Preface

When we sat down five years ago to plan the first edition of *Infectious Diseases* we were determined to make it make it innovative, comprehensive and accessible. It is very gratifying to record that the responses we have had from colleagues all over the world suggest that, in large part, we succeeded in those aims. Many of the ideas that we introduced have proved popular with our readers, in particular the use of full-color illustrations, the down-loadable slide picture library, the Practice Points feature of common but difficult problems, and the international scope of both the content and the authorship. It was this success, as well as the breathtaking speed with which new developments in infectious diseases were occurring, that persuaded us that a second edition could no longer be delayed.

In putting together this second edition we have looked rigorously at all parts of the book, re-structuring where necessary, adding and updating material and inviting new editors to strengthen the team. The emergence of unsuspected clinical syndromes (West Nile fever in the USA is just one example), and unwanted challenges for infectious diseases physicians (sadly, the spectre of bioterrorism has found its way on to these pages) has resulted in new chapters and new authors. But we were also keen to continue the innovative approach that we took for the first edition, and have added a substantial new element to the book, the *Infectious Diseases* website. Although this existed in a rudimentary form before, for this second edition Steven Opal has taken the lead in creating an extraordinary resource of material that will complement the book.

No project of this size and complexity can be undertaken without the help of a very large number of people. Section editors and authors have worked against a very challenging timetable to ensure that the book is as up-to-date as possible. We are also indebted to the publishers, and in particular to Shuet-Kei Cheung, who was in at the beginning of the project and worked tirelessly to see it through to production, and also to Deborah Russell and Jill Day for their contributions.

A final word of thanks must go to the Section Editors who worked on the first edition: Claude Carbon, David Durack, Don Louria, Bruce Polsky and Paul Quie, and to Donald Armstrong, whose vision contributed so much. Without their input we would never have had the opportunity to work on this second edition. We are greatly indebted to them.

Jonathan Cohen
William G Powderly

Contributors

Michael Adler CBE MD FRCP FFPHM

Professor of Genitourinary Medicine
Department of STDs
Royal Free and University College Medical School
London, UK

Kjell Alestig MD PhD

Professor of Infectious Diseases
Department of Infectious Diseases
Sahlgrenska University Hospital
Goteburg, Sweden

Upton Allen MBBS MS FAAP FRCPC

Edmund D Pellegrino Professor
Chairman,
Department of Medicine
State University of New York at Stony Brook
New York, NY, USA

William A Lynn MD FRCP

Divisional Director, Medicine and A&E
Infection and Immunity Unit
Ealing Hospital
Southall, UK

Keith PWJ McAdam MD FRCP

Wellcome Professor of Clinical Tropical Medicine
London School of Hygiene and Tropical Medicine
London, UK

John T Macfarlane MA DM FRCP MRCGP

Consultant Physician
Respiratory Medicine Unit
Nottingham City Hospital
Nottingham, UK

Alasdair MacGowan BMedBiol MD FRCP(Ed) FRCPath

Professor of Clinical Microbiology and Antimicrobial Therapeutics
Department of Medical Microbiology

Bristol Centre for Antimicrobial Research and Evaluation
Bristol, UK

Andrew D Mackay MRCPath MA MRCP

Consultant Microbiologist
Greenwich District General Hospital
London, UK

Philip A Mackowiak MD

Professor of Medicine;
Vice Chairman
Department of Medicine
Chief,
Medical Care Clinical Center
VA Maryland Health Care System
University of Maryland School of Medicine
Baltimore, MD, USA

Kim Maeder RN MN CIC

Infection Control Program
Harbor — UCLA Medical Center
Torrance, CA, USA

Janine R Maenza MD

Clinical Assistant Professor of Medicine
Primary Infection Clinic
University of Washington
Seattle, WA, USA

Adel A F Mahmoud MD PhD

President,
Merck Vaccines,
Merck & Co., Inc.
Adjunct Professor of Medicine,
Case Western Reserve University
Whitehouse Station, NJ, USA

Timothy Mailman MD FRCPC

Assistant Professor in Pediatrics
Dalhousie University
IWK Health Center
Halifax, NS, Canada

Janice Main FRCP (Edin & Lond)

Senior Lecturer in Infectious Diseases and Medicine
Imperial College School of Medicine
St Mary's Hospital
London, UK

Dennis G Maki MD

Professor of Medicine
Head,
Section of Infectious Diseases
Attending Physician,
Center for Trauma and Life Support
Department of Infectious Diseases / Medicine
University of Wisconsin Hospital and Clinics
Madison, WI, USA

Julie E Mangino MD

Associate Professor of Clinical Internal Medicine
Division of Infectious Diseases, and Medical
Director,
Department of Epidemiology
The Ohio State University College of Medicine
Columbus, OH, USA

Oscar Marchetti MD

Division of Infectious Diseases
Department of Internal Medicine
Centre Hospitalier Universitaire Vaudois
Lausanne, Switzerland

Per-Anders Mårdh MD PhD

Professor of Medicine
Department of Obstetrics and Gynecology
University Hospital
Lund, Sweden

Kieren A Marr MD

Assistant Professor of Medicine
University of Washington

Fred Hutchinson Cancer Research Center
Seattle, WA, USA

Pablo Martín-Rabadán MD DTM&H

Consultant Physician
Servicio de Microbiologia y Enjermedades Infecciosas
Hospital General Universitario Gregorio Maranon
Madrid, Spain

Augusto Julio Martinez MD

(Deceased)
Professor of Pathology
University of Pittsburgh School of Medicine
Pittsburgh, PA, USA

Adolfo Martínez-Palomo MD DSc

Professor of Experimental Pathology
Department of Experimental Pathology
Center for Research and Advances Studies
México DF, Mexico

Ellen M Mascini MD PhD

Medical Microbiologist
Eijkman-Winkler Center for Microbiology, Infectious Diseases and Inflammation
Utrecht, The Netherlands

Peter R Mason MRCPath

Professor of Laboratory Medicine
Biomedical Research and Training Institute
Harare, Zimbabwe

Kenneth H Mayer MD

Professor of Medicine and Community
Health, Brown University;
Director of Brown University AIDS Program;
Medical Director of Research,
Fonway Community Health
Infectious Diseases Division
The Miriam Hospital
Providence, RI, USA

Joseph B McCormick MD

Regional Dean and James H Steele Professor
School of Public Health
University of Texas Houston Health Science Center
Brownsville, TX, USA

Michael W McKendrick MBBS MRCP

Lead Physician
Department of Infection and Tropical Medicine
Central Sheffield University Hospitals Trust
Royal Hallamshire Hospital
Sheffield, UK

Barbara McKeown MRCPI FRCR

Consultant Radiologist
Department of Radiology
Peterborough District Hospital
Peterborough, UK

Albert T McManus PhD

Senior Scientist;
Chief,
Laboratory Division
US Army Institute of Surgical Research
Houston, TX, USA

Francis Mégraud MD

Professor of Bacteriology
Laboratoire de Bactériologie
Hôpitaux Pellegrin
Bordeaux, France

Andre Z Meheus MD PhD

Professor,
Epidemiology and Social Medicine
University of Antwerp
Antwerp, Belgium

Marian G Michaels MD MPH

Associate Professor of Pediatrics and Surgery

Division of Allergy, Immunology and Infectious Diseases
Childrens Hospital of Pittsburgh
Pittsburgh, PA, USA

Dana Milatovic MD PhD

Associate Professor
Eijkman-Winkler Institute for Microbiology,
Infectious Diseases and Inflammation
Utrecht, The Netherlands

Michael A Miles MSc PhD DSc FRCPath

Professor of Medical Protozoology
Department of Infectious and Tropical Diseases
London School of Hygiene and Tropical Medicine
London, UK

Alastair Miller MA MBBS FRCP FRCP(Ed) DTM&H

Consultant Physician;
Honorary Senior Lecturer
Worcester Acute Hospitals Trust
Worcester Royal Infirmary
Worcester, UK

Marie-Paule Mingeot-Leclercq MSc PharmD PhD

Professor of Pharmacology and Biochemistry
Unité de Pharmacologie Cellulaire et Moléculaire
Brussels, Belgium

Thomas G Mitchell PhD

Associate Professor of Molecular Genetics and Microbiolgy
Department of Molecular Genetics and Microbiology
Duke University Medical Center
Durham, NC, USA

Julio SG Montaner MD FRCPC FCCP

Professor of Medicine and Chair of AIDS Research
St. Paul's Hospital/University of British Columbia
Vancouver, BC, Canada

Martin Montes MD

Fellow,
Infectious Diseases
Infectious Diseases
University of Texas Houston Medical School
Houston, TX, USA

Valentina Montessori MD FRCPC

Clinical Assistant Professor
Canadian HIV Trials Network,
Division of Infectious Diseases
British Columbia Centre for Excellence in HIV/AIDS
St Paul's Hospital / University of British Columbia
Vancouver, BC, Canada

John Z Montgomerie MB, ChB, FRACD

Professor Emeritus
Department of Medicine
Keck School of Medicine,
University of Southern California
Los Angeles, CA, USA

Jose G Montoya MD

Assistant Professor of Medicine,
Stanford University
School of Medicine;
Co-Director,
Toxoplasma Serology Laboratory
Division of Infectious Diseases and Geographic Medicine
Stanford University School of Medicine
Stanford, CA, USA

Philippe Moreillon MD PhD

Professor
Institute of Fundamental Microbiology
University of Lausanne
Lausanne, Switzerland

Peter Morgan-Capner BSc, MBBS, FRCPath, FRCP, Hon FFPHM

Honorary Professor of Clinical Virology
Department of Microbiology
Royal Preston Hospital
Preston, UK

Peter J Moss MD MRCP DTM&H

Consultant in Infectious Diseases
Castle Hill Hospital
Cottingham
East Riding, UK

Richard E Moxon MA FRCP FRCPCH, FMedSci

Head,
Department of Paediatrics and Molecular Infectious Diseases Group
University of Oxford
Oxford, UK

Section 1 - INTRODUCTION TO INFECTIOUS DISEASES

Claus O Solberg

Chapter 1 - Nature and Pathogenicity of Micro-organisms

Menno Kok
Jean-Claude Pechère

In our daily life we are surrounded by a wealth of micro-organisms, the majority of which are inoffensive. Human existence would be impossible without these micro-organisms, as they play critical roles in processes as diverse as photosynthesis, nitrogen fixation, production of vitamins in the human intestine and decomposition of organic matter. They are the sole, true 'recyclers' of our planet. Micro-organisms are also the major driving force behind the evolution of life. They evolved photosynthesis and respiration, which have since been acquired by present-day eukaryotes, and they mediate genome rearrangements in infected host cells.

In a rather simplified view, micro-organisms may be considered to be no more than 'little machines that multiply'. In fact, this is what they do best. We are starting to understand some of the strategies micro-organisms have developed to stay alive, grow and reproduce. The lifestyle of a micro-organism is intimately related to its environment, whether that environment is the human body or a polluted riverbed. Some highly specialized micro-organisms have adapted to the harsh conditions of hot ocean vents, oil tanks or nuclear reactors; others prosper on waste dumps. Still others have been tempted by the abundant resources provided by higher organisms, such as plant root-colonizing bacteria and our own intestinal flora.

In this chapter we shall examine the lifestyle of pathogenic micro-organisms and how they infect us, reproduce and cause disease. We shall use the word 'pathogenicity' to indicate the capacity to cause disease (or damage). Although the word 'virulence' is often used in the same sense, it refers more specifically to transmissibility or infectiousness of micro-organisms.

The world of pathogenic microbiology is immensely diverse, ranging from prion proteins to worms. A better understanding of the behavior of these infectious agents will help us to design strategies for disease prevention and treatment.

DEFINITION AND COMPARISON OF INFECTIOUS AGENTS

The definition of an 'infectious agent' was proposed by J Henle in 1840 and put to the test by the German physician Robert Koch. In 1876, Koch reported experiments on mice with *Bacillus anthracis* showing that:

- a single micro-organism could be isolated from all animals suffering from anthrax;
- the disease could be reproduced in an experimental host by infection with a pure culture of this bacterium; and
- the same micro-organism could subsequently be reisolated from the experimental host.

These three criteria define an infectious agent.

Even though a clear oversimplification, we will divide infectious agents into four groups, presented here in the order of increasing complexity.

Prions

Prions are the simplest infectious agents. They consist of a single protein molecule denoted PrP (Prion Protein). The infectious particle, known as PrP^{Sc} (Sc denotes scrapie), is identical to the ubiquitous cellular protein PrP, except that it is folded in an abnormal conformation. The PrP^{Sc} particle has the following characteristics:

- the prion disease spongiform encephalopathy is transmissible between different species such as sheep and goats (see Chapter 26);
- even with the most advanced analytic techniques, no nucleic acid could be detected in infective prion particles; therefore, prions do not carry the genetic code for their own de novo synthesis;
- the PrP^{Sc} protein catalyzes the conformational change of PrP into PrP^{Sc} . The latter is remarkably resistant to heat and chemical agents, making it difficult to disinfect contaminated material; and
- as prions induce the conversion of an endogenous protein, their ability to produce disease is host dependent and subject to genetic variation.

For a detailed description of the biology of prions see Chapter 223 .

Viruses

Viruses contain at least two types of macromolecules: nucleic acid and protein. All viruses share the following characteristics:

- they are small — the largest known virions are produced by poxvirus (approximately 230 × 270nm) and most viruses of medical importance are smaller than 200nm in diameter;
- they contain only one species of nucleic acid, either DNA or RNA, whereas bacteria always have both species;
- they attach to their host cell with a specific receptor-binding protein;
- they cannot replicate autonomously; in order to reproduce its genomic information a virus requires the assistance of a living eukaryotic or prokaryotic cell; and
- when a virus infects a cell, information contained in the viral genome is used to divert the cellular machinery towards the production of new viral particles.

'Defective' and 'simplified' viruses

Some infective agents share many features with viruses but seem to be even more primitive. Some very small viruses require the assistance of another virus in the same host cell for their replication. The nonpathogenic dependoviruses owe their name to their dependence on an adenovirus or, occasionally, a herpesvirus to assist in their replication. The delta agent, also referred to as hepatitis D virus, is too small to code for even a single capsid protein and needs help from hepatitis B virus for transmission. Hepatitis B and D are often co-transmitted. Viroids are ssRNA molecules that do not code for any protein species. As the delta agent, they are likely to replicate by using the cellular RNA polymerase.

Bacteria and archaea

Bacteria (eubacteria) and archaea (archaeabacteria) have long been united under the name 'prokaryotes'. Today, this terminology ('everything that is not eukaryote') is considered inadequate.[1] The main characteristics of prokaryotes, compared with eukaryotes, are given in Table 1.1 . Bacteria and archaea invariably have a DNA genome which, unlike the eukaryotic genome, is not physically

TABLE 1-1 -- Comparison of prokaryotes and eukaryotes.

COMPARISON OF PROKARYOTES AND EUKARYOTES		
Feature	**Prokaryotes**	**Eukaryotes**
Chromosome	Single, circular	Multiple
Gene organization	Operon-polycistronic mRNA	Single genes and block of genes
Nucleosomes	No	Yes
Nuclear membrane	No	Yes
Mitosis	No	Yes
Introns in genes	No	Yes
Transcription	Coupled with translation	Separate from translation
mRNA	No terminal polyadenylation (except archaeabacteria); polygenic	Terminal polyadenylation; usually monogenic
First amino acid	Unstable formylmethionine (except archaeabacteria)	Methionine
Ribosome	70S (30S + 50S)	80S (40S + 60S)
Cell wall	Presence of muramic acid, D-amino acids, peptidoglycan (except archaeabacteria and mycoplasma)	No muramic acid, D-amino acids, or peptidoglycan
Membrane	No sterols or phosphatidyl-choline (except mycoplasma)	Sterols and phosphotidyl-choline
Endoplasmic reticulum	No	Yes
Mitochondria	No	Yes
Lysosomes and peroxysomes	No	Yes
Movement	By flagella, composed of a single fiber	Ameboid, by cilia or cilia-like flagella

separated from the rest of the cell contents by a membrane. Neither size (mycoplasmas are as small as viruses, about 200nm in diameter) nor obligatory reproduction

in eukaryotic cells supplies definitive criteria to distinguish bacteria and archaea from viruses. However, in contrast to viruses, prokaryotes always contain both DNA and RNA. Even obligate intracellular bacteria, like *Chlamydia* spp. and *Rickettsia* spp., which appear to have adopted a virus-like lifestyle, remain enclosed within their own cell envelope throughout their life cycle and provide their own nucleic acid and protein reproduction machineries.

Based on extensive nucleotide sequence data, it has been suggested that archaea are more closely related to eukaryotes than to bacteria. Indeed, these micro-organisms, which seem to have a particular preference for hostile environments seeded with toxic

TABLE 1-2 -- **Comparison of bacteria and fungi.**
Adapted from Kobayashi.[2]

COMPARISON OF BACTERIA AND FUNGI		
Characteristics	**Bacteria**	**Fungi**
Cell volume (μm^3)	0.6–5.0	Yeast: 20–50; molds; greater than yeast
Nucleus	No membrane	Membrane
Mitochondria	No	Yes
Endoplasmic reticulum	No	Yes
Sterol in cytoplasmic membrane	No (except for mycoplasma grown on sterols)	Yes
Cell wall components	Muramic acids and teichoic acids; no chitin, glucans or mannans	Chitin, glucans and mannans; no muramic acids or teichoic acids
Metabolism	Autotropic or heterotropic	Heterotropic
Sensitivity to polyenes	No	Yes

chemicals, deep-sea hydrothermal vents and oil deposits, share with eukaryotes at least one feature that is absent from bacteria — their genes frequently bear introns. Archaea do not play any role in human medicine. In contrast, eubacteria include the hundreds of bacterial species that are commensal or pathogenic for humans. Bacteria come in various shapes and sizes (typically in the range of 1–2µm diameter). With the exception of *Mycoplasma* spp., bacteria characteristically have a rigid cell wall.

Eukaryotes

Eukaryotes have subcellular compartimentalization. DNA transcription, photosynthesis, respiration and protein modification are physically restricted to specific organelles: the nucleus, chloroplasts, mitochondria and the Golgi system.

TABLE 1-3 -- The four major classes of fungi.

THE FOUR MAJOR CLASSES OF FUNGI	
Class	**Representative genera**
Phycomycetes	*Rhizopus, Mucor*
Ascomycetes	*Neurospora, Penicillinium, Aspergillus*
Basidiomycetes	Mushrooms, rusts, smuts
Denteromycetes (or fungi imperfecti)	Most human pathogens

TABLE 1-4 -- Proptozoa that are important in humans.

