowel fluid at one autopsy. The worms enter the crypts and cause atrophy, the villi are flattened and denuded, the mucosal glands are denuded and the lamina propria is infiltrated with inflammatory cells. Other organs are

also affected by malnutrition and hypokalemia. Most of the pathology is in the jejunum. [25]

Nematodes living in tissues

Trichinella spiralis

Trichinella spiralis is the only species in the genus of any importance; the other six species are parasites of lower animals and rarely infect humans. The parasites are related to other trichiurids in having a slender anterior and a wider posterior end. Stichocytes line the stichosome in the anterior end. Female worms measure 2–4mm and males 1–1.5mm. Infections are acquired by eating uncooked muscle containing encysted larvae from infected animals, usually pigs.

The larvae are digested from the cyst, pass to the small intestines and burrow beneath the epithelium where they develop into adults, re-enter the gut lumen and reproduce. The larvae produced enter the gut wall, are picked up by the blood and carried throughout the body to striated muscle where they become encysted. The adult worms cause a transitory enteritis and malabsorption, eosinophilia and excessive secretion of mucin. The larvae entering the muscle cell cause alterations in morphology, which results in the characteristic 'nurse cell'. Morphologic and molecular changes occur in the cell until it eventually becomes calcified. The larvae can remain alive for many years in the cell. Chronic inflammatory cells may surround the parasitized muscle cell. Vasculitis may cause periorbital edema and neurologic manifestations and there may be a trichinal myocarditis.

Filarial nematodes

The filarial nematodes are long and slender and are found in the lymphatics, tissues and body cavities. The life cycles of some of the filarids are presented in Figure 246.2 . Microfilariae are produced by female worms and arthropods are the vectors (see Chapter 170).

Wuchereria bancrofti, Brugia malayi and *Brugia timori*

The lymphatic filarids *W. bancrofti, B. malayi* and *B. timori* produce microfilariae that usually appear in the blood between 2200 and 0200 hours (nocturnal periodicity). *Wuchereria bancrofti*, found in some of the Pacific Islands, produces microfilariae that appear in the blood in the daytime (diurnal periodicity). Mosquitoes obtain blood at night and the larvae develop into the infective stage in 10–14 days. At the next feeding the infective larvae migrate from the thoracic muscles of the mosquito to the proboscis and crawl into the hole made by the bite. The larvae migrate in the host until they reach the definitive habitat and develop into adults. The worms copulate and the females produce microfilariae; the life cycle of *W. bancrofti* is a few months longer than that of *B. malayi*. Infections may persist for several years.

The pathogenesis of lymphatic filariasis has been a matter of debate and a model integrating various aspects of the parasitosis has been proposed. [16] It has also been suggested that *Wobachia*, an endosymbiont of filarids, may be associated with the pathogenesis. On the other hand, the pathology of lymphatic filariasis may be associated with immunologic responsiveness. [17] Some people who have the infection are microfilaremic but without antibodies or disease, whereas other are amicrofilaremic and have antibodies. There is an inflammatory stage with lymph channel irritation. Adult worms can be found in the lymph vessels, primarily the axillary, epitrochlear, inguinal and pelvic nodes as well as those in the testis, epididymis and spermatic cord. Attacks of lymphangitis and lymphadenitis may develop, followed by orchitis, funiculitis and epididymitis, especially in bancroftian infections. Blockage of the lymph flow by the inflammatory reaction and granuloma formation leads to lymphatic varicoses and lymphedema. Hyperplasia of the connective tissue and cellular infiltration and induration of the tissue may take place, with thickening and verrucous changes in the skin leading to elephantiasis.

Tropical pulmonary eosinophilia, 'Weingarten's syndrome', occurs in some endemic areas and is caused by granulomas containing degenerating microfilariae in the lung, spleen and lymph nodes. Patients have a cough, asthma, pulmonary infiltration, elevated eosinophils and antifilarial antibodies, but no microfilariae.

Onchocerca volvulus

Onchocerca volvulus adults are coiled in fibrous tissue nodules in the subcutaneous tissue. The females may reach 50cm in length and 0.5mm in diameter and the microfilariae produced are released into the interstitium of the skin. Males are smaller, being 5cm in length. Microfilariae are picked up by biting flies or black flies of the genus *Simulium* and after developing to the infective stage the larvae are introduced into a host at the next feeding. The larvae migrate through the tissue and after many months settle down, usually in pairs, and become encapsulated (see Fig. 246.2).

The microfilariae leave the nodule and migrate through the dermis, provoking a dermatitis; microfilariae in the eye chamber may lead to blindness. There may be a loss of skin elasticity in the pelvic region leading to hanging groin. Eye lesions begin with punctate keratitis and small opacities in the cornea caused by degenerating microfilariae, which evoke an eosinophilia. Sclerokeratitis follows. The endosymbiotic *Wobachia* bacteria in the worm may be associated with the pathogenesis of river blindness.[18] In Africa and Venezuela the nodules are located on the trunk and limbs, whereas in Mexico and Guatemala the nodules are usually on the head.

Loa loa

The African eye worm *Loa loa* actually moves through subcutaneous tissue and often traverses the conjunctiva. The males are 3–4cm and the females 4–7cm in length and 3–5mm wide. Microfilariae have a diurnal periodicity and are ingested by species of *Chrysops* at the time of a blood meal. The larvae develop to the infective stage in 10–13 days and enter the host through the hole made by the bite at the next feeding (see Fig. 246.2). The adult worms cause little damage as they migrate quickly through the tissue. Transient swellings (Calabar swellings), a subcutaneous edema caused by an allergic reaction to metabolic products of the worms or dead worms, may occur. Eosinophilic hypersensitivity reactions develop to the worms and microfilariae along with lymphadenitis.

Mansonella ozzardi, Mansonella perstans and *Mansonella streptocerca*

These are tissue parasites found in the mesenteries, visceral fat, skin and deep connective tissue. Microfilariae are found in the blood and skin and deep connective tissue. The vectors are species of *Culicoides* and *Simulium* (see Fig. 246.2). Most infections provoke little pathology except for articular pain, inguinal adenopathy, skin rash and dermatitis.

Dracunculus medinensis

Dracunculus medinensis is similar to the filarids. The females measure up to 120cm long and 2mm wide and the males 2cm. The worms mature in the connective tissue; gravid females then migrate to the subcutaneous tissue where they cause ulcers through which larvae are released when the lesion is immersed in water. The larvae are ingested by copepods and develop into infective larvae in 2 weeks. When the copepods are ingested in drinking water the larvae are liberated, penetrate the

digestive tract and develop into adults in the connective tissue in a year (see Fig. 246.2). A painful localized reaction develops around the ulcer and multiple blisters and tracts may also develop. The tracts may become secondarily infected with bacteria. Once the uterus is emptied the worms may withdraw and die in the tissue. On the other hand, degeneration

of the worm may lead to subcutaneous abscess and eventual calcification.

Angiostrongylus cantonensis

Angiostrongylus cantonensis is found naturally in the lungs of rats. The larvae produced by the females move up the pulmonary tree, are swallowed and pass out in the rat feces. Molluscs (snails and slugs) serve as intermediate hosts and, when eaten by rats, the larvae are digested out of the snail tissue, migrate from the gut to the brain, and after 3 weeks migrate to the lungs. Larvae are produced by adult females a few weeks later. Humans who ingest snails or slugs acquire the infective larvae, which migrate to the central nervous system (CNS) and cause eosinophilic meningitis. The females reach 2–3cm and the males 1–2cm in length and 0.2–0.3mm in width. In most human infections the larvae die in the brain and cord and elicit an inflammatory reaction in the meninges. Eosinophils, monocytes and foreign body giant cells infiltrate around the dead worms. Tissue necrosis is also evident. Larvae are reported in the eye, and are often recovered from cerebrospinal fluid (CSF). Adult worms have been found on a few occasions in the pulmonary artery.[9]

Anisakis simplex and Pseudoterronova decipiens

Anisakis simplex larvae measure 2–3cm by 0.3–0.6mm and *Pseudoterranova decipiens* 2–3cm by 0.3–1.2mm. They are found in the muscle and body cavity of marine fish and squid. When eaten by marine mammals (e.g. whales, seals, porpoises) the worms mature in the stomach and the females deposit eggs in the feces. In the ocean, a larva hatches from the egg and is eaten by a small marine crustacean. When the crustacean with a third-stage larva is eaten by fish the freed larva migrates to the abdominal cavity. When infected fish are eaten raw by humans the liberated larvae penetrate the stomach or small intestine and provoke a foreign body reaction around the worm. The submucosa becomes edematous with massive cellular infiltration. An abscess develops, characterized by necrosis and hemorrhagic and eosinophilic infiltration.

Gnathostoma spinigerum

Gnathostoma spinigerum is a robust nematode with a large globose head surrounded by rows of spines. The females measure 1–1.5cm by 1–2.5mm and the males 1–2.5cm by 1–2mm. The adults are coiled in the wall of the digestive tract of dogs and cats. Eggs pass in the feces, embryonate in fresh water and are ingested by copepods. The larvae hatch and develop into the second larval stage. When the copepod is eaten by a second intermediate host, the third-stage larva develops, and when this is eaten by a dog or cat the worm penetrates the gut wall and matures. Humans who eat infected fish, frogs or other aquatic food, raw or fermented, acquire the infection and the larvae migrate through the tissue. In the skin there are patches of edema, which last a few days and reappear elsewhere. The areas may be large and itchy with a rash and pain, producing lesions similar to those of cutaneous larva migrans. There is peripheral eosinophilia. The CNS may be invaded, resulting in an eosinophilic myeloencephalitis with eosinophilic pleocytosis and bloody and xanthochromic CSF. The eye may also be invaded, causing palpebral edema, exophthalmos and subconjunctival hemorrhage.

Larva migrans

Cutaneous larva migrans is caused by dog or cat hookworm larvae that enter the skin and are unable to complete the life cycle. They either migrate through subcutaneous tissue or encyst in the tissue and the larvae may cause serpiginous erythematous tracts. The tracts eventually become dry and encrusted.

Visceral larva migrans is caused by the dog and cat ascarid larvae (*Toxocara* spp.) that escape from eggs that are accidentally swallowed. The larvae migrate through the tissue and encyst as second-stage larvae. The migrating larvae produce tracts with hemorrhagic necrosis and eosinophilic and lymphocytic infiltration. Migration into the liver causes enlargement and it becomes studded with nodules containing eosinophils and plasma and giant cells. There may be interstitial eosinophilia in the lungs. Focal lung granulomas may develop around disintegrating larvae. Larvae may also enter the eye and cause endophthalmitis and retinal detachment and some larvae may enter the CNS and heart (see Chapter 174).

Trematodes living in liver, lungs, intestines and blood

Although many trematodes infect humans, only a few are considered to be important pathogens. These flat worms are found in all organs, especially the intestines, and a few are found in the liver, lungs and blood. They are hermaphoditic except for the schistosomes. The life cycles of the important trematodes are presented in Figure 246.3 .

The opisthorchid liver flukes

Clonorchis sinensis, Opisthorchis viverrini and *Opisthorchis felineus* are found in the bile ducts. The worms are flat or leaf-like and about 1.5cm long and tapered at both ends. There are two branched testes at the posterior end. The eggs produced pass down the bile ducts to the intestine and out with the feces. In water, snails of a number of species (*Parafossarulus, Thiara* and *Bithynia*) serve as the first intermediate host; they ingest the egg and the miracidium is released from the egg. After reproducing by polyembryony, cercariae are produced that leave the snail and encyst as metacecariae in freshwater fish (cyprinids or carp). When the fish is eaten raw or improperly cooked the metacercariae are digested out of the fish and migrate down the bowel and then into the bile passages. There may be mechanical irritation, inflammation of the bile ducts with metaplasia and proliferation of the epithelium and periductal fibrosis. Pancreatic ducts may show epithelial metaplasia and partial obstruction. There is often biliary stone formation and bacterial superinfection. Cholangiocarcinoma is a possible complication and DNA carcinogens may be associated with such tumor formation. There may also be an association with nitrosamines, which are commonly found in Asian foods.[26]

Fasciolopsis buski

Fasciolopsis buski is the largest intestinal trematode of humans, measuring 5–7cm by 8–20mm by 1–3mm. It has an oral and ventral sucker, two large ceca, two branched testes and a central and coiled uterus. Eggs pass in the feces into water and the hatched miracidium enters a specific planorbid snail. Cercariae released from the snail attach to aquatic vegetation and form into metacercariae. When eaten the metacercariae excyst and attach to the mucosa of the small intestine. Large numbers of worms cause bleeding at attachment sites, excess mucus secretion and obstruction. Toxic secretions and excretions may be absorbed, causing generalized edema and cachexia. Death can result from massive infection.

Fasciolia hepatica

Fasciolia hepatica is acquired by eating aquatic vegetation on which the metacercariae are attached. Upon ingestion the metacercariae are released and penetrate the gut wall, traverse the peritoneal cavity, pass through the liver capsule into the liver parenchyma and into the bile duct. The migratory stages are characterized by hepatomegaly and hemorrhagic necrotic worm tracts. Eosinophils and other inflammatory cells are present. In chronic infections there may be mechanical irritation, because of the large size of the fluke and toxic metabolites, and hyperplasia of the biliary epithelium resulting in obstruction in some cases. Worms may also re-enter the liver parenchyma. The worms are large, 4cm in length and 1.5cm wide, with a large cephalic cone at the anterior end. The egg passes

down the bile duct to the intestines and out with the feces. It hatches in the water and the miracidium enters into snails of the genus *Lymnea*. Cercariae are released and encyst on all varieties of aquatic vegetations.

Paragonimus westermani

Paragonimus westermani usually resides in pairs in the lung. They are reddish brown, plump bodied and shaped like coffee beans, and measure about 1.2cm long, 0.6cm wide and 0.4cm thick. They have two large branching testes in the posterior half of the body. Eggs enter the alveoli, are coughed up and swallowed, and pass

out in the feces or in sputum. The egg hatches in water, enters a specific snail and multiplies, and released cercariae enter crabs and crayfish where the metacercariae encyst. When the infected crustacean is eaten the metacercariae are released from the cyst, penetrate the gut wall and enter into the peritoneum, diaphragm and lung.

Young migrating worms produce local hemorrhage and cellular infiltration. These worms may settle in ectopic locations and evoke a pronounced tissue reaction. In the lung and other locations a leukocytic infiltration develops around the worm and fibrous tissue infiltrates to form a cyst wall. Eggs may migrate into pulmonary tissue and other locations and evoke granulomatous reactions. Cerebral paragonimiasis often develops, with hemorrhage, eosinophils, a yellowish exudate and Charcot-Leyden crystals. Some lesions may eventually calcify.

Other species of *Paragonimus* can also infect humans and invade subcutaneous tissue and the abdominal cavity.

Other intestinal fluke infections

Most intestinal fluke infections are innocuous unless there is a large number of worms. Bleeding and ulceration, inflammation and excess mucus secretion may result from *Echinostoma* spp. and heterophyid infections. The eggs of the heterophyids are tiny and may be carried by the lymphatics and venules to ectopic locations such as the heart and evoke granulomas. Eggs of the intestinal flukes pass in the feces and hatch in water and the miracidia enter snails. Cercariae emerging from the snails enter fish and other aquatic animal life and when these animals are eaten the metacercariae excyst and develop into adults in the small intestine.

Human schistosomes

Human schistosomes are found in the venous bloodstream. Eggs are passed into water and the miracidia released search out specific snails in which to continue the life cycle. Cercariae released from the snails penetrate the skin and the larval schistosomulae migrate to the lungs and then to the mesenteric and vesical veins. Eggs carried back through the mesenteric veins to the liver are responsible for granuloma formation. The liver becomes enlarged, especially the left lobe. The spleen may become enlarged and portal hypertension develops and leads to obstructive liver disease, esophageal varices and ascites. Egg granulomas also form, especially in the large intestine.

Gastrointestinal symptoms such as diarrhea with blood, mucoid stools and a protein-losing enteropathy are not uncommon. In urinary schistosomiasis hematobia egg granulomas develop in the bladder, possibly leading to cancer. Inflammation and fibrosis of the urethral wall lead to stenosis, irregular dilatations and hydronephroses. Secondary bacterial infections are common and can lead to renal failure and death. *Schistosoma haematobium* eggs may reach the lung and cause fibrosis and lead to cor pulmonale. *Schistosoma japonicum* is responsible for cerebral schistosomiasis, and spinal cord involvement is reported in *S. mansoni* infections.

The schistosomes are the only trematodes with separate sexes. They have oral and ventral suckers. The females are 1.5–2.5cm in length and 0.2–0.3mm in diameter. The male is 0.5–2.0cm and, although flat, usually curls up to form the gynecophoral canal in which the female lies. the female leaves the male, crawls to the small venules close to the lumen of the gut or urinary bladder and deposits eggs. The miracidium releases enzymes to work with the spines on the *S. mansoni* and *S. haematobium* eggs to digest the tissue and enter the lumen of the intestine and bladder. Some eggs are carried back via the venules and veins to the liver. The life cycles of the human schistosomes are presented in Figure 246.3 .

Cestodes living in the intestines and tissues

Adult tapeworms residing in the intestines do not cause serious disease, but larval stages of two species are highly pathogenic. The adults in the intestines pass eggs, which are taken up by an intermediate host (Fig. 246.4).

Eggs of *T. saginata* and *T. solium* are ingested by bovids and swine and the larval or cysticercus stages develop in muscles. When the meat is eaten insufficiently cooked the cysticerci are released and develop into adults in the small intestine.

The life cycles of the fish tapeworm *D. latum* and related species involves two intermediate hosts: a copepod and a fish. The egg hatches in water and the corricidium is taken in by a copepod and develop into a procercoid larva. When eaten by a fish the larva develops into a pleroceroid larva and when the fish is eaten the larva becomes an adult in the intestine.

Hymenolepid cestodes often require an insect (beetles and fleas) as an intermediate host. *Hymenolepis nana* can also be acquired by ingestion of the egg. Some strains of *H. nana* are also capable of internal autoinfection of humans.

Morphologically, all tapeworms have a scolex and neck, and immature, mature and gravid proglottids. The scolex of *D. latum* has a sucking groove as a hold-fast organ, whereas the other tapeworms have a scolex with four suckers, and *T. solium* and *H. nana* have a rostellum on the scolex with rows of hooklets. Each mature proglottid is hermaphroditic with both male and female sex organs. The lengths and width of each species varies with the longest being *D. latum* (2–15m), followed by the taeniids (1–4m), *H. nana* (1.5–4cm) and *H. diminuta* (1–6cm).

Usually, only one *Taenia* spp. in the intestines causes little disease. There may be some irritation at the site of attachment. Infection with more than one worm may cause intestinal and appendiceal blockage. At times the worms or proglottids block the pancreatic or bile ducts. Toxic substances from the worms may be responsible for systemic manifestations. The fish tapeworm causes decreased vitamin B12 absorption and eventual macrocytic and megaloblastic anemia.

Larval stages of tapeworms also infect humans (Fig. 246.5). Infection with the plerocercoid larva of diphyllobothriid species such as *Spirometra* is the cause of sparganosis. The larvae acquired from eating aquatic animals or drinking copepods in water penetrate the gut wall and migrate through the tissue. Animal poultices used in Asia are another source of infection. The larvae cause painful inflammatory swellings or transient lesions. The parasite may invade the eye causing periorbital edema.

Humans who become infected with the eggs of *T. solium* may develop cysticercosis. The larvae invade the muscles, brain, eye and skin. Although the cyst may remain intact and dormant for years, it may eventually break and the released fluids cause granulomas and calcification. Subcutaneous nodules are palpable and their presence usually indicates CNS involvement. Neurocysticercosis is responsible for arachnoiditis with pleocytosis and increased protein in the CSF. Intense inflammation may develop around dead or dying parasites.

Echinococcosis or hyatid disease develops in humans who accidentally ingest the eggs of the dog tapeworms *E. granulosus* or *E. multilocularis*. The egg hatches in the duodenum and the oncosphere

Figure 246-5 Life cycles of important human tapeworms; adults living in tissues and intestines and blood: humans are accidental hosts.

penetrates the gut and becomes established in the liver and other organs. A cyst develops brood capsules and protoscolices proliferate from the inner germinal epithelium of the brood capsule. An outer laminated acellular limited membrane forms and the cyst develops over many years. Unilocular cysts develop with *E. granulosus* and multilocular alveolar cysts with *E. multilocularis*. Cysts develop in many organs, especially the liver, lungs, brain and bones. A host inflammatory reaction produces fibroblasts, giant cells and mononuclear and eosinophilic cells. A fibrotic capsule eventually develops. The cyst may become calcified and the parasites destroyed. Rupture of the cyst releases fluids that can cause anaphylactic shock and the scolices may spread to set up new foci in other areas. The adult

worms are parasites of canines and the intermediate host can be any animal, but most often are sheep for *E. granulosus* and rodents for *E. multilocularis*.

PREVENTION

Most parasitic infections can be prevented if good sanitary practices are followed. The soil-transmitted nematodes can be controlled and possibly eradicated with proper disposal of feces. This is true for most intestinal parasites, even those that require an intermediate host. The disposal of fecal matter into water bodies containing molluscan intermediate hosts perpetuates trematode infections. The construction and use of sanitary privies will go a long way toward preventing infections of all types, but in most endemic areas these practices are usually not followed and indiscriminate defecation is the trend. Infection with skin-penetrating helminths such as hookworm and *Strongyloides* spp. can be prevented by wearing shoes and protective clothing.

Arthropod-borne helminthiasis, such as filariasis, can be prevented by the use of insecticides in houses. Breeding areas of the vectors can also be treated with insecticides. The use of repellents will also help, as will sleeping under insecticide-impregnated bed nets.

The avoidance of water known to harbor snail vectors will prevent schistosome infections. The destruction of snail breeding areas and the use of molluscicides will help to control infections.

The ingestion of raw foods should be restricted in endemic areas. The eating of raw fish is a practice in many countries, and if this is discouraged certain trematode and cestode infections could be prevented. The cooking of marine fish would prevent anisakiasis. Similarly the cooking of aquatic vegetation would prevent trematode infection such as fascioliasis and fasciolopsiasis. Undercooked beef and pork are responsible for trichinosis and tapeworm infections and through cooking will destroy the parasites. Freezing foods will kill most parasites and in the future irradiation of foods will make food safe.[27] Microwave treatment, however, is not considered adequate for destroying parasites.

The use of anthelmintics can be used to eliminate helminthic infections. Mebendazole, albendazole and praziquantel have been used in mass treatment campaigns for some nematode and trematode infections. Antifilarial drugs have been used in mass treatment programs and have even been included in table salt distributed to population group. Reduction of infections in a population will be of significant benefit and will augument control and eventual eradication programs. These methods along with education programs would be a definite adjunct to prevention and control.

DIAGNOSIS

The diagnosis of helminthic infections depends upon the location of the parasite in the body. The majority of worms are in the digestive tract and the diagnosis is made by stool examination. Blood is examined for parasites in the circulatory system, and urine and sputum are examined for worms in the genitourinary systems and respiratory passages. Tissue parasites are diagnosed by biopsies and by immunologic methods. Many techniques have been developed to aid in the diagnosis and most of these have been presented in detail.[28]

Stool specimens (see Chapter 165)

Intestinal parasites are detected by examination of one or preferably more than one stool specimen.[29] The stools should be collected in a clean dry container and examined as soon as possible after being passed. A direct examination is made by making wet films on a clean microscope slide. A small portion of feces is mixed with a drop of saline on the slide and examined under low power (×100) and high power (×450) magnification, if needed. The preparation should not be too thick; it should be thin enough to read newsprint through it. Iodine stain preparations can also be used, especially for protozoan infections, but do not add a great deal to the observation of helminth eggs and larvae. If a stool specimen cannot be examined within a few hours after passage it should be placed into 10% formalin or another preservative. The examination can then be done when it is more convenient.

Concentration techniques are also available. The simplest is sedimentation of feces in a tube or sedimentation flask and the sediment is then examined microscopically. The formalin-ethyl acetate technique, in which the stools are mixed with saline and passed through gauze or a screen, is widely used. The material collected is centrifuged several times in saline and finally formalin. Ethyl acetate is added and the preparation is centrifuged slowly. The detritus layer and supernatant are poured off and the sediment examined microscopically. The zinc sulfate flotation method is another simple technique in which small samples of feces are mixed thoroughly with zinc sulfate (1.18 sp gr or 1.2 sp gr for formalized stools). This may be centrifuged or permitted to stand for a period and the surface fluids examined for eggs. This method is unsatisfactory for operculated eggs, however. Eggs from various helminths as well as larvae of hookworm and *Strongyloides* are depicted in Figure 246.6 and Figure 246.7 .

The Kato method to examine stools has been modified into the Kato-Katz technique for estimating the number of eggs in the feces. Screened feces are placed into a small hole in a template, which delivers 41.7mg feces onto a microscope slide. A Cellophane square soaked in a glycerine-malachite green is placed onto the feces and the preparation is permitted to stand for 30–60 minutes. The glycerine clears the fecal material and eggs can be seen against a green background. This technique is especially good for thick-shelled eggs such as those of *A. lumbricoides, T. trichiura* and *S. mansoni*. The preparation should be examined within 30 minutes for thin-shelled eggs such as hookworm, which may dissolve if they stand for too long. The number of eggs observed is multiplied by 24 to obtain the number of eggs/g of feces. The Kato method uses only the glycerine-soaked Cellophane and is not quantitative.

Fecal cultures can be used to recover nematode larvae, especially of the hookworms and *Strongyloides* spp. The feces are mixed with charcoal with a small amount of water and placed into a Petri dish with moist filter paper lining the bottom of the dish. This is kept at room temperature for several days and the larvae will migrate to the surface of the charcoal. The culture is placed into a Baermann apparatus consisting of a funnel with rubber tubing attached to the stem and a pinch-clamp closing the tube. A sieve is placed into the top of the funnel and lined with gauze. The funnel is filled with warm water and the culture placed onto the gauze. The apparatus stands at room temperature for 10–12 hours and the fluid is drawn off through the tubing into a glass flask. Larvae can be collected from the flask and examined microscopically to determine the species.

The Harada-Mori technique is also used to culture feces and recover larvae. Filter paper strips are coated on one side with feces

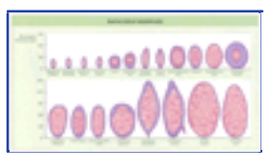

Figure 246-6 Relative size of helminth eggs. HHS Publication No. (CDC 89-8116)

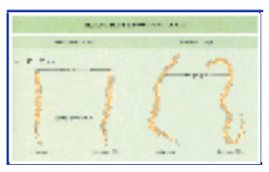

Figure 246-7 Hookworm and *Strongyloides* larvae. HHS Publication No. (CDC 89-8116)

and placed into a tube containing a small amount of water. The tube is kept upright so that the filter paper is kept moist by capillary action. After 4–10 days the filter paper is removed and the water examined for larvae.

An agar plate culture for *Strongyloides* spp. has been developed.[30] A few grams of feces are placed into the center of the agar and the plate is incubated at room temperature for 48 hours. Tracks are made by the parasite in the agar and the larvae can be recovered by a Pasteur pipette and placed onto a microscope slide for identification.

Eggs of some parasites can be picked up on perianal swabs. Swabs such as scotch tape or paddle swabs are placed on the perianal area and then placed under a microscope for examination. Pinworm, tapeworm and *A. lumbricoides* eggs can be recovered.

Eggs of *Schistosoma* spp. can be found in feces using some of the above-mentioned examinations. An egg hatching technique can also be used in which feces are placed into a sidearm flask and water added until it reaches a level just below the sidearm. When the suspension settles more water is added until the level is above

the sidearm. A dark cloth or bag is placed over the flask without covering the sidearm. The sidearm is then placed into the light and hatching miracidia from the schistosome eggs will be attracted to the light. They can be examined microscopically.

Specimens can be collected directly from the duodenum and examined for helminthic infections. Material collected by duodenal aspiration can be examined microscopically for *Strongyloides* and *Ascaris* spp. and flukes.

The Entero-Test or string capsule is also available for examining duodenal specimens. A gelatin capsule containing a string is swallowed and the end of the string taped to the cheek. The string in the capsule contains a small weight that carries the string down the duodenum after the capsule dissolves. After 4 hours the string is pulled up and the mucus adhering to the string is placed onto a microscope slide and examined.

Tapeworm proglottids are at times found in stool specimens. These segments should be washed in water and placed between two microscope slides. The slides are than tied together with string and the specimens placed into a fixative — alcohol, formalin, acetic acid (AFA). After fixation the worms can be stained and examined for specific identification. If the proglottids have rosette-shaped uterine branches the worm can be identified as a diphyllabothriid. The number of uterine branches of *Taenia* spp. can be counted and the specimen identified as *T. solium* (6–11) or *T. saginata* (15–20). India ink can be injected into the uterine pore and the branches are then more easily counted.

Adult trematodes found in feces should be washed and placed between two microscope slides that are then tied together with string. The specimens are than placed into a fixative such as AFA. After fixation the worms can be stained and examined for speciation.

Sputum specimens

Sputum to be examined for eggs or larvae should be mixed with 3% sodium hydroxide, centrifuged and the sediment examined.

Urine specimens

Urine specimens will sometimes help in the diagnosis of *S. haematobium* eggs or microfilariae of *W. bancrofti* and *O. volvulus*. The urine specimen is centrifuged and the sediment examined.

Blood samples

Several of the filarial infections can be diagnosed by the examination of drops of blood from finger or ear lobe pricks. The blood is placed onto a microscope slide and covered with a coverglass and examined under low power for thrashing microfilariae. For specific identification thick blood smears are made with several drops of blood, the smear is permitted to dry for several hours and then stained with Giemsa stain. Identifications are based upon for example microfilarial sizes, cephalic space and tail nuclei. Microfilariae of *W. bancrofti*, *B. malayi*, *B. timori*, *L. loa* and *Mansonella* spp. are present in the blood. *Onchocerca volvulus* microfilariae are found in skin snips.

Blood should be obtained at night for most lymphatic filariae and in the daytime for *L. loa* and *Mansonella* spp. Microfilariae can also be recovered from blood by membrane filtration. In some cases of lymphatic filariasis adult worms may be seen by ultrasound and the worms can be seen 'dancing' in the lymph channels.[31]

Cerebrospinal fluid

Cerebrospinal fluid is examined for evidence of helminthic infections. Eosinophilic pleocytosis is suggestive of angiostrongyliasis, paragonimiasis, cysticercosis, gnathostomiasis and schistosomiasis. Larvae of *A. cantonensis* are reported in CSF, especially in children, and *T. spiralis* larvae can be found in the CSF in very heavy infections. The CSF is centrifuged and the sediment examined for evidence of a helminth infection.

Tissue specimens

Tissue specimens may be taken and examined for helminthic infections. Muscle biopsies can be sectioned, stained and examined microscopically for *T. spiralis*, or the muscle can be pressed between to two glass slides and examined for trichina larvae.

Rectal and bladder biopsy specimens can be examined for schistosome eggs. Skin biopsies may reveal the presence of microfilariae of *O. volvulus* or *Mansonella* spp. Fluid obtained from suspected hydatid cysts, although dangerous to obtain, may reveal scolices of *E. granulosus*. Biopsies can also be made when anticipating a diagnosis of gnathostomiasis, sparganosis or infection with another migrating helminth.

Immunodiagnostic tests

There are myriad immunodiagnostic tests available to aid in the diagnosis of helminthic infections. Immunologic tests, however, only offer a presumptive diagnosis, and the finding of the worms, eggs or larvae provides the definitive diagnosis. Immunologic tests are useful when the parasite is not demonstrated such as in cases of toxocariasis and in some cases of cysticercosis and echinococcosis. Immunodiagnostic tests have been developed for most parasitic disease to detect antibodies as well as antigens. Techniques in molecular biology have also been emerging and may eventually become valuable tools in detecting helminthic infections.[32]

Detailed information on immunologic and molecular methods in the diagnosis of parasitic diseases has been presented elsewhere.[33] Older tests such as complement fixation are still of value in the diagnosis of cysticercosis, paragonimiasis and schistosomiasis, especially for indicating active infections. Gel diffusion has been used in fascioliasis and the circumoval precipitation test (COPT) is used to detect antibodies in cases of schistosomiasis. In the latter, eggs of schistosomes develop precipitates around the shell in the presence of antibody-positive sera.

The enzyme-linked immunosorbent assay (ELISA) is currently one of the most widely used tests for many parasitoses. Indirect fluorescent antibody is also used, especially on tissue and parasite sections, to detect antigenic material. The indirect hemagglutination test along with EIA (enzyme immunoassay) is used for hydatid disease and EIA for cysticercosis. An EIA test is now recommended for strongyloidiasis, toxocariasis and other larval migrans. It is also of value in the diagnosis of paragonimiasis, schistosomiasis, trichinosis, angiostrongyliasis, gnathostomiasis and filariasis. *Taenia*-specific antigens can be detected in human feces by ELISA.[34]

The immunoblot or Western blot is being applied to the diagnosis of most helminthiases, especially fascioliasis, schistosomiasis, paragonimiasis and cysticercosis. Molecular diagnostics have been reported for most species of parasites, and mostly applied to research laboratories; the detection of DNA by the polymerase chain reaction (PCR) is reported for the most important human helminths. For example, a PCR assay has been developed to detect *W. bancrofti* DNA in blood[35] and a PCR to determine the presence of *W. bancrofti* DNA in vector mosquitoes.[36]

CLINICAL MANIFESTATIONS

An intestinal helminthiasis is usually unnoticed unless a large worm is found by the patient in the feces.

Pinworms

Pinworms generally cause little disease, but in children infections lead to perianal itching, eczema, nose-picking, pica and loss of sleep. Worms may migrate into the vagina, uterus and fallopian tubes and peritoneal cavity. Pinworms can be responsible for recurrent urinary tract infections in young girls.

Ascariasis

Ascariasis is innocuous unless the worms become erratic and migrate into vital organs or pass out of one of the orifices — nose, mouth or anus. Erratic ascariasis may be caused by anesthesia, trauma or some medications, such as tetrachloroethylene. A bolus of a large number of worms can cause volvulus or intussusception,

abdominal distress,

pneumonitis and cough, and disease is often associated with malnutrition and decreased growth.

Trichuriasis

Severe trichuriasis can lead to abdominal discomfort, dysentery, colitis, anemia and bloody stools. There may be nutritional loss, weight loss and malnutrition. Rectal prolapse occurs with some infections.

Hookworm

Hookworm larvae entering the skin may provoke a ground itch and secondary bacterial infections. Migrating larvae can cause pneumonitis and eosinophilia, and worms in the intestine can cause abdominal pain, nausea, vomiting and diarrhea. Large numbers of worms sucking blood cause iron deficiency anemia, hypoproteinemia and hepatosplenomegaly, and children will have impaired mental, physical and sexual development. Blood loss can be as high as 0.3ml/day/adult *Ancyclostoma duodenale*. Severe malnutrition develops, especially with concomitant infections with *A. lumbricoides* and *T. trichura*

Toxocariasis (see Chapter 174)

Toxocariasis (visceral larva migrans) causes hypereosinophilia, hepatomegaly and symptoms of chronic pulmonary inflammation with cough. There may also be visual difficulties due to retinochoroiditis or peripheral retinitis. Dog hookworm larvae in the skin cause cutaneous larva migrans and serpingous tunnels may present with intense pruritus. The lesion becomes erythematous and sometimes vesicular. *Ancylostroma caninum* may cause eosinophilic lesions in the intestines leading to abdominal pain.[6]

Strongyloides stercoralis

Early infections with *S. stercoralis* are similar to hookworm infections, causing ground itch and pneumonitis. Worms in the intestines cause inflammation, irritation, diarrhea, intestinal bleeding and melena. Sprue-like symptoms may also develop, along with malabsorption, weight loss and eosinophilia. Dermal lesions may occur at irregular intervals with urticarial eruptions on the buttocks, termed larval currens. Immunocompromised people, especially those with HTLV-1 associated lymphoma, are at risk of developing disseminated strongyloidiasis and present with severe enteritis, a protein-losing enteropathy, bronchitis, pneumonia, pleural effusion, cough and a blood-tinged sputum with rhabditiform larvae. Eosinophilia is usually absent in these cases. Death may result. Disseminated strongyloidiasis may also present as Gram negative pneumonia or meningitis, or as a polymicrobial bacteremia, with bacteria being spread by worms migrating from the bowel.

Capillariasis philippinensis

Capillariasis philippinensis leads to a protein-losing enteropathy, malabsorption, electrolyte imbalance, weight loss, wasting and death. Patients initially present with abdominal pain, borborygmi and diarrhea. Untreated infections usually lead to death.[24]

Trichinosis

Trichinosis is asymptomatic except when a large number of trichina larvae are ingested. After the worms become adults in the small intestines, symptoms of gastroenteritis develop, with nausea, abdominal pain, anorexia, diarrhea, fever and weight loss. Larvae are produced after copulation and these are able to enter the blood and are carried to striated muscles. During the migratory phase, muscle and joint pain develop, followed by periorbital edema and eosinophilia. Larvae passing through the heart can cause cell destruction, acute inflammatory changes and interstitial myocarditis. The infection can also cause neurologic and pulmonary complications. Dead larvae in the muscle eventually become calcified.

Lymphatic filariasis (see Chapter 170)

Symptoms associated with lymphatic filariasis are associated with the host's immune status; little immunity is associated with more severe disease. Early symptoms are fever, lymphangitis, lymphedema and lymphadenitis, which may be transitory and occur periodically. Scrotal involvement leads to orchitis, hydrocele and chyluria. Worms may block the lymph flow by an inflammatory reaction and the development of granulomas around the worms and these lead to lymphatic varicoses and eventual skin fibrosis, thickening and elephantiasis. Renal lesions may also occur, with microfilariae in the urine and chyluria. There may be enlargement of the legs, arms, scrotum, mammary glands and vulva. Tropical pulmonary eosinophilia with fever, splenomegaly, pulmonary infiltrates and hypereosinophilia is associated with *W. bancrofti* and *B. malayi* infections. Microfilariae are absent and are probably destroyed by host immune mechanisms in chronic infections.

Subcutaneous migration of *L. loa* may cause transient swelling known as Calabar swellings, which are a local reaction to the worm and its products. It is characterized by fever, eosinopilia and the urticarial swellings, which are more common in Caucasians. Migrating adult worms may pass over the bridge of the nose or through the conjunctiva across the eyeball. Migration of the worms in abnormal locations can cause symptoms in the scrotum, bowel, kidney and heart, but not usually in natives living in the African endemic areas. Visitors suffer more than indigenous populations.

Oncocercomas due to *O. volvulus* develop over bony prominences. Some nodules develop in deeper tissue and are unnoticeable. Dermatitis and blindness are caused by the microfilariae. Recent investigations suggest that the inflammatory response in the eye is induced by the endosymbiontic *Wobachia* bacteria released by dead microfilariae. [18] Lymph nodes in the groin may show lymphocyte depletion and fibrosis, followed by 'hanging groin,' especially in Africans. In the Americas nodules commonly develop on the upper part of the body, whereas in Africa the nodules develop on lower parts of the body.

Mansonellosis may cause:

- dermatitis (*M. streptocerca*);
- swellings on the hands and face, joint pains and itching (*M. perstans*); and
- allergic manifestations, articular pain, itching, headache, lymphadenopathy and eosinophilia (*M. ozzardi* in the Americas).

Guinea worm

Guinea worm in the subcutaneous tissue elicits allergic manifestations such as itching. When the female worms get close to the skin there is a localized erythema followed by pruritus, nausea, vomiting, diarrhea or asthmatic symptoms. The worm will secrete a toxic substance that causes a blister, which breaks when the area comes in contact with water, and the female releases larvae when the lesion opens up. The area becomes painful. The worm will eventually die and is resorbed or becomes calcified.

Angiostrongylus cantonensis and *Angiostrongylus costaricensis*

Migrating third-stage larvae of *A. cantonensis* may cause vague symptoms of gastroenteritis, vomiting, headache and fever. Once the worms reach the CNS they cause headache, nausea, vomiting, stiff neck, myalgia, pain and paresthesia. Coma may be a feature of heavy infections. Worms have been seen in the eyes of some patients. There may be paralysis of eye muscles. Frequent signs are abnormal tendon reflexes including abnormal Achilles' reflex, a positive Kernig's sign and impaired sensorium and vision. Infections with a large number of worms may be fatal.[9]

Abdominal angiostrongyliasis due to *A. costaricensis* resembles acute appendicitis. A tumor-like mass is palpable in the right lower quadrant. There may be fever, diarrhea or vomiting, along with eosinophilia.[37]

Gnathastome and anisakid larvae

Shortly after ingestion of gnathostome larvae there are symptoms of nausea, vomiting, pruritus and urticaria, and at times upper abdominal pain. Larval invasion into the liver will cause right upper quadrant tenderness and changes in liver function. In the lung there is a pulmonary infiltration and pneumothorax in patients with pleural infusion. Larvae migrating through the subcutaneous tissue and skin cause a rash along with red pruritic painless swellings. Invasion of the CNS often leads to death.

Anisakid larvae in the throat may lead to a 'tickle-throat', causing cough, but when they invade the mucosa of the intestinal tract they provoke eosinophilic granuloma formation, severe abdominal pain, nausea, vomiting and diarrhea. Usually, only a single worm is involved and the symptoms disappear when it is removed.

Trematodes

The trematodes, like the nematodes, cause little disease unless a large number of worms are involved. The liver flukes (*C. sinensis*, *O. viverrini*, *O. felineus*) in the bile ducts may cause symptoms early in the infection such as hepatomegaly, jaundice, diarrhea, anorexia, epigastric pain and fever. Repeated infection over a period of years may lead to ductal fibrosis, obstruction, cholangitis, cholecystitis and cirrhosis, and in some patients cholangiocarcinoma.

The sheep liver fluke *F. hepatica*, because of its large size, may block the bile ducts and cause cholangitis. Toxic secretions cause fever, chills, jaundice, an enlarged tender liver, cough, vomiting, abdominal symptoms and eosinophilia. Young worms may attack the pharyngeal mucosa, causing bleeding and edema. This occurs after eating raw sheep liver containing the parasite. The condition has been called halzoun.

The large intestinal fluke *F. buski* may cause intestinal blockage and toxemia when there is a large number of worms. Eosinophilia is common and ulcers may develop, which often hemorrhage. It causes abdominal distension, hunger pains and increased appetite, diarrhea and a foul-smelling yellowish stool. Allergic manifestations, nausea, vomiting, ascites and cachexia develop as a result of toxins secreted by the worms. Other intestinal flukes cause little disease, but tiny eggs of the heterophyids may enter the mucosa and are carried to ectopic locations such as the brain and heart, provoking granuloma formation. Echinostomes may produce inflammation and ulceration with diarrhea and abdominal pain.

The young lung fluke of *P. westermani* produces little disease during migration, but once established in the lung may cause fever, dyspnea, cough, chest pain and the production of a rusty sputum. At first the disease is often thought to be tuberculosis. The worms may enter the cranial cavity and invade the brain causing fever, headache, nausea, vomiting and visual disturbances, convulsions and meningeal signs.

Schistosome infections **(see Chapter 167)**

There may be petechial hemorrhages at the site of penetration where schistosome cercariae enter the skin. There will be localized edema and pruritus. After a few weeks there are toxic or allergic reactions and symptoms include fever, nausea, abdominal pain, rigor, urticarial rashes and eosinophilia. This acute stage is known as Katayama syndrome. In the chronic stage granulomas have formed around the eggs in tissue and hepatomegaly develops and the spleen becomes enlarged. This is followed by esophageal varices and finally ascites. Intestinal disease, usually with *S. mansoni* and *S. japonicum*, may involve the entire intestine or more often the large bowel. There may be abdominal cramps, tenderness and bloody mucoid stools. A protein-losing enteropathy, weight loss and anemia may also develop.

Features of *S. haematobium* infection are dysuria, urinary frequency and hematuria. Eosinophils in the urine are not uncommon. Heavy infections, with the deposition of many eggs in the bladder tissue, can lead to squamous cell carcinoma.

Pulmonary involvement can be a feature of all schistosome infections, and causes cor pulmonale with dyspnea, cough and hemoptysis.

Cerebral manifestations are common in oriental schistosomiasis, with symptoms of lethargy and confusion followed by speech difficulties and optical field defects. *Schistosoma mansoni* occasionally causes the spinal cord symptoms of a transverse myelitis, usually in the lumbar region. Flaccid paralysis of the lower limbs is also reported.

Tapeworm (see Chapter 168)

Tapeworm, even the larger ones, in the small intestines provoke few symptoms. Patients usually become aware of being infected only when worm segments are passed in the feces. If *D. latum* attaches to the proximal portion of the jejunum vitamin B12 deficiency results, with the development of pernicious anemia. This was seen in Finland but is now very rare. Sparganosis associated with other diphyllobothriid species causes painful inflammatory swellings, which may be transient. Spargana in the eyes cause intense reactions and periorbital edema.

Taenia spp. in the intestine are asymptomatic in most patients, but some have hunger pains, abdominal discomfort and indigestion. Patients usually become symptomatic when proglottids are found in the feces or passing from the anus. Eosinophilia is not uncommon. Cysticercosis or infection with larvae of *T. solium* is a serious disease, especially if there are cysticerci in the CNS. Cysticerci in the muscle are asymptomatic, but can give rise to myositis, fever and eosinophilia. The cysticerci usually die and become calcified. Cysticerci in the eye cause visual symptoms such as a decrease in visual acuity, retinal edema and hemorrhage. Neurocysticercosis results in arachnoiditis with CSF pleocytosis and an increase in CSF pressure. Obstructive hydrocephalus, cerebral infarction, epilepsy, papilledema, vomiting, headache, a toxic gait and intellectual deterioration may also develop. Dead or dying parasites may exacerbate symptoms, and location of the parasite in the CNS is responsible for a variety of CNS symptoms.

Hyperinfections with *H. nana* may cause diarrhea, loss of appetite, abdominal pain, headache, weakness, and at times epileptoid convulsion, dizziness and eosinophilia. *Hymenolepis diminuta* may cause diarrhea.

Hydatid disease **(see Chapter 169)**

There are usually no symptoms with hydatid disease until the cysts arelarge and in vital organs. Many years are usually required for a cyst to reach a significant size. Cysts in the liver may put pressure on the bile ducts and blood vessels. Large cysts in the lung can cause cough, shortness of breath and chest pains. Involvement of the CNS results in different symptoms depending upon the location of the cyst. Leaks of hydatid fluid sensitize the patient and can cause anaphylactic shock. A cyst in the eye causes proptosis.

MANAGEMENT (see Chapter 209)

Management of helminthic infection is variable and depends upon:

- the specific parasite;
- its location in the host; and
- the number of worms involved.

Usually anthelmintics are effective, but in some cases surgical or other intervention may be necessary. Follow-up examination and anthelmintic treatment may be required. The currently used anthelmintics are discussed in the *The Medical Letter*:[38]

- the soil-transmitted helminths *A. lumbricoides, T. trichiuria* and hookworm, found in the intestines, respond to mebendazole 100mg q12h for 3 days, pyrantal pamoate 11mg/kg once or albendazole 400mg once;
- *Strongyloides* spp. infections will respond to thiabendazole 50mg in two doses for 2 days or ivermectin 200mg/kg/day for 1–2 days; albendazole 400mg/day for 3 days may also be effective; the hyperinfection syndrome requires prolonged treatment;
- children with a history of erratic ascariasis should be treated with pyrantal pamoate first because some anthelmintics cause erratic ascariasis;
- pinworm infections are easily treated with mebendazole 100mg once followed by another dosage of 100mg in 2 weeks; pyrantal pamoate 11mg/kg or albendazole 400mg repeated 2 weeks later are also effective;
- mebendazole 200mg q12h for 20 days or albendazole 200mg q12h for 10 days along with fluid and electrolyte replacement are recommended for intestinal

capillariasis; treatment is repeated in the case of relapses by giving mebendazole for 30 days or albendazole for 20 days;[24] and
¦ the use of anthelmintics in trichinosis is debatable; symptomatic treatment with corticosteroids is recommended and mebendazole at dosages of 200–400mg q8h for 3 days then 400–500mg q8h for 10 days, or albendazole 400–800mg may provide some benefit.

Hookworm disease with anemia may require blood transfusion and long-term treatment with ferrous sulfate until hemoglobin levels become normal.

The two anthelmintics used to treat lymphatic filariasis are:

¦ diethylcarbamazine (DEC); and
¦ ivermectin (see Chapter 170).

Diethylcarbamazine can be given in dosages of 6mg/kg for 10–12 days. Filarial lymphangitis and side-effects can be managed with antihistamines and antipyretics. Tropical pulmonary eosinophilia is treated with DEC, 6mg/kg in three doses for 21 days from diagnosis. Single-dose treatment with DEC or ivermectin, or both, repeated at 6-month intervals for a few years shows promise for both the treatment and control of lymphatic filariasis.[39] Treatment of filariasis with an antibiotic may affect the endosymbiontic *Wobachia*, which may have an affect on the fertility of the parasite.[17]

In the past DEC has been used to treat onchocerciasis, but has been replaced with ivermectin because of severe side-effects. The recommended dose of ivermectin is 150mg/kg once, repeated at 3- to 12-month intervals for a few years.

Loiasis can be treated by surgical removal of the worm as it passes over the nose or the eye. Diethylcarbamazine is effective, first in low dosages of:

¦ 50mg on day 1;
¦ 50mg q8h on day 2;
¦ 100mg q8h on day 3; and
¦ 6mg/kg/day in three doses on days 4–21.

Antihistamines and corticosteroids are used in case of side-effects. Ivermectin in a single dose of 200mg/kg caused a decrease in microfilariae. Mebendazole may also be useful. Diethylcarbamazine can be used as prophylaxis.[40]

Mansonella spp. infections do not usually require treatment, but DEC or mebendazole and possibly ivermectin can be used. Ivermectin is reported to be effective against *M. streptocerca*.[41]

Angiostrongyliasis caused by *A. cantonensis* is usually self-limiting in light infections. Some investigators recommend symptomatic treatment and not an anthelmintic because drugs can kill the worms too quickly and cause more pathology. However, albendazole and mebendazole have been reported to be effective for pediatric cases in Taiwan.[42]

Angiostrongylus costaricensis infection is treated surgically. Similarly gnathostome infections are treated surgically, but the use of albendazole shows promise.[43] Anisakiasis is also treated surgically or by removal of the worms from the stomach by gastroscopy. No specific anthelmintic treatment is needed for transient anisakiasis.

Visceral larva migrans due to *T. canis* is usually self-limiting and symptomatic treatment and corticosteroids are beneficial. However, DEC 6mg/kg/day for 7–10 days, albendazole 400mg q12h for 3–5 days or mebendazole 100–200mg q12h for 5 days have been reported to be of some value. Cutaneous larval migrans can be treated with thiabendazole either topically or as 50mg/kg/day in two doses. Ivermectin 150–200mg/kg once or albendazole 200mg q12h for 3 days have also been used (see Chapter 174).

Fluke infections

Nearly all fluke infections are treated with praziquantel, 75mg/kg/day for 1–2 days. The Chinese liver fluke *C. sinensis* responds to praziquantel. *Opisthorchis viverrini* and *O. felineus* are also treated with the drug.

Albendazole 10mg/kg/week is also effective against *C. sinensis* and may also be useful for the other opisthorchiids.

The intestinal flukes *F. buski, H. heterophyes, M. yokogawai* and the echinostomes can be treated with praziquantel 75mg/kg/day in three doses for 1 day. Tetrachlorethylene 0.1ml/kg is also effective.

Praziquantel is ineffective in treating the sheep liver fluke, *F. hepatica*. Bithional 30–50mg/kg on alternate days for 10–15 doses was used in the past, but is no longer being manufactured in Japan. Triclabendazole 10mg/kg once has been shown to be effective[44] and is the drug of choice. Dehydroemetine 1mg/kg/day for 10 days has been used, but is more toxic than other drugs.

Praziquantel is effective against *Paragonimus* spp. in dosages of 75mg/kg/day in three doses for 2 days. Biothional had also been used.

The three major schistosomes, *S. mansoni, S. japonicum and S. haematobium*, respond to praziquantel (see Chapter 167). The dosage for *S. mansoni* and *S. haematobium* is 40mg/kg in two doses for 1 day, and for *S. japonicum* 60mg/kg/day in three doses for 1 day. Oxamniquine 15mg/kg once is effective against *S. mansoni* and metrifonate 10mg/kg once every other week for a total of three doses is effective against *S. haematobium*. The latter regimen may be effective against *S. mansoni* located in the perivesical plexis. Surgery is often required for esophogeal varices; splenectomy and splenorenal shunting will relieve portal pressure. Concomitant bacterial infection associated with schistosomiasis should be treated with antibiotics following antischistosome therapy. Schistosome dermatitis should be treated palliatively with antipruritics and antihistamines.

Cestode infections (see Chapter 168)

Praziquantel is effective for treating cestode infections. Adult *T. saginata, T. solium* and *D. latum* can be treated with praziquantel 10mg/kg once. An alternative drug for *T. saginata* and *D. latum* is niclosomide 2g in four chewable tablets. However, this drug causes side-effects, the proglottids disintegrate and the scolex is not easily found. Treatment may have to be repeated a few months later. Paramomycin 1g q4h for 4 days may be used, but there may be gastrointestinal disturbances. Atebrine, 0.8g divided in half and given in half-hour intervals, will often provide the whole worm intact. It is given on an empty stomach and a saline purge is given 2 hours after treatment.

The recommended treatment for *T. solium* is praziquantel; other drugs may be deleterious to the proglottids, releasing eggs, which may lead to cysticercosis.

The recommended treatment for cysticercosis is albendazole, 15mg/kg in 2–3 doses over 8–28 days, repeated as necessary. Praziquantel is also used in a dosage of 50mg/kg/day in three doses for 15 days. The cyst may also be surgically removed. Surgery (and not chemotherapy) is recommended for intraocular cysticercosis.

Sparganosis is also treated surgically or with praziquantel with a total dose of 120–150mg/kg over 2 days.[45] *Hymenolepis nana* is treated with praziquantel 25mg/kg once and *H. diminuta* with 10mg/kg once or niclosamide 2g in a single dose.

Surgery was the recommended treatment for hydatid cysts until albendazole was found to be effective at a dosage of 400mg q12h for 28 days, repeated if necessary after 14 days for up to 12 cycles. Percutaneous drainage with ultrasound guidance in addition to albendazole has been found to be valuable in the treatment of hepatic hydatid cysts. *Echinococcus multilocularis* is more difficult to treat, but albendazole should be effective (see Chapter 169).

Chapter 247 - Arthropods

Thomas R Fritsche

NATURE

The phylum Arthropoda is the largest and most varied of the animal phyla, consisting of more than one million described species among a total of 30 million or more. An exceedingly small number of this total directly or indirectly affect human health, but those that do are responsible for significant morbidity and mortality. Species responsible for human disease include representatives of all major arthropod classes (Table 247.1).

PATHOGENICITY

Direct tissue invasion

Arthropods responsible for superficial tissue invasion (referred to as infestation) include chigoe fleas and scabies mites, whereas invasion of deeper body tissues and cavities (referred to as infection) may be produced by dipteran larvae (maggots) and pentastomids. Tissue invasion of any sort by maggots is referred to as myiasis, and may occur either in living or devitalized tissues, depending upon the species.[1] [2] [3]

Envenomation and hypersensitivity reactions

Humans are continually subjected to the stings and bites of many different arthropods. Reaction to these attacks varies greatly and depends upon:

- the species involved;
- the type of saliva or venom being introduced into the wound;
- the location of the wound; and
- an individual's physiologic response, which may vary depending upon previous sensitization.

Arthropod stings and bites cause only local tissue reactions in most people, but some people have serious systemic reactions, including anaphylaxis.[4] [5] [6]

Vesication

Some of the larger tropical species of millipedes are capable of spraying an irritating and vesicating (blister-causing) chemical, which is used for defensive purposes, from glands located on each body segment.[7] Blister beetles are so named because of the presence of the vesicating compound cantharidin in their body fluids. Upon handling these attractive beetles, cantharidin may be released, resulting in the appearance of fluid-filled skin blisters several hours following exposure.[1] [8] [9]

Transmission of infectious agents

During the act of feeding, many species of arthropods are capable of either mechanically or biologically transmitting agents responsible for serious infectious disease (Table 247.2). Filth flies, which include the common house fly *Musca domestica,* and cockroaches have been incriminated in the mechanical transmission of the agents of bacillary dysentery, cholera, typhoid, viral diarrhea, amebic dysentery and giardiasis, pinworms and tapeworms. Arthropod vectors responsible for the biologic transmission of infectious agents may serve either:

- as simple amplification vehicles for the organism; or
- in a more complex role involving changing life cycle stages of certain parasites.[1] [3] [9] [10]

PREVENTION

Principles of prevention are directed at limiting skin and mucous membane exposure to crawling and flying arthropods and their emanations. This may be accomplished by avoiding locations serving as a habitat for those arthropods posing the greatest threat to an individual such as:

- gardens, fields, orchards or unclean picnic areas that attract bees, wasps and yellowjackets;
- crawl spaces, wood sheds or outdoor privies, which may harbor venomous spiders or scorpions;
- domiciles conducive to cockroach, bedbug or kissing bug habitation; and
- outdoor environments known to be a source of ticks and biting diptera.

Remaining indoors during evening hours lessens the risks associated with exposure to mosquitoes. The wearing of light-colored clothing, especially long pants, long-sleeved shirts and closed-toed shoes when working outdoors or pursuing outdoor recreation is less attractive than dark clothing, short pants, short-sleeved shirts and opened-toed shoes to flying insects and allows the wearer to more readily recognize the presence of ticks and other crawling arthropods. Gloves also provide additional protection when gardening, but the use of scented lotions, perfumes or soaps should be discouraged. [8] [11]

In addition to these simple measures, the use of insect repellents is an important preventative when the threat of exposure to noxious or serious pests cannot otherwise be easily mitigated. A variety of chemical repellents are available on the market. Those containing the compound *N,N*-diethyl-*M*-toluamide are among the most widely used and come in a variety of preparations for use on clothing and skin in concentrations varying from about 10 to 100%. The use of high-concentration products on children is not advised because there are reports of associated seizures. [8] [12]

Use of mosquito nets during night-time hours and headnets at other times is mandatory in areas where mosquitoes are plentiful, especially in the tropics and subtropics, where they serve as vectors for malaria, filariae, viruses and other infectious agents. Impregnation of nets with insecticides has proved to be especially effective in decreasing the transmission rates of malaria in highly endemic areas. [13]

Desensitization regimens are highly effective in preventing anaphylaxis in individuals who have become sensitized to bee and wasp venoms. Venom immunotherapy is usually indicated for those who have a history of moderate-to-severe anaphylaxis, positive venom skin tests and are at risk of subsequent stings. It is not indicated for those who experience transient pain and local swelling.[5] Despite the use of desensitization, up to 15% of individuals whose initial anaphylactic reaction is judged to be severe continue to be at risk for anaphylaxis if re-stung. [14] Immunotherapy reagents are also available and may prove useful for individuals with intractable allergies to, for example, cockroaches and dust mites.[8]

TABLE 247-1 -- Arthropods of medical importance and the threats they pose to human health.

ARTHROPODS OF MEDICAL IMPORTANCE AND THE THREATS THEY POSE TO HUMAN HEALTH

Class	Subclass	Order	Pathogenic potential
Insecta (insects)		Anoplura (sucking lice)	Biting pests, local hypersensitivity, biologic vectors
		Siphonaptera (fleas)	Biting pests, local hypersensitivity, biologic vectors, superficial tissue invasion (*Tunga penetrans*)
		Dictyoptera (cockroaches)	Mechanical vectors, allergies
		Hemiptera (bedbugs, kissing bugs)	Biting pests, local and rarely systemic hypersensitivity, biologic vector (kissing bugs)
		Hymenoptera (bees, wasps, ants)	Envenomation, local and systemic hypersensitivity including anaphylaxis, biting pests (ants)
		Coleoptera (beetles)	Mechanical and biologic vectors, urticating hairs (larvae), vesicating fluids (adults)
		Lepidoptera (moths, butterflies, caterpillars)	Urticating hairs and venomous spines (larvae), urticating hairs and scales (adults)
		Diptera (flies, mosquitoes, biting midges)	Biting pests, local hypersensitivity, mechanical and biologic vectors, tissue invasion (myiasis)
Arachnida (arachnids)	Scorpiones (scorpions)		Envenomation with neurotoxins
	Araneae (spiders)		Envenomation with neurotoxins and necrotoxins
	Acari (ticks, mites, chiggers)		Biting pests, local hypersensitivity, allergies (mites), biologic vectors, superficial tissue invasion (*Sarcoptes scabiei*), neurotoxins (ticks)
Diplopoda (millipedes)			Vesicating fluid
Chilopoda (centipedes)			Envenomation, local and rarely systemic hypersensitivity
Crustacea (crustaceans)		Copepoda (copepods, water fleas)	Biologic vectors
		Decapoda (crabs, crayfish)	Biologic vectors
Pentastomida			Tissue and body cavity infection

CLINICAL MANIFESTATIONS, EPIDEMIOLOGY AND DIAGNOSTIC MICROBIOLOGY

Specimens recovered by physicians or submitted by patients may take the form of intact organisms or parts of organisms, skin scrapings, tissues, sputum, urine, stool, articles of clothing, bedding, carpeting and foodstuffs. It is not uncommon for patients to submit arthropods recovered from the toilet bowl following a bowel movement or urination, raising concern that they may have an intestinal or bladder infection. Such an occurrence is usually coincidental and not related to infection. Although the more common forms of medically important arthropods, especially ectoparasites (fleas, lice, mites and ticks) may be readily identifiable, detailed identification of other arthropods, especially larval forms, may require consultation with a specialist in entomology. Repeated examinations fail to reveal the presence of arthropods or parasites in cases of delusional parasitosis; it is imperative that the affected individual's domicile is thoroughly examined to rule out the possibility of unrecognized mite infestations following abandonment of an attached rodent or bird's nest.[10] [15]

Insects

Insects comprise more than 90% of all described arthropod species and include many of the vectors responsible for the transmission of serious infectious diseases.

Sucking lice, order Anoplura

Sucking lice are dorsoventrally flattened, wingless insects that have characteristic claws on the ends of each leg, which allow attachment to body hairs or clothing. All species suck blood and may cause unexplained dermatitis as a result of their repetitive feeding activities and chronic exposure of the skin to louse saliva and feces. Although named for their primary site of attachment, they do not always remain confined to that location.

The head louse, *Pediculus capitis,* and the body louse, *P. humanus*, are indistinguishable to the non-specialist. They are longer than they are wide and grow to about 3mm in length (Fig. 247.1). Biologic differences are apparent; only *P. humanus* transmits the agents of epidemic typhus, trench fever and relapsing fever (see Table 247.2).[3] Infestations with both species occur among people living in crowded conditions who have little opportunity for bathing and laundering. Children of school-age are at particular risk for acquiring head lice through the sharing of caps, clothing and combs.[2] [16] Lice eggs (known as nits) are typically 1mm long and when unhatched have an intact operculum (Fig. 247.2). Head louse nits are deposited primarily on hair shafts close to the scalp, especially along the nape of the neck, whereas nits of body lice are deposited primarily upon clothing. Because such objects as hair casts, dander, hair spray and fungal hair infections may mimic nits, differentiation is important. Transmission of body lice occurs primarily through the sharing of infested clothing and bedding because they tend to deposit their eggs in clusters, especially along seams or waistbands.

The public louse, *Phthirus pubis,* is distinctly different from the others; it is rounder, measuring up to 2mm in diameter, the abdomen is more crab-like, and their first pair of legs is significantly smaller and more slender than the other pairs (Fig. 247.3). Pubic lice and their nits are found primarily on pubic hairs, but may extend to the chest, armpit and facial hair. Transmission occurs primarily

TABLE 247-2 -- Summary of the major arthropod genera involved in the biologic transmission of infectious diseases.*

SUMMARY OF THE MAJOR ARTHROPOD GENERA INVOLVED IN THE BIOLOGIC TRANSMISSION OF INFECTIOUS DISEASES				
Class	**Subclass/order**	**Genus**	**Etiologic agent**	**Disease**

Insecta	Anoplura	*Pediculus*	*Rickettsia prowazekii*	Epidemic typhus
			Bartonella quintana	Trench fever
			Borrelia recurrentis	Epidemic relapsing fever
	Siphonaptera	*Xenopsylla*	*Yersinia pestis*	Plague
			Rickettsia typhi	Murine typhus
		Nosopsyllus	*Rickettsia typhi*	Murine typhus
		Ctenocephalides	*Dipylidium caninum*	Dog tapeworm disease
	Hemiptera	*Panstrongylus, Rhodnius, Triatoma*	*Trypanosoma cruzi*	Chagas' disease
	Coleoptera	*Dermestes, Tribolium, Tenebrio*	*Hymenolepis nana, H. diminuta*	Hymenolepiasis
	Diptera	*Aedes*	Flaviviruses	Dengue, yellow fever
			Other arboviruses	Febrile illness, encephalitis
		Anopheles	*Plasmodium* spp.	Malaria
			Brugia malayi	Filariasis
			Arboviruses	Febrile illness, encephalitis
		Culex	*Wuchereria, Brugia*	Filariasis
			Arboviruses	Febrile illness, encephalitis
		Culicoides	*Mansonella* spp.	Filariasis
		Glossina	*Trypanosoma brucei*	African sleeping sickness
		Chrysops	*Los loa*	Loiasis
			Francisella tularensis	Tularemia
		Simulium	*Onchocerca volvulus*	Onchocerciasis
			Mansonella ozzardi	Filariasis
		Phlebotomus, Lutzomyia	*Leishmania* spp.	Leishmaniasis
			Bartonella bacilliformis	Bartonellosis
			Phlebovirus	Sandfly fever
Arachnida	Acari (ticks)	*Ixodes*	*Borrelia burgdorferi*	Lyme disease
			Ehrlichia spp.	Human granulocytic ehrlichiosis
			Babesia spp.	Babesiosis
			Arboviruses	Encephalitis
		Dermacentor	*Rickettsia rickettsii*	Rocky Mountain spotted fever
			Rickettsia siberica	Siberian tick typhus
			Francisella tularensis	Tularemia
			Coltivirus	Colorado tick fever
			Other arboviruses	Encephalitis
		Amblyomma	*Rickettsia rickettsii*	Rocky Mountain spotted fever
			Rickettsia conorii	Boutonneuse fever
			Ehrlichia chaffeensis	Human monocytic ehrlichiosis
			Francisella tularensis	Tularemia
		Rhipicephalus	*Rickettsia rickettsii*	Rocky Mountain spotted fever
			Rickettsia conorii	Boutonneuse fever
		Haemaphysalis	*Rickettsia siberica*	Siberian tick typhus
			Rickettsia conorii	Boutonneuse fever
			Arboviruses	Encephalitis, Kyasanur Forest disease
		Hyalomma	*Rickettsia siberica*	Siberian tick typhus
			Arbovirus	Crimean-Congo hemorrhagic fever
		Ornithodoros	*Borrelia* spp.	Relapsing fever
	Acari (mites)	*Leptotrombidium*	*Rickettsia tsutsugamushi*	Scrub typhus
		Liponyssoides	*Rickettsia akari*	Rickettsialpox
Crustacea		Decapods	*Paragonimus* spp.	Paragonimiasis
		Copepods	*Diphyllobothrium* spp.	Diphyllobothriasis
			Dracunculus medinensis	Guinea worm disease
			Gnathostoma spinigerum	Gnathostomiasis

** Adapted from Fritsche, 1999.*[10]

Figure 247-1 Adult *Pediculus capitis*, the human head louse. Note the prominent claws for grasping hair.

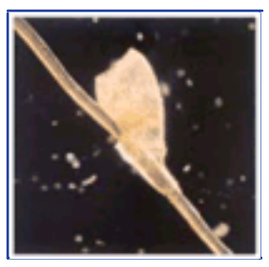

Figure 247-2 Egg or nit of human head louse attached to a hair shaft. Note that the operculum is missing indicating previous emergence of the larval louse.

during sexual intercourse. The life cycle for all human lice averages 3–4 weeks.[2] [9]

Fleas, order Siphonaptera

Fleas are small (1–2mm), laterally compressed, wingless ectoparasites with long muscular legs adapted for jumping great distances (Fig. 247.4). Fleas that attack humans include both blood-sucking pests (many species) and tissue-penetrating jiggers or chigoes. Infestations commonly occur with exposure to domestic animals and pets; the most pestiferous species are the dog flea (*Ctenocephalides canis*), the cat flea (*C. felis*) and the human flea (*Pulex irritans*). Some individuals become highly sensitized to flea bites, whereas others are unaffected. Fleas probe their hosts repeatedly, often leaving clustered bite sites, which may produce intense itching with papule formation in sensitized individuals. Cat and dog fleas are also the usual intermediate hosts for the tapeworm *Dipylidium caninum* and less frequently for *Hymenolepis diminuta* and *H. nana*. Because larvae of these species often develop in an animal's bedding or in carpets and furniture, eradication may require fumigation and cleaning of these articles. The Oriental rat flea, *Xenopsylla cheopis*, is an extremely important species because it transmits the plague bacillus *Yersinia pestis* and the agent of murine typhus, *Rickettsia typhi* (see Table 247.2). Although normally parasitizing several species of rats, this flea readily attacks humans should the rodent host die.[1] [3] [8]

Tunga penetrans, the jigger or chigoe flea, is found in both Central and South America and regions of tropical Africa. The female flea attaches to and embeds itself in the skin, especially between the toes and under the toenails, where it grows to the size of a small pea.

Figure 247-3 Adult *Phthirus pubis*, the human crab louse. The bodies of these lice are rounder and more crab-like than those of head or body lice. *With permission from ASM Press.*

Figure 247-4 Adult *Ctenocephalides canis*, the dog flea. Note the strong muscular hind legs.

After the eggs are discharged, the flea dies, prompting an inflammatory response and possible secondary bacterial infection. Tungiasis is diagnosed by identifying the dark portion of the flea's abdomen (displaying the respiratory spiracles) protruding from the skin surface of an enlarging lesion.[1] [8] [9]

Cockroaches, order Dictyoptera

Cockroaches are nuisance pests that have closely adapted themselves to human habitation, sharing our food, shelter and warmth. In addition to mechanically transmitting pathogenic bacteria, they may also spread hepatitis virus and polioviruses, intestinal protozoa and enteric nematodes. Allergies and asthma may develop in some individuals following exposure to their excreta, cast skins or body parts.[8]

Cosmopolitan species include *Blattela germanica* (the German cockroach), *Blatta orientalis* (the Oriental cockroach) and *Periplaneta americana* (the American cockroach).

Control programs include limiting entry to buildings, denying access to food, and the use of pesticides.[9] [17]

Bedbugs and kissing bugs, order Hemiptera

Bedbugs (family Cimicidae) and kissing bugs (family Reduviidae) are blood-sucking insects that have a long narrow proboscis, which is folded underneath the body when not in use. Bedbugs (*Cimex lectularius* and *C. hemipterus*) are reddish-brown, dorsoventrally flattened, wingless insects that are approximately 5mm in length (Fig. 247.5). They are cosmopolitan in distribution and will attack almost any mammal, feeding primarily at night. During daylight hours they hide under mattresses, loose wallpaper and floorboards. Although not

known to transmit disease, bedbug bites may cause painful wheals or bullae, depending upon an individual's sensitivity to their saliva.[1] [3] [18]

Kissing bugs (genera *Triatoma, Rhodnius, Panstrongylus*) have a cone-shaped head on a narrow neck and an abdomen that is widened in the middle. These insects are black or brown and some have orange and black markings on the abdomen. They average 1–3cm in length and unlike bedbugs have well-developed wings for flight. Like bedbugs, kissing bugs are relatively painless feeders on vertebrates and produce similar skin reactions. In Mexico and Central and South America they transmit the agent of Chagas' disease, *Trypanosoma cruzi*, in the feces, which is secondarily inoculated into the skin by the human host while scratching.[1] [9]

Assassin bugs are closely related to kissing bugs and are also able to transmit *T. cruzi*. Unlike kissing bugs, assassin bugs have less conspicuous body markings and produce a painful bite.