IMPORTANT PROTOZOA IN HUMANS			
Category	**Species**	**Disease**	**Estimated worldwide prevalence of human infections**
Protozoa	*Toxoplasma gondii*	Toxoplasmosis	1–2 billion
	Entamoeba histolytica	Amebiasis	200–400 million
	Trichomonas vaginalis	Trichomoniasis	15% of women
	Plasmodium spp.	Malaria	200–300 million
	Giardia lamblia	Giardiasis	200 million
	Trypanosoma cruzi, T. brucei	Chagas' disease: African sleeping sickness	15–20 million
	Leishmania donovani, L. tropica	Leishmaniasis	1–2 million
Helminths	*Ascaris lumbricoides*	Ascariasis	1 billion
	Necator americanus	Hookworm disease	800–900 million
	Schistosoma mansoni	Schistosomiasis	200–300 million
	Wuchereria bancrofti	Lymphatic filariasis	200 million
	Enterobius vermicularis	Pinworm infection	60–100 million
	Strongyloides stercoralis	Strongyloidiasis	50–80 million
	Onchocerca volvulus	Onchocerciasis	50 million

Fungi

Fungi and bacteria play similar roles in the biosphere, share the capacity to produce infectious disease and both have rigid cell walls, but their cellular architecture is completely different (Table 1.2). Pathogenic fungi occur in two forms: the filamentous molds and the unicellular yeasts. There are four major classes of fungi (Table 1.3). *Pneumocystis carinii*, which causes severe pneumonia in immunosuppressed hosts, was long considered to be a protozoan. However, its ribosomal RNA, which was recently sequenced, showed greater similarity to that of fungi than to protozoa.[3]

Protozoa

Protozoa (Table 1.4) are unicellular eukaryotes. In contrast to fungi, they have a flexible cell membrane. Their movements can be ameboid or directed by cilia or cilia-like flagella. Pathogenic protozoa often have complex life cycles with both intrahuman and extrahuman stages. The sources of parasites in the environment are called reservoirs, which include other animals or free forms of the parasite found in the external environment (e.g. food contaminated with *Toxoplasma gondii* oocysts from cat feces).

Some protozoa that are pathogenic for humans, such as the malaria parasite, trypanosomes, *Leishmania* spp. and *Toxoplasma* spp., invade deep tissues and reside inside host cells, at least during part of their life cycle. These protozoa do not survive for long in the external environment and they are often transmitted by living vectors such as flies and mosquitoes. Other protozoa are extracellular (e.g. the agents of amebiasis and giardiasis) and possess vegetative and resistant forms. The

trophozoite produces the active disease and allows vegetative growth and multiplication, whereas the highly resistant cyst form, which is able to survive in hostile environments, assures transmission between hosts.

Parasitic worms

Helminths are the largest parasites that infect humans. They are multicellular organisms ranging from 1cm to 10m in size. They usually are encased by an outer membrane or cuticle that protects internal differentiated organ systems. Helminths (or worms) are classified into three groups, generally distinguishable by their shape:

- nematodes (or roundworms),
- cestodes (or tapeworms), and
- trematodes (or flukes).

Some helminths have complex life cycles that may include successive animal reservoirs and insect vectors.

GENERAL PROPERTIES AND CLASSIFICATION OF VIRUSES

Structure of viruses

The whole virus particle, the virion, is designed to protect the viral genome and to mediate the migration of the virus and the invasion of the target host cell. The viral genome can be packaged in a nucleocapsid, which in some virus families contains a number of enzymes required for the early stages of virus multiplication. The capsid may in turn be surrounded by an outer membrane.

The genome

The genome is made up of either DNA or RNA, associated with proteins or polyamines. The size of nucleic acid per virion ranges from 3 to 300kb. There may be only one gene in the smallest virions, whereas the largest genomes, such as vaccinia, may encode hundreds of proteins. The Parvoviridae, which include the virus that causes erythema infectiosum, have a 5.5kb DNA genome, which codes for only three polypeptides. This may explain why these viruses need help from a larger virus, i.e. adenovirus, for their replication.

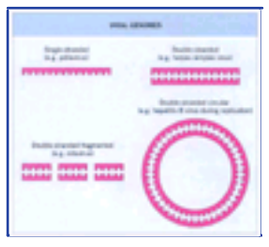

Figure 1-1 Viral genomes.

The nucleic acid may be either double stranded or single stranded (Fig. 1.1). The nucleic acid of all DNA viruses except parvoviruses is double stranded. In contrast, the nucleic acid of all RNA viruses except the reoviruses (e.g. influenza, bunya and arenaviruses) is single stranded. The genome may be linear or circular, and non-segmented or segmented. Genome segmentation, a general feature of reoviruses, favors gene exchange between co-infecting virions. RNA virus genomes change at high frequency through point mutations, which helps viral evasion of the human immune response.

Some viral DNA molecules may contain alternative nucleotides, which inhibit host cell nucleases and thus protect the viral genome. Linear DNA genomes may contain terminal redundancies, allowing incomplete replication products to recombine, or they may carry proteins at both ends, that play a role in priming of DNA replication. Some viral DNA is flanked by repeat sequences, which suggests relatedness with transposable elements.

Most human RNA viruses have single-stranded genomes. This RNA molecule may have either of two possible polarities. The positive-strand RNAs can act directly as messengers for protein synthesis; they resemble eukaryotic RNAs with a cap at the 5' end and a poly-A chain at the 3' end. The negative-strand RNAs need to be transcribed by a viral RNA transcriptase into mRNA. Negative-strand RNA genomes have neither a cap structure nor a poly-A tail. Retroviruses first synthesize a DNA copy of the positive-strand RNA genome, which integrates into the cellular DNA and may subsequently serve as a template for mRNA synthesis.

The capsid

The viral genome is protected by a protein coat, the capsid or nucleocapsid. The capsid is made of knob-like structures known as capsomeres, which consist entirely of proteins coded by the viral genome. The capsid accounts for a large portion of the viral mass. Papilloma virus produces only two capsid proteins and poliovirus four, but more complex viruses may encode a much larger variety of capsid proteins. Different nucleocapsid morphologies have been observed by electron microscopy (Fig. 1.2).

Picornaviruses, adenoviruses and papovaviruses have a nucleocapsid structure with icosahedral symmetry. The capsid consists of 20 triangular facets and 12 corners or apices. Influenza, measles and rabies virus form capsids with helical symmetry. The central core is formed by the nucleic acid genome, around which the nucleocapsid proteins are arranged like the steps of a spiral staircase, forming long cylinders.

More complex virion morphologies also exist. Bacteriophages, which use bacteria as hosts, have additional attachment structures fixed to the capsid. The nucleocapsid of orthopoxviruses, such as variola and vaccinia virus, consists of a network of tubules, sometimes surrounded by an envelope, forming a brick-shaped virion.

The envelope

In some viruses the nucleocapsid is surrounded by an outer envelope. Enveloped viruses contain nucleocapsids of either icosahedral (e.g. herpesviruses and togavirus, which causes rubella) or helical symmetry (e.g. influenza virus). The outer envelope consists of a lipid bilayer, derived from the host cell membrane, in which the viral glycoproteins are embedded. The viral matrix proteins (M proteins) are firmly associated with the envelope. Matrix proteins play an important role in the structural organization of the virion and are thought to connect the capsid to the viral glycoprotein inserted in the lipid bilayer. Besides oligosaccharide residues, the glycoproteins contain a membrane anchor and, in many cases, one or two molecules of fatty acid. Glycoproteins play a key role in the attachment of virions to the cell surface and penetration into the cell. Some viruses, such as the influenza virus, have glycoproteins with neuraminidase activity; this promotes the release of newly formed viral particles from the host cell membrane. Once released from the host cell, virions are metabolically inert. The virus only comes 'alive' after entry into a suitable host cell and activation of its genome.

Classification of viruses

Viruses are classified into families, subfamilies and genera. The most important families are summarized in Table 1.5 . Classification criteria include the nucleic acid species, the number and polarity of the nucleic acid strands, the presence or absence of a lipid envelope and the symmetry (icosahedral, helical or complex) of the nucleocapsid.

Viral gene expression strategies

Viral infection can be separated into two phases. In the early phase of infection, the virus establishes the proper cell environment required for viral genome replication and the viral DNA or RNA polymerase is produced. In the late phase, the viral genome is amplified and the structural components of the virion accumulate. At this point a considerable part of the cellular metabolism is committed to viral reproduction. Eventually the virion is assembled from its components and leaves the cell. Four viral replication strategies can be distinguished (Fig. 1.3).

Positive-strand RNA viruses

In positive-strand RNA viruses, the viral genome has the right polarity to serve immediately as a messenger RNA. The first step in viral infection consists of a complete translation of the genome to produce a polyprotein, which is sequentially processed into smaller polypeptides. Enzymatic cleavage of the composite protein is at least partially autocatalytic. In the early phase, processing preferentially produces proteases and the RNA-dependent polymerase. In the late phase of infection, processing is reoriented towards the production of the structural proteins. This scheme applies to picornaviruses, flaviviruses and hepatitis C viruses.

For other virus families (e.g. togaviruses, coronaviruses, caliciviruses and hepatitis E viruses), the incoming genome is only partially translated to produce the proteases and the RNA polymerase. The portion of the genetic information that encodes the structural proteins is expressed from a transcript derived from the RNA intermediate in genome replication.

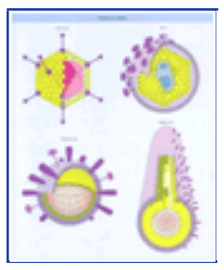

Figure 1-2 Examples of virions. Adenovirus is an icosahedral DNA virus without an envelope; fibers extend from the 12 points of the icosahedral coat; DNA forms a ribbon-like molecule. Approximate size 80nm. HIV-1; glycoprotein (GP) molecules protrude through the lipid membrane; the icosahedral capsid encloses a vase-shaped nucleocapsid, in which the diploid RNA is enclosed. Approximate size 100nm. Influenza virus is an enveloped RNA virus, containing nucleocapsid of helical symmetry; spikes of hemagglutinin and neuraminidase protrude from the lipid bilayer. Approximate size 100–200nm. Rabies virus is a helical RNA nucleocapsid with a bullet-shaped lipoprotein envelope, in which approximately 200 GPs are embedded. Approximate size 150nm. (The diagram is not to relative scale.) *Adapted from Collier and Oxford[4] by permission of Oxford University Press.*

TABLE 1-5 -- Classification of viruses.

CLASSIFICATION OF VIRUSES				
Family name	**Example**	**Genome size (kb) and polarity (+ or -)**	**Morphology**	**Envelope**
DNA viruses				
Single-stranded				
Parvoviridae	Human parvovirus B19	5 (±)	Icosahedral	No
Mixed-stranded				
Hepadnaviridae	Hepatitis B	3 (±)	Icosahedral	Yes
Double-stranded				
Papovaviridae	Wart virus	8 (±)	Icosahedral	No
Adenoviridae	Adenovirus	36–38 (±)	Icosahedral	No
Herpesviridae	Herpes simplex	120–220 (±)	Icosahedral	Yes
Poxviridae	Vaccinia	120–280 (±)	Complex	Yes
RNA viruses				
Single-stranded				
Picornaviridae	Poliovirus	7.2–8.4 (+)	Icosahedral	No
Togaviridae	Rubella	12 (+)	Icosahedral	Yes
Flaviviridae	Yellow fever	10 (+)	Icosahedral	Yes
Coronaviridae	Infectious bronchitis	16–21 (+)	Helical	Yes
Rhabdoviridae	Rabies	13–16 (-)	Helical	Yes
Paramyxoviridae	Measles	16–20 (-)	Helical	Yes
Ozthomyxoviridae	Influenza	14 (-)	Helical	Yes
Bunyaviridae	California encephalitis	13–21 (-)	Helical	Yes
Arenaviridae	Lassa fever	10–14 (-)	Helical	Yes
Retroviridae	HIV-1	3–9 (+)	Icosahedral	Yes
Filoviridae	Marburg, Ebola	19 (-)	Helical	Yes
Double-stranded				
Reoviridae	Rotavirus	16–27 (±)	Icosahedral	No

Negative-strand RNA viruses

The early phase is characterized by 'primary transcription' of the infecting genome by an RNA-dependent RNA polymerase. Primary transcription generates a positive-strand RNA species, which can act as a mRNA for viral protein synthesis. In the late phase of genome replication, transcription and viral protein synthesis are simultaneously amplified.

In the case of the ambisense viruses, such as arenaviruses and some members of the bunyaviruses, the situation is somewhat more complex. The intermediate in genome-replication, positive-strand RNA species also acts as a template for mRNA synthesis. This transcription strategy does not, however, result in the synthesis of complementary mRNA, because half of the genome is transcribed in one polarity and the other half in the opposite polarity.

DNA viruses

In the early phase, the virus 'takes the decision' whether or not to pursue exponential replication of its genome. If the cellular physiology favors virus amplification, the early phase is used to create the conditions that allow efficient DNA synthesis and the cellular S phase is induced. Alternatively, viral gene expression is confined to the functions that prevent the efficient genome synthesis and the virus remains in a latent form.

In the case of ssDNA viruses (e.g. parvoviruses), the incoming genome is first used to express proteins that permit the synthesis of the complementary DNA strand.

Double-stranded DNA is an obligatory replication intermediate.

The late phase is devoted to the accumulation of the structural components of the virion.

Viruses using reverse transcription

In the case of the retroviruses, genome synthesis takes place in two distinct steps:

- In a preliminary step, the viral RNA genome enters the cell together with the viral reverse transcriptase, which was synthesized and incorporated into the virion during the previous infection cycle.
- The RNA genome is converted to a dsDNA copy by reverse transcriptase and integrates into the cellular chromosome as a proviral genome. This remains in the 'dormant state' as long as the cells are quiescent, which represent conditions that do not favor virus multiplication.

In the case of the more complex retroviruses (e.g. spumaviruses, lentiviruses), transcription by the cellular RNA polymerase II of the integrated viral DNA first produces multispliced mRNAs, which direct the synthesis of regulatory proteins. As a consequence of the accumulation of certain regulatory proteins, the processing of the viral transcripts changes and becomes oriented towards the production of unspliced or simply spliced mRNAs representing the viral genomes and serving the synthesis of the structural proteins.

GENERAL PROPERTIES AND CLASSIFICATION OF BACTERIA

Bacteria are small (0.6–4.0μm) unicellular organisms; 3×10^{12} bacteria weigh in the order of 1g. Under optimal physiologic conditions, a bacterium may divide between two and three times per hour. This means that theoretically in one day nearly 300g of bacterial mass can be produced from a single bacterial cell. Such small organisms profit from a favorable cell surface-to-volume ratio, which allows metabolic fluxes largely superior to those attained by the larger eukaryotic cells. Bacteria react very quickly to environmental changes, using regulation at the level of gene transcription to adapt their physiology.

Bacteria were probably the first cells to appear on earth more than 3.5 billion years ago. They have since developed into an overwhelming

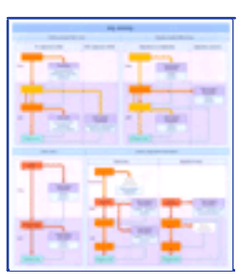

Figure 1-3 Viral 'lifestyles'.

diversity representing the bulk of the world's biomass today. Although evolution has not lead to bacteria associating into multicellular organisms, they are capable of cell-to-cell communication.[5] By using low molecular weight compounds, bacteria have found a way to 'see' how dense their local population is and decide whether or not to activate developmental programs such as plasmid conjugation, light production (in association with deep-sea fish) or virulence gene expression.

Different cell morphologies can be observed with light microscopy (e.g. spherical cocci, rod-shaped bacilli, curved vibrios). Electron

Figure 1-4 Bacterial cell walls. (a) *Mycoplasma pneumoniae* has a single membrane, made up of phospholipids and membrane proteins. (b) In Gram-positive organisms the cytoplasmic membrane is covered with a thick layer of peptidoglycan; chains of lipoteichoic acid protrude outside. (c) The cell wall of a Gram-negative rod is more complex. The layers are: the cytoplasmic membrane; the periplasmic space; a layer of peptidoglycan, which is thinner than that in Gram-positive bacteria; and an asymmetric outer membrane. The inner leaflet of the outer membrane is made of phospholipids. The outer leaflet has lipopolysaccharides as its principal lipids; porins, which are channel-forming proteins often organized as trimers, allow the penetration of hydrophilic molecules through the outer membrane. (d) The peptidoglycan of *Staphylococcus aureus* has polysaccharide chains ('backbone') that are alternating residues of *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc). Tetrapeptides are attached to MurNAc and are linked together by pentaglycines bridging the L-lysine of each tetrapeptide chain to the D-alanine of the neighboring one.

microscopy unveils a distinctive cell wall, a simple nuclear body without a nuclear membrane and the presence in the cytoplasm of ribosomes and mesosomes, sometimes granules of reserve material, but no endoplasmic reticulum and no organelles such as mitochondria or chloroplasts.

Bacterial dichotomy revealed by a simple staining technique

In 1884, the Danish bacteriologist Hans-Christian Gram developed a simple staining technique that distinguishes two types of bacteria: the Gram-positive and the Gram-negative bacteria. The distinction is based on the ability of one group of bacteria, the Gram positives, to retain a crystal-violet-iodine dye in the presence of alcohol or acetone. Gram-negatives lose the dye and can be counterstained with other dyes such as fuchsin. This simple observation turned out to reflect distinctive structures. Gram-positive bacteria characteristically have a thick wall made up mainly of a vast molecule of peptidoglycan, with protruding chains of teichoic acids. Gram-negative bacteria have an additional membrane (the outer membrane) surrounding the peptidoglycan skeleton in the periplasm (Fig. 1.4). *Escherichia coli* is an example of a Gram-negative bacterium; it is rod shaped and growing cells are between 2 and 4μm long.

The rigid cell wall determines the shape of bacteria and allows them to resist the osmotic pressure caused by the large difference in solute concentration between the cytoplasm and the environment. *Mycoplasma* spp. lack peptidoglycan and thus have neither a rigid wall nor a defined shape.

Organization of the bacterial cell

The bacterial cytoplasm does not contain physically separated compartments. Thus DNA replication, transcription, protein synthesis, central metabolism and respiration all take place in the same environment. Complex biochemical processes may nonetheless be spatially organized in the cell. Transcription of DNA into mRNA and translation of the mRNA into protein are coupled processes. This means that polysomes are linked to the DNA, via the enzyme RNA polymerase (Fig. 1.5). The cytoplasmic membrane not only contains numerous metabolite transport systems, but it is the site of intense enzymatic activity as well. Like eukaryotic cells, bacteria possess efflux systems that allow them to expel unwanted substances from the cytoplasm into the environment.

The genetic information is usually stored in a single chromosome. Bacterial chromosomes vary considerably in size. The *Haemophilus influenzae* chromosome, the first completely sequenced genome of a cellular life form, is 1.83 million base pairs (Mbp) long and encodes 1703 putative proteins. [7] The chromosome of laboratory strains of *Escherichia coli* K12 is approximately 2.5 times bigger (5Mbp), though still rather small if compared with the 30Mbp *Bacillus megaterium* genome, and is more than 500 times the length of the cell (Fig. 1.6).

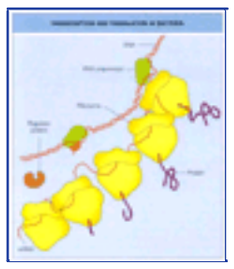

Figure 1-5 Transcription and translation in bacteria (*Escherichia coli*).