Bees, wasps and ants, order Hymenoptera

Hymenopterans are social insects that readily defend their nests when disturbed. In nonreproductive females the ovipositor is modified as a stinger capable of injecting venom for use in the capture of prey or for defense. The venom of bees (genera *Apis, Bombus*), paper wasps (genus *Polistes*), hornets (genus *Vespa*) and yellowjackets (genera *Vespula, Paravespula* and *Dolichovespula*) causes only transient swelling and discomfort in most individuals, but may be responsible for systemic reactions, including anaphylaxis, in others who have been previously sensitized. The africanized honey bee was introduced into Brazil in 1956 and has since spread throughout parts of South, Central and North America. These bees, which are more easily provoked than other honey bees, exhibit massive stinging behavior, although their venom is no more toxic than that of the European honey bee.[5] [8]

Many species of ants are problematic for humans because of their abilities to bite, and some groups, such as harvestor ants (genus *Pogonomyrmex*) in North America, fire ants (genus *Solenopsis*) in North and South America, bull ants (genus *Myrmecia*) in Australia and *Myrmica* ants elsewhere are capable of giving painful stings, to which some individuals may develop serious allergic reactions.[19] Fire ants in particular are easily disturbed and will attack in large numbers.[8]

Beetles, order Coleoptera

Although beetles are perhaps best known as pests of agricultural crops, some species can give a painful bite, and others, especially the blister beetles, can exude vesicating fluids, including cantharidin, that cause dermatitis or blister formation. Cantharidin is the chief component of the aphrodisiac known as 'Spanish Fly'. The larvae of

Figure 247-5 Adult bedbug *Cimex lectularius.* *With permission from ASM Press.*

certain larder beetles have barbed urticating hairs, which may be responsible for dermatitis or, if ingested, irritation of the gastrointestinal tract. Larval and adult larder and grain beetles can also serve as intermediate hosts for the rodent and human tapeworms *H. diminuta* and *H. nana*.[1] [3] [8]

Moths and butterflies, order Lepidoptera

Certain larvae (caterpillars) of lepidoptera possess urticating hairs or spines capable of injecting venom when handled. Although most effects of these toxins remain localized to the skin and can produce a severe local burning sensation, systemic effects, including shock and paralysis, have been reported.[8] Adult tussock and gypsy moths are known to have urticating scales and hairs that can cause dermatitis, eye irritation and respiratory tract irritation, especially among forestry workers.[20]

Flies, mosquitoes and midges, order Diptera

Diptera are characterized by the presence of a single pair of membranous wings. Among all arthropods, they are responsible for the greatest share of human disease through their blood-sucking activities, direct tissue invasion by larval forms (myiasis) and mechanical or biologic transmission of infectious agents (see Table 247.2). Bites from a variety of flies, mosquitoes and biting midges often cause local irritation from sensitivity to the saliva and, in some individuals, systemic reactions. In addition to blood-sucking activities, the repeated attacks themselves can be physically and psychologically damaging.

Myiasis may occur in an accidental, facultative or obligatory fashion and involve cutaneous, auricular, ocular, nasopharyngeal, gastrointestinal or genitourinary sites. Pseudomyiases occur occasionally and can cause significant psychologic distress, but usually result from the contamination of sputum, urine or stool samples with fly eggs following improper collection or storage.[8] [10]

Accidental and facultative myiasis

The house fly, *Musca domestica*, has no requirement for developing in mammalian tissue, yet is occasionally found in dead tissue or under plaster casts. This type of accidental myiasis is not uncommon, but is rarely clinically significant. Facultative myiasis is most often caused by blowflies and flesh flies, which ordinarily feed on dead tissues, but may move into adjacent viable tissues or infest exposed ulcers or traumatic wounds.

Obligatory myiasis

Obligatory myiasis is caused by certain species that develop only in living tissues. Those species that infect humans are all of zoonotic origin. The human botfly, *Dermatobia hominis,* develops in boil-like subcutaneous lesions with the posterior end of the maggot appearing at the skin surface (Fig. 247.6). This species is most commonly found in individuals who have spent time in Central or South America or, less frequently, Africa. Other botflies that occasionally infest humans are those parasitic on domestic and wild animals, including the horse botfly *Gasterophilus intestinalis*, cattle botfly *Hypoderma bovis*,

Figure 247-6 Larva of *Dermatobia hominis*, the human botfly, following recovery from a furuncular skin lesion. *With permission from J Brad Thomas, David L Bergeron and James J Plorde.*

the sheep botfly *Oestrus ovis* and rodent botflies of the genus *Cuterebra*.[21]

The tumbu fly (*Cordylobia anthropophaga*), found in sub-Saharan Africa, also causes a furuncular-type of myiasis. Eggs of this species are usually laid on the ground or on hanging laundry and larvae rapidly penetrate the skin upon contact.

The most serious obligatory myiasis is caused by the Old World screw-worm, *Chrysomya bezziana,* and the New World screw-worm, *Cochliomyia hominivorax*. These species lay their eggs directly on their cattle hosts, usually on wounds or near the nostrils. The larvae actively feed and move through living tissues. Human infections can be particularly destructive if the larvae invade the eye, nose or mouth. A variety of other species are also known to be responsible for traumatic obligatory myiasis in humans.[3] [8] [9] [22]

Arachnids

Medically important arachnids include the scorpions, spiders, ticks and mites. Scorpions and spiders are best known for their abilities to inject poisonous venoms, whereas ticks and mites are best known as vectors for viral, bacterial and protozoal pathogens.[1] [11] [18]

Scorpions, subclass Scorpiones

Scorpions are predatory in nature and paralyze their intended victim with a neurotoxic venom from the sting, which may also be used for defensive purposes. Toxicity to humans varies depending upon the species. Many elicit no more reaction than that of a bee sting, but some species are deadly, causing over 1000 deaths annually, especially among children. Poisonous species occur in the western hemisphere, Europe, Africa and the Middle East.[1] [3] [4] [8]

Spiders, subclass Araneae

Spiders lack a tail with attached stinger, but instead have fang-like chelicerae among their mouthparts, through which venom can be expressed. Although the majority of spiders are venomous, few have chelicerae capable of penetrating human skin; among those that can most envenomations produce no more than transient local effects with pain, numbness, erythema and swelling (e.g. wolf spiders in the genus *Lycosa* and tarantulas, among many others). More serious disease results from those species capable of producing local or systemic arachnidism with potent dermonecrotic enzymes or neurotoxins, respectively.[8]

Necrotic arachnidism occurs worldwide and is produced most commonly by a number of species in the genus *Loxosceles*, especially the cosmopolitan *L. reclusa* (brown recluse), whereas in South America *L. laeta* is well known for producing severe dermonecrosis. Variously named violin, fiddleback or recluse spiders, they measure 1–2cm long, are tan to dark brown in color and have a darkened violin-shaped marking oriented base forward on the dorsum of the cephalothorax. When present in homes they are reclusive in their habits, preferring undisturbed areas. Their bite is painless and often goes unrecognized until several hours later when the

area becomes red, swollen and painful. The venom contains multiple enzymes including sphingomyelinase D and is both dermonecrotic and hemolytic, producing variable degrees of cutaneous necrosis and sloughing of the involved skin over several days. The resulting lesion may be difficult to heal and subject to secondary infection. Systemic reactions such as hemolysis and acute renal failure occur rarely.[1] [3] [8] Other spider genera implicated in producing necrotic arachnidism include the hobo spider *Tegenaria agrestis* in Europe and the Pacific Northwest of North America, crab spiders (genus *Sicarius*) in Africa and sac spiders (genus *Chiracanthium*), which are found worldwide.[4] [23]

Widow spiders (genus *Latrodectus*) are found worldwide and are responsible for systemic arachnidism through the action of a potent neurotoxin capable of producing weakness, myalgia, paralysis and convulsions, and occasionally death. Latrodectism is one of the

Figure 247-7 Female *Lactrodectus mactans*, the black widow spider. Note the characteristic red hourglass marking on the underside of the abdomen. *With permission from New England Journal of Medicine 1994;331:777.*

leading causes of death from arthropod envenomations worldwide, with published mortality rates varying from < 1 to 6%.[4] *Latrodectus mactans,* the black widow, and *L. geometricus*, the brown widow, are among the most widespread species. Female widow spiders vary in appearance by species, being glossy black to brown with a characteristic red or orange hourglass-shaped marking on the underside of the abdomen, and displaying a leg span of 3–4cm (Fig. 247.7). They live in protected locations such as woodsheds, basements and outdoor privies. [3] [8] Other spiders producing dangerous neurotoxins include the funnel web spiders (genus *Atrax*) in Australia and armed spiders (genus *Phoneutria*) in South America.

Ticks, subclass Acari

Unlike spiders and scorpions, ticks have a fused cephalothorax and abdomen and a characteristic toothed hypostome for feeding. Tick development progresses through four stages — egg, larva, nymph and adult — with a blood meal required for progression. Humans usually acquire ticks in grassy or brushy areas in close proximity to the usual animal hosts. All species are obligate blood-sucking ectoparasites and are important vectors of viral, bacterial and protozoal pathogens to humans and domestic animals (see Table 247.2). Their feeding activities may also produce local tissue damage and blood loss, especially in livestock and wildlife, or tick paralysis, a syndrome caused by a neurotoxin secreted by a tick's salivary glands that produces ascending flaccid paralysis and toxemia. The symptoms may closely mimic those of Guillain-Barré syndrome, poliomyelitis or botulism. Removal of the attached tick, often found in an unnoticed location such as above the hair line on the nape of the neck, usually results in resolution of the symptoms within hours to days.[24] [25]

Species affecting humans include members of the family Ixodidae (hard ticks) and Argasidae (soft ticks):

- hard ticks have anteriorly directed mouthparts and a sclerotized plate or scutum, on the dorsum, with the scutum covering the entire dorsum of the male, but only the anterior portion in the female, allowing the body to swell when engorged (Fig. 247.8); and
- argasid ticks have a soft leathery body lacking a scutum and ventrally directed mouthparts that are not visible when viewed from above (Fig. 247.9).

Unengorged ticks are generally 2–5mm long, but may enlarge to several times this size following engorgement. Engorged hard ticks may mimic soft ticks, so care must be exercised in their identification.[24] Most ticks found crawling on or embedded in human skin are hard ticks. Soft ticks tend to feed only briefly and then often at night.

Figure 247-8 Nonengorged adult female *Dermacentor variabilis*, the common dog tick, of the family Ixodidae (hard ticks). *With permission from Northwest Infectious Disease Consultants.*

Figure 247-9 Nonengorged adult *Ornithodoros hermsi*, of the family Argasidae (soft ticks). *With permission from Northwest Infectious Disease Consultants.*

Disease transmission is produced most commonly by hard ticks in six genera (see Table 247.2). *Ixodes* spp., primarily *I. scapularis* and *I. pacificus* in North America and *I. ricinus* and *I. persulcatus* in Europe and parts of Asia, are responsible for transmitting the agents of Lyme disease, babesiosis and human granulocytic ehrlichiosis (Fig. 247.10). The latter is an emerging rickettsial-like disease that produces an influenza-like illness that varies from being subclinical to fatal. Old World *Ixodes* spp. are also capable of transmitting encephalitis-producing arboviruses. *Dermacentor variabilis* and *D. andersoni* are vectors for the agents of Rocky Mountain spotted fever, tularemia and Colorado tick fever in the New World, whereas *D. marginatus*, *D. silvarum* and *D. nuttalli* are capable of transmitting Siberian tick typhus and encephalitis-producing arboviruses in Europe and Asia.[3] [8] [11] [26]

Ticks in the genera *Amblyomma* and *Rhipicephalus* are found worldwide and are capable of transmitting Rocky Mountain spotted fever in the New World. *Rhipicephalus* ticks also transmit boutonneuse fever in southern Europe and Africa, whereas *Amblyomma* ticks have recently been implicated as vectors of *Ehrlichia chaffeensis*, the agent of human monocytic ehrlichiosis. Infection with this organism produces an illness similar to that of human granulocytic ehrlichiosis and the disease has been documented widely in the USA as well as in Europe and Africa. [8] [26]

Haemaphysalis ticks transmit Siberian tick typhus in parts of Eurasia, boutonneuse fever in Africa, and arboviruses responsible for encephalitis in parts of Eurasia and Kyasanur Forest disease in India.

Hyalomma ticks are widespread in parts of Europe, Africa and Central Asia and transmit both Siberian tick typhus and the viral agent of Crimean-Congo hemorrhagic fever.[3] [8]

Soft ticks of the genus *Ornithodoros* occur in many parts of the New and Old worlds and are important vectors of the relapsing fever spirochetes (*Borrelia recurrentis* and related forms; see Table 247.2). [11]

Mites, subclass Acari

Mites are microscopic (usually <1mm) arachnids that are widely distributed in the environment. Medically important species may:

- attack humans directly;
- serve as vectors for infectious diseases; and
- cause dust allergies.

Most humans are naturally infested with both *Demodex folliculorum* and *D. brevis*, the follicle mites. Follicle mites are minute (0.1–0.4mm) elongated parasites with stubby legs that can be recovered from hair follicles and sebaceous glands. They are common incidental findings on histologic skin preparations. Although their presence has been associated with various skin conditions, they are commonly found in healthy individuals as well, which makes their significance hard to assess.[27]

Sarcoptes scabiei, the itch or mange mite, is of greater medical importance because of its ability to create serpiginous tunnels through the upper layers of the epidermis. Transmitted through personal contact, these mites are found primarily in the interdigital spaces and the flexor surfaces of the wrists and forearms, and less commonly in other areas, including the breasts, buttocks and external genitalia. Inflammation and intense itching results from the tunneling activity and from the deposition of eggs and excreta. Clinical manifestations vary depending upon the degree of sensitization to the parasites and their products. Lesions often become secondarily infected. A generalized dermatitis occurring in the presence of thousands of mites, typically in elderly or immunocompromised individuals, is known as crusted or Norwegian scabies (Fig. 247.11). Diagnosis is made by placing skin scrapings collected from tunneled areas in 20% potassium hydroxide or mineral oil for clearing and

---

Figure 247-12 Adult *Sarcoptes scabiei*, the human itch or mange mite, seen in skin scrapings. *With permission from New England Journal of Medicine 1994;331:777.*

examining under the microscope. Detection of eggs, six-legged larvae and eight-legged nymphs or adults is diagnostic, but may be difficult to demonstrate (Fig. 247.12).

A number of animal mite species can attack humans for a blood meal, either as larval forms or as adults, when the normal mammalian or bird hosts are not available.[15] [28] [29] Larval chigger mites (family Trombiculidae) are problematic in many parts of the world because their saliva can produce large wheal-and-flare reactions with intense itching. Often red in color, these tiny six-legged larvae commonly attach to the skin in areas where clothing is restrictive such as ankles, waistline, armpits and wrists. In parts of Asia and Australia trombiculid mites are vectors for transmitting the agent of scrub typhus (see Table 247.2).[3] [9]

Classes of lesser medical importance

Millipedes and centipedes

Millipedes are worm-like arthropods with numerous apparent body segments, each with two pairs of legs, that are commonly found in and under decaying vegetation.

Many species produce vesicating secretions composed of quinonoids and parabenzoquinones from glands located on each body segment. Larger tropical forms (up to 25cm) can squirt these secretions over several centimeters when handled roughly. Exposure of the skin or mucous membranes to these fluids may produce a burning sensation and blister formation. Exposure of the eye may result in periorbital 'burns', conjunctivitis and keratitis, which may progress to corneal perforation and blindness.[7] [8]

Centipedes are flatter than millipedes, have only one pair of legs per body segment and display long antennae. They are fast moving and can inflict a painful sting from a pair of forward-directed pincers that are modified from the first pair of legs. The larger species (26–45cm) found in subtropical and tropical regions are able to penetrate human skin when handled, giving a painful burning sting with a local tissue reaction. Although systemic reactions can occur in individuals who have been previously sensitized, fatalities are rare.[3] [8]

Crustaceans

Crustaceans, most notably crabs, crayfish and microscopic copepods are of medical importance by serving as hosts and vectors for larval stages of several different helminths (see Table 247.2). [1] [18]

Pentastomes

Pentastomes or tongue worms are arthropods of uncertain affinities that possess few distinctive morphologic characteristics. Larval stages resemble mites and have occasionally been reported producing liver and lung infections in humans in Asia and Africa. Adult stages are wormlike organisms that live in the nasal passages of certain predatory reptiles, birds and mammals; they have been recovered from the nasopharynx of individuals from the Middle East and Africa where they are responsible for an obstructive condition known as halzoun.[1] [18]

MANAGEMENT

Medical management of most exposures to arthropods involves:

- removal of the offending organism if attached or embedded;
- palliative treatment for most bites and stings;
- use of antihistamines for local and systemic allergic phenomena and epinephrine (adrenaline) for serious systemic reactions; and
- administration of appropriate antivenoms for exposure to certain spider bites and scorpion stings.

Most embedded chigoe fleas and maggots can be removed as a minor surgical procedure either with a sterile needle, curettage or excision; use of mineral oil alone to occlude the spiracles (breathing tubes) of maggots at the skin surface may result in their spontaneous emergence. Care must be taken to ensure complete removal or serious secondary infection may result. Similarly, removal of the mouthparts of attached ticks is important as transmission of infectious agents may continue for a period of time should they remain embedded. Tweezers may be used to grasp the tick as close as possible to the skin surface followed by the use of steady pressure in a direction perpendicular to the skin.[8] [11]

Physiologic responses to the large variety of arthropod bites and stings varies significantly between individuals. Exposure to the excreta, molted skins and body parts of cockroaches, lice, fleas, bedbugs, scabies mites and dust mites may produce sensitization. Treatment is usually directed at counteracting the effects of histamine and other vasoactive compounds, released either by mast cells as a consequence of previous sensitization or introduced as a component of hymenopteran venom. Administration of oral, and occasionally parenteral, antihistamines may be indicated, depending upon the severity of symptoms. The development of systemic allergic reactions, most commonly associated with bee and wasp stings, may result in anaphylaxis and irreversible shock. Angioedema of the upper airway may produce occlusion, whereas pulmonary edema and bronchial constriction may result in respiratory failure, requiring the immediate administration of epinephrine and/or bronchodilators. [3] [4] [8]

Treatment for the effects of biting arthropods and exposure to the spines and urticating hairs of lepidoptera and coleoptera includes palliative remedies such as antipruritic lotions, creams and ointments, and, if more severe, a short course of systemic corticosteroids. Respiratory allergies, usually developing following sensitization to dust mites or cockroaches, are treated using inhaled corticosteroids or cromolyn sodium (sodium cromoglicate), although removal or control of the offending allergen should be attempted.

Bites or stings that involve neurotoxic or necrotic venoms are managed by counteracting the effects of the venom and providing supportive treatment. Antivenoms for widow spider bites are commercially available. Antivenoms for bites by South American *Loxosceles* spiders and stings by scorpions are available locally in endemic areas.[3] [4]

Eradication of body lice, head lice, pubic lice and scabies mites often becomes a challenge for both patient and physician and

reports of insecticide-resistant strains have made the task more complex. Mechanisms of resistance are unclear and the possibility of reinfestation or noncompliance with treatment regimens must be taken into account. Generally:

- body lice are treated with a combination of pyrethrins with piperonyl butoxide;
- head lice and public lice are treated using 1% permethrin lotion or lindane (1% gamma benzene hexachloride lotion or shampoo); and
- scabies infestations are usually treated with 5% permethrin cream, 10% crotamiton lotion or cream or 1% lindane lotion or cream.

With any of these compounds there is a possibility of allergic skin reactions; in addition lindane has the potential for central nervous system toxicity, especially in children and the elderly.[3] [8]

Management of delusional parasitoses are invariably difficult and time-consuming, requiring a team approach involving the family practitioner, dermatologist and psychiatrist. Treatment may include the use of psychoactive drugs such as pimozide or risperidone.[30]

Figure 1-1 Viral genomes.

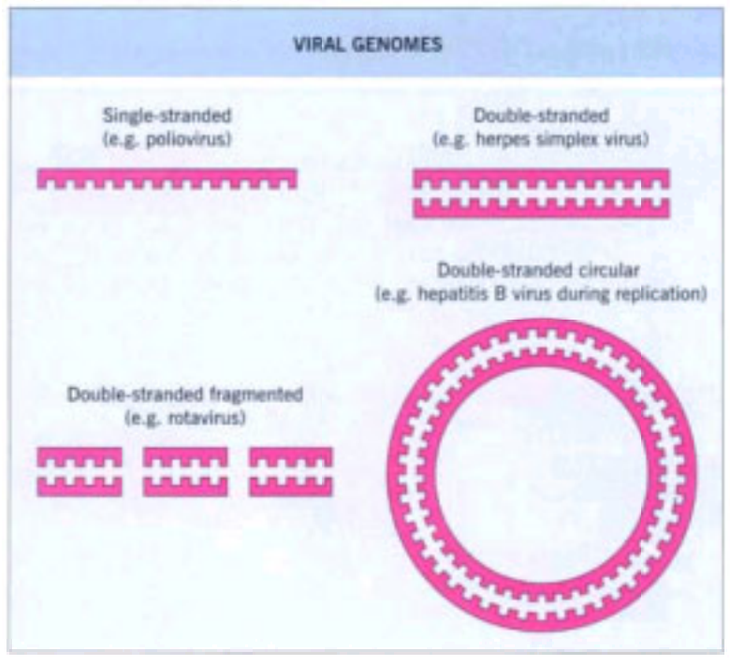

Figure 1-2 Examples of virions. Adenovirus is an icosahedral DNA virus without an envelope; fibers extend from the 12 points of the icosahedral coat; DNA forms a ribbon-like molecule. Approximate size 80nm. HIV-1; glycoprotein (GP) molecules protrude through the lipid membrane; the icosahedral capsid encloses a vase-shaped nucleocapsid, in which the diploid RNA is enclosed. Approximate size 100nm. Influenza virus is an enveloped RNA virus, containing nucleocapsid of helical symmetry; spikes of hemagglutinin and neuraminidase protrude from the lipid bilayer. Approximate size 100–200nm. Rabies virus is a helical RNA nucleocapsid with a bullet-shaped lipoprotein envelope, in which approximately 200 GPs are embedded. Approximate size 150nm. (The diagram is not to relative scale.) *Adapted from Collier and Oxford*[4] *by permission of Oxford University Press.*

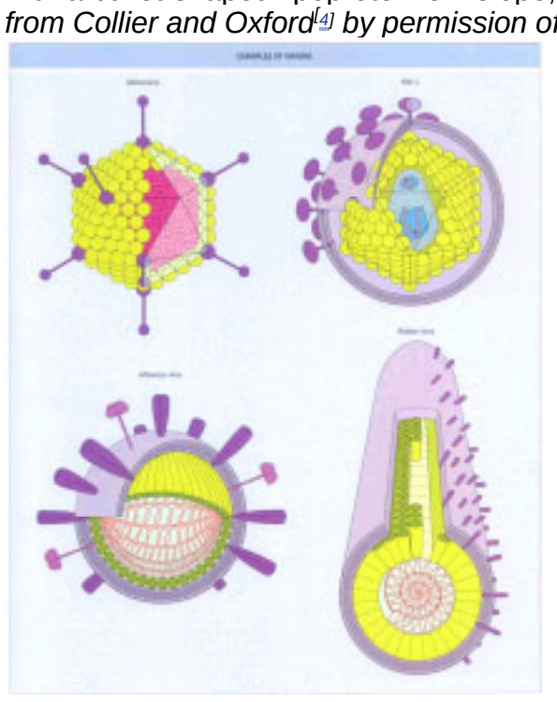

Figure 1-3 Viral 'lifestyles'.

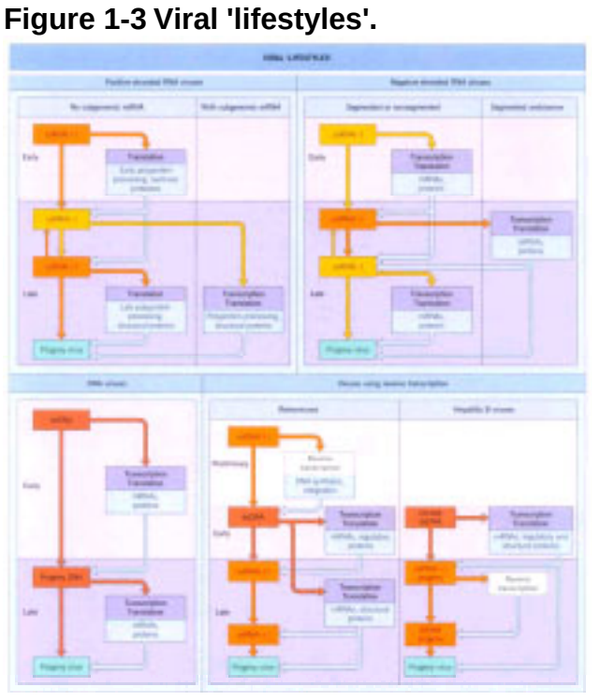

Figure 1-4 Bacterial cell walls. (a) *Mycoplasma pneumoniae* has a single membrane, made up of phospholipids and membrane proteins. (b) In Gram-positive organisms the cytoplasmic membrane is covered with a thick layer of peptidoglycan; chains of lipoteichoic acid protrude outside. (c) The cell wall of a Gram-negative rod is more complex. The layers are: the cytoplasmic membrane; the periplasmic space; a layer of peptidoglycan, which is thinner than that in Gram-positive bacteria; and an asymmetric outer membrane. The inner leaflet of the outer membrane is made of phospholipids. The outer leaflet has lipopolysaccharides as its principal lipids; porins, which are channel-forming proteins often organized as trimers, allow the penetration of hydrophilic molecules through the outer membrane. (d) The peptidoglycan of *Staphylococcus aureus* has polysaccharide chains ('backbone') that are alternating residues of *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc). Tetrapeptides are attached to MurNAc and are linked together by pentaglycines bridging the L-lysine of each tetrapeptide chain to the D-alanine of the neighboring one.

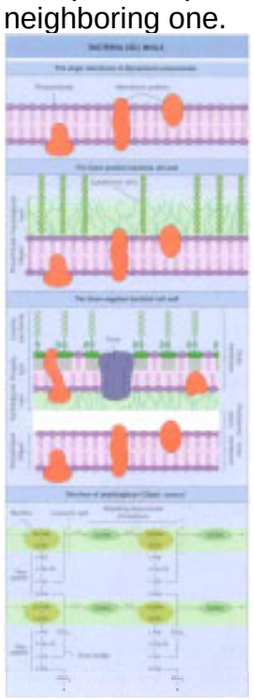

Figure 1-5 Transcription and translation in bacteria (*Escherichia coli*).

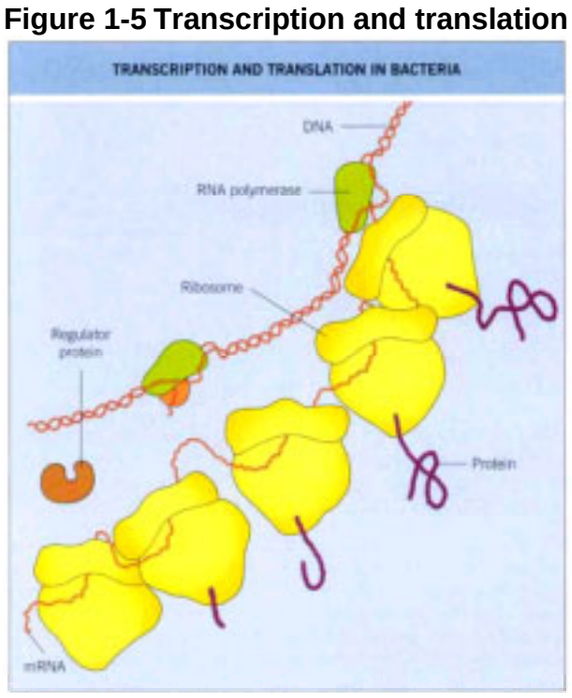

Figure 1-6 Genetic information in bacteria. This example is *Escherichia coli*. Additional genetic information may be supplied by extrachromosomal elements such as plasmids or bacteriophages. Bacteria may carry a variety of these 'mobile genetic elements', which may transfer readily from one cell to another. The electron micrograph shows a 8.65kb *E. coli* plasmid that confers sulfonamide and streptomycin resistance (left) and a single-stranded derivative of the plasmid (right).

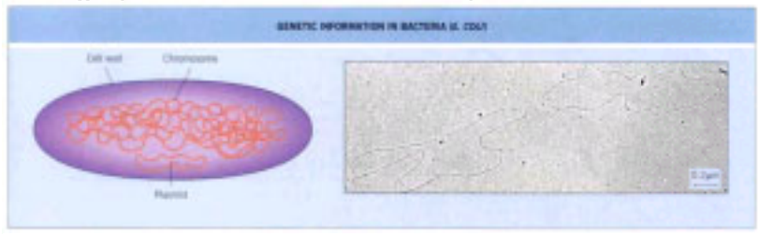

Figure 1-7 Flagella and motility in bacteria.

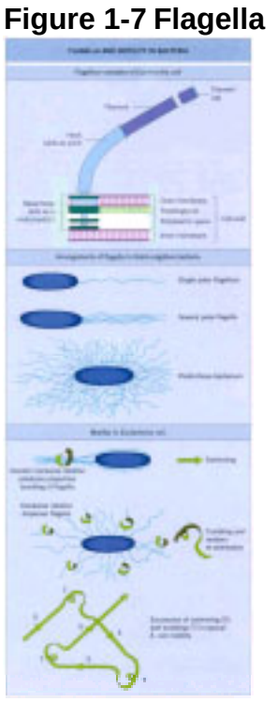

Figure 1-8 Contamination of humans by micro-organisms. Many parts of the body are colonized by normal flora, which can be the source of endogenous infection. Large numbers of micro-organisms are found in moist areas of the skin (e.g. the groin, between the toes), the upper respiratory tract, the digestive tract (e.g. the mouth, the nasopharynx), the ileum and large intestine, the anterior parts of the urethra and the vagina. Other routes are interhuman transmission of infections and exposure to exogenous contamination.

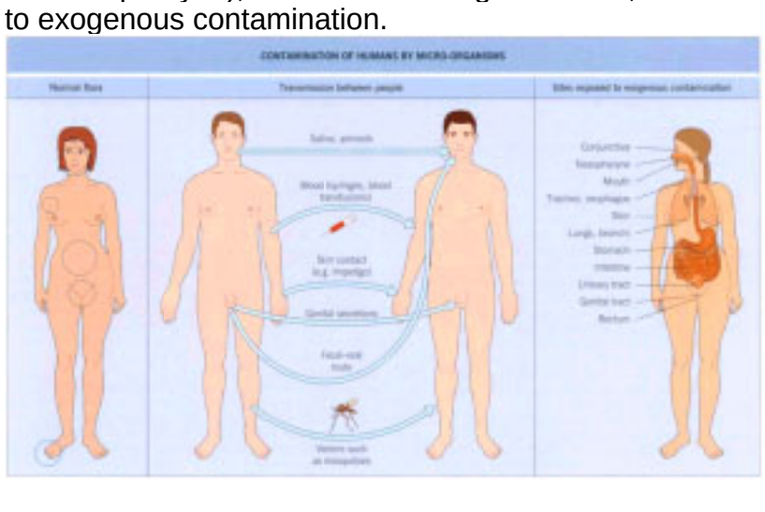

Figure 1-9 Bacterial adherence.

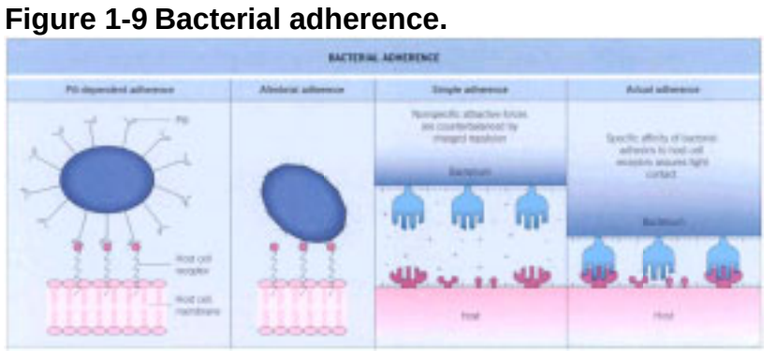

Figure 1-10 Structure of P-pilus in *Escherichia coli.*

Figure 1-11 Cell wall of *Streptococcus pyogenes.* The proposed model of the M protein is based on current sequence and structural data. ARP, immunoglobulin A receptor protein; FcR, receptor for the Fc portions of immunoglobulin. *Adapted from Kehoe.*[14]

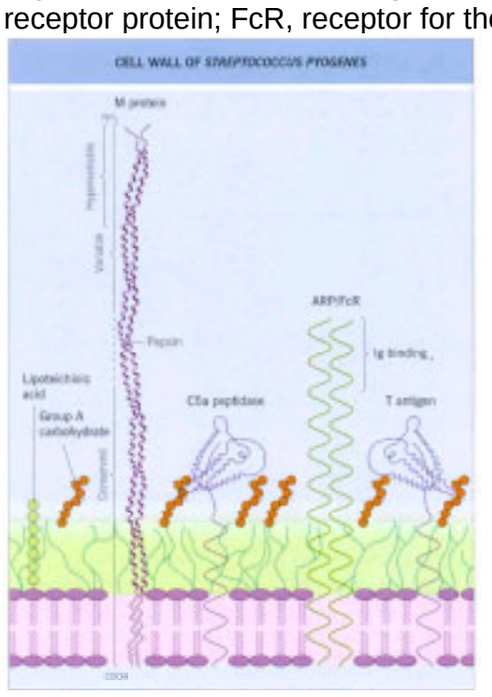

Figure 1-12 Opsonization and phagocytosis of bacteria. Bacteria are covered with IgG, specific for surface antigens. Bound IgG interacts with the phagocyte Fc?-receptor and pseudopods are formed, engulfing the bacterium into the host cell.

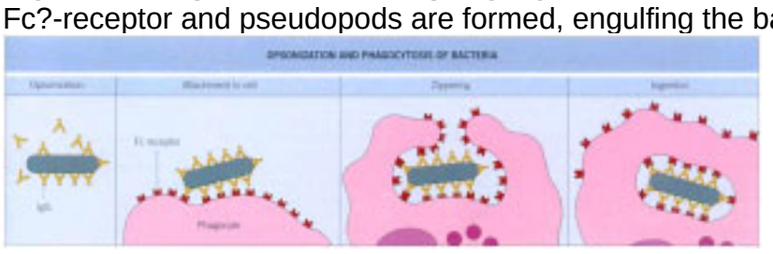

Figure 1-13 Enteropathogen-M cell interactions. (a) An uninfected M cell, enclosed between two adjacent enterocytes. The basolateral side forms a pocket where lymphocytes and macrophages are located. (b) Enteroadherent *Escherichia coli* forms microcolonies at the M cell surface, but is not internalized. (c) *Vibrio cholerae* undergoes transcytosis but is efficiently phagocytosed in the submucosa. (d) *Campylobacter jejuni* and *Yersinia* spp. undergo transcytosis, replicate in the submucosa and disseminate. (e) *Salmonella* spp. are transported across M cells, leading to destruction of the M cell. (f) *Shigella flexneri* is endocytosed by M cells, escapes into the cytoplasm, replicates, is propelled by actin tails and spreads to adjacent enterocytes. *Adapted from Siebers and Finlay.*[17]

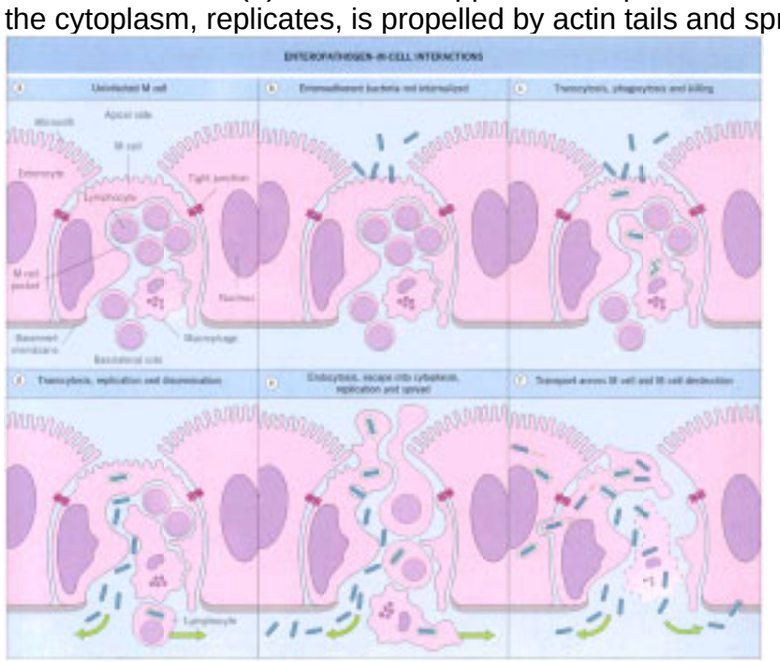

Figure 1-14 Genetic organization of the invasion region in *Salmonella* and *Shigella* spp. Identical patterns indicate topologically conserved blocks of genes. Each genus has genes that are unique. Despite remarkable genetic similarities, the invasion strategies of the two bacteria are quite different (see Fig. 1.13). *Adapted from Galan.*[19]

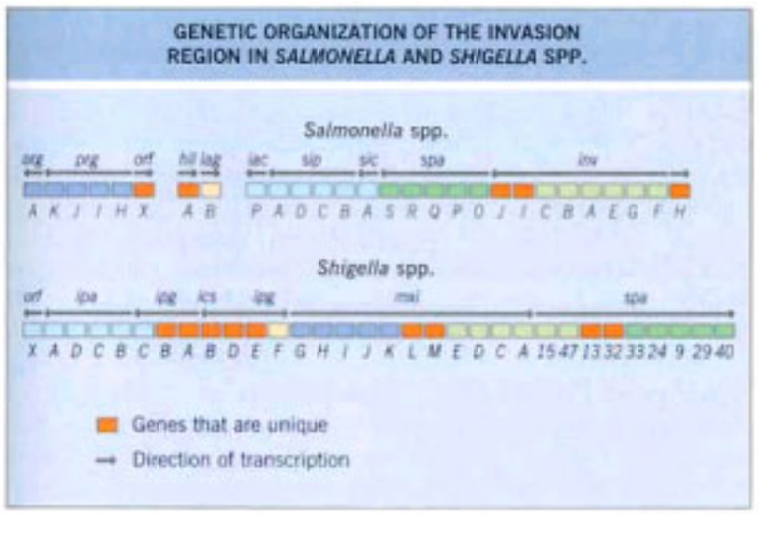

Figure 1-15 Actin-based motility in *Listeria monocytogenes.* The bacterium moves forwards at the rate of actin-filament growth behind the pathogen. *Adapted from Sanders and Theriot.*[27] The EM shows a section of a CaCo-2 cell infected with *Listeria monocytogenes*; the bacterium protrudes into the cytoplasm of an adjacent cell; protrusion is limited by a double membrane (arrowheads).

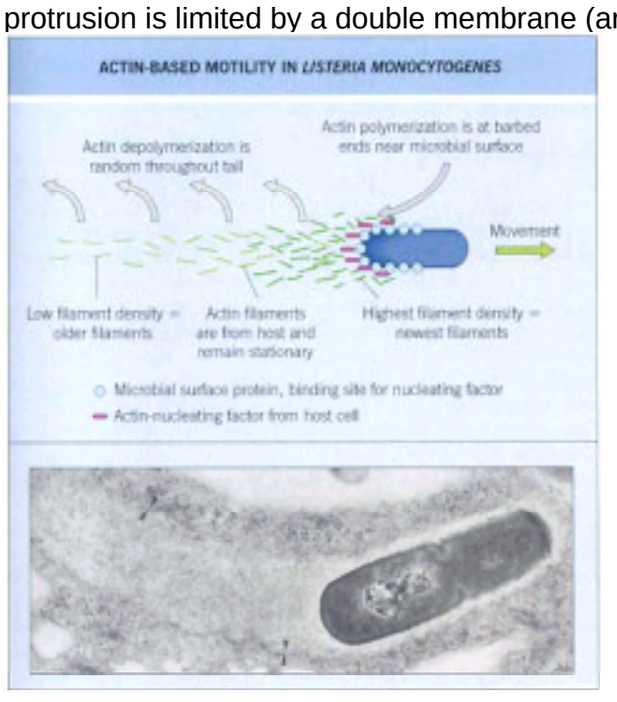

Figure 1-16 Intracellular life cycle of *Listeria monocytogenes*.

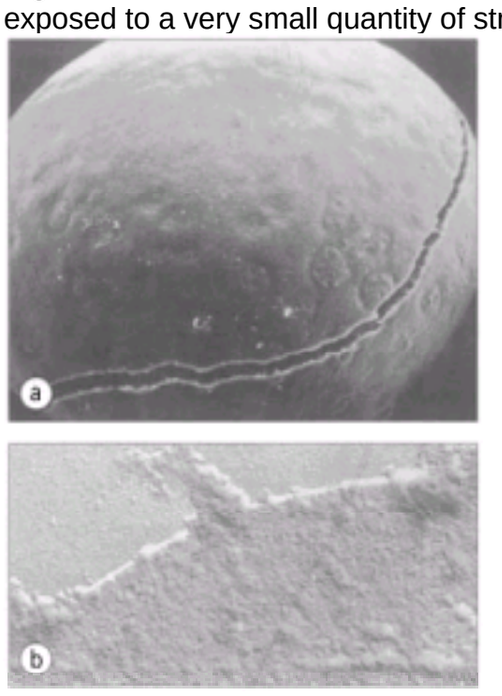

Figure 1-18 Diphtheria toxin synthesis and mode of action. (Top) The 25-residue leader sequence is cleaved off by the bacterial leader peptidase; the A and B subunits are generated from the precursor protein by a 'trypsin-like enzyme'. Once in the cytoplasm of a targeted eukaryotic cell, the A chain, responsible for ADP-ribosyl transfer, is disconnected from the B chain, responsible for receptor binding and membrane insertion. (Bottom) The B chain binds to a specific receptor on the eukaryotic cell. After endocytosis, acidification in the endosome induces insertion of the B chain into the endosomal membrane and translocation of subunit A into the cytosol, where it catalyzes the ADP ribosylation of EF-2. As a result, protein synthesis is inhibited and the targeted cell dies.

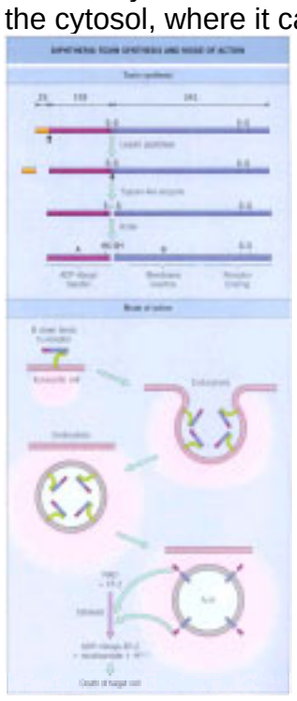

Figure 1-19 Iron regulation of diphtheria toxin synthesis. High iron concentrations in the environment repress the synthesis of diphtheria toxin: when bound to iron, DtxR-Fe acts as a transcriptional repressor of the *tox* gene.

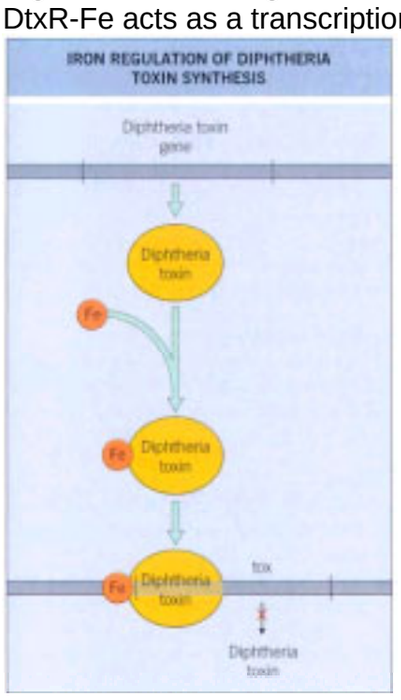

Figure 1-20 Apoptosis induced by Sendai virus. Morphologic changes in the apoptotic Sendai infected cell (right) include the typical condensation of chromosomal DNA. *Courtesy of Dr Dick Compans and Dr Kiyoshi Tanebayashi.*

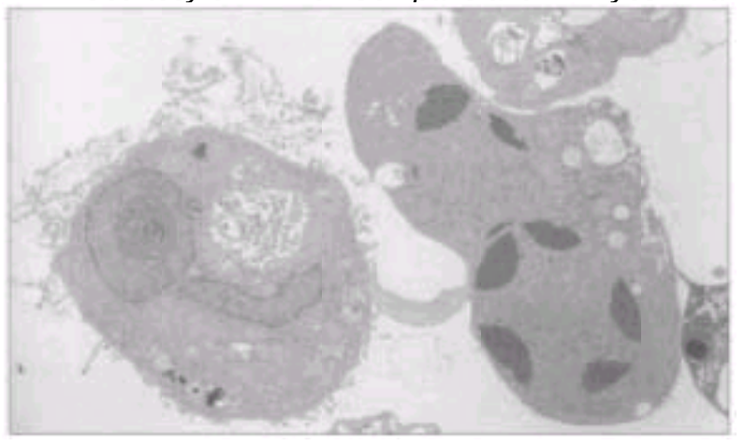

Figure 1-21 Virus-induced cytopathic effects.

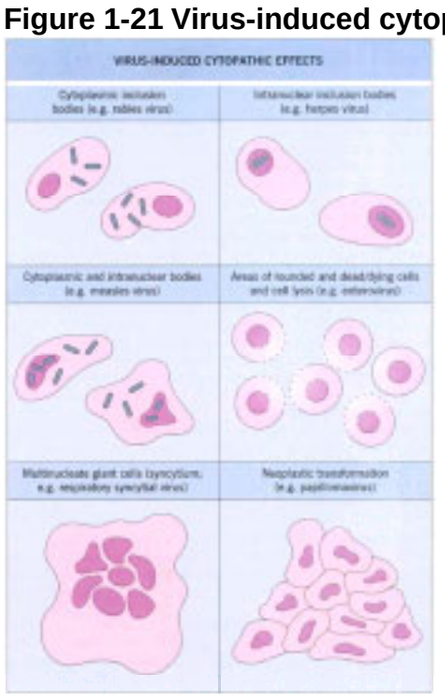

Figure 1-22 Phagocytosis and bacterial resistance to killing.

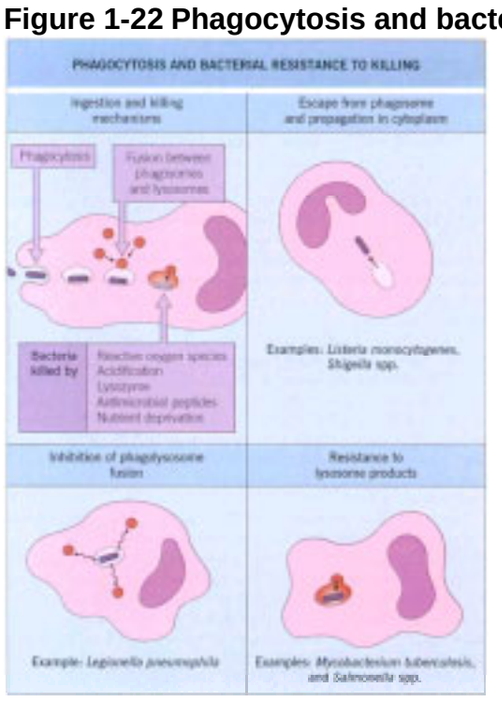

Figure 1-23 Mechanism of resistance to macrophage antimicrobial peptides by *Salmonella* spp. *Salmonella* produces the SapA (A) peptide, which complexes with host cell antimicrobial peptides. Other proteins encoded by the *sap* locus (SapB, SapC and SapD) are required for the transport of the SapA-antimicrobial peptide complex into the cytosol where the antimicrobial peptide is degraded.

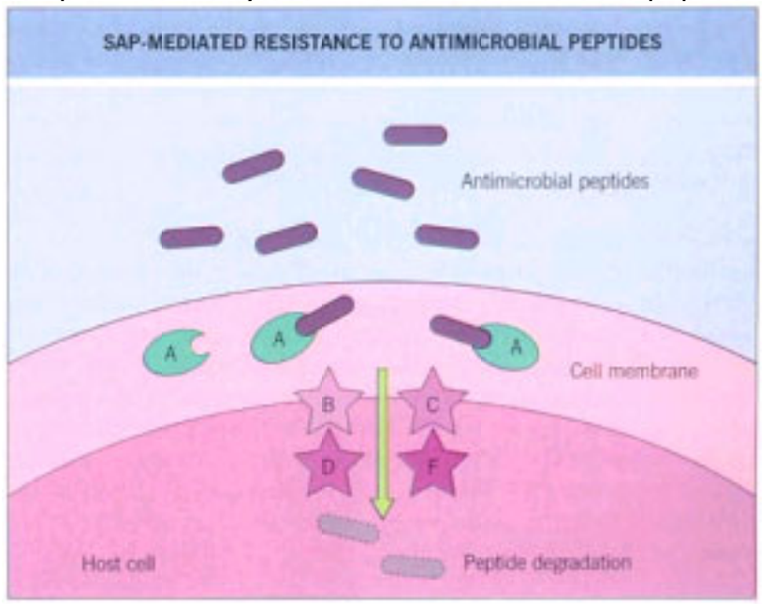

Figure 1-24 Antigenic and phase variations in microbial pathogens. Three mechanisms are shown. (Top) Exchange of DNA between nonexpressed copies of *pil*S and the expressed gene *pil*E in *Neisseria gonorrhoeae* can change the expressed antigen. (Middle) A switch mechanism is responsible for the (mutually exclusive) production of type A and type B flagella in *Salmonella typhimurium*. Phase variation depends on the orientation of a DNA fragment adjacent to the type A flagella gene. When A is expressed (a) from the promoter in the invertable fragment, the repressor for the type B flagella is expressed at the same time. As a consequence the type B flagella gene is repressed. Inversion of the DNA fragment abolishes expression of the A-repressor gene and the B-repressor gene (b). In this situation type B flagella are produced. (Bottom) Antigenic shift by gene reassortment results from infection of a single cell by two different virions.

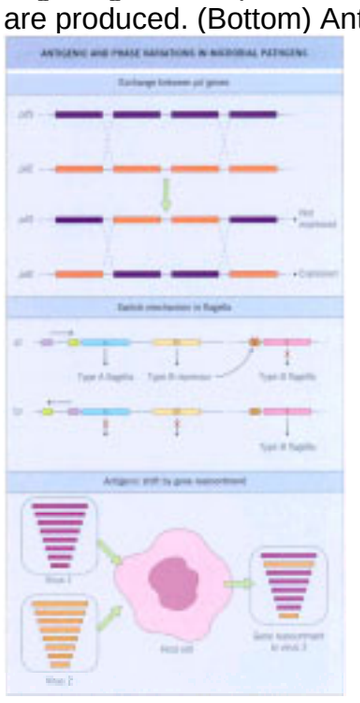

Figure 2-1 Pathways of inflammation induced by microbial components. Components of Gram-negative organisms (LPS) and Gram-positive bacteria (peptidoglycan) can activate similar pathways. C3a, biologically active soluble cleavage product of the activation of complement factor 3; C5a, biologically active soluble cleavage product of the activation of complement factor 5; DIC, disseminated intravascular coagulation; IFN, interferon; IL, interleukin; PMNL, polymorphonuclear leukocyte; TNF, tumor necrosis factor.

Emerging infections: microbial threats to health in the United States. Washington DC: National Academy Press; 1992.*[3] *(In March 2003, the Institute of Medicine published a successor to this report, entitled Microbial threats to health: emergence, detection, and response.)*

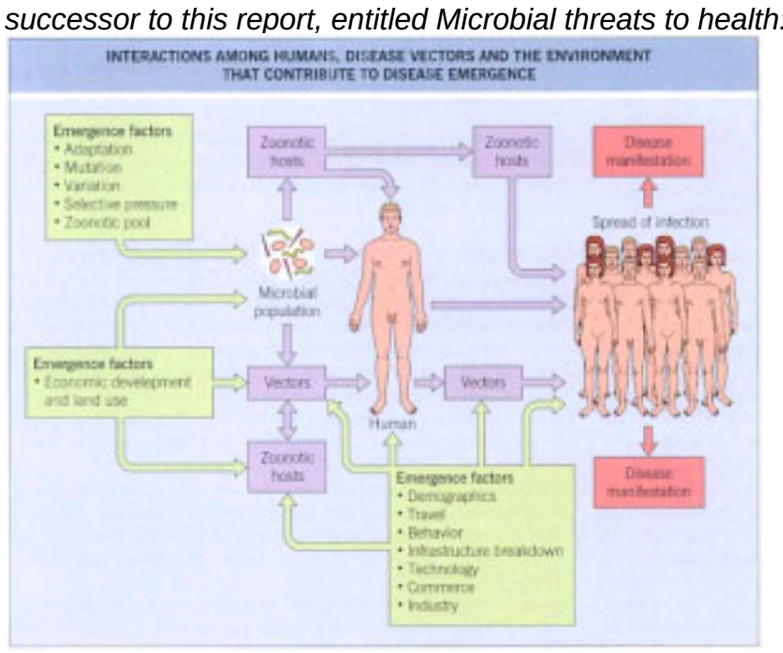

Figure 4-2 Spread of West Nile virus in the United States. In the 4 years since West Nile virus was first reported in the USA (in New York City), it has been detected in 44 states. *Source: National Center for Infectious Diseases, Centers for Disease Control and Prevention.*

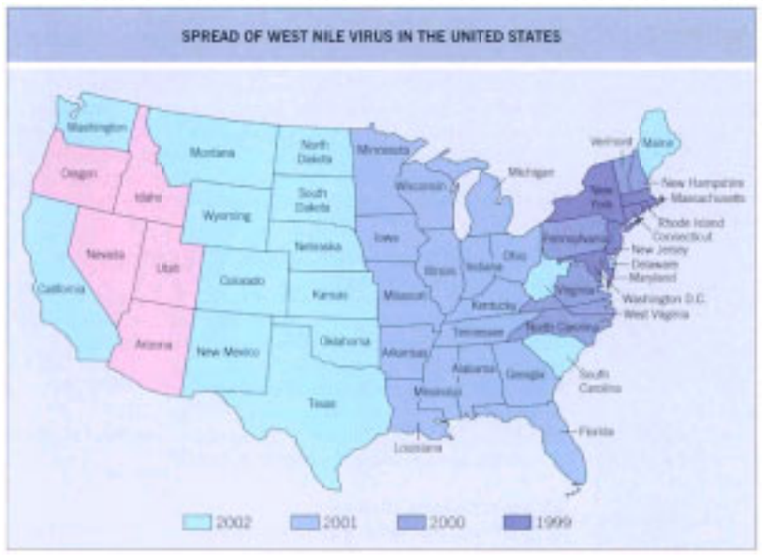

Figure 4-3 International tourist arrivals, 1950–99. International travel has increased by 160 million tourist arrivals since 1990, from 500 million to more than 660 million in 1999. In 1950, 15 countries received nearly 100% of the 25 million international tourist arrivals. In 1999, at least 70 countries and territories each received more than one million international tourist arrivals. The rate of growth in international arrivals in Africa alone was 7.8%, nearly twice the world average. ('Tourism' in these statistics includes business travel.) *Source: World Tourism Organization. WTO tourism highlights 2000, August 2000.*

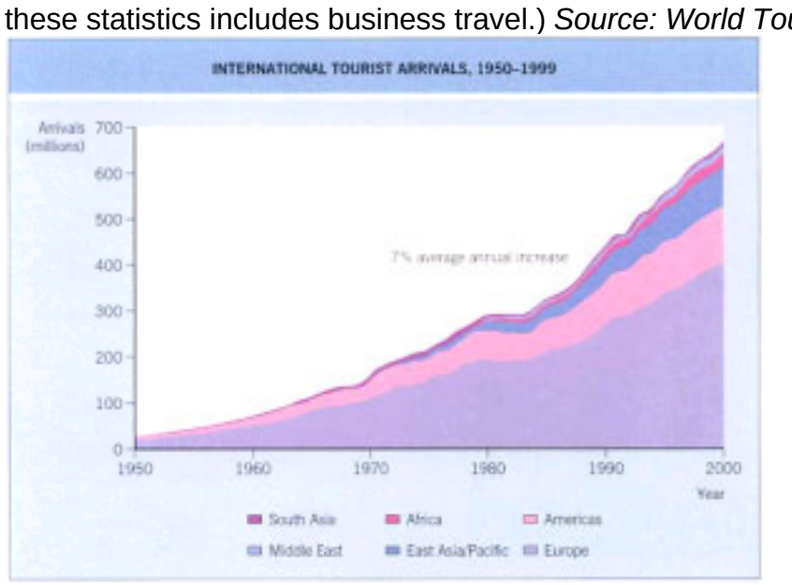

Figure 4-4 Leading infectious killers. *Source: World Health Organization. Overcoming antimicrobial resistance. Geneva: WHO.*

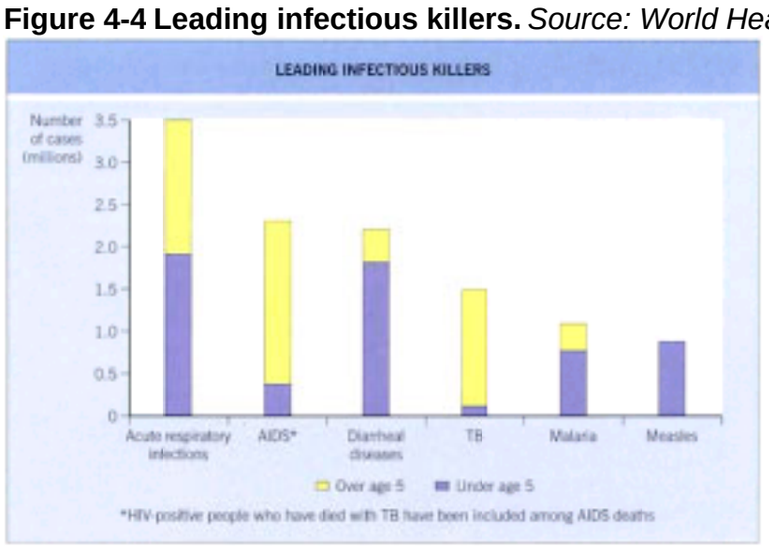

Figure 4-5 Estimated AIDS incidence (*adjusted for reporting delays), deaths and prevalence, by quarter-year of diagnosis/death — United States, 1981–2000. AIDS incidence increased rapidly through the 1980s, peaked in the early 1990s and then declined. The peak of new diagnoses was associated with the expansion of the AIDS surveillance case definition in 1993 (CDC. HIV/AIDS surveillance report, 2000;1 2[1]). As of 1996, sharp declines were reported in AIDS incidence and deaths. From 1998 through June 2000, AIDS incidence and deaths leveled off and AIDS prevalence continued to increase. Throughout the epidemic, approximately 85% of persons diagnosed with AIDS were aged 20–49 years. *Source: Centers for Disease Control and Prevention. HIV and AIDS — United States, 1981–2000. MMWR 2001;50(21);430–4.*

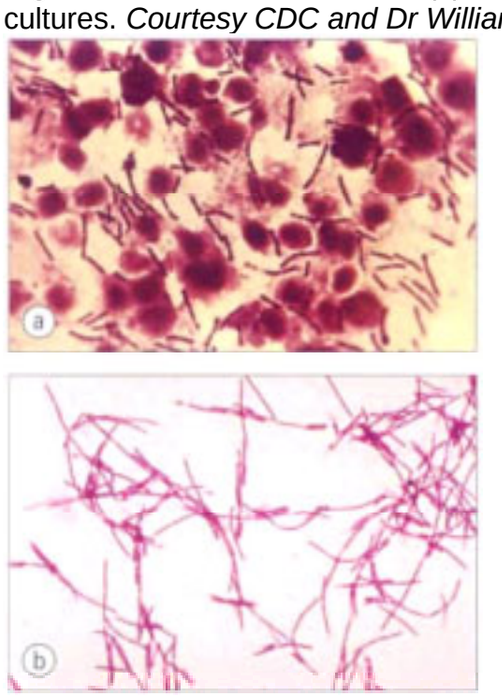

Figure 6-3 Third day of rash in smallpox. Additional lesions continue to appear and some of the papules are becoming obviously vesicular. *From Fenner et al.,*[20] *with permission of the World Health Organization.*

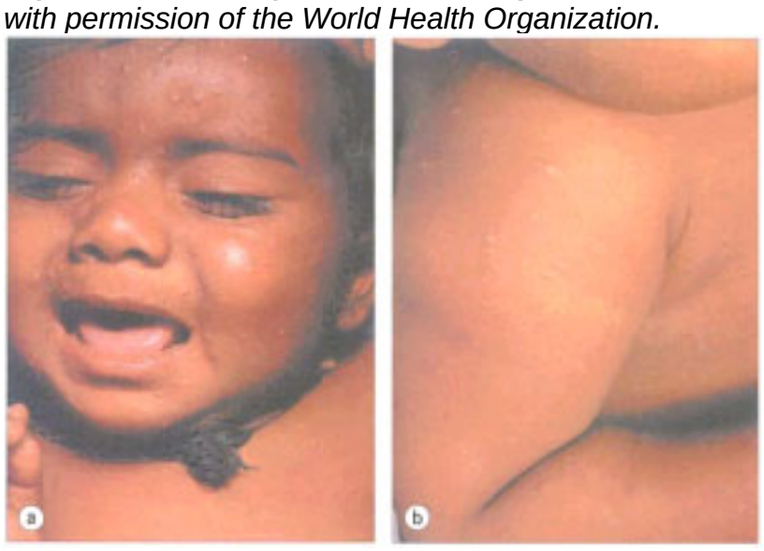

Figure 6-4 Fifth day of rash in smallpox. Almost all the papules have now become vesicular or pustular, the truly 'vesicular' stage usually being very brief. Some of the lesions on the upper arm show early umbilication. *From Fenner et al.,*[20] *with permission of the World Health Organization.*

Figure 6-5 Eighth day of rash in smallpox. This case is now clearly classified as discrete ordinary-type smallpox. In the confluent subtype of ordinary-type smallpox the lesions would have been confluent on the face and forearms: in the semiconfluent subtype they would have been confluent on the face but not on the forearms. *From Fenner et al.,*[20] *with permission of the World Health Organization.*

Figure 6-6 Twentieth day of rash in smallpox. The scabs have separated except on the palms of the hands and the soles of the feet, leaving depigmented areas. *From Fenner et al., [20] with permission of the World Health Organization.*

Figure 7-1 The microbial revolution of the 1990s: bacterial genome sequencing. (1) Construction of a random gene library. (2) Random sequencing of thousands of clones. (3) Closure phase (which can be very labour-intensive). (4) Collation and annotation of the final sequence *(reproduced from Moxon[30] with permission from The Lancet)*

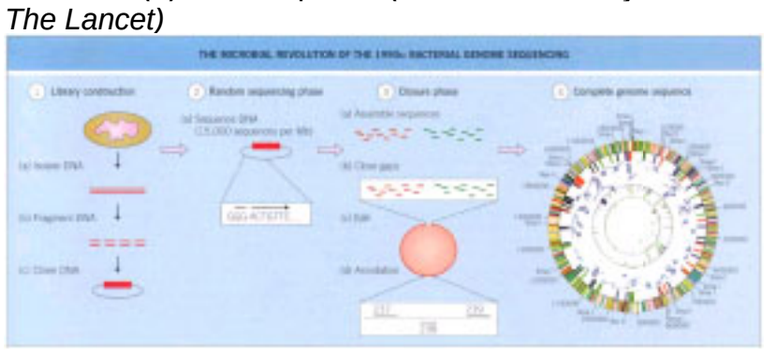

Figure 7-2 How a whole-genome sequence of a pathogenic microbe can be used to develop a candidate vaccine. (1) Representation of lipopolysaccharide (LPS), a major surface antigen of *H. influenzae* and a potential vaccine candidate. The lipid A (endotoxin) is inserted into the cell envelope of the bacterium to which are attached inner and outer core saccharides (uppermost in figure). These oligosaccharides are important in the interactions of the bacterium with host cells. (2) Whole-genome sequence of *H. influenzae* Rd that includes all of the genes involved in the biosynthesis of *H. influenzae* LPS of this strain (reproduced with permission from Fleischmann et al[1]). (3) DNA sequences (or their deduced amino-acid sequences), publicly available in databases (e.g. GenBank, EMBL), are used as probesto search and identify homologues (candidate LPS genes) in the *H. influenzae* complete genome sequence. (4) These candidate *H. influenzae* LPS genes can be further investigated to confirm or reject their role in LPS biosynthesis through appropriate experimental methods. (5) Oligonucleotide primers can be constructed to obtain multiple copies of each of the candidate LPS genes using polymerase chain reaction (PCR). (6) The PCR amplified candidate LPS genes are cloned into a suitable plasmid vector and mutations are constructed. In this example, the candidate LPS gene has been disrupted by an insertion of a cassette of DNA containing a gene for kanamycin resistance; this also acts as a selectable marker. (7) The cloned mutant gene is introduced into *H. influenzae* by transformation (allelic replacement); the phenotype of the parent strain and its mutant can then be compared to determine whether there are differences in LPS phenotype. (8) Immunoblotting is used to compare the reactivity of a monoclonal antibody (specific for LPS) in the parent and mutant strains; in this example, the LPS of the mutant has lost its capacity to bind to the monoclonal antibody, whereas colonies of the parent strain bind this antibody. This provides strong evidence in support of a function for this gene in LPS biosynthesis. (9) Further tests of biological function on parent and mutant can be done to further characterise the role of LPS, for example, its role in virulence. (10) Information on the many genes involved in LPS biosynthesis provides detailed information on the structure and its potential for use in vaccine development. *(Reproduced from Moxon[30] with permission from The Lancet.)*

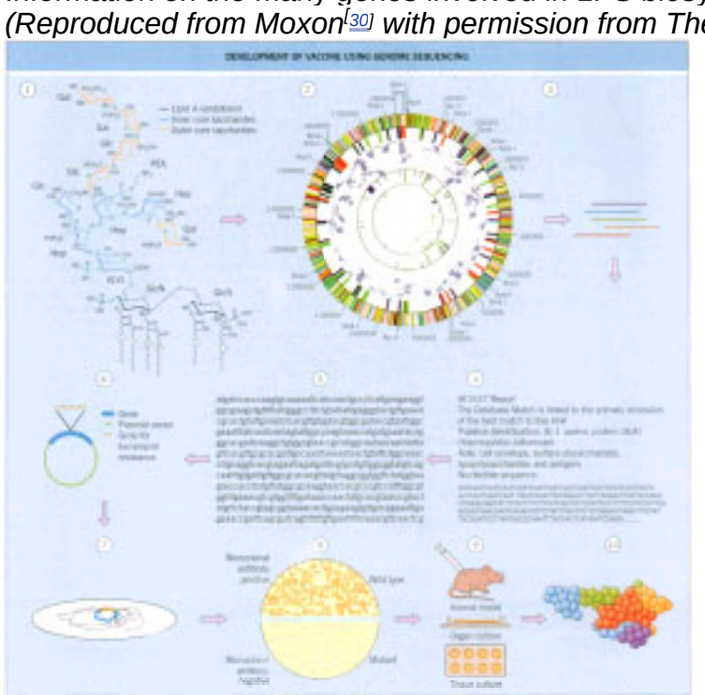

Figure 7-3 Assignment of gene function.

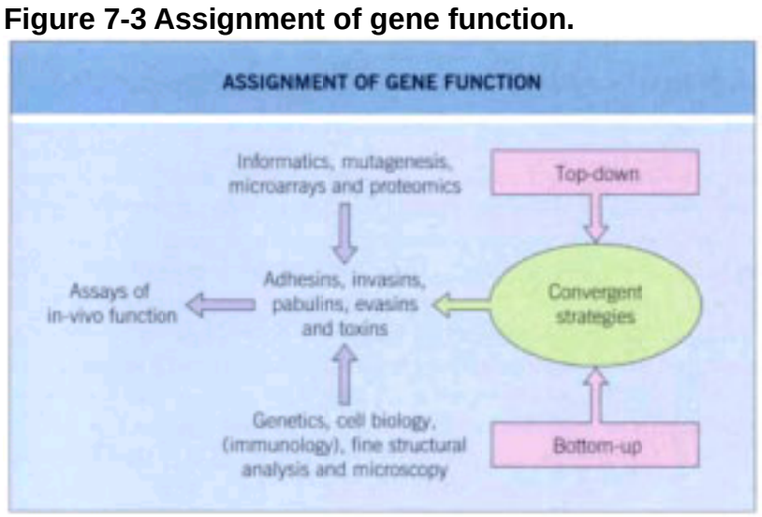

Figure 7-4 Comparing gene expression using a DNA microarray. The color of each spot relates to the level of expression of every gene on the microarray. *Further details can be obtained from http://www.ifr.ac.uk/safety/microarrays*

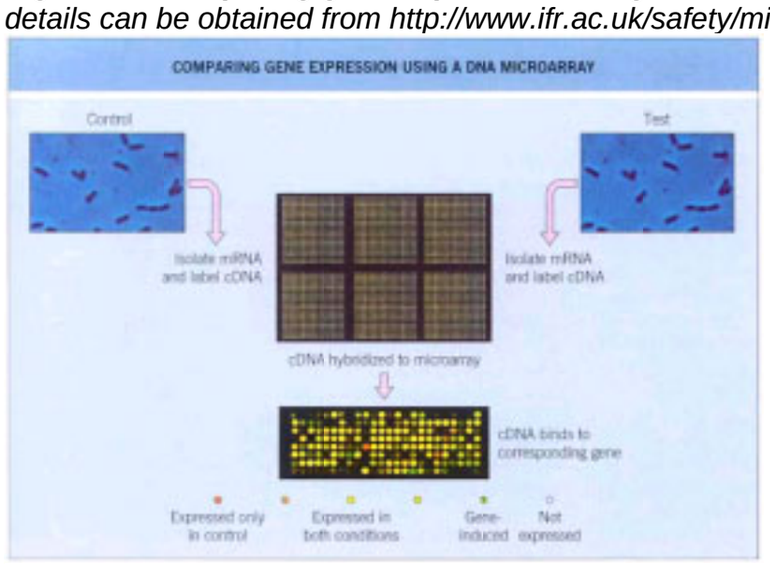

Figure 8-1 Incidence of measles in the USA 1960–90. The effect of measles and measles/mumps/rubella immunization on the incidence of measles and of SSPE in the USA, showing that both are prevented by the live attenuated vaccines.

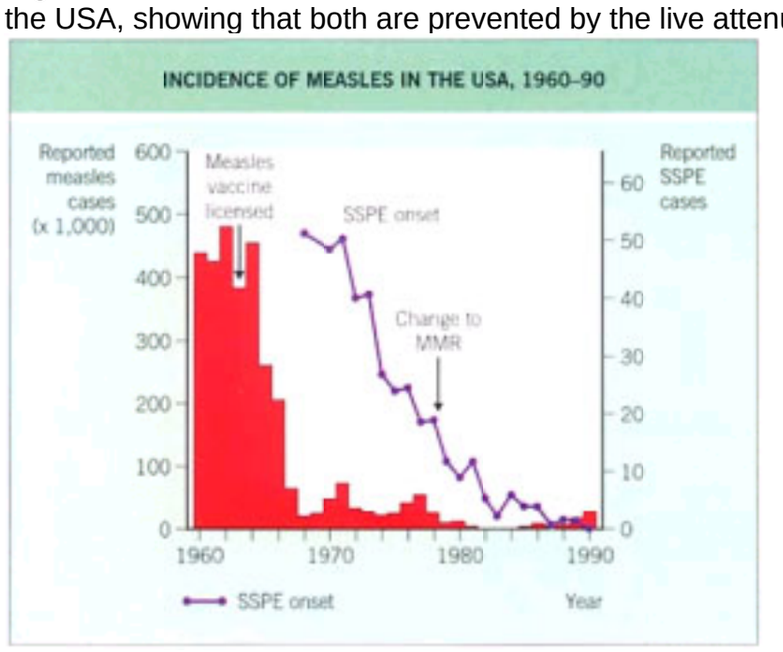

Figure 8-2 The acute rash of measles. Marked conjunctivitis accompanied the maculopapular skin lesions in this unimmunized adult.

Figure 8-3 Secondary invasion by *Staphylococcus aureus* in measles. Ill-defined basal opacities were seen in a patient who had moderate respiratory failure; *S. aureus* was isolated from sputum (same patient as in Fig. 8.2).

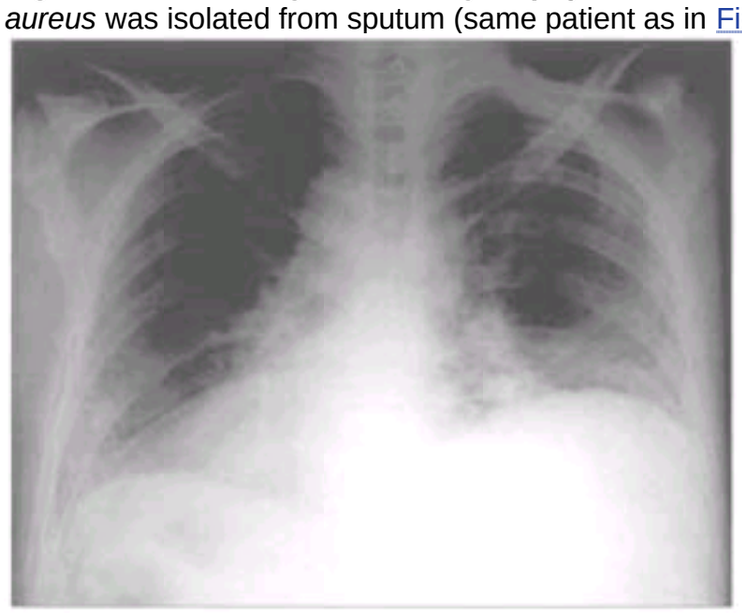

Figure 8-4 Secondary infections complicating measles. Perioral infection and paranasal herpes simplex lesion in a 2-year-old girl.