The bacterial chromosome codes for polypeptides and stable RNA molecules such as transfer RNA and ribosomal RNA molecules. *E. coli* probably contains well over 1500 different polypeptides with a variety of functions, such as maintenance of membrane structure; transport; respiration; degradation of nutrients; synthesis of amino acids, sugars, nucleotides, lipids and vitamins; and production of polymers such as DNA, RNA, proteins and polysaccharides. Mobile genetic elements, such as plasmids, bacteriophages and transposable elements, are important sources of genetic variation. They supply genes that are not essential for bacterial growth but may offer a selective advantage under specific conditions. Virulence factors and antibiotic resistance elements are frequently associated with these

Figure 1-6 Genetic information in bacteria. This example is *Escherichia coli*. Additional genetic information may be supplied by extrachromosomal elements such as plasmids or bacteriophages. Bacteria may carry a variety of these 'mobile genetic elements', which may transfer readily from one cell to another. The electron micrograph shows a 8.65kb *E. coli* plasmid that confers sulfonamide and streptomycin resistance (left) and a single-stranded derivative of the plasmid (right).

mobile DNA structures. Comparison of the genome sequences of the harmless laboratory strain *E. coli* K12 and the human pathogen *E. coli* 0157:H7, first isolated and identified following a 1982 outbreak of hemorrhagic colitis caused by contaminated hamburgers, revealed impressive differences between the two strains.[8] No less than 1387 new genes were identified in the latter, of which at least some will be involved in virulence.

Transcription and translation in bacteria

Gene expression is usually regulated at the level of transcription initiation by regulator proteins and occasionally by small RNA molecules, which interact with the 'promoter DNA' and with the enzyme RNA polymerase (see Fig. 1.5). The promoter is the site where RNA polymerase opens ('melts') the dsDNA to synthesize an RNA copy of one of the two DNA strands. A sigma factor transiently interacts with the polymerase when it binds the promoter DNA and determines the nucleotide sequence specificity of the enzyme. Bacterial cells produce multiple sigma factors, each controlling the expression of a set of genes. Three types of RNA are produced: regulatory RNA, 'stable' RNA and messenger RNA (mRNA). Stable RNAs include the transfer RNA molecules, which position the amino acids on the ribosomes during protein synthesis and are important structural components of the ribosomes. Messenger RNA molecules are generally quite unstable but are protected from premature degradation by ribosomes, the protein synthesis machines.[6] Transcription and translation are coupled in bacteria; ribosomes bind the mRNA as soon as it 'leaves' RNA polymerase and start protein synthesis by coupling the initiator amino acid (formyl-methionine) to the second amino acid in the coding sequence and uncoupling it from the tRNA molecule. As mRNA elongation proceeds, more ribosomes bind to the messenger RNA to form a 'polysome'. The polypeptides that are produced by the ribosomes fold either spontaneously or with the help of molecular chaperones into their native structures. Bacterial mRNAs generally encode more than one protein. The bacterial protein synthesis machinery is an important target for antibiotics.

Motility

Many bacterial species are equipped with a sophisticated detection system — 'chemotaxis' — which allows them to detect very small variations in concentrations of either valuable or harmful substances in the surrounding environment. [9] Flagella are the effectors of chemotaxis (Fig. 1.7). By changing the direction of flagellar rotation, micro-organisms swim towards sites favorable to survival and growth. Amino acids and sugars are powerful chemoattractants.

Figure 1-7 Flagella and motility in bacteria.

TABLE 1-6 -- Important steps in microbial pathogenesis.

IMPORTANT STEPS IN MICROBIAL PATHOGENESIS
• Encounter
• Attachment to host cells
• Local or general spread in the body (invasion)
• Cell and tissue damage
• Evasion of host defenses
• Shedding from the body

Although many pathogenic species are flagellated, a role for motility in virulence has not been established in all cases.

PATHOGENESIS OF INFECTIOUS DISEASE

The key microbial factors involved in the onset and spread of microbial infection can be identified by carefully analyzing the interaction of the micro-organism with its host (Table 1.6). Molecular techniques have contributed considerably to our present understanding of microbial pathogenesis. Insight into the intimate relationship between host and pathogen will help us find the answers to the all-important questions: how can we eliminate the cause of disease and how can we reduce its harmful effects on the human body?

Each pathogen has its own infection strategy, resulting in the development of a disease pattern with distinct symptoms. In the following sections we shall examine the lifestyles of some pathogenic species.

Contamination

In the developed areas of the world, the majority of human infections are caused by pathogens belonging to the normal microflora of the host (so-called endogenous infections), whereas those caused by exogenous micro-organisms have steadily declined over the past century. In contrast, exogenous infections are still prevalent in poorer areas.[10]

Endogenous infections and normal microbial flora of the human host

The fetus *in utero* is normally sterile but right after birth it starts building up its indigenous microflora, which will quickly outnumber its own cell content; a normal adult carries more than 10 [14] bacteria, which represents roughly 10 bacteria for each eukaryotic cell. In addition to bacteria, we may provide hospitality to an estimated 150 viral species, to fungi, protozoa and worms. The indigenous flora, or 'normal flora', is found in any part of the body exposed to the outside environment — the mouth, nose and the oropharynx, the anterior part of the urethra and vagina and other moist areas of the skin (Fig. 1.8). The human microbial population is especially dense in the large intestine; it has been estimated that each gram of stool specimen contains about 10[12] bacteria. The normal flora is well adapted to its niche and may multiply rapidly under favorable nutritional conditions such as those found in the colon. Although the host's age and physical condition, and especially antibiotic treatment, may induce more or less important variations, the microbial population of the gastrointestinal tract seems to be stable, consisting of more than 99% of obligate anaerobic species. Facultative anaerobes such as *E. coli*, which are frequently used as markers for environmental pollution with human feces, represent less than 1% of the normal flora.

Figure 1-8 Contamination of humans by micro-organisms. Many parts of the body are colonized by normal flora, which can be the source of endogenous infection. Large numbers of micro-organisms are found in moist areas of the skin (e.g. the groin, between the toes), the upper respiratory tract, the digestive tract (e.g. the mouth, the nasopharynx), the ileum and large intestine, the anterior parts of the urethra and the vagina. Other routes are interhuman transmission of infections and exposure to exogenous contamination.

Transient micro-organisms, ingested with food or water, will normally pass through the high flow rate, central region of the gastrointestinal tract without being able to penetrate the mucous gel that overlays the intestinal epithelium or to reach the epithelial surface, which is densely populated by the indigenous flora. The top two-thirds of the ileum are less densely populated by the normal flora, probably owing to a combination of high motility and the acidity of the stomach contents. Population levels of the different areas of the gastrointestinal tract are controlled mainly at the level of metabolic competition, the normal flora being well adapted to the low oxidation reduction potentials and tightly adherent to the mucosal epithelium. Pathogens that use the gastrointestinal tract as a portal of entry must find ways of dealing with the fierce microbial competition.

The skin is much less densely populated by the indigenous flora. In comparison with the gastrointestinal tract, it supplies a considerably less stable microenvironment and one that is often devoid of water. Although impermeable to bacteria, a number of parasites, among them *Schistosoma mansoni* which poses a major health threat in developing countries, can penetrate the intact human skin. Moreover, skin disruptions due to lacerations or insect bites may allow entry of pathogenic microbes into the body.

The large majority of micro-organisms that belongs to the human flora reside on the body surface without creating any damage. This peaceful co-habitation can be called symbiotic if in a 'both sides win' relationship; it is beneficial for both the host and the microbes. Some bacteria find shelter and food in the intestine and, in turn, supply vitamins or digest cellulose. However, symbiotic relationships are rather uncommon. More frequently, the micro-organisms, rather than the host, derive benefit from the association. These inhabitants of our body are called commensals. True commensals do not invade the host and, therefore, do not elicit an immune response. Parasitism constitutes a third category where the micro-organisms, after invading the host, cause an infection.

The separation between parasitism, commensalism and symbiosis is not always clearly defined and the condition of the host may make a big difference. Some micro-organisms, referred to as opportunistic pathogens, are commensals in the majority of people but cause disease in an immunocompromised host. With the progress of medicine, more and more highly immunocompromised hosts can be saved from a premature death, creating at the same time a growing human reservoir for opportunistic pathogens.

The host and its indigenous microflora maintain a delicately balanced relationship that, when disrupted, may lead to the development of infectious disease.

An inevitable consequence of antibiotic treatment is the (local) elimination of susceptible bacteria which, owing to fierce competition, are quickly replaced by antibiotic-resistant species. This phenomenon can cause diseases such as candidiasis, pseudomembranous colitis or severe enterococcal superinfection.

Any rupture of the body surface may favor the development of an infection. *Staphylococcus aureus* on our hands will become an invader and cause an infection as soon as we neglect a local wound. Dirty wounds containing soil particles are readily infected. Organisms with less pronounced pathogenic potential, such as *Staphylococcus epidermidis*, may also be involved.

The case of opportunistic infections in the immunocompromised host, already discussed, is another example of endogenous infection

promoted by a rupture of the balance between the host and its microflora.

Probiotics (live micro-organisms) may help to restore the natural flora. For example, *Saccharomyces boulardii* may be used to treat colitis associated with *Clostridium difficile*.

Exogenous infections

Exogenous infections occur after a direct contamination from microbial populations in the environment:

- in air, soil and water,
- in live animals,
- in other people with infections, and
- in healthy people who are carriers.

Humans are continuously in intimate contact with the large exogenous microbial populations in the air, soil and water, which all harbor highly pathogenic bacteria such as *Clostridium tetani* and *Bacillus anthracis*. Important pathogenic species, such as *Staphylococcus aureus, Clostridium perfringens* and *Clostridium botulinum*, may be present in our food and cause food poisoning.

Live animals represent another important source of exogenous micro-organisms. Infectious diseases of animals that may be transmitted to humans — the so-called zoonoses — include brucellosis, tularemia, plague, toxoplasmosis and rabies. In addition, microbial pathogens can be transmitted from animals to humans by insect vectors like flies, mosquitoes and ticks.

The most important sources of exogenous infections are probably humans themselves (see Fig. 1.8). Well-known examples of human-to-human transmission include the common cold, AIDS, other sexually transmitted diseases, measles, diphtheria, tuberculosis and typhoid fever. Cross-infection in hospitals poses enormous problems, especially in intensive care units.

Several regions of the body may be exposed to exogenous contamination (see Fig. 1.8). Healthy people may be carriers if they harbor and excrete potentially disease-producing micro-organisms. For instance, people recovering from typhoid fever may retain *Salmonella typhi* in the gallbladder and continue to excrete the pathogen in the feces long after recovery from the disease. These people are chronic carriers, even though they usually have mounted a protective immune response against the bacterium.

Exogenous infections, predominant in the past, have dramatically declined in the developed world thanks to improved hygiene, vaccination programs and infection control programs. They are, however, still prevalent in areas with limited resources. Community-acquired pneumonia, diarrheal diseases, malaria, AIDS and

tuberculosis are the main causes of over-mortality in developing countries.

The infection process

Three stages in the infection process may be functionally distinguished:

- attachment of the micro-organism to the target cell(s) and, for intracellular pathogens, entry into the host cell;
- development of the infection, local multiplication of the pathogen and spread of the micro-organism to distant sites; and
- shedding of the organism and transfer to a new host.

Attachment to host cells

Only a few pathogens have the capacity to penetrate our body directly through the skin. Examples include the cercariae of various schistosome species, which can invade the skin with the help of their glandular secretions, and pathogens that enter the body after a bite (e.g. *Simulium* blackfly bite for *Onchocercus volvulus*, anopheles mosquito bite for malaria), intramuscular or intravenous injection, blood transfusion or after injury of the body surface.

Although 'free' micro-organisms exist (for instance, in the lumen of the intestine or in the saliva) most members of the human flora need to be attached to a cellular surface to avoid being swept away by the biologic fluxes such as urine or the passage of the alimentary bolus. For many microbial pathogens, adherence to the epithelial surface of the respiratory, digestive or reproductive mucosa is a compulsory step in pathogenesis.

Adherence

The approach of micro-organisms to an epithelial surface is guided by a balance between attractive and repulsive forces. Eventually, multiple high-affinity contacts between the microbe and the cellular surface may establish a virtually irreversible association between the two. Such contacts may involve nonspecific interactions, such as those between exposed hydrophobic structures on the microbial cell envelope and lipophilic areas on the cell membrane. Glycocalyx, made essentially of a mixture of polysaccharides, and 'slime', produced in particular by *Staphylococcus epidermidis*, may mediate nonspecific adherence between prokaryotic and eukaryotic cells.

Specific adherence involves microbial adhesins on the one side and host cell receptors on the other. Although the interaction between adhesins and cell receptors may be highly specific, this is not always the case. The specificity can be tested by artificially blocking adherence with an excess of purified adhesin or receptor or with antibodies directed against one of these two. The specificity accounts for the early observation that many pathogens distinctively infect certain areas or organs of the body and not others. For instance, *Streptococcus pneumoniae* causes pneumonia but not urethritis, whereas *Neisseria gonorrhoeae* exhibits the opposite pattern of specificity. The receptors for poliovirus, rhinovirus and HIV are expressed only by specific cell types, restricting virus infection accordingly. These and many other examples support the notion that adhesins determine the tropism of microbial pathogens. On the other hand, cell receptors for many organisms are ubiquitous and these organisms (e.g. influenza virus) have no tissue restriction.

Ubiquitous receptors

Fibrinogen, fibronectin, collagen and heparin-related polysaccharides are major components of the extracellular matrix (ECM), which coats the mucosal surface of epithelial cells. Members of the integrin family are involved in the interaction between the ECM and the underlying epithelium. A number of components of the ECM are used as receptors for microbial adhesins. Fibronectin specifically binds fibronectin-binding factors on the cell envelopes of *Staphylococcus aureus*, *Streptococcus pyogenes*, *Treponema pallidum* and *Mycobacterium* spp.; fibrinogen binds groups A, C and G streptococci and a member of the integrin family binds the major invasion factor of *Yersinia pseudotuberculosis*. Their abundance and structural conservation among mammalian species make ECM components ideal targets for bacterial adhesins.

Bacterial adhesins

Close contact between micro-organism and host cell represents an essential step in pathogenesis. It optimizes the interaction of microbial virulence factors with the target cell to allow the pathogen to penetrate or cause local cell damage, or both. Other possible functions of adhesins include modulation of the inflammatory response, adhesin-directed degranulation from mast cells and adhesin-mediated bacterial phagocytosis by neutrophils. Bacteria use two general strategies to attach themselves to host cells: fimbrial and afimbrial adhesion (Fig. 1.9).[11]

Pili and fibrillae

Attachment of bacteria to the plasma membrane can be mediated by filamentous structures protruding from the bacterial surface,

Figure 1-9 Bacterial adherence.

called fimbriae or fibrillae. The classification of these colonization factors is based on morphologic criteria. Fimbriae (or common pili) are rigid hair-like structures with a regular diameter, whereas fibrillae are flexible and have an irregular diameter. These structures are distinct from flagella, which are responsible for bacterial motility (see Fig. 1.7), and sex pili, which are associated with bacterial conjugation.

Twenty different colonization factors have been described for *E. coli*.[12] One of these, the so-called P-pili expressed by uropathogenic *E. coli* strains, mediates adherence of the bacterium to the urinary mucosa to avoid elimination by the urinary flux. P-pili consist of a long and rigid base section attached to an outer membrane scaffold, and a short flexible tip (Fig. 1.10).[13] The rigid section measures about 7nm in diameter, with a central channel approximately 1.5nm wide, and is 1–2µm long. It is composed of hundreds of pyelonephritis-associated (PapA) pilin subunits arranged in a right-handed helix. The pilus tip is 2nm in diameter with a 15nm pitch composed of PapE monomers. The PapG monomer is located at the end of the tip and is the actual adhesin. It recognizes the glycolipid receptor globobiose (a-1–4 linked di-galactose) on the host cell surface. During pilus formation, the tip is assembled and exported first, followed by the

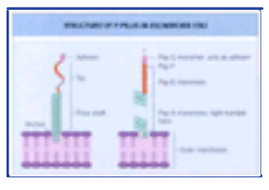

Figure 1-10 Structure of P-pilus in *Escherichia coli.*

addition of the pilin subunits forming the shaft. The assembly of pili requires periplasmic chaperones, which assist in protein folding and assembly but never become part of the pili structure.

Afimbrial adhesins

Afimbrial adhesins, such as lectins (carbohydrate-binding proteins), also mediate tight binding between the bacteria and the host cell but, unlike pili, they do not form supramolecular structures. Similar adhesins exist in viruses, fungi and protozoa. Afimbrial binding has been extensively studied in *Streptococcus pyogenes* (Fig. 1.11). Two surface components are believed to be critical in the colonization of an epithelial surface: lipoteichoic acid and fibronectin-binding protein.

Purified lipoteichoic acid binds to fibronectin and inhibits the binding of *S. pyogenes* to oral epithelial cells. The binding properties are confined to the lipid moiety of lipotechoic acid. Similarly, artificially added fibronectin-binding protein inhibits adhesion of *Strep. pyogenes* to epithelial cells even after the streptococci have been

depleted of lipoteichoic acid.

The complex surface of this micro-organism also includes the M protein.[15] This protein is a major virulence factor but it does not seem to be involved in adherence to epithelial cells, as was previously assumed. However, the M protein binds fibrinogen in a stoichiometric fashion and exerts an antiphagocytic effect, which may partially explain its role in virulence.

Viral adhesion

Viral adhesion and invasion are generally mediated by the same viral proteins and may be considered as a single continuous event. Initial attachment represents the first in a series of steps that ultimately leads to the delivery of the viral genome to its site of replication. Nonenveloped viruses appear to pass or slide through the plasma membrane directly. Enveloped viruses, such as measles and mumps virus, enter the cell after fusion with the plasma membrane.[16] These virions have a fusion protein that initiates the contact between the two membranes. Virus internalization may be mediated by a protein called clathrin, which forms membrane invaginations containing the virion. Once in the cytoplasm, the virus escapes from the clathrin-coated pits to reach the cytosol. The low pH inside the vacuole triggers escape of the virion.

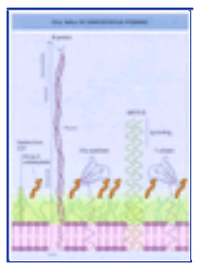

Figure 1-11 Cell wall of *Streptococcus pyogenes.* The proposed model of the M protein is based on current sequence and structural data. ARP, immunoglobulin A receptor protein; FcR, receptor for the Fc portions of immunoglobulin. *Adapted from Kehoe.*[14]

Receptor availability on the cell determines whether a virus particle will bind to its surface. Cell specificity may thus be rather relaxed for viruses that use ubiquitous receptors and, on the other hand, be strongly restricted for viruses that require two or more cellular receptors simultaneously. An example of the latter is HIV; it requires co-expression of CD4 and chemokine receptors for efficient adhesion and invasion of the target cell. Herpes simplex virus 1 has an enveloped icosahedral capsid. The envelope contains at least 12 glycoproteins, of which two (glycoproteins B and C) interact with heparin sulfate on the plasma membrane. A second, specific interaction is probably required between glycoprotein D and an as yet unidentified cellular receptor to trigger fusion of the viral envelope and the plasma membrane. Following fusion, the capsid is released in the cytosol and is transported to the nuclear membrane. Herpes simplex virus first infects epithelial cells of the skin and mucosal surfaces, where the initial replication cycles take place, to pass into axon termini of neurons, the ultimate infection site.

Viral adherence and invasion can be blocked by neutralizing antibodies, which specifically bind the active site(s) of the adhesin(s). However, many viruses have hidden this region in a protein pocket (or 'canyon'), making it physically inaccessible to potentially neutralizing antibodies, thus escaping humoral immunity.

INVASION

Invasive and noninvasive micro-organisms

Many micro-organisms, including those of the natural flora, remain at the epithelial surface without invading the underlying tissue (Table 1.7). This type of colonization is usually harmless although it may, in some cases, induce damage to adjacent cells through the production of toxins or elicit a local inflammatory or allergic response. Nonpenetrating micro-organisms include *Streptococcus pyogenes* and *Corynebacterium diphtheriae*, which cause pharyngitis, *Mycoplasma pneumoniae*, which causes atypical pneumonia, and *Trichomonas vaginalis*, a cause of vaginitis.

Other micro-organisms gain access to deeper tissues only after a physical or chemical injury of the epithelial barrier. *Staphylococcus aureus*, a harmless microbe when on the skin, may become a dangerous toxin-producing pathogen once it penetrates the body.

Invasive micro-organisms exhibit the capacity to penetrate the target tissue to which they adhere without the need for local disruption of the protective epithelium. Invasive bacteria have developed the capacity to enter host cells, which are not naturally phagocytic. Penetration into these 'nonprofessional' phagocytes is achieved by:

- specific attachment to the host cell; and
- induction of local rearrangements of the cytoskeleton, through polymerization and depolymerization of actin.

This results in the formation of pseudopod-like structures, which eventually engulf the pathogen into the host cell (Fig. 1.12). In order to induce ingestion by the host cell, the pathogens may produce surface proteins called invasins.

In some cases infection remains confined to the epithelial surface (see Table 1.7), but in others the micro-organism may be transported across the superficial epithelium to be released into subepithelial space. This process is called transcytosis and involves the host cell actin network (see below). After transcytosis, the underlying tissues may be invaded and infected and the infection may eventually spread all over the body (e.g. *Neisseria meningitidis* may get across the pharyngeal epithelium and cause meningitis, and *Salmonella typhi* may cross the intestinal epithelium and cause typhoid fever). For a more detailed analysis of the mechanisms of invasion, we shall use the example of enteroinvasive pathogens.

Enteroinvasive pathogens and the membranous cell gateway

Acute infectious diarrhea may cause the clinical spectrum of dysentery and bloody diarrhea. It occurs when the pathogen invades the intestinal mucosa and causes structural damage to the intestine. The immunologic protection of the intestine is performed by the gut-associated lymphoid tissues, which are separated from the intestinal lumen by a specialized follicle-associated epithelium. In the follicle-associated epithelium, membranous cells (M cells) play a prominent role because they are specialized in the transport of antigens. Enteroinvasive viruses, protozoa and bacteria exploit the transport facilities provided by M cells to invade the host. Entry (and passage) of M cells by these pathogens is preceded by adherence, in the case of reovirus type 1 through the specific adhesins s1 or µ1 of the outer capsid. Enteroinvasive bacteria such as *Salmonella*, *Shigella* and *Yersinia* spp. appear to distinguish between different subsets of M cells. Membranous cells produce glycocalyx, which contains a distinctive profile of lectin-binding sites. Diversity in lectin-binding sites between different locations of the gut may account for the tropism of enteric pathogens, such as the preferential colonization of colonic mucosa by *Shigella* spp. rather than *Salmonella* spp., which are more commonly found at the end of the ileum. Following adherence, the interactions with the M cells vary according to the pathogen (Fig. 1.13). Enteroadherent *E. coli* is not internalized and

TABLE 1-7 -- Interaction of micro-organisms with epithelial cells.

INTERACTION OF MICRO-ORGANISMS WITH EPITHELIAL CELLS			
	Order	**Micro-organism**	**Disease**

Generally confined to epithelial surfaces	Bacteria	*Bordetella pertussis*	Pertussis
		Chlamydia trachomatis	Trachoma, urethritis
		Corynebacterium diphtheriae	Diphtheria
		Streptococcus pyogenes	Uncomplicated pharyngitis
	Viruses	Coronaviruses	Common cold
		Rhinoviruses	Common cold
		Rotaviruses	Diarrhea
	Fungi	*Candida albicans*	Thrush
		Trichophyton spp.	Athlete's foot
	Protozoa	*Giardia lamblia*	Diarrhea
		Trichomonas vaginalis	Vaginitis
Enter through the epithelium	Bacteria	*Mycobacterium tuberculosis*	Tuberculosis
		Brucella melitensis	Brucellosis
		Neisseria meningitidis	Meningitis
		Salmonella typhi	Typhoid fever
		Treponema pallidum	Syphilis
		Yersinia pestis	Plague
	Viruses	Measles virus	Measles
		Rubella virus	Rubella
		Varicella	Chickenpox
		Poliovirus	Poliomyelitis
	Fungi	*Cryptococcus* spp.	Cryptococcosis
		Histoplasma spp.	Histoplasmosis
	Protozoa	*Toxoplasma gondii*	Toxoplasmosis
		Entamoeba histolytica	Liver abscess

hence is not invasive. *Vibrio cholerae* is taken up and transported by the M cells but rapidly killed thereafter. It is considered to be invasive at the cellular level but not at the clinical level.

Detailed molecular analyses of virulence factors produced by enteroinvasive *Shigella* spp. have revealed that all virulent species harbor a 220kb plasmid, of which a 31kb fragment, encoding 32 genes, is both necessary and sufficient for invasion of epithelial cells.[18] The four invasion plasmid antigens (IpaA, B, C and D) encoded by this fragment are key players in the invasion process. Secretion of the 'Ipa complex' is induced by contact with the target cells and is accomplished by a specialized entry-associated secretion apparatus encoded by a set of genes (*mxi*, *spa*) located in the same region of the virulence plasmid. The *Salmonella* spp. entry functions are clustered in a 35–40kb region of the chromosome at centisome 63.[19] Such clustering of virulence genes is a typical example of a genetic 'pathogenicity island'.[20] These pathogenicity islands are often

Figure 1-12 Opsonization and phagocytosis of bacteria. Bacteria are covered with IgG, specific for surface antigens. Bound IgG interacts with the phagocyte Fc?-receptor and pseudopods are formed, engulfing the bacterium into the host cell.

transmissible from one microbial species to another as a single DNA fragment by way of mobile genetic elements such as plasmids, transposons or bacteriophages. In *Vibrio cholerae* the A- and B-subunits of cholera toxin are encoded by a bacteriophage that integrates into the bacterial genome and may, in concert with yet another bacteriophage, facilitate horizontal spread of the toxin genes.[21]

The *Salmonella* and *Shigella* spp. genes involved in invasion of the eukaryotic host cell are homologous and have been remarkably well conserved with respect to both the individual coding sequences and their genetic organization (Fig. 1.14).[22] Using a needle-like complex, [23] the bacteria translocate a number of effector proteins into the cytosol and the plasma membrane of the target cell.[24] Some of these effector proteins specifically modify the activities of cellular GTPases, inducing the alterations of the cytoskeleton required for bacterial internalization. [25] The interplay between target cell and bacteria during the invasion processes of

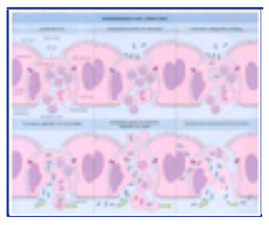

Figure 1-13 Enteropathogen-M cell interactions. (a) An uninfected M cell, enclosed between two adjacent enterocytes. The basolateral side forms a pocket where lymphocytes and macrophages are located. (b) Enteroadherent *Escherichia coli* forms microcolonies at the M cell surface, but is not internalized. (c) *Vibrio cholerae* undergoes transcytosis but is efficiently phagocytosed in the submucosa. (d) *Campylobacter jejuni* and *Yersinia* spp. undergo transcytosis, replicate in the submucosa and disseminate. (e) *Salmonella* spp. are transported across M cells, leading to destruction of the M cell. (f) *Shigella flexneri* is endocytosed by M cells, escapes into the cytoplasm, replicates, is propelled by actin tails and spreads to adjacent enterocytes. *Adapted from Siebers and Finlay.*[17]

these two genera is different, however. Another important difference between the pathogenic lifestyles of these two bacterial species involves the intracellular fate of the bacteria. Once internalized, the bacteria find themselves enclosed by a host cell membrane in an endocytic vesicle, deprived of nutrients. In professional phagocytes, such as macrophages and dendritic cells, these endosomes are programmed to fuse to a prelysosome, releasing the hydrolytic enzymes required for the destruction of the bacterial cell. Soon after entry into the cell, *Shigella* spp. escape from the endosome into the nutritious cytoplasm, but *Salmonella* spp. have adopted an entirely different strategy. Salmonellae modify the endocytic pathway of the host cell by means of virulence factors encoded largely, but not exclusively, by a second pathogenicity island,[26] thus avoiding exposure to bactericidal mechanisms of the cell. Although only some of the cellular targets of the translocated bacterial virulence proteins have been identified to date, it is clear that the physiology of the infected cell is profoundly modified to suit bacterial growth and maintenance.

Actin-based intracellular motility of microbial pathogens

Enteroinvasive micro-organisms use passive actin modification to invade nonprofessional phagocytes such as epithelial cells. Local modification of the cytoskeleton is induced by the pathogen by diverting the signaling pathways of the host cells. In addition, some bacteria use active actin modification to move in the cytoplasm. They induce the formation of actin cross-linked filaments, which assemble in characteristic 'comet-like tails' (Fig. 1.15).[27] [28] Elongation of the actin filaments generates sufficient force to move the micro-organisms through the cytoplasm at rates of 2–100µm/min. Pathogens

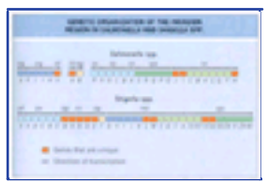

Figure 1-14 Genetic organization of the invasion region in *Salmonella* and *Shigella* spp. Identical patterns indicate topologically conserved blocks of genes. Each genus has genes that are unique. Despite remarkable genetic similarities, the invasion strategies of the two bacteria are quite different (see Fig. 1.13). *Adapted from Galan.*[19]

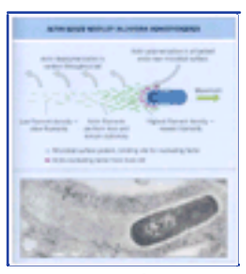

Figure 1-15 Actin-based motility in *Listeria monocytogenes.* The bacterium moves forwards at the rate of actin-filament growth behind the pathogen. *Adapted from Sanders and Theriot.*[27] The EM shows a section of a CaCo-2 cell infected with *Listeria monocytogenes*; the bacterium protrudes into the cytoplasm of an adjacent cell; protrusion is limited by a double membrane (arrowheads).

that use the actin skeleton for intracellular spread include bacteria (e.g. *Listeria monocytogenes*, *Shigella* spp., *Rickettsia* spp.) and viruses (e.g. vaccinia, measles, rabies).

The intracellular life cycle of *L. monocytogenes* illustrates this strategy (Fig. 1.16). [29] [30] Under natural conditions, *Listeria* first penetrates enterocytes and probably M cells and subsequently spreads through the body to infect a variety of host cells, including endothelial cells, Kupffer cells, hepatocytes and phagocytes. Entry is facilitated

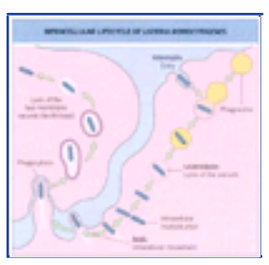

Figure 1-16 Intracellular life cycle of *Listeria monocytogenes.*

by the products encoded by the internalin (*inl*) family of genes, which seem to confer tropism for different cell types. Once inside the cell, *L. monocytogenes* remains confined to the phagosome for only a short time. Following lysis of the endosomal membrane, it escapes into the cytosol. Membrane lysis is achieved by a production of listeriolysin-O, which attains maximum activity under the acidic conditions of the intravacuolar environment. Once in the cytosol, the bacteria multiply and migrate towards the plasma membrane by using the actin-based mechanism as described above. Actin polymerization is mediated by the *L. monocytogenes* protein ActA, localized at one end of the bacterium. For spread to neighboring cells, *L. monocytogenes* requires bacterial lecithinase and phospholipase C, which stimulate lysis of the two membranes that separate the bacterium from the cytoplasm of the newly infected cell. Interestingly, most of the virulence genes associated with this process are clustered in a single region of the *L. monocytogenes* chromosome.

Subepithelial invasion and spread through the body

Invasion from the site of infection can only be achieved by micro-organisms that effectively resist the host defense mechanisms in the subepithelial space, most prominently phagocytosis.

The lymphatic network is often used as a means of transport and successful micro-organisms may rapidly reach the nearest local lymph nodes, which have an important filtering function. In the lymph nodes, resident macrophages and polymorphonuclear cells actively fight the invaders. As a result the first line of lymph nodes are often inflamed. If the invading micro-organism is sufficiently virulent or present in sufficiently large numbers, it may pass into efferent lymphatic vessels to be conducted to the bloodstream. The result is primary bacteremia or viremia. Some microbes can enter directly into the blood vessels via an injury. A typical example is provided by viridians streptococci, which enter the bloodstream during dental extraction, enabling them to infect a cardiac valve and produce endocarditis. Insect bites (malaria and arthropod-borne viruses) or damage to the blood vessel wall inflicted by hemorrhagenic viruses are alternative ways to circumvent the body's first line of defense: the mucosal immune system.

Once in the bloodstream, the micro-organisms may circulate as either an extracellular or an intracellular species. Pathogens have been found in polymorphonuclear cells (staphylococci), lymphocytes (HIV), macrophages (*Mycobacterium tuberculosis*) and even in red blood cells (*Plasmodium* spp.), which provide protection against potent humoral factors in the serum, such as complement.

Infection of distant target organs

Transported by the bloodstream, the invasive micro-organisms can reach distant target organs and create infective metastases throughout the body. Almost any tissue can be reached, but the organs containing abundant capillary and sinusoid networks (e.g. lungs, liver, kidneys) are especially exposed, because blood flows slowly at these sites and transported micro-organisms get the opportunity to adhere and establish an infection. From the target organs, the invaders may produce a secondary bacteremia or viremia, in which microbial counts in the blood are generally higher than during primary infections.

The example of measles virus

Measles virus adheres to the CD46 receptor.[31] Infection of a nonimmune host proceeds by invasion of the epithelial surface of the respiratory mucosa, where the virus undergoes limited replication. The virus subsequently migrates to the regional lymph nodes and those micro-organisms that survive local macrophage attack will enter the bloodstream, causing a primary viremia. When the infection becomes generalized, several target areas are affected, including the lungs, the skin and the central nervous system. At this stage, the virus undergoes further replication in the leukocytes (causing leukopenia) as well as in the lymphoid tissues and in the target organs. The result is secondary viremia and fever. Rash appears later and is due to the destruction of infected cells by cytotoxic T cells rather than to a direct cytopathic effect of the virus on skin cells.

These pathogenic steps correspond to different clinical periods. During the initial encounter with the virus, the viral spread to target organs and the primary viremia, there are no clinical symptoms; this corresponds to the incubation period, which lasts for about 10 days. After this, disease develops and about 4 days later (i.e. typically 14 days after contamination) the skin rash occurs, corresponding to local inflammation and cellular immunity.

Serum resistance in Neisseria gonorrhoeae *and* Salmonella *spp.*

Immunocompetent hosts contracting gonorrhea usually do not develop a systemic disease. Human serum contains a variety of humoral factors, including the complement system, which provide effective protection against *N. gonorrhoeae*.

Complement is both a major effector of specific humoral immunity and a participant in natural (innate) immunity. The complement system involves some 30 serum proteins and is aimed at extracellular pathogens. It may be activated by one of two convergent pathways. The 'classic pathway' is activated by specific binding of either two IgG or one IgM molecule to a circulating target. The first component of the complement system (C1) binds in a co-operative fashion to two adjacent Fc fragments of the immunoglobulin attached to the target and initiates a proteolytic activation cascade, culminating in the erection of a multiprotein complex that strongly stimulates phagocytosis. The complement system may directly induce cytolytic activity through the membrane attack complex anchored on the microbial envelope. The

'alternative pathway' does not depend on the availability of specific immune globulins and is initiated directly by fixation of complement proteins to specifically recognized structures on the target surface. The outcome of both pathways is in many respects similar.

The ability to resist complement killing contributes to the virulence of *Salmonella* spp. Complement resistance can be provided by very long O-side chains of *Salmonella* lipopolysaccharide (LPS). In addition, the outer membrane protein Rck (resistance to complement killing) may provide protection of the bacterium against complement-mediated killing. The last step in the assembly of the membrane attack complex onto the bacterial membrane (insertion of polymerized C9 into the outer membrane) is prevented by Rck. The *rck* gene is located on the large virulence plasmids of *Salmonella dublin* and *Salmonella typhimurium*.

Some strains of *N. gonorrhoeae* are serum resistant and do cause disseminated infection in normal hosts. These strains are protected against complement by changes in the carbohydrate portion of their lipo-oligosaccharide. In some of the resistant strains, a galactose residue of LPS covalently binds an activated form of sialic acid from human blood, thus abolishing complement activation.[32] In addition, individuals with genetic defects in the terminal complement components (C6–C9) are unable to assemble the membrane attack complex. They are more susceptible to disseminated neisserial infections although there is a lower case mortality.

Cell and tissue damage induced by micro-organisms

Infectious disease is often characterized by cell and tissue damage. Paralysis in poliomyelitis, exanthem in varicella, gastroduodenal ulcers in *Helicobacter pylori* infections and bloody diarrhea in shigellosis all result from damage caused directly or indirectly by micro-organisms. Cell damage can be generated by a variety of different mechanisms (Table 1.8).

Bacterial toxins

Bacteria produce a large diversity of toxins, which have been classified according to their mode of action (Table 1.9 , Fig. 1.17). Traditionally, exotoxins (or excreted toxins) are distinguished from endotoxin (equivalent to the lipopolysaccharide of the outer membrane of Gram-negative bacteria). However, some of the so-called exotoxins are actually intracellular and are released into the environment only after cell lysis. The pneumolysin of *Streptococcus pneumoniae*, for example, is cytoplasmic, the adenylate cyclase of *Bordetella pertussis* is associated with the cytoplasmic membrane and the heat-labile toxin I (LT-1) from *E. coli* is periplasmic. The genetic information that encodes bacterial toxins is frequently carried on mobile DNA elements, which may readily pass from one microbial host to another. The toxins associated with diphtheria, botulism and scarlet fever, as well as Shiga-like toxin in *E. coli*, are encoded by temperate bacteriophages. Genes for LT-I and methanol-susceptible heat-stable toxin (Sta) of *E. coli* are carried on plasmids.

Toxins deregulate the physiology of the host cell before or during bacterial adhesion and invasion. The bacteria may profit from the induced damage, which compromises the cellular defense against the intruder and release of nutrients from the cytosol.