Figure 8-5 Incidence of rubella in England and Wales. The effects of different immunization programs are shown. *Data from Bannister et al. Infectious disease, 2nd ed. Oxford: Blackwell Science; 2000: 234.*

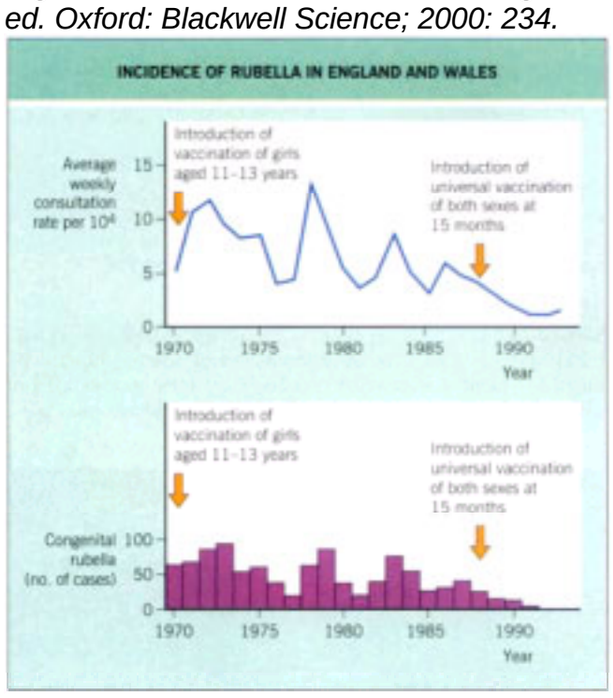

Figure 8-6 Rubella. This patient had a typical early maculopapular rash, irritating conjunctivitis and painful occipital lymphadenopathy.

Figure 8-7 The lesions of varicella. Papules, vesicles and pustules, some of which are beginning to crust from the center, are seen.

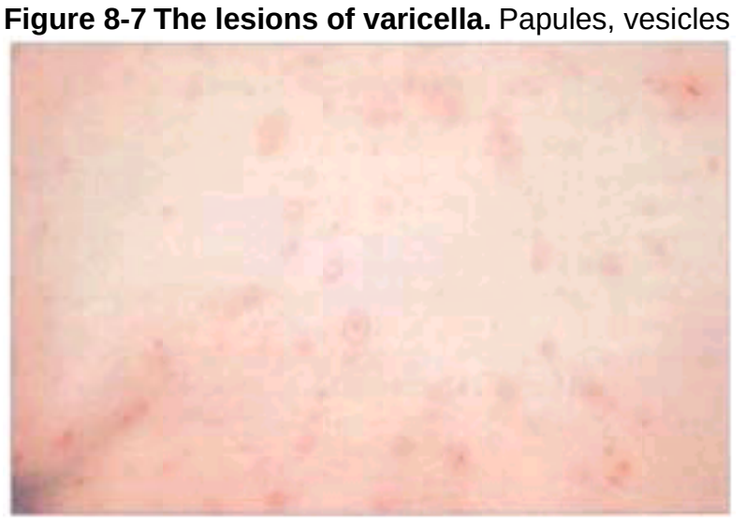

Figure 8-8 Course of varicella in a 54-year-old woman. Low arterial oxygen saturation precedes respiratory and hemodynamic failure.

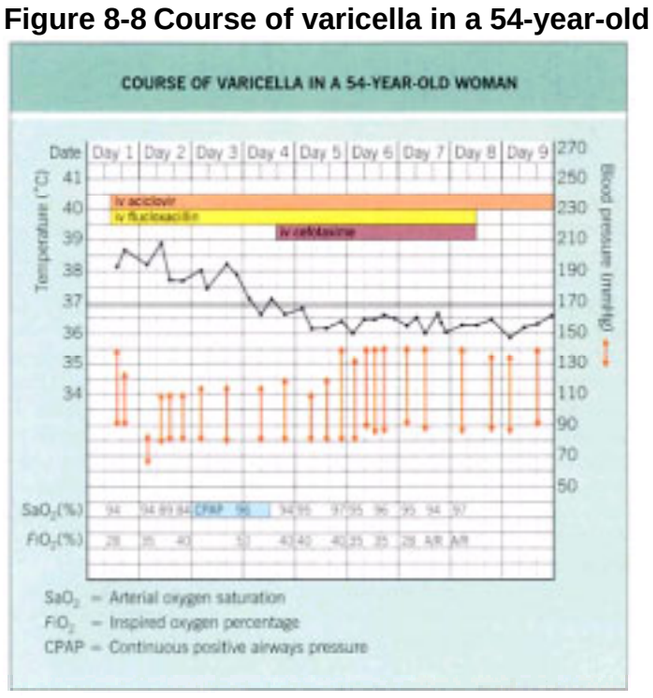

Figure 8-9 The rash of herpes zoster. It can be seen that the lesions occur in groups, with coalescence of lesions in the larger groups.

Figure 8-10 Secondary staphylococcal infection of varicella lesions. Staphylococcal pyrogenic exotoxin has caused a 'scalded skin' type of lesion surrounding the infected spots. *Courtesy of Dr MG Brook.*

Figure 8-11 Varicella-zoster virus infection. Infection in a patient who had a history of varicella in childhood, had recently had a thymectomy and was taking high-dose prednisone (prednisolone): initially localized lesions on the neck were quickly followed by an extensive, varicella-type rash.

Figure 8-12 Hand, foot and mouth disease. Typical vesicles are seen on the foot of a 3-year-old child.

Figure 9-1 Cutaneous infection at the previous insertion site of an intravenous catheter. Organisms from the skin were likely introduced into the dermis and subcutaneous tissue at the time of catheter insertion. Many of these infections remain superficial, but in this patient suppurative thrombophlebitis with bacteremia ensued.

Figure 9-2 Diffuse skin involvement. Petechial lesions in a patient with *Staphylococcus aureus* bacteremia, endocarditis and acute aortic insufficiency.

Figure 9-3 Carbuncle of the buttock caused by *Staphylococcus aureus.* This large carbuncle developed over the course of 7–10 days and required surgical drainage plus treatment with antibiotics. The patient had previously experienced numerous episodes of *Staph. aureus* cutaneous abscesses. He carried the staphylococci in his anterior nares.

Figure 9-4 Staphylococcal nasal carriage. This patient had a small staphylococcal abscess beneath the mucosa of the nose, illustrating how *Staphylococcus aureus*, which colonizes the nares, can infect skin and submucosa. Intact mucosa is highly resistant to infection; such infections usually occur as a result of defects in the mucosal membranes or via hair follicles inside the nose.

Figure 9-5 Swimmer's itch. Diffuse folliculitis can be caused by *Pseudomonas aeruginosa* (hot tub folliculitis), schistosomes (swimmer's itch) or *Staphylococcus aureus* (folliculitis). This young man had been fishing in an alkaline lake in the western part of the USA. He had been fishing from a 'float tube' and had exposed only his hands and arms to the water. The rash was associated with severe itching. Although his white blood count was not elevated 35% of the white cells were eosinophils.

Figure 9-6 Staphylococcal scalded skin syndrome. Flaccid bullae occur as single or multiple lesions. Examination of a frozen tissue section reveals that the cleavage plane is at the stratum corneum. This disease must be distinguished from toxic epidermal necrolysis (see Fig. 9.7).

Figure 9-7 Toxic epidermal necrolysis. This picture shows a skin slough (Nikolsky's sign), which resulted when lateral pressure was applied by the thumb in a plane parallel to the skin surface. This disorder is more common in adults, has a high mortality rate and is usually caused by medications.

Figure 9-8 Impetigo. (a) Impetigo in a homeless man. Both *Staphylococcus aureus* and group A streptococci were cultured from these lesions. (b) Impetigo, with initial vesicles changing to crusts.

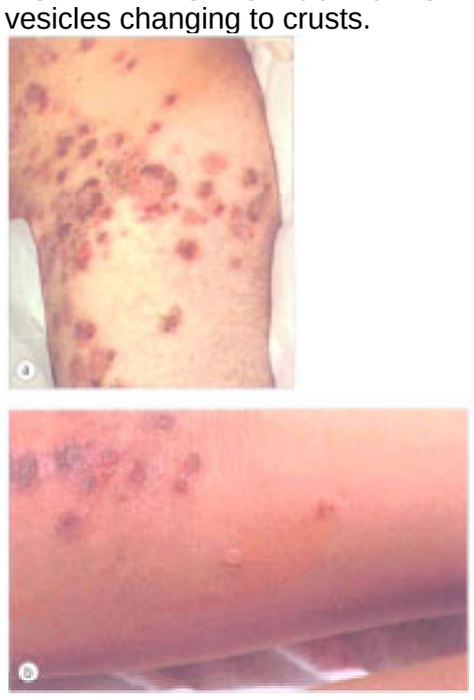

Figure 9-9 Erysipelas. This form of cellulitis is caused by *Streptococcus pyogenes* and is most common in the elderly. Unique characteristics include a fiery red or salmon color, well-demarcated edges, desquamation after 5–7 days and location on the face or lower extemities. This picture was taken 48 hours after treatment with penicillin when the brilliant red salmon color had evolved to a reddish blue color. On the second day of treatment patients usually have less pain and fever subsides, but swelling may be more extensive.

Figure 9-10 Cellulitis. In contrast to erysipelas, cellulitis is a pink color rather than brilliant red and has indistinct margins. *Staphylococcus aureus* and group A, C and G streptococci are the most common etiologies. Many other bacteria may cause cellulitis (see Table 9.1).

Figure 9-11 Cellulitis. (a) This case was caused by *Staphylococcus aureus* and is spreading centripetally from a central localized focus of infection. The redness and swelling characteristic of cellulitis are apparent over the upper eyelid. (b) The cellulitis has developed from a localized staphylococcal abscess formed in a meibomian gland (chalazion).

Figure 9-12 *Staphylococcus aureus* cellulitis of the nose. The focal lesion began in a hair follicle inside the nose, with redness, swelling and pain. Rarely, such lesions on the nose are complicated by extension into the cavernous sinus via veins draining the central part of the face.

Figure 9-13 Lymphangitis. Cellulitis caused by group A streptococci began below the knee and rapidly spread; about 4 hours later lymphangitis had spread up the inner aspect of the thigh.

Figure 9-14 Cellulitis of the lower leg associated with chronic venous insufficiency. Streptococci of groups A, B, C and G are the most common isolates. Group B streptococci seldom cause cellulitis in previously healthy hosts, but should be considered in people who have peripheral vascular disease or diabetes mellitus.

Figure 9-15 Gram stain of purulent material demonstrating *Staphylococcus aureus.* The microbial etiology of cellulitis may be suspected based upon signs, symptoms and history; however, definitive diagnosis requires Gram stain and culture. If there is no portal of entry, aspiration or even punch biopsy of cellulitic skin yields a positive culture in only 20% of cases.

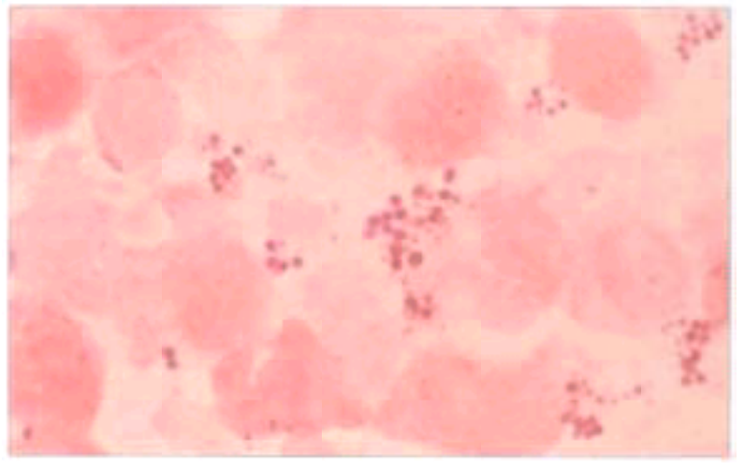

Figure 9-16 Cellulitis at the elbow associated with olecranon bursitis. (a) Pale pink erythema on the inner aspect of the elbow. (b) Careful inspection demonstrates a focal infection over the point of the elbow. Fluid aspirated from the olecranon bursa yielded a pure culture of *Staphylococcus aureus*.

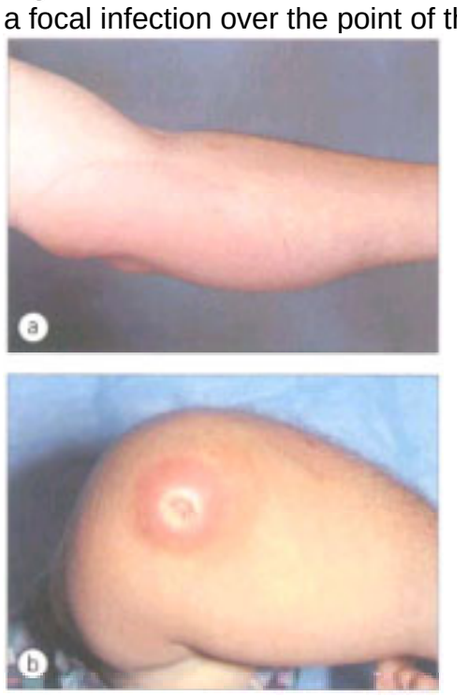

Figure 9-17 Erythema and swelling of the face due to a tooth abscess. (a) Swelling of the face, on inspection resembling periorbital cellulitis. (b) Further inspection reveals a gingival abscess above the patient's left upper canine tooth.

Figure 10-1 Differential diagnosis of infections involving muscle and fascia. Red, severe; orange, moderate; yellow, mild-to-moderate; blue, mild; white, none.

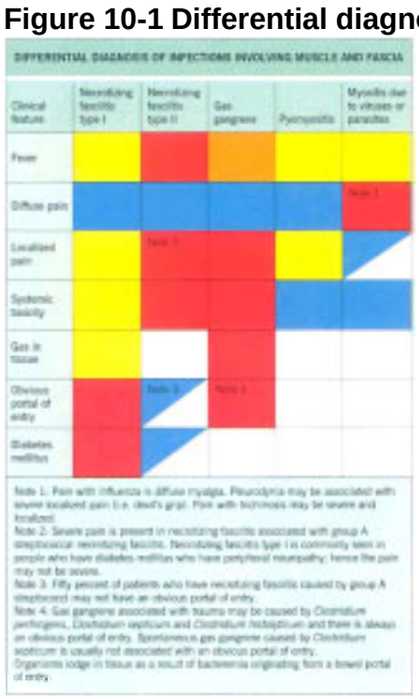

Figure 10-2 Histopathologic examination of tissue from a patient who has necrotizing fasciitis with extension into the underlying musculature. Note the absence of acute inflammatory cells in the area of muscle necrosis. When present, infiltrating granulocytes can be seen at the interface between normal and necrotic tissue and are often massed within small postcapillary venules.

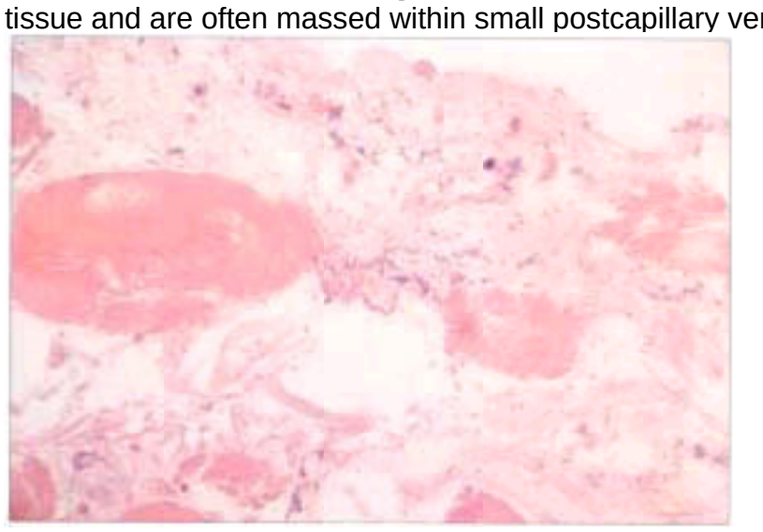

Figure 10-3 Ludwig's angina. Infection begins with a break in the mucosal lining in the oropharynx; oral bacterial flora invade the soft tissues at the base of the tongue and penetrate through the floor of the mouth and into soft tissue of the neck. The floor of the mouth is elevated and patients talk as though they have a 'hot potato' in their mouth. Potential airway obstruction is a major concern. Although patients usually respond to penicillin, surgical consultation should be obtained and CT or MRI scans are useful for determining whether a necrotizing process is present.

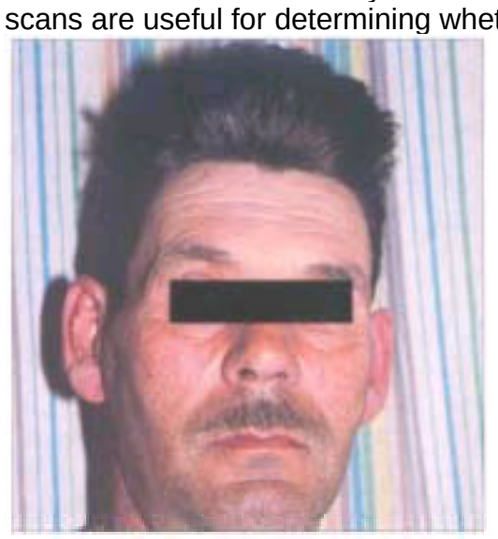

Figure 10-4 Computerized tomography of a soft tissue infection of the neck. This infection is caused by group A streptococci, which invaded as a rare complication of a previous 'strep throat'. Surgical drainage yielded a pure culture of group A streptococci and established a diagnosis. The patient was treated with intravenous penicillin for 10 days and made a good recovery.

Figure 10-5 Type II necrotizing fasciitis caused by group A streptococci. (a) This patient was a 60-year-old man who had type II diabetes mellitus and who had a 3-day history of malaise, diffuse myalgia and low-grade fever. Over the course of 2–3 hours the pain became excruciating and was localized to the calf. During this time the calf swelled. Note that the skin over the anterior shin looks relatively normal, but that two small purple bullae are present. (b) Extensive necrotizing fasciitis was present on surgical exploration. In addition, myonecrosis was present beneath the fascia. The patient developed profound hypotension, acute respiratory distress syndrome and renal failure. He died despite aggressive surgical and medical management. There was no definable portal of entry, yet group A streptococci were grown from deep cultures and from blood.

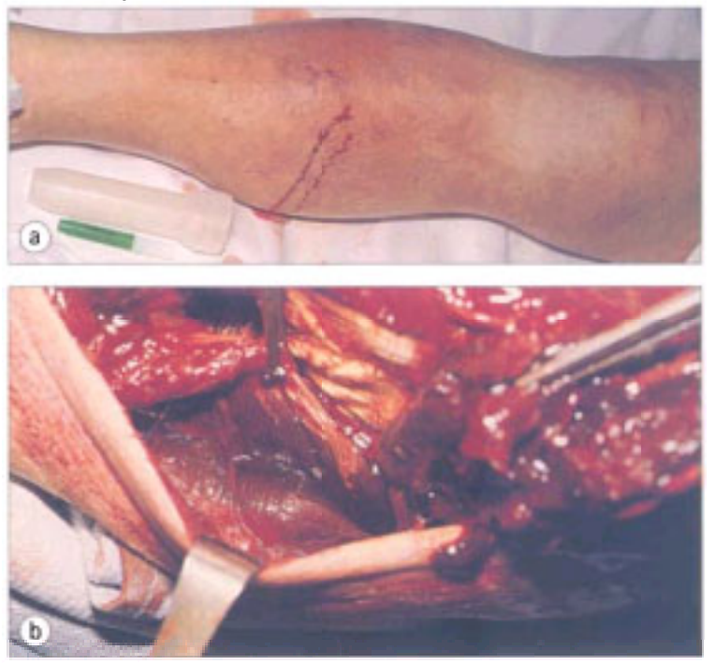

Figure 10-6 Postpartum sepsis due to group A streptococci. The patient was a 24-year-old woman who delivered a normal child. Thirty-six hours after delivery she developed fever, leukocytosis with marked left shift and increasing low abdominal pain. This MRI demonstrates swelling of the uterus, although not out of proportion for a recent delivery. There was no gas in the tissue. An emergency laparotomy revealed necrosis of the mucosa of the uterus, necrotizing fasciitis and myonecrosis of the uterus.

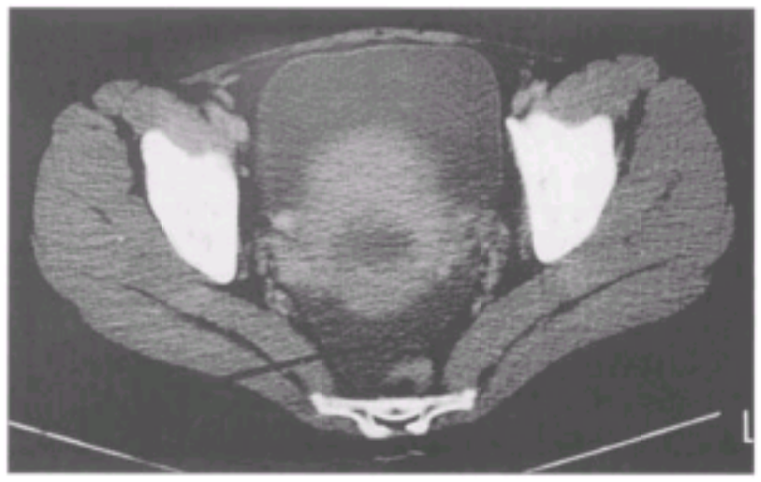

Figure 10-7 Type I necrotizing fasciitis. A 24-year-old man had been in good health but was awakened with severe perineal pain. (a) This photograph was taken 3 hours later. Note the massive swelling of the scrotum. (b) Soft tissue radiograph shows gas in the tissues of the thigh, buttocks, scrotum and anterior abdominal wall. Surgical inspection revealed brownish fluid in the scrotum, with gray, dull-colored, friable fascia but normal underlying musculature. Cultures grew *Enterococcus faecalis*, *Bacteroides fragilis*, *Escherichia coli* and anaerobic streptococci. The patient was treated with ampicillin, clindamycin and gentamicin for 3 weeks and surgical drains were placed in the scrotum, buttocks, thigh and anterior abdominal wall. There was an excellent clinical response. In some cases, surgery of a more radical nature may be necessary.

Figure 10-8 Colonies of *Clostridium perfringens* growing on an anaerobic blood agar plate. Theta toxin causes the clear zone of hemolysis closest to the colony. A second area of partial hemolysis is caused by a-toxin, an enzyme with phospholipase C activity.

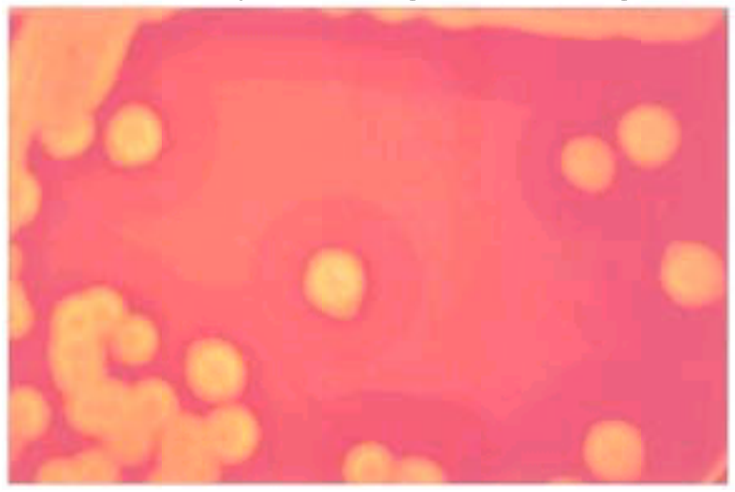

Figure 10-9 Extensive gas gangrene of the arm due to *Clostridium perfringens.* A 35-year-old man sustained a knife wound to the forearm. He did not seek medical care, but 36 hours later experienced severe pain in the upper arm and came to the emergency room. There was extreme tenderness of the arm and crepitus was easily demonstrated. A radiograph also demonstrated gas in the deep soft tissues. Surgical debridement and antibiotics were instituted, but later amputation at the level of the shoulder was necessary. A pure culture of *C. perfringens* was grown from the deep tissues.

Figure 10-10 *Clostridium perfringens* in a patient who has extensive gas gangrene. (a) Tissue Gram stain of tissue removed from the arm of the patient described in Figure 10.9 . Note that the bacteria are rod shaped but gram variable. Note also that there are few if any acute inflammatory cells at the site of infection. (b) Transmission electron micrograph of *C. perfringens*. Note the endospores.

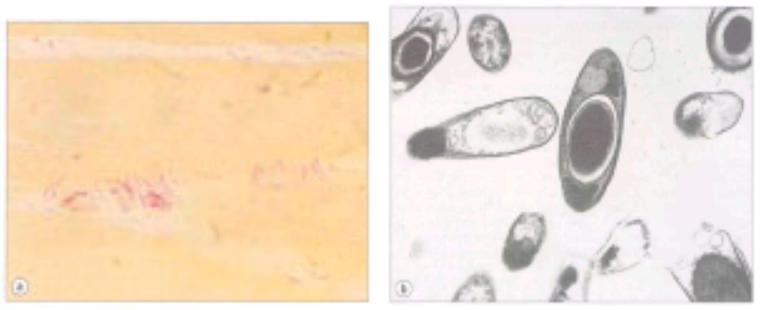

Figure 10-11 Spontaneous necrotizing fasciitis due to *Clostridium septicum.* This patient developed the sudden onset of severe pain in the forearm. Swelling rapidly ensued and he sought medical treatment. Crepitus was present on physical examination and gas in the soft tissue was verified with routine radiographs. Immediate surgical debridement revealed necrotizing fasciitis but sparing of the muscle. Note the purple-violaceous appearance of the skin. See also Figure 10.12 .

Figure 10-12 Colonic carcinoma in a patient who has spontaneous gas gangrene caused by *Clostridium septicum.* The patient described in Figure 10.11 was found to have a mass in the colon. Surgical resection revealed an adenocarcinoma, which probably served as a portal of entry for the *Clostridium septicum* bacillus. Hematogenous seeding of the forearm resulted in spontaneous gas gangrene.

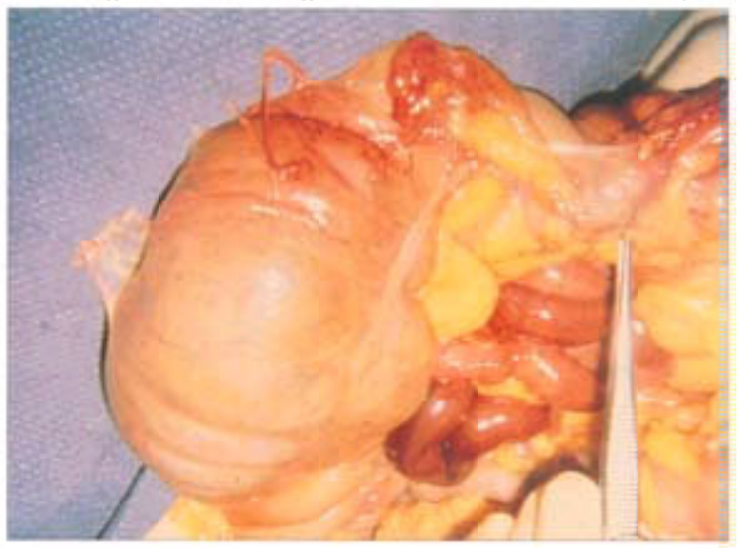

Figure 10-13 MRI scan showing high signal STIR sequence (consistent with marked edema) in the adductor muscles of the patient's left leg in a patient with *Staphylococcus aureus* bacteremia (arrow). At operation, necrotic and infected muscle was decompressed and debrided. This represents the 'woody' stage, prior to muscle liquefaction and the formation of frank abscesses.

Figure 19-1 Corneal edema and fibrinous anterior chamber exudate in a traumatic foreign body-induced endophthalmitis. Any posterior vitreal or retinal view is obscured by the anterior corneal and aqueous haze.

Figure 19-2 B-scan ultrasound of the eye showing total vitreous opacity of a severe endophthalmitis in patient seen in Figure 19.1 . This horizontal 'cut' through the eye shows the normally 'transparent' vitreous cavity to be filled with inflammatory debris, but there is no obvious retinal detachment.

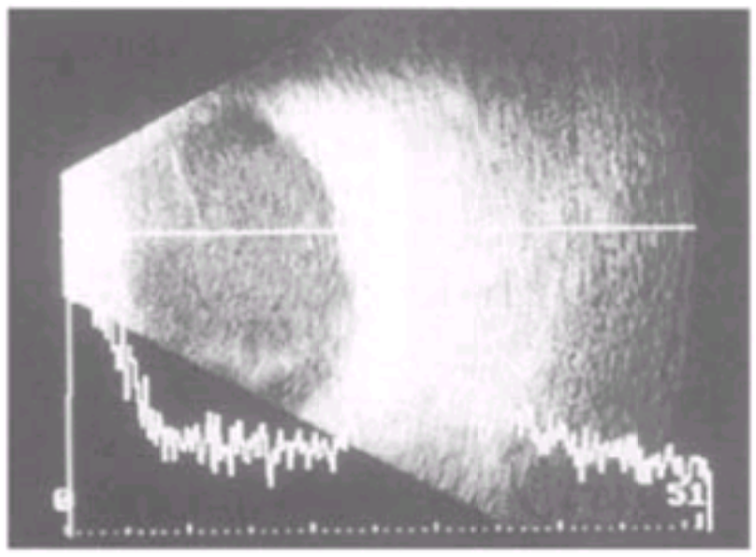

Figure 19-3 A dense vitreous abscess in advanced endophthalmitis. This partially treated postoperative endophthalmitis has vitreous cellular and protein deposits obscuring the retinal view.

Figure 19-4 The typical posterior capsular opacities seen in a late-onset *Staphylococcus epidermidis* endophthalmitis. These deposits are actual coccal colonies, which are frequently removed at subsequent vitrectomy surgery to open up the capsular bag to intraocular antibiotics.

Figure 19-5 A 'quiet' endogenous fungal endophthalmitis with small hypopyon. This eye is relatively quiet with little chemosis, injection and pain, but has a small hypopyon and some small fungal 'balls' on the temporal iris.

Figure 19-6 The degraded ophthalmoscopic retinal view obtained in patient seen in Figure 19.5 . The corneal edema and anterior chamber activity make vitreous and retinal observation difficult.

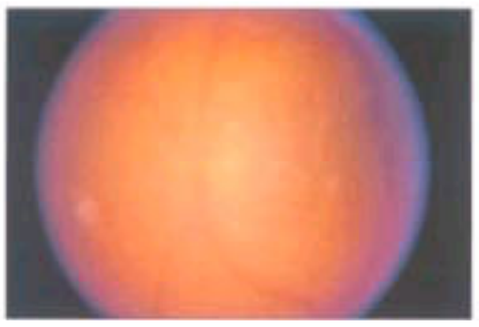

Figure 19-7 Fungal 'fluff balls' on the iris seen in a fungal endophthalmitis. Although these are not pathognomonic, their appearance raises the real possibility that the infection is of fungal origin.

Figure 19-8 Horizontal computerized tomography scan section of eye seen in Figure 19.1 and Figure 19.2 revealing metallic intraocular foreign body in vitreous cavity (arrow). This CT scan demonstrates that the vitreous opacity seen by ultrasound is 'invisible' to this investigation.

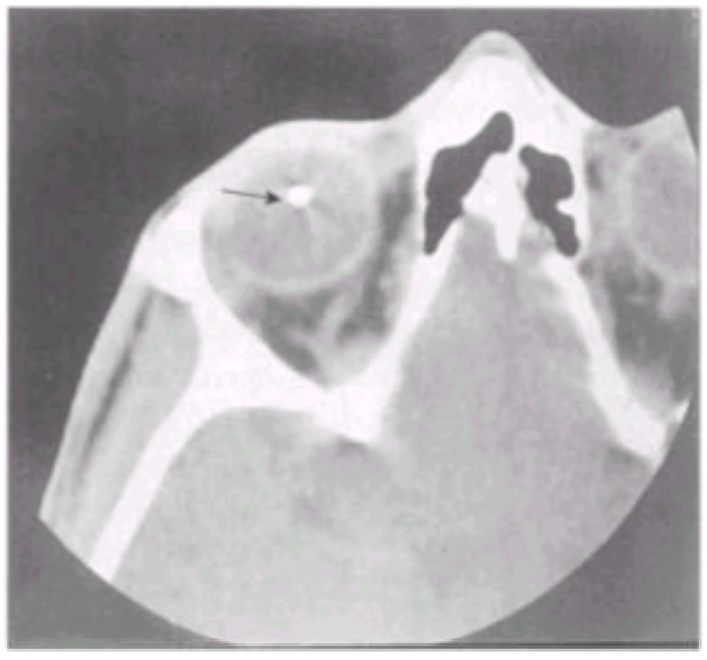

Figure 20-1 Major structures of the eye.

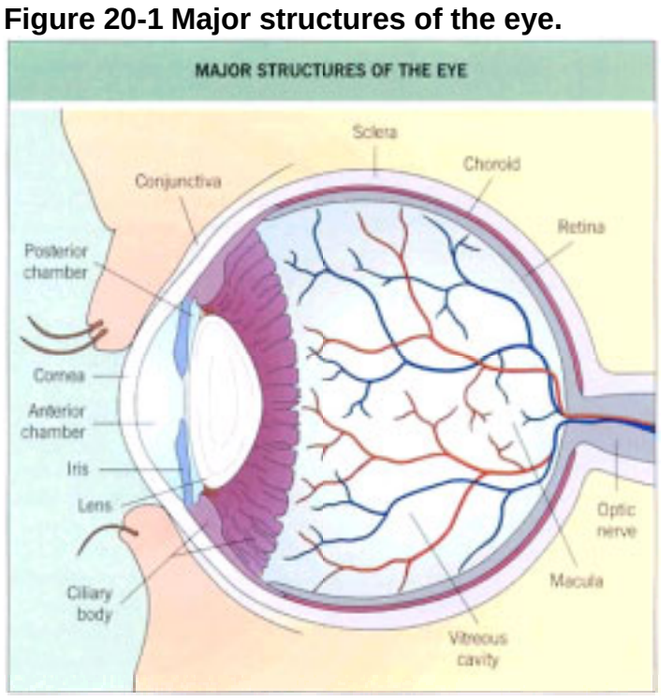

Figure 20-2 Retinal inflammatory vascular sheathing (vasculitis). This case occurred secondary to sarcoidosis.

Figure 20-3 Hypopyon. The finding of a hypopyon (layered inflammatory cells in the anterior chamber of the eye) usually denotes a severe anterior uveitis.

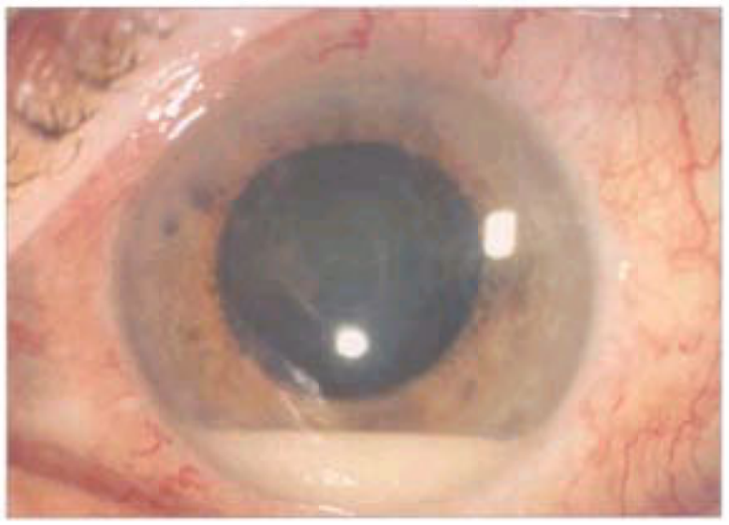

Figure 20-4 Salt-and-pepper fundus. The pigment alterations in the macula give a 'dirty' appearance to the retina. The lesion occurred following congenital rubella infection. The vertical black line across the fovea is a focusing stick.

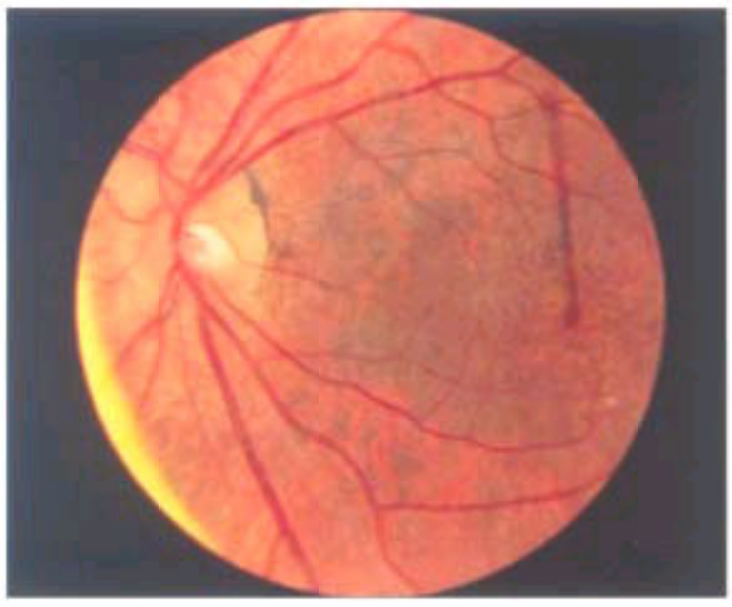

Figure 20-5 Macular retinitis. This patient has subacute sclerosing panencephalitis.

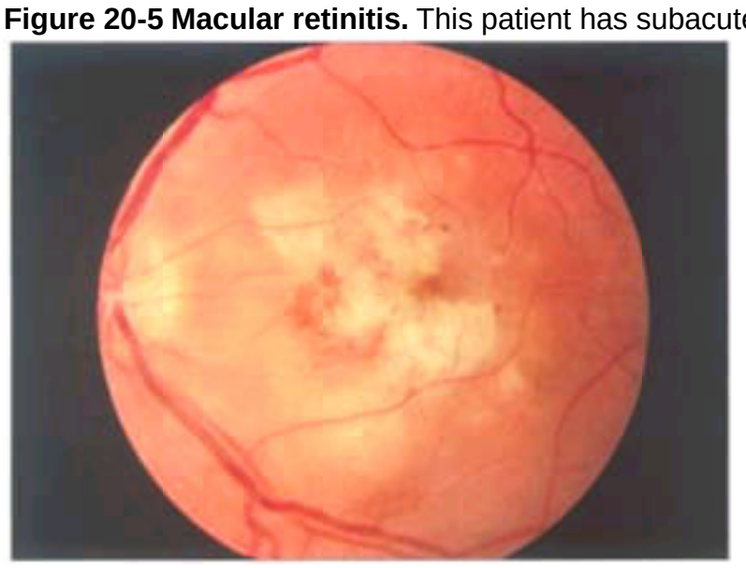

Figure 20-6 Neuroretinitis with a macular star associated with *Bartonella* infection. Note the swelling of the optic disk with hard exudate in the macula in the so-called 'stellate' pattern.

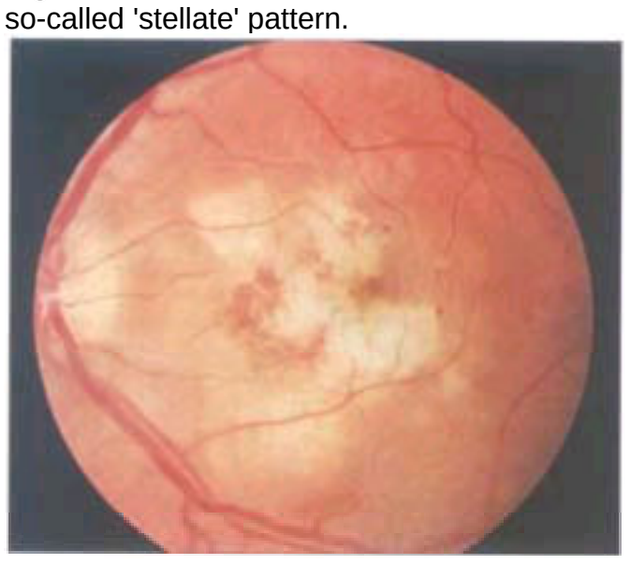

Figure 20-7 A focal area of superficial retinitis and vitritis. This occurred secondary to *Candida* albicans.

Figure 20-8 The classic ocular findings of previous histoplasmosis. Note the peripapillary atrophy and punched-out yellowish chorioretinal scars. An old choroidal neovascular membrane is present in the center of the histoplasmosis scar temporal to the macula.

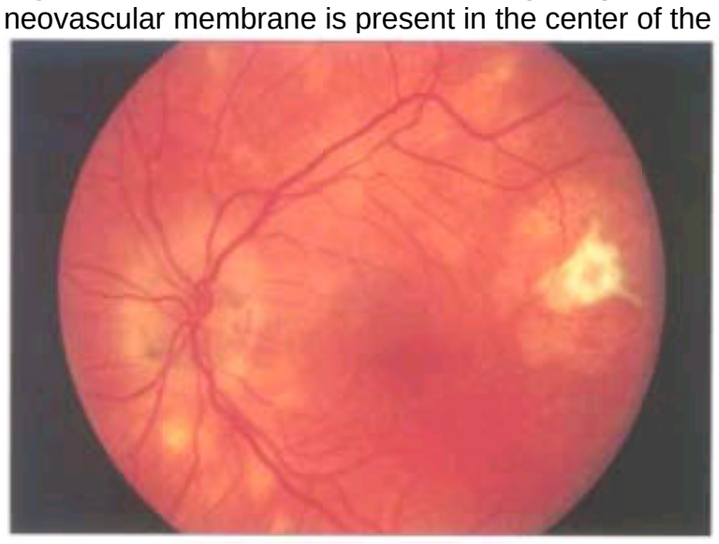

Figure 20-9 A *Nocardia* chorioretinal abscess. This abscess is in the macula of a patient on systemic immunosuppression following heart transplant.

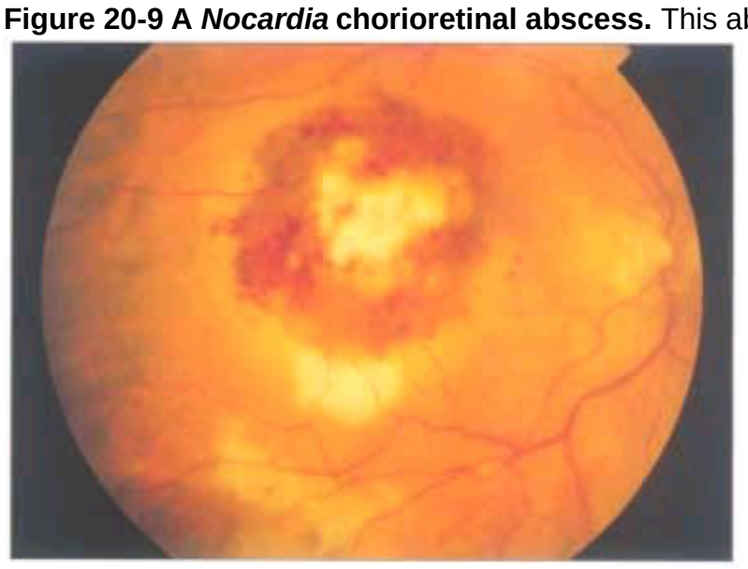

Figure 20-10 Ocular toxocariasis. (a) The posterior pole of a left eye affected by toxocariasis. There is severe macular distortion and dragging of the retina toward a granuloma in the inferotemporal retinal periphery. (b) The periphery of the inferotemporal retina in the same eye showing the granuloma.

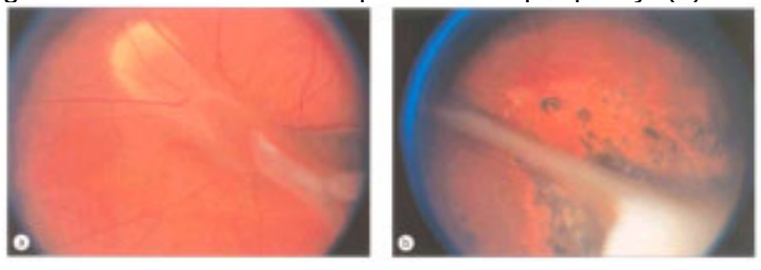

Figure 20-11 An old, inactive congenital macular toxoplasmosis scar. The patient's vision was 20/400.

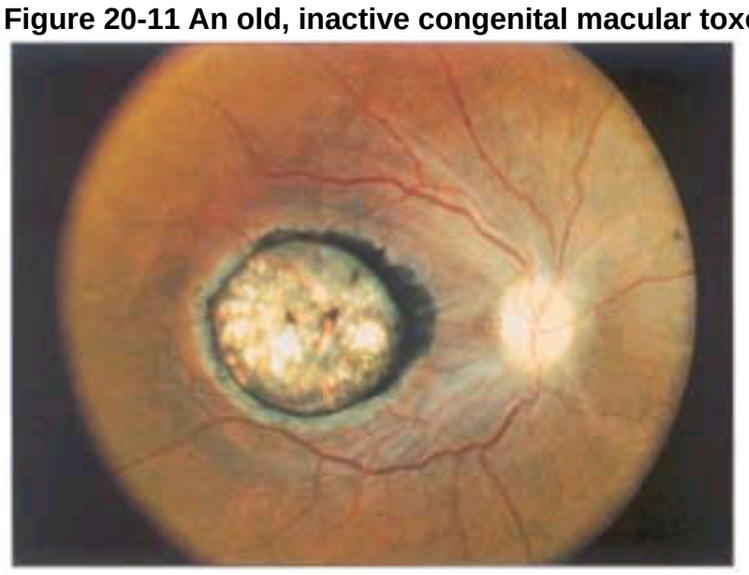

Figure 20-12 A reactivated area of retinal toxoplasmosis. The lesion is the area of whitening and is adjacent to an old scar, just temporal to the macula of the left eye.

Figure 20-13 Typical appearance of the retina in the acute retinal necrosis syndrome. There is dense peripheral retinal whitening with a geographic border. Satellite lesions are common. The view is hazy owing to vitritis.

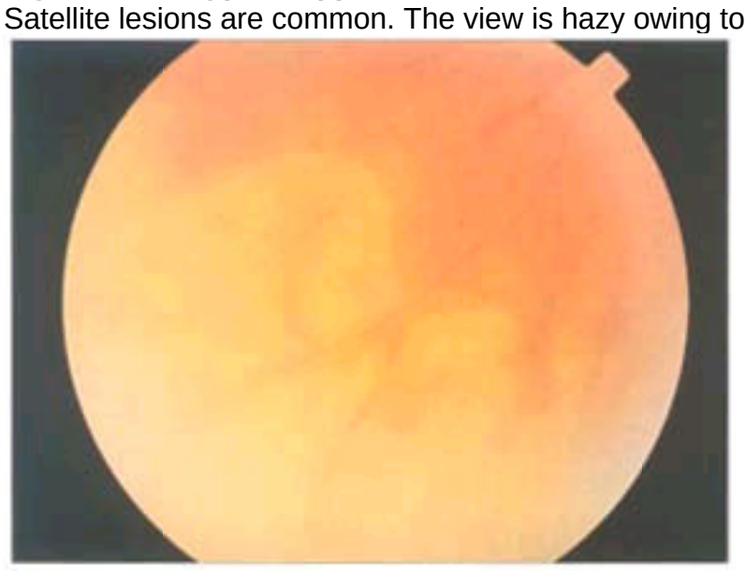

Figure 20-14 Cytomegalovirus infection with granular retinal whitening along the major blood vessels with mild hemorrhage. The view is clear because there is only mild vitritis.

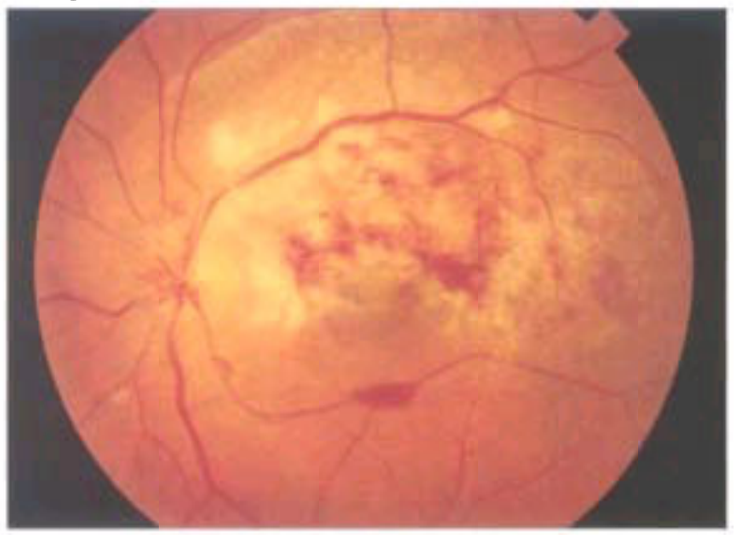

Figure 20-15 HIV retinopathy. There are multiple superficial white patches in the retina (cotton-wool spots). These do not affect vision and typically wax and wane over time.

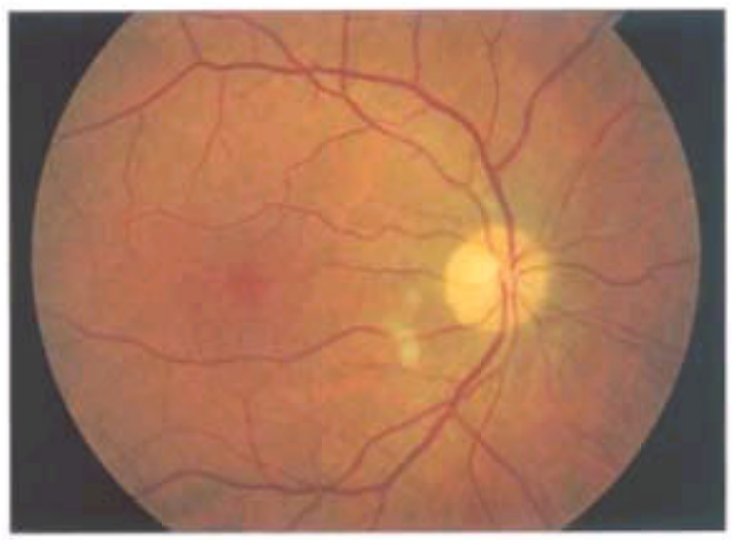

Figure 21-1 Frost suture. A 5.0 silk suture is placed at the upper lid margin through half the tissue thickness (above) and used to tape the lid shut (below).

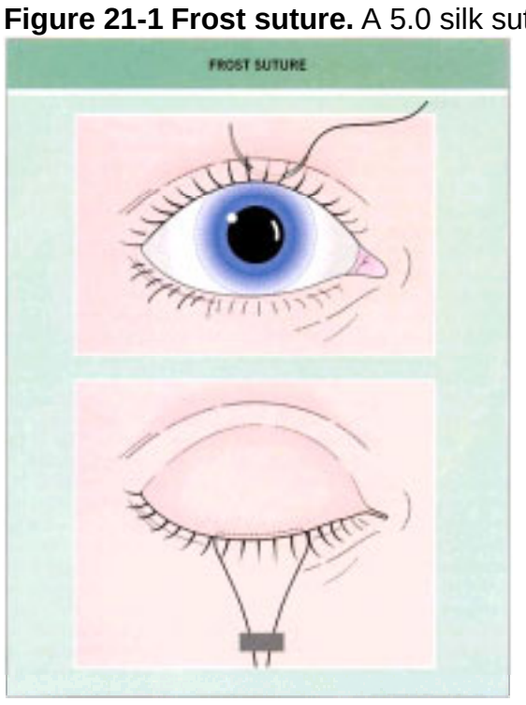

Figure 22-1 Pathogenesis of meningitis.

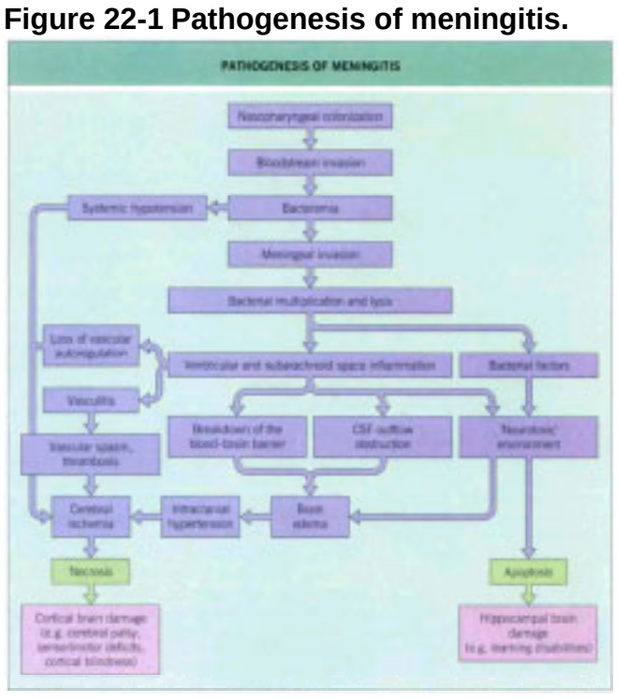

Figure 22-2 Subarachnoid and perivascular inflammation in meningitis. The inflammation in the subarachnoid space extends into the Virchow-Robin spaces along the vasculature.

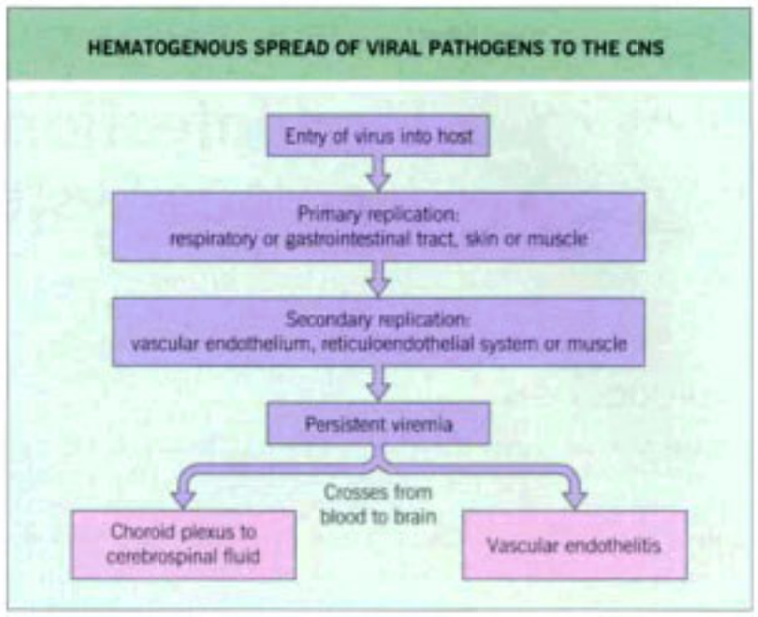

Figure 23-3 Pathogenesis of viral central nervous system infections: neuronal transmission.

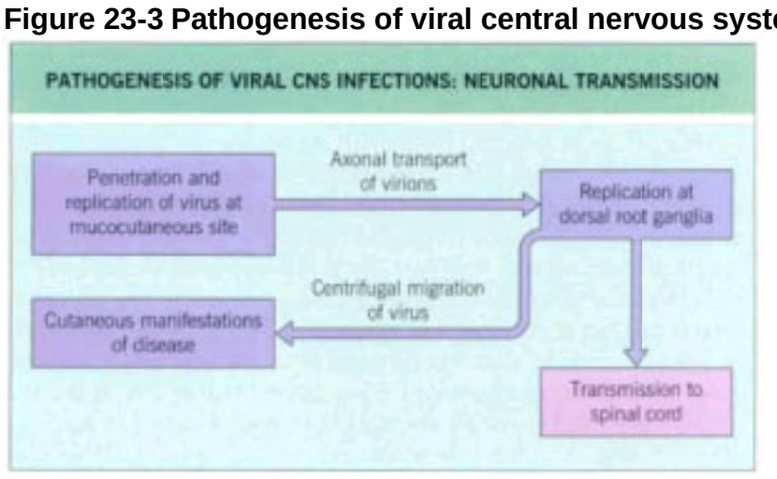

Figure 23-4 Herpes simplex encephalitis. Basilar view of herpes simplex encephalitis showing (a) hemorrhagic necrosis of temporal lobes. (b) Coronal section of brain from patient with herpes simplex encephalitis. [49]

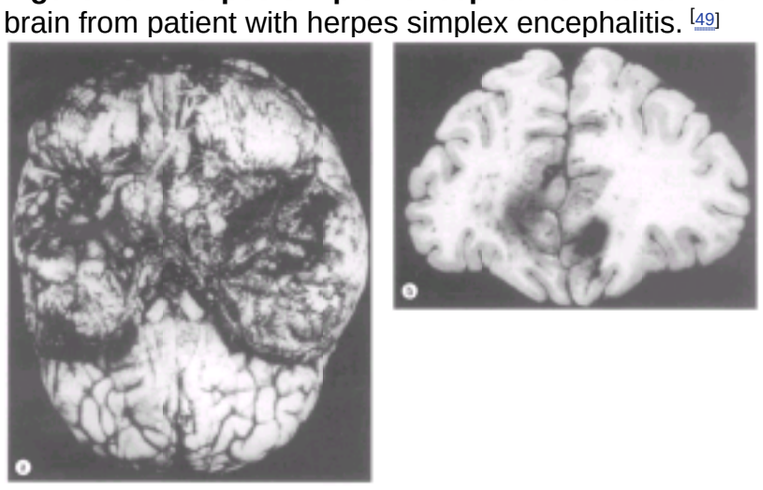

Figure 23-5 Approach to the patient who has presumed viral central nervous system disease.[56]

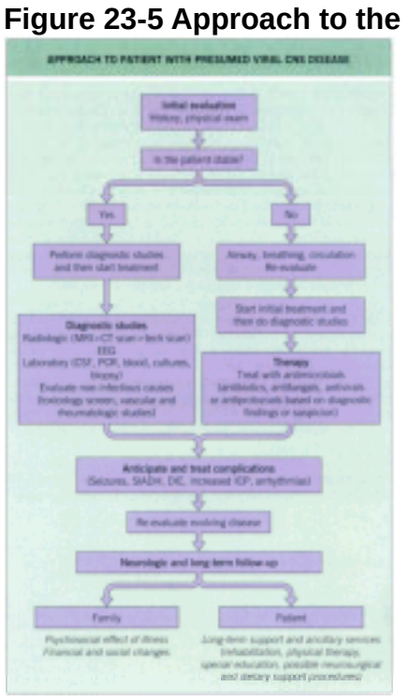

Figure 24-1 Anatomic relationships between potential contiguous sources of infection and sites at which focal pyogenic central nervous system infections may occur.

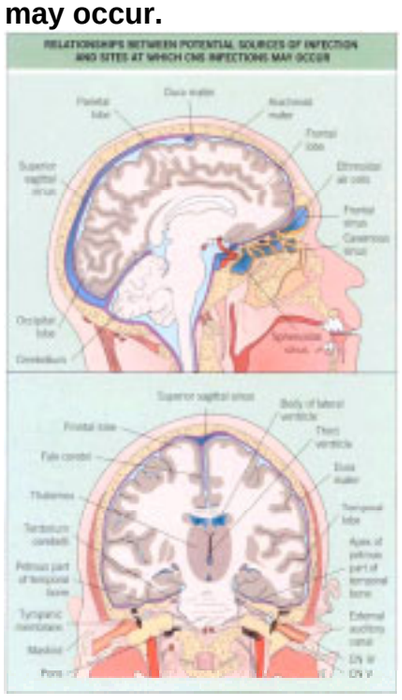

Figure 24-2 Contrast-enhanced CT scan of the head in the coronal projection of a 43-year-old man with an atrial septal defect that persisted after attempts at surgical repair. The patient presented with seizures after undergoing dental work for which he did not receive antimicrobial prophylaxis. Note the ring-enhancing lesion in the right frontoparietal region with edema and mass effect.

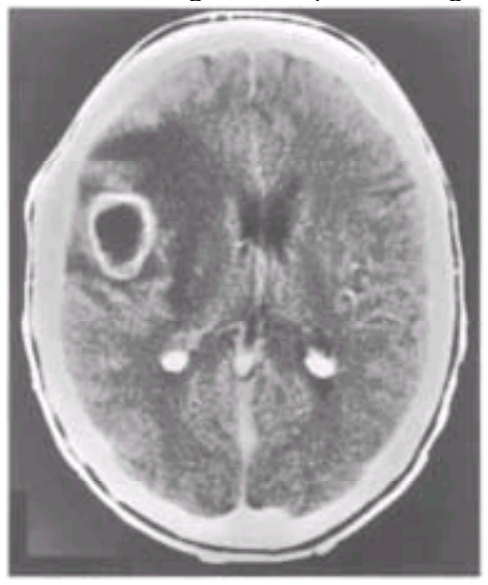

Figure 24-3 Contrast-enhanced CT and MRI scans of the head in the coronal projection of a 43-year-old woman with headaches after a recent fall on her head. (a) CT scan image reveals a cystic ring-enhancing lesion in the left cerebellum. Note the prominent bone artefact. (b) T1-weighted MRI scan image reveals an enhancing cystic lesion in the left cerebellum with significant surrounding edema. Bone artefact is absent. Both CT and MRI scans were felt to be most consistent with a primary or metastatic neoplasm, but culture of material obtained at stereotactically guided aspiration grew *Staphylococcus aureus*.

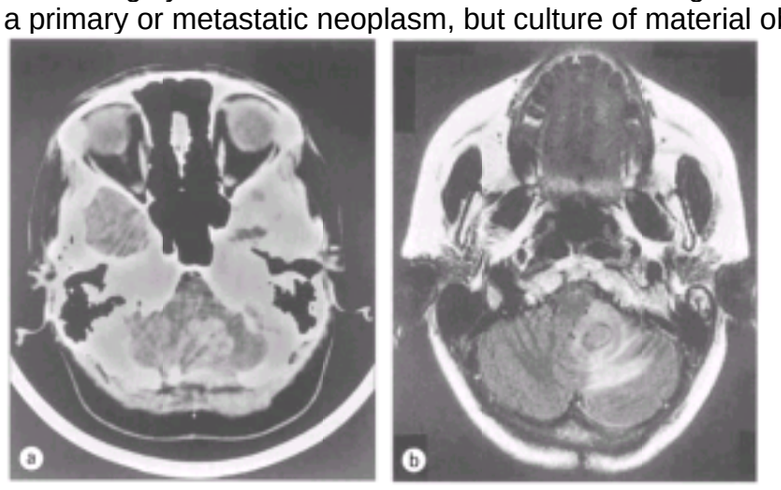

Figure 24-4 Contrast-enhanced CT scans of the head in the coronal projection of a 66-year-old woman with a group B streptococcal brain abscess demonstrating evolution of the abscess during and after surgical and antimicrobial therapy. (a) The original scan demonstrates a hypodense necrotic center surrounded by an enhancing capsule and hypodense edema. (b) Seven weeks later, after stereotactically guided aspiration and a full course of antimicrobial therapy, the central cavity can no longer be seen, although the enhancement and surrounding edema persist to a small degree.

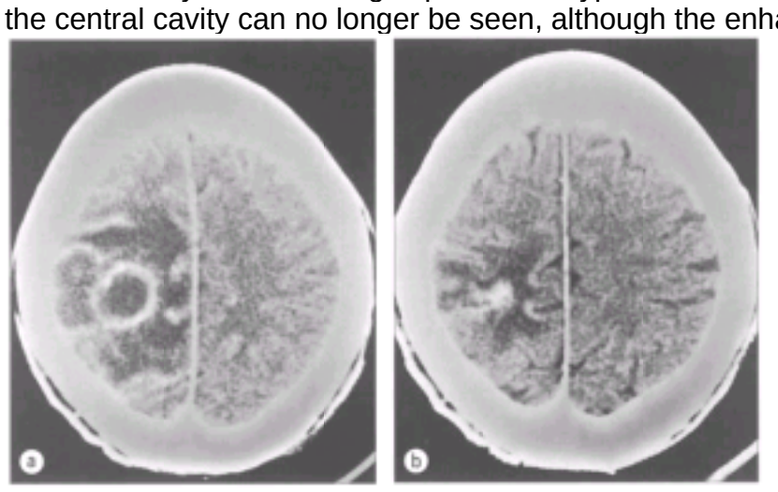

Figure 24-5 Contrast-enhanced CT scan of the head in the coronal projection of a 23-year-old man with fever and headache. There is a small isodense extra-axial fluid collection in the subdural space on the right, with significant mass effect shown by right-to-left midline shift and effacement of the right lateral ventricle. There was also opacification of the frontal and ethmoid sinuses, suggesting sinusitis as the source of this subdural empyema.

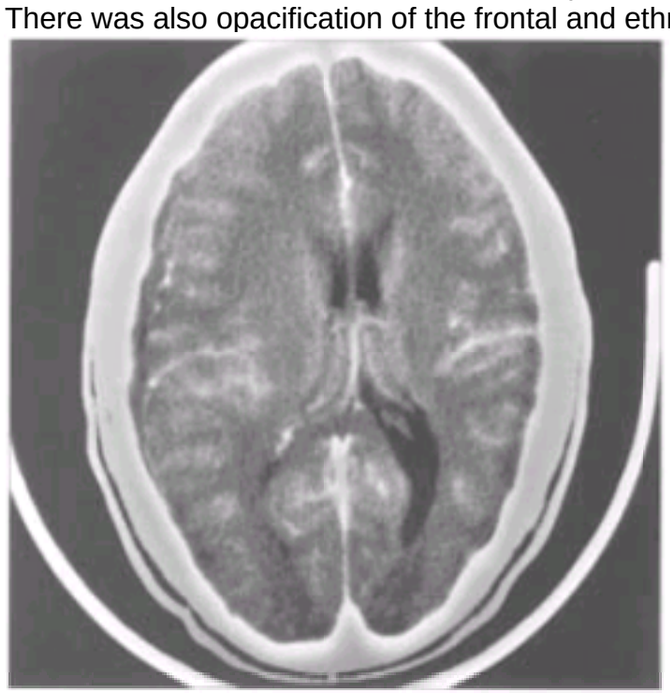

Figure 24-6 Contrast-enhanced CT scan of the head in the coronal projection of a 19-year-old man with otitis media who presented with sinus congestion 1 week earlier. Plain films of the sinuses revealed opacification of the right maxillary and ethmoidal sinuses and an intracranial air-fluid level. Note the intracranial gas in the right frontal region abutting a hypodense region in the epidural space with ring enhancement and surrounding edema, representing an intracranial epidural abscess.

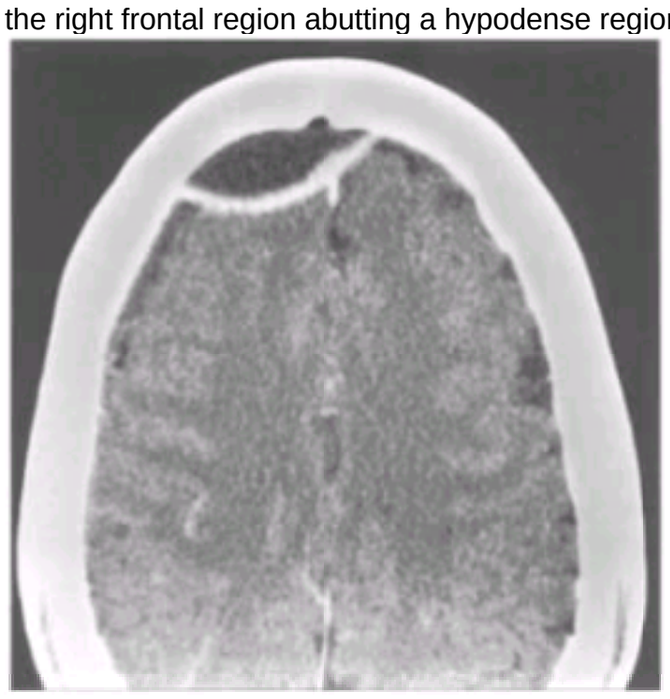

Figure 24-7 Contrast-enhanced MRI scan of the head in the sagittal projection of a 29-year-old man with sinus congestion and headache. There is non-uniform signal intensity of the cavernous venous sinuses, indicating cavernous sinus thrombosis. The sphenoid, ethmoidal and maxillary paranasal sinuses also demonstrated abnormal signal intensity.

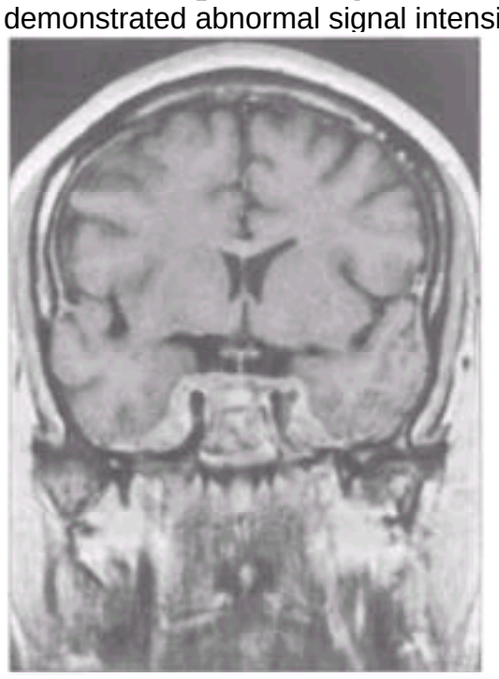

Figure 24-8 Contrast-enhanced MRI scan of the spine in the coronal projection of a 28-year-old man with a 1-week history of headache, fever and sweats. Physical examination demonstrated meningismus but no focal neurologic deficits. Scans in the sagittal section demonstrated a substance nearly isointense with the spinal cord and running nearly the length of the cord. This scan clearly demonstrates impingement and anterior displacement of the cord by the spinal epidural abscess.

Figure 25-1 Reported number of tetanus cases in the USA (1947–97).

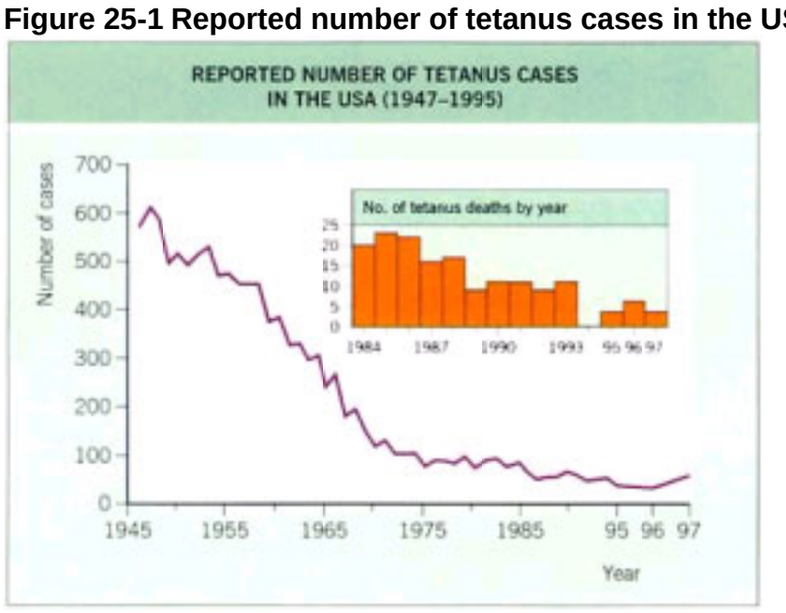

Figure 25-2 Sites of action of tetanospasmin. Tetanospasmin (TS) is produced by *Clostridium tetani* at the site of the wound and binds and internalizes at the neuromuscular junction into the a motor neuron. It then travels by retrograde axonal flow to the cell body and diffuses out into the synapses and extracellular space of the CNS. It enters other neurons and travels further into the CNS. Its major effect is to inhibit transmitter release from the glycinergic presynaptic inhibitory neuron but it can also inhibit release of transmitters at the excitatory synapses and of acetylcholine at the neuromuscular junction.