The diphtheria toxin as example of an A–B toxin

Diphtheria toxin belongs to the so-called A–B toxins (Fig. 1.18). These toxins are bifunctional molecules. Portion A mediates the enzymatic activity responsible for the toxicity after internalization into the target cell, but cannot penetrate by itself. Portion B is not toxic but binds to a cell receptor localized on the cell surface and mediates the translocation of the A chain into the cytosol. Portion B accounts for the cell specificity of the A–B toxins. The receptor recognized by the B chain of diphtheria toxin is a heparin-binding precursor of epidermal growth factor. Epidermal growth factor is an important hormone for growth and differentiation of many different cell types.

Uptake of diphtheria toxin proceeds via receptor-mediated endocytosis. Acidification of the endocytic vesicle induces a confirmational

TABLE 1-8 -- Mechanisms of cell and tissue damage produced by micro-organisms.

MECHANISMS OF CELL AND TISSUE DAMAGE PRODUCED BY MICRO-ORGANISMS		
	Mechanism	**Examples**
Direct damage by micro-organisms	Production of toxins	See Table 1.9
	Production of enzymes	Proteases, coagulase, DNAses produced by *Staphylococcus aureus*
	Apoptosis	HIV ($CD4^+$ T cells); *Shigella flexneri* (macrophages)
	Virus-induced cytopathic effects:	
	Cell lysis	Cytomegalovirus
	Formation of syncytium	Respiratory syncytial virus
	Inclusion bodies	
	Intracytoplasmic	Rabies
	Nuclear	Herpesviruses
	Transformation	Human papillomaviruses type 16
Damage via the host immune response	Cytotoxic T cells and natural killer lymphocytes	Production of the measles rash
	Autoimmunity	Acute rheumatic fever
	Immediate hypersensitivity	Rashes associated with helminthic infections
	Cytotoxic hypersensitivity	Cell necrosis induced by hepatitis B
	Immune complexes	Glomerulonephritis in malaria
	Delayed type hypersensitivity	Tuberculous granuloma

TABLE 1-9 -- Examples of bacterial toxins.

EXAMPLES OF BACTERIAL TOXINS					
Toxin type	**Example of sources**	**Toxin**	**Targets**	**Mechanisms**	**Effects**
Endotoxin (LPS, lipid A)	Gram-negative bacteria	Endotoxin	Macrophages, neutrophils, lymphocytes, plasma components	Activation of target cells, complement; release of IL-1, TNF, kinins	Septic shock
Membrane-disrupting toxins	*Staphylococcus aureus*	a-Toxin	Many cell types	Formation of pores	Tissue necrosis
	Listeria monocytogenes	Listeriolysin	Many cell types	Formation of pores at acidic pH	Escape from the phagosome
	Clostridium perfringens	Perfringolysin-O	Many cell types	Phospholipase (removes polar head groups from phospholipids)	Gas gangrene

A–B-type toxins	*Clostridium tetani*	Tetanospasmin	Synaptic transmission	Inhibits release of inhibitory neurotransmitters	Spastic paralysis
	Clostridium diphtheriae	Diphtheria toxin	Many cell types	ADP ribosylation of EF-2	Paralysis
	Vibrio cholerae	Cholera toxin	Intestinal cells	ADP ribosylation of adenylate cyclase, leading to rise in cyclic AMP	Profuse watery diarrhea
Superantigen	*Streptococcus pyogenes*	Streptococcal pyogenic exotoxin	T cells, macrophages	T cell stimulation, release of IL-1, IL-2, TNF; possible enhancement of LPS activities	Fever, eruption, toxic shock-like syndrome
	Staphylococcus aureus	Toxic shock toxin	T cells, macrophages	Same as streptococcal pyrogenic toxin	Toxic shock syndrome

change in the enclosed holotoxin, enabling the A subunit to traverse the membrane and reach its cytoplasmic target. The A subunit of diphtheria toxin catalyzes ADP-ribosylation of the elongation factor-2 (EF-2). After attachment of the ADP-ribosyl group, EF-2 becomes inactive, causing the death of the target cell.

Only *Corynebacterium* lysogenic for temperate bacteriophage carrying the *tox* gene produce the toxin. The *tox* gene is under the control of the repressor protein DtxR, which forms a complex with iron, DtxR-Fe (Fig. 1.19), binds DNA and represses *tox* expression. Thus diphtheria toxin is only synthesized under low iron conditions, suggesting that it may be produced to stimulate iron release from target cells. Interestingly, the *Pseudomonas aeruginosa* exotoxin A has a very similar structure, but uses a different cell receptor: the a-2 macroglobin low-density lipoprotein receptor. Like diphtheria toxin, exotoxin enters the cell via receptor-mediated endocytosis but the toxin is released only after passage through the Golgi system.

Hydrolyzing enzymes

Microbial pathogens often secrete hydrolyzing enzymes, such as proteases, hyaluronidases, coagulases and nucleases. As such, these enzymes cannot harm the host cells and they are therefore not considered to be toxins. However, in the context of an ongoing infection

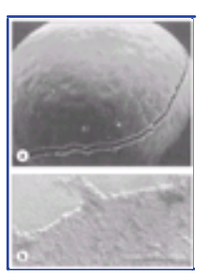

Figure 1-17 Action of bacterial toxins. (a) *Xenopus* oocyte treated with the cytolytic delta toxin (perfringolysin) of *Clostridium perfringens*. (b) Rabbit erythrocyte exposed to a very small quantity of streptolysin-O, produced by *Streptococcus* A,C,G. Hemoglobin escapes from sites of membrane rupture. *Courtesy of Dr J Alouf.*

they are assumed to facilitate colonization of host tissues by a variety of mechanisms, such as proteolysis of IgA; fluidification of pus; induction of plasma clotting, which may hinder the influx of phagocytes into the focus of infection; and a general disorganization of the host tissue structure. The release of hydrolytic enzymes by phagocytes damaged by a bacterial toxin may have similar effects.

Apoptosis

Apoptosis is a process in which the cell activates an intrinsic suicide program. It plays a key role in processes like organ development, tissue repair and maintenance of the dynamic equilibrium of the immune system. These processes critically depend on the generation of self-limiting organized structures through addition of new cells and elimination of 'old' cells. The morphologic changes associated with apoptotic death are a reduction of the volume of the cytosol and nuclear condensation (Fig. 1.20). The genome is fractionated by an endonuclease activity that cuts the DNA into multiples of 180–200bp. [33] Finally, the remains of the cell are removed by phagocytosis.

Apoptosis is distinct from necrosis. In necrosis, which may, for example, be induced by a bacterial toxin, the cell does not participate actively in its own death. Another important difference between apoptosis and necrosis is that the former does not usually induce proinflammatory responses that usually accompany the latter.

Many viruses trigger apoptotic death of the infected host cell. For instance, apoptosis seems to contribute to the depletion of $CD4^+$ T cells, both in cell culture and in HIV-infected people.[34] Apoptotic cells have also been observed in infections caused by Epstein-Barr virus and adenoviruses. Bacteria can also induce apoptosis. *Bordetella pertussis*, the agent of whooping cough, triggers macrophage apoptosis by interfering with cellular regulation at the level of the cytoplasmic second messenger cyclic AMP (cAMP).[35] The bacterium induces high levels of cytoplasmic cAMP, favoring the induction of apoptosis. *Shigella flexneri*, the etiologic agent of dysentery, can kill macrophages by apoptosis. Cell death is induced by invasion plasmid antigen B (IpaB) encoded by the *Shigella* virulence plasmid (see Fig. 1.14). [36] The *Shigella* IpaB protein binds to the host cytoplasmic enzyme interleukin-1ß converting enzyme (caspase-1) and activates it.[37] Caspase-1 activates the proinflammatory cytokines IL-1 and IL-18 by proteolytic cleavage and initiates one of the proapoptotic pathways. In *Salmonella* infection of macrophages and dendritic cells, the IpaB homolog SipB similarly activates caspase-1 to stimulate secretion of the proinflamatory

Figure 1-18 Diphtheria toxin synthesis and mode of action. (Top) The 25-residue leader sequence is cleaved off by the bacterial leader peptidase; the A and B subunits are generated from the precursor protein by a 'trypsin-like enzyme'. Once in the cytoplasm of a targeted eukaryotic cell, the A chain, responsible for ADP-ribosyl transfer, is disconnected from the B chain, responsible for receptor binding and membrane insertion. (Bottom) The B chain binds to a specific receptor on the eukaryotic cell. After endocytosis, acidification in the endosome induces insertion of the B chain into the endosomal membrane and translocation of subunit A into the cytosol, where it catalyzes the ADP ribosylation of EF-2. As a result, protein synthesis is inhibited and the targeted cell dies.

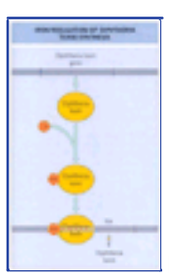

Figure 1-19 Iron regulation of diphtheria toxin synthesis. High iron concentrations in the environment repress the synthesis of diphtheria toxin: when bound to iron, DtxR-Fe acts as a transcriptional repressor of the *tox* gene.

cytokine IL-18 and induce apoptosis.[38] Timely induction of apoptosis in dendritic cells may well allow Salmonellae to exploit the mobility of these host cells to migrate away from the intestinal mucosa and establish systemic infection.

Virus-induced cytopathic effect

Most viruses severely damage the cells they infect, sometimes inducing distinctive cytopathic effects that may be useful in diagnosis (Fig. 1.21). A large variety of mechanisms may be involved in these cytopathic effects, some being direct consequences of the presence of the virus, others resulting from the host immune response.

Virus infection may result in the intracellular accumulation or release of a number of small molecules, including reactive oxygen and nitrogen intermediates, which may play an important role in certain types of cell destruction, particularly in macrophages. Rotavirus, cytomegalovirus and HIV can produce significant increases in intracellular calcium, which seems to be a common pathway for the development of irreversible cell injury.

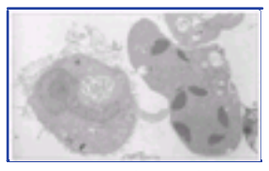

Figure 1-20 Apoptosis induced by Sendai virus. Morphologic changes in the apoptotic Sendai infected cell (right) include the typical condensation of chromosomal DNA. *Courtesy of Dr Dick Compans and Dr Kiyoshi Tanebayashi.*

In addition to cell lysis, other cytopathic effects exist. Paramyxoviruses such as respiratory syncytial virus, parainfluenza viruses, and measles virus, as well as herpesvirus and some retroviruses, cause the formation of multinucleated giant cells. The formation of these giant cells (syncytia) is mediated by virus-encoded fusion proteins. Viral infection can also produce eosinophilic or basophilic inclusion bodies, which appear in the cytoplasm or the nucleus. Inclusion bodies may represent aggregations of mature virions, areas of altered staining at sites of viral growth or simply degenerative changes.

Host cell transformation by viruses results in increased cellular multiplication rates and disorderly growth. It may be caused by DNA viruses (for instance, Burkitt's lymphoma associated with Epstein-Barr virus) or retroviruses (adult T-cell leukemia caused by human T-cell lymphotropic virus type 1). Malignancy is induced by the expression of viral oncogenes. High-risk human papilloma viruses (such as HPV16) usually only transiently infect the basal cells of the cervical mucosa, to be cleared by the host immune response. However, in a minority of women persistent infections with high levels of viral DNA may develop. These persistent infections may eventually progress to invasive carcinoma.[39] Two viral proteins, E6 and E7, play co-operative roles throughout viral multiplication, pathogenesis and malignant transformation, which correlates with integration of viral DNA into the genome.[40] By specifically interacting with an impressive variety of cellular targets these proteins remodel the cell cycle and modify cell differentiation of the basal cells of the cervical epithelium, creating an environment

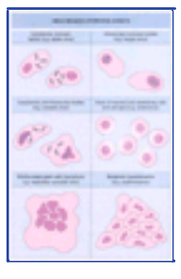

Figure 1-21 Virus-induced cytopathic effects.

supportive of viral replication. Due to the inactivation of tumor suppressor proteins p53 and Rb by E6 and E7, chromosomal destabilization, enhancement of foreign DNA integration and mutagenicity, the infected cells may transform to a malignant phenotype.

Damage resulting from cytotoxic lymphocytes

The most effective host defense mechanism against most viral infections is mediated by the $CD8^+$ cytotoxic T lymphocytes (CTLs). The CTLs recognize, attack and lyse virus-infected cells that present viral antigens on their surface in the context of MHC class I molecules. In addition to CTLs, natural killer lymphocytes similarly kill virus-infected cells. The cytotoxic reaction contributes to the pathologic and clinical picture of many viral diseases. The characteristic measles rash is produced after the attack of CTLs on skin cells infected by the measles virus. This explains why children with defects in cell-mediated immunity do not develop a rash during measles infection. In this disease, rash indeed represents a good immune response by the host, whereas its absence may signal uncontrolled viral growth. It is also believed that lymphocyte-induced cytotoxicity contributes to the pathology associated with persistent virus infections, such as the subacute sclerosing panencephalitis caused by a defective measles virus.

Harmful immune responses

The destructive potential of the immune system is considerable. It can damage the host in a variety of ways.

Autoimmunity

Autoimmune reactions break the rules of the 'self versus nonself' dichotomy. Autoimmune reactions, directed against 'self-proteins', may result from partial identity of antigenic determinants of the host and an infective agent or from alterations of self-components caused by infection. Acute rheumatic fever occurring after group A streptococcal pharyngitis has been associated with antigens found in the cell wall of the streptococcus. These antigens cross-react with components of the endocardium and the joint synovial membrane molecules and thus induce an autoimmune response. Heat shock proteins, which are omnipresent and remarkably conserved proteins in nature, are often associated with autoimmunity. Mycobacterial infection may give rise to antibodies and T cells that are reactive to both the microbial (nonself) and the host (self) heat shock proteins.

Autoimmune reactions that follow an infection may also result from the release of self-components that are normally sequestered in a compartment that is relatively inaccessible to the immune system. Multiple sclerosis might provide an example of this type of autoimmune disease, although this is hypothetical because correlation of the disease with a microbial infection has yet to be established.

Hypersensitivity reactions

Hypersensitivity reactions occur if the host immune system seemingly overreacts to microbial infection. Hypersensitivity reactions have been classified by Gell and Coombs into four types.

Type I or immediate hypersensitivity

Type I hypersensitivity occurs within minutes of antigen exposure. It results from antigen binding to mast cell-associated IgE. Vasoactive amines are released and anaphylactic reactions may develop. Certain forms of rash after helminth infections seem to be due to this type of hypersensitivity.

Type II or cytotoxic hypersensitivity

Type II hypersensitivity is a consequence of the binding of specific antibodies to cell surface-associated antigens. Antibody binding mediates cytoxicity via complement activation or natural killer cells. Thus cells bearing microbial antigens may be lyzed via an antibody-dependent mechanism. Such a mechanism has been suggested to account for liver cell necrosis during hepatitis B infection.

Type III or immune complex-mediated hypersensitivity

Type III hypersensitivity is induced by classic complement activation, caused by extracellular antibody-antigen complexes. This causes inflammation and changes in

vascular permeability and it attracts neutrophils to tissues where the immune complexes are deposited, including the kidneys, joints and small vessels of the skin. Glomerulonephritis in malaria is probably due to this mechanism.

Type IV or delayed-type hypersensitivity

Type IV hypersensitivity typically occurs at least 48 hours after exposure to an antigen. It involves activated T cells, which release cytokines, macrophages attracted by these cytokines, and cytotoxic $CD8^+$ T cells.

Prolonged antigen exposure

During prolonged antigen exposure, such as in chronic infections, granuloma can be formed. Delayed-type hypersensitivity and granuloma play a major role in tissue damage observed during infections with slow-growing intracellular organisms, such as *Mycobacterium tuberculosis* (tuberculosis) and *Mycobacterium leprae* (leprosy), and histoplasmosis. Many of the clinical manifestations of chlamydial disease, in particular trachoma, seem to result from a delayed-type hypersensitivity triggered by chlamydial heat shock proteins. In spite of the involvement of bacterial heat shock proteins, this is not an autoimmune phenomenon, because the unique rather than the conserved portions of these proteins seem to be implicated here.

Superantigens and bacterial components associated with toxic and septic shock

Toxic shock and septic shock are exceptionally impressive syndromes associated with a variety of infectious diseases. Severe hypotension, multiple organ failure and intravascular disseminated coagulopathy occur in the most severe cases. Pathogenesis of these syndromes is complex. Various bacterial components, including lipopolysaccharides, peptidoglycan, lipoteichoic acid and (in some cases) toxins acting as superantigens (see Table 1.9) trigger an intense, potentially lethal host response. In the cascade of events leading to this condition, some cells (e.g. macrophages, neutrophils and/or T cells) play important roles (see Chapter 9 and Chapter 56) as well as releasing high levels of inflammatory response mediators, notably tumor necrosis factor and interleukin-1.

How micro-organisms escape host defense

In spite of the efficacy of host defense mechanisms, microbial pathogens can still infect humans and cause disease. This is in part due to the very potent weapons micro-organisms have (a single gram of crystalline botulinum toxin could potentially kill more than 1 million people) but it is also due to the intricate strategies that micro-organisms use to evade host defenses (Table 1.10).

Surviving the phagocyte and complement attack

Immediately after passage of the epithelial surface, the invading micro-organism encounters the most powerful actors of host defense: phagocytes. Two main types of phagocytes are involved, the polymorphonuclear neutrophils (PMNs) and the macrophages. 'Professional' phagocytes can bind micro-organisms with a variety of receptors, some of which specifically interact with bacterial lipopolysaccharide or with antibodies bound to the microbial surface (opsonized micro-organisms). The micro-organisms usually pass into the cell via phagocytosis or pinocytosis, although some (especially viruses) may enter the cytosol directly.

TABLE 1-10 -- Evasion of host defenses.

EVASION OF HOST DEFENSES	
Mechanism	**Examples**
Surviving the phagocyte and complement attack	
Inhibition of chemotaxis	C5a Peptidase by *Streptococcus pyogenes*
Killing the phagocyte before ingestion	a-Toxin and leukocidin by *Staphylococcus aureus*
Avoiding ingestion	Bacterial capsules (e.g. *Streptococcus pneumoniae*)
	LPS O antigen in Gram-negative rods
	Coating with IgA antibodies (*Neisseria meningitidis*)
	M protein (*Streptococcus pyogenes*)
Surviving within phagocytes	Inhibition of phagolysosome fusion (*Chlamydia trachomatis*)
	Escape from phagolysosome (*Listeria monocytogenes*)
	Resistance to lysosomal products (*Salmonella typhimurium*)
	Inhibition of early host gene expression (*Mycobacterium tuberculosis*)
Antigenic variations	Shift and drift in influenza A virus
Tolerance	Prenatal infections
Immunosuppression	
Destroying lymphocytes	Depletion of $CD4^+$ cells by HIV
Proteolysis of antibodies	IgA protease by *Haemophilus influenzae*
Presence in inaccessible sites	Latent infection in dorsal root ganglia (herpes simplex virus)

Bacteria invariably go through an endosomal stage, in which they will be exposed to a multitude of phagocyte defense mechanisms such as acidification, exposure to reactive oxygen species, bacteriocidic peptides and hydrolytic enzymes released after phagosome-lysosome fusion. In addition, in the endosomal pathway, micro-organisms are deprived of the nutritional wealth of the cytosol. Finally, the pathogens are killed and degraded and the microbial antigens may be presented to lymphocytes. However, micro-organisms have developed strategies to avoid, mislead, deregulate or even profit from phagocytes.[41]

Inhibition of the mobilization of phagocytes

Extracellular micro-organisms can avoid phagocytes by inhibiting chemotaxis or complement activation (see below). A bacterial enzyme that degrades complement protein C5a, a main chemoattractant for phagocytes, has been discovered recently in *Streptococcus pyogenes*. Pertussis toxin catalyzes ADP-ribolysation in neutrophils, which causes a rise in intracellular cAMP levels and ultimately impairs chemotaxis. Other examples of toxins that are directed against phagocytes include a-toxins produced by *Staphylococcus aureus*, streptolysins produced by *Streptococcus pyogenes* and the ?-toxin of *Clostridium perfringens*.