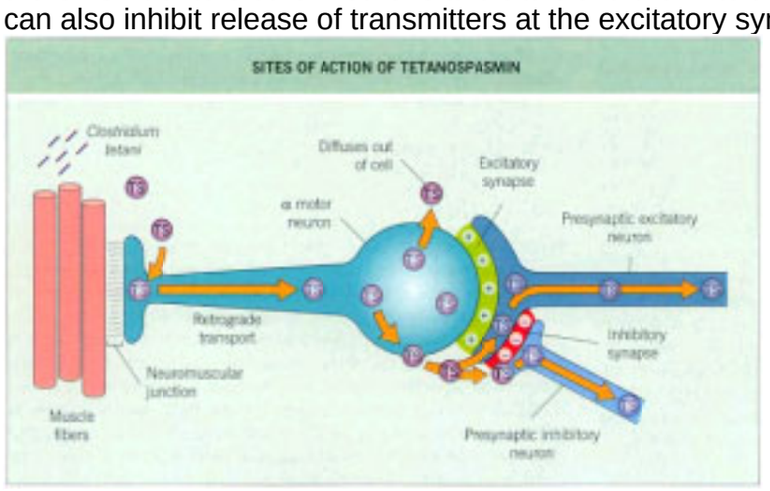

Figure 25-3 Facial spasm and risus sardonicus in a Filipino patient who has tetanus.

Figure 25-4 Botulinum toxin in its derivative and activated forms.

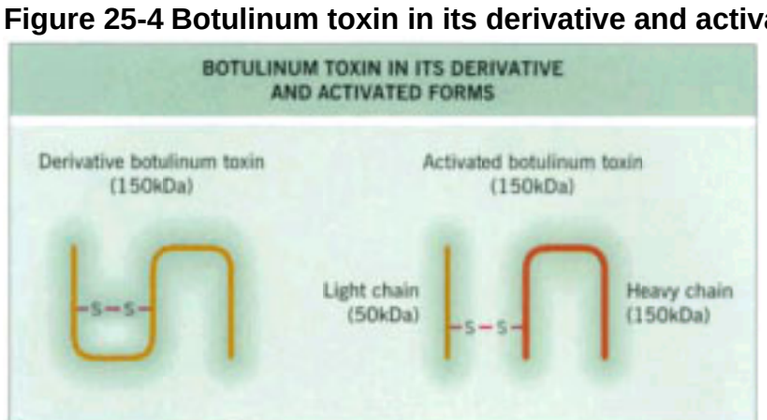

Figure 25-5 Action of diphtheria toxin. The binding subunit attaches to the cell surface and the toxin enters the cell. After endocytosis the toxin is cleaved and the active A subunit is released. This then catalyzes the cleavage of nicotinamide adenine dinucleotide (NAD) and the transfer of adenine diphosphate ribose (ADPR) to EF-2. EF-2 is essential for ribosomal reactions at the acceptor and donor sites, whereby the mRNA code is transferred via tRNA to an amino acid sequence and the building of a polypeptide chain. EF-2-ADPR is incapable of adding amino acids to a polypeptide chain and protein synthesis is stopped.

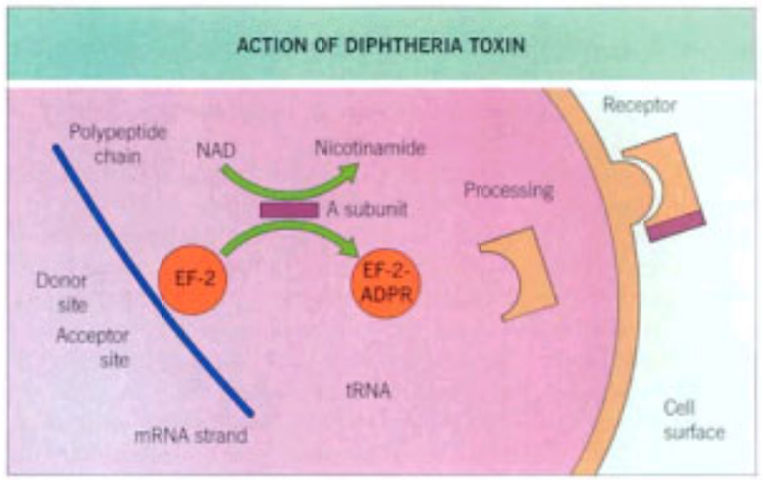

Figure 26-1 Structure of the human prion protein. Model of glycosylated human prion protein indicating positions of *N*-linked glycans (blue), the single disulfide bond linking helixes 2 and 3, and the glycosylphosphatidylinositol (GPI) anchor to the outer surface of the cell membrane. *Courtesy of Dr Richard Sessions and Mr Ray Young.*

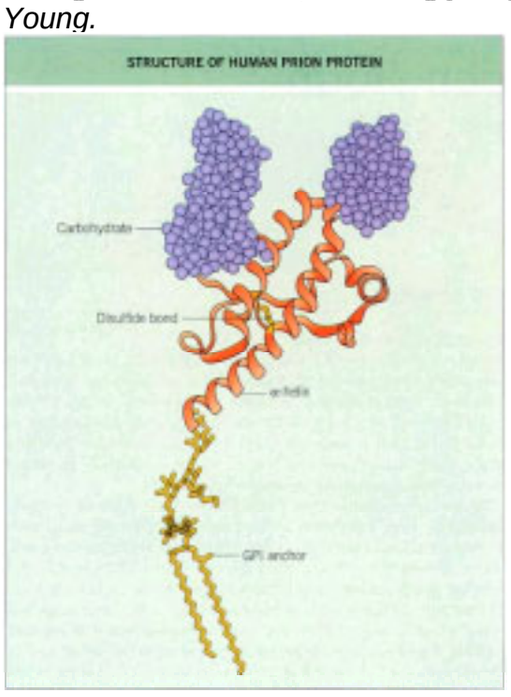

Figure 26-2 Prion propagation. Schematic representation of a possible mechanism for prion propagation. The predominantly a-helical form of the normal prion protein (PrP^{C}) proceeds via an unfolded state (a) to refold into a predominantly ß-sheet form (ß-PrP) (b). Prion replication may require a critical 'seed' size. Further recruitment of ß-PrP (c) or unfolded PrP (d) occurs as an essentially irreversible process. *Courtesy of Prof Tony Clarke and Mr Ray Young.*

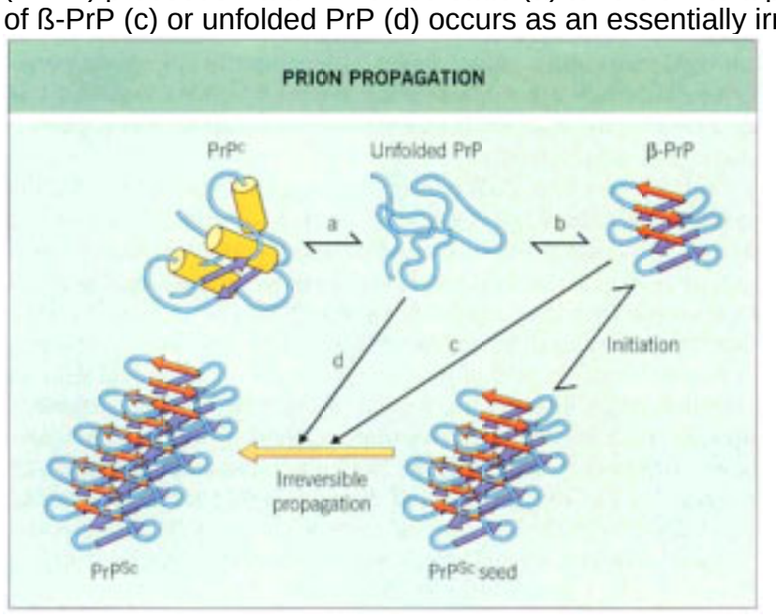

Figure 26-3 Pathogenic mutations and polymorphisms in the human prion protein. The pathogenic mutations associated with human prion disease are shown above the PrP coding sequence. These consist of 1, 2 or 4–9 octapeptide repeat insertions within the octarepeat region between codons 51 and 91, a deletion of 2 octapeptide repeats; and various point mutations causing missense amino acid substitutions. Point mutations are designated by the wild-type amino acid preceding the codon number, followed by the mutant residue, using single-letter amino acid conventions. Polymorphic variants are shown below the PrP coding sequence. Deletion of one octapeptide repeat is not associated with disease.

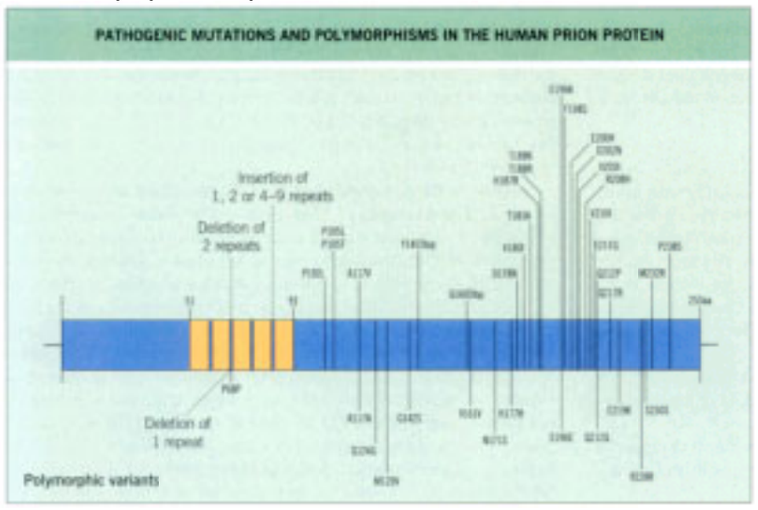

Figure 26-4 Axial T_2 -weighted MRI brain demonstrating high signal bilaterally in the posterior thalamus (arrowed) — the 'pulvinar sign' in a patient with vCJD.

Figure 26-5 Western blot demonstrating the presence of PrP^{Sc} in brain and tonsil from a patient with vCJD. The presence of PrP^{Sc} is revealed after proteinase K (PK) treatment, which digests the normal form of PrP (PrP^{C}) but not the pathological form (PrP^{Sc}). *Courtesy of Ms Susan Joiner and Dr Andy Hill.*

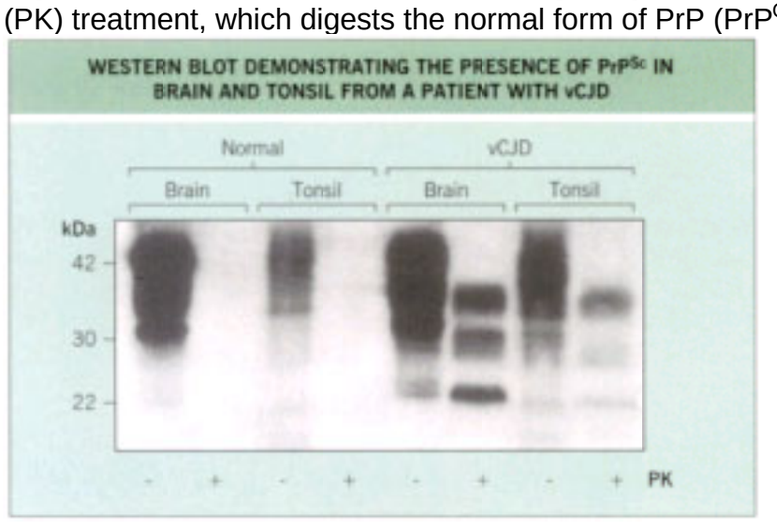

Figure 26-6 Neuropathology of prion disease — histopathological findings in vCJD. (a) Florid plaques, a characteristic feature of vCJD pathology. They consist of a round amyloid core (arrowed) surrounded by a ring of vacuoles (hematoxylin and eosin stain). (b) Spongiform degeneration in prion disease. This area shows severe vacuolization (spongiosis), there is severe neuronal loss and many strongly reactive astrocytes (arrowed) (hematoxylin and eosin stain). (c) Immunostaining of the pathological prion protein. The specimen is pretreated to denature the normal PrP and staining with a prion protein antibody reveals the presence of plaques (P) and synapses (S) staining positively for PrP^{Sc} . (d) Detection of pathological prion protein in the follicular dendritic cells in a tonsil. Accumulation of prion protein in lymphoreticular organs, such as spleen, tonsils or appendix, is a specific finding in vCJD and is not present in other forms of CJD. Therefore tonsillar biopsies can be used to specifically diagnose vCJD when clinical symptoms are only emerging. *Courtesy of Dr Sebastian Brandner.*

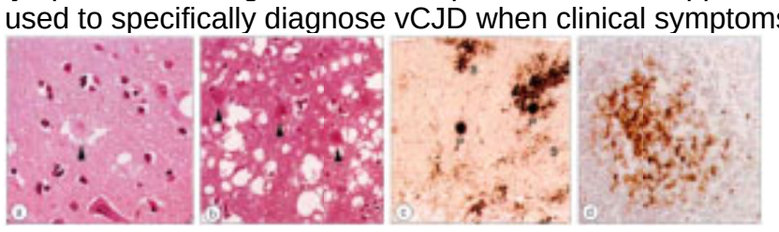

Figure 26-7 The tissue distribution of PrP^{Sc} in vCJD compared to classic CJD. In vCJD PrP^{Sc} is found in lymphoreticular tissue as well as brain and spinal cord. Using highly sensitive immunodetection methods, PrP^{Sc} has also been found in the optic nerve, retina, adrenal gland and rectum. *Courtesy of Dr Jonathon Wadsworth and Mr Ray Young.*

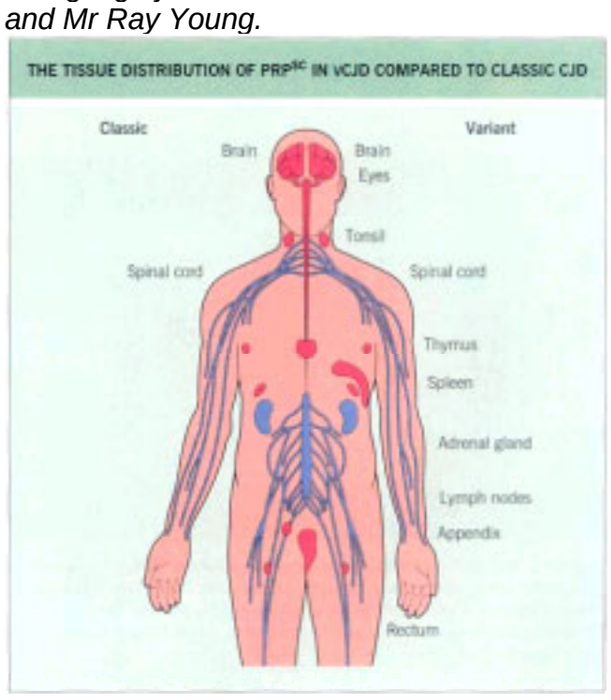

Figure 27-1 Postinfectious encephalomyelitis. (a, b) MRI of brain at presentation showing asymmetric demyelination of cortical white matter. Basal ganglia were also involved bilaterally (not shown). (b) At 7 weeks, the distribution is more symmetric. (c) Residual lesions at 4 months, with full clinical recovery.

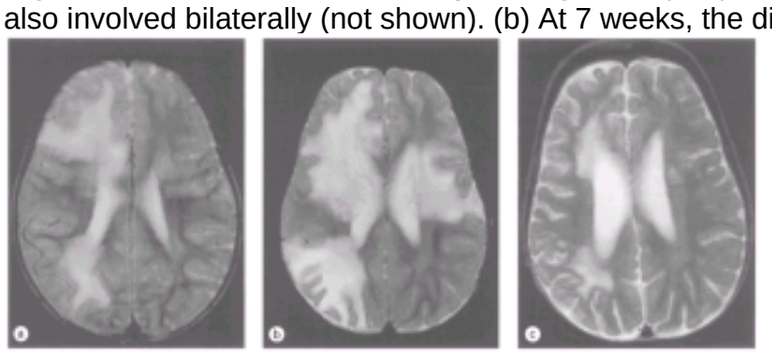

Figure 28-1 Routes of drainage of ventriculoperitoneal and ventriculoatrial shunts. Ventriculoperitoneal shunts drain CSF from the cerebral ventricles to the peritoneal cavity via catheter tubing implanted superficially over the rib cage. The lower end of the peritoneal catheter lies free in the abdomen. Ventriculoatrial shunts drain CSF via a convenient neck vein such as the jugular and the superior vena cava to the right atrium.

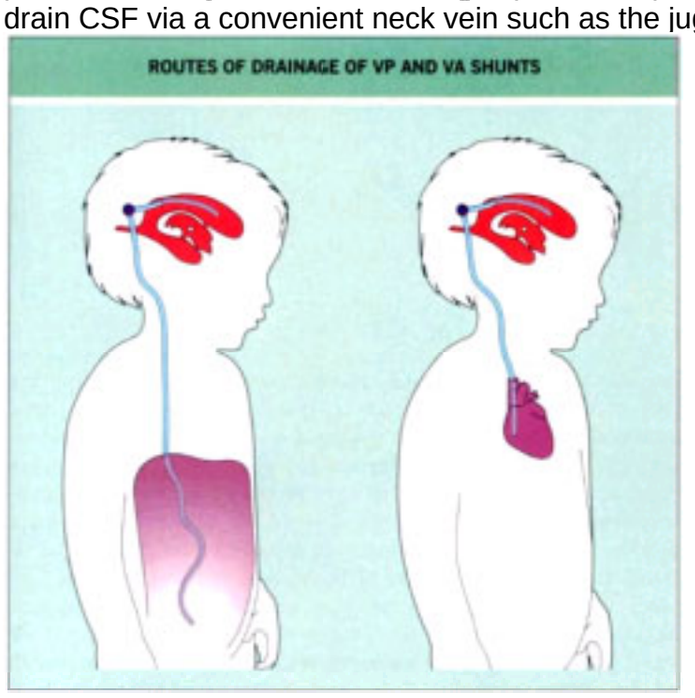

Figure 28-2 External shunt infection in a premature infant with poor nutritional status. The infection can be caused by organisms introduced at surgery or they may gain access through minor skin abrasions and pressure necrosis. Differing from the more common internal shunt infections, they are usually caused by *Staphylococcus aureus* and constitute a wound infection enhanced by a foreign material.

Figure 28-3 Cystic obstruction of a ventriculoperitoneal shunt caused by shunt infection with *Staphylococcus epidermidis.* Bacteria and bacterial products entering the peritoneal cavity via the shunt catheter evoke an inflammatory response involving the greater omentum, which seals off the catheter outlet. The resulting cyst fills with CSF, giving rise to recurrence of the hydrocephalus. Cystic obstruction can occur from noninfective causes but unlike those cases caused by infection, which present within 6–9 months of surgery, they can arise at any time.

Figure 29-1 Global annual poliomyelitis cases reported to the World Health Organization 1974–99.

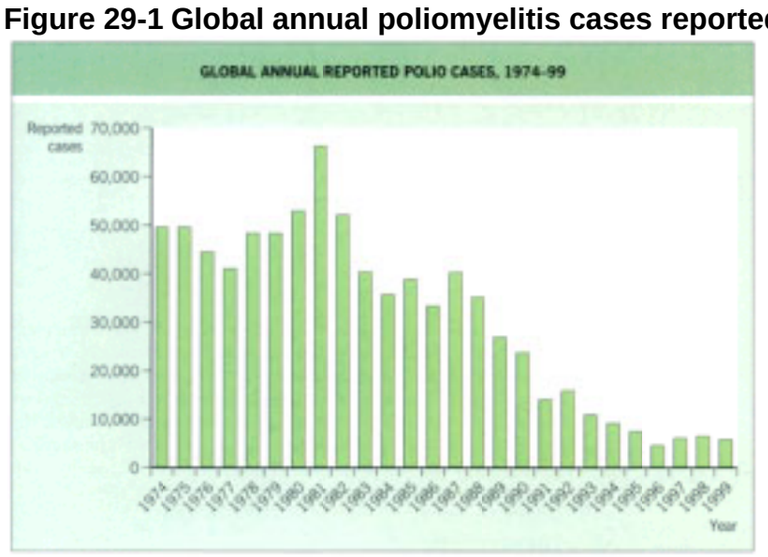

Figure 29-2 Total number of cases of paralytic poliomyelitis and vaccine-associated poliomyelitis in the USA 1960–98.

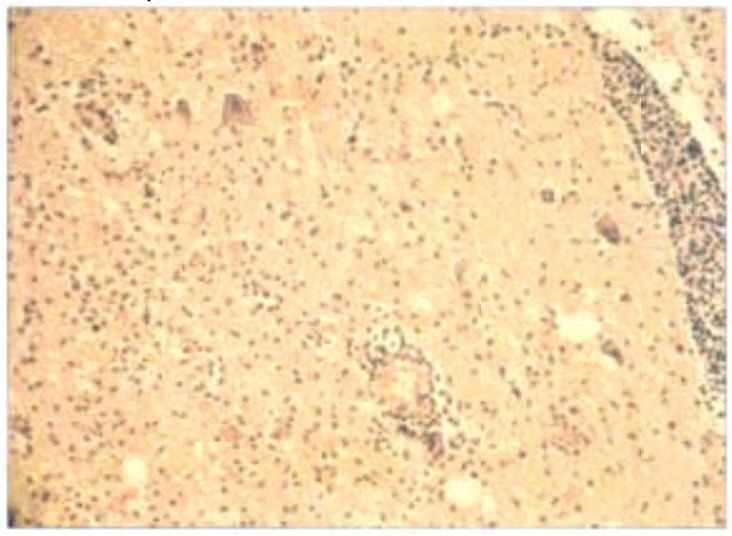

Figure 29-4 Incidence of herpes zoster at different ages.[12]

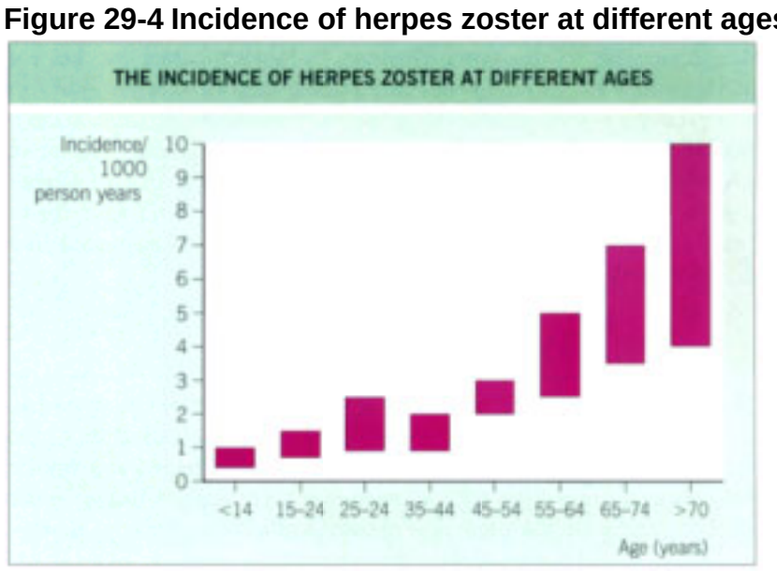

Figure 29-5 Typical dermatomal rash of herpes zoster.

Figure 29-6 Hutchinson's sign. When the rash of herpes zoster involves the skin at the tip and side of the nose it indicates that the nasociliary branch of the trigeminal nerve is involved and there is an increased risk of uveal tract inflammation and ocular damage.

Figure 29-7 Life cycle of HTLV-I. HTLV-1 infection is initiated by cell-free virions or, more commonly, by cell-to-cell virus transmission. The two RNA genome copies are converted into double-stranded DNA provirus by the viral enzyme reverse transcriptase and the proviral DNA is integrated into the host chromosome. Transcription is activated by the viral Tax protein. In the early stages of infection both Tax and Rex proteins are produced. The Rex protein directs the preferential transport of unspliced or singly spliced viral messages to the cytoplasm for translation into structural proteins for virion assembly.

Figure 38-1 DNA fingerprint patterns of 10 Mycobacterium abscessus isolates from an outbreak of M. abscessus infection in a hemodialysis center. Lanes 1–5 are identical strains of *M. abscessus* recovered in blood cultures from five different patients, indicating a common source of infection. Lanes 6–10 are the same strain of *M. abscessus* recovered by sampling a water treatment system contaminated by *M. abscessus*, the source of the patients' isolates. *Courtesy of Dr Yansheng Zhang and Dr Richard J Wallace Jr.*

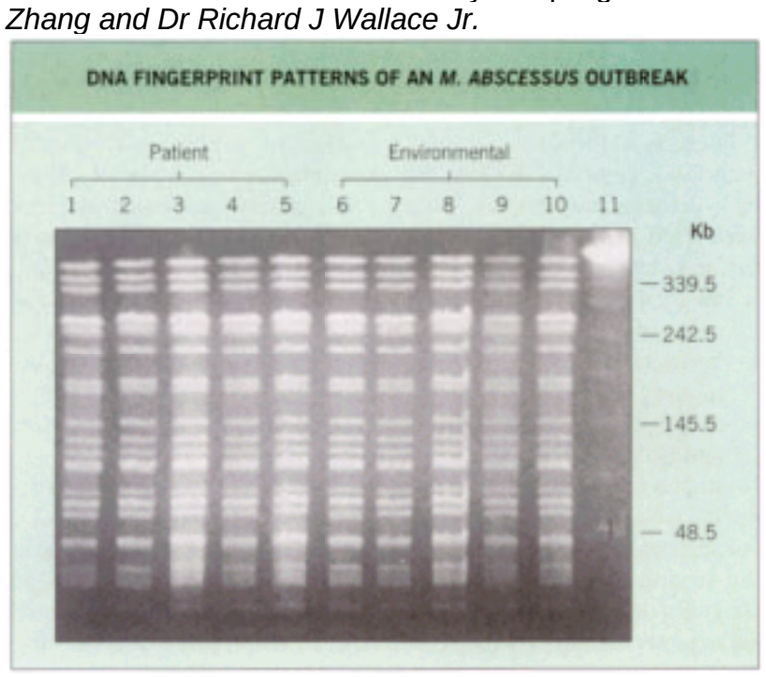

Figure 38-2 DNA fingerprint patterns of nine *Mycobacterium avium* complex (MAC) respiratory isolates (lanes 1–9) collected over an approximately 7-year period from a 67-year-old woman with nodular- bronchiectatic MAC lung disease. Each of the MAC isolates has a distinct DNA fingerprint pattern that suggests repeated reinfection by new MAC strains rather than relapse of infection from a single MAC strain.

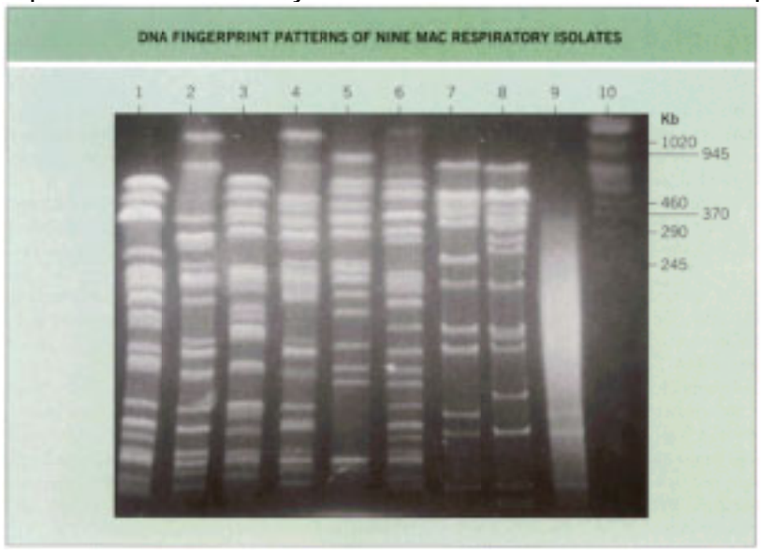

Figure 38-3 Cytokine pathways involved in mycobacterial infection and host response. Mycobacteria infect macrophages and stimulate production of interleukin (IL)-12. Interleukin-12, composed of p35 and p40 subunits, recognizes its receptor on T cells or natural killer (NK) lymhocytes, causing phosphorylation of the cytoplasmic kinases, Tyk2 and Jak2. This results in phosphorylation of signal transducer and activator of transcription (STAT)4, leading to production of interferon (IFN)-?, tumor necrosis factor (TNF)-a and granulocyte-macrophage colony stimulation factor (GM-CSF). Interleukin-12 also stimulates production of IL-2, which feeds back on the T or NK lymphocyte. Interferon-? binds to its receptor on the macrophage, causing aggregation of IFN-?R1 and IFN-?R2 and phosphorylation of the cytoplasmic Janus kinases, Jak1 and Jak2. Consequently, cytosolic STAT1 is phosphorylated, homodimerized and transported to the nucleus, where it upregulates IFN-? responsive genes. Interferon-? and GM-CSF stimulate macrophages to produce TNF-a, which in conjunction with IFN-? drives forward the production of IL-12 and reactive oxygen intermediates, such as superoxide and nitric oxide. *Adapted with permission from Holland SM. Host susceptibility factors in mycobacterial infection: genetics and body morphotype. Infect Dis Clin North Am 2002;16:163–86.*

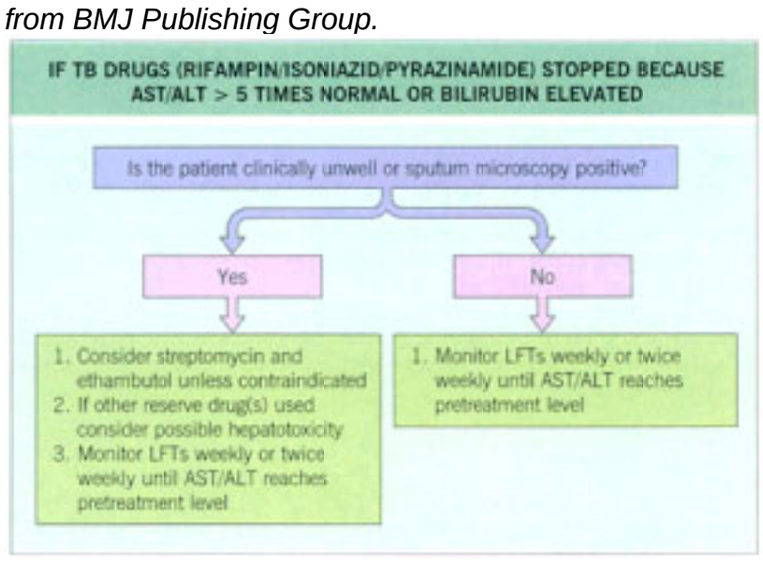

Figure 40.f-1 A schematic representation of the role played by bacteria in COPD. There is limited evidence at the present time for the steps indicated by broken arrows which suggest that inflammation might be caused by lower airway bacterial colonization (LABC) and that airway infections might lead to progression of COPD.

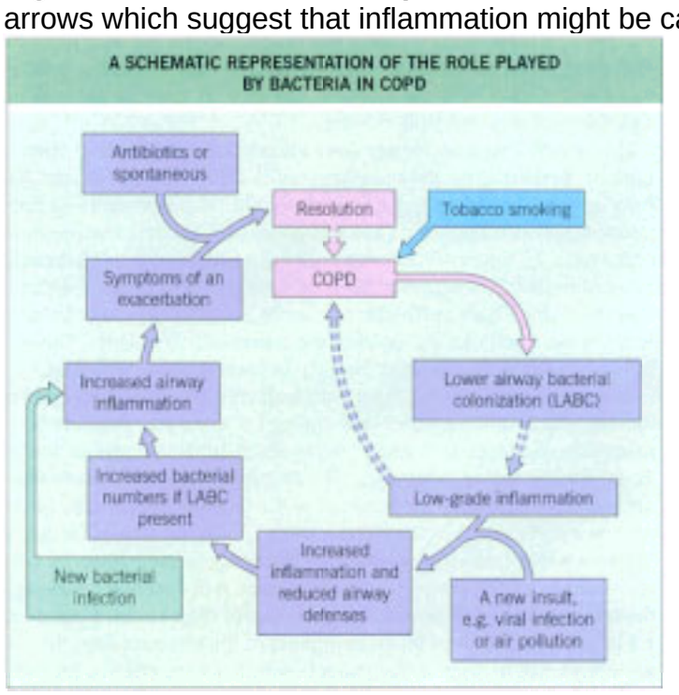

Figure 40.f-2 A decision tree outlining how choices about whether or not to prescribe an antibiotic for patients with airway diseases can be made. There is very little evidence that one antibiotic is superior to another, but concern about antibiotic resistance will influence choice in severe cases. An antibiotic which is resistant to ß-lactamase enzyme and potent against the major pathogens should be chosen. Ciprofloxacin is indicated when there is concern about *Pseudomonas aeruginosa*. Evidence shows that this bacterium is usually only a consideration in patients with FEV1 =50% predicted, although in my own experience it is only patients with even more severe airflow obstruction in whom it occurs or in those patients who also have bronchiectasis.

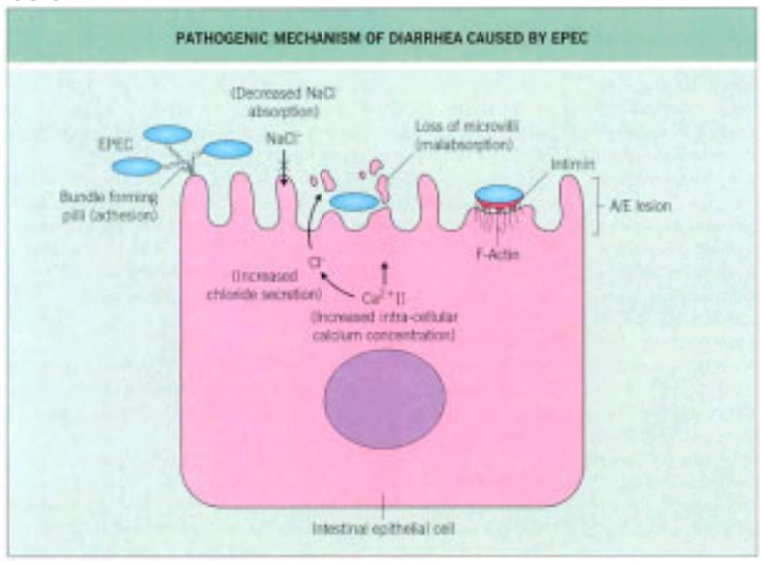

Figure 43-3 Pathogenic mechanism of toxin-mediated diarrhea.

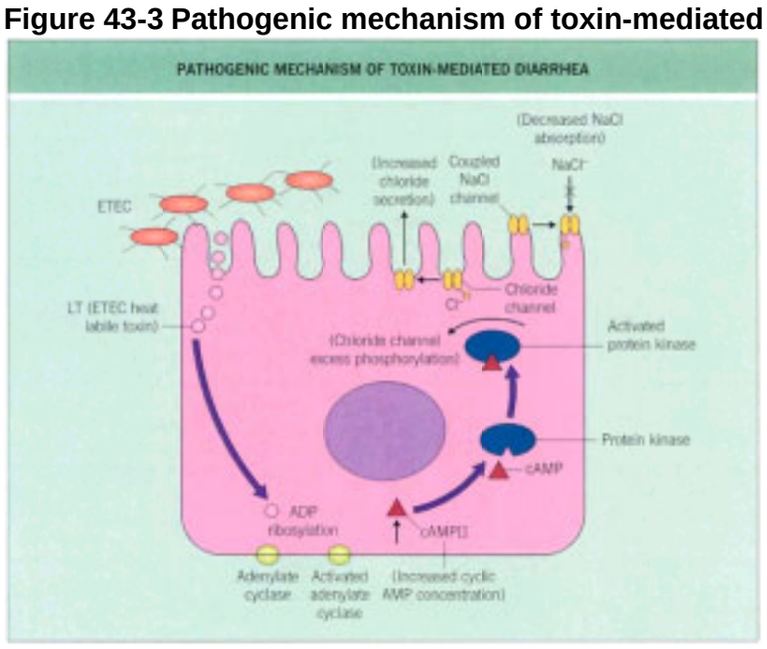

Figure 44-1 The pathogenesis model for hospital-acquired *Clostridium difficile*-associated diarrhea (CDAD). This 'three-hit' model of *C. difficile* pathogenesis shows that exposure to antibiotics establishes susceptibility to infection. Once susceptible, the patient may acquire nontoxigenic (nonpathogenic) or toxigenic strains of *C. difficile* (the second 'hit'). Acquisition of toxigenic *C. difficile* may be followed by asymptomatic colonization or *C. difficile*-associated disease, depending on one or more factors (the third 'hit'). Inadequate anamnestic IgG response to toxin A produced by toxigenic *C. difficile* strains is an important host factor determining disease outcome.[9]

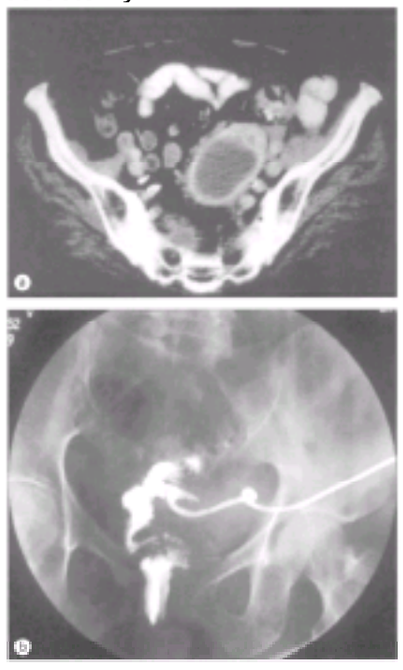

Figure 47-3 Multiple intra-abdominal abscesses following appendectomy of perforated appendicitis.

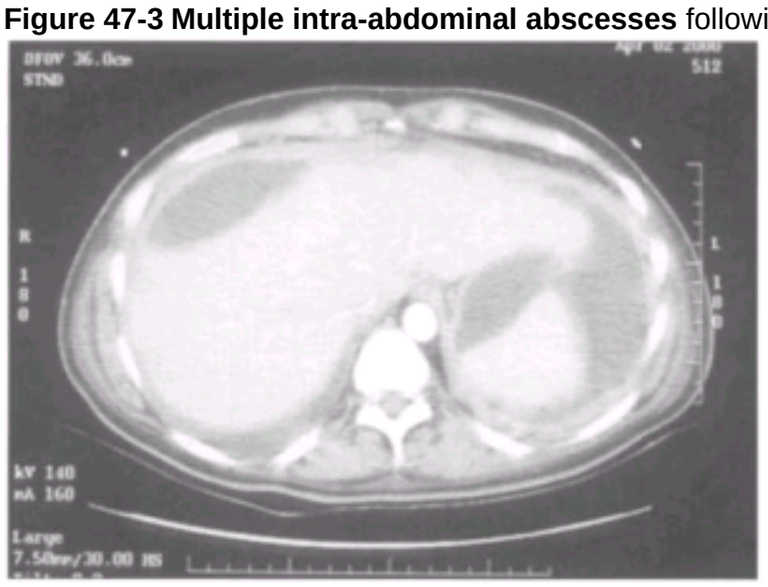

Figure 47-4 Pancreatic drainage for lesser sac infection during the course of acute necrotizing pancreatitis. The difficulty in removing necrotic debris through the narrow catheter is suggested by the abscess's persistence. Follow-up operative intervention was required.

Figure 48-1 Seroprevalence of hepatitis E IgG in selected world populations.

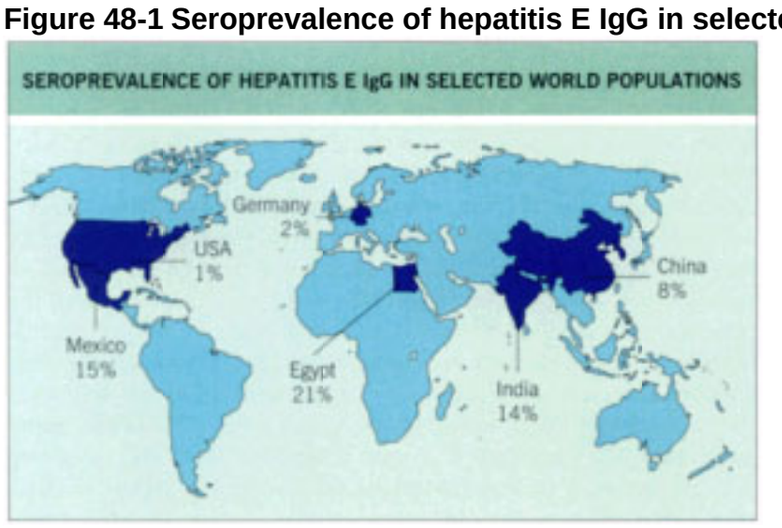

Figure 48-2 Hepatitis B virus replication. Viral DNA present in the nucleus is transcribed to RNA, which then acts as a template for protein synthesis (viral coat-HBsAg and viral proteins essential for infectivity and replication-HBcAg). Viral particles are then assembled and secreted from the cell cytoplasm. For every complete virion a large number of incomplete particles derived from HBsAg alone are exported. HBV, hepatitis B virus; HBsAg, hepatitis B surface antigen; HBcAg, hepatitis B core antigen.

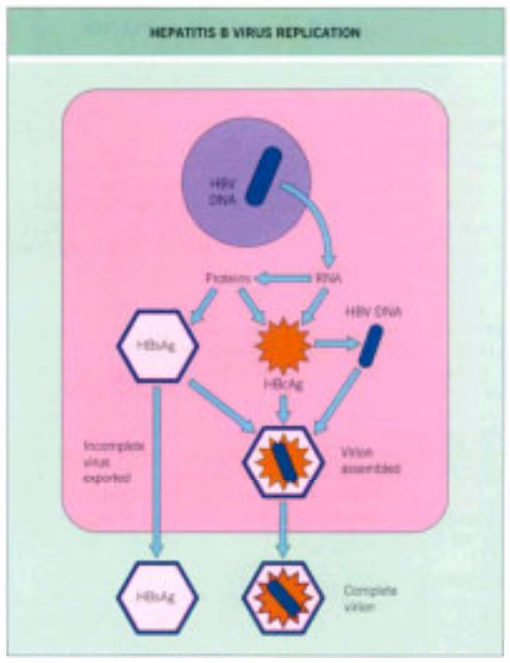

Figure 48-3 Phases of chronic hepatitis B infection. Initial infection is usually in childhood and has a long immune tolerant phase. Immune recognition then develops which can allow inactivation of hepatitis B by either clearance of infected cells (with associated liver cell damage) or suppression of viral antigen expression on infected hepatocytes. This produces viral inactivation. In a significant proportion of patients where this has occurred, a third phase develops, where replication of HBV resumes due to viral escape mutants, leading to HBV DNA again appearing in serum and the risk of chronic liver disease.

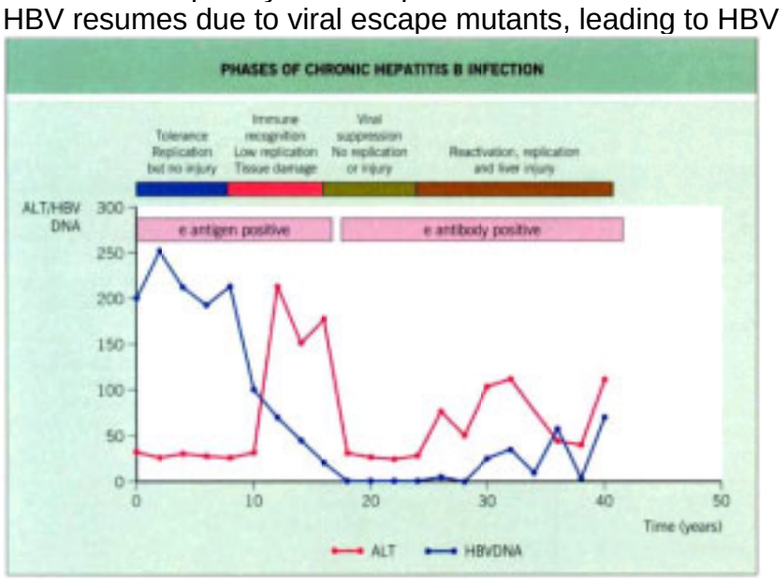

Figure 48-4 Facial stigmata of chronic liver disease. This woman presented with serologically proven acute hepatitis A virus infection. She has multiple stigmata of chronic liver disease including facial spider nevi and was shown to have pre-existing cirrhosis.

Figure 48-5 Vasculitic rash in a patient who has mixed cryoglobulinemia.

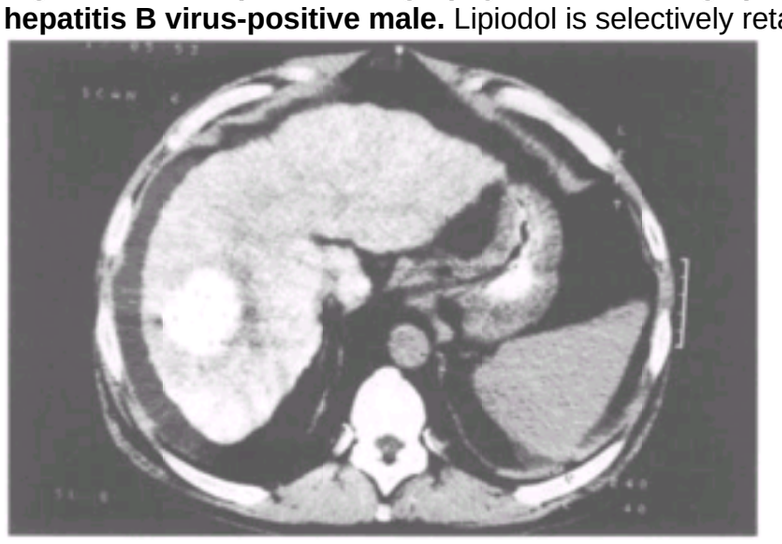

Figure 48-9 Serologic markers in acute self-limiting hepatitis B virus infection. HBV, hepatitis B virus; HBeAg, hepatitis B e antigen. Measurements in arbitrary units.

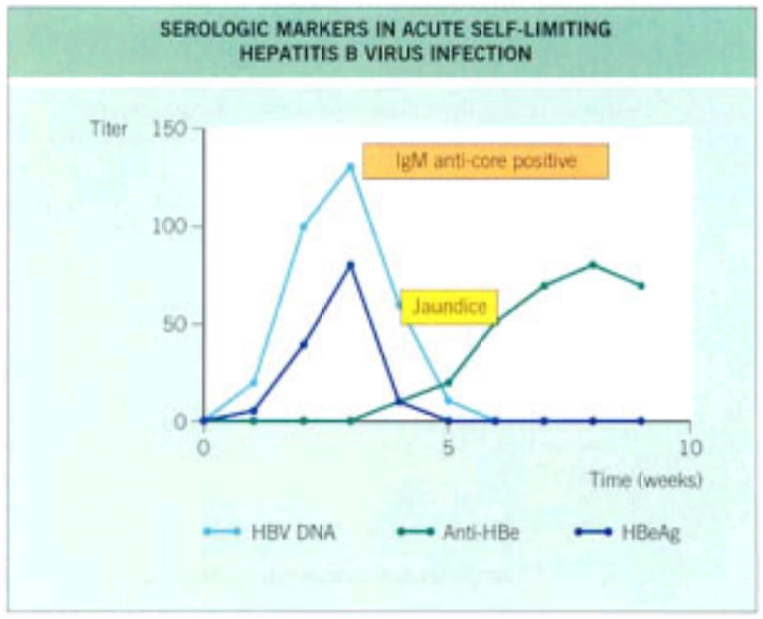

Figure 48-10 The appearance of hepatitis C virus RNA, anti-hepatitis C virus and elevated ALT in acute hepatitis C virus infection. HCV, hepatitis C virus; ALT, alanine transaminase. Measurements in arbitary units.

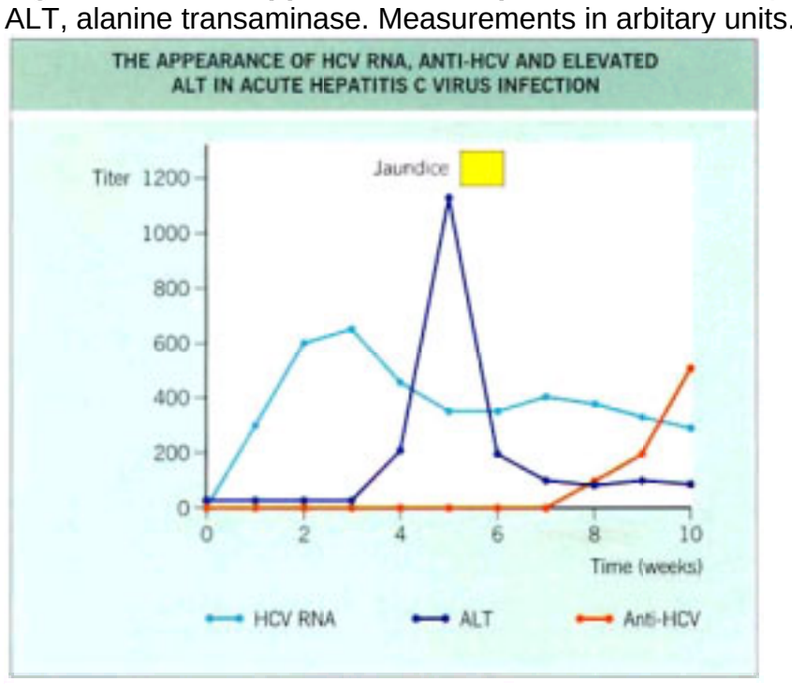

Figure 48-11 Production of hepatitis B core antigen and hepatitis B e antigen and the generation of e antigen-negative mutants. Hepatitis B virus (HBV) has a closed circular genome that contains insufficient bases to produce all its required proteins. It therefore uses different start points for transcription, enabling it to use the same base sequence to produce different proteins. Two important proteins, e antigen and core antigen, are produced by transcription of the same region with overlap; e antigen is produced from the core protein by cleavage at a specific site.

Diagnosis of osteomyelitis in the presence of soft tissue infection and radiologic evidence of osseous abnormalities. AJR Am J Roentgenol 1991;157:807–12.*

Figure 52-13 Leukocyte scintigram of the hands. This scan is from the same patient as the scan in Fig. 52.12 . Again there is intense uptake in distal first phalanx, but there is no accumulation of leukocytes in the multiple neuropathic joints. *With permission from Jacobson AF, Harley J, Kipsky B, Pecoraro R. Diagnosis of osteomyelitis in the presence of soft tissue infection and radiologic evidence of osseous abnormalities. AJR Am J Roentgenol 1991;157:807–12.*

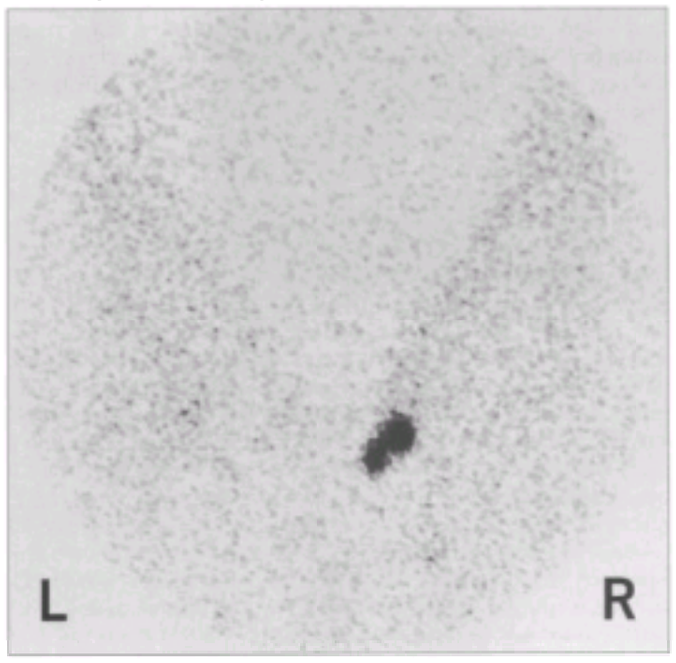

Figure 52-14 T1-weighted image of the foot. The scan reveals forefoot amputation and a normal signal in distal tibia, talus and posterior calcaneus. The interior portion of the calcaneus has edema. The remainder of the tarsal bones have been destroyed and replaced by a pale, heterogeneous inflammatory mass.

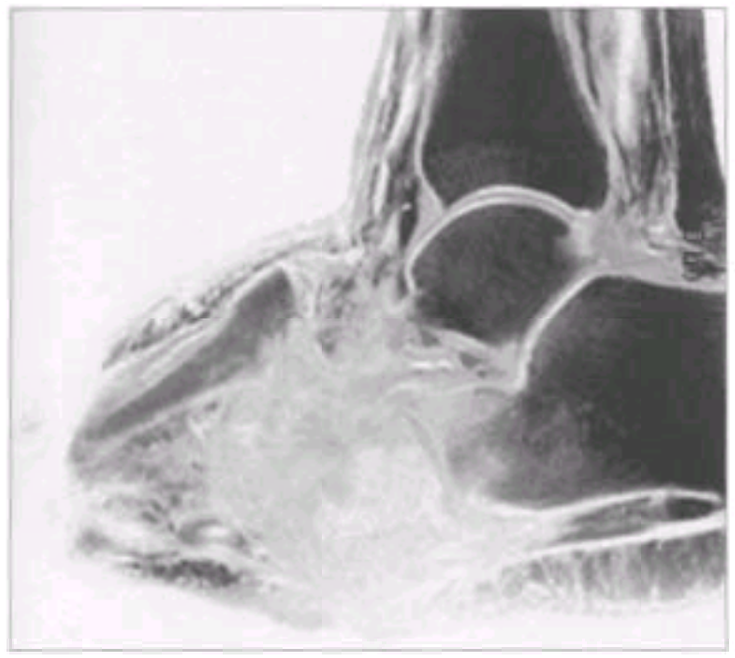

Figure 52-15 Diabetic foot infections. Algorithmic approach to diagnosis and management. *Adapted with permission from Lipsky et al.*[3]

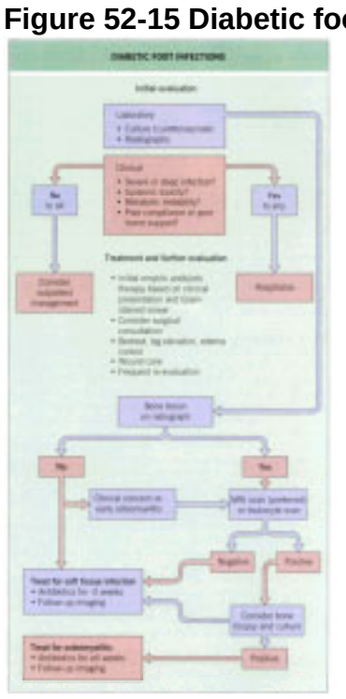

Figure 53-1 Bacterial adherence to the implant, bacterial multiplication on the surface and biofilm formation. An ineffective host response triggers bone resorption, contributing to loosening, which is accelerated by wear particles and the host response to them.

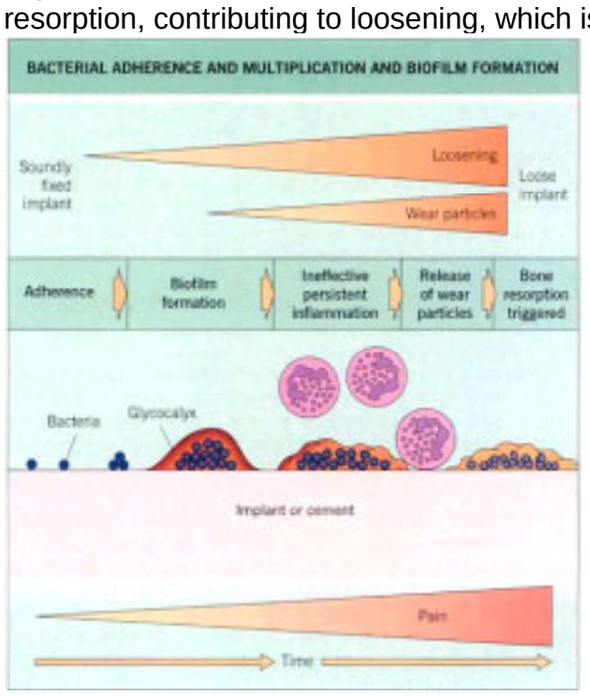

Figure 53-2 Histologic features of infection. Periprosthetic tissue from a clinically infected total hip replacement from which multiple specimens grew an indistinguishable organism. Numerous neutrophils are present in the tissue.

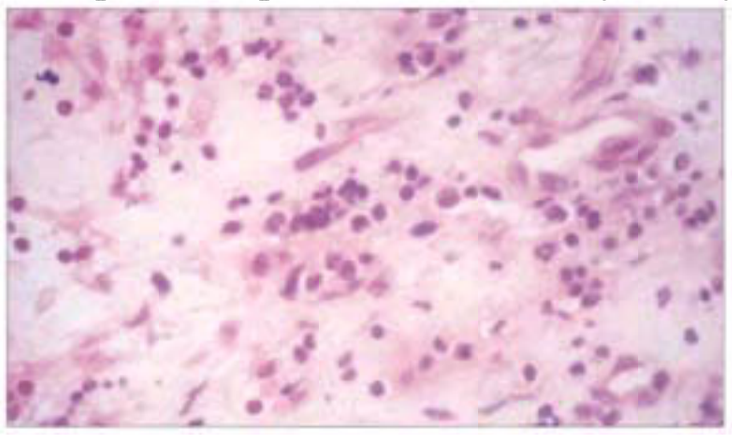

Figure 53-3 An acutely infected knee replacement. The site was washed out but the infection failed to resolve. At reoperation the implant was found to be loose and it needed to be removed. *Staphylococcus aureus* was grown from deep specimens.

Figure 53-4 A sinus tract discharging from an infected total hip replacement. *Staphylococcus aureus* was grown from deep specimens. Note the Koebner phenomenon; this patient's psoriasis was probably a significant risk factor for infection.

Figure 53-5 Implant loosening in late infection. (a) Radiograph of the infected hip shown in Figure 53.4 . There is an obvious radiolucent line at the bone-cement interface. This implant required revision. (b) Radiograph of a loose knee replacement, showing resorption of bone beneath the tibial component, a cause of instability. Coagulase-negative staphylococci were grown from multiple deep specimens.

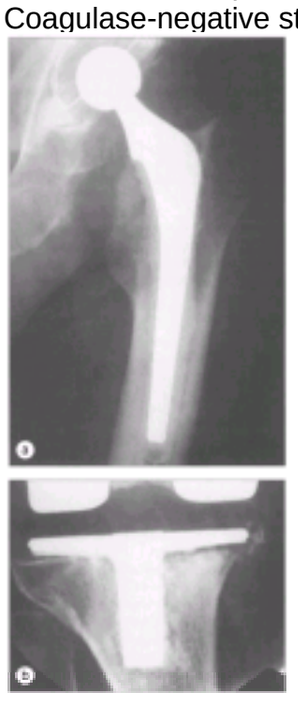

Figure 54-1 Life cycle of *Ixodes scapularis* (also known as *Ixodes dammini*). The life cycle spans 2 years. Eggs hatch in the spring; six-legged larvae develop and feed once in the summer, acquiring *Borrelia burgdorferi* from their preferred host, the white-footed mouse. Next spring, the larvae molt into eight-legged nymphs, which feed once; mice are the preferred host, humans not being necessary for the ticks' life cycle. The nymphs molt into adult male and female ticks; mating often occurs while the female feeds on a deer, and the male may remain on the deer, the female falling off and then laying eggs. Adapted, with permission, from an illustration by Nancy Lou Makris in Rahn and Malawista.[30]

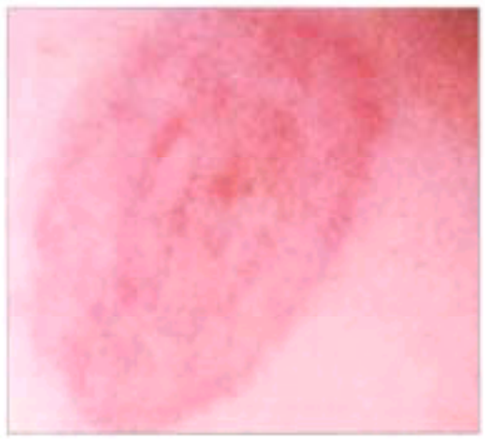

Figure 54-5 Erythema migrans. A lesion with a dusky center, a common variant. *Courtesy of Dr Steven Luger.*

Figure 54-6 Multiple erythema migrans lesions. Lateral (a) and posterior (b) views of the same patient with multiple erythematous macules of EM. Secondary lesions result from hematogenous spread. They may occur anywhere in the body. Secondary lesions are usually of uniform color and lack in duration. *Courtesy of Dr Steven Luger, Old Lyme, Connecticut, USA.*

Figure 54-7 Acrodermatitis chronicum atrophicans. Typical inflammatory bluish-red lesions of acrodermatitis chronicum atrophicans. Lesions usually occur on acral portions of extremities. *Courtesy of Dr Eva Asbrink.*

Figure 54-8 The usual serologic response in Lyme disease. Specific IgM becomes detectable 1–2 weeks after symptom onset and the appearance of erythema migrans. The later appearance of IgG is frequently concurrent with systemic manifestations. IgG is nearly always elevated with late disease. Typically, and even in untreated patients, IgM falls over 4–6 months; persistence for longer than this predicts later manifestations.

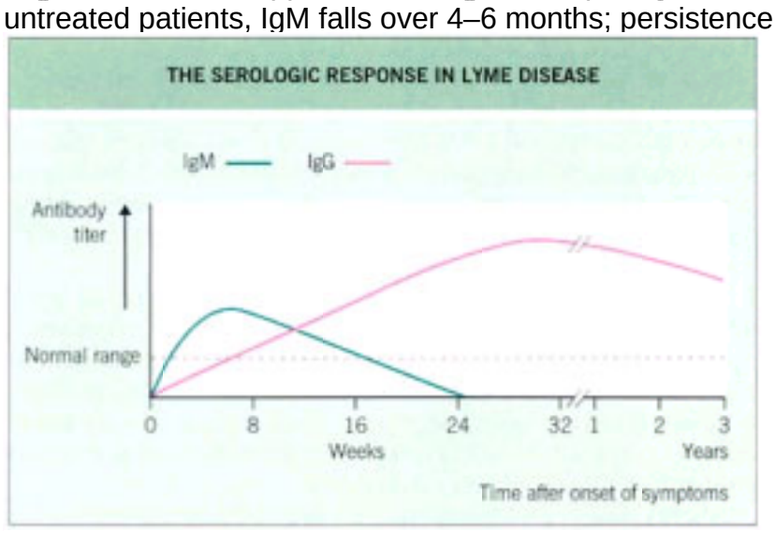

Figure 56-1 Potential risk factors leading to sepsis.

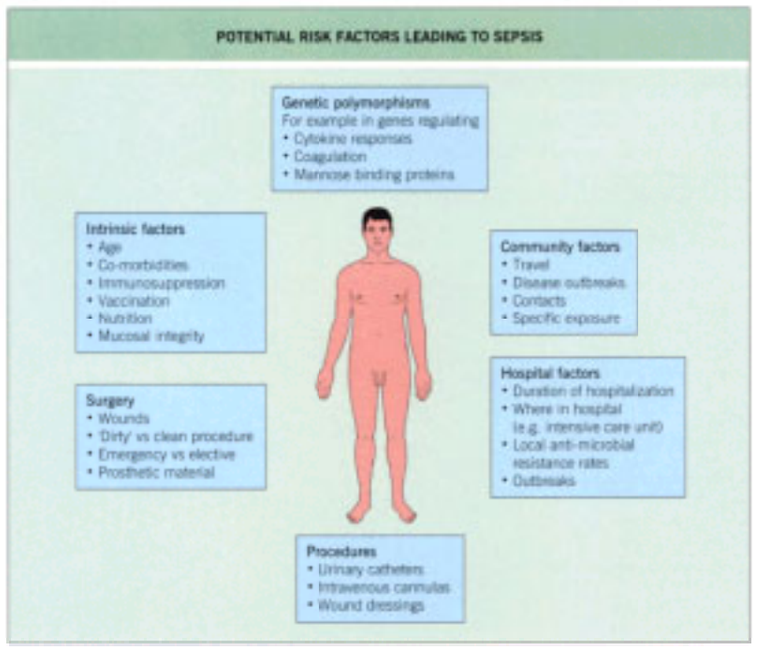

Figure 56-2 Positive blood cultures in severe sepsis. *Data from Bochud et al.* [42]

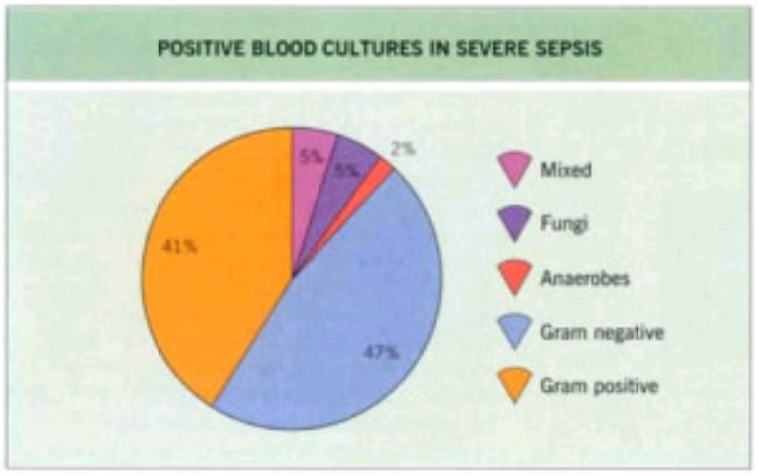

Figure 56-3 The Gram-negative bacterial cell wall. In the cell wall of a Gram-negative bacteria such as *Escherichia coli*, the inner membrane is composed of phospholipids and membrane proteins and is separated from the outer membrane by the periplasmic space and peptidoglycan. Lipopolysaccharide (expanded box) is found only in the outermost leaflet of the outer membrane with the lipid A moiety in the membrane and the polysaccharide (O) side chain directed outwards. Lipid A is highly conserved across Gram-negative bacteria and consists of a phosphorylated diglucosamine backbone decorated with six or seven acyl side chains. Dephosphorylation or deacylation of lipid A abrogates its toxicity. Lipid A is covalently linked to an inner core of sugar residues that is relatively well conserved across species and antibodies directed against the core may protect against challenge with heterologous Gram-negative bacilli. The core is followed by an outer polysaccharide chain, of repeating sugar residues, that varies between different of bacterial strains (O antigen). Antibodies directed against the O antigen will only protect against challenge with that individual bacterial strain. Gal, D-galactose; Glc, D-glucose; GlcNAc, *N*-acetyl-D-glucosamine; KDO, 3-deoxy-D-manno-octuylosonic acid; Hep, L-glycero-D-mannoheptose.

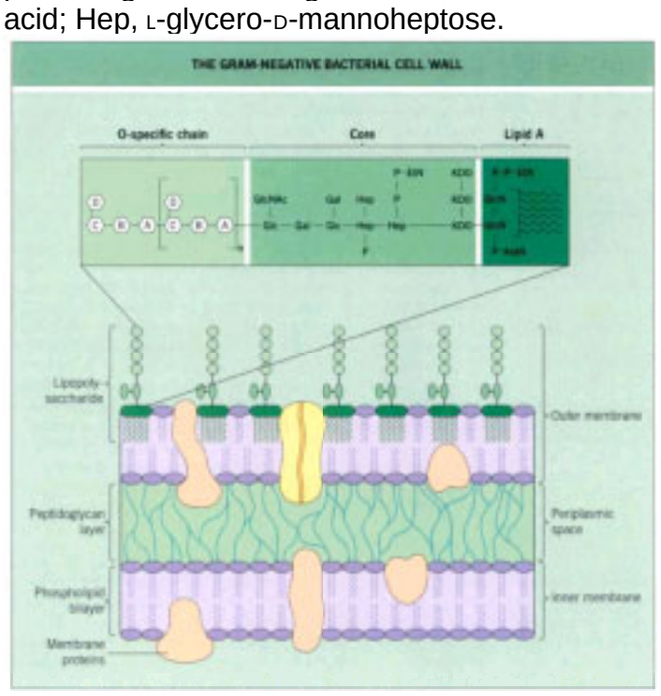

Figure 56-4 CD14 and toll receptor pathway of cellular activation by bacterial lipopolysaccharide. Schematic representation of events at the inflammatory cell surface. Lipopolysaccharide (LPS), either free or as part of lipoprotein complexes, is bound by LPS-binding protein (LBP) in the fluid phase. The LPS-LBP complex binds to the cell surface receptor CD14 on neutrophils and macrophages. CD14 lacks an intracellular domain and acts as a co-receptor presenting LPS to toll-like receptor 4 (TLR4), leading in turn to activation of intracellular signalling and gene activation. MYD88, myeloid differentiation factor 88; NF?B, nuclear factor kappa B; I?B, inhibitor of kappa B; IRAK, interlkeukin 1 receptor-associated kinase; TRAF6, tumour necrosis factor receptor-associated factor 6; MAP3K, mitogen-activated protein 3-kinase

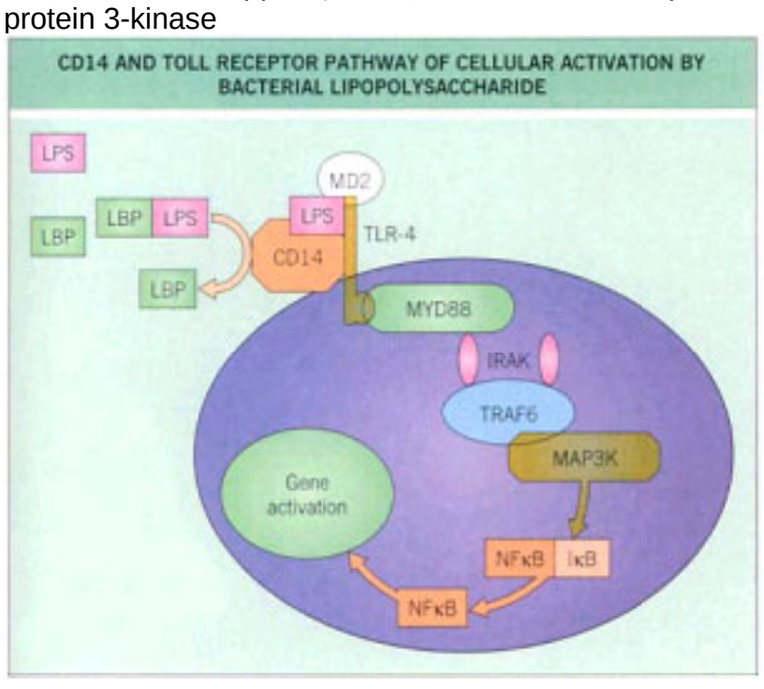

Figure 56-5 T-cell activation by superantigens. In the conventional response to bacterial antigens (bottom) the antigen is processed and presented by the antigen-presenting cell (APC) in association with MHC II. Only T cells with the correct antigen recognition site can then be activated (i.e. this is a highly antigen-specific process). Superantigens (top) are able to bypass this process by bridging between MHC II and the Vß subunit of the T-cell receptor. Thus the entire population of T cells expressing that particular Vß subunit can be activated; this can be up to 20% of the total T-cell population. *Adapted from Sriskandan and Cohen. The pathogenesis of septic shock. J Infect 1995;30:201–6.*

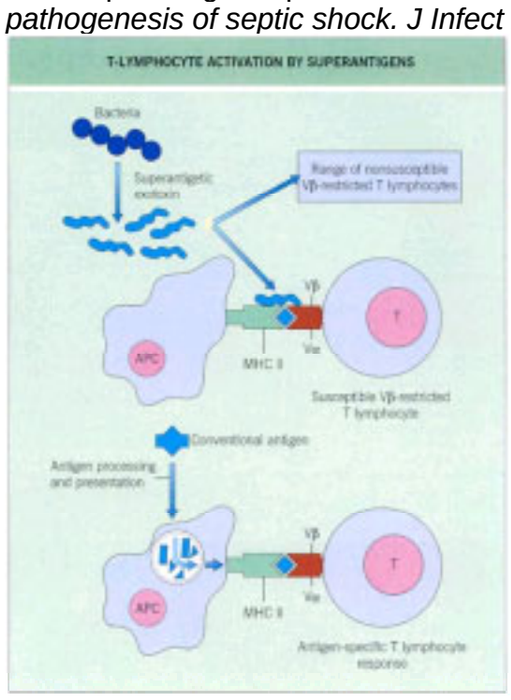

Figure 56-6 Interaction of inflammatory pathways in severe sepsis. ARDS, adult respiratory distress syndrome; IFN-?, interferon-?; IL, interleukin; IL-1Ra, interleukin-1 receptor antagonist; LBP, LPS-binding protein; LPS, lipopolysaccharide; NO, nitric oxide; TGF-ß, transforming growth factor-ß; sTNFr, soluble TNF receptor.

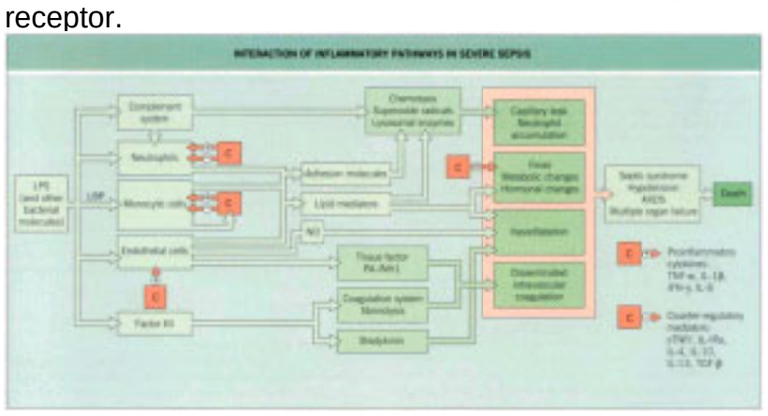

Figure 56-7 Organ failure in severe sepsis. Organ dysfunction and finally organ failure is the result of cellular hypoxia and acidosis. Hypoxia and acidosis result both from a failure of oxygen delivery due to disturbances in circulation and limitation of the cellular ability to use oxygen as a result of mitochondrial dysfunction.

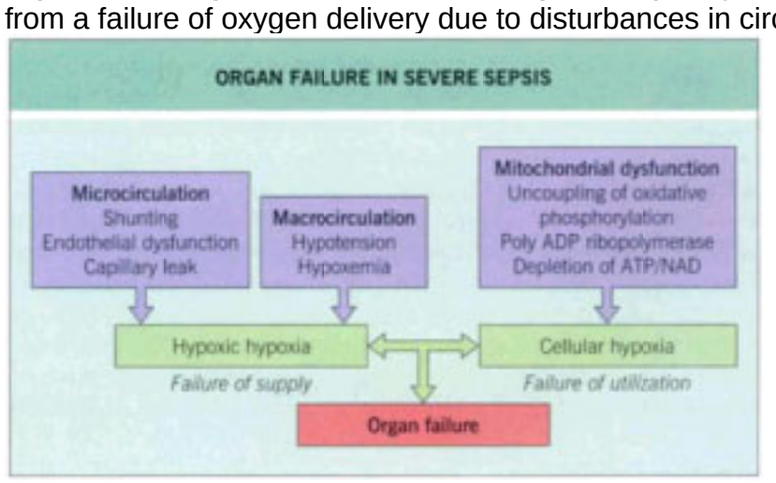

Figure 56-8 Systemic manifestations of Gram-negative bacterial sepsis. Observation chart of a 49-year-old woman admitted to hospital with a suspected drug fever. For the first 24 hours she was observed without antimicrobial chemotherapy and demonstrated a persistent fever and tachycardia (sepsis). At this point she suddenly became confused, hypotensive and oliguric indicating the development of severe sepsis. The underlying cause was an *Escherichia coli* bacteremia from an unsuspected urinary tract infection. She responded to fluid replacement and antibiotics and made a full recovery.

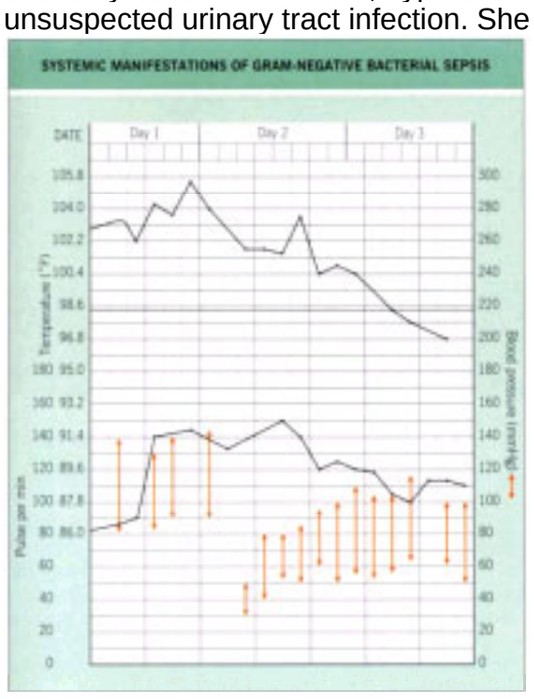

Figure 56-9 Toxic shock syndrome. A 30-year-old woman presented with a short history of fever, breathlessness, diarrhea and abdominal pain. She was pyrexial and hypotensive with a blanching macular rash noted on day 2. Blood cultures grew a Group A ß-hemolytic streptococcus. Laparotomy revealed 800ml of peritoneal pus with no intestinal perforation consistent with spontaneous bacterial peritonitis. She required ventilatory support plus inotropes to maintain blood pressure for 6 days and developed evidence of disseminated intravascular coagulation (DIC) and adult respiratory distress syndrome (ARDS). She made a gradual recovery complicated by an enterococcal urinary tract infection, finally leaving hospital 27 days after presentation. The group A streptococcal isolate from her blood was subsequently shown to release streptococcal mitogenic exotoxin Z (SMEZ) a potent superantigen. *Courtesy of P Gothard and S Sriskandan, Hammersmith Hospital, London.*

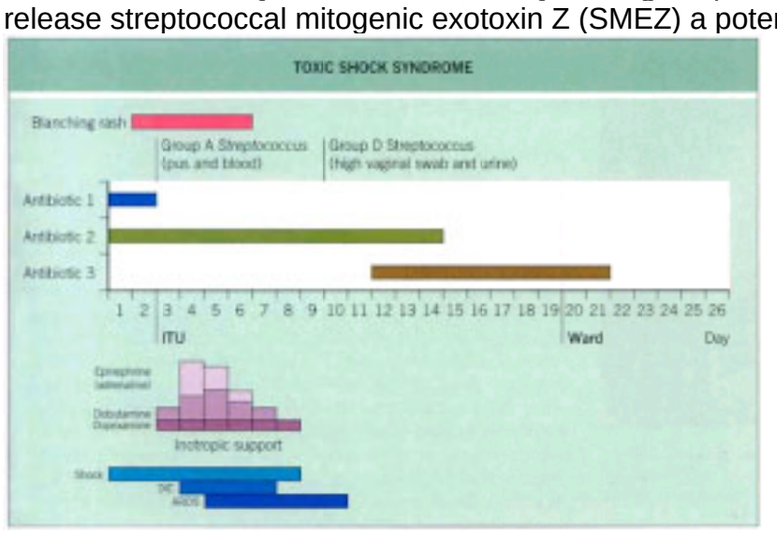

Figure 56-10 Cutaneous changes in meningococcal infection. (a) Petechial hemorrhages are the hallmark of meningococcal infection and may be found on the periphery or as in this case the conjunctivae. (b) In severe disease the purpura may become confluent (purpura fulminans) and lead to severe digital gangrene. *Courtesy of J Cohen, Brighton.*

Figure 58-3 Cardiomegaly in a patient who has pericarditis. The presence of a 'water-bottle' heart on this plain film suggests a large pericardial effusion.

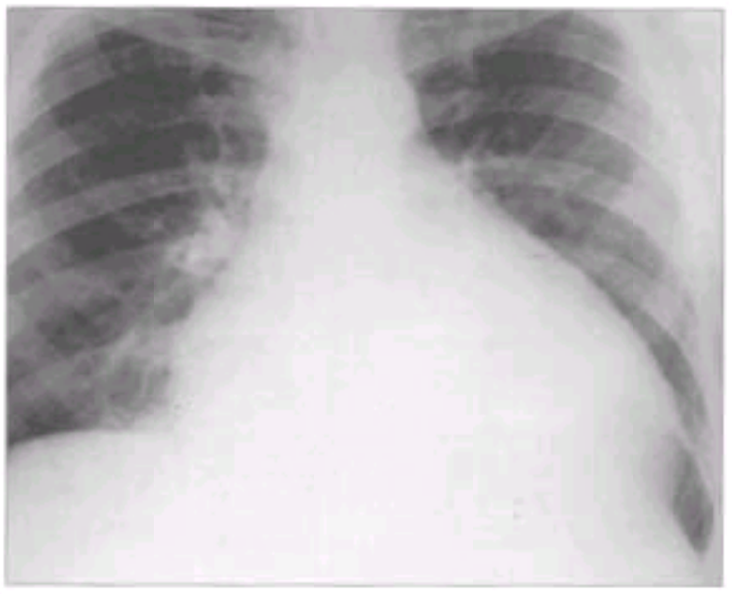

Figure 58-4 Electrocardiogram of a patient who has early acute pericarditis. Note the presence of diffuse ST segment elevation and PR depression in the inferolateral leads (arrows). 25mm/s; 10.0mm/mV; F–W 0.05–100.

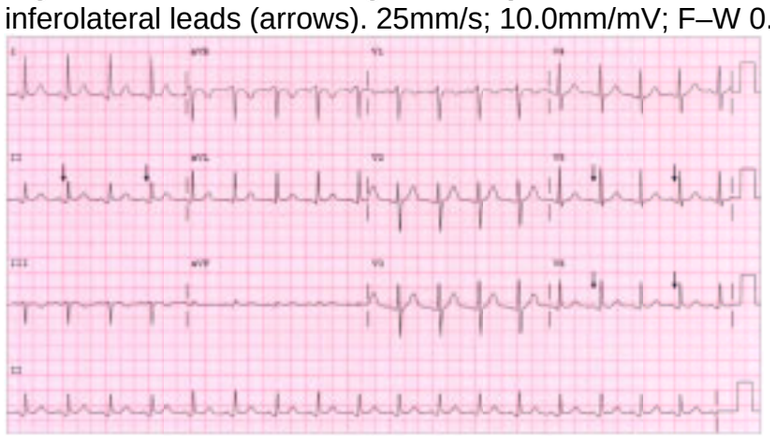

Figure 58-5 Chest CT of a patient who has a large crescent-shaped pericardial effusion.

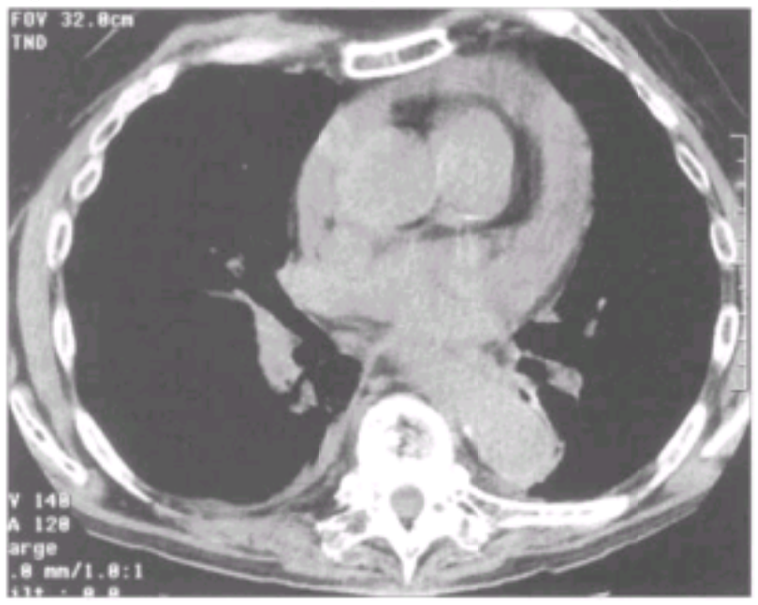

Figure 59-1 Scanning electron microscopy of a rabbit aortic valve leaflet. (a) A normal valve, covered by a monolayer of endothelial cells. (b) The meshwork of fibrin and platelets covering a damaged valve. Mechanical lesions of the valve were created by inserting a catheter through the right aortic carotid and across the aortic valve.

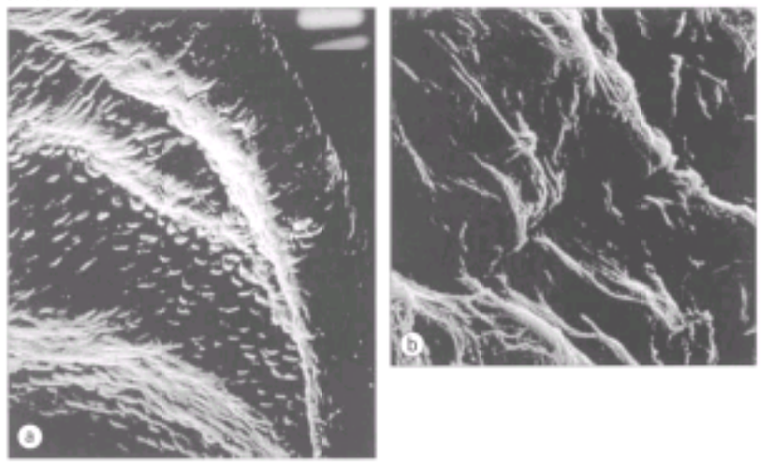

Figure 59-2 Colonization and infection of an endothelial lesion by *Staphylococcus aureus.* Exposure of the subendothelial matrix triggers the deposition of platelet-fibrin clots and other plasma-soluble and matrix proteins, including fibrinogen, fibrin, fibronectin and thrombospondin. Triggering of the coagulation cascade is also mediated by tissue factor, which contributes to platelet activation and the constitution of a nonbacterial thrombotic vegetation. *Staphylococcus aureus* is equipped with a wealth of surface determinants that may promote binding and colonization of nonbacterial thrombotic vegetations. The best known of these are fibrinogen-binding protein (or clumping factor), fibronectin-binding protein and coagulase. These factors are likely to mediate direct and/or indirect attachment to vascular lesions and promote infection.

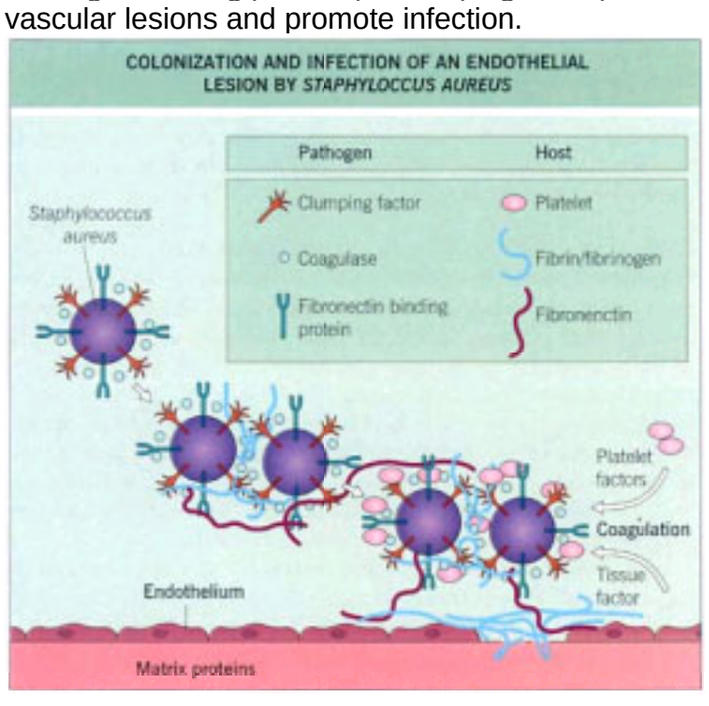

Figure 59-3 Microscopic appearance of a vegetation from a patient suffering mitral valve infective endocarditis due to *Streptococcus sanguis.* The purple area represents clusters of streptococci packed within a fibrin-platelet meshwork. Professional phagocytes are essentially absent from the lesion.

Figure 59-4 Transesophageal echocardiography of a mitral valve infective endocarditis. (a) Mass attached to anterior leaflet. (b) Prolapse of the leaflet due to rupture of chordae tendinae. The echo is from the patient shown in Figure 59.3 . Arrows indicate a large pediculated vegetation, which oscillates from the left ventricle to the left atrium during systole. *Courtesy of Dr X Jeanrenaud.*

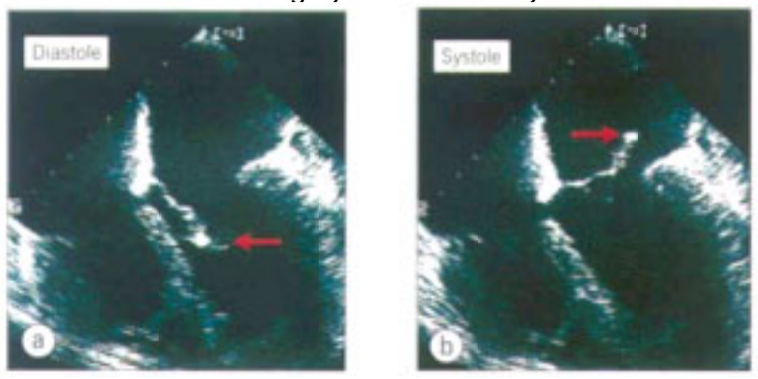

Figure 59-5 Aortic valve of a patient undergoing emergency valve replacement for acute endocarditis caused by *Staphylococcus aureus.* In this patient, emergency valve replacement was mandatory because of multiple embolizations and acute heart failure. Here, the aorta has been opened and the valve is viewed from its upper side. The lower tweezers are holding a valve leaflet covered with vegetations. Next to the upper tweezers, a portion of a cuspid with a normal appearance can be distinguished.

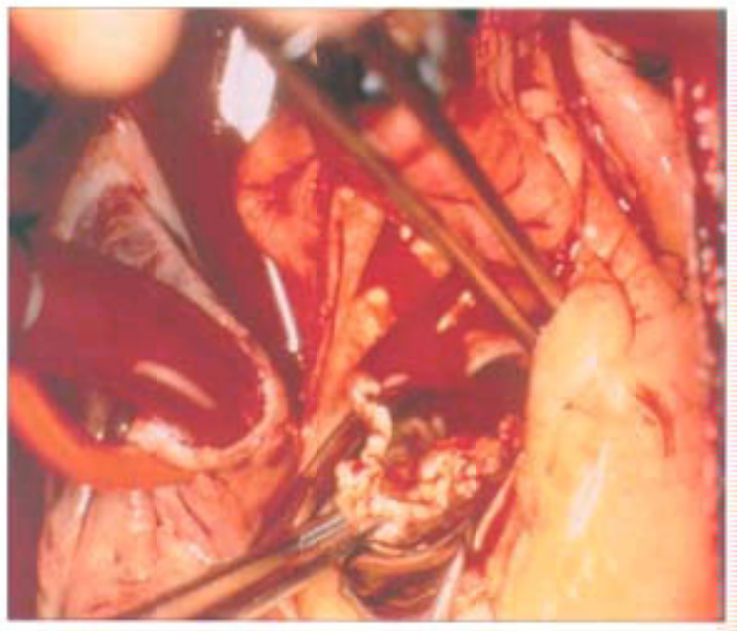

Figure 59-6 Skin lesions (Janeway spots) on the foot (a) and septic emboli of the retina (b), the results of peripheral emboli in acute endocarditis caused by *Staphylococcus aureus.* These occurred in the patient described in Figure 59.5 and were present on admission to hospital.

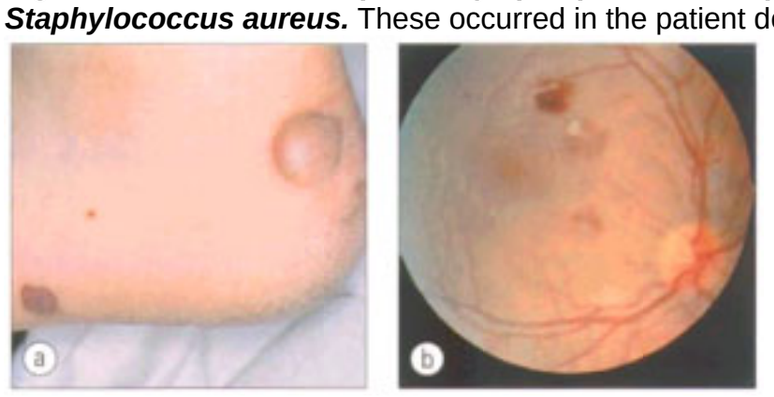

Figure 59-7 A cerebral abscess (a) and multiple abscesses and ischemic necroses of the spleen (b), the result of peripheral emboli in acute endocarditis cause by *Staphylococcus aureus.* Again these occurred in the patient described in Figure 59.5 ; they developed after admission to hospital.

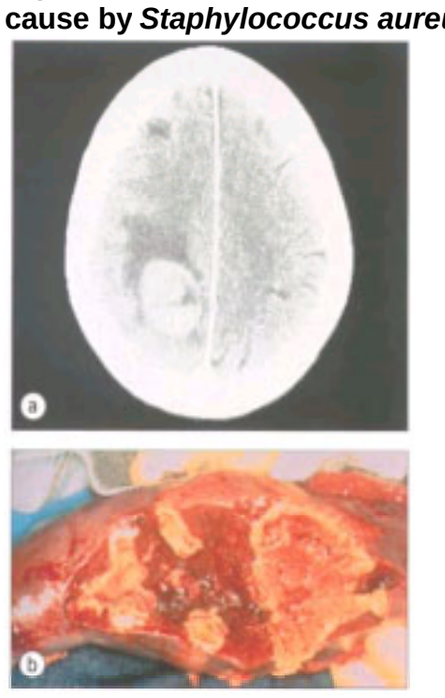

Figure 59-8 Osler node on the thumb during subacute endocarditis. This was a rounded, tender, inflamed mass about 5mm in diameter.

Figure 59-9 Blood culture-negative aortic valve endocarditis caused by *Tropheryma whippelii* in a 48-year-old patient. The patient was admitted to hospital for acute abdominal pain. Abdominal surgery revealed an ischemic necrosis of the transverse colon, presumably due to arterial embolization. An echocardiogram revealed exuberant vegetations on the aortic valve. All blood cultures were negative. Emergency valve replacement was performed for cardiac insufficiency. *Tropheryma whippelii* infection was identified by histology and by using broad-spectrum PCR amplification of the surgical material. The patient was treated with long-term (>1 year) trimethoprim-sulfamethoxazole (see Table 59.5). *With permission from Bugon and Moreillon.*[49]

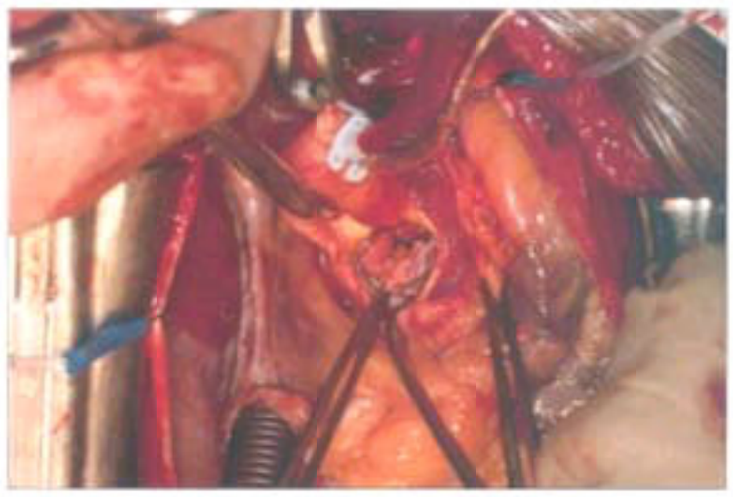

Figure 60-1 (a) Chest radiograph of a 15-year-old boy who had multiple recurrences of acute rheumatic fever, showing gross cardiac enlargement and failure. He had mitral regurgitation and stenosis, and aortic regurgitation and stenosis. He died 2 days after this radiograph was taken, of intractable cardiac failure. (b) Postmortem cardiac examination of the same boy, showing thickened, shortened mitral valve cusps with calcific vegetation and thickened chordae tendinae. *(Photographs kindly provided by Professor Bart Currie, Darwin, NT, Australia.)*

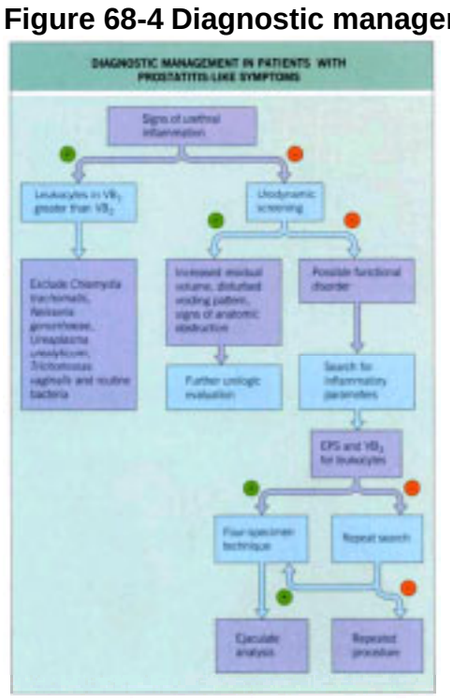

Figure 69-1 Uropathogenic strain of *Escherichia coli.* Note the typical virulence properties, including adhesive fimbriae, cytotoxins, lipopolysaccharide (LPS), capsular polysaccharide, the aerobactin system and outer membrane proteins important in serum resistance. Bacterial interactions with host cells trigger cytokine production, inflammatory cell infiltration and bacterial internalization within epithelial cells. Internalized bacteria can multiply intracellularly and stimulate sloughing, rupture, necrosis or apoptosis of host cells.

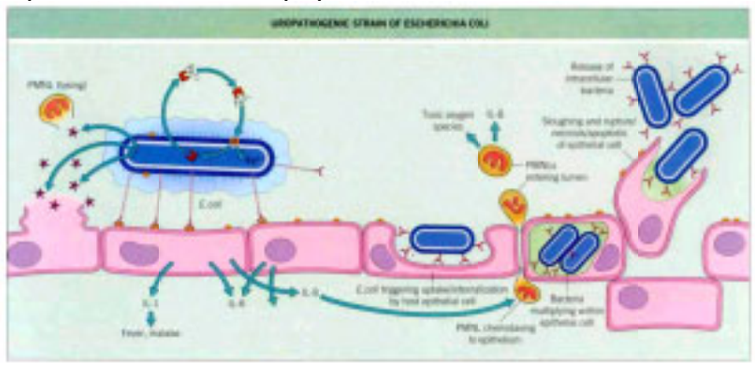

Figure 69-2 Acute pyelonephritis. Note interstitial edema, tubules packed with PMNLs and a diffuse interstitial acute inflammatory infiltrate in this autopsy specimen from a diabetic patient who had refractory *Escherichia coli* urosepsis.

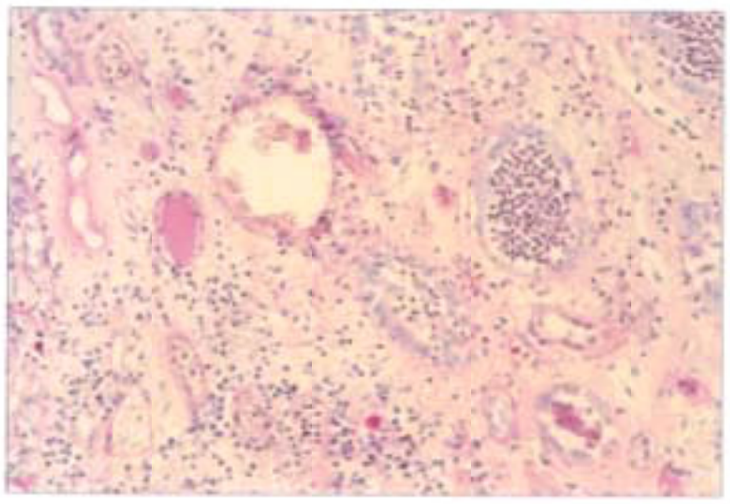

Figure 69-3 Emphysematous pyelonephritis. Cortical necrosis (solid arrow), diffuse cortical hemorrhage (open arrow) and dilatation of the collecting system (arrowheads) in a nephrectomy specimen from a diabetic patient who received combined medical/surgical therapy and survived emphysematous pyelonephritis due to an unusual pathogen, namely *Candida albicans*.

Figure 69-4 Acute papillary necrosis (arrows) in an autopsy specimen from a diabetic patient who died from refractory *Escherichia coli* urosepsis. Necrotic papillae (arrows) failed to take up formalin, so appear pink, in contrast to the grayish-tan formalinized tissue.

Figure 69-5 Febrile urinary tract infection with white blood cell count of 36,000/ml (girl, 3 years). (a) Precontrast CT scan: left kidney is diffusely swollen; parenchymal attenuation is the same as that of the right kidney. (b) Postcontrast CT scan: wedge-shaped regions of hypoenhancing parenchyma in the left kidney are most pronounced in the posterior portion. Inflamed parenchyma enhances from 32 to 93 Hounsfield units (HU), whereas normal kidney enhances from 33 to 140HU. The right kidney shows normal cortical enhancement and pronounced medullary blush. *With permission from Talner.*[45]

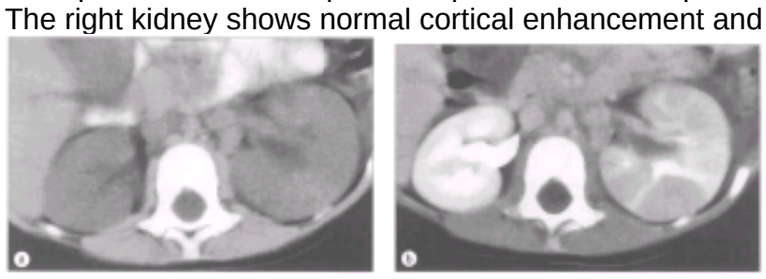

Figure 69-6 Woman with clinical signs of acute pyelonephritis. (a) Precontrast CT scan: focal bulge present in anterolateral aspect of left kidney. Attenuation is the same as that of normal kidney parenchyma. (b) Postcontrast CT scan: rounded and streaky regions of hypoenhancing parenchyma in the left kidney are most pronounced anterolaterally. Attenuation in the region of interest (cursor) was 22HU on precontrast scans and increased to 93HU on postcontrast scans. Normal parenchyma increased from 25–130HU. *With permission from Talner.*[45]

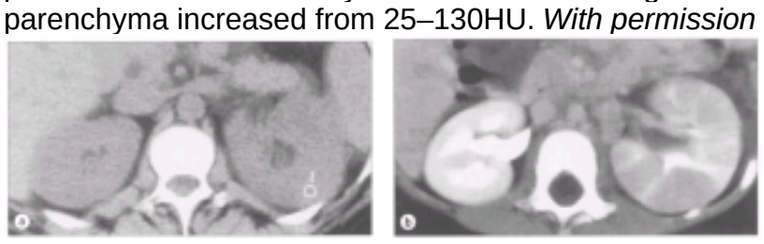

Figure 69-7 Acute pyelonephritis with small intrarenal abscess. (a) Precontrast CT scan shows small region of low attenuation (arrows). (b) On the postcontrast CT scan, the abscess (A) fails to enhance at all. Surrounding inflamed parenchyma bulges and enhances less than adjacent normal parenchyma. (c) Follow-up CT scan obtained after prolonged antibiotic therapy. The abscess has resolved without drainage. The focal swelling is gone but the parenchyma still shows hypoenhancement. *With permission from Talner.*[45]

Figure 69-8 Renal abscess perforating into subcapsular and perinephric spaces (woman, 29 years). (a) Postcontrast CT scan. Dumbbell-shaped nonenhancing region laterally in right kidney represents parenchymal abscess breaking through subcapsular and perinephric spaces. Note marked thickening of perinephric fascia posterolaterally. (b) CT section obtained caudal to (a). Note thickening of perinephric inflammation. At this level there is a small pararenal abscess pocket adjacent to the liver. *With permission from Talner.*[45]

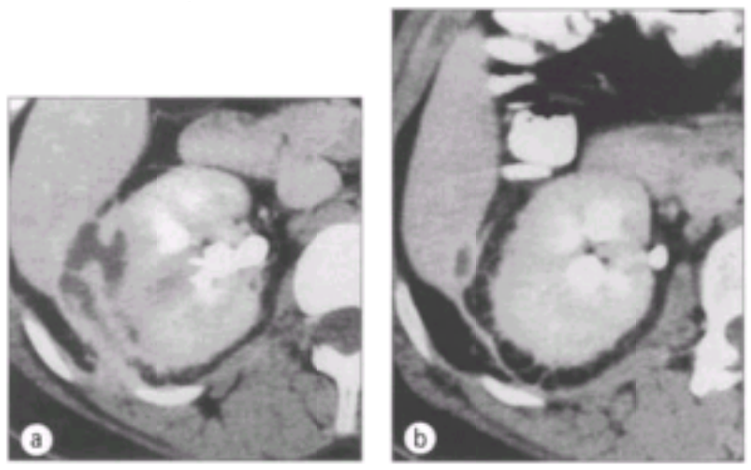

Figure 70-1 Nephrocalcinosis complicated by relapsing *Pseudomonas aeruginosa* infection. Plain film of the abdomen showing multiple bilateral renal stones. This 31-year-old woman has had recurrent stone formation since the age of 18 despite dietary manipulation and repeated lithotripsy. Urinary infection with *P. aeruginosa* was identified at 24 years of age with subsequent recurrent episodes of symptomatic upper tract infection. She has been maintained on suppressive ciprofloxacin therapy for years with control of symptomatic infection.

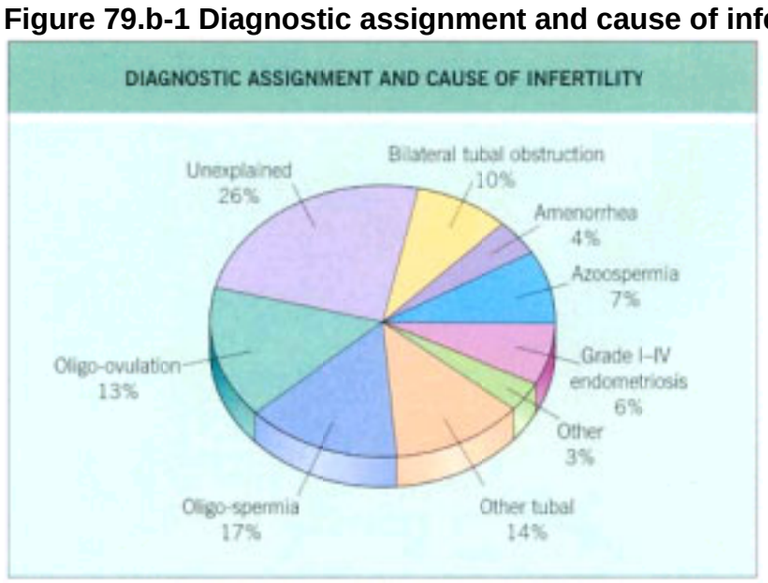

Figure 80-1 Distribution of baseline oral temperatures in healthy men and women. Frequency distribution of 700 baseline oral temperatures obtained during two consecutive days of observation in 148 healthy young volunteers. Arrow indicates location of 98.6°F (37°C). *With permission from Mackowiak et al.*[21] *Copyright 1992, American Medical Association.*

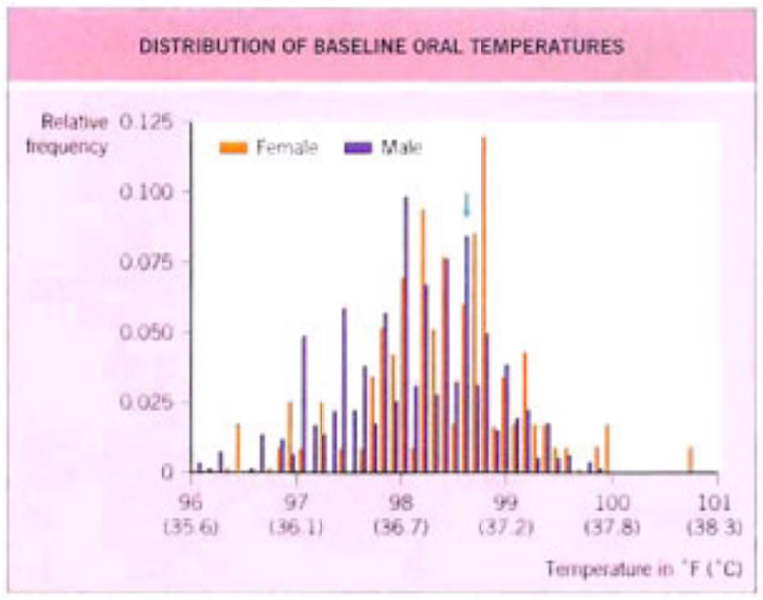

Figure 80-2 Sagittal view of the brain and upper spinal cord. The figure shows the multisynaptic pathway of skin and spinal thermoreceptors through the spinothalamic tract (STT) and reticular formation (RF) to the anterior hypothalamus, the preoptic region and the septum. *Redrawn with permission from Mackowiak.*[1]

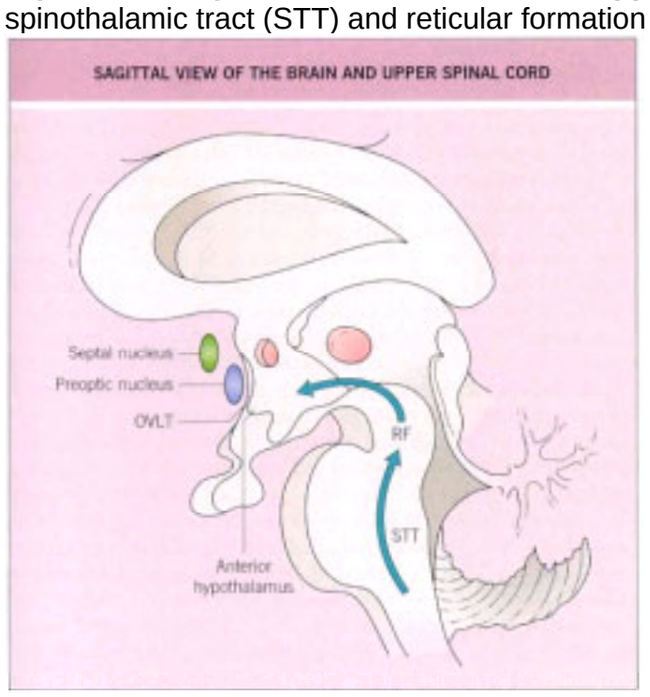

Figure 80-3 Events during fever and defervescence. When pyrogens are present in the preoptic region the whole body and neuronal responses are as shown by the purple lines. Upper: Normally the firing rates of warm-sensitive and temperature-insensitive neurons functionally overlap at 98.6°F (37°C), the set-point of thermoregulatory neurons. During pyrogen inhibition of warm-sensitive neurons this overlap occurs at the raised set-point of 102.2°F (39°C). Center: During fever, heat production is initially great but, as body temperature rises towards 102.2°F, heat production diminishes and should cease at 102.2°F. Lower: During fever initiation, shivering causes an increase in hypothalamic temperature and then ceases as the temperature reaches 102.2°F. During defervescence the hypothalamus activates heat loss responses such as sweating. *Adapted with permission from Boulant.*[23]

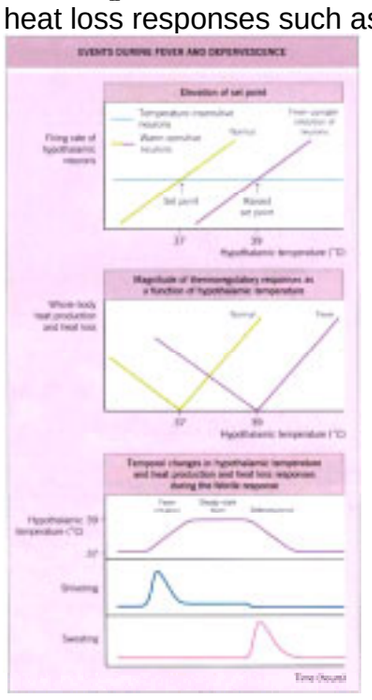

Figure 80-4 Production of fever. Microbial agents, inflammatory agents and some cytokines induce the synthesis and release of pyrogenic cytokines from a variety of cells. These cytokines, in turn, trigger specialized endothelial cells of the hypothalamic vascular organs, which release PGE_2 . Elevated PGE_2 then brings about increases in cyclic adenosine monophosphate (cAMP) monoamines and calcium in the thermoregulatory center of the anterior hypothalamus, resulting in a resetting of the thermostatic temperature from normothermia to febrile levels. These neurotransmitters then activate the vasomotor center, which brings about vasoconstriction (heat conservation) and increased heat production, both resulting in an increase in blood temperature (fever). Regardless of the cause of fever, antipyretics inhibit this pathway by preventing the increase in cytokine-mediated PGE_2 production in the hypothalamus. IFN, interferon.

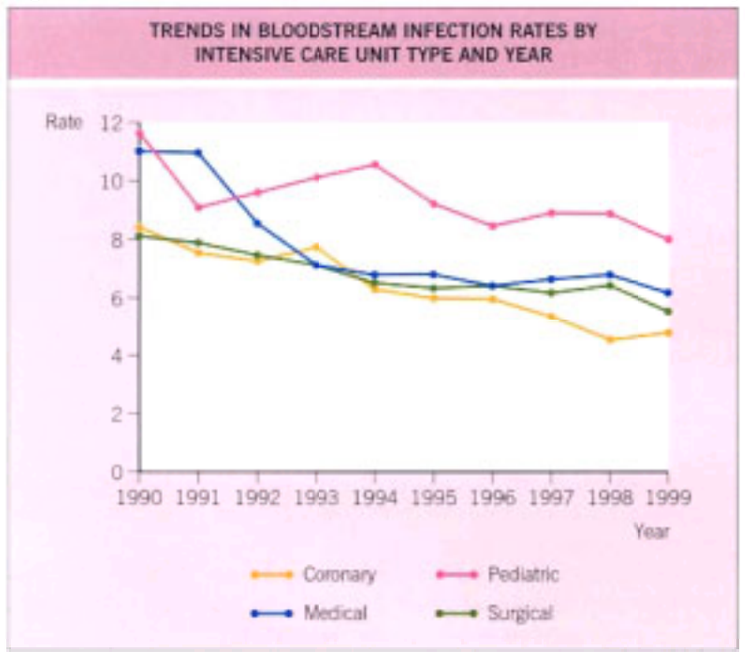

Figure 87-3 Endogenous and exogenous sources of hospital infection. Hospital infection can originate from an endogenous source or from an exogenous route. Endogenous infection may occur by translocation of resident microflora secondary to a breach in host defense (top). Exogenous infection may result from transmission from patient to patient or from health care worker to patient. It can also occur after exposure of a susceptible patient to a contaminated environmental source, such as inadequately disinfected medical devices (bottom).

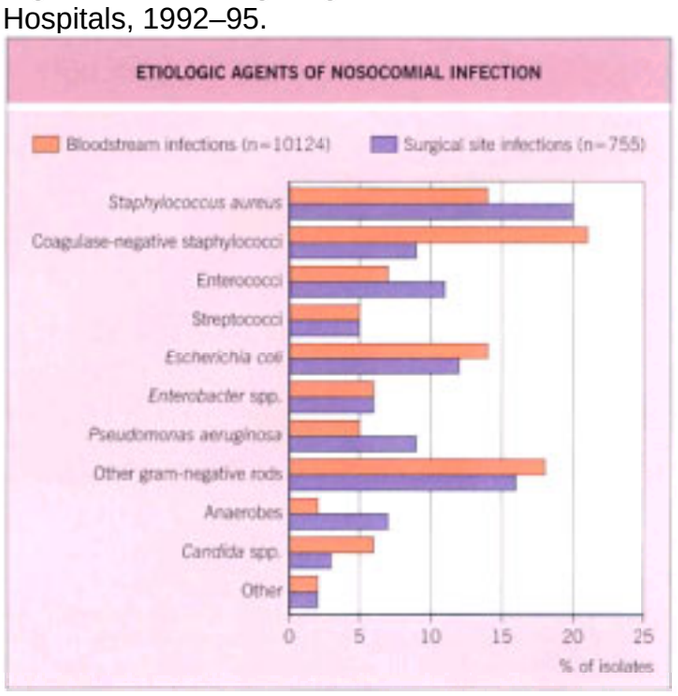

Figure 87-8 Selected antimicrobial resistant pathogens associated with nosocomial infections in intensive care unit patients. Comparison of resistance rates from January-December 2000 with 1995–99, NNIS Surveillance. CNS, coagulase-negative staphylococci; 3rd ceph, resistance to 3rd generation cephalosporins.

Figure 87-9 Demonstration of nosocomial transmission of a clone of methicillin-resistant *Staphylococcus aureus.* PFGE pattern of macrorestriction fragments cleaved with the rarely cutting enzyme *Sma I* of genomic DNA from MRSA. The same genotype (type D4) is found in isolates from 12 patients and 2 colonized health care staff, indicating that some members of staff may be involved in transmission in an intensive care unit department. Unrelated genotypes are also observed (B2–G1). Size marker, kb: kilobase pairs.

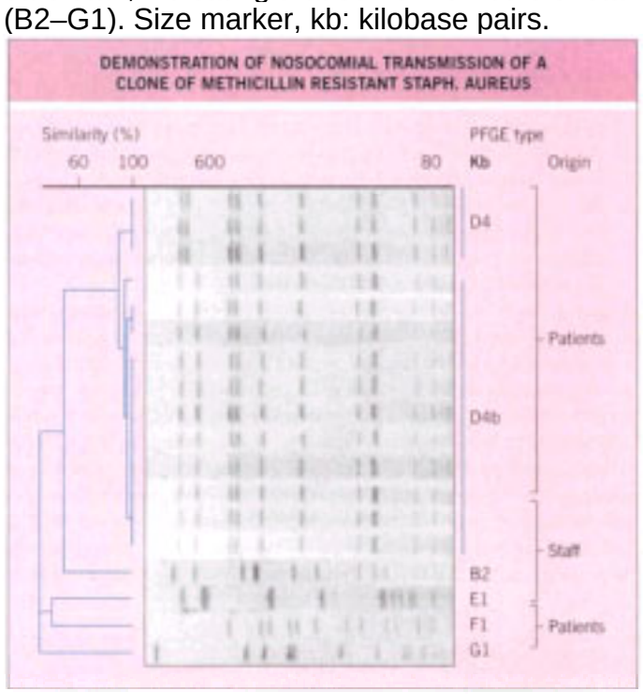

Figure 87-10 Restriction analysis of bacterial genome polymorphism. Chromosomal DNA is released after lysis of the bacterial cells. Restriction endonucleases that recognize commonly occurring sites will cut DNA in many small fragments. After conventional electrophoresis, these fragments are transferred onto a membrane and revealed by hybridization with labeled probes (Southern blot analysis). Alternatively, DNA can be restricted by endonucleases that recognize only rarely occurring sites. The few large, or macrorestriction, fragments are then separated by PFGE analysis.

Figure 96.f-1 Contact evaluation: circles of exposure. Circles are constructed based on length of time of exposure and intensity of exposure. The innermost circle represents the highest risk; individuals in this circle are the first priority for screening. Circles of risk are constructed with each having less exposure — and thus less risk — until the PPD conversion rate in a circle is equivalent to the prevalence of LTBI in the local population.

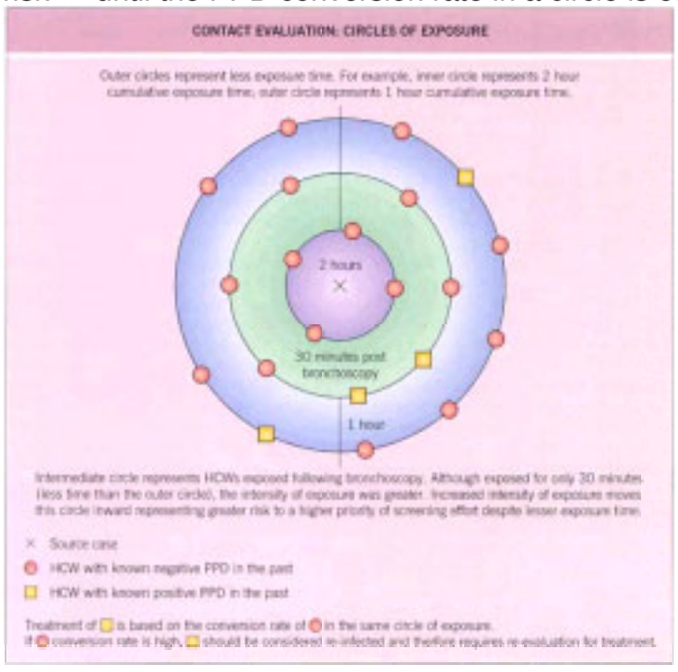

Figure 97-1 Toll-like receptors and identified ligands to date. The identified ligands that bind and signal via TLRs are shown here. Note that TLR2 and TLR6 combine to form a functional heterodimer to recognize peptidoglycan, and probably further combinations of TLRs will be identified, which will increase the diversity of ligands that are recognized. LAM, lipoarabinomannan.

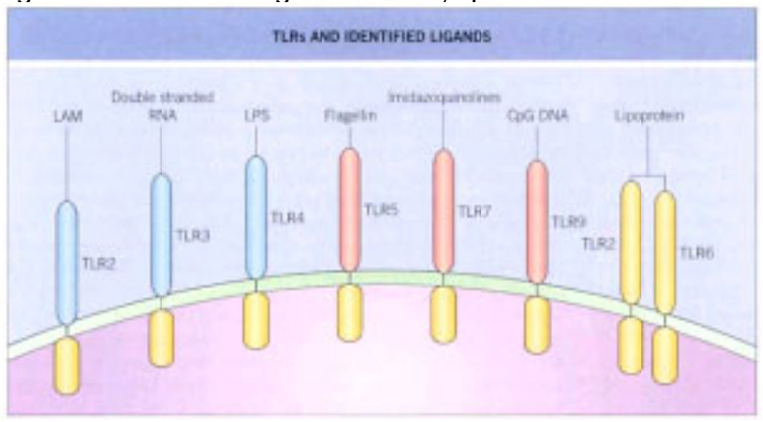

Figure 97-2 Pathways for the generation of the major antimicrobial effector mechanisms of macrophages. This shows the pathways for the generation of ROIs from NADPH oxidase, a process initiated by FcR cross-linking, or exposure of cells to IFN-?. Similar activation can also induce the production of RNIs from L-arginine, catalyzed by inducible nitric oxide synthase (iNOS). Also listed are various examples of bacterial genes or gene products that are known to counteract components of these pathways.

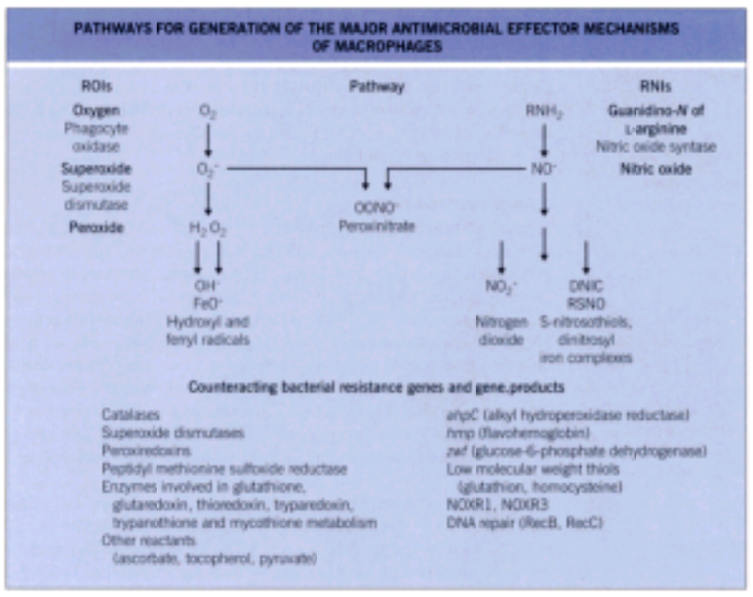

Figure 97-3 Pathways of antigen processing for activation of T-cell subsets. (a) CD4 T cells: within the APCs secreted or somatic antigens are digested by vacuolar proteases, which generate peptides of 15–22 amino acids in length — these peptides are loaded onto major histocompatibility complex (MHC) class II molecules in a specialized compartment before being transported to the cell surface. (b) CD8 T cells: endogenous antigens are cleaved in the cytoplasm by the proteasome to generate peptides of a final length of 8–9 amino acids — these are loaded onto MHC class I molecules in the endoplasmic reticulum (ER) and transported to the cell surface in association with ß$_2$ -microglobulin (ß$_2$ m). (c) CD1-restricted T cells: glycolipid antigens are presented by CD1 molecules on the surface of APC. Recent observations suggest that some processing events are required that involve components of the MHC class II pathway, but that antigen is loaded onto CD1 in the ER, similar to the MHC class I. (d) ?d T cells: to date no processing event or presentation molecule has been identified, but there is some suggestion that the nonpolymorphic Qa-1 molecule can function in antigen presentation. CTL, cytotoxic T lymphocyte; TAP, transporter associated with antigen processing.

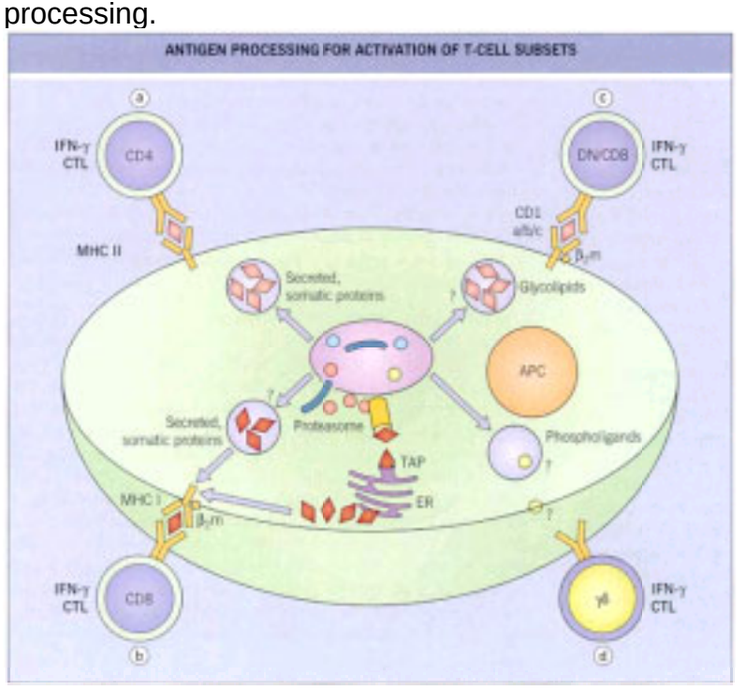

Figure 97-4 Differentiation of CD4 T-helper cell subsets and their effector functions in infection. Under the influence of cytokines produced by dendritic cells (DC) and NK cells, Th0 cells differentiate into Th1 cells (promoted by IL-12 and IL-18) or Th2 cells (promoted by IL-4). These differentiated T cells produce a characteristic pattern of cytokines, which perform various effector functions to eliminate pathogens. The major cytokine produced by Th1 cells is IFN-?, which promotes macrophage activation, critical in the elimination of intracellular pathogens. Th2 cells produce IL-4 and IL-5, which are critical for B-cell maturation and immunoglobulin class switching and hence are important in the control of helminths and extracellular pathogens. Note that via the production of these cytokines, each subset of Th cells can downregulate the differentiation of the other. DC1, myeloid dendritic cells derived from $CD14^+$ monocytes, which produce mainly IL-12; DC2, lymphoid dendritic cells derived from $CD4^+$ precursors, which produce mainly IL-4.

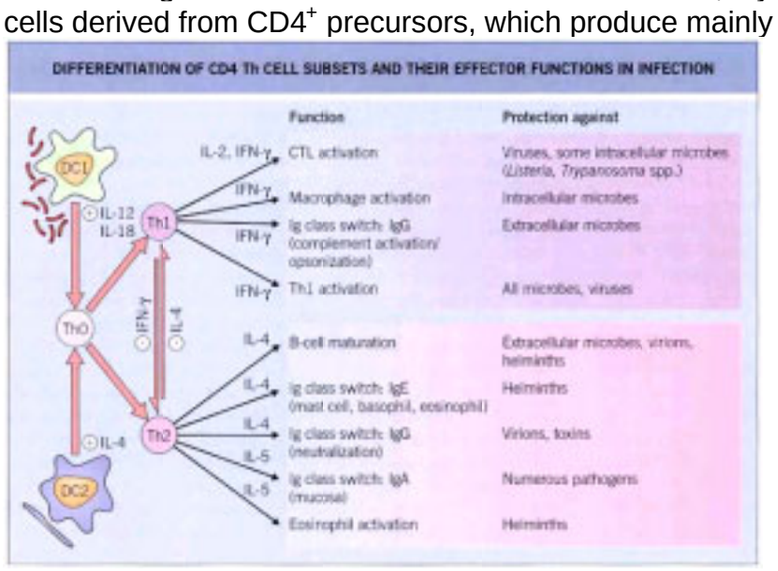

Figure 97-5 Kinetics of the immune response and the cell populations involved. Summary of the kinetics of the immune response to infection, from the recognition of microbial agents that initiates events, through to the generation of an effector T-cell response. The effector cytokines have been colored red for inhibitory and green for stimulatory.

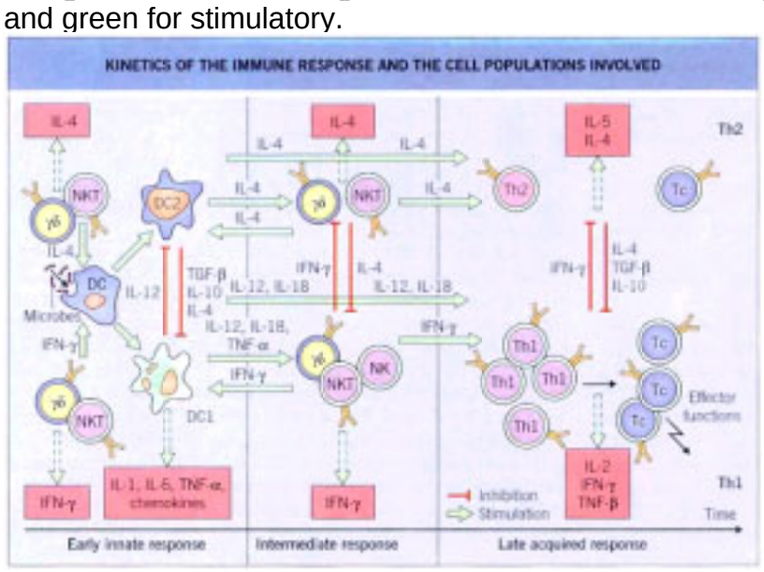

Figure 98-1 Neutrophil granules. Neutrophils contain primary, secondary and tertiary granules, each of which has specific contents that are produced at different points in myeloid ontogeny. The larger, azurophilic primary granules contain a host of proteins, only some of which are listed here. Note that secondary granule deficiency affects both all secondary granule contents as well as the primary granule defensins. Primary granules fuse in Chediak-Higashi syndrome, along with a smaller number of secondary granules, to give the characteristic cell inclusions.

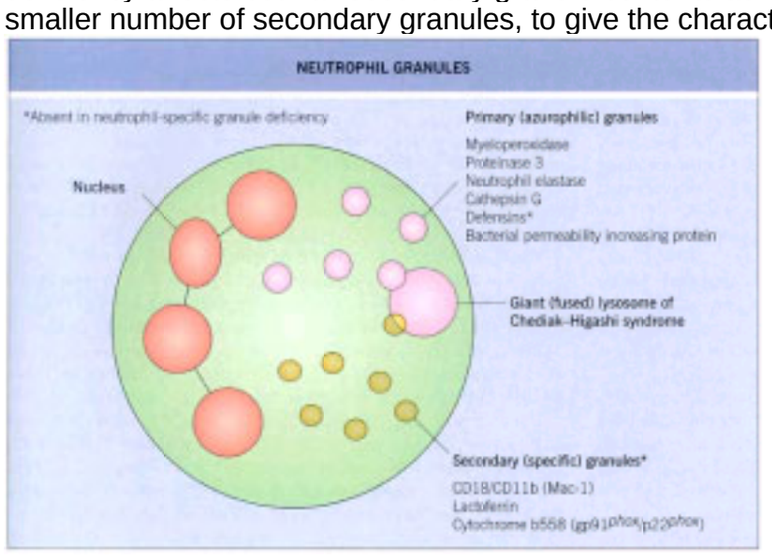

Figure 98-2 The NADPH oxidase. Cellular activation leads to assembly of the nascent NADPH oxidase by joining of secondary granule membrane and cytosolic components. The generation of an intravacuolar charge is rectified by potassium influx, which in turn liberates neutrophil elastase (NE) and cathepsin G (CG) from their associated matrix (**). As classically conceived, an ingested organism is shown degrading its own hydrogen peroxide, thus eliminating a supplement to the defective metabolic pathway in CGD. However, the pathologic relevance of the role of catalase in bacterial or fungal virulence is unclear.

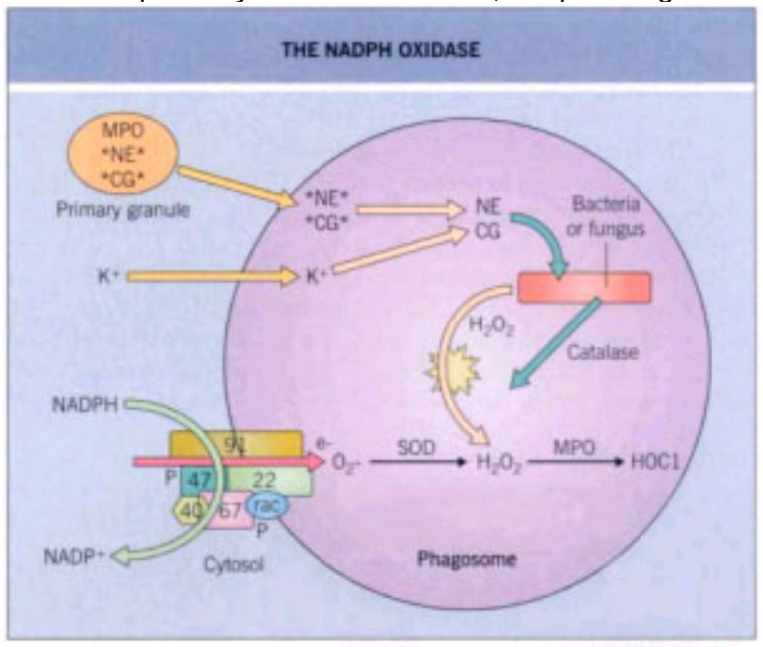

Figure 98-3 Manifestations of chronic granulomatous disease. (a) Pneumonia due to *Aspergillus* spp. can present subtly, both clinically and radiographically. This patient was asymptomatic but had multifocal pneumonia due to *Aspergillus fumigatus*. (b) Wound dehiscence typically presents 5–10 days postoperatively. It is an exuberant granulation tissue on biopsy and is best treated with short courses of corticosteroids. (c and d) Liver abscesses due to staphylococci are quite common in CGD ((c) arrow) and typically require *en bloc* resection because of their dense, granulomatous nature (d).

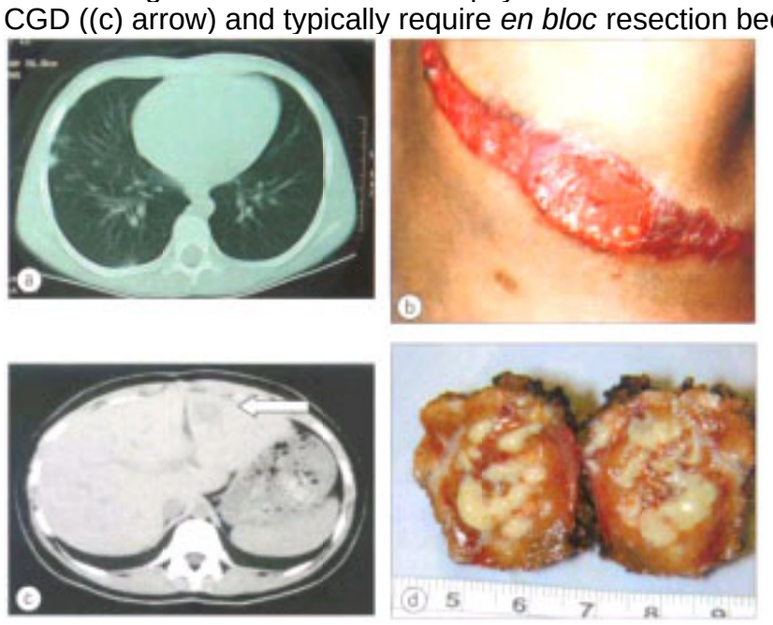

Figure 98-4 Leukocyte adhesion. Neutrophils sample the endothelium in the postcapillary venules through a series of receptors. Depicted here are the selectin and integrin pathways, which are critical for neutrophil adhesion (monocytes and eosinophils have other ligand and receptor options). CD15s binds to selectins on the endothelium with loose adhesion, allowing closer sampling of the endothelium for tight adhesion in the setting of endothelial activation, mediated through the integrins. Neutrophil integrins bind to intercellular adhesion molecules (ICAMs).

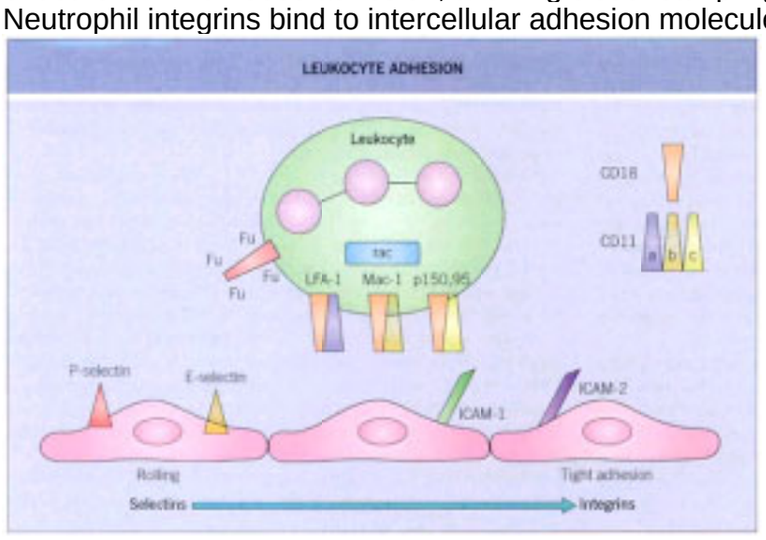

Figure 98-5 Examples of leukocyte adhesion deficiency type 1. (a) A biopsy from the bowel of a patient with extensive inflammation and intestinal ulceration. Note the abundance of neutrophils intravascularly (arrow) but the paucity of neutrophils in the parenchyma. (b) Characteristic dystrophic or 'cigarette paper' scarring following skin ulceration in a boy who has LAD1.

Figure 98-6 Critical cytokine pathways in the control of mycobacteria. Mycobacteria and salmonellae stimulate the elaboration of IL-12 by infected macrophages, leading to the production of IFN-? by T cells and NK cells. IFN-? in turn stimulates macrophages to produce TNF-a and IL-12. The critical signaling molecules STAT1 and NEMO are also indicated. IL-12-independent pathways for IFN-? production are also indicated (IL-15, IL-18), which work in concert with IL-12 for lymphocyte stimulation. Other, as yet undefined pathways are also suggested.

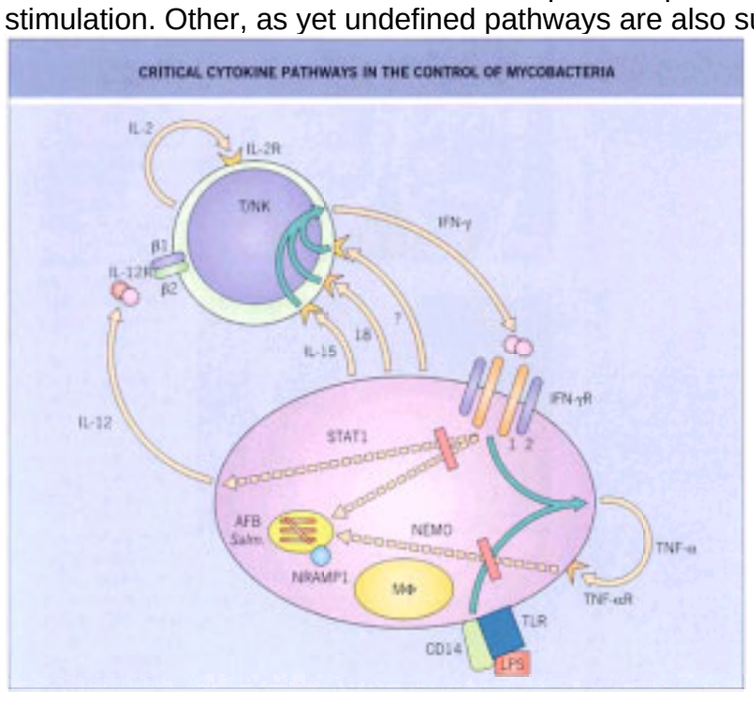

Figure 98-7 In-vitro and clinical aspects of IFN-?R1 deficiency. (a–c) Flow cytometry for the IFN-?R1 on peripheral blood monocytes. Dotted lines indicate the background fluorescence of the sample with an irrelevant antibody. (a) Normal IFN-?R1 fluorescence intensity. (b) Monocytes from a child who has complete IFN-?R1 deficiency. Note the lack of specific staining for IFN-?R1. (c) Increased intensity of IFN-?R1 staining on monocytes from a patient who has MAC osteomyelitis. (d) Chest radiograph from the same patient showing extensive right lung infection with MAC. (e) The corresponding magnetic resonance image of his distal femora (arrow indicates the infected lesion).

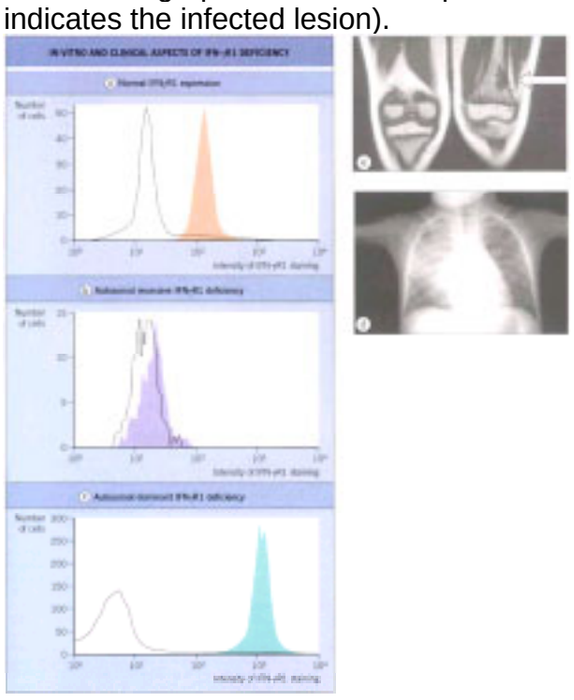

Figure 98-8 Clinical manifestations of hyper-IgE (Job's) syndrome. (a) Computerized tomogram of the chest showing characteristic postinflammatory pneumatocele formation. Note the development of bilateral aspergillomata with inflammation of the cavity walls. (b) A panoramic radiograph of the dentition of a 33-year-old woman who has HIES shows the characteristic retention of primary teeth due to failure of deciduation. (c) Extensive scoliosis is demonstrated in this radionuclide bone scan of a 25-year-old woman who has HIES. A list of some of the characteristic features of the syndrome is included in Table 98.2 .

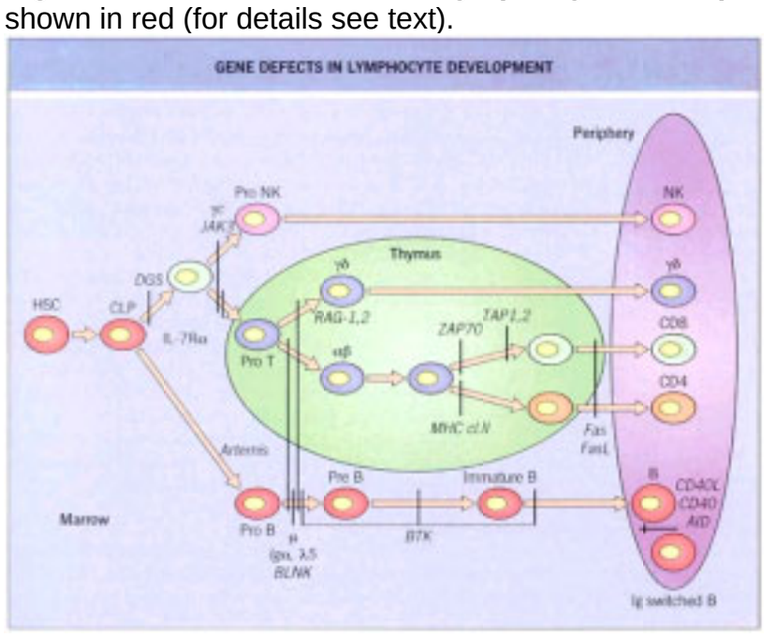

Figure 98-14 Receptors using the ? chain/JAK3 pathway. The six interleukin receptors that use the common ? chain/JAK3 pathway for signaling.