Killing the phagocytes before being ingested

Many soluble products excreted by bacteria are potentially toxic for phagocytes entering the foci of infection. Streptolysin O binds to cholesterol in cell membranes, which results in rapid lysis of PMNs. In the process, the lysosomes are also disrupted and release their toxic contents, which may have deleterious effects on the neighboring cells. *Staphylococcus aureus* produces a, ß and ? toxins, as well as leucocidin, which can kill and lyze the PMNs. Several toxins from *Clostridium perfringens* produce similar effects. Indeed, pus sampled from gas gangrene may contain numerous Gram-positive rods without any visible PMNs.

'Professional' phagocytes as vectors

Legionella pneumophila provokes entry in mononuclear phagocytes by accumulating complement factor C3bi on the envelope of the organism. This complement factor is a ligand for the phagocyte receptor CR3, and enhances phagocytosis. Following uptake, *Legionella* remains in the phagosomes, which do not fuse with lysosomes and thus provide protection. Alveolar macrophages are host cells for *Mycobacterium tuberculosis*. [42] Like *Legionella*, phagocytosed *Mycobacterium* prevents fusion with the lysosome and assumes a latent lifestyle. Many years after initial infection, resident *Mycobacterium* may be reactivated and cause acute disease.

Avoiding ingestion

The surface of numerous pathogenic bacteria is covered with a loose network of polymers, which constitutes the bacterial capsule.[43] Capsular material may be very thin, visible only be electron microscopy, as is the case with the hyaluronate capsule of *Streptococcus pyogenes*. In some species (*Streptococcus pneumoniae*, *Klebsiella pneumoniae*) capsule material is abundant, easily visible with a light microscope and responsible for a mucoid aspect of the bacterial colonies. Most of the capsules are composed of polysaccharides, others are made of proteins or a combination of carbohydrate and protein. Some capsule contents mimic host polysaccharides and are thus recognized as 'self' by the host immune system. Examples are the capsules of *Neisseria meningitidis*, which contain sialic acid, and *Streptococcus pyogenes*, which contain hyaluronic acid.

Capsules may protect bacteria from complement activation.[32] As a result, capsulated bacteria are not immediately recognized as invaders by the phagocytes. Capsulated *Streptococcus pneumoniae* resist engulfment by macrophages and PMNs and are virulent; however, noncapsulated strains are easily phagocytosed and are avirulent.[44] There are more than 80 distinct capsular serotypes, with different contributions to virulence, ranging from the highly virulent pneumococci of serotype 3 to the low virulent serotype 37.

The outer membrane of Gram-negative bacteria is covered with LPS, which serves as an attachment site for the complement fragments C3b (required for the triggering of the alternative pathway) and C5b. The polysaccharide chain of LPS (the O antigen) may contain sialic acid, which prevents formation of C3 convertase, and very long O antigen chains prevent the bacterial killing by the membrane attack complex (which is made from C5b, C6, C7, C8 and C9, and forms pores in the outer membrane of Gram-negative bacteria).

Meningococci circulating in the blood are coated with IgA, which is not an activator of the complement cascade. *Schistosoma mansoni* incorporates decay accelerating factors in its membrane; these are host plasma proteins that inhibit deposition of C3 onto host cell membranes. Activation of complement in the blood is thus avoided by the parasite.

Matrix proteins, which form fibrillae (see Fig. 1.11), are considered to be the primary virulence determinants of *Streptococcus pyogenes*. Matrix protein renders the bacteria resistant to phagocytosis by human neutrophils. Matrix fibrillae are approximately 50–60nm in length and exhibit a seven-residue periodicity. They exist as stable dimers, arranged in a coiled coil configuration, with the carboxylterminal portion closely associated with the cell wall (see Fig. 1.11). Streptococci that express M proteins on their surface are poorly opsonized by the alternative pathway and resist PMN phagocytosis. In contrast, streptococci that fail to express M protein are readily opsonized and phagocytosed. Resistance to phagocytosis can be

overcome by antibodies directed against type-specific M epitopes. The mechanism of antiphagocytic activity of M proteins is still unclear. According to one hypothesis, fibrinogen, known to bind to M protein, may hinder access to complement-binding sites on the bacterial surface, disguising the pathogen as 'self'. In another hypothesis, a complement control protein (protein H), which also binds M, may be responsible for the observed complement resistance of virulent *Streptococcus pyogenes*.

Survival within phagocytes

Once ingested by the phagocyte, the pathogen may survive and grow using a variety of strategies (Fig. 1.22). Some microbes prevent exposure to hydrolytic enzymes by inhibiting fusion of the phagosome and the lysosome, others survive within the phagolysosome because they resist enzymatic degradation or neutralize toxic products to which they are exposed in this compartment. Some bacterial pathogens (such as Salmonellae discussed above) extensively modify endosomes into customized survival vesicles. Certain types of bacteria rapidly escape from the phagolysosome and propagate in the cytoplasm, as described above for *Listeria monocytogenes*. Recent studies suggest that intracellular pathogens, notably *Mycobacterium tuberculosis*, may inhibit the early host response at the level of host gene expression.

Inhibition of phagolysosomal fusion

Salmonella spp. have developed several strategies to survive and propagate in macrophages; *Salmonella* spp. that lack this capacity to survive in macrophages are avirulent. Several hours after infection *in vitro*, two distinct *Salmonella* populations can be seen in the macrophage. One consists of rapidly dividing bacteria located in

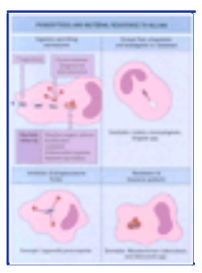

Figure 1-22 Phagocytosis and bacterial resistance to killing.

large unfused phagosomes. This population may rapidly grow and kill the macrophage, leading to the liberation of intracellular bacteria.[45] *In vivo*, this population may be responsible for the acute stage of salmonellosis.

The second population of *Salmonella* consists of nondividing organisms located in phagolysosomes. This population resists the toxic effect of lysosomal products and is believed to account for the prolonged survival of *Salmonella* spp. in the body. Long-living stromal macrophages of the bone marrow may act as long-term *Salmonella* carriers and be responsible for the very late relapses of salmonellosis that are seen in some patients. The dormant phase represents a well-regulated physiologic condition associated with nutrient deprivation *in vitro*.

Inactivation of reactive oxygen species

Reactive oxygen species damage DNA and inhibit the bacterial oxidative phosphorylation. Bacteria may escape from the damaging effect of reactive oxygen species by rapid detoxication of the bactericidal products and by efficient DNA repair. Several bacterial pathogens produce superoxide dismutase (SOD) and catalase, two enzymes that might eliminate the reactive oxygen species and damage to DNA may be efficiently repaired through a RecA-dependent pathway. In Salmonellae the RecA pathway seems to be more important than the production of SOD and catalase because mutants that produce neither SOD nor catalase remain virulent, whereas *rec*A mutants are avirulent. However, the ability of this bacterial species to modify the endocytic pathway of the host cell seems to be the most important mechanism of resistance to reactive oxygen species. In macrophages, virulent Salmonellae localize in phagosomes devoid of NADPH oxidase, the enzyme that drives the respiratory burst. [46]

Resistance to antimicrobial peptides

Several cationic peptides are produced within the lysosomal granules and are believed to kill intracellular pathogens by forming channels in the bacterial cell wall. *Salmonella* spp. resist these antimicrobial peptides by at least two complementary mechanisms, one of which, encoded by the *sap* locus, is characterized in some detail (Fig. 1.23). It seems that the SapA protein forms a complex with the antimicrobial peptides, reducing the deleterious effect on the bacterial membranes.

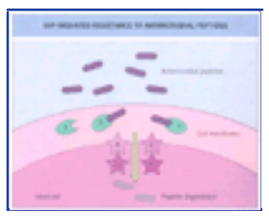

Figure 1-23 Mechanism of resistance to macrophage antimicrobial peptides by *Salmonella* spp. *Salmonella* produces the SapA (A) peptide, which complexes with host cell antimicrobial peptides. Other proteins encoded by the *sap* locus (SapB, SapC and SapD) are required for the transport of the SapA-antimicrobial peptide complex into the cytosol where the antimicrobial peptide is degraded.

TABLE 1-11 -- Examples of antigenic variations.

EXAMPLES OF ANTIGENIC VARIATIONS	
Genetic mechanisms	**Examples**
Recombination between different copies of pilin genes	Pili in *Neisseria gonorrhoeae*
Phase variation — turning expression of an antigen on or off ('flip-flop')	Flagella in *Salmonella*; pili in *Neisseria gonorrhoeae*
Gene reassortment between two strains infecting the same cell	Influenza virus type A
Mutation of surface antigens	Influenza virus type A, B and C
Gene switch leading to surface glycoprotein changes	*Trypanosoma brucei*

Other proteins encoded by the *sap* locus (SapB, SapC and SapD) allow the transport of the SapA-peptide complex into the cytosol. Within the cytosol, peptidases degrade the antimicrobial peptides.

Antigenic and phase variations

A powerful survival strategy for a pathogen would be to mislead the specific host immune response by 'changing appearances'. Three examples of molecular mechanisms used to achieve antigenic variation, one each by a bacterium, a virus and a protozoan, are illustrated below (Table 1.11).

Antigenic variation in Neisseria gonorrhoeae

Neisseria gonorrhoeae varies the composition of at least three major components of its outer membrane: the pili, which mediate the initial attachment to host cells; the membrane protein P.II, responsible for closer attachment resulting in phagocytosis; and LPS, described earlier.

Antigenic variations in the major pilin subunit are essentially due to recombination between different copies of *pil* genes scattered over the chromosome (Fig. 1.24). Only one or two of these are expressed (*pil*E, where E denotes 'expressed') at any point in time, but an array of antigenically distinct pili may be produced in response to an antibody challenge. In addition to this mechanism, pili are subject to phase variation (i.e. switches between *pil*-positive and *pil*-negative variants). Phase variation is controlled at the transcriptional level.

The P.II protein is similarly subject to genetic variation. As a consequence, the specific immune response never quite catches up with genetic variation in the bacterial population. The combination of this mechanism, LPS sialylation (see above) and IgA protease production makes *Neisseria gonorrhoeae* a very recalcitrant pathogen.

Shift and drift in influenza A viruses

Nearly every year, during the recurrent influenza epidemics, vaccination programs are confronted with the problem of antigenic variation. Two different mechanisms account for genetic variation of influenza virus. Antigenic shift results from the infection of a single cell by two different influenza strains. 'New' genomes may be assembled from the available genetic information, leading to gene exchange between the two parent strains. Antigenic shift may result in dramatic changes in the antigenic composition of the surface hemagglutinin (which binds the host cell receptor) or the neuraminidase (which modifies these receptors), and cause devastating epidemics in immunologically unprepared populations. Antigenic drift results from high mutation rates associated with RNA viruses. In influenza viruses A, B and C, mutants with antigenic changes tend to have a selective advantage over the nonmutant viral population. Therefore, new strains are continually being selected, as exemplified by the 1997 outbreak of 'chicken flu' in Hong Kong.

Figure 1-24 Antigenic and phase variations in microbial pathogens. Three mechanisms are shown. (Top) Exchange of DNA between nonexpressed copies of *pil*S and the expressed gene *pil*E in *Neisseria gonorrhoeae* can change the expressed antigen. (Middle) A switch mechanism is responsible for the (mutually exclusive) production of type A and type B flagella in *Salmonella typhimurium.* Phase variation depends on the orientation of a DNA fragment adjacent to the type A flagella gene. When A is expressed (a) from the promoter in the invertable fragment, the repressor for the type B flagella is expressed at the same time. As a consequence the type B flagella gene is repressed. Inversion of the DNA fragment abolishes expression of the A-repressor gene and the B-repressor gene (b). In this situation type B flagella are produced. (Bottom) Antigenic shift by gene reassortment results from infection of a single cell by two different virions.

Antigenic variations in Trypanosoma brucei

African trypanosomes (*Trypanosoma brucei*) are flagellated protozoa, transmitted to humans by several species of *Glossina* (tsetse).

The parasite survives in mammalian body fluids thanks to antigenic variation of the variant surface glycoprotein (VSG), which forms a 15nm thick monolayer covering most of the parasite surface.[47] Within a single generation, most or all of the 10^7 VSG molecules may be replaced by an unrelated species, stemming from a repertoire of an estimated 1000 genomic copies of the gene. The VSG gene is invariably expressed from a polycistronic transcription unit, in the so-called telomeric expression site adjacent to the telomeric repeats. During chronic infection, patients experience successive episodes of parasitemia, each episode coinciding with the expression of a new VSG on the surface of the parasite. With this strategy, trypanosomes avoid complete eradication by the specific immune response, while maintaining the pathogenic burden at sublethal levels. The closely related *T. brucei brucei*, which causes the bovine disease nagana, does not spread to humans because it is sensitive to high-density lipoprotein in human serum.

IMMUNOSUPPRESSION

The most illustrative example of immunosuppression induced by microbial infection is provided by HIV. Human immunodeficiency virus circulating in the bloodstream readily infects $CD4^+$ lymphocytes, macrophages and dendritic cells. The destruction of $CD4^+$ T-helper cells is particularly detrimental to the host and accounts for the emergence of a variety of opportunistic infections as soon as the T-cell counts drops below a critical level.

Other viruses may produce immunosuppression in a more subtle fashion. Measles virus infects both B cells and T cells, interfering with the immunocompetence of the host. As a consequence, in areas with a high prevalence of tuberculosis, measles epidemics may be followed by outbreaks of tuberculosis. Gonococci, meningococci and *Haemophilus influenzae* produce proteases that hydrolyze secretory IgA1 antibodies. Protease-negative mutants of these bacterial strains are less virulent,

suggesting a role for mucosal IgA1 antibodies in host defense against these pathogens.

CONCLUSION

Throughout evolution, humans, like all mammalian species, have maintained an intimate relationship with the microbial world. We have survived thanks to the efficient defense mechanisms we have developed against potentially dangerous micro-organisms. Pathogenic micro-organisms are still here because they have found ways of avoiding elimination by their host or by the microbial competition. 'Successful' pathogens have developed strategies to enter the body and reach and colonize their favorite niche, while defying the powerful human immune system.

In this chapter we have looked into microbial survival strategies. Although some of these have been analyzed in 'molecular detail', a lot remains to be discovered. Future remedies for infectious diseases are likely to be aimed at specific molecular interactions between the pathogenic micro-organism and its host.

Chapter 2 - Host Responses to Infection

Steven M Opal
Gerald T Keusch

INTRODUCTION

The need for parasitism, as for evil, has never been satisfactorily explained. In its less severe manifestations — for example, competitive interactions within the food chain — parasitism could have led to the classic 'fight or flight' response because the ability to withstand an 'eat or be eaten' situation would have obvious survival value. However, when competing organisms are placed within a balanced ecosystem they do not require overly aggressive parasitism for survival. The hallmark of such ecosystems is that the individual organisms within it consume no more than they need for survival, for to do so would perturb the whole system.

Recently, it has become increasingly apparent that the effects of interrelated systems permeate our lives, and, as a result, we are all beginning to think ecologically. This readily extends to clinical microbiology and infectious diseases, in which ecologic niches and ecosystems determine the nature and components that make up our microbial flora, as well as their impact on health and disease.

In this sense, 'normal flora' can be considered as an example of 'ecoparasitism', which implies a balanced system that sustains multiple microbial species, each occupying a particular niche. If this is so, then the development of specific host defenses to normal flora might be unnecessary and potentially detrimental if there is a 'cost' resulting from the diversion of metabolic resources from other vital functions to the synthesis of unneeded immune cells and their products. However, host defenses have evolved in a complex and functionally overlapping manner, suggesting that true parasitism has always been a serious threat to survival and that evolution of pathogens and host defenses are linked by selection pressures.

It is important at the outset to understand that host defenses are not limited to the immune response, defined as an induced cellular or humoral defense mechanism that is specific for the challenging agents or their cell-free antigens.[1] The simple presence of an intact integument, effective cough mechanisms, normal gastric acid secretion, peristalsis, or mucin production may exert profound protective effects for the host in the context of host-pathogen interactions. In addition, many metabolic and physiologic events are initiated in the course of infections, and these must be understood as being part of the host response to microbial challenge. The context is even broader, for these events are not restricted to infection but are part of a stereotyped response to other processes that activate the inflammatory response, including trauma and surgery, vasculitis and connective tissue diseases such as rheumatoid arthritis. Nonantigen-specific metabolic events are also triggered by inflammation of any etiology; their relationship to host response is discussed first in this chapter because they are the least appreciated events in host defense, and because they appear to be of survival value and are as dependent on molecular signaling as the antigen-specific responses are.

GENERAL SIGNS, SYMPTOMS AND CONSEQUENCES OF THE HOST RESPONSE TO INFECTION

The classic peripheral signs and symptoms of inflammation (rubor, calor, dolor, tumor and functio laesa — redness, heat, pain, swelling and loss of function) commonly go hand in hand with general systemic signs and symptoms such as fever, chills, myalgias, headache and anorexia (Table 2.1). This relationship between peripheral and systemic responses is one consequence of the common mechanisms that initiate and mediate these events (Fig. 2.1). With progression of the underlying process involved in the activation of inflammation, a clinically recognizable syndrome — the systemic inflammatory response syndrome — may manifest itself. When the systemic inflammatory response syndrome is caused by infection it is called sepsis, which, if uncontrolled, can evolve further into severe sepsis and septic shock, with its life-threatening consequences of refractory hypotension and

TABLE 2-1 -- Consequences of the general symptom responses to infection and inflammation.