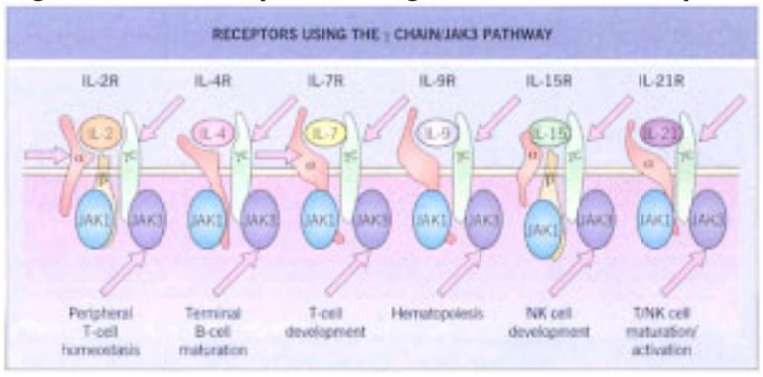

Figure 98-15 ?**c/JAK3/STAT signaling.** ?c/JAK3/STAT signaling is initiated by binding of the cytokine to its receptor. Heterodimerization (1) of the receptor chains (one IL-specific chain and the ?c) allows for reciprocal tyrosine phosphorylation (2a) of JAK3 and other JAK molecules, leading to their activation. Activated JAKs then phosphorylate (2b) tyrosine residues on both receptor subunits, creating docking sites for the STATs. These signaling elements are themselves tyrosine phosphorylated by the JAKs (2c), in order to dimerize and translocate to the nucleus (3), where they bind to consensus sequences within regulatory regions of cytokine-inducible genes and act as transcription factors driving transcription of the target genes.

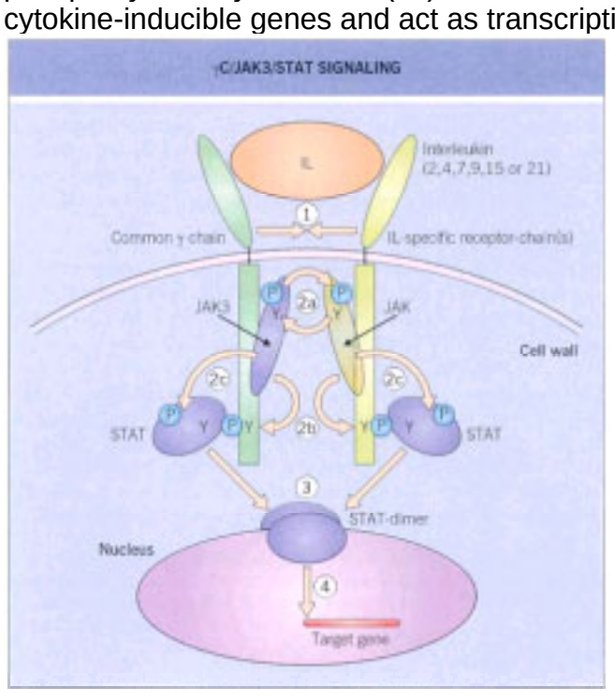

Figure 98-16 V(D)J recombination process. Diagram showing the V(D)J recombination process with the genes involved in T^- B^- SCID and Omenn syndrome.

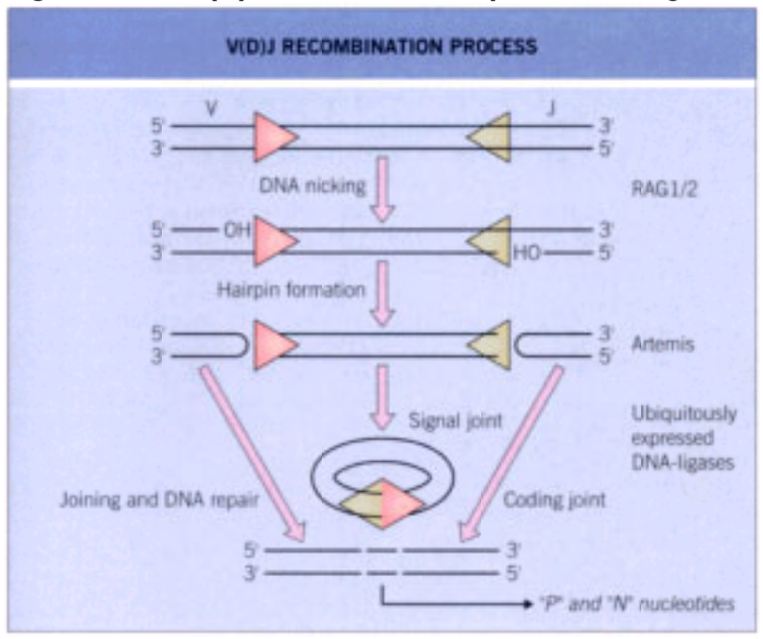

Figure 98-17 A baby who has Omenn syndrome. Note the diffuse erythema.

Figure 98-18 T cell receptor signaling. Stimulation of T cells through the CD3/TCR complex results in activation of p56lck, a src-tyrosine kinase, that mediates tyrosine-phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) in the CD3-?, -d, -epsilon and -? chains. ZAP-70, an intracellular tyrosine kinase, is then recruited into the CD3/TCR complex through binding of its SH2 domains to phosphorylated ITAMs of the ? chain. ZAP-70 itself becomes phosphorylated by Src-family protein tyrosine kinases. Phosphorylation triggers ZAP-70 activation, allowing phosphorylation of downstream signaling molecules such as linker for activation of T cells (LAT) and SLP-76.

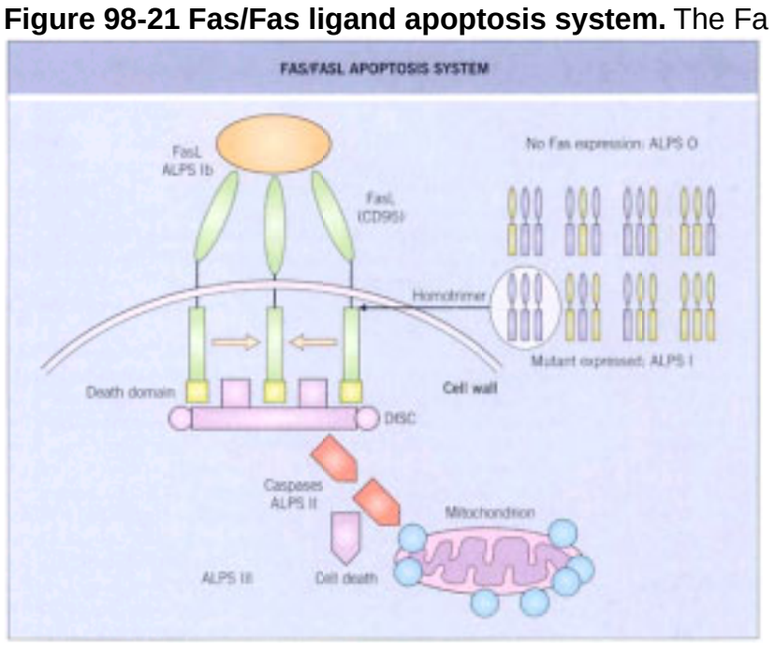

Figure 99-1 Mechanism of action of the different immunosuppressive agents currently in use in clinical practice.

Figure 99-2 Mechanism of action of ciclosporin A. Ciclosporin A inhibits T-cell activation by interfering with calcineurin. It is a lipophilic undecapeptide reversible inhibitor of T-cell activation that acts by interfering with calcineurin. The T-cell receptor induces signaling through an elevation in concentration of Ca^{2+} in the cytoplasm. This activates the transcription factor AP-1. The Ca^{2+} binds to calcineurin, which in turn dephosphorylates the cytoplasmic form of NFAT. Then NFAT migrates into the nucleus and forms a complex with AP-1. This complex can induce the transcription of genes required for T-cell activation including IL-2. In the presence of CsA a complex forms with cyclophilin (Cyp). The CsA-Cyp complex can bind to calcineurin, blocking its ability to activate NFAT, and therefore inhibiting T-cell activation.

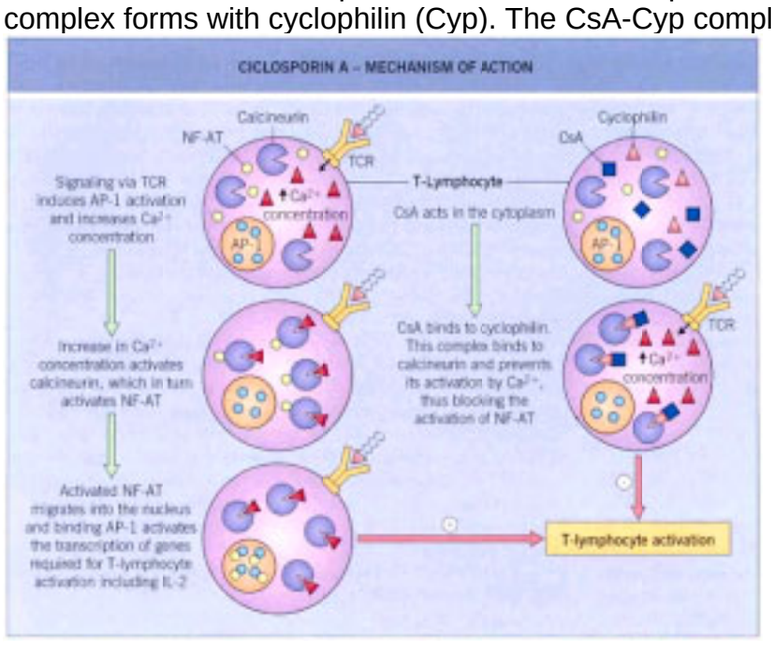

Figure 99-3 Mechanism of inhibition of purine synthesis by mycophenolic acid. MPA inhibits inosine monophosphate dehydrogenase (IMPDH) and leads to the depletion of guanosine nucleotides. PRPP, 5-phosphoribosyl-1(a)-pyrophosphate; ribose-5P, D-ribose-5'-phosphate.

Injection of radiographic contrast material (black arrow) demonstrates the pancreatic duct (arrowhead) in communication with the pancreatic pseudocyst.

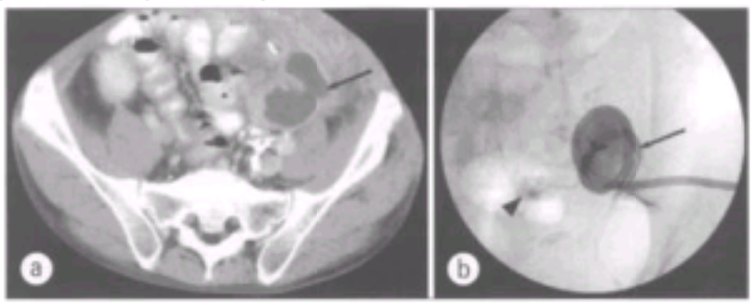

Figure 106-4 Algorithm for evaluating enterically drained pancreas transplant patients with abdominal pain.

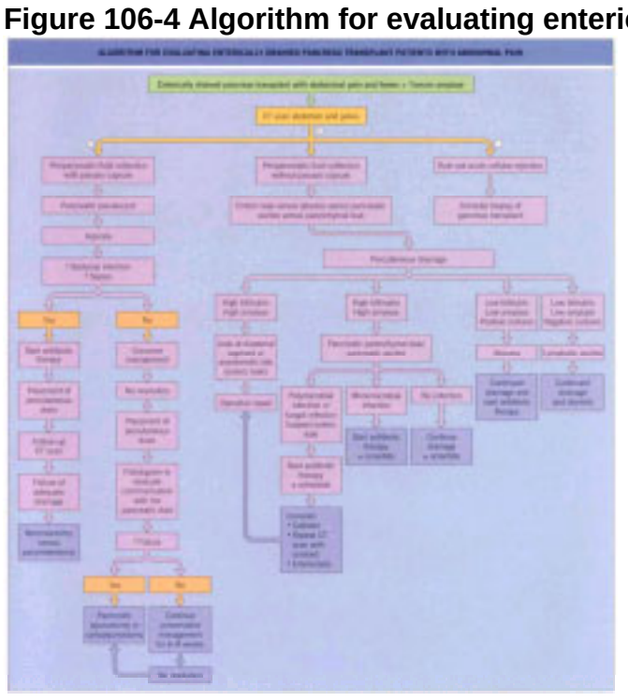

Figure 108-1 A large necrotizing lesion caused by herpes simplex type-1 in a patient who has a teratoma. Herpetic stomatitis is common in immunosuppressed patients and is often atypical; any ulcerating lesion in the perioral region should be considered to be herpetic until proved otherwise.

Figure 108-2 Extensive dermatophyte infection in a bone marrow transplant recipient. Many other infections (and graft-versus-host disease) can give a similar appearance but the diagnosis is quickly established by biopsy and microscopy. This condition is limited to the skin but nevertheless requires systemic antifungal therapy.

Figure 108-3 Extensive skin lesions caused by *Mycobacterium chelonae* in a patient who had polyarteritis nodosa. The lesions were palpable but not especially painful.

Figure 109-1 Normal splenic architecture in the adult human. PLS, periarterial lymphatic sheath; PA, penicillary arteriole; MZ, marginal zone (B lymphocytes predominate); WP, white pulp (T cells predominate); RP, red pulp (vascular cords and venous sinuses). Hematoxylin and eosin stain.

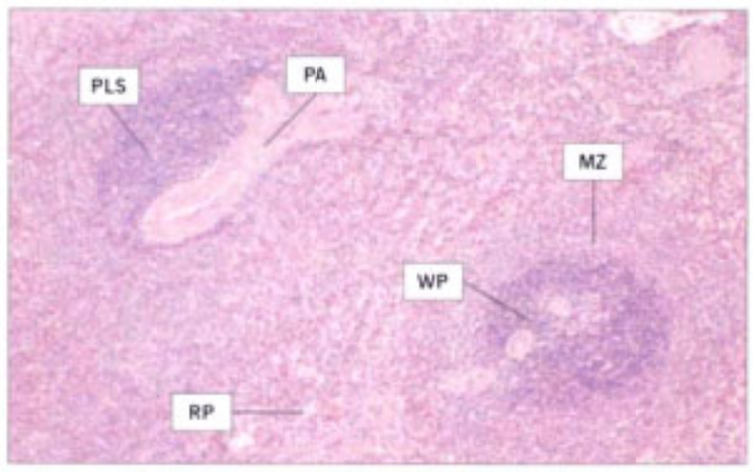

Figure 109-2 Peripheral blood smear of a patient who has pneumococcal sepsis and meningitis. Note polymorphonuclear leukocyte with several bacterial diplococci in the cytoplasm. Wright stain.

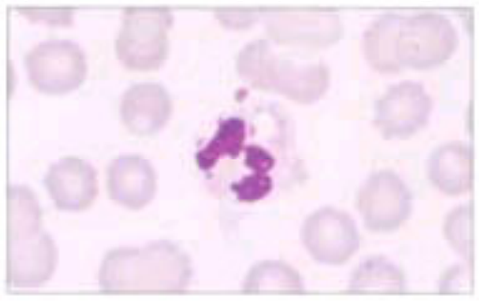

Figure 109-3 Gram stain of cerebrospinal fluid of a patient who has pneumococcal meningitis. Note numerous Gram-positive cocci in pairs and a single lymphocyte.

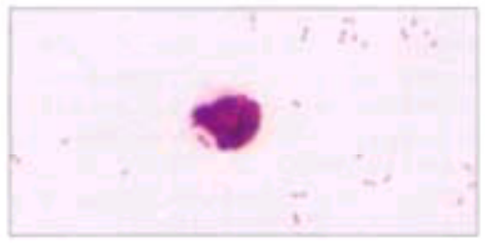

Figure 111-1 A T2-weighted MRI of the liver in a 24-year-old woman being treated for lymphoma who has chronic disseminated (hepatosplenic) candidiasis. The hepatic lesions are central densities surrounded by zones of lower signal intensity which create a 'bull's eye' appearance. Smaller lesions are also visible in the spleen, particularly in the subcapsular region.

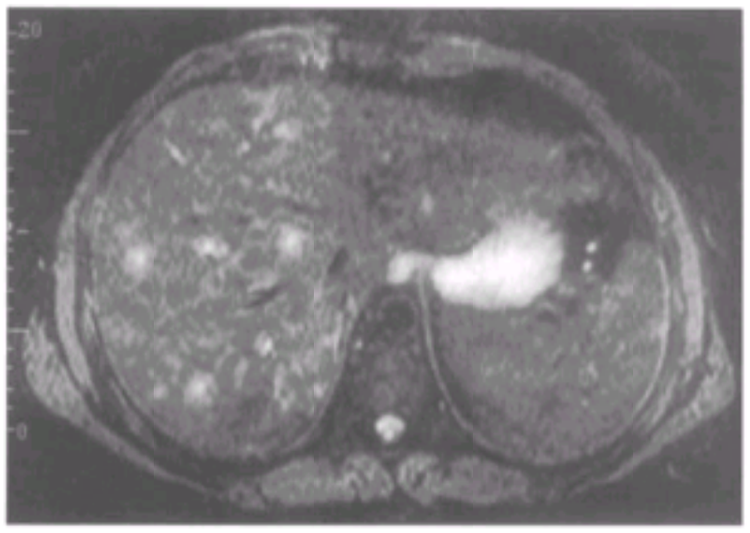

Figure 111-2 Aspergillosis. (a and b) A chest radiograph to evaluate persistent neutropenic fever in a patient with relapsed leukemia showed subtle increased markings in the right lower lung. (c) A chest CT scan obtained the same day showed a significant area of consolidation not apparent on the chest radiograph. Bronchoalveolar lavage grew *Aspergillus fumigatus*. This case illustrates the appropriate use of a chest CT scan in patients with persistent neutropenic fever at high risk for invasive mold infection. (d) Invasive pulmonary aspergillosis in another patient showing necrosis and invasive hyphae (Gomori methenamine silver).

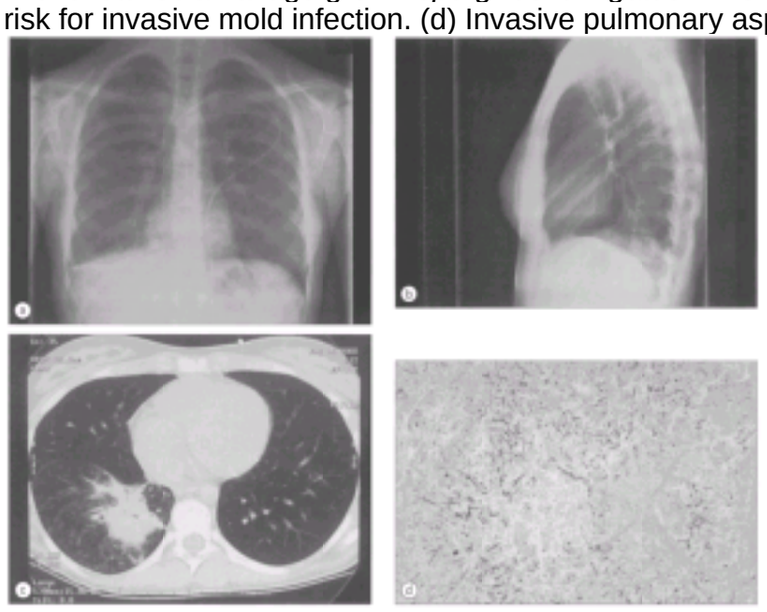

Figure 112-1 Hemorrhagic labial HSV lesions in a patient with leukemia and chemotherapy-induced thrombocytopenia. Diagnosis of HSV disease may be difficult and needs confirmation by virus culture or PCR.

Figure 112-2 Aciclovir-resistant perineal ulcerative HSV lesions after allogeneic SCT.

Figure 112-3 Mechanisms of HSV and VZV resistance to antiviral drugs. Most cases of HSV and VZV resistance are due to mutations in the gene of the virus-encoded thymidine kinase, which result in a reduced or abrogated conversion of aciclovir to aciclovir monophosphate. This leads to low or absent levels of aciclovir triphosphate, the active metabolite that inhibits the viral DNA polymerase and acts as DNA chain terminator. Viral replication may then occur despite aciclovir therapy. Foscarnet and cidofovir do not require viral thymidine kinase-dependent intracellular activation. Resistance to these two drugs may occur if HSV or VZV resistance is caused by mutations in the viral DNA polymerase gene *(adapted from*[8] *)*.

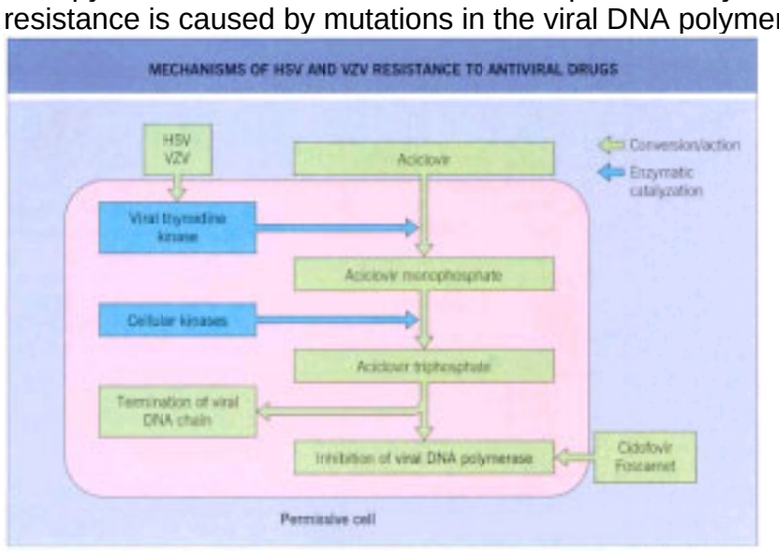

Figure 112-4 (a,b) **Disseminated cutaneous lesions in a patient with chronic lymphocytic leukemia who developed fatal varicella despite rapid initiation of intravenous aciclovir therapy.** Varicella lesions are numerous and hemorrhagic.

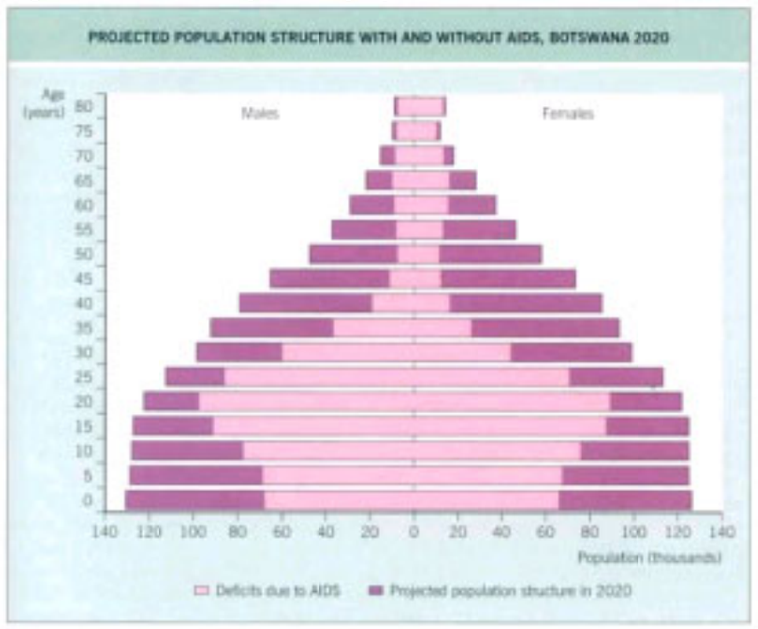

Figure 116-1 Approaches to preventing HIV transmission.

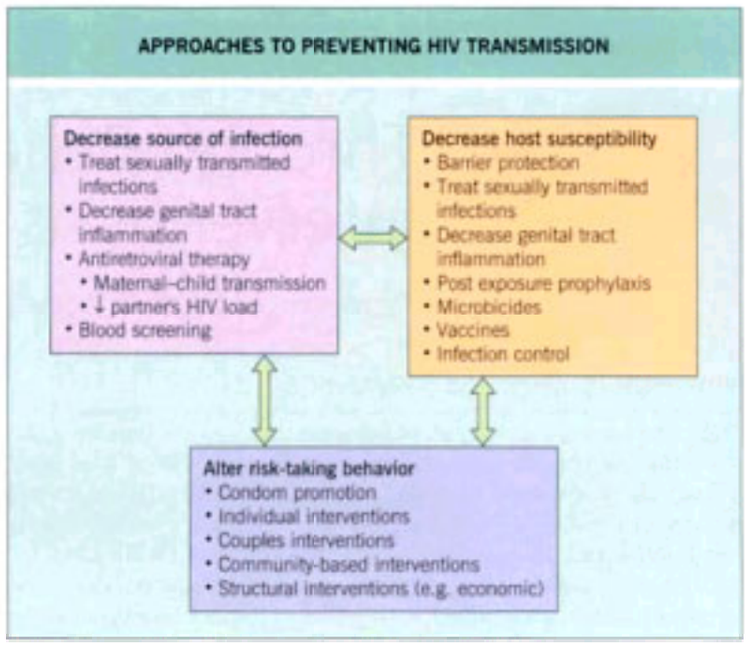

Figure 118-1 Two newer methods for studying responses to HIV vaccines. (a) and (b) are representative negative and positive wells (respectively) from an interferon-? (IFN-?) ELISPOT assay. Mononuclear cells are separated from blood, placed in wells coated with antibody against IFN-?, and stimulated overnight with (b) or without (a) peptides from the antigen of interest. On stimulation, antigen-specific T cells release IFN-?; the captured IFN-? is stained using a second antibody with an enzymatic tag to develop a color change, much like a conventional ELISA test. A colored spot appears for each cell producing IFN-?. The lower panels are representative of the result from a cytokine flow cytometry (CFC) assay. Whole blood from an HIV^{+} patient is cultured without (c) or with (d) peptides from the HIV *gag* gene in the presence of an inhibitor of Golgi secretion. Newly synthesized cytokine within the cells, in addition to cell surface markers, are then stained using fluorescently labeled antibodies and analyzed on a fluorescence activated cell sorter (FACS). The cells in (c) and (d) have been labeled for CD3 (general T-cell marker), CD4 (helper class of T cells) and CD69 (activation marker); they are also permeabilized and stained to reveal intracellular IFN-?. The cells staining for CD3 but not CD4 (i.e. CD8 or effector T cells) were selected using automated software. The upper right quadrant indicates which of the CD8 cells are newly activated (CD69 positive) and producing IFN-?.

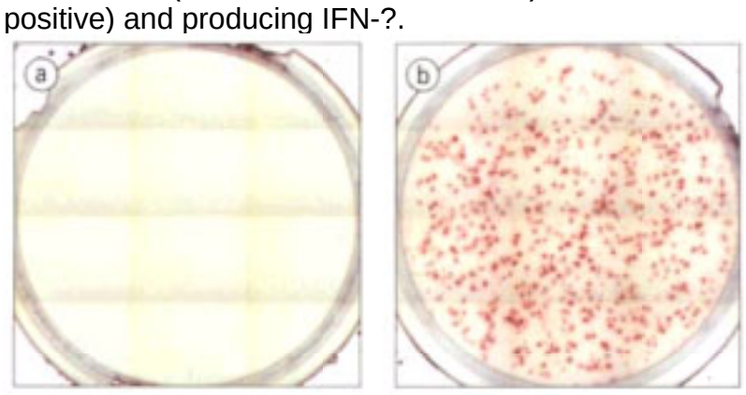

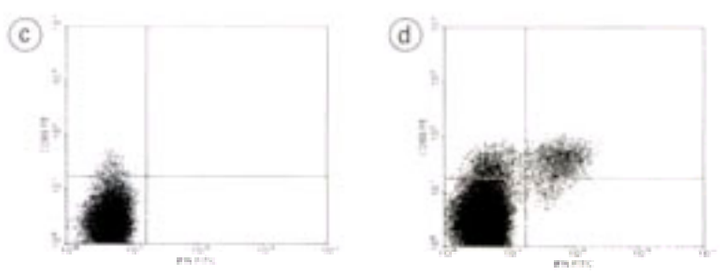

Figure 120-1 Kinetics of viral load and immune response during the phases of HIV-1 infection. After HIV-1 exposure, initial virus replication and spread occur in the lymphoid organs, and systemic dissemination of HIV-1 is reflected by the peak of plasma viremia. A clinical syndrome of varying severity is associated with this phase of primary HIV-1 infection in up to 70% of HIV-1-infected persons. Downregulation of viremia during the transition from the primary to the early chronic phase coincides with the appearance of HIV-1-specific cytotoxic T cells and with the progressive resolution of the clinical syndrome. The long phase of clinical latency is associated with active virus replication, particularly in the lymphoid tissue. During the clinically latent period, $CD4^+$ T cell counts slowly decrease, as does the HIV-1-specific immune response. When $CD4^+$ T cell counts decrease below H 200 cells/µl (i.e. when overt AIDS occurs), the clinical picture is characterized by severe constitutional symptoms and by the possible development of opportunistic infections and/or neoplasms.

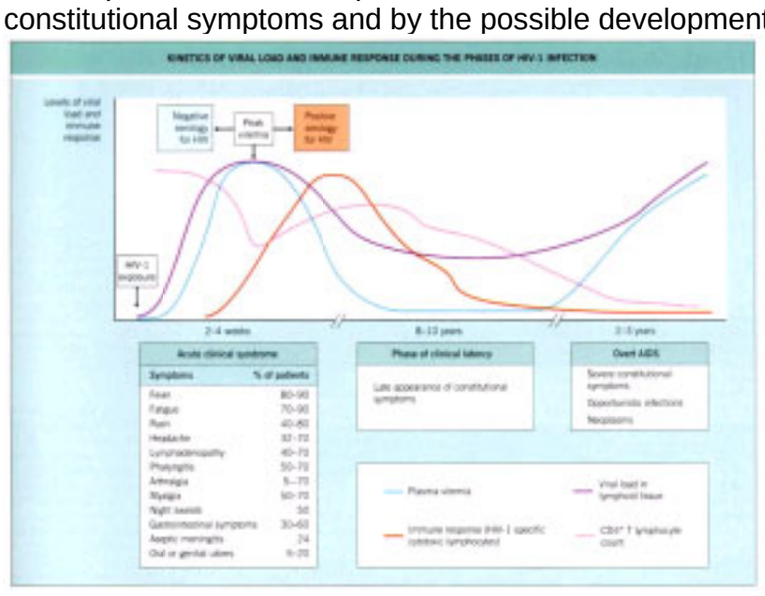

Figure 120-2 Changes in viral load, CD4$^+$ T cells and immune response in the different natural courses of HIV-1 infection. Typical progressors represent 60–70% of the total HIV-1-infected population, rapid progressors represent 10–20%, slow progressors represent 5–15% and long-term nonprogressors represent 1%.

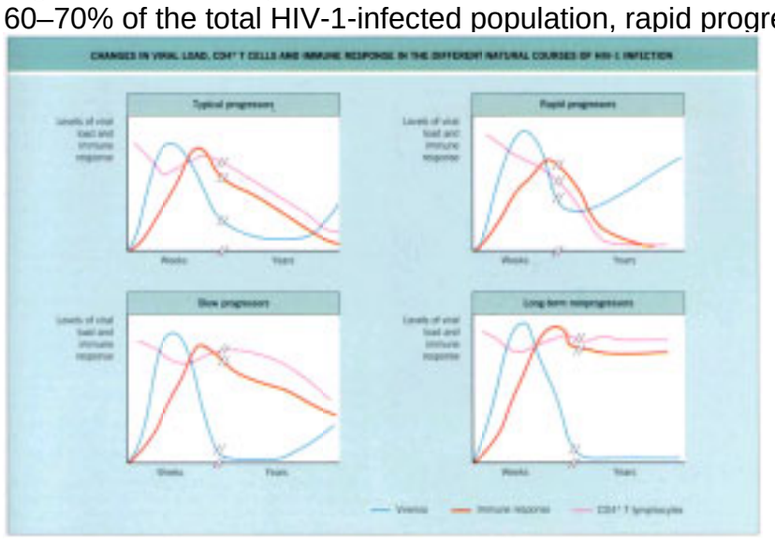

Figure 120-3 Transmission of HIV-1 at the mucosal surface. After entry at the mucosal epithelium, Langerhans cells, also named epidermal dendritic cells, can either be infected by R5 (macrophage (M)-tropic) strains of HIV-1 or pick up HIV-1 virions. Epidermal, DC-SIGN-negative dendritic cells are thought to select for the M-tropic viruses that are the most frequently transmitted variants. The M-tropic HIV-1 carried by epidermal dendritic cells can bind to additional subepithelial DC-SIGN-positive dendritic cells. DC-SIGN can capture HIV-1 on the cell surface of dendritic cells without allowing viral entry. It is thought that DC-SIGN-positive dendritic cells play the major role in the delivery of virus to T cells, thus greatly amplifying HIV-1 infection.

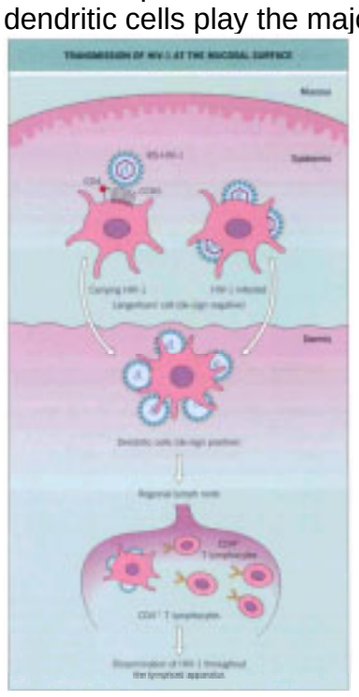

Figure 120-4 Changes in virus distribution within lymph nodes during the transition from the acute to the chronic phase of HIV-1 infection. (a) During the initial weeks of primary HIV-1 infection, the virus is detected in lymphoid tissue as individual virus-expressing cells. This is shown by in-situ hybridization for the detection of HIV-1 RNA (white dots indicate HIV-1 RNA-positive cells). (b) Numerous individual virus-expressing cells seen in the acute phase. (c) Elevated virion levels are found in the circulation in the acute phase. (d) After transition to the chronic phase of the disease, virions trapped in the follicular dendritic cell network become the dominant form of HIV-1, as shown by in-situ hybridization for the detection of HIV-1 RNA (diffuse white areas indicate virus trapped within follicular dendritic cells). (e) Binding of virions on the extracellular surface of follicular dendritic cells in the chronic phase. (f) The number of circulating virions is dramatically reduced in the chronic phase.

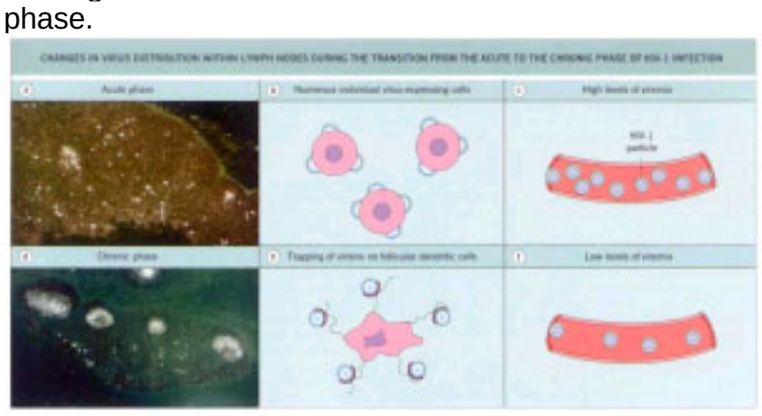

Figure 120-5 Three-phase decay model of virus replication. Viremia below 50 HIV-1 RNA copies/ml plasma does not correspond to complete suppression of virus replication. Residual viremia (5–10 HIV-1 RNA copies/ml plasma) may still be detected 48 weeks after initiation of HAART. However, it is still unclear whether HAART induces complete suppression of virus replication and, if it does, what duration of HAART is needed to achieve this goal.

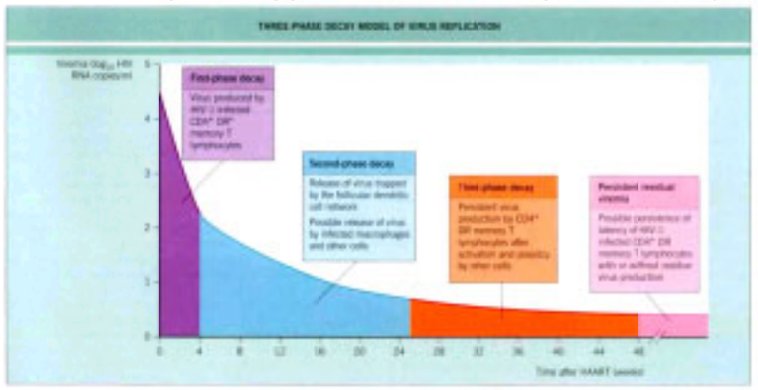

Figure 121-1 HIV-1 virion. The glycoprotein gp120 constitutes the outer envelope of the virus and is noncovalently linked to the transmembrane protein gp41. The matrix protein (p17) bridges the envelope protein with the cone-shaped structure formed by the capsid protein (p24). The viral genomic RNA and processed nucleocapsid (NC; p7) and Pol proteins, reverse transcriptase (RT) and integrase (IN), are located inside the capsid core. PR, protease.

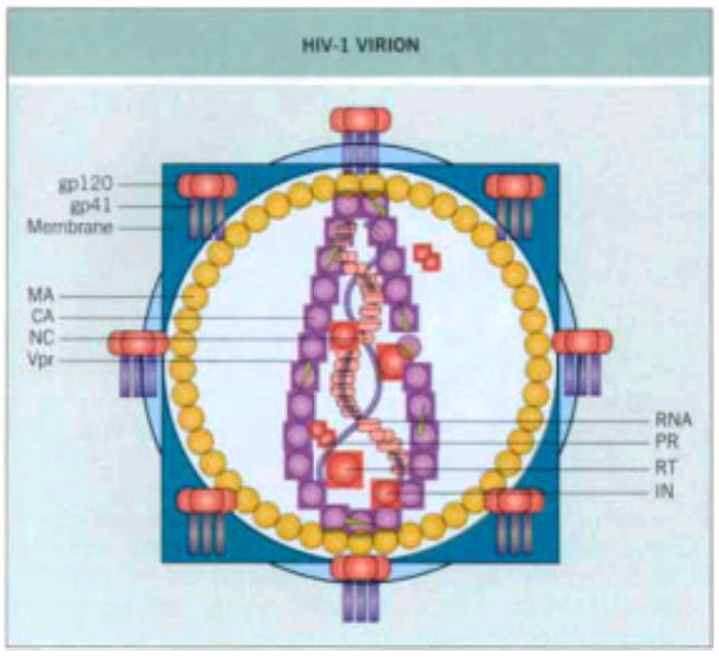

Figure 121-2 Genetic organization of HIV-1 and known functions of gene products. The structural genes are *gag, gag-pol* and *env*. Catalytic proteins are encoded by the *pol* gene. Regulatory proteins are translated from fully spliced mRNA. Within the HIV-1 genome, there are additional open reading frames that flank the *env* gene and encode several regulatory proteins including Vif, Vpr, Tat, Rev, Vpu and Nef. LTR, long terminal repeat; PIC, pre-integration complex consisting of viral cDNA, IN, RT, Vpr, MA and NC.

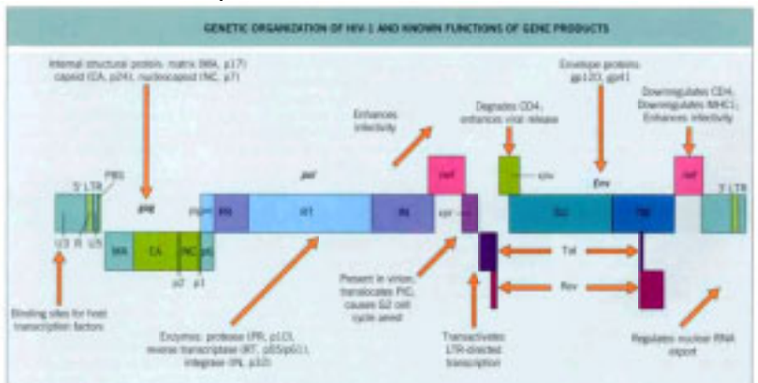

Figure 121-3 Processing of Gag and Gag-Pol proteins. The Gag proteins are initially translated as a 55kDa polyprecursor. Proteolytic processing of Pr55Gag generates several mature products. The catalytic proteins, including reverse transcriptase (RT), integrase (IN) and protease (PR), are first produced as a Gag-Pol precursor (Pr160Gag-Pol) through a translational frameshift mechanism; Pr160Gag-Pol is then cleaved to the smaller enzymatically active subunits.

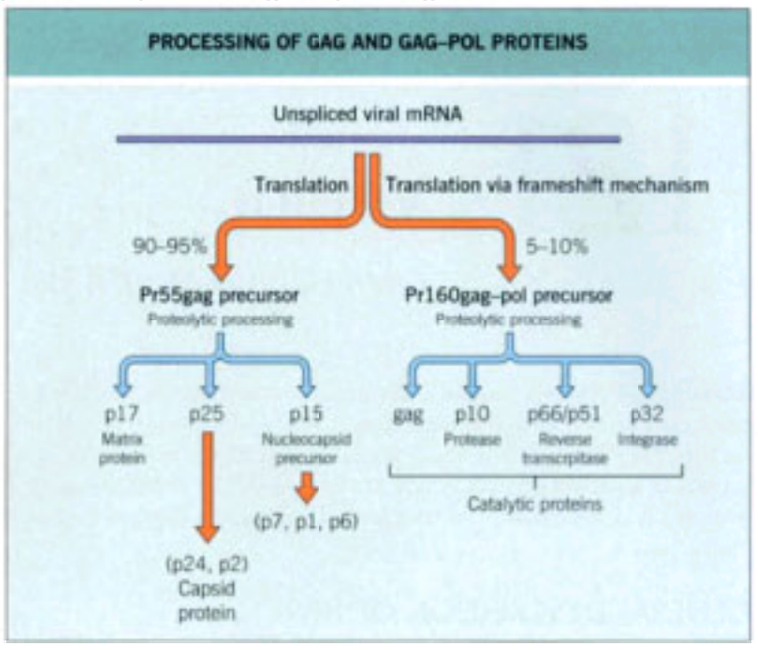

Figure 121-4 The HIV-1 life cycle. The diagram shows the various stages involved, including entry, uncoating, reverse transcription, integration, expression of proviral genome, viral assembly and particle release.

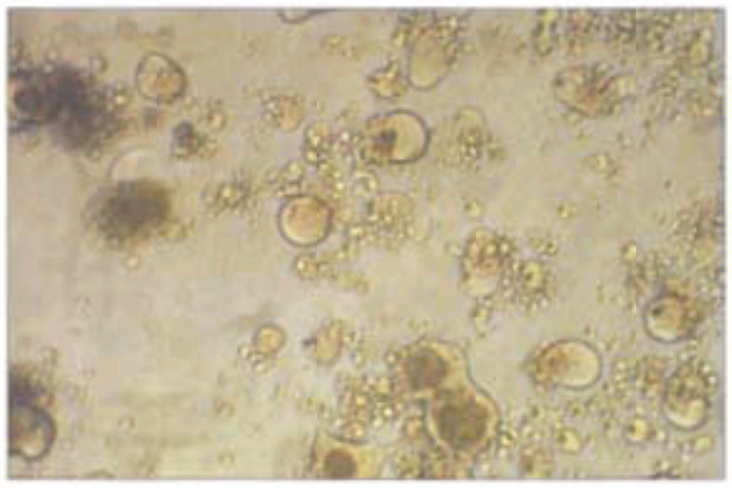

Figure 137-3 Relationship between co-receptor usage and cellular tropism of HIV-1.

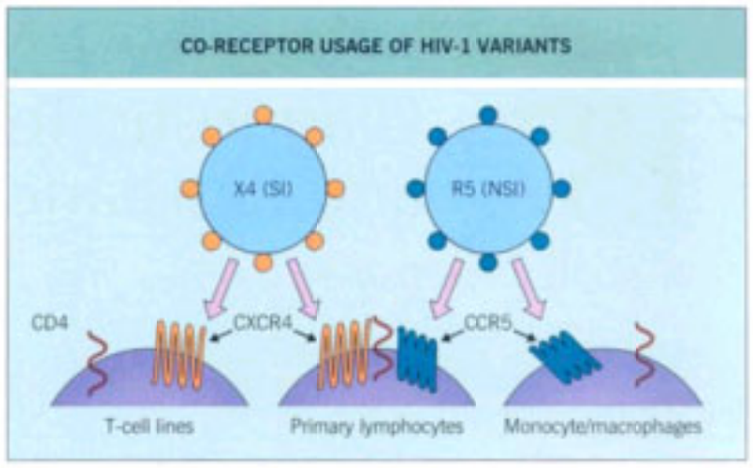

Figure 137-4 HIV-1 drug resistance assay. RT, reverse transcription reaction; cDNA, complementary DNA; PR-RT, protease and reverse transcriptase gene; IC_{50} , 50% inhibitory concentration.

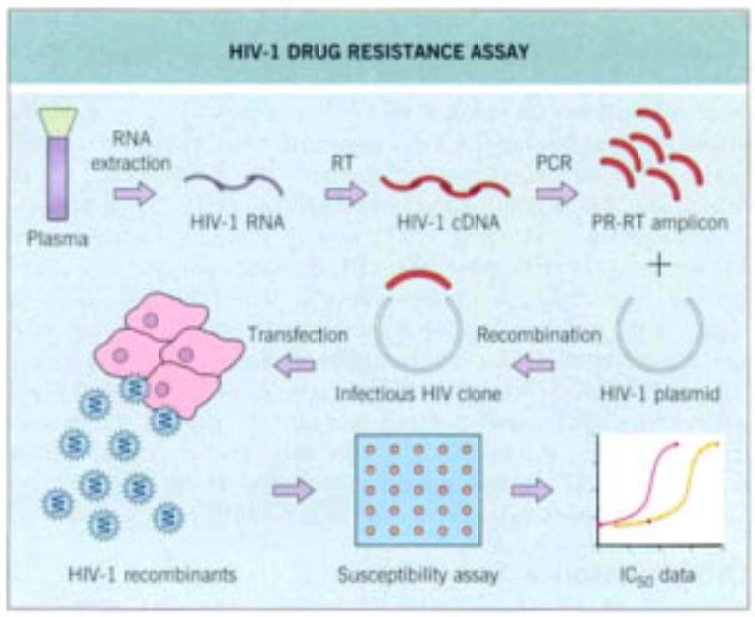

Figure 137-5 Kinetics of viral markers during primary HIV-1 infection. The first positive viral marker is plasma RNA 11–12 days after infection. p24 Antigenemia is detectable on day 14 or 15. The first anti-HIV antibodies are detectable by third-generation ELISAs on days 20–21. (Pink, plasma HIV RNA; purple, p24 antigenemia; blue, anti-HIV antibody).

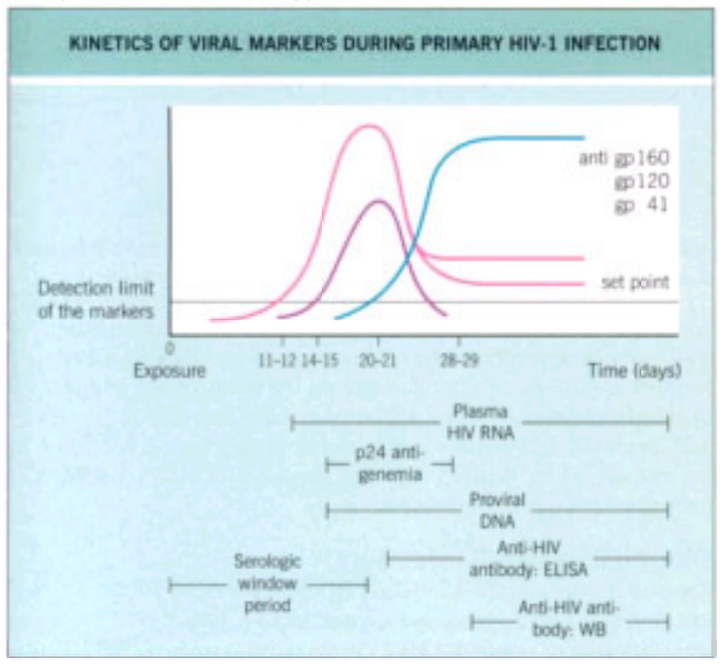

Figure 137-6 Western blot reactivity in one HIV-1 seroconverter. Lanes 1 and 2, negative (NC) and positive controls (PC). Lanes 3–10, serial samples collected on days (D) 0, 2, 3, 5, 7, 12, 22 and 30. Day 0 corresponds to the first collected sample. Anti-p24 was the first antibody detected, rapidly followed by anti-gp160, p55, p40 and gp120. Later, gp41 and p18 are weakly reactive.

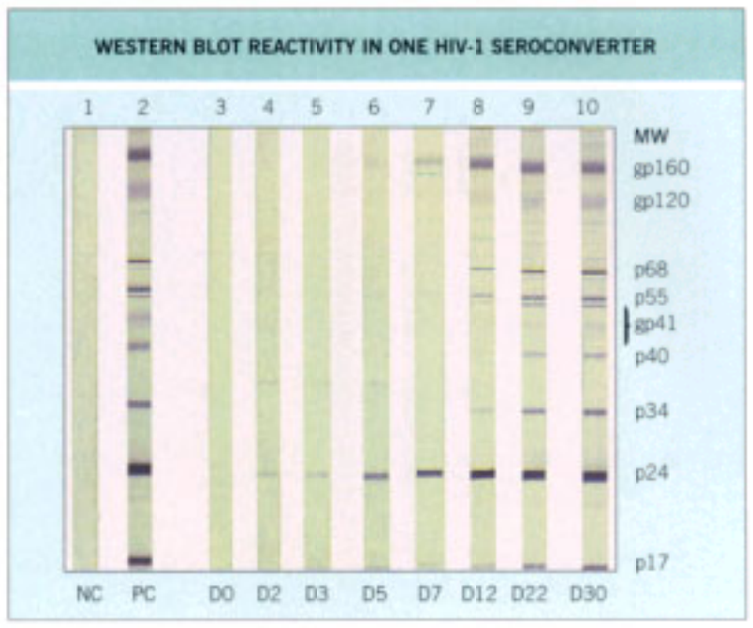

Figure 137-7 Different Western blot patterns of nine samples. Samples 1, 2 and 3 are from recent seroconverters infected by HIV-1 subtype B. Western blot is weakly reactive on gp41 and *pol* products. Patient 4 has a slight decrease in *gag* products by WB. Patients 5 and 6 are fully WB reactive. Patient 7 is a recent seroconverter infected by HIV-1 subtype A. gp120 and gp41 are weakly reactive. Patient 8 is infected with HIV-1 group O. The WB pattern is highly suggestive of infection by a variant, with no *env* reactivity and strong *pol* reactivity. Patient 9 is in the terminal phase of AIDS, with disappearance of *gag* reactivity.

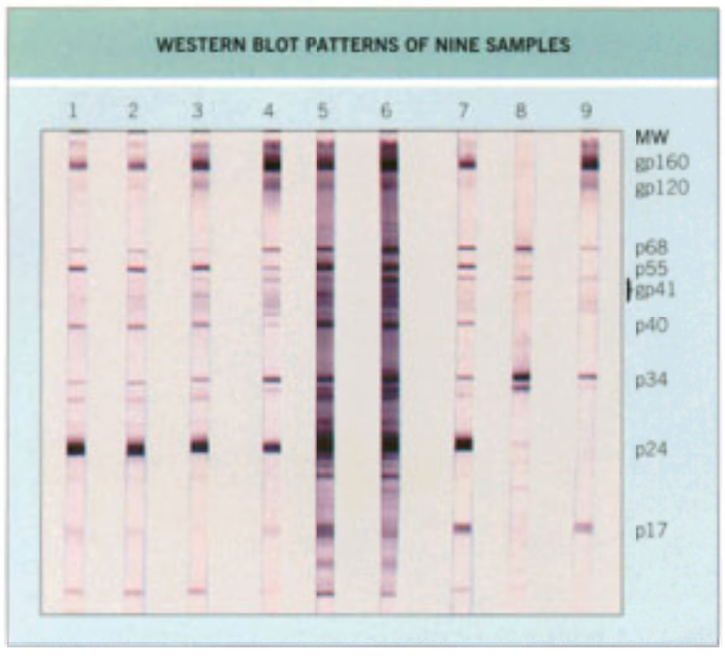

Figure 137-8 Mutations in HIV-1 reverse transcriptase and protease associated with drug resistance. Wild-type amino acids are shown above the bar, and mutant amino acids are shown below the bar. Numbers indicate amino acid position. Vertical bars indicate cross-resistance. Bold-face indicates major protease inhibitor resistance mutations. Complete explanation of figure and footnotes available at www.iasusa.org. *From D'Aquila et al.*[28] *, reprinted with permission.*

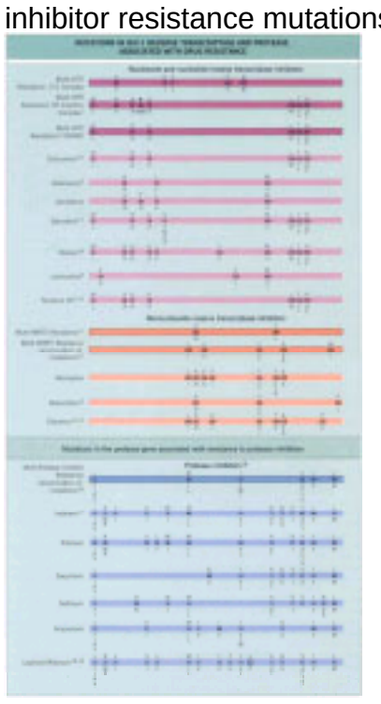

Figure 137-9 Relationship of trough drug concentration (C_{min}) to the 50% inhibitory concentration (IC_{50}) required for viral inhibition. IQ, inhibitory quotient (C_{min} :IC_{50}).

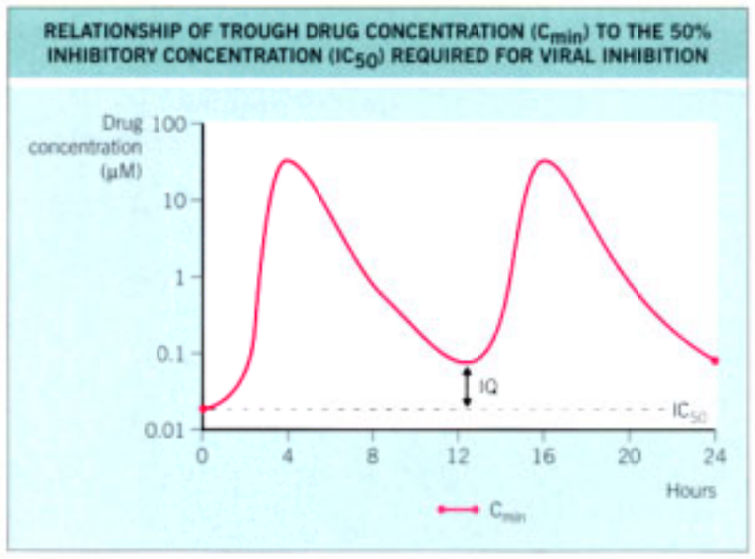

Figure 138-1 Prognostic contribution of viral load determinations at different CD4$^+$ levels. For a given CD4$^+$ lymphocyte count, individuals with high viral load will have a more rapid decline in CD4$^+$ count and therefore a worse clinical prognosis (demonstrated by the downward shift of the survival curve). The viral load is an independent predictor of rapidity of disease progression. A more aggressive virus phenotype — syncytium-inducing versus non-syncytium-inducing — may also adversely affect prognosis, as may viral strains that are resistant to antiretroviral medications.

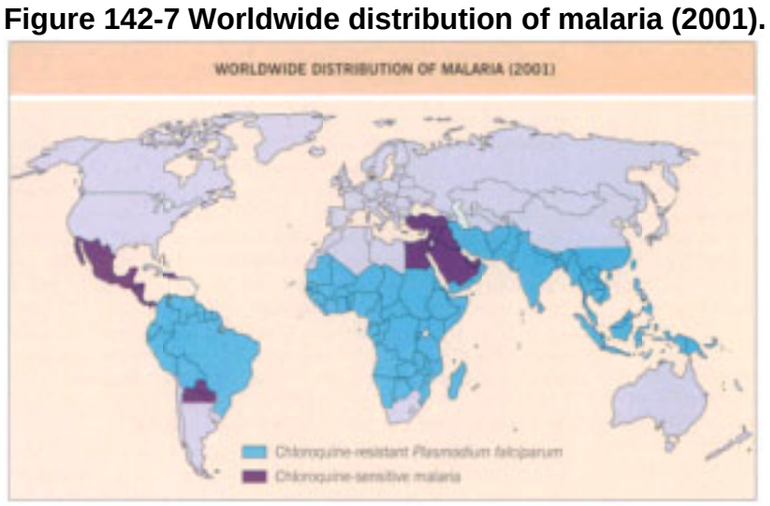

Figure 143-1 Estimated monthly incidence of health problems for travelers to tropical areas. *Adapted from reference* [18] .

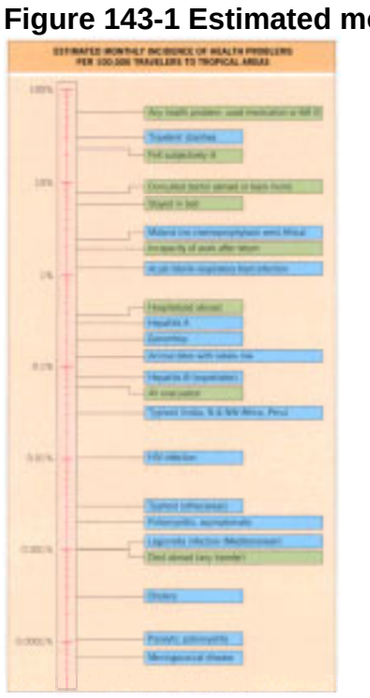

Figure 144-1 Food-borne transmission probably accounts for the majority of diarrheal illness in travelers and expatriates. The high rates of shigellosis and campylobacteriosis compared with cholera among travelers in cholera-endemic areas suggest that they may be better able to avoid exposure to contaminated water than to contaminated food.

Figure 144-2 A suggested approach to the evaluation and management of acute diarrhea in the returned traveler. The most likely pathogens for each scenario are given.

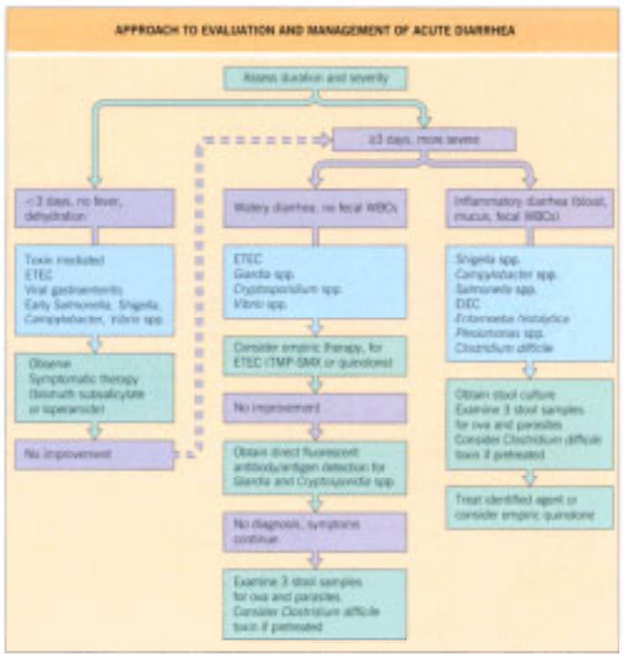

Figure 144-3 A suggested approach to the evaluation and management of chronic diarrhea in the returned traveler. The presence of significant weight loss or evidence of malabsorption should influence the pace and aggressiveness of the evaluation. This approach is designed for use in a Western setting.

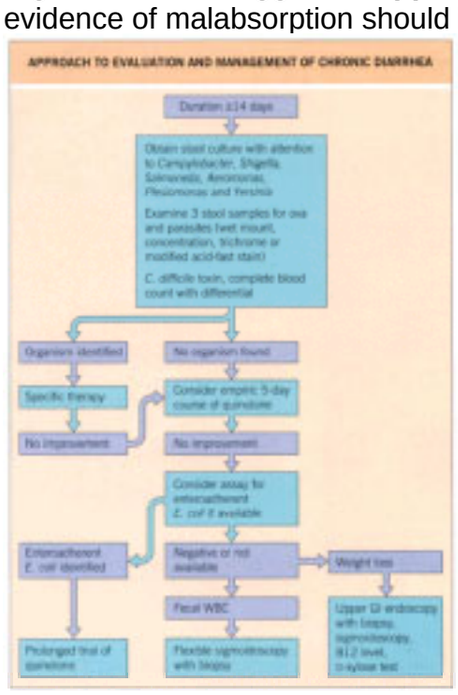

Figure 145-1 Temperature pattern in a patient with dengue fever.

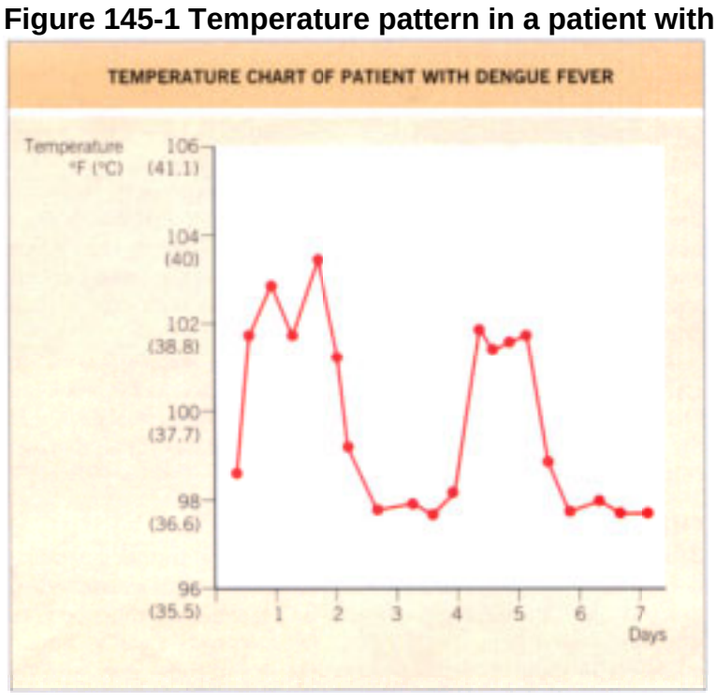

Figure 146-1 Rose spots. In *Salmonella typhi* and *S. paratyphi* infections (enteric fever) classic rose spots of 1–3mm diameter can be found, especially on the abdominal wall, lower thorax and back of the trunk. These are small erythematous macular lesions, which tend to come and go during infection. *Courtesy of Anthony Bryceson.*

Figure 146-2 Trypanosomal rash. In fair-skinned individuals, each peak of fever may be accompanied by a remarkable skin eruption in the form of annular patches of erythema. In other cases, the rash may be more generalized, as seen here on the sixth day of an infection with *Trypanosoma brucei rhodesiense*. *Courtesy of Anthony Bryceson.*

Figure 146-3 Subconjunctival hemorrhages and jaundice in leptospirosis. Asymptomatic or atypical infection probably occurs in 90% of cases and, in some tropical areas, leptospirosis may account for up to 15% of all patients with undiagnosed pyrexia. While this form can be mild, the infection may develop into a generalized septic form with confusion within 1–2 weeks. This is characterized by fever, myalgia and often subconjunctival hemorrhages. The patient illustrated was in the second week following the onset of symptoms. The most dangerous form (Weil's disease) may be very severe and can involve several organs, with jaundice, renal failure, haemorrhagia, vascular collapse and obtundation.

Figure 146-4 Meningococcal septicemia. Meningococcal infections are common in the tropics, most notably in the relatively dry 'meningococcal belt' of sub-Saharan Africa, stretching from Senegal and the Gambia in the west to Ethiopia in the east. The nonblanching skin rash and the petechiae and purpura are often difficult to see in individuals with pigmented skin, as is demonstrated in this patient.

Figure 146-5 Section of *Angiostrongylus cantonensis* larvae in meninges of human brain. Humans may be infested by ingesting third-stage larvae in raw or inadequately cooked intermediate hosts such as snails, prawns, frogs or fish, or in contaminated salads. The larvae migrate to the brain, where they cause eosinophilic meningitis or meningoencephalitis. The diagnosis is aided by the serologic examination of paired specimens, using a specific antigen from adult worms. *Courtesy of Colonel JC Crook, RAMC.*

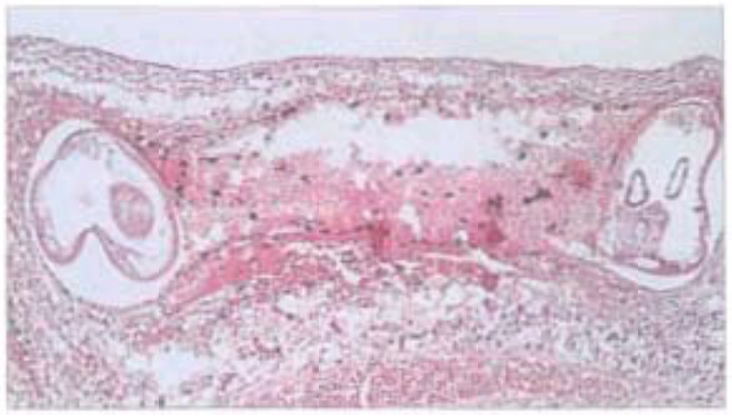

Figure 146-6 Management of a confused or comatose traveler who has suspected viral hemorrhagic fever, malaria or an HIV-related problem.

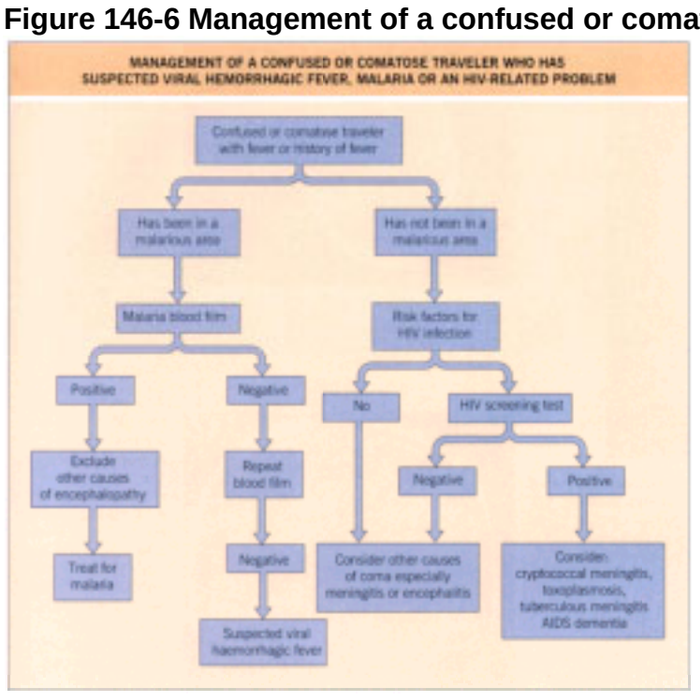

Figure 146-7 Peripheral blood film of a patient with past malaria. The patient had returned 5 days previously from Malawi, having been treated there for malaria. At this stage no parasites were visible on the film. She was confused and delirious on admission and was found to have a profound acidosis (pH 6.98) and acute renal failure, thought to be due to the malaria. She was hypotensive, which suggested a secondary bacterial infection, and was found to have a *Salmonella* sepsis. Secondary bacterial infections are not uncommon in severe malaria associated with immunosuppression. The only evidence on blood film for malaria was the presence of malarial pigment (hemozoin) in many of the neutrophils, one of which is demonstrated here (arrow).

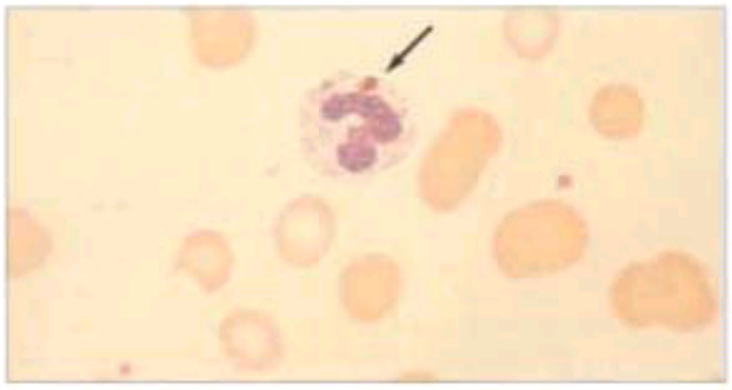

Figure 146-8 Toxoplasmosis. This patient presented to the hospital confused, with a right-sided stroke. An astute doctor requested an HIV test, which was positive. The CT scan carried out with injected contrast shows a typical ring-enhancing lesion in the left internal capsule with considerable surrounding edema. Further lesions were noted on different sections. The *Toxoplasma* IgG was positive and the patient made a full response to anti-*Toxoplasma* therapy.

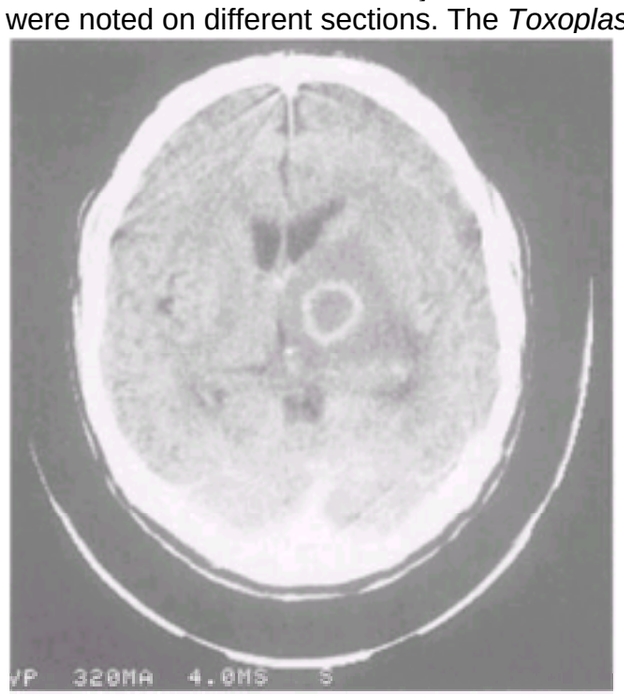

Figure 146-9 Tuberculous meningitis. A CT scan of the brain showing increased uptake of contrast around the vessels at the base of the brain in the circle of Willis in a patient with tuberculous meningitis. Obtundation in a patient presenting with tuberculous meningitis is an indication for the use of steroids.

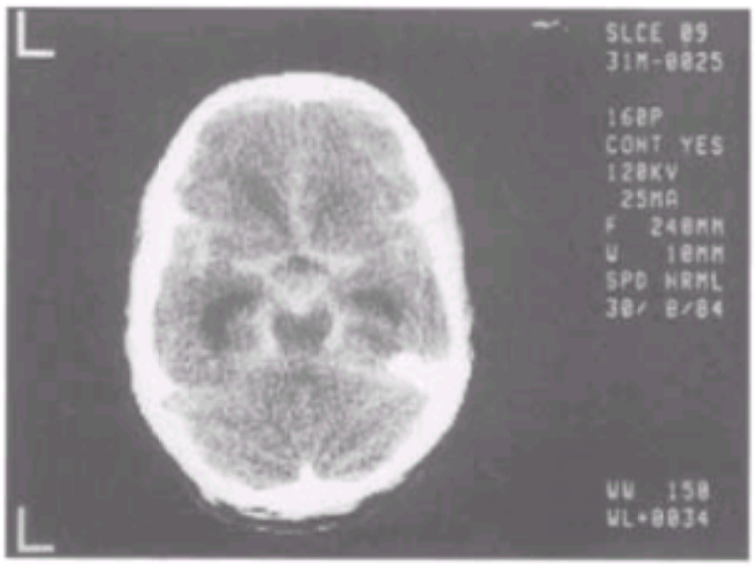

Figure 146-10 Coronal section of brain in cerebral cysticercosis. This magnetic resonance imaging scan shows a cyst with a surrounding white area of edema. While this 22-year-old man presented with focal convulsions of his left arm, edematous lesions placed more centrally, especially within the brain stem, can lead to both confusion and coma.

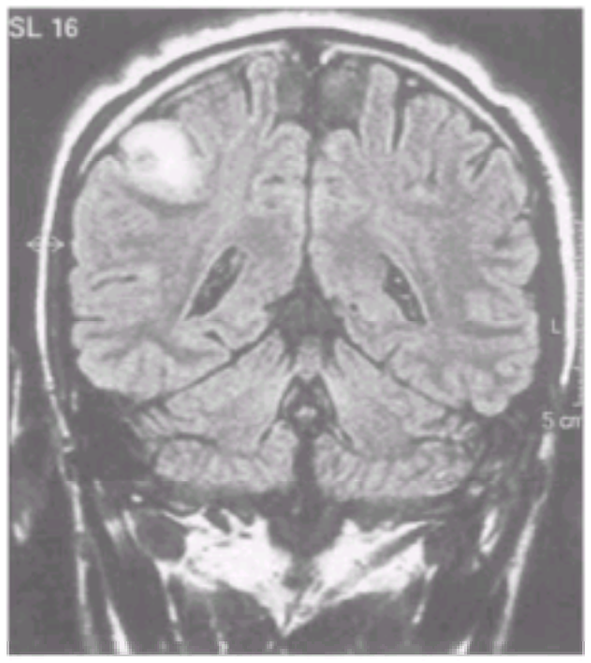

Figure 147-1 Pityriasis versicolor. The rash shows confluent scaly macules.