CONSEQUENCES OF THE GENERAL CLINICAL RESPONSES TO INFECTION AND INFLAMMATION		
Sign/symptom	**Metabolic effect**	**Benefit for host**
Fever	Increased energy consumption is required to cause and maintain body temperature above normal	Beneficial effect on survival at moderate increases (102–104°F (39–40°C)). May be detrimental with more marked increases (e.g. >107°F (>42°C))
	Enzyme reactions are accelerated	
Anorexia	Decreased nutrient intake requires catabolism of body stores for new protein synthesis	No apparent benefit in infection
	Amino acids are converted to glucose by way of hepatic gluconeogenesis	May permit survival during the healing process after trauma
Lethargy	Decreased voluntary activity reduces energy needs	Benefits of rest documented in some infections (poliovirus, Coxsackie B4 virus) in which exercise increases severity of clinical manifestations
		Allows metabolic support to be directed to host defense responses
Myalgia	Result of muscle activity and muscle catabolism to breakdown muscle protein releases amino acids into the circulation	Generates heat to elevate body temperature
		Provides source of amino acids for increased protein synthesis of host defense molecules and cells

Figure 2-1 Pathways of inflammation induced by microbial components. Components of Gram-negative organisms (LPS) and Gram-positive bacteria (peptidoglycan) can activate similar pathways. C3a, biologically active soluble cleavage product of the activation of complement factor 3; C5a, biologically active soluble cleavage product of the activation of complement factor 5; DIC, disseminated intravascular coagulation; IFN, interferon; IL, interleukin; PMNL, polymorphonuclear leukocyte; TNF, tumor necrosis factor.

multiple-organ dysfunction syndrome (Fig. 2.2 ; see Chapter 56). If these events are viewed in evolutionary terms, there must be a range within which they are beneficial to the host in response to the inflammatory stimulus or for combating an infection, but when they occur in excess and are uncontrolled they may be harmful or even lethal. It is not always clear, however, what the beneficial effect may be or where the threshold for adverse effects begins.

Fever

Fever, the most readily recognized manifestation of inflammation, has no doubt been known since the first parent touched her or his hand to the forehead of a sick

child. The importance of fever as a marker of clinical status and the need for the body

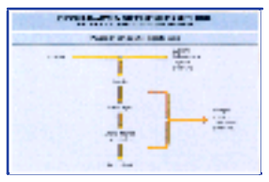

Figure 2-2 Systemic inflammatory response syndrome, septic shock and multiple organ dysfunction syndrome.

to control temperature in response to contagion were also recognized long before the instruments of clinical thermometry were introduced into common use for quantifying body temperature (see Chapter 80). [2]

Fever is now understood as an elevation in body core temperature resulting from a resetting of the thermostatic regulatory system. The core temperature in fever usually follows the same diurnal variation as that exhibited in health but with exaggerations in the slope and height of the peaks, and the temperature often returns to normal levels between fever spikes. Temperature may also be continuously elevated, without returning to a normal baseline. These various fever patterns occur because fever is a regulated process in which alterations in the thermostatic control mechanisms in the hypothalamus

Figure 2-3 Tertian and quartan malarial fever patterns.

of the brain are used to regulate heat production and heat loss in response to the new thermostatic set point to achieve the new temperature. Because there are important individual variations in the fever response to a given stimulus as well as variations in the response to different stimuli and in the effects of light-dark cycles and hormonal controls on body temperature, graphs of fever plotted against time have not proved to have much diagnostic significance (as was once believed when little else of specific diagnostic value was available — for example, tertian and quartan fever patterns were once thought useful for the presumptive etiologic diagnosis of malaria but are rarely observed; Fig. 2.3).

Normal body temperature is classically described as 98.6°F (37°C) ± 1.8°F (1°C) (95% CI); it is lowest in the early morning and highest in the evening (Fig. 2.4). Recent evidence indicates that mean body temperature may actually be closer to 98.2°F (36.8°C) (see Chapter 80 and Chapter 81 for a detailed discussion of thermoregulation and fever). This is one reason why there is no single, uniformly agreed upon definition for the lower limit of fever. Functionally, it has been defined as 99.0°F (37.2°C) in the early morning and 100.0°F (37.8°C) in the evening hours. However, as body temperature cools below 96.8°F (36°C), metabolic processes slow, brain function may become impaired, respiration slows and metabolic needs decline. Controlled hypothermia, as in cardiac surgery, or accidental hypothermia induced by immersion in cold water may, for a while, protect vital organs. However, as the period of hypothermia becomes longer and the temperature continues to drop, metabolism becomes increasingly anaerobic, resulting in acidosis and ultimately in fatal cardiac arrhythmias.

The principal mechanism for generating heat is muscle activity, which burns energy and produces work, with heat as a byproduct. In the development of a febrile response, involuntary muscle activity is controlled by the central nervous system (CNS), resulting in the shivering and rigors that occur as the temperature begins to climb. The slope of the rise and the ultimate peak of the temperature are also regulated by heat-loss mechanisms, and it is the combination of heat production and heat loss that results in the clinical temperature curve (Table 2.2). Heat loss occurs via four principal mechanisms under physiologic control:

- conduction,
- convection,
- radiation, and
- sweating.

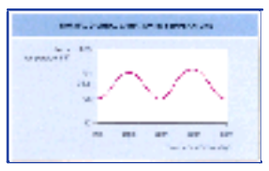

Figure 2-4 Normal diurnal variation in temperature. *These data are from eight healthy volunteers (see Chapter 80).*

TABLE 2-2 -- Physiology and mechanisms of thermoregulation.

PHYSIOLOGY AND MECHANISMS OF THERMOREGULATION			
Process		**Mechanism and clinical manifestations**	**Physiologic regulation**
Heat generation	Metabolic heat production	Involuntary muscle activity generating heat without work; manifested by shivering	Yes, by way of hypothalamic thermoregulatory centers; highly efficient
	Heat retention	Peripheral vasoconstriction lowers skin temperature and reduces heat loss by all mechanisms listed below	Yes, by way of vasomotor responses
Heat loss	Conduction	Heat transfer by direct contact of skin and another surface at a lower temperature; no clinical manifestations	Indirectly, by way of vasomotor responses; inefficient and limited because temperature equilibration rapidly occurs
	Convection	Heat transfer from skin to ambient air, facilitated by moving air; cooling of skin may induce shivering and vasoconstriction	Indirectly, by way of vasomotor responses
	Radiation	Heat transfer to another surface at a lower temperature without direct contact; no clinical manifestations	Indirectly, by way of vasomotor responses
	Sweating	Activation of sweat secretions consumes energy and releases heat through evaporation of sweat	Directly, by control of sweat glands by the hypothalamic thermoregulatory centers Indirectly, by vasomotor responses

Conduction is the direct transfer of heat between two surfaces in direct contact, from the higher to the lower temperature surface, until the temperature at the interface is equalized.

Convection is the removal of heat from a solid body to air at a cooler temperature, and it is facilitated by moving air across the convecting body, as by the use of a fan.

Radiation is the transfer of heat from one surface to another at a lower temperature across a distance. Black surfaces can absorb this radiated heat whereas white surfaces may reflect it; thus, the nature as well as the temperature of the surface receiving radiated heat determine the efficiency of the process. Each of these mechanisms depends on the temperature at the skin surface, and this is physiologically controlled by vasodilatation, which brings warmed blood to the skin and warms the skin surface.

Sweating is an important and effective mechanism of heat loss, as any one who has defervesced after taking aspirin will attest, because profuse sweating accompanies

the rapid decline in body temperature toward the normal range.

The sequential engagement of these mechanisms results in shaking chills as muscle activity and peripheral vasoconstriction are called into play. This is followed by a sensation of fever as vasodilatation occurs to bring heat to the surface for conductive, convective and radiative loss of heat in order to blunt the rise in core temperature. This is followed by profuse sweating as core temperature is rapidly brought to a lower level before the next fever spike initiates the entire sequence again.

Fever also has an upper limit, with temperatures above 106–108°F (41–42°C) rarely if ever noted.[3] At sustained temperatures above this range, as may occur during heat stroke or malignant neuroleptic syndrome, pathologic abnormalities occur; these abnormalities include:

- acid-base changes due to hyperventilation and respiratory alkalosis,
- hypokalemia,
- hypernatremia and other electrolyte abnormalities,
- circulatory failure,
- shock, and
- disseminated intravascular coagulation, with cell swelling and damage in the brain, kidneys and liver, along with widespread hemorrhages.

Structural and metabolic alterations also occur, any one of which carries the potential of death; these changes include:[4]

- hypoxia and mitochondrial damage,
- energy depletion,
- protein denaturation,
- protein phosphorylation,
- ribosomal dysfunction,
- diminished protein synthesis,
- lysosomal enzyme release,
- changes in cytoskeletal and structural proteins,
- altered cell membrane fluidity, owing to altered cholesterol and phospholipid content, and
- degradation or damage of DNA.

Temperature is regulated by warm- and cold-sensitive neurons in the CNS located in the preoptic region, anterior hypothalamus and adjacent septal areas.[5] Direct temperature alterations induced in these regions of the brain lead to all of the behavioral and physiologic events involved in normal thermoregulatory responses. The preoptic region and the anterior hypothalamus are strategically located near the organum vasculosum of the lamina terminalis, the site of transfer of cytokines from blood to brain. This is significant because some cytokines (e.g. interleukin (IL)-1ß and tumor necrosis factor (TNF)-a and, possibly, IL-6 and interferon (IFN)-?) are the principal peripheral signals to the brain to reset the normal temperature set point to cause fever (Fig. 2.5).[6] This signaling is mediated through the production of prostaglandin E_2 and is regulated by a number of possible endogenous antipyretic mediators. These include arginine vasopressin, a-melanocyte-stimulating hormone, catechols, glucocorticoids and their inducers (which block the upregulation of cytokine

Figure 2-5 Mechanisms of fever. Fever may be induced either by exogenous pyrogens, such as microbes or their toxins, or by endogenous pyrogens.

genes), lipocortin (which is a mediator of glucocorticoid function) and natural cytokine inhibitors and soluble cytokine receptors.

Is there any benefit from the fever response? If the results of a set of truly brilliant investigations using the cold-blooded lizard, *Dipsosaurus dorsalis*, can be extrapolated to humans, then fever is a true determinant of the outcome of infection.[7] [8] [9] *Dipsosaurus dorsalis* is a typical poikilotherm and it lacks the physiologic mechanisms for temperature regulation. Nonetheless, in common with other cold-blooded animals, it regulates body temperature as much as possible through the use of behavioral modifications rather than physiologic mechanisms. Thus, it will move between sun and shade as necessary to maintain a constant temperature during the daytime. When placed within an environmental chamber that is able to maintain a gradient of temperature, the animal migrates to the area that allows its core temperature to approximate 101.3°F (38.5°C). However, when the lizards are injected with lipopolysaccharide (LPS) endotoxin or infected with a natural bacterial pathogen, *Aeromonas hydrophila*, the high and low temperature set points triggering migration are both increased (Fig. 2.6) and they migrate in the chamber in order to increase their core temperature by 2–4°F (1–2°C) in the first 24 hours and by another 2–4°F (1–2°C) in the second 24 hours. If the temperature rise is prohibited by keeping the lizards in a chamber with a set temperature or by injecting salicylate, both the incidence of bacteremia and the mortality rate increase (Fig. 2.7). When body temperature is, in a similar manner, fixed at over 107.6°F (42°C), mortality increases further and both infected and uninfected lizards are affected.

These data clearly show that fever is protective and that there is an upper limit beyond which the increased temperature is itself detrimental. There are no clearer demonstrations of the selective advantage of moderate elevations of temperature in host responses than these classic studies of the 1970s. Since then, no convincing mechanism by which this survival advantage is mediated has been demonstrated, in *D. dorsalis* or, if it pertains, in the higher mammals,

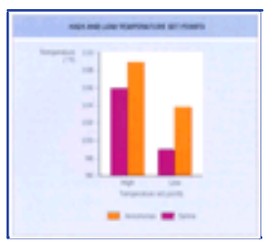

Figure 2-6 High and low temperature set points. The temperature set point is the temperature at which the animal modifies temperature by moving in the temperature gradient chamber. The increased high and low set points in the animals challenged with *Aeromonas hydrophila* result in higher than normal temperature. The data were obtained 3–6 hours after injection with saline or *A. hydrophila*. *Data from Vaughan et al.*[10]

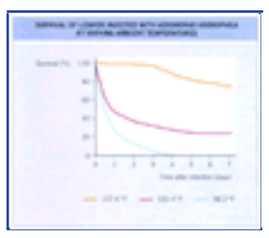

Figure 2-7 Survival of lizards injected with *Aeromonas hydrophila* at varying ambient temperatures. *Data from Kluger et al.*[7]

including humans. However, a murine experimental model has recently been developed to study the impact of alterations of core body temperature by an externally controlled system of temperature regulation. In this model of bacterial peritonitis, a survival advantage was demonstrated in those animals with a febrile core temperature, which demonstrated improved bacterial clearance and enhanced local cytokine generation compared with animals whose core temperatures were maintained in the normothermic range.[11] The question of optimal body temperature for patients during the course of treatment of an ongoing microbial infection has never been satisfactorily answered in a prospective clinical trial. Nonetheless, some investigators have concluded that it is unwise to modify the fever response to infection by the use of antipyretics such as salicylates.[12]

There are consequences of fever other than death that may affect the benefit-risk ratio of this classic host response. One of these is an increase in energy requirements. This increase occurs, in part, because of the biophysical temperature coefficient effect, by which there is an approximately 10% increase in the rate of

enzymatic reactions with an increase in reaction temperature of 1°C (Q_{10} effect). The Q_{10} effect occurs regardless of the cause of the increased temperature; infection triggers this effect, as does artificially increasing the temperature within a heat chamber.

Although this may speed up reactions that yield products of benefit to the host in fighting infection (e.g. the enzymes that result in bactericidal reactive oxygen intermediates such as hydrogen peroxide, superoxide, or hydroxyl radicals), the Q_{10} effect also means that increased energy is required to drive the reactions. This increase in energy needs is not restricted to reactions that benefit the host; all enzyme reactions are affected. Second, the metabolic activity underlying the muscular activity that generates heat in order to raise the core temperature necessitates increased energy expenditures. Third, energy is consumed in the increased metabolic activity needed for the synthesis of the large amounts of new proteins and new cells needed to combat the infection. In fact, energy requirements in humans with sepsis are 35–40% above basal needs.[13]

Anorexia

Loss of appetite is an early manifestation of infection. It is regulated in the CNS, where satiety or hunger is perceived and the appropriate feeding behaviors are triggered. Experiments in which cytokines such as IL-1ß or TNF-a were systemically administered to various species of animals have demonstrated the ability of these cytokines to induce a sharp diminution in food intake.[14] [15] [16] Such experiments suggest that the same cytokines that result in the fever response may also act to alter appetite and food consumption. Principles of 'conservation' of responses may be operative here, for the same response occurs with trauma. Although totally speculative, it is possible that in trauma the injured host may be better served by resting and allowing healing to begin than by foraging for food, and therefore anorexia may make it easier for the injured animal to remain quiescent. In support of this idea, it is striking that IL-1ß induces slow-wave sleep patterns in the brain,[17] which explains why fatigue usually accompanies fever and anorexia in infection and is a part of the teleologic interpretation of these events. Sleep also serves to reduce substrate requirements over and above basal needs, by reducing physical activity and muscle metabolism.

The underlying mechanisms that regulate appetite and food intake are currently being defined, at least in the setting of obesity and hormonal disorders such as diabetes mellitus. Leptin, a recently described cytokine-like peptide mediator produced by adipocytes, is one factor that appears to be involved (Fig. 2.8).[18] Genetically determined obesity disorders in experimental animals have played an essential role in the identification of leptin and the leptin receptor, and it is already clear that defects in either the ligand or the receptor may be responsible for some animal feeding disorders that underlie obesity. Administration of leptin to experimental animals leads to reduced food intake and reduced body weight,[19] and when it is administered directly into the lateral ventricle the effect on food intake occurs within 30 minutes.[20] Leptin appears to act by inhibiting the release of neuropeptide Y in the hypothalamus,[21] which may be the proximate regulator of food-seeking behavior, hyperphagia and energy homeostasis in response to reductions in body energy stores.[22]

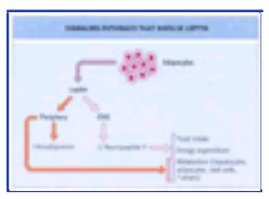

Figure 2-8 Signaling pathways that involve leptin.

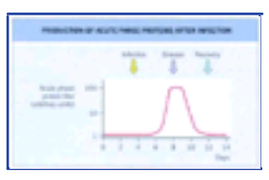

Figure 2-9 Production of acute-phase proteins after infection. Infection causes a rapid increase in the production of these proteins.

TABLE 2-3 -- Acute-phase proteins produced in response to infection in humans.

ACUTE PHASE PROTEINS PRODUCED IN RESPONSE TO INFECTION IN HUMANS		
Acute phase reactant		**Role**
Dramatic increases in concentration	C-reactive protein	Fixes complement, opsonizes
	Mannose-binding protein	Fixes complement, opsonizes
	a_1 -acid glycoprotein	Acts as transport protein
	Serum amyloid A protein	Uncertain
Moderate increases in concentration	a_1 -proteinase inhibitors	Inhibits bacterial proteases
	a_1 -antichymotrypsin	Inhibits bacterial proteases
	C3, C9, factor B	Increase complement function
	Ceruloplasmin	Oxygen scavenger
	Fibrinogen	Coagulation
	Angiotensin	Elevates blood pressure
	Haptoglobin	Binds hemoglobin
	Fibronectin	Cell attachment

Leptin may also be one of a group of proteins whose production is markedly accelerated in the course of an acute inflammatory reaction under the influence of IL-6 (Fig. 2.9). [23] Such proteins are collectively called acute-phase proteins, and it is presumed that they serve some specific role in host response to the acute injury. Some acute-phase proteins have immune regulatory functions (C-reactive protein,[24] IL-11 and IL-6,[25] and G-CSF[26]), others have procoagulant activity (C-reactive protein,[24] reduced synthesis of endogenous anticoagulant,[27] fibrinogen, clotting factors) and yet others stimulate complement (C-reactive protein,[24] synthesis of complement components) or bind to bacterial endotoxin (LPS-binding protein [28] and amyloid proteins[29]). However, as with fever, the extent of the acute-phase response may determine whether the effect is beneficial with respect to the host's response to the initiating stimulus or whether it has harmful consequences (Table 2.3). It is often difficult to sort this out in vivo, because typically there are multiple events occurring at the same time, many of which have overlapping functional impact.

HOST METABOLIC RESPONSES TO INFECTION

Infection results in marked changes in host metabolism, characterized by a dramatic increase in metabolic activity and altered priorities of synthesis. These adaptive responses involve a remarkable array of metabolic activities, including energy, protein, vitamins and minerals.

Energy metabolism

Because of increased metabolic demands in the infected host, it does not make any immediate sense for appetite and food intake to diminish as much as they do in infection; if anything, appetite should be ravenous in order to provide for the increased substrate needs without constricting basal maintenance requirements or resorting to the use of host stores. Yet nature has apparently chosen self-sufficiency as the guiding principle for this situation, and the infected patient reduces voluntary activity and begins to use his or her own sources of energy. Initially the energy store consumed consists primarily of liver glycogen, but within hours this resource is depleted. Because glycogen stores are not sufficient to serve as much more than a buffer for energy needs between feedings it soon becomes necessary to find an alternative source. This is the dilemma of reduced food intake: the energy source must be found within the host. The most abundant energy store in the body is fat; however, during infection and in contrast to starvation, fat utilization is inhibited by the same cytokine mediators that initiate fever and other host responses. This

means that the host must turn to muscle protein as the main reservoir for energy, requiring proteolysis and conversion of amino acids to glucose via gluconeogenesis in the liver. Direct measurements in septic patients have documented increased amino acid turnover in muscle and conversion of amino acids to glucose in the liver.[30] The same events have been shown to occur in patients in whom the inflammatory response is triggered by trauma or surgery.