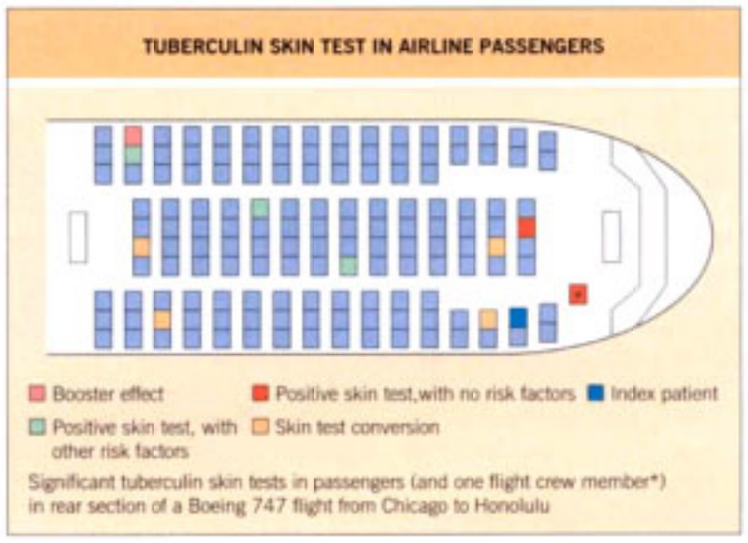

Figure 151-3 Diagnostic/treatment flow chart for cough in travelers.

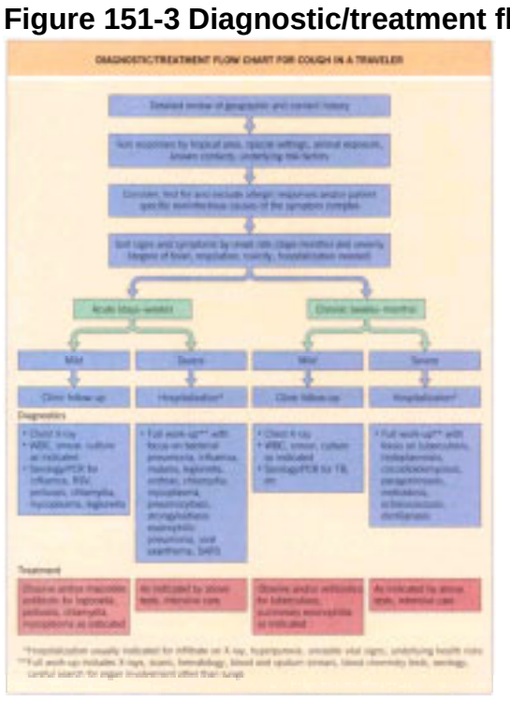

Figure 152-1 Early rash of dengue fever.

Figure 153-1 Animal rabies cases by geographic region for 1998. A total of 32,342 cases are displayed here. According to WHO sources in the 34th World Survey (Via Rabnet document, 2000, WHO/CDS/CSR/APH/99.6), based upon data from 110 countries reporting out of 193 members, wildlife rabies predominates in some regions, such as the USA and Canada, whereas dogs remain a significant reservoir in many other countries. Values shown are percentages. (Note: Rabies has been diagnosed among bats in Australia but these do not appear in the above report.)

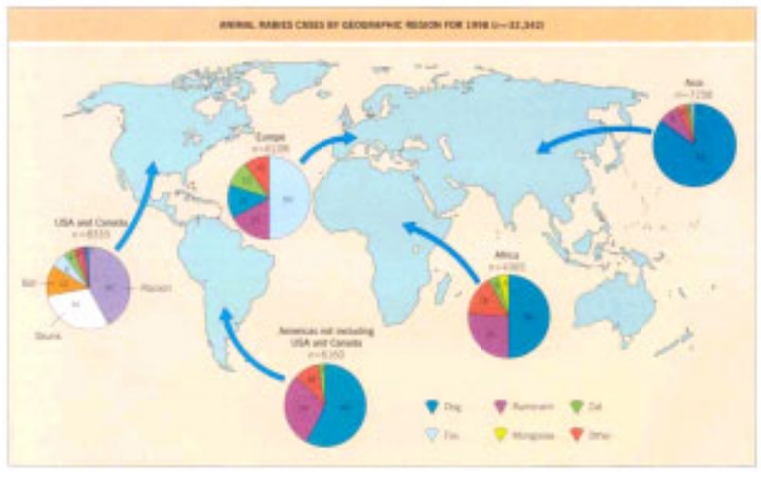

Figure 153-2 A preventable case of rabies in a returned traveler. The patient had been traveling for 6 months. She did not receive pre-exposure rabies vaccine and despite multiple opportunities, did not receive postexposure prophylaxis.[10]

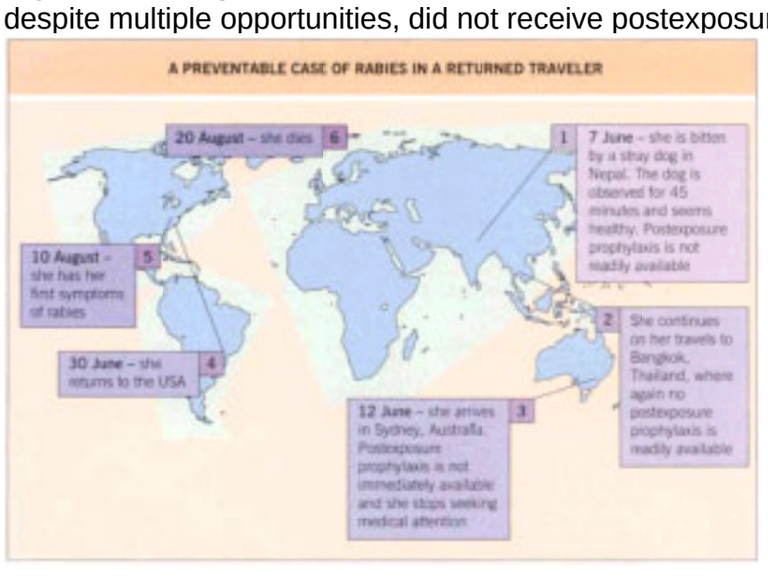

Figure 154-1 The clinical-immunologic spectrum of leprosy. This reflects the underlying host immunity as measured by the T-cell and antibody responses to *M. leprae*. Spontaneous fluctuations in the immune response are responsible for reversal reactions and erythema nodosum leprosum (ENL). TT, tuberculoid leprosy; BT, borderline tuberculoid; BB, mid-borderline leprosy; BL, borderline lepromatous leprosy; LL, lepromatous leprosy; IFN, interferon; IL, interleukin.

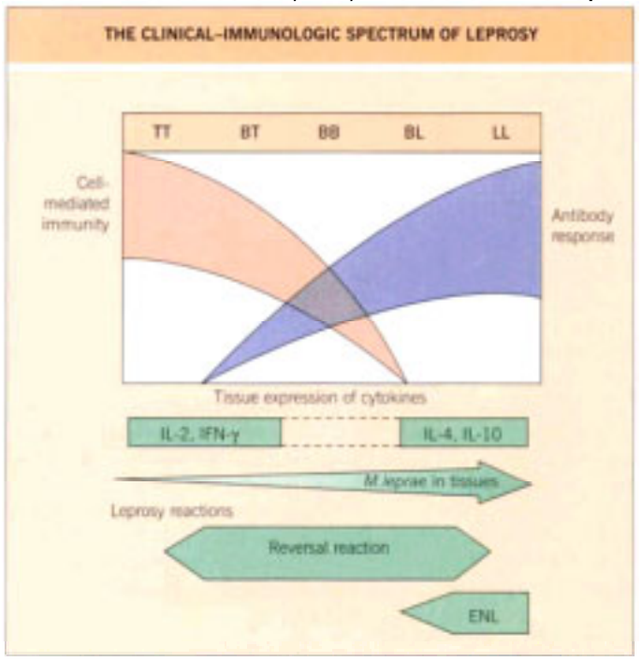

Figure 154-2 Tuberculoid leprosy. Single hypopigmented anesthetic plaque with raised border and dry surface.

Figure 154-3 Borderline tuberculoid leprosy. Three large well-defined erythematous patches with reduced sensation, spreading borders and satellite lesions.

Figure 154-4 Mid-borderline leprosy. Characteristic target lesion with raised erythematous annular border and 'punched-out' central area with impaired sensation.

Figure 154-5 Lepromatous leprosy. Multiple, small, slightly erythematous macules with intact sensation and symmetric distribution. The skin smears of both the lesions and intervening skin are positive for acid-fast bacilli.

Figure 154-6 Nodular lepromatous leprosy. Diffuse infiltration of the skin by multiple nodules of varying size, each teeming with bacilli.

Figure 157-1 The causative organisms of sleeping sickness in humans. Reproduction of Dutton's original drawing of *Trypanosoma brucei gambiense* from the blood of a man. The organisms possess nucleus kinetoplast and flagella, and their relative size can be assessed from the red blood cell diameter of 7µm.

Figure 157-2 Endemic areas for trypanosomiasis.

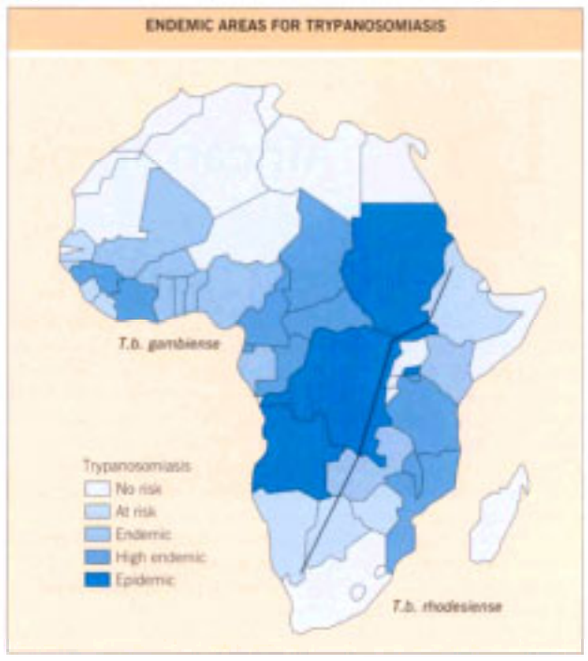

Figure 157-3 Typical chancre of a patient infected with *Trypanosoma brucei rhodesiense*.. The chancre develops at the site of the infecting fly bite.

Figure 157-4 Emergency treatment center Uganda. This center was established to provide facilities for the care and treatment of patients with sleeping sickness during the epidemic in Busoga.

Figure 157-5 Comatose terminal stage patient with sleeping sickness. Note the degree of cachexia.

Figure 157-6 Treatment of a patient with an intravenous injection of melarsoprol. It is vital to adhere to the schedules of treatment and to have a scrupulous technique of injection in order to avoid destruction of local tissue as a result of leakages of the melarsoprol suspended in propylene glycol.

Figure 158-1 Potential routes to the brain and spinal cord for parasitic protozoa and helminths. Collateral circulation (e.g. in hepatosplenic schistosomiasis with portal hypertension) allows ova to embolize via portopulmonary anastomoses to the lung and thence to the systemic circulation. Batson's vertebral venous plexus allows retrograde access to the spinal cord and brain by parasites and/or ova.

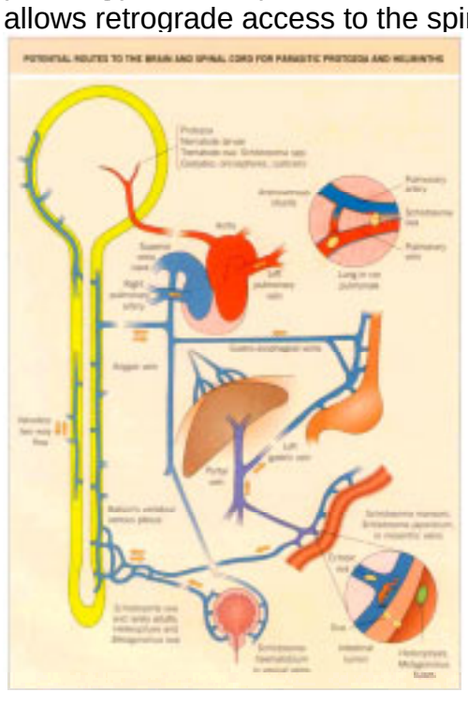

Figure 158-2 Toxoplasma abscess. (a) This CT brain scan shows a toxoplasma abscess in the left internal capsule, compressing the lateral ventricles. Contrast demonstrates a typical ring-enhancing effect. (b) Same patient after 17 days of treatment with pyrimethamine and sulfonamide showing resolving abscess.

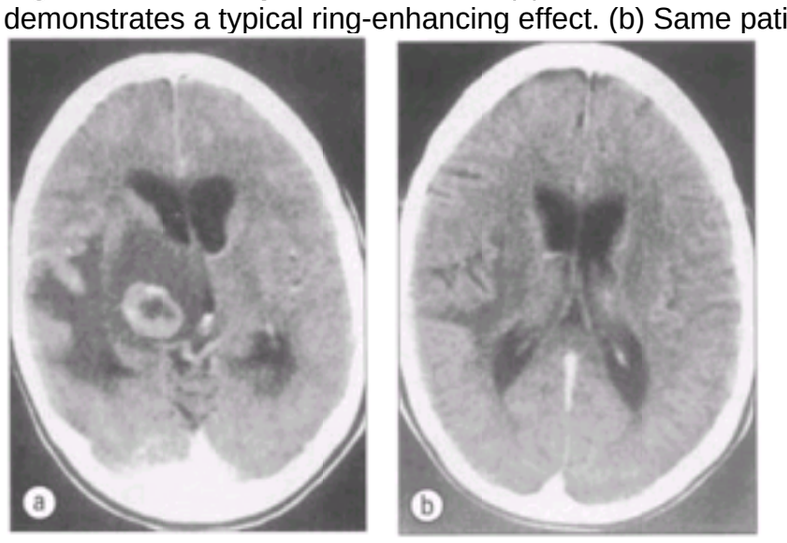

Figure 158-3 Coronal MRI of brain showing living cysticercus, with the scolex appearing as a hyperintense center ('pea in the pod' appearance). There is no visible inflammatory reaction.

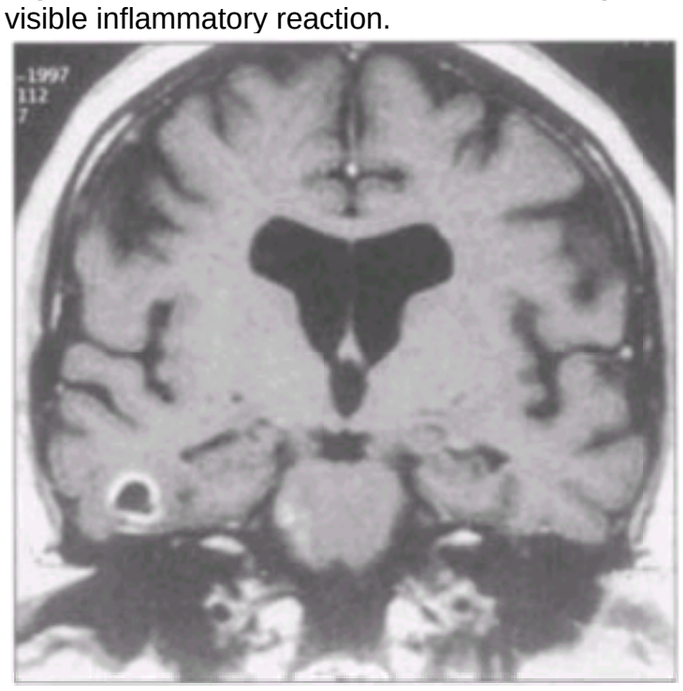

Figure 158-4 Cerebral cysticercus. (a) This MRI of brain shows a dying cysticercus surrounded by intense inflammation. (b) Post-contrast MRI T2-weighted image demonstrating the isointense wall of the cyst and surrounding hyperintense edema.

Figure 166-1 Distribution map of malaria. Despite intensive control measures over the past 50 years, malaria is still widely distributed in the tropics and subtropics. The breakdown of large-scale vector control operations and the emergence of multidrug-resistant parasites have even led to an increase in the incidence of malaria in some regions. O, areas where malaria has disappeared, been eradicated or never existed; +, areas with limited risk; + +, areas where malaria transmission occurs. *(Adapted from WHO 1999, Map No. WHO 99419 EF.) Courtesy of Dr C Lavaissiere.*

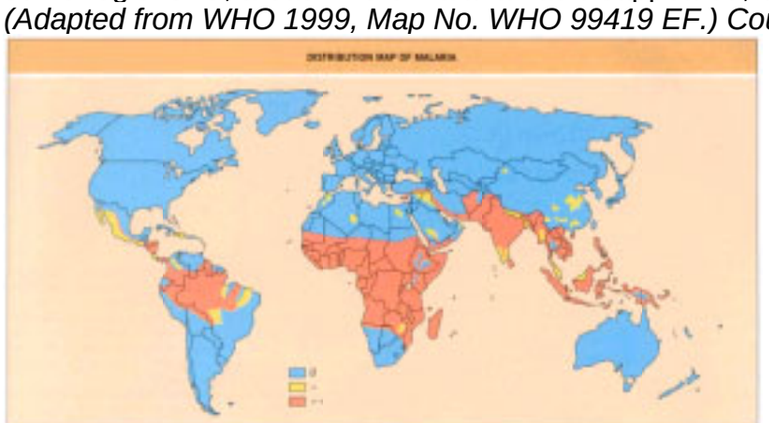

Figure 166-2 Major cell interactions in the pathogenesis of falciparum malaria. The injected sporozoites invade hepatocytes. Merozoites released from rupturing liver schizonts invade red cells. The parasite matures via the ring to the trophozoite to the erythrocytic schizont stage. Such schizonts can bind to uninfected red cells (rosette formation) or to the endothelial cells lining the postcapillary venules (cytoadherence). When the mature schizont ruptures, 'toxin'-like molecules are released which induce the release of proinflammatory cytokines such as TNF-a.

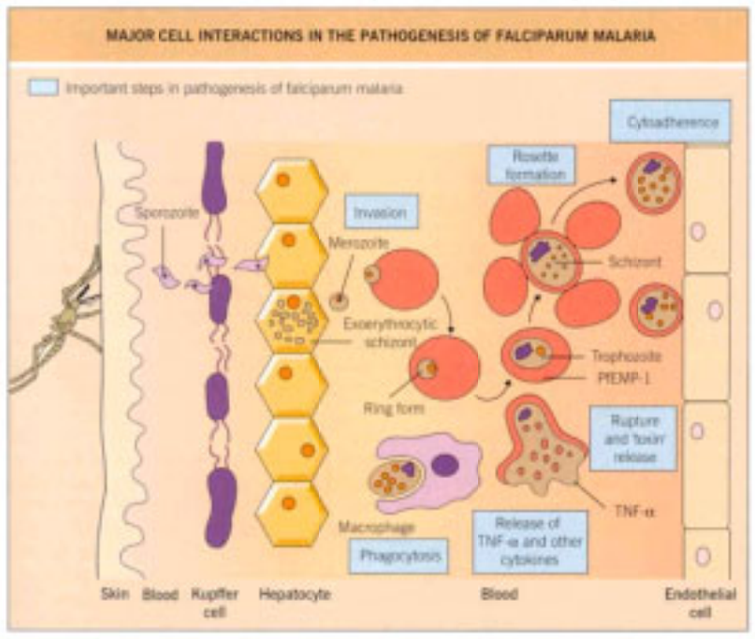

Figure 166-3 Retinal hemorrhage in severe *falciparum* malaria. Examination of the fundus is important in the physical examination of a patient with severe *falciparum* malaria as it can give some indication as to prognosis. In this case the hemorrhage is near the macula. Such hemorrhages have been found in as many as 18–30% of patients with cerebral malaria. In children, additional changes of extramacular whitening and changes in which the vessels turn white in isolated segments, often at branch points, occur.

Figure 166-4 Massive hepatosplenomegaly in a patient with severe malarial anemia due to *P. falciparum.* This CT scan of the abdomen was taken in a traveler from West Africa who, after a prolonged history of fevers, presented with a hemoglobin concentration of less than 50g/l. The scan shows a massively enlarged liver, the left lobe of which is encircling an equally enlarged spleen.

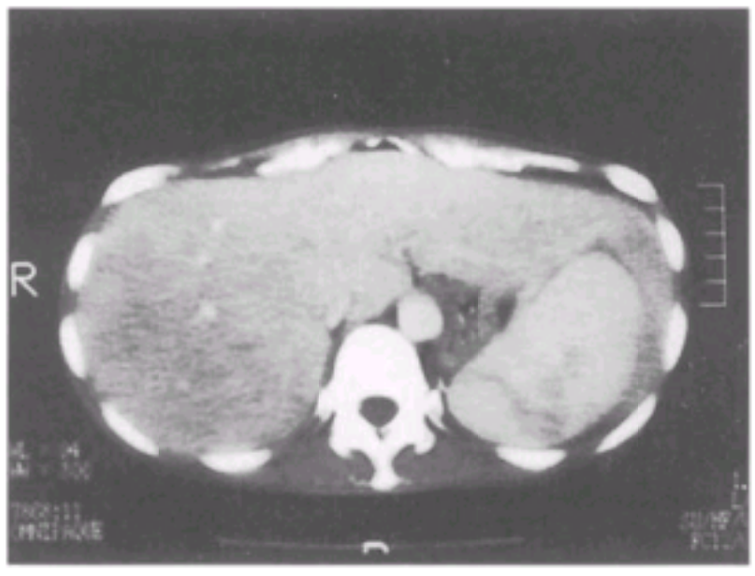

Figure 166-5 Chest radiograph of a patient with acute respiratory distress sydrome (ARDS) due to *falciparum* malaria. This X-ray shows new, bilateral, diffuse, homogeneous pulmonary infiltrates without cardiac failure, fluid overload, chest infection or chronic lung disease in an adult with severe *falciparum* malaria. The prognosis is poor. This condition is rare in children.

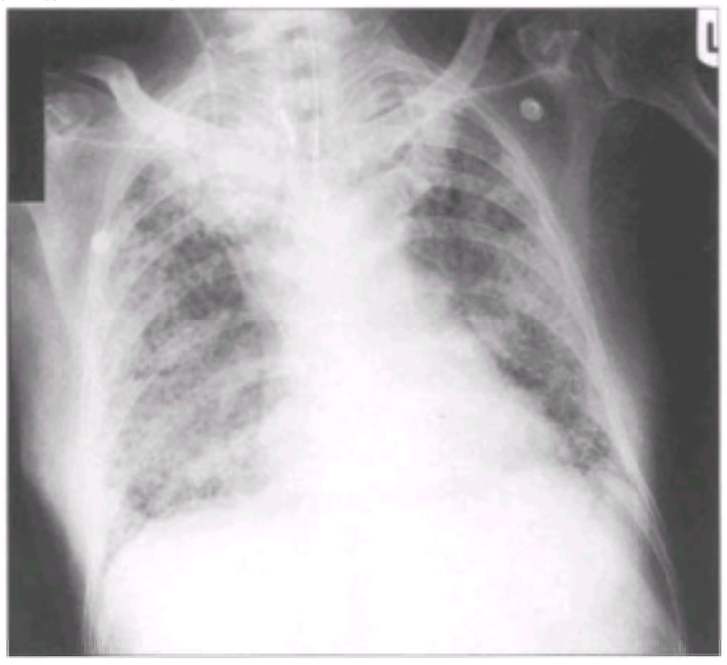

Figure 166-6 Disseminated intravascular coagulation in *falciparum* malaria. Bleeding into the skin seen in a patient with a thrombocytopenia, a prolonged prothrombin time, increased fibrinogen degradation products and hypofibrinogenemia. The patient had no signs of cerebral malaria.

Figure 166-7 Blackwater fever. Urine specimen on admission (left) and days 2, 3 and 4 in a cross-Africa traveler with *falciparum* malaria on quinine treatment, showing the characteristic dark urine of blackwater fever, which showed gradual clearing. The same patient presented with a fever 1 week later and when treated presumptively for malaria with quinine, developed dark urine once again. Renal function was only mildly impaired.

Figure 166-8 Thin blood films from patients with malaria. (a) Delicate small ring forms of *Plasmodium falciparum* showing multiply infected red cells and a characteristic 'appliqué' form in the uppermost parasite in the central red cell where the parasite appears as if it is applied to the surface, rather than within the red cell. (b) Ring forms of *P. falciparum* in a heavy infection and where the pH of the stain is 7.2 rather than 6.7 showing the irregular, basophilic Maurer's clefts in the cytoplasm of infected cells characteristic of *P. falciparum.* (c) Very early trophozoites of *P. falciparum* in the peripheral blood film of a patient with severe disease. The relative size and presence of pigment indicate the greater maturity of the parasite and may indicate a poorer prognosis. (d) Peripheral blood film from a patient with *vivax* malaria showing mixed ring and schizont forms. The ring forms are far more fleshy and ameboid and the cytoplasm of the infected cell shows the characteristic regular and eosinophilic Schüffner's dots, which help in diagnosis. (e) Peripheral blood film from a patient with *ovale* malaria showing a small ring form on the left, which could quite easily be mistaken for *P. falciparum*. The larger central parasite has enlarged the cell into an oval shape and has also formed a fimbriated fringe at the upper pole of the cell. (f) Peripheral blood film from a patient with *malariae* malaria showing the characteristic rosette schizont with daughter merozoites (usually eight) around a central piece of pigment (*hemazoin*). The ring forms of this species characteristically form a band stretching across the width of the red cell.

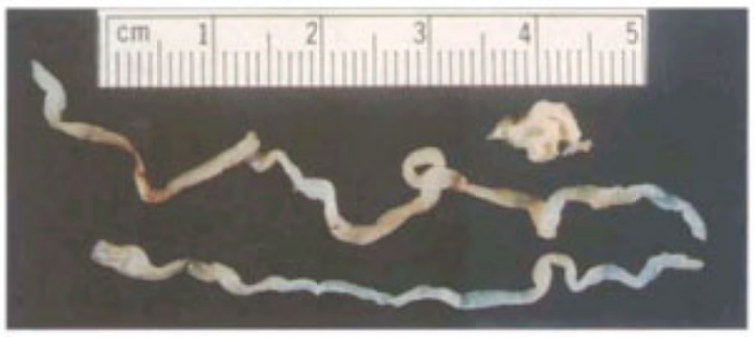

Figure 168-4 *Taenia saginata.* A mature worm may be over 33 feet (10m) long.

Figure 168-5 An adult liver fluke (*Clonorchis sinensis*). The worm is typically about 0.75 inches (2cm) in length.

Figure 168-6 Low-power section of a human bile duct containing adult *Clonorchis sinensis* flukes.

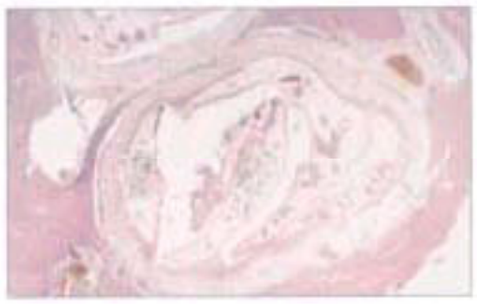

Figure 168-7 Shadowing in the right upper zone with cavitation in a 6-year-old-boy with an African lung fluke infection (*Paragonimus uterobilateralis*).

Figure 169-1 Life cycle of *Echinococcus granulosus.* Adult tapeworms parasitize the small intestine of definitive hosts, mainly dogs (1). Parasite proglottids and eggs are shed with the feces (2), such eggs being infectious for intermediate hosts including humans (3). Hydatid cyst formation occurs predominantly in the liver (4), but also in lungs and other organs. Imaging techniques such as CT (5) demonstrate well-delineated, fluid-filled, usually unilocular bladder-like lesions. Internal daughter cysts may be visible in larger cysts as septated segments within the primary cyst. Histologically, the cyst by itself consists of a very thin inner germinal and nucleated layer with a predominantly syncytial structure (6). The germinal layer is externally protected by an acellular laminated layer of variable thickness. The endogenous formation of brood capsules and protoscolices is a prerequisite for completion of the life cycle (6), which occurs when definitive hosts ingest protoscolex-containing hydatid cysts.

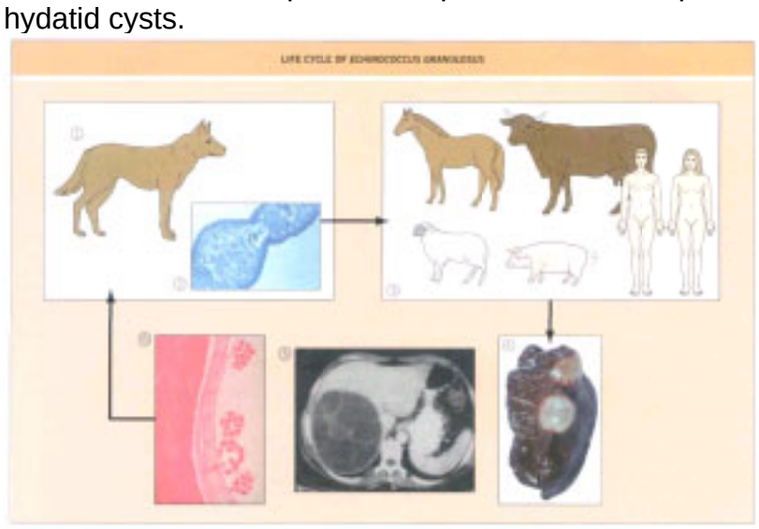

Figure 169-2 Primary sites of metacestode development in humans. Organ distribution of the primary sites of metacestode development for *Echinococcus granulosus* (cystic echinococcosis) and *Echinococcus multilocularis* (alveolar echinococcosis) in human disease.

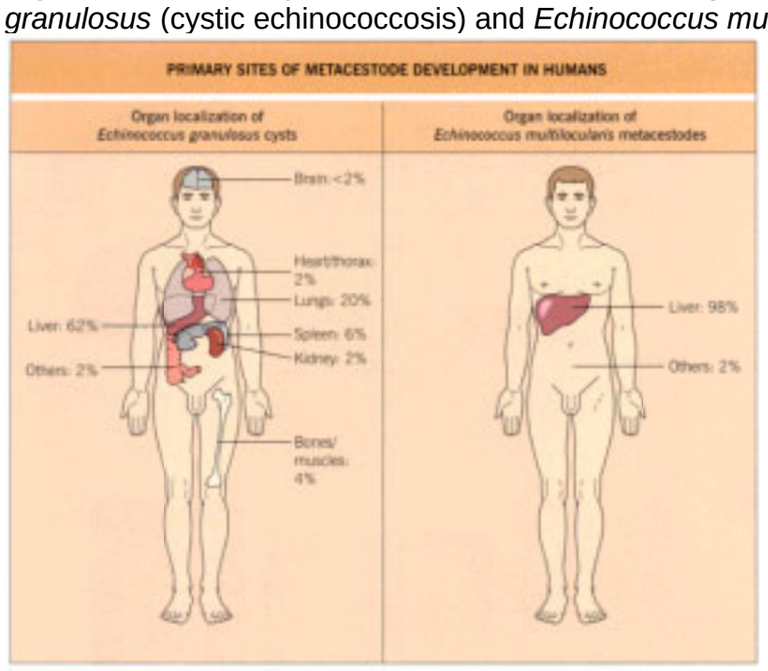

Figure 169-3 Life cycle of *Echinococcus multilocularis.* This involves predominantly foxes as definitive hosts (1) and occasionally other carnivores such as domestic dogs or house cats. Egg production by the tapeworm starts as early as 28 days after infection (2). Eggs must be ingested by a suitable intermediate host (3), including humans and various rodent species (4). As a result, the parasite metacestode primarily becomes established in the liver. Macroscopically, the typical lesion is characterized by a dispersed mass of fibrous tissue with a multitude of interconnected vesicles ranging from a few millimeters to centimeters in size (5). The lesion often contains focal necrotic zones with scattered calcifications, as demonstrated by CT (6). Histologically, the hepatic lesion consists of a conglomerate of small vesicles and cysts demarcated by a thin laminated layer with or without an inner germinal layer and, predominantly in the rodent intermediate host, protoscolex formation (7). Oral ingestion of protoscolex-containing metacestodes by definitive hosts completes the life cycle.

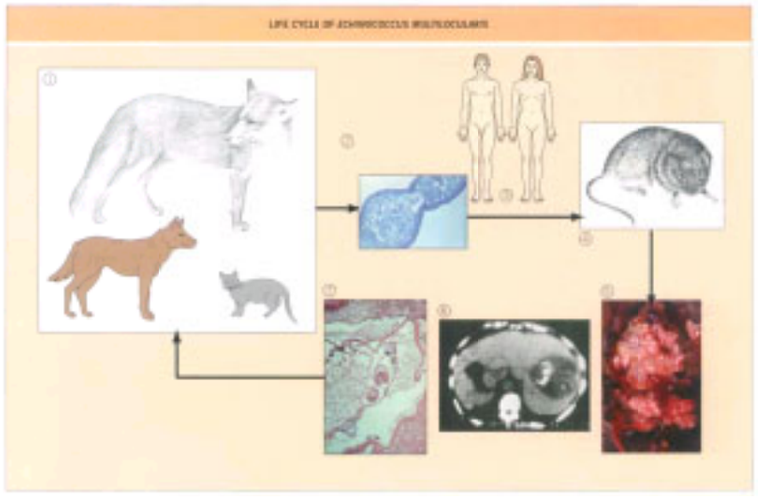

Figure 170-1 Elephantiasis. (a) Already advanced elephantiasis in a 14-year-old Indian girl who has bancroftian filariasis. Although such clinical expression of filarial disease is more commonly seen in adults, infection in endemic areas is usually established in early childhood. (b) Scrotal elephantiasis in an adult man who has bancroftian filariasis.

Figure 170-2 Onchocerciasis. Evidence of excoriation caused by the patient's trying to relieve the maddening pruritus caused by onchocerciasis. Note also the marked dermal atrophy associated with chronic infection.

Figure 170-3 *Loa loa* adult worm. The worm has been teased from the subcutaneous tissue after incision was made through a small pruritic papule (0.5cm in diameter) in an expatriate patient who had loiasis. Such papules can occur spontaneously or after treatment with DEC.

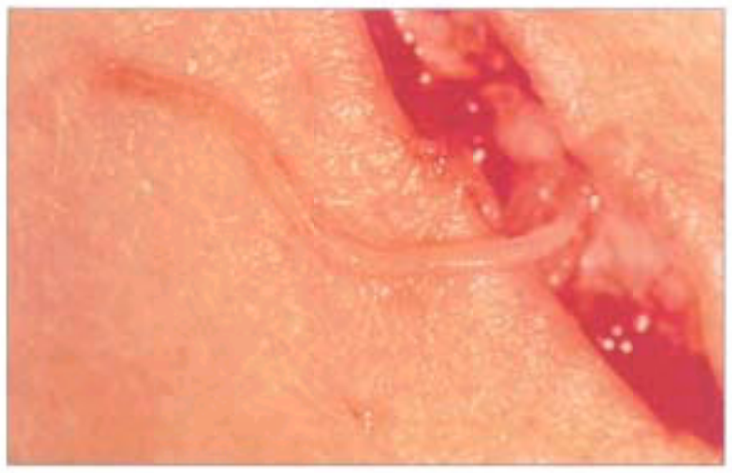

Figure 171-1 Erythrocyte passage into the venous sinuses of the spleen. A red cell passing between endothelial cells (arrow shows direction of movement) from the cordal tissue to the vascular sinus. Sickle cells do not have this deformability, so they accumulate in the spleen. Modified from Weiss.[1]

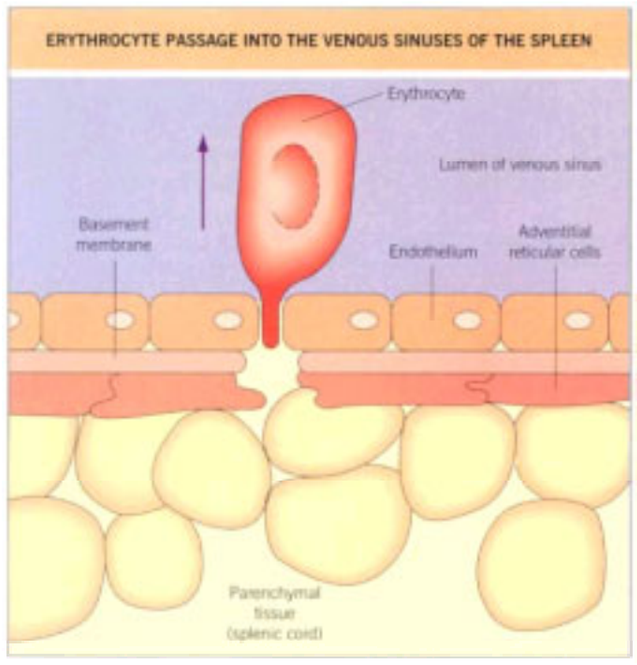

Figure 171-2 ^{99m} Technetium sulfur colloid scans (posterior view) in a 2-year old child with SS disease and splenomegaly. (a) The scan shows hepatic uptake but no splenic uptake. (b) A repeat scan 6 days after a blood transfusion shows restoration of splenic uptake of colloid. From Pearson *et al.*[5]

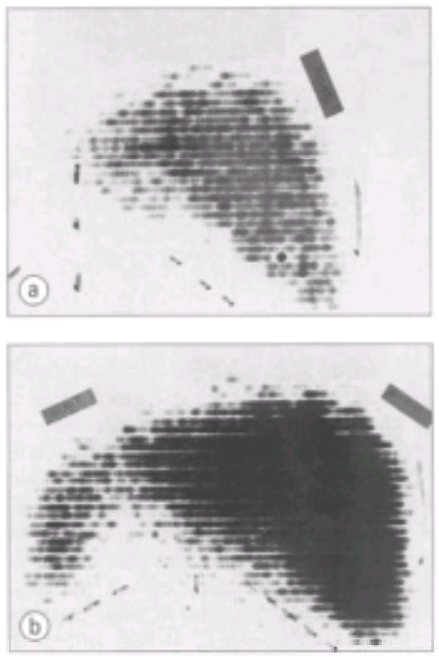

Figure 171-3 Experience with pneumococcal sepsis in Jamaican children from birth to 6 years of age. Pre-trial experience shows that sepsis episodes commenced at 6 months and 9 or 10 episodes occurred before 3 years. During penicillin prophylaxis from 6 months to 3 years, no episodes occurred but seven episcodes occurred after cessation of penicillin. The numbers by the arrows refer to pneumococcal serotypes.

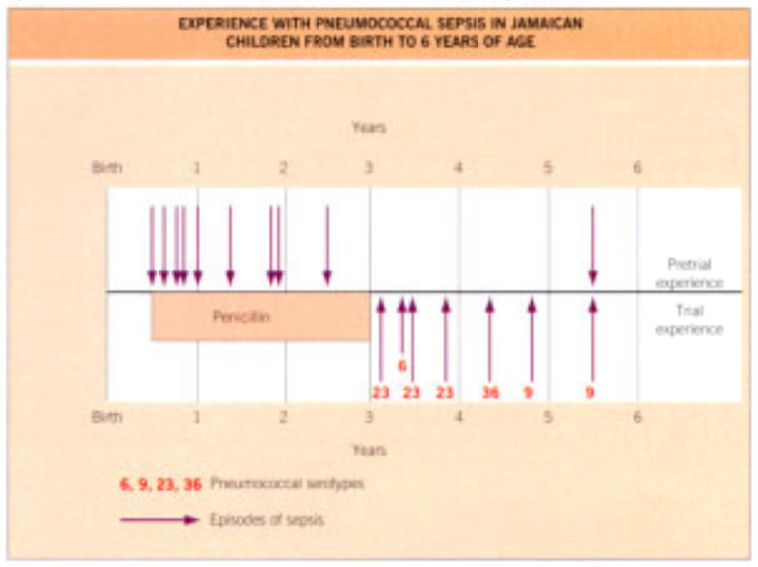

Figure 172-1 Global distribution of visceral leishmaniasis. More than 90% of VL cases occur in India/Nepal/Bangladesh, Sudan/Ethiopia and Brazil.

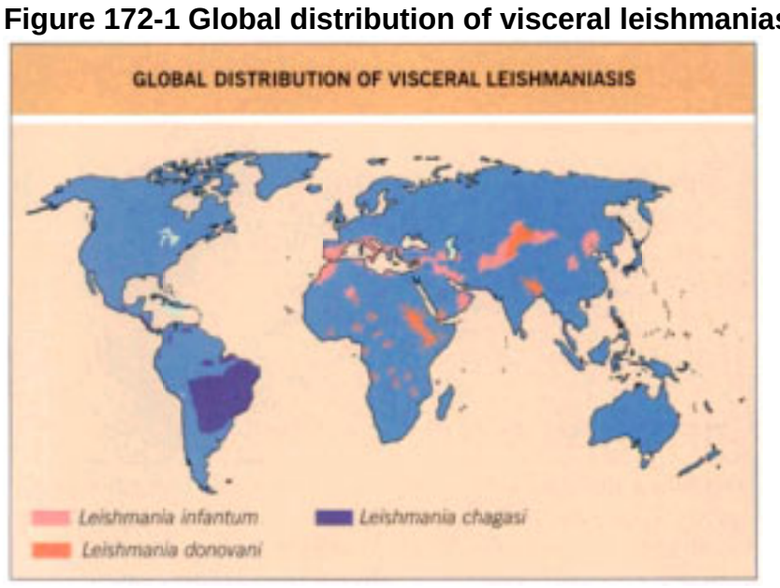

Figure 172-2 Global distribution of cutaneous leishmaniasis. More than 90% of CL cases occur in the regions of Brazil/Peru, Algeria, Saudi Arabia and Syria/Iraq/Iran/Afghanistan.

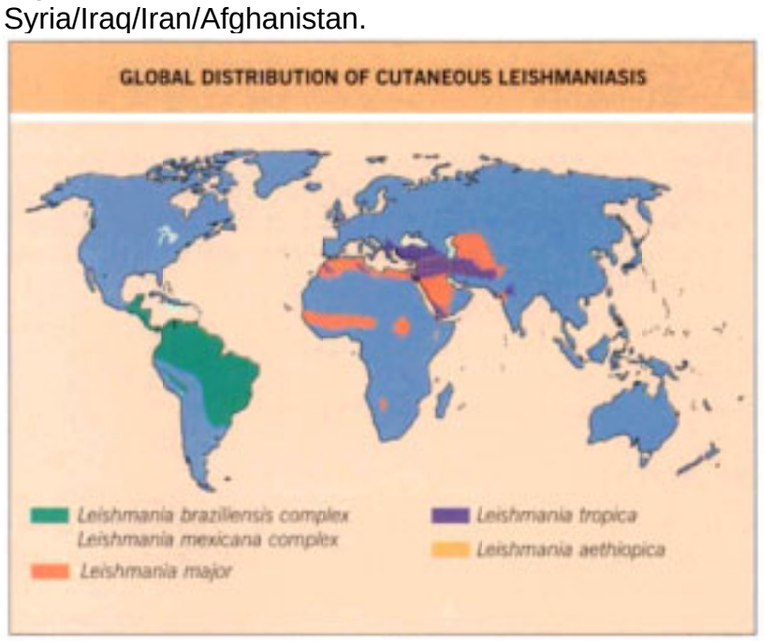

Figure 172-3 Visceral leishmaniasis. (a) Hepatosplenomegaly and pallor in a 29-year old Italian man. (b) Splenomegaly and pallor in a 23-year old Angolan. Both complained of weight loss, fatigue and fever of several weeks' duration.

Figure 172-4 Cutaneous leishmaniasis. *Leishmania tropica* recidivans leishmaniasis lesions on the face and forearm of a Syrian girl. These had been present for 4 years with slow healing in the center and multiple recurrences despite courses of intralesional meglumine antimonate.

Figure 172-5 Mucocutaneous leishmaniasis. A young man from Peru who had a 2-year history of slow enlargement of the lips and ulceration of the nostrils. *Courtesy of Professor Luis Valda Rodriguez.*

Figure 172-6 Amastigotes (Leishman-Donovan bodies) in bone marrow aspirate from a patient who had *Leishmania infantum* visceral leishmaniasis and AIDS. The nucleus and kinetoplast stain deeply with Giemsa and give the organism its characteristic appearance. *Histoplasma* spp. are the main source of mistaken identification in bone marrow smears, but lack these structures. Amastigotes measure 2–3μm in length and are found within macrophages in tissue sections, but usually lie free in smears because infected macrophages burst as they are smeared.

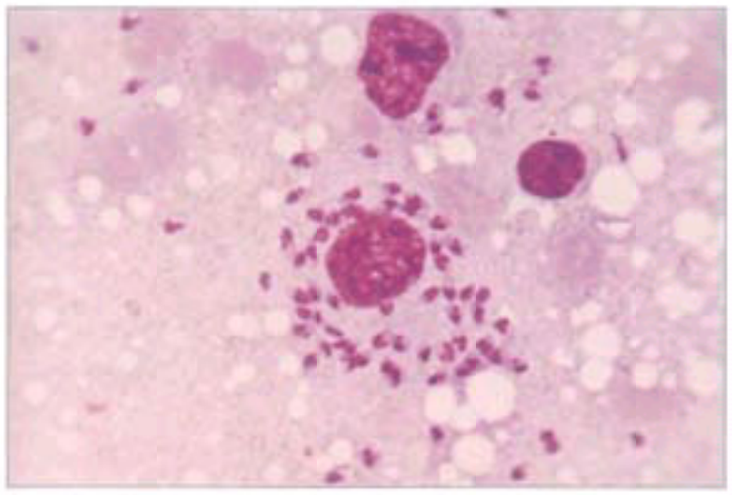

Figure 172-7 Splenic aspiration. The picture shows a splenic aspirate being performed under field conditions on a child suffering from *Leishmania donovani* kala-azar in south Sudan. The procedure is simple, painless and safe if the prothrombin time is normal and the platelet count is above 40×10^9 /l. Palpate the spleen and mark its outline. Using a 1.25 inch (30mm) long 21-gauge needle attached to a 5ml syringe, penetrate the skin over the spleen. Withdraw the plunger 1 ml and plunge the needle into the spleen upwards at an angle of 45° and withdraw immediately, maintaining suction. The tiny amount of material obtained is sufficient for culture and smear. *Courtesy of Drs Robert Wilkinson and Jill Seaman.*

Figure 172-8 Slit skin smear. The picture shows a slit skin smear being taken from the edge of a chronic *Leishmania infantum* ulcer obtained in Malta. Smears are taken from the raised edge of the ulcer or center of the nodule, where amastigotes are most abundant. The skin is cleaned and then firmly pinched throughout the procedure to squeeze away blood. A 5mm-long and 3mm-deep incision is made and then the scalpel is turned through 90° and the blade is used to scrape the edge of the slit. A line of tissue scrapings is gently streaked on to a slide and the process is repeated until two or three lines of scrapings are present on at least two slides. Further scrapings and fluid oozing from the pinched slit are put into culture medium.

Figure 177-1 Life cycles of *Francisella tularensis.* The two major life cycles in nature are shown. In cycle (a), which is dominant in North America, *F. tularensis* is maintained predominantly among lagomorphs and hard ticks. In cycle (b), which is dominant in Eurasia, *F. tularensis* is principally maintained among cricetine rodents, especially field voles and mice, water voles and other aquatic rodents. Humans are incidental hosts that are infected by tick vectors and by the bites of flies or mosquitoes that have contaminated mouthparts, by direct contact with infected animal carcasses or other contaminated materials, by ingestion of contaminated matter or by inhalation of infectious aerosols or dusts.

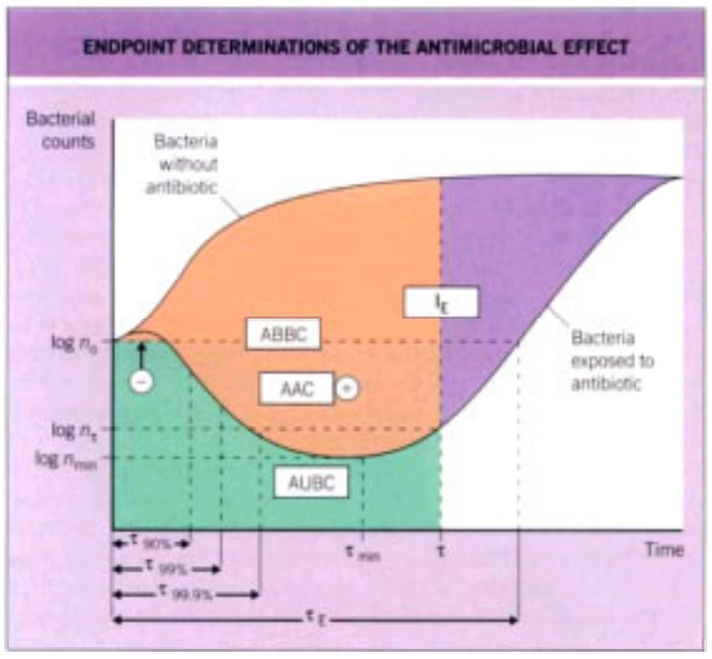

Figure 188-1 Diversity of ß-lactam antibiotics: main ring structures, names and representative antibiotics.

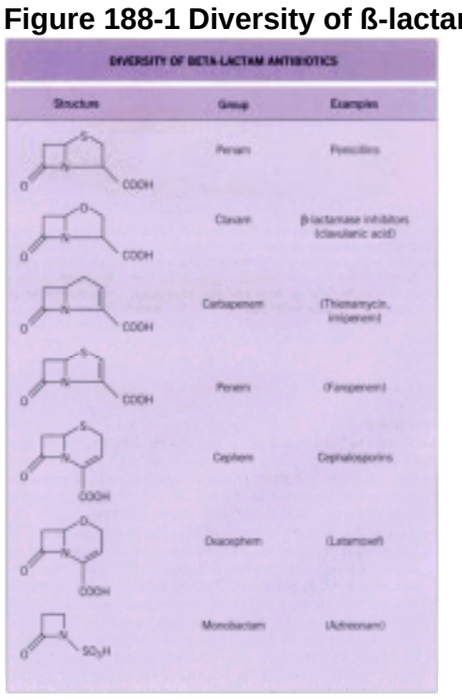

Figure 188-2 Site of action of antibiotics that perturb the synthesis of peptidoglycan. The peptidoglycan unit is formed in the cytosol of bacteria by the binding to uridine diphosphate (UDP)-*N*-acetylmuramic acid of a short peptide (the nature of which differs between bacteria). This precursor is then attached to a lipidic carrier and added to *N*-acetylglucosamine before crossing the bacterial membrane. At the cell surface peptidoglycan units are reticulated by the action of transglycosylases (catalyzing the polymerization between sugars) and of transpeptidases (catalyzing the polymerization between peptidic chains). The antibiotics act as follows: fosfomycin is an analog of phosphoenolpyruvate, the substrate of the *N*-acetylglucosamine-3-*o*-enolpyruvyl transferase synthesizing *N*-acetylmuramic acid from *N*-acetylglucosamine and phosphoenolpyruvate; cycloserine is an analog of D-Ala and blocks the action of D-Ala racemase and D-Ala:D-Ala ligase; bacitracin inhibits the transmembrane transport of the precursor; vancomycin binds to D-Ala-D-Ala termini and thus inhibits the action of transglycosylases and transpeptidases; and ß-lactams are analogs of D-Ala-D-Ala and suicide substrates for transpeptidases.

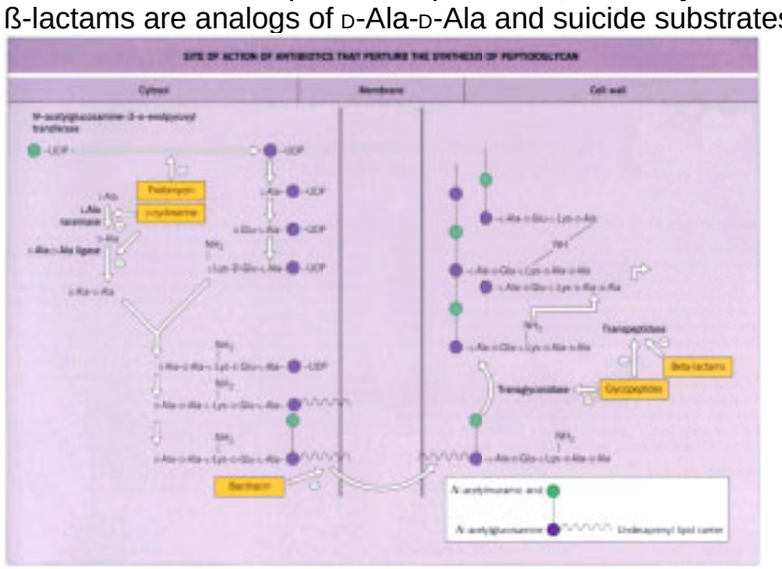

Figure 188-3 ß-Lactam antibiotics as substrates for transpeptidases and ß-lactamases. The left part of the illustration shows how a ß-lactam covalently binds to the transpeptidases. Hydrolysis of this acylated enzyme is very slow (one ß-lactam per hour), making the enzyme inactive. The right part of the illustration shows that the same reaction occurs in the case of a ß-lactamase. Hydrolysis of the acylated enzyme is, however, very rapid (1000 ß-lactams per second), making the antibiotic inactive and regenerating the enzyme for a new cycle of hydrolysis.

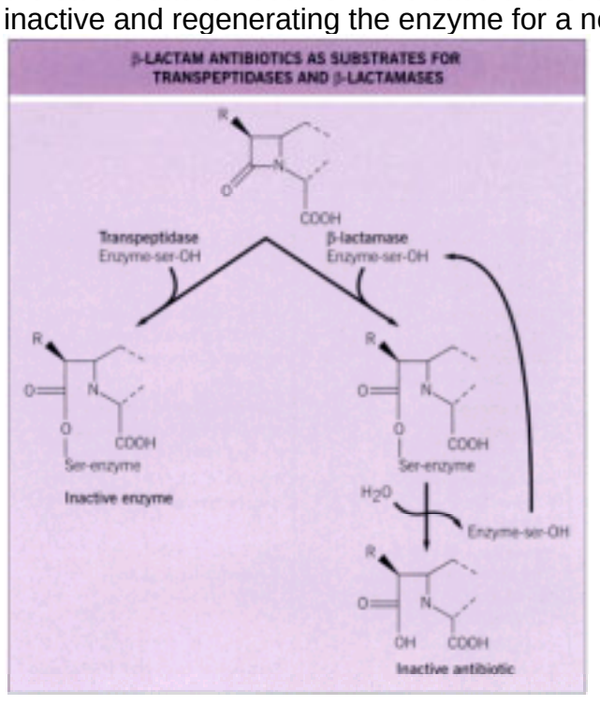

Figure 188-4 Structural modifications of ß-lactam antibiotics that overcome ß-lactamase degradation. A first strategy, applied in penicillins, cephalosporins, oxacephems and monobactams consists of the introduction of a large side chain on the nucleus, possibly containing a substituted imine or alkene. A second strategy, applied in oxacephems and cefoxitin consists of the introduction of a methoxy group on the ß-lactam ring.

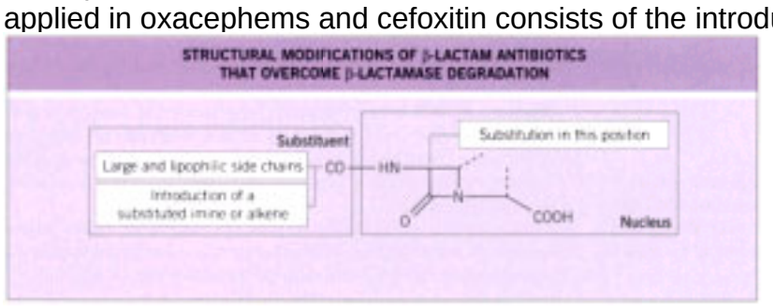

Figure 188-5 Analogy of structure between antibiotics acting on cell wall synthesis and the physiologic substrate. The two antibiotics act as analogs of the corresponding substrate.

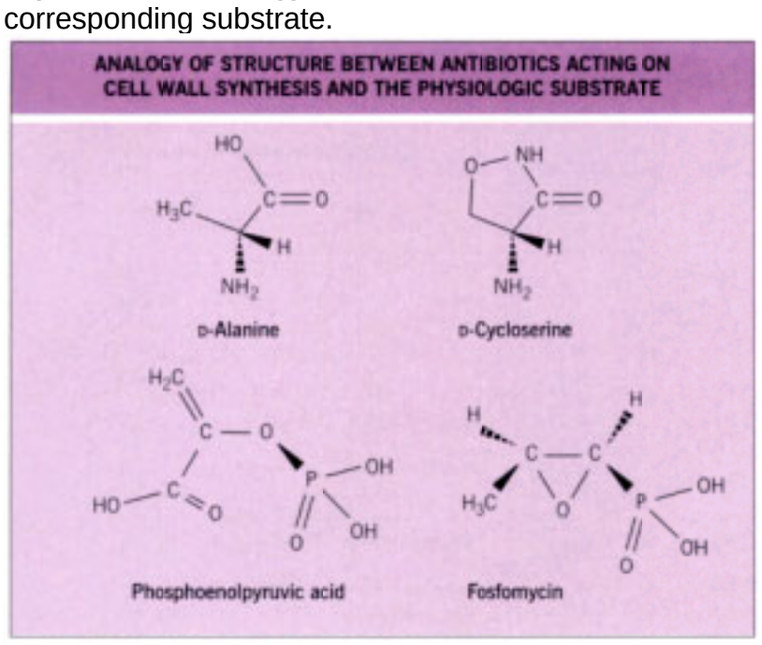

Figure 188-6 Structural formulae of the 2-deoxystreptamine-containing aminoglycosides. The numbering of the atoms shown here follows the recommendations from Nagabushe *et al.*[16] with the primed numbers (') being ascribed to the sugar attached to C4 of the 2-deoxystreptamine (as this C is of the R configuration) and the doubly primed numbers ('') being ascribed to the sugar attached to either the C6 (S configuration) for the 4,6-disubstituted 2-deoxystreptamine or the C5 (R configuration) for the 4,5-disubstituted 2-deoxystreptamine. Molecules indicated in bold denote the aminoglycosides in widespread clinical use.

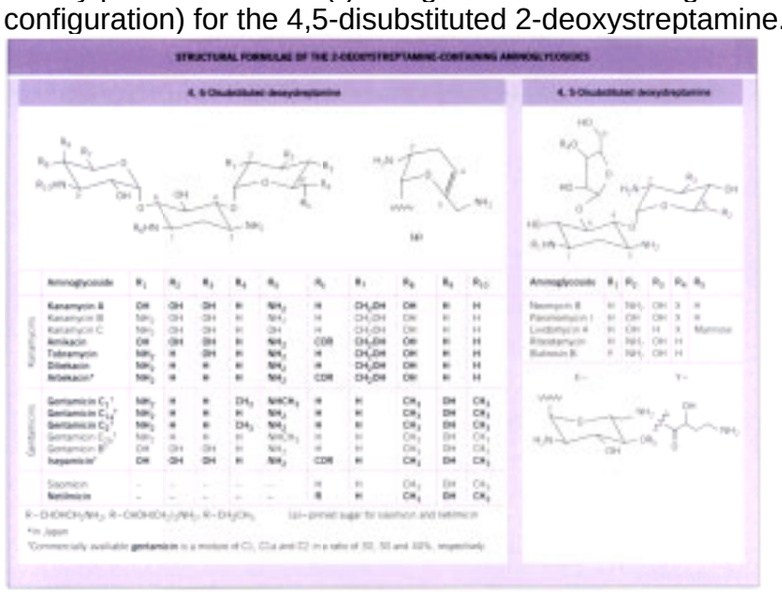

Figure 188-7 Major aminoglycoside-modifying enzymes that act on kanamycin C. This aminoglycoside is susceptible to the largest number of enzymes. The *N*-acetyltransferases (AACs) affect amino functions and the *o*-nucleotidyltransferases affect hydroxyl functions. Each group of enzymes inactivates specific sites, but each of these sites can be acted upon by distinct isoenzymes (Roman numerals) with different substrate specificities (phenotypic classification). At least one enzyme is bifunctional and affects both positions 2" (*o*-phosphorylation) and 6' (*N*-acetylation). The main aminoglycosides used clinically on which these enzymes act are amikacin (A), dibekacin (DbK), commercial gentamicin (G), gentamicin B (Gmb), kanamycin A (K), isepamicin (I), netilmicin (N), sisomicin (S) and tobramycin (T). The drug abbreviations that appear in parentheses are those for which resistance was detectable *in vitro* although clinical resistance was not conferred. *Data from Shaw et al.*[19]

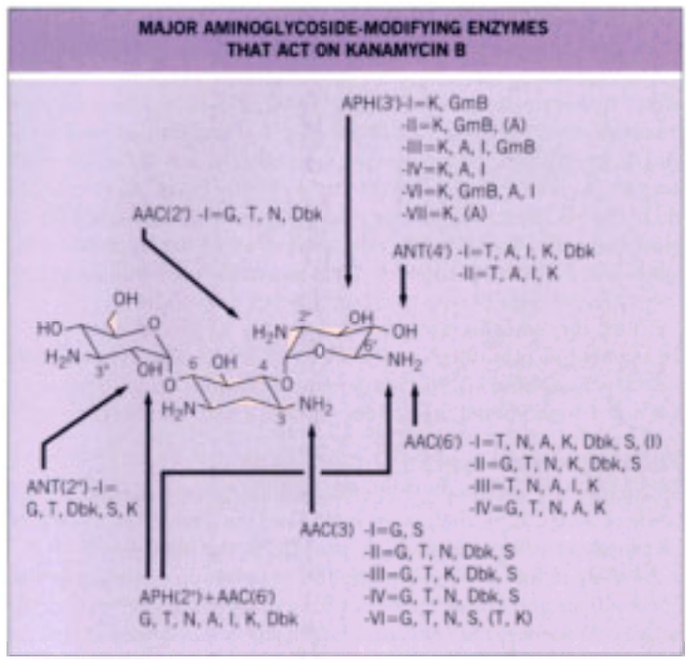

Figure 188-8 Accumulation, intrabacterial activity and efflux of tetracyclines. Tetracyclines diffuse freely through the extracellular membrane of Gram-negative bacteria. Penetration inside bacteria is an energy-dependent process depending on the pH and Mg^{2+} gradient between the extracellular medium of Gram-positive bacteria or the periplasmic medium of Gram-negative bacteria and the intracellular medium. Only the protonated form is highly diffusible, so accumulation is favored by lowering of the extracellular pH. Once inside the cytosol the tetracycline molecule forms a nondiffusible complex with Mg^{2+} . This type of complex with a bivalent cation is also the substrate of the efflux pumps present in the membrane of resistant bacteria and acting as H^+ antiports (pink circle). The antibacterial action of the teracyclines (T) is due to the binding to the 30S subunit of the ribosomes. In the pretranslocational state, tetracyclines inhibit the binding of aminoacyl tRNA (arrow 1) to the A-site (yellow part of the ribosome). In the post-translocational state, tetracyclines protrude in the P-site (white part of the ribosome) and inhibit the binding of the peptidyl tRNA (arrow 2). *Data from Geigenmüller and Nierhaus*[21] *and Yamaguchi et al.*[23]

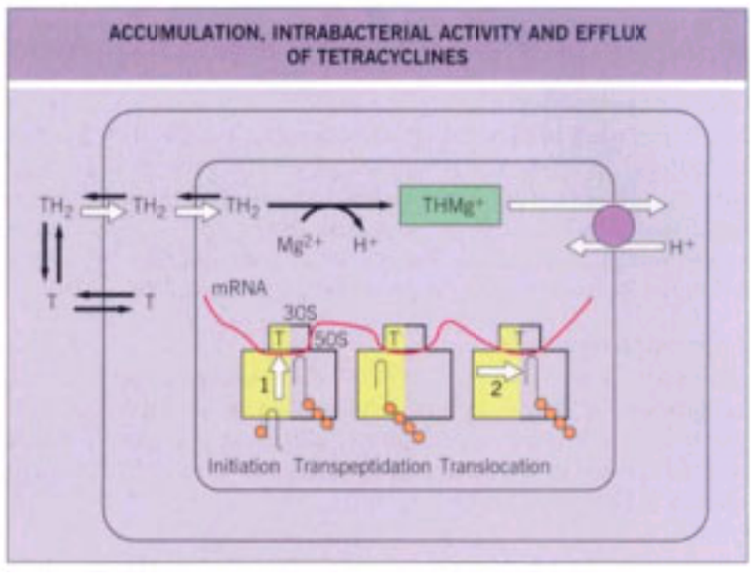

Figure 188-9 Chemical structure of the macrolides. The upper panel shows the degradation of erythromycin in the gastric milieu (substituents responsible for the instability of the miolecule are shown in gray). 16-membered macrolides and ketolides are intrinsically stable. The structural modifications conferring stability in acidic milieu to 14- and 15-membered macrolides are highlighted in gray in the middle panel. The lower panel compares the binding of macrolides and ketolides to the petidyl transferase site of the 50S subunit of ribosomes. Macrolides are characterized by a single anchoring point and ketolides by a double anchoring point, which increases the affinity of ketolides for wild type and methylated ribosomes.

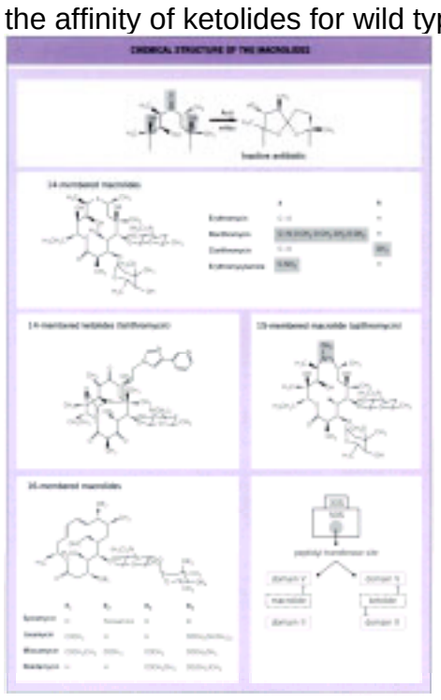

Figure 188-10 Structural activity relationship for linezolid, the first oxazolidinone, and mode of action. The drug prevents the formation of the ternary complex between mRNA, ribosome subunits and $tRNA^{met}$ necessary for protein synthesis.

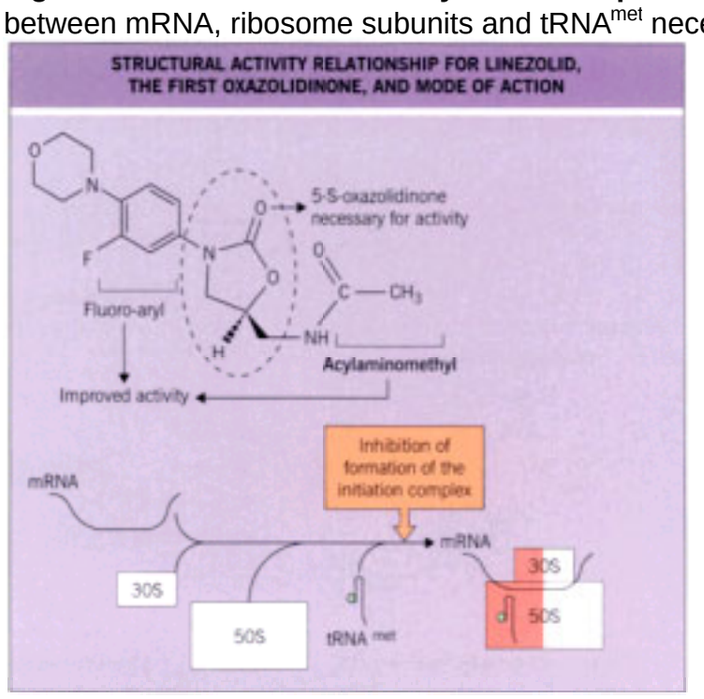

Figure 188-11 Structure-activity, structure-pharmacokinetics and structure-toxicity relationships of the fluoroquinolones. These considerations form the basis of the rational development of the new molecules of this class, which have a very extended spectrum (including Gram-positive bacteria and anaerobes), a long half-life and minimal phototoxicity and metabolic interactions.

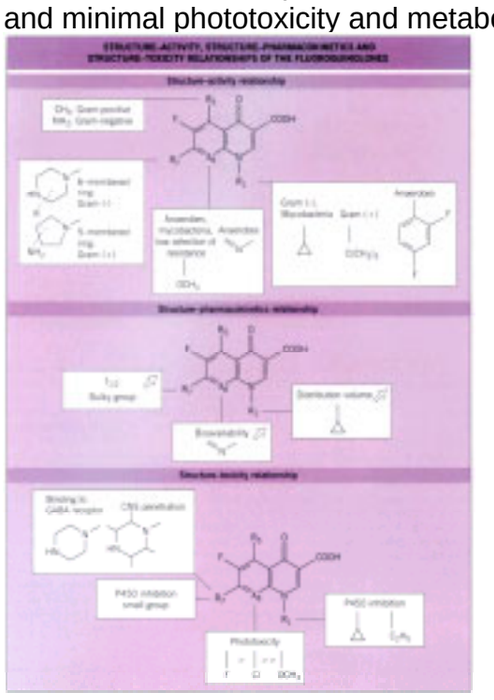

Figure 188-12 Ternary complex formed between DNA, DNA-gyrase or -topoisomerase IV and stacked fluoroquinolones. Subunits A form covalent bonds via Tyr122 with the 5' end of the DNA chain. The binding site for fluoroquinolones is located in the bubble formed during the local opening of the DNA molecule. The right panel shows the parts of the antibiotic molecules interacting with DNA, with the enzyme or favoring the stacking of the fluoroquinolone molecules. *Adapted from Shen et al.*[45]

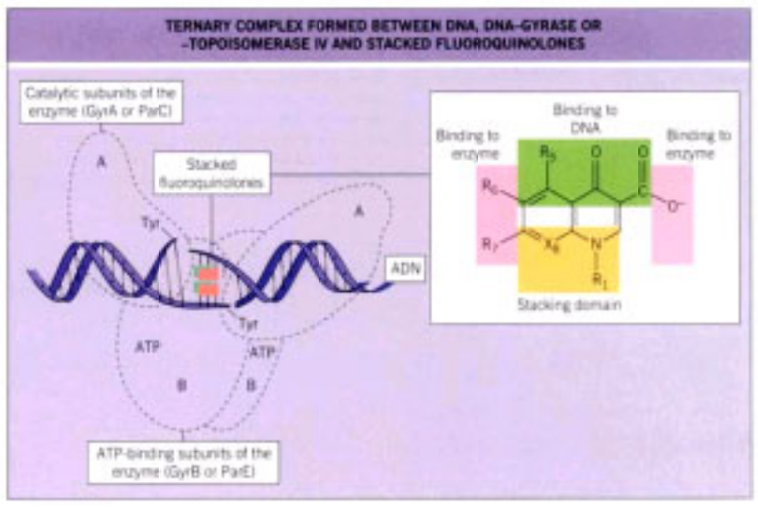

Figure 188-13 Modes of action of nitrofurans and nitroimidazoles. The modes of action include passage through the cell membrane, reduction to highly reactive products, interaction with intracellular targets and release of inactive end products.

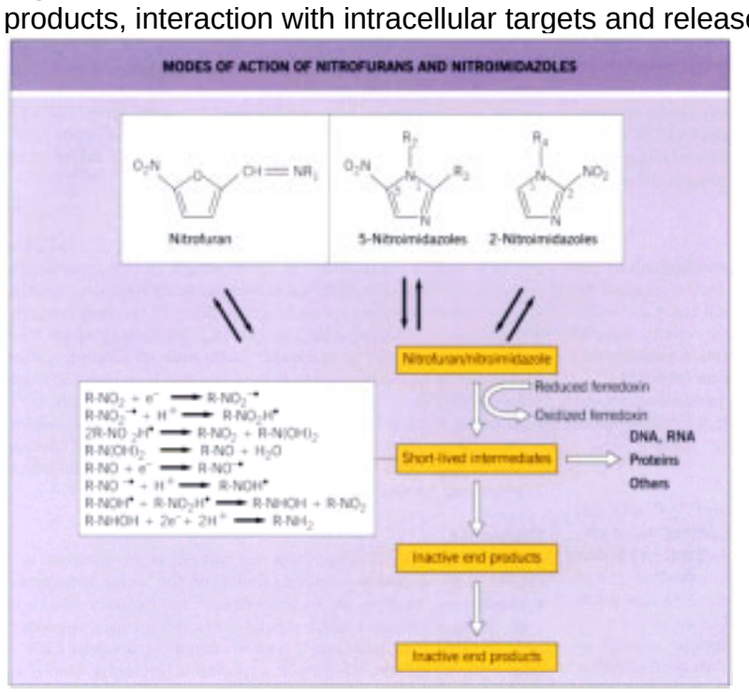

Figure 188-14 Mode of action of rifamycins. Synthesis of mRNA by RNA polymerase is shown in the upper panel and inhibition by rifamycins (R in the green squares) is shown in the lower panel. The RNA polymerase core is made up of four subunits, of which the ß' subunit binds to the DNA template and the ß subunit binds the ribonucleotide diphosphate (NDP; triangle). The s factor only participates to the initiation step by allowing for the recognition by the enzyme core of promoter sequences on the DNA template. Rifamycins bind to the ß subunit. They do not interfere with the binding of the nucleotide diphosphate, but rather inhibit the transcription initiation either by impairing the formation of the first phosphodiester bond or the translocation reaction of the newly synthesized dinucleotide.

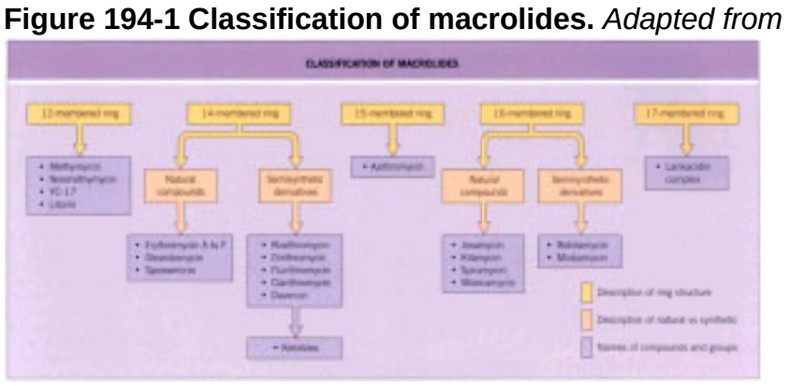

Figure 194-2 Possible molecular action of streptogramins. In the absence of streptogramins, the exit channel for peptide chains is free. In the presence of streptogramins, type A may induce a conformational change of L10 and L11, leading to an increase in the association of type B streptogramins for L24 and to a constriction of the exit channel. L10, L11 and L24 are the main proteins of the exit channel of peptide chains. *Adapted from Pechère.*[5]

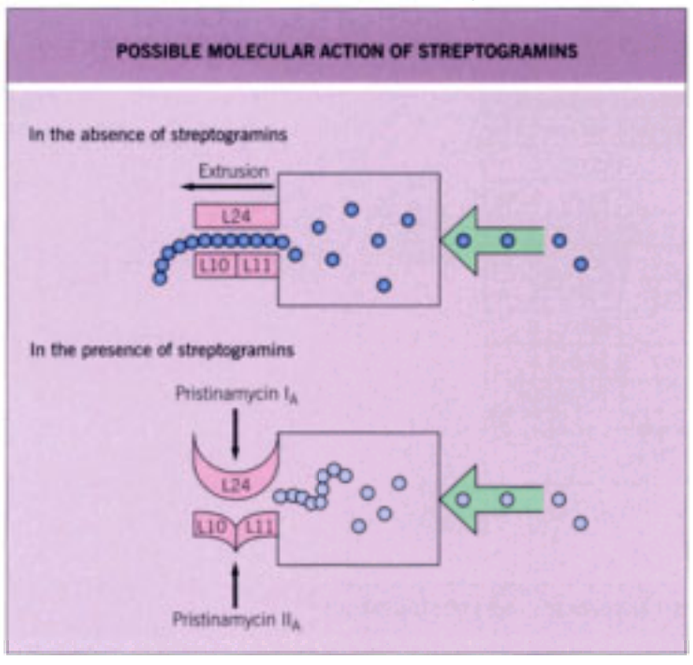

Figure 196-1 Chemical structures of the aminoglycosides. All aminoglycosides include an aminocyclitol (a central six-membered ring containing amino groups), which is linked to two or more amino- or non-amino-containing sugars by glycosidic bonds. For streptomycin, the aminocyclitol ring is a streptidine, whereas for the remainder of the clinically available aminoglycosides it is 2-deoxystreptamine. Neomycin contains approximately equal amounts of neomycin B (R_1 =H; R_2 =CH_2 NH_2) and neomycin C (R_1 =CH_2 NH_2 ; R_2 =H). Kanamycin is principally kanamycin A, as shown. Gentamicin is gentamicin C complex with roughly equal amounts of C_1 (R_1 =R_2 =CH_3), C_{1a} (R_1 =R_2 =H) and C_2 (R_1 =CH_3 ; R_2 =H).

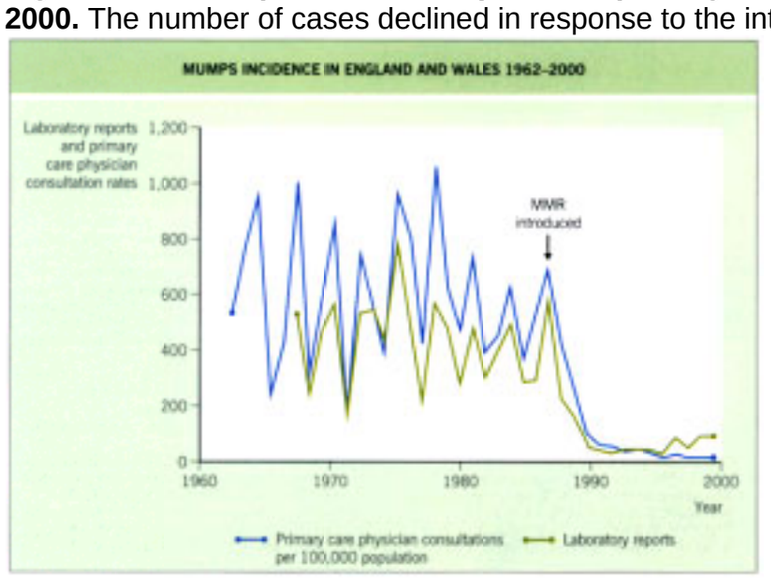

Figure 213-1 Poliovirus type 1. The particles in this electron micrograph are negatively stained with 0.5% uranyl acetate.

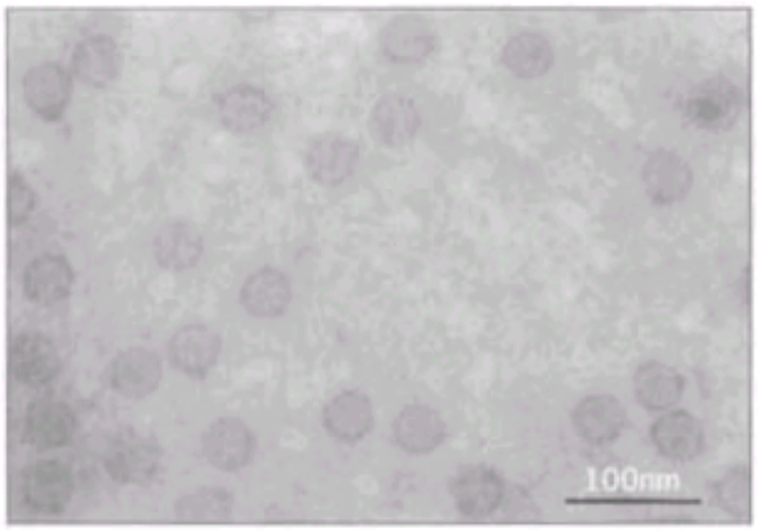

Figure 213-2 Organization of the poliovirus genome. The single-stranded genomic RNA of poliovirus (2.4×10^6 Da, approximately 7500 nucleotides) has positive-stranded sense and codes in a single open reading frame for capsid and functional proteins (modified according to Racaniello[3]). The boxes represent the coding region; the lines represent the nontranslated regions (NTR) at the 5'- and 3'-termini (5'- and 3'-NTRs). A small hydrophobic protein is covalently linked to the terminal uracil of the 5'-NTR and called 'virus protein genome linked' (VPg). The 5'-NTR has a significant secondary structure and contains the initiation site for translation at nucleotide position 741 (the internal ribosome entry site). The 3'-NTR (72 nucleotides) is polyadenylated (62 nucleotides on average). The coding region of the genome is translated into a large precursor polyprotein. Region P1 codes for the capsid proteins VP0 (precursor of VP4 and VP2), VP1 and VP3. Regions P2 and P3 code for functional proteins (e.g. 2A codes for a protease, 3B codes for VPg, 3C and 3CD code for proteases, and 3D codes for the RNA polymerase). Three proteases mediate processing of the precursor proteins: protease 2A releases the P1 capsid precursor from the nascent polyprotein, and the proteases 3C and 3CD mediate most of the other cleavages before and during virus assembly. Virus assembly is completed when a single RNA molecule is surrounded by its capsid with 60 protomers, in which the precursor VP0 is then cleaved into mature VP4 and VP2. It is postulated that the viral RNA is involved in this final cleavage.

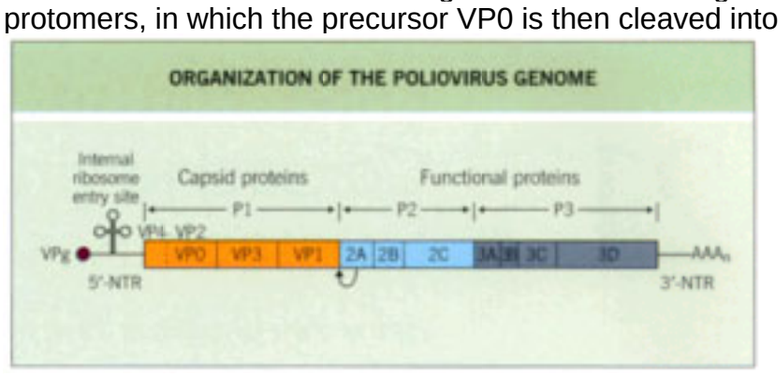

Figure 213-3 Epidemiologic survey of reported enterovirus infections. This epidemiologic survey by the German Association for Prevention of Virus Diseases (DVV) for the years 1984 and 1985 demonstrates that most infections with coxsackieviruses groups A and B and echoviruses in Germany occur during summer and autumn. *Data from Habermehl and Knocke.*

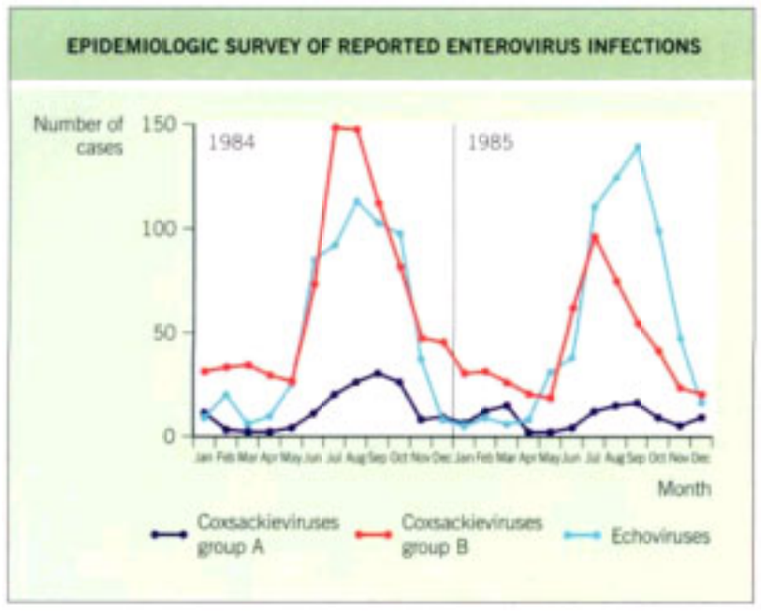

Figure 213-4 Receptor-mediated entry of poliovirus into host cells. The entry of poliovirus into HEp-2 cells is followed by transmission electron microscopy of ultrathin sections of synchronously infected cells.[31] [32] (a) Poliovirus (v) adsorbs at the cell surface immediately after infection (0 minutes after infection). (b) Beginning 1 minute after infection, poliovirus is located at areas of the cell surface that have clathrin-coated pits (cp), at which the surface membrane starts to invaginate. (c) Five minutes after infection, poliovirus is taken up by clathrin-coated vesicles (cv) into the cytoplasm. (d) Between 15 and 20 minutes after infection, poliovirus is within intracellular clathrin-free vesicles or endosomes (e), which are suggested as the sites of viral uncoating.

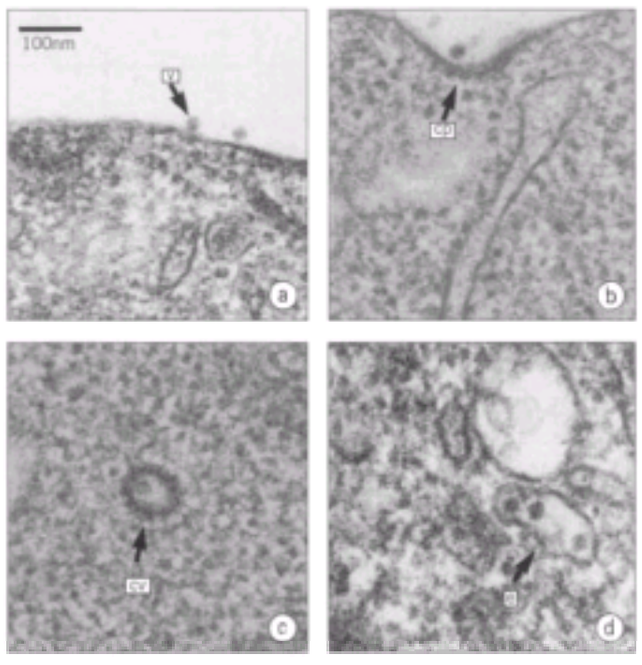

Figure 213-5 The reproduction cycle of poliovirus. Receptor-mediated entry of poliovirus is completed by the release of the viral RNA from the virus capsid (uncoating). The syntheses of viral protein and RNA are the next reproduction steps. The viral precursor polyprotein is autocatalytically cleaved by viral proteases, resulting in the viral RNA polymerase and, via several precursor proteins, in the virus capsid proteins (see Fig. 213.2). The viral RNA polymerase mediates viral transcription (i.e. de-novo synthesis of positive-stranded RNA via negative-stranded RNA templates). Maturation of the virus is completed by encapsidation of one molecule of positive-stranded RNA into a capsid with the complete set of proteins VP1, VP2, VP3 and VP4. RI, replicative intermediate.

Figure 213-6 The poliovirus-induced cytopathic effect. The cytopathic effect of poliovirus type 1 in monolayers of HEp-2 cells (a, c, e) is demonstrated in comparison to noninfected control cells (b, d, f) by light microscopy, scanning electron microscopy and transmission electron microscopy. [35] (a) Light microscopy of infected cells stained with hemalum-eosin shows rounded cells with pyknotic nuclei and condensed chromatin (8 hours after infection). (b) Light microscopy of control cells. (c) Scanning electron microscopy demonstrates severe rounding of the infected cells (12 hours after infection). The infected cells are characterized by elongated filopodia and microvilli at the cell surface; these are collapsed or even lost. (d) Scanning electron microscopy of control cells. (e) Transmission electron microscopy of ultrathin sections reveals infected pyknotic cell condensation of chromatin arranged in patches in a lobed nucleus and clusters of vesicles in the cytoplasm (8 hours after infection). (f) Transmission electron microscopy of control cells.

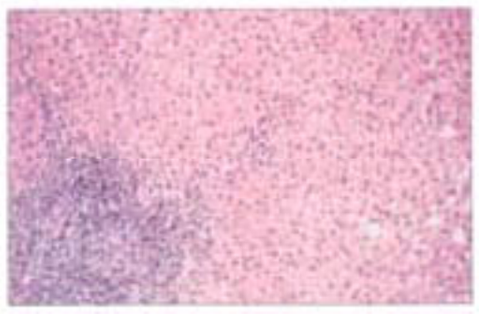

Figure 215-1 Organization of herpesvirus genomes. Inverted repeat sequences in VZV, HSV and CMV allow the genome to recombine in 2,4, and 4 isomers, respectively. Both HSV and CMV have a UL (long unique base sequence) and a US (short unique base sequence) each terminated by two sets of inverted repeated sequences. The repeated sequences allow the UL and US to invert relative to one another, so yielding four isometric forms of DNA. As there is only one set of inverted repeats in VZV, only two isomers of DNA can be produced. Both EBV and HHV-8 have only one isomeric form with several unique regions surrounded by direct repeated sequences.

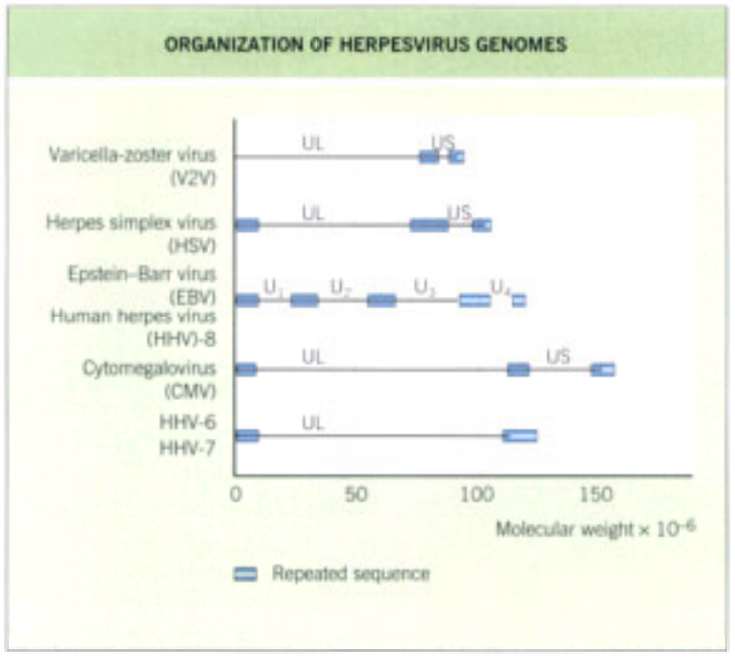

Figure 215-2 Enveloped virus particle. (a) Thin section. (b) Negative staining. These electron microscopic views (×140,000) show HSV. The DNA is surrounded by a nucleocapsid comprised of 162 individual protein subunits (150 hexavalent capsomers and 12 pentavalent capsomers) arranged in the form of an icosahedron. The nucleocapsid is in turn enclosed by the tegument and virus envelope bearing glycoprotein spikes. *Courtesy of Hans Gelderblom*.

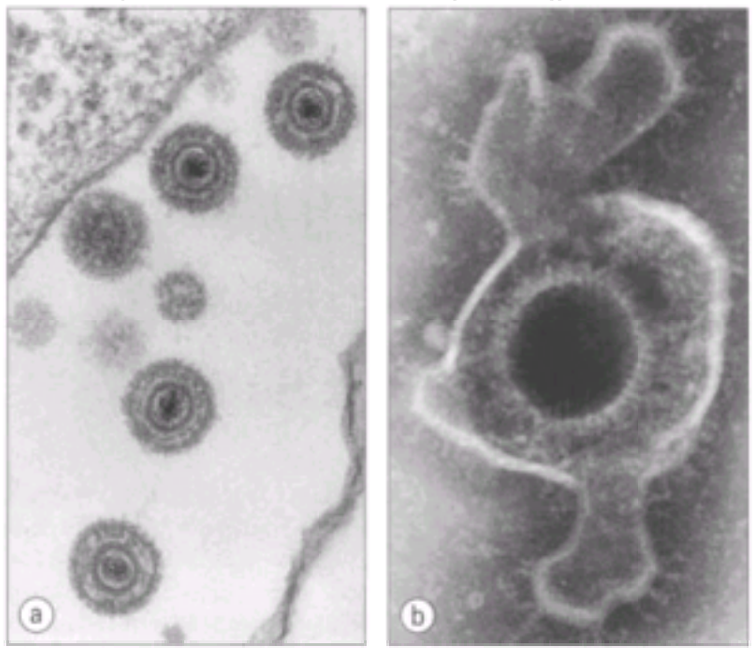

Figure 215-3 Phylogenetic relationship between the human herpesviruses and herpes B virus. The tree was created by neighbor-joining analysis of the glycoprotein B gene sequences. HVS, herpesvirus simiae (herpes B virus). *Adapted from Schultz, 2000.*[5]

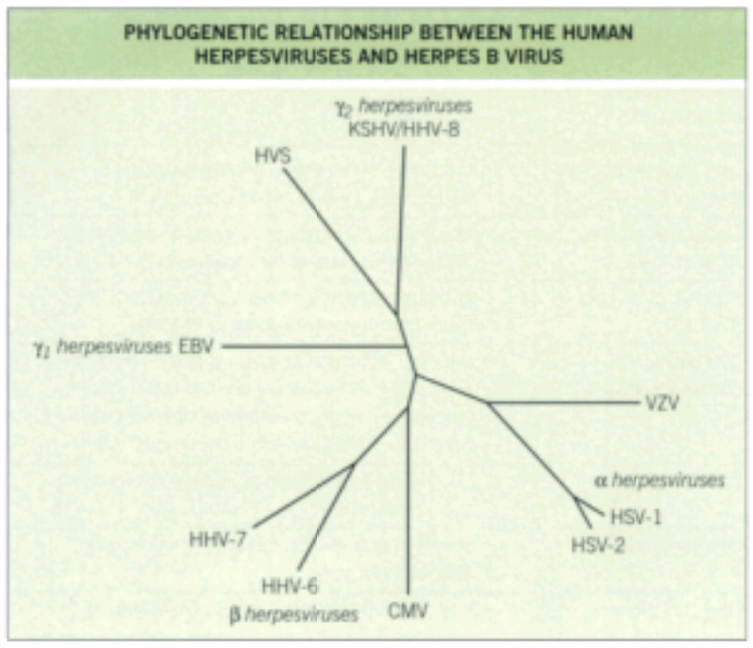

Figure 215-4 Herpesvirus replication. The tegument proteins effect the shut-down of host cell metabolism. On entry to the nucleus the DNA circularizes and binds a tegument protein and cellular factors to initiate transcription. Transcription and translation occur in three phases: immediate-early, early and late. Capsid proteins migrate into the nucleus and the viral DNA is encapsidated. The viral glycoproteins are extensively modified post-translationally by transit through the Golgi apparatus. The glycoproteins diffuse to the nuclear envelope. The nucleocapsids bud through the modified nuclear membrane and exit the cell via the endoplasmic reticulum or are released on cell lysis.

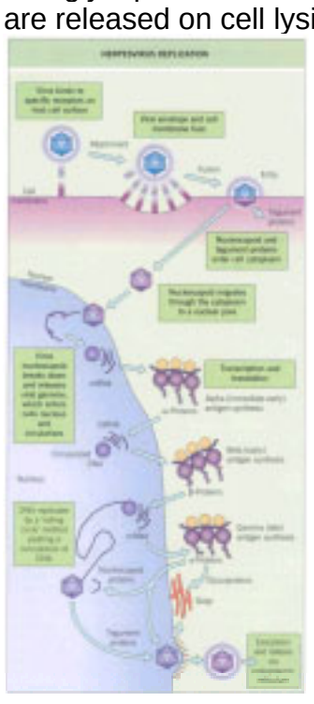

Figure 215-5 Pathogenesis of varicella-zoster virus infection.

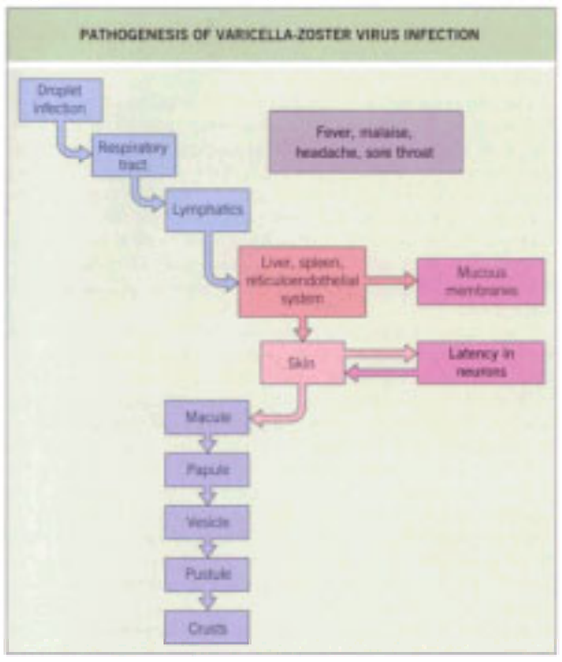

Figure 215-6 Pathogenesis of Epstein-Barr virus infections. Infection may result in lytic infection of the cell or cell immortalization, which can be distinguished by the production of virus and the expression of different viral proteins and antigens. Figure 218-1 A negative-stained M form of molluscum contagiosum virus. Molluscum contagiosum virus from lesion material.

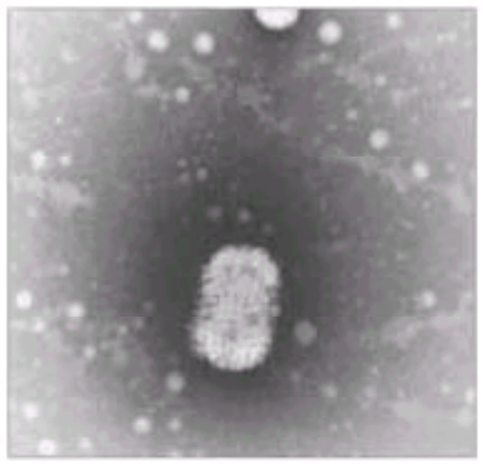

Figure 218-2 The cytoplasmic poxvirus replication cycle. Poxvirus virions containing early RNA transcription machinery attach to, and fuse with, the plasma membrane (uncoating I). Early genes are expressed that code for a variety of functions that modify the host cell for optimal virus replication, attentuate the host response to infection and mediate virus synthetic processes. After further uncoating (II), the virus genome is replicated via concatamers, late transcription factors are expressed from intermediate genes and late gene RNA is synthesized. Late genes encode the early transcription system, enzymes and structural proteins necessary for virion assembly, which commences with the formation of membrane structures in the intermediate compartment and the packaging of resolved unit length genomic DNA. The intracellular mature virion has two membranes derived from the intermediate compartment. It may remain in the cytoplasm or (in certain virus species) become occluded in an A-type inclusion body or become wrapped by a further two membranes in the Golgi and exported from the cell with the loss of one membrane (extracellular enveloped virions). The extracellular enveloped virions are thought to be most important in cell-to-cell spread and systemic disease. This replication scheme is based on the study of the prototypic poxvirus vaccinia.[1] Other poxvirus species probably vary from this model mainly in the types of growth factors and host response modifiers encoded by the virus and the amounts of extracellular enveloped virions produced. *Adapted from Moss.*[1]

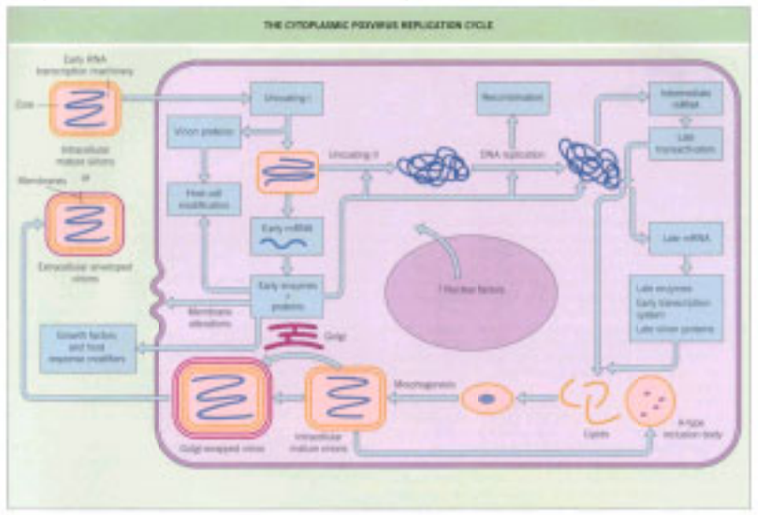

Figure 218-3 Molluscum contagiosum lesion. In this lesion a major and minor umbilicus has formed as a result of the hypertrophy of infected cells and hyperplasia of the basal cells, which caused a severe invagination of the epidermis but no loss of integrity of the basement membrane. The molluscum bodies stain as pink to purple acidophilic hyaline masses up to 37 × 27µm in size. Small arrows: molluscum bodies. Large arrows: epidermis-dermis boundary. (H & E.)

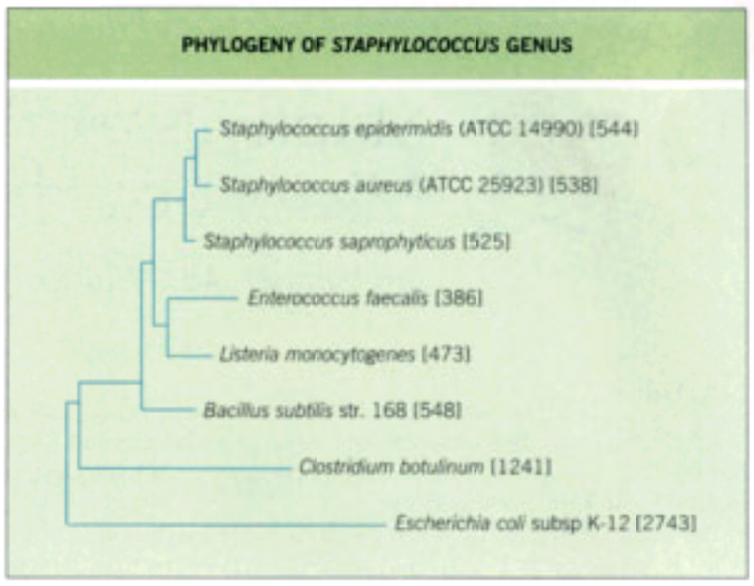

Figure 224-4 Structure of the peptidoglycan layer. The peptidoglycan layer consists of three integral parts. The glycan chains are built with 10–12 alternating *N*-acetylglucosamine (Glu) and *N*-acetylmuramic acid (Mur) subunits jointed with ß-1,4 glycosidic bonds. Vertical pentapeptide side chains are linked to the muramic acids subunits, and the side chains are in turn cross-linked with diagonal intrapeptide bridges. For example, the glycan chains in *Staphylococcus aureus* are cross-linked with pentaglycine bridges attached to L-glycine in one pentapeptide chain and D-alanine in an adjacent chain.

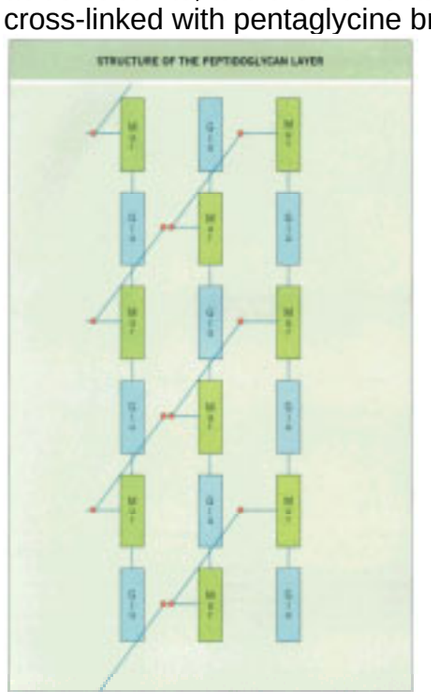

Figure 224-5 Structure and sorting of protein A. Structure of the cell wall anchor of surface proteins in *Staphylococcus aureus* and other Gram-positive bacteria. (a) Cell wall sorting of surface proteins consists of four distinct steps, which lead to the proteolytic cleavage of the polypeptide chain between threonine (T) and glycine (G). The carboxyl of threonine is subsequently amide-linked to the free amino group in the pentaglycine cross-bridge of the staphylococcal cell wall. The cell wall linkage of surface proteins in *S. aureus* (b) is compared with that proposed for other Gram-positive bacteria such as *Streptococcus pyogenes* (c) and *Listeria monocytogenes* (d). NacGlu, *N*-acetylglucosamine; NacMur, *N*-acetylmuramic acid. *Adapted with permission from Crossley and Archer.*[5]

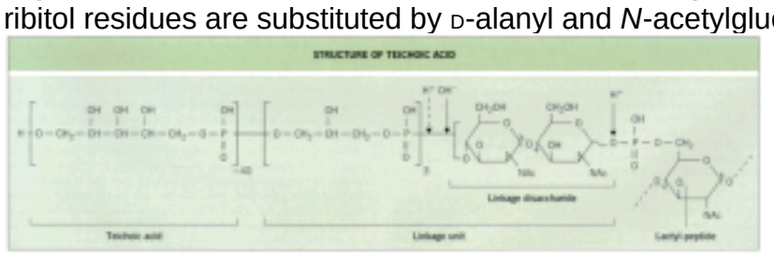

Figure 224-7 Phage type III of *Staphylococcus aureus.*

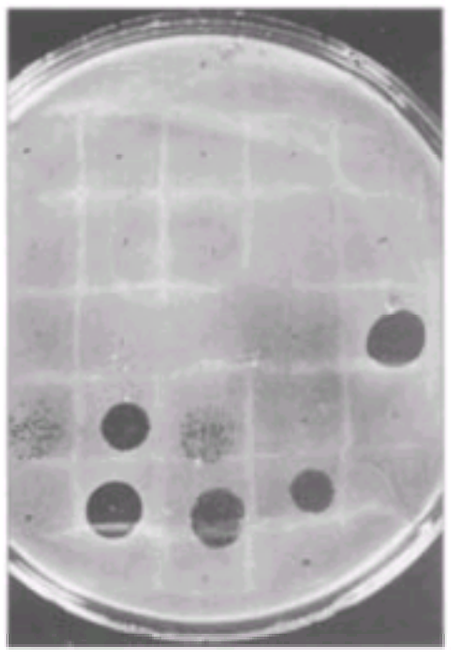

Figure 224-8 Bacterial adherence. The figure illustrates the events associated with bacterial (B) adherence to a biomaterial in relation to time and the molecular sequence in bacterial attachment, adhesion, aggregation and dispersion at substratum surface. A number of possible interactions may occur depending on the specificities of the bacteria or substratum system, the distance from the biomaterial and the stage of adherence. The attachment stage is mediated by non-specific forces. Adhesion is driven by specific adhesin-receptor interactions. The final aggregative step results in a bacterial macrocolony on the biomaterial surface in which the bacteria are firmly adherent to the biomaterial and each other. Bacterial exopolysaccharide blankets the macrocolony and may serve to improve the nutritional microenvironment and protect the bacteria from host defenses. In the dispersion phase, bacteria disaggregate, break loose from the macrocolony and drift free into the bloodstream. *Adapted with permission from Gristina AG. Biomaterial centered infection: microbial adhesion versus tissue integration. Science 1987;237:1588. © 1987 American Association for the Advancement of Science.*

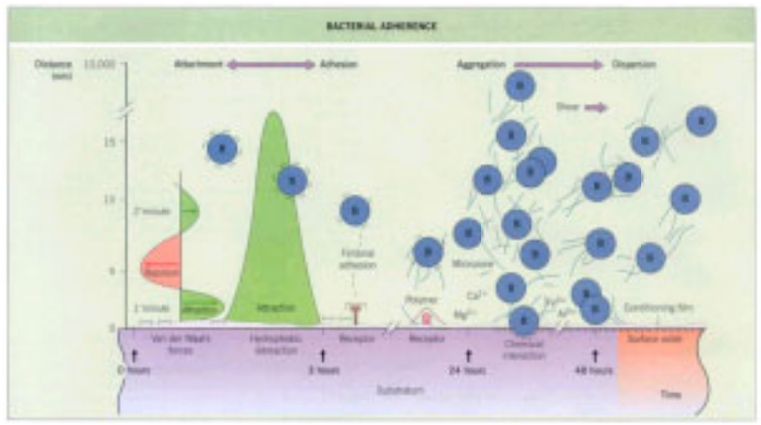

Figure 224-9 Opsonization of unencapsulated staphylococci. Opsonization through complement activation is primarily a function of C3b and iC3b. When antibody (ab) molecules bind to antigen, the antigen-antibody complex activates the first complement component, C1. C1 is then converted into an esterase, initiating the classical pathway. Additionally, some cell-wall components can activate the alternative pathway.

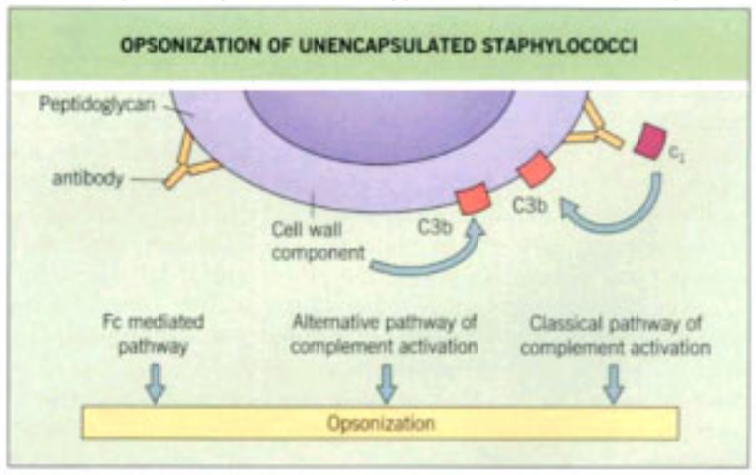

Figure 224-10 Prevention of opsonization in encapsulated staphylococci. (Left) The capsule of *Staphylococcus aureus* prevents binding of antibodies to peptidoglycan: no opsonization. (Right) The capsule prevents binding of opsonins on the cell wall of *Staphylococcus aureus* to complement and Fc receptors on PMNLs.

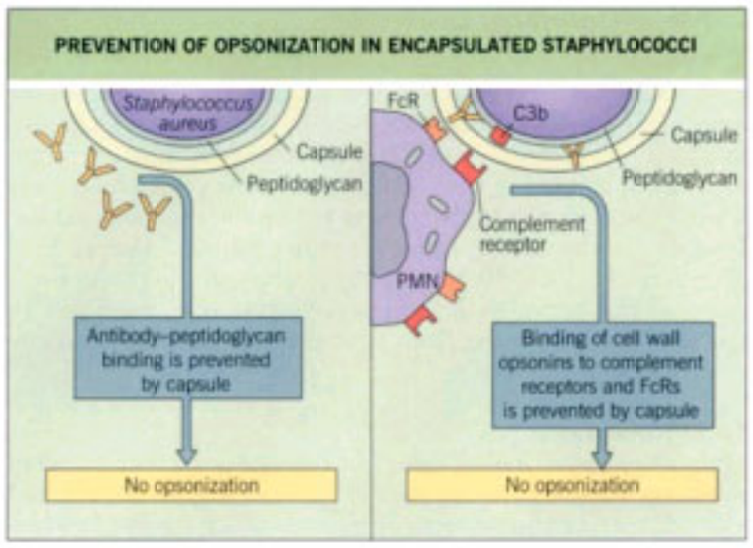

Figure 224-11 Differences between antigen and superantigen. Staphylococcal enterotoxin and TSST-1 act as superantigens, binding directly to MHC class II and the Vß chains of the T cell receptor (TCR) without the need for normal antigen processing.

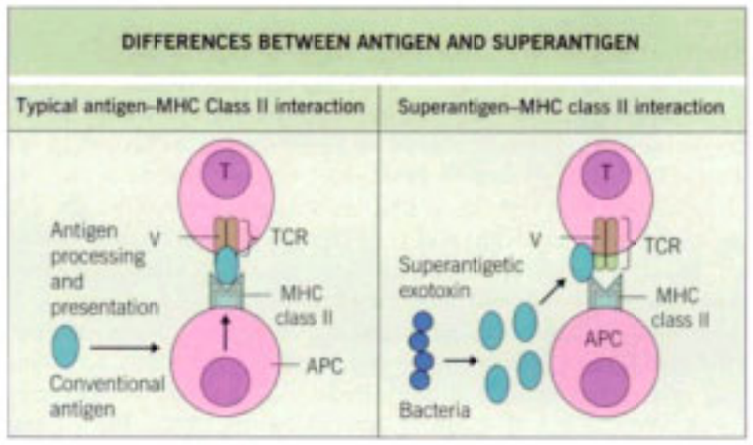

Figure 224-12 Potential sources for bacterial contamination of intravascular catheters. Bacteria gain access to the catheter by the following routes: contamination of the catheter hub, contamination of the infusate, transcutaneous migration and hematogenous seeding.

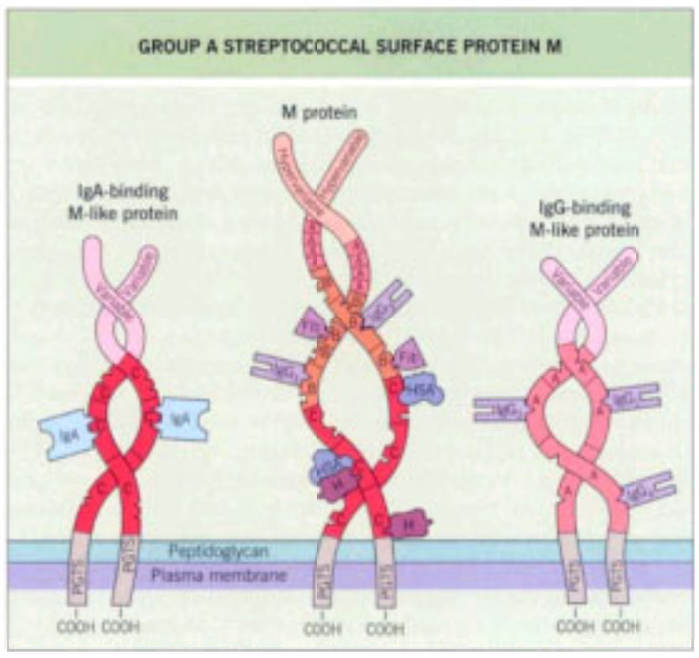

Figure 225-16 The role of streptokinase in acute poststreptococcal glomerulonephritis. Theoretic model of the pathogenesis of acute post-streptococcal glomerulonephritis as induced by streptokinase. The affinity of the streptokinase isotypes (Ska) is probably dependent on differences in the amino acid composition. This model explains the early deposition of C3b in the glomeruli that is typical of the early phase of acute post-streptococcal glomerulonephritis. Ska, streptokinase from Group A streptococci.

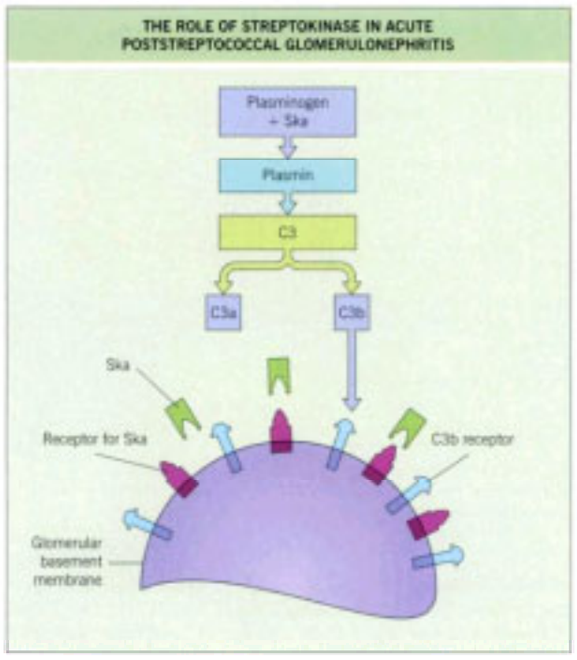

Figure 225-17 Pathogenesis of streptococcal toxic shock syndrome. In this model, patients who have opsonizing antibodies against the M antigen are protected against infection. In the absence of these antibodies, they may develop a serious infection if they are also lacking neutralizing antibodies against the streptococcal pyrogenic exotoxins which, as superantigens, may induce a cytokine cascade. This process will be hindered by the presence of toxin-neutralizing antibodies. The affinity of the toxins to the class II major histocompatibility complex of antigen presenting cells (APC) and T-cell receptors of specific Vß (variable region of ß chain of the T cell receptor) bearing T cells determines the outcome in each individual patient.

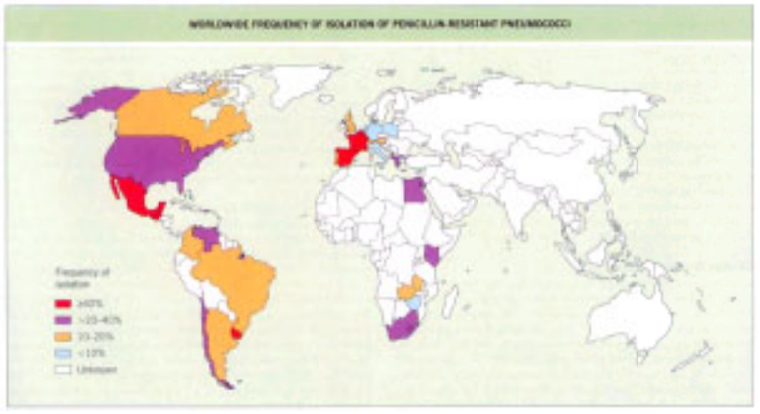

Figure 226-1 Tests for the identification of *Listeria monocytogenes.* (a) CAMP test. Enhanced hemolysis patterns for *L. monocytogenes* (left) and *Streptococcus agalactiae* (right) colonies are shown; these are growing adjacent to a streak of *Staphylococcus aureus* colonies in the center. (b) Demonstration of motility of *L. monocytogenes* grown in semisolid agar at room temperature. Note that the migration of the organism from the central stab is more pronounced at the surface of the soft agar, forming the typical umbrella-shaped pattern in both tubes.

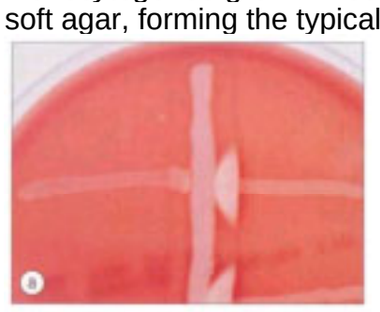

Figure 226-2 *Listeria monocytogenes* can invade both 'professional' phagocytic cells — polymorphonuclear leukocytes and monocytes — and nonphagocytic cells. Attachment of the bacteria to the surface of nonphagocytic cells may be determined by heparin sulfate recognition proteins on the surface of the organism. Once internalized, the bacterial product listeriolysin O will lyse the phagosome, liberating the bacteria into the cytoplasm, where they proliferate. After a few hours, actin filaments polarize at one end of the bacterium, propelling it to the internal membrane surface. The organism will break through the membrane to enter the exterior of the cell or an adjacent cell.

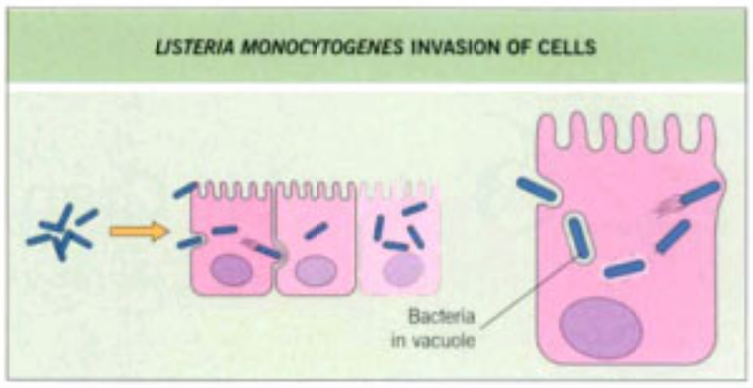

Figure 226-3 Phagocytosis of *Listeria monocytogenes.* Opsonized *L. monocytogenes* is phagocytosed by professional phagocytic cells through a complement-receptor-mediated process. Once ingested into a phagosome of a monocyte or macrophage, most bacteria are quickly killed by oxidative radicals (O_2^-), lysozyme, nitric oxide (NO) and other products of the cell. Tissue macrophages produce a variety of protein products essential for the activation of natural killer (NK) cells (interleukin(IL)-12), T cells (IL-1) and polymorphonuclear (PMN) leukocytes and other monocyte/macrophages (tumor necrosis factor (TNF)-a). These cells in turn produce cytokines, interferons (IFN), interleukins that cause cell proliferation (IL-2; macrophage colony stimulating factor (M-CSF)) or further activation of cell populations involved in elimination of the organism and of infected nonprofessional cells.

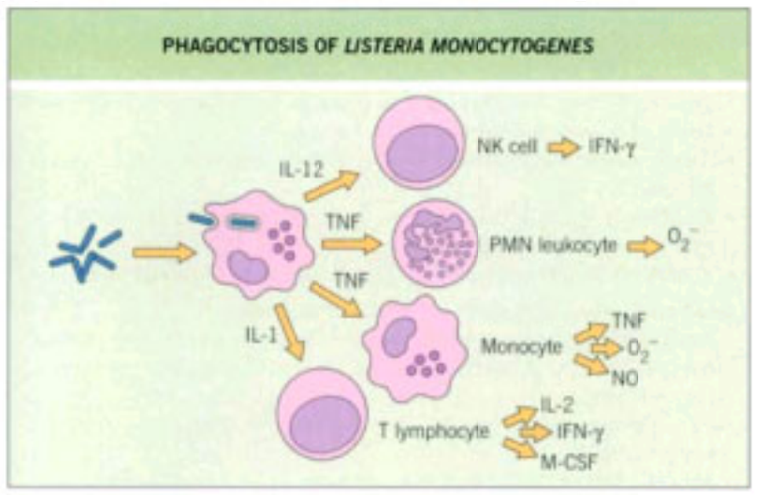

Figure 226-4 Recognition and destruction of *Listeria*-infected cells. Cytotoxic T lymphocytes and NK lymphocytes migrate to the site of infection and recognize and destroy *Listeria*-infected cells by the presence of listerial peptides on the surface of such cells. Intracellular bacteria are then exposed to the extracellular environment. Organisms in the extracellular space are efficiently phagocytosed and killed by polymorphonuclear leukocytes (PMN) and monocytes that have been primed or activated by cytokines (TNF-a, M-CSF, IL-8) and IFN-?.

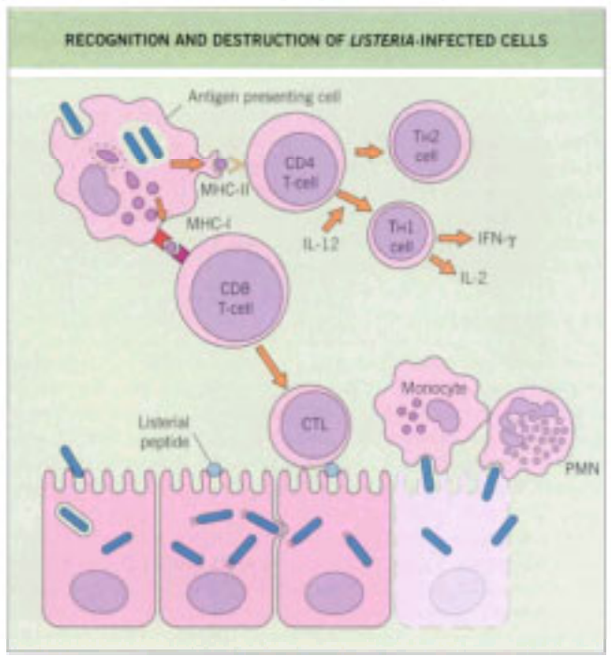

Figure 226-5 Gram stain of clinical specimen showing intra- and extracellular Gram-positive bacilli.

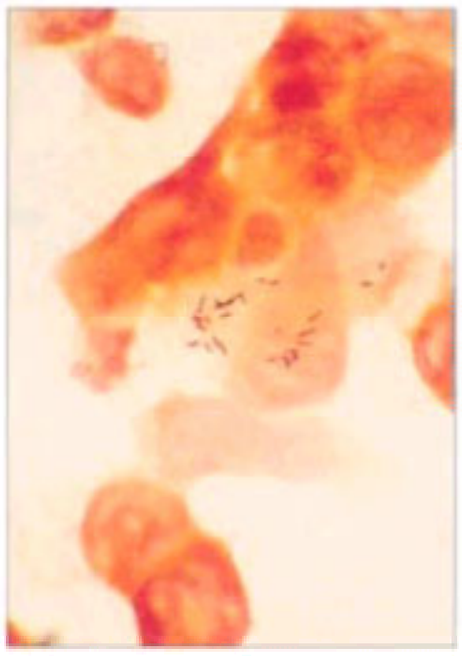

Figure 226-6 Skin rash on premature infant who has sepsis due to *Listeria monocytogenes.* This form of infection, known as granulomatosis infantisepticum, is characterized by disseminated microabscesses on the skin, spleen and liver. The elevated pale patches (1–2mm in diameter) on the skin are clearly seen in contrast to the bright erythema of surrounding skin.

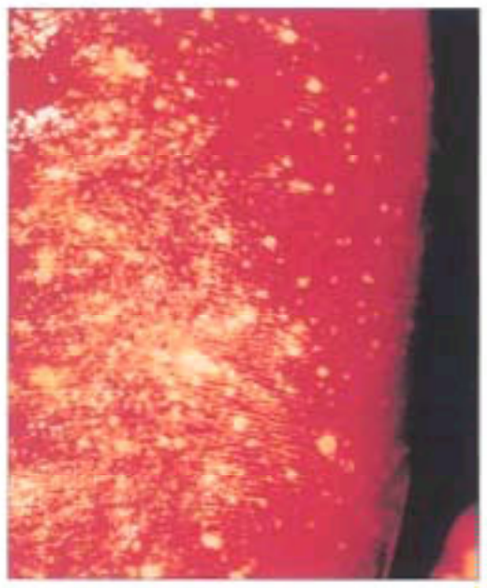

Figure 226-7 Phagocytosis of anthrax bacilli and ingestion of spores. Vegetative bacilli are relatively resistant to phagocytosis by polymorphonuclear leukocytes and monocytes, whereas spores are readily ingested. Once ingested by polymorphonuclear leukocytes or macrophage cells, however, the spores germinate into vegetative forms, which are able to reduce the normal production of bactericidal oxidative radicals by the cell. *Bacillus anthracis* produces lethal toxin (LT) and edema toxin (ET), which are cidal to cells and inhibit TNF-a production and oxidative radical production by phagocytic cells.

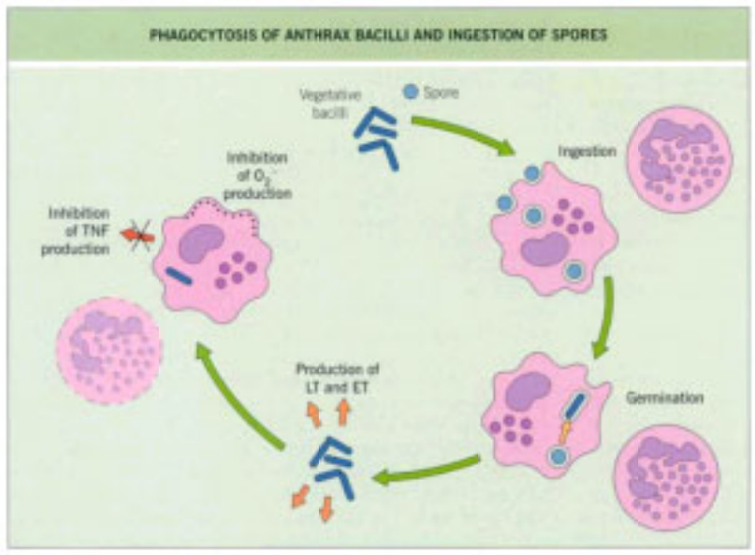

Figure 226-8 Cutaneous anthrax, demonstrating marked erythema, edema and vesicle rupture.

Figure 226-9 Chinese letter and picket-fence appearance of *Corynebacterium* spp. on Gram-stained smears.

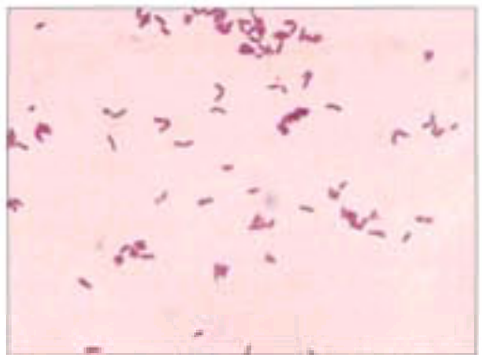

Figure 226-10 Molecular action of *Corynebacterium diphtheriae.* The B subunit of diphtheria toxin (DT) binds to host cell receptor. Proteolytic cleavage of the B subunit from the A subunit (the active DT) in cell endosome. The DT-A subunit escapes from the endosome into the cytoplasm, where it inhibits the transfer of triple code from mRNA to growing polypeptide at the ribosomes on the endoplasmic reticulum. It does this by modifying the enzyme elongation factor (EF)-2 that catalyzes this mRNA transfer.

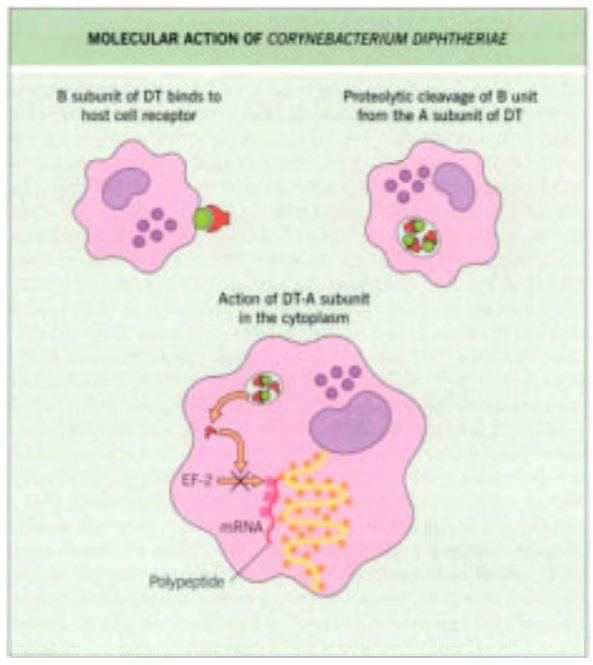

Figure 226-11 Detection of diphtheria toxin production. The Elek test detects DT production in a bacterial clinical isolate. A paper strip soaked in diphtheria antitoxin is placed perpendicular to a horizontal streak of bacterial growth. If it produces toxin, an arrow-shaped precipitin line develops in the agarose plate.

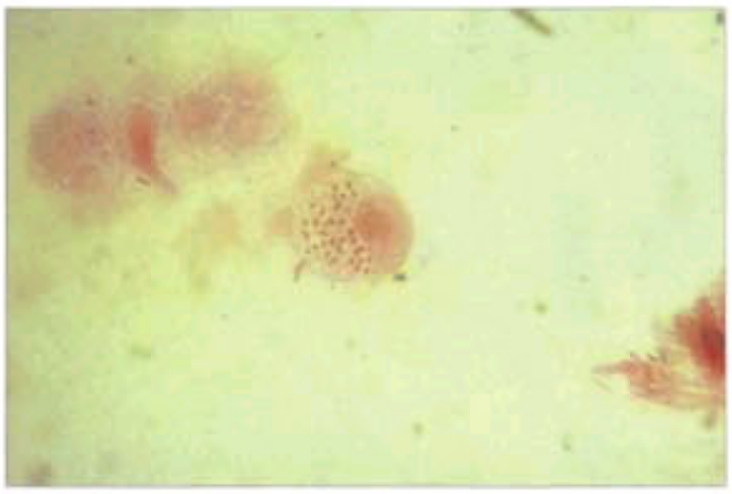

Figure 228-1 Major structural cell wall compounds of Enterobacteriaceae. The figure also illustrates the molecular organization of the outer membrane, and the most likely positions of outer membrane constituents are indicated. Lipopolysaccharide and phospholipid molecules are the major constituents of the asymmetric bilayer. Divalent cations (not indicated) are believed to play important roles in interactions of LPS: Only three types of protein are shown: the pore proteins (LamB protein not shown), OmpA protein and lipoprotein (their interactions with peptidoglycan and lipoprotein are not shown — that such interactions occur cannot be excluded). Several O-antigen chains are much longer than shown here. Enterobacterial core antigen has been omitted for simplicity. The P pili and fimbriae are discussed and illustrated in more detail in Chapter 1 .

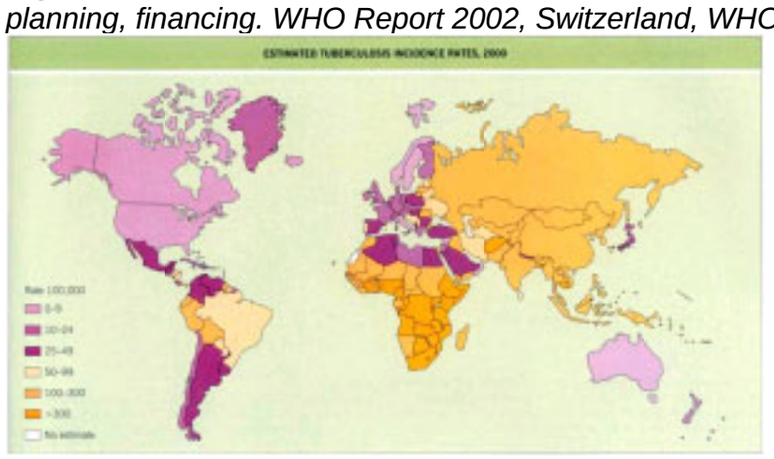

Figure 233-6 Macrophage phagocytosis and evasion of tubercle bacilli. The tubercle bacilli bind via lipoarabinomannan (LAM) (1) or complement receptors (2); phagocytosis occurs (3) with the activation of an oxidative burst (4); glycolipids (GL), sulfatides (ST) and LAM can downregulate the oxidative burst (5); reactive nitrogen intermediates may play a role in antimycobacterial activity (6), as does the acidic pH of the phagolysosome (7). Finally, the production of ammonia by tubercle bacilli may diminish the effect of reactive nitrogen intermediates (8) and contribute to the failure to form a phagolysosome fusion (9). Tubercule bacilli may evade the antimycobacterial activities of the phagolysosome by producing a hemolysin that releases the bacilli into the cytoplasm (10). NADP, nicotinamide adenine dinucleotide phosphate; NADPH, nicotinamide adenine dinucleotide phosphate, reduced form; SOD, superoxide dismutase. *Adapted from Chan and Kaufmann.* [16]

Figure 233-9 Immunoperoxidase stain of *Mycobacterium avium* complex in the bone marrow of a patient who has HIV infection and disseminated disease. The presence of mycobacteria in the bone marrow and blood of a patient is the microbiologic hallmark of disseminated MAC disease. The presence of mycobacteria in bone marrow sections using either an immunoperoxidase stain or a conventional acid-fast stain requires the presence of approximately 1.5×10^4 bacilli/g of bone marrow.

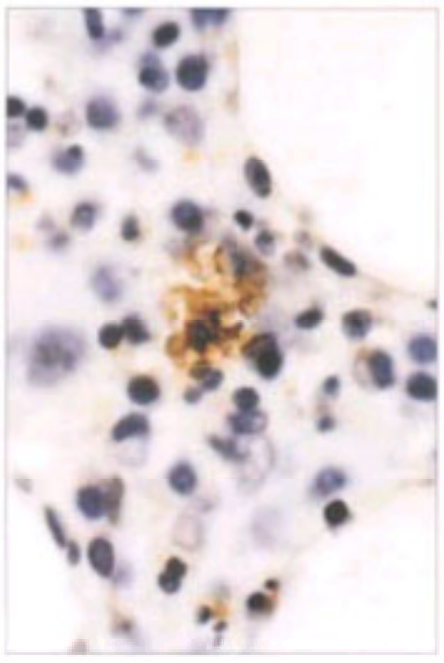

Figure 233-10 Ziehl-Neelsen acid-fast stain of sputum containing 4+ tubercle bacilli. *Courtesy of S Froman and A Gaytan.*

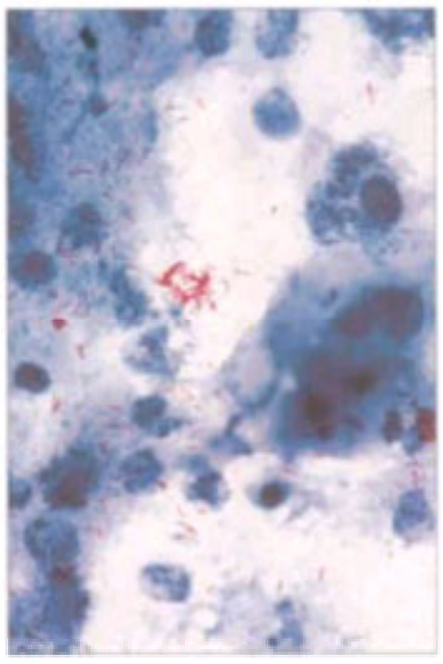

Figure 233-11 Sites of action or presumed sites of action of antimycobacterial agents. DHFR, dihydrofolate reductase; DHPS, dihydropteroate synthase; PABA, *p*-aminobenzoic acid; PAS, *p*-aminosalicylic acid. *Figure adapted from Parsons et al.*[105] *and Young.*[106]

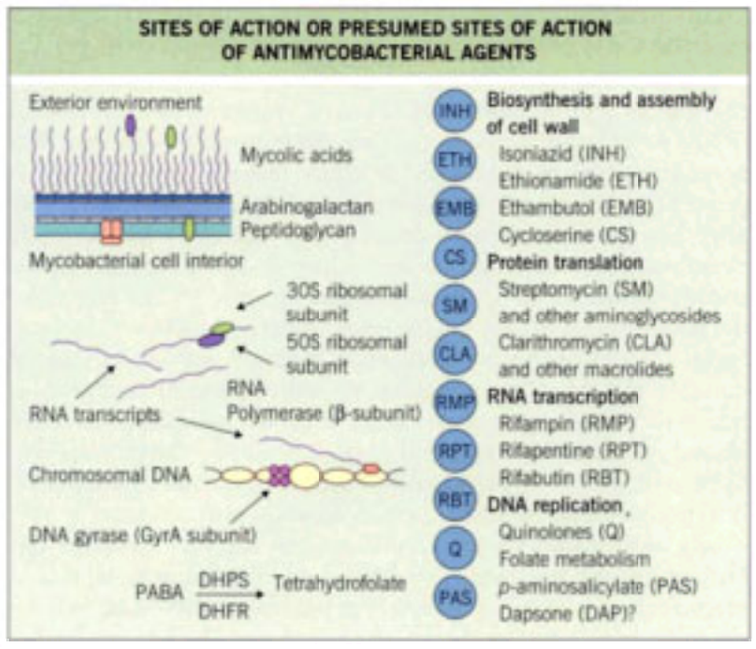

Figure 233-12 Acid-fast stain of a section of small intestine from a patient who has HIV infection and disseminated *Mycobacterium avium* disease. The photomicrograph shows many acid-fast bacilli within a villus tip of the intestinal tract biopsy. The cuboidal cells at the periphery of the tip are in disarray and appear abnormal with cell nuclei not evenly distributed at the base of the cells. There is no evidence of granuloma, but the overwhelming number of mycobacteria may be partially obscuring the host's cellular response. The histopathology is consistent with the symptoms of patients with MAC gastrointestinal tract infections, including abdominal pain, diarrhea and wasting. *Courtesy of LS Young.*

Figure 234-1 Electron micrograph of a mycoplasma organism. It has a diameter of approximately 300nm and lacks a rigid cell wall containing peptidoglycan.

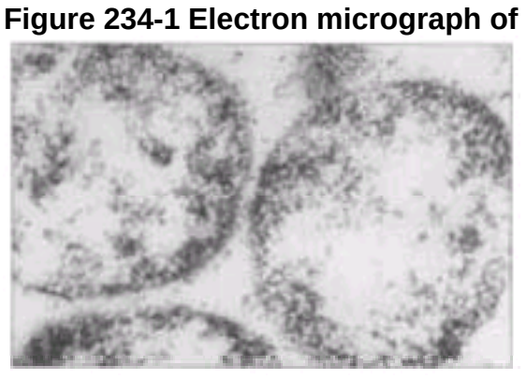

Figure 234-2 Electron micrograph of a mycoplasma organism producing filamentous structures in a broth culture. This gives the organism the appearance of a fungal mycelium. ('Myco' in mycoplasma refers to this feature.)

Figure 244-9 Characteristic star-shaped morphology of the cyst of *Acanthamoeba* sp. demonstrated by a corneal scraping stained with Hemacolor. *Courtesy of Dr Theodore.*

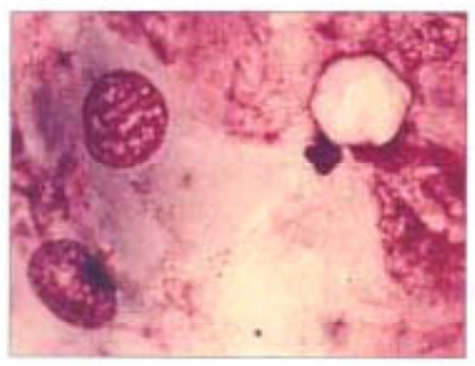

Figure 245-1 *Plasmodium vivax* life cycle. The life cycle starts when an infected mosquito feeds, inoculating the sporozoite form of the parasite, which infects the hepatocytes. The parasite cells then multiply (liver schizonts) and are liberated into the circulation to invade red cells where they grow (trophozoites) and divide (schizonts). Some trophozoites differentiate into gametocytes infective for mosquitoes.

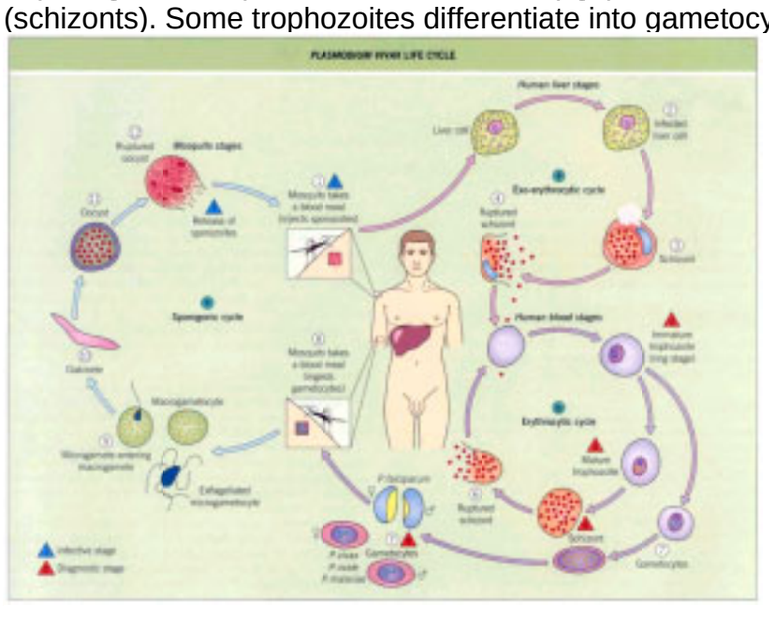

Figure 245-2 World distribution of malaria and areas of drug resistance, 2001.

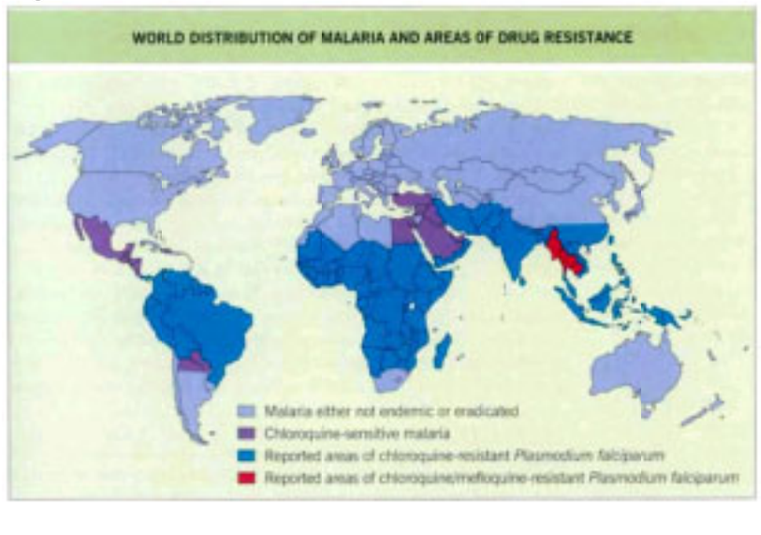

Figure 245-3 *Babesia* spp. Single and multiple intraerythrocytic parasites can be seen. The arrow marks a typical Maltese cross.

Figure 245-4 Toxoplasmic encephalitis in person who has AIDS. A cranial CT scan shows bilateral contrast-enhanced ring lesions with peripheral edema and mass effect.

Figure 245-5 Fundoscopic image of toxoplasmic chorioretinitis. Most cases presenting in adults represent a late manifestation of a congenitally acquired toxoplasmosis.