At the same time, glucose turnover and blood glucose levels are elevated and glucose oxidation is increased; these changes are associated with hyperinsulinemia, hyperglucagonemia and increases in plasma growth hormone levels. In this array of characteristic responses, carbohydrate metabolism in sepsis resembles a state of 'pseudodiabetes'. Peripheral insulin resistance in muscle limits the use of glucose for energy and drives the utilization instead of branched-chain amino acids for energy. Thus, the local proteolytic events in muscle are made more efficient because branched chain amino acids are released and can be used in situ. As the complexities of the changes induced by infection and inflammation become better characterized, the more intricate and coordinated they appear. The response to infection is not a patchwork quilt; rather, it is a work of art.

Vitamin metabolism

Previous studies of vitamin metabolism in infection have not revealed any striking changes that either support the host response or contribute to a metabolic imbalance. Some vitamins are lost in the urine in greater amounts than normal during inflammation, but this has not been seen as clinically important, at least in the short term. Certainly, individual and multiple vitamin deficiencies have been well documented as exerting influences on the host immune system but, with the exception of vitamin A deficiency, the setting of acute infection or inflammation does not itself significantly alter vitamin status. The exception, vitamin A deficiency, has long been known to progress rapidly during infection, and the early changes in the eye that occur in vitamin A deficiency can rapidly progress to blinding keratomalacia following an acute diarrheal infection or measles.

However, a growing body of data indicates that vitamin A is also an acute-phase reactant, being removed from the circulation during infection or acute inflammation. Where the vitamin goes, in what form, how, and what it does there is not known in detail. However, it is reasonable to presume that this, like other acute-phase responses, has evolved through selection and therefore has functional significance in the host response to infection. Vitamin A is commonly known for its role in vision, and for too many students of medicine and biology this is its only recognized role. However, vitamin A and its metabolic products function as transcriptional regulators of many genes, many of which have obvious immunologic functions.[31] [32] Thus, the movement of retinol from plasma to tissue during infection has the potential for transcriptionally activating genes that are critical to host responses. In the mammalian host, this may be an example of a global regulatory pathway that is activated by cytokines released during the response to infection or inflammation.

Vitamin C has received considerable public attention, at least as much for the prominence of some of its proponents as for the evidence that it is an acute-phase reactant with a physiologic role in the host response to infection. Indeed, whether increased vitamin C intake alters the course of infection is still controversial.

Another antioxidant vitamin, a-tocopherol or vitamin E, appears to play a more definitive role in host defense, and a number of vitamin E supplementation trials, especially in older people, have demonstrated that additional vitamin E enhances immune responses and, by this effect, may decrease infectious morbidity.[33] [34] If this is true, it is not yet known whether supplementation is correcting a functional deficiency or not. This is, however, a different issue from that of acute host responses altering vitamin distribution during infection, as occurs with vitamin A.

Minerals

Acute reductions in plasma iron and zinc and an increase in plasma copper have long been known to accompany acute infection and inflammation (Fig. 2.10). The physiologic interpretation of the rapid development of hypoferremia and hypozincemia at the onset of infection has been that of an acute deficiency state. In the case of iron, this has also been interpreted to be of survival value, because the sequestration of iron should reduce the amount available for micro-organisms that require iron for survival, growth and replication. This putative host defense has been termed 'nutritional immunity'. There are many reasons to believe that nutritional immunity may not be physiologically relevant, principally because most bacteria and higher organisms have highly evolved iron acquisition systems that enable the microbes to compete for iron with protein-bound iron in the host. Indeed, many micro-organisms use low concentrations of free iron as a signal to activate genes involved in virulence or resistance to host defenses. Low free iron is also used to signal transcriptional activation of the genes involved in microbial iron binding and

Figure 2-10 Acute cation response in infection and inflammation.

Figure 2-11 Microbial gene regulation via *Fur* gene.

uptake. In one commonly used microbial regulatory gene, ferric uptake regulator (*fur*), the gene product, Fur, is an iron-binding protein that, in the iron-replete form, recognizes a palindromic sequence in the promoter region of iron-regulated genes and blocks transcription (Fig. 2.11). In a low iron environment, Fur does not interact with its DNA binding site and transcription proceeds.[35] [36]

Infection also activates host genes involved in production of the iron-binding protein ferritin, which results in iron uptake into cells, while at the same time reducing synthesis of transferrin, the soluble circulating iron-binding protein that transfers iron from the circulation to an intracellular compartment. [37] [38] Similarly, infection activates the synthesis of metallothienene, the intracellular zinc binding protein, resulting in the sequestration of zinc within cells. These responses are triggered by certain cytokines produced in the inflammatory response (e.g. IL-1ß and TNF-a). In this manner, inflammation, whether due to infection or trauma, induces hypoferremia and hypozincemia. Because IL-1 is so important in the activation of immune host responses, coregulation of the metabolic response and immune activation suggests that the two are, in some way, functionally linked. This view also belies the characterization of infection-mediated hypoferremia and hypozincemia as acute deficiency states.

If the shift of iron and zinc from one host compartment to another is not designed by nature to inhibit microbial growth, then what is its purpose? Both iron and zinc serve as important active centers in metalloenzymes and transcription factors, many of which are involved in DNA synthesis and cell replication such as occurs in response to infectious or inflammatory challenges. In fact, it is not possible for the host to make a response that involves cell division without iron metalloenzymes and zinc-finger transcription factors.

Figure 2-12 Pathologic effects of infection. B, B derived lymphocytes; IFN, interferon; IL, interleukin; PMNL, polymorphonuclear leukocyte; T, T lymphocytes; TNF, tumor necrosis factor.

Because the activation of the humoral and cellular limbs of the immune response is a direct reflection of clonal selection and amplification of lymphoid cells, production of macrophage antigen-presenting cells and increased generation of polymorphonuclear phagocytic cells, the efficient utilization of iron and zinc in support of DNA synthesis and cell division is a prerequisite for the full host response. It appears that a mechanism to promote this has become a part of the acute host response to infection, and the same set of mediators is involved in the catabolic and anabolic events.

ANTIMICROBIAL HOST RESPONSES TO INFECTION

General principles of microbial pathogenesis

If the host response to infection is geared to host defense, then these events should relate to the mechanisms of disease pathogenesis caused by infectious agents. With few exceptions, microbial pathogens act directly on or in the host. The exceptions are limited; they include, for example, micro-organisms that may produce toxic molecules outside the host that can cause disease without infection, such as the *Staphylococcus aureus* enterotoxins involved in food poisoning. However, even these may have profound effects on the immune system in their role as superantigens. Pathogenic organisms typically interact directly with the host, and they are capable of finding a niche in which the organism they can grow, possibly invade across the skin or the mucous membranes and then disseminate, evade host defenses and cause changes in host physiology that translate into symptoms of the illness. Pathogens may produce specific metabolic products that directly damage cellular structure, alter host metabolic processes or produce antigens that elicit potentially injurious immunologic responses (Fig. 2.12). There are at least four separate stages of the host-pathogen interaction that lead to possible pathology or pathophysiologic responses (Table 2.4):

- colonization,
- invasion,
- multiplication, and
- dissemination.

TABLE 2-4 -- Stages in host-pathogen interactions.

STAGES IN HOST-PATHOGEN INTERACTIONS		
Stage	**Mechanism**	**Utility to pathogen**
Colonization	Ligand-specific adherence to host receptors, commonly by way of specific sugar-protein interactions	Provides initial niche for the pathogen to establish and initiate adverse effects on the host
Invasion	Penetration of skin, mucosa or other epithelial membranes to reach the circulation or specific target organ or cell type	Provides entry of pathogen to the host; may also enter immunologic sanctuary, where it is sequestered and protected from host immune responses
Multiplication	Depends on preferred niche of the organism and its growth rate; multiplication may be slow or rapid, intracellular or extracellular	Organism increases in number and may be better able to survive host defenses
Dissemination	Organisms may spread locally or disseminate widely, depending on biologic attributes	Organism infects multiple sites, where it may cause added disease symptoms and survive indefinitely

Colonization

The initial encounter with the host is generally followed by multiplication of the organism. If this occurs on a mucous membrane it is considered colonization. Pathogens must have some means of establishing themselves in their preferred niche. Often these means involve the production of specific colonization factors that allow the organisms both to identify their niche and to attach in a way that allows them to overcome host measures aimed at dislodging them. This is obvious in the gastrointestinal tract (Table 2.5), in which the host produces liters of protease-rich wash fluids in the succus entericus,

TABLE 2-5 -- Microbial attachment in the intestinal tract.

MICROBIAL ATTACHMENT IN THE INTESTINAL TRACT			
Micro-organism	**Disease**	**Attachment site**	**Mechanism**
Vibrio cholerae	Cholera	Intestinal epithelium	Specific bacterial molecule (adhesin) binds to oligosaccharide receptor on cell
Escherichia coli (certain strains)	Diarrhea		
Salmonella typhi	Enteric fever		
Shigella spp.	Dysentery	Colonic epithelium	Bacteria induce epithelial cells to engulf them
Giardia lamblia	Diarrhea	Duodenal, jejunal epithelium	Protozoa bind to mannose-6 phosphate on host cell; also have mechanical sucker
Entamoeba histolytica	Dysentery	Colonic epithelium	Lectin on surface of amebae binds to asialofetuin on host cell
Poliovirus	Poliomyelitis	Intestinal epithelium	Viral capsid protein reacts with specific receptor on cell
Rotavirus	Diarrhea	Intestinal epithelium	Viral outer capsid protein binds to glycolipid receptor on cell

as well as sticky mucins, and then propels these through the gut by means of peristalsis. Without an attachment strategy, potential pathogens may be washed through, explaining why the most efficient pathogens have developed molecular attachment strategies utilizing cell-bound colonization antigens. Typically these are proteins that recognize and bind to specific host glycoconjugates. They are present on the microbial cell surface, often on specialized structures that extend out from the cell surface, such as pili or fimbriae,[39] or sometimes on specialized microbial organelles.[40] This suggests the utility of a host strategy to resist this attachment not only in a non-specific manner but also by developing anti-attachment mechanisms (e.g. by producing specific carbohydrate receptor blocking macromolecules or antibodies).

Figure 2-13 Invasion of micro-organisms across the intestinal mucosa.

Invasion

Attachment may lead to colonization on the mucosal surface but it may also lead to invasion across the epithelial cell layer. Microbial invasion is a complex process resulting from the sequential interaction of microbial products with the host cell.[41] [42] These interactions are often cell-signaling events, and host responses include: [43]

- the activation of protein kinases,
- protein phosphorylations, and
- major rearrangements of the cellular cytoskeleton.

An example is the initial interaction of *Salmonella typhimurium* and the host cell, which results in an active, kinetic 'ruffling' of the cell surface, reminiscent of the effect of growth factors;[44] this is associated with the uptake of the bacteria within host membrane-delimited vesicles. Noninvasive organisms in the vicinity can also be swept up into these vesicles and enter the host cell cytoplasm in a process known as 'passive entry'. [45] The importance of this passive entry depends on the subsequent fate of the ingested organisms, which results from the ability of the organism to resist the microbicidal reactions of the inflammatory response. Recent evidence indicates that gene products from pathogenicity islands of some *Salmonella* spp. actually disrupt oxidative bactericidal mechanisms within phagocytic cells.[46]

Recent studies of the invasion mechanism of *Shigella flexneri* have revealed a different aspect of the role of the host inflammatory response (see Chapter 43 and Chapter 228).[47] First, *Shigella* spp. do not appear to invade across the luminal epithelial cell membrane, as previously thought. Rather, when intestinal epithelial cells are mounted on collagen-coated filters and allowed to form tight junctions, the bacteria are invasive only from the basal surface. Nonetheless, when *S. flexneri* are placed within a loop of intestine in an in-vivo experiment in animals, the organisms invade, cause inflammation and result in fluid production. The interesting aspect of

this is that if the inflammatory response is prevented by the administration of IL-1 antagonists or if the ability of polymorphonuclear leukocytes (PMNLs) to migrate is blocked by the administration of antibodies to PMNL surface antigens involved in locomotion (such as CD18), then no invasion occurs. If neutrophil chemotaxis is blocked, then *Shigella* spp. invasion is markedly reduced and no symptoms of disease ensue.

These findings demonstrate that the initial microbe-host interaction triggers an influx of PMNLs that is necessary for the subsequent, more massive invasion of organisms across the mucosa (Fig. 2.13). These results have changed the paradigm for the sequence of inflammatory responses in shigellosis from that of a reaction to invasion to

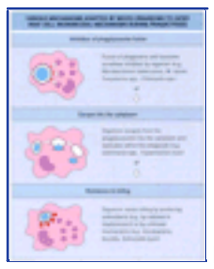

Figure 2-14 Various mechanisms adopted by micro-organisms to avoid phagocytosis.

Figure 2-15 Nonimmunologic host defenses.

an integral and essential part of invasion. In other words, infection with *Shigella* spp. is a clear example of host-mediated pathogenesis. This also demonstrates the ingenious nature of microbes in host-pathogen interactions, and the ability of pathogenic micro-organisms to take advantage of and subvert host defense systems for their own welfare. A better-known example of this is the use by HIV of the lymphocyte and macrophage cell surface differentiation antigen CD4, together with host cell chemokine receptors, to enter the target cells.[48] The virus then replicates, thereby initiating the destruction of immunologically active cells in the process and leading, ultimately, to AIDS (see Chapter 120).

Multiplication and dissemination

These examples of colonization and invasion also highlight two other aspects of microbial pathogenesis: multiplication and, in some instances, dissemination. Multiplication may occur on mucosal surfaces, in tissues (e.g. in an abscess) or within cells. Some micro-organisms have become adapted to survival and multiplication within the phagocytic cells, using a number of strategies to evade the host's microbicidal mechanisms (Fig. 2.14). Because of their ability to survive and multiply within these professional host defense cells, such micro-organisms are referred to as 'facultative intracellular pathogens'; they include *Salmonella typhi*, *Legionella pneumophila*, *Listeria monocytogenes*, *Mycobacterium tuberculosis*, *Leishmania donovani* and *Toxoplasma gondii*. These organisms are able to avoid harmful effects of host defenses by a variety of measures. For example, some prevent the fusion of phagocytic vesicles with lysosomes, some block the acidification response within the vesicle by escaping to the cytoplasm, some interfere with oxidative killing enzymes[46] and others just resist everything the macrophage can throw at them.[49]

Whereas systemic dissemination of micro-organisms is generally associated with systemic manifestations of illness, such manifestations can occur in the absence of dissemination. For example, in

diphtheria, the organisms colonize and multiply on the mucous membranes of the upper airway, but they produce an exotoxin that is transported systemically and leads to clinical illness, owing to its ability to inhibit mammalian cell protein synthesis and cause tissue damage. Systemic invasion may also occur by devious means. For example, the gonococcus can attach to sperm and ride upstream through the female genital tract to the fallopian tubes, where the organism can cause acute salpingitis. [50]

Nonimmunologic host defenses

There are a number of important non-antigen-specific host defenses that are important components of the host barrier to infection (Fig. 2.15). These defenses may be altered by genetics, disease or drugs, and, in the altered state, they can predispose the host to certain groups of infectious agents. It is often possible to improve the resistance of the host by modifying these defenses (if they are recognized and known to the physician and if there are intervention strategies available).

Integument and mucous membranes

The physical barriers to infectious organisms constitute one aspect of host defense; because they are not specific or induced as a response to microbial stimuli, they are not immunologic defenses. For example, the skin and mucous membranes are the first contact between micro-organisms and the host and they are of major importance as barriers. This can be readily appreciated; ask any nail-biter how often he or she develops local cellulitis (paronychia). The most likely answer will be that this is a common occurrence if the integrity of the cuticle is damaged. This provides a portal of entry for *S. aureus*, a colonizer of the skin, which is then able to enter the subcutaneous tissues. The importance of the intact integument has been shown in an experimental reproduction of the nail-biting situation, in which the skin of an experimental animal is painted with viable *S. aureus* and a suture is placed through the skin. Where the suture breaks the intact skin, cellulitis develops; in unbroken skin, nothing happens.

The breached skin barrier is, of course, a hallmark of surgery. A natural example of this also occurs in transmission of the protozoan pathogen *Trypanosoma cruzi*, the cause of South American trypanosomiasis (see Chapter 173). The infectious stage of this parasite develops in the gut of an insect vector from the species of reduviid ('kissing') bugs. When the insect bites a host to take a blood meal, it deposits infectious feces nearby; the parasite can now enter through the broken skin created by the bite, usually because the host rubs the injured site and mechanically brings the organism into the breach in the skin (Fig. 2.16).

It should also be appreciated that many pathogens have developed the means of invading through an intact integument (often via hair follicles) or across mucous membranes after reaching these sites by means of ingestion, inhalation or insertion, as in the gut, respiratory or genital tracts, respectively. The mechanisms employed may differ in detail but are generally similar in principle.[51] To some extent, washing the skin with soap and water can reduce the surface pathogen load; however, excessive washing can remove beneficial lipids from skin that protect against microbial invasion.

Gastric acid

Micro-organisms are vulnerable to extremes of pH, and for many that normally enter the host via the oral route, the low pH that may be achieved in the stomach is sufficient to kill them. In this sense, gastric acid can be considered a non-specific host defense mechanism. For example, *Vibrio cholerae* is very sensitive to acid in vitro, and people who are unable to secrete normal amounts of gastric acid because of gastritis, ulcer surgery or the use of antacids or drugs that block acid secretion are especially susceptible to clinical cholera. This

Figure 2-16 Life cycle of *Trypanosoma cruzi.*

was noted during the seventh pandemic spread of cholera in Europe and Israel in the 1970s, when clinical cases were observed to occur preferentially in hypochlorhydric people. Although acid killing may not be a specific mechanism, certain micro-organisms seem to be able to resist acid-mediated damage by means of genetically controlled properties. Thus, the acid resistance of *Shigella* spp. is associated with the activation of acid-resistance genes, which are growth-cycle regulated as the micro-organisms enter the stationary growth phase. This is a very functional response on the part of the micro-organism because the acid-resistant phenotype is achieved just as the bacterium is excreted into the environment and thus occurs before it infects a new susceptible host (Fig. 2.17). In this manner, *Shigella* spp. are prepared in advance to survive passage through the stomach of the potential new victim. Their ability to resist acid is one reason why so few *Shigella* organisms are needed to cause clinical illness in humans — namely because of their likely safe passage through the stomach (see Chapter 43).

Non-specific defense at the mucosal surface

Mucosal surfaces represent an enormous surface area and carry a huge burden of micro-organisms as normal (or abnormal) flora, especially at the upper and lower ends of the gastrointestinal tract (Fig. 2.18). There, the number of indigenous established micro-organisms, the majority of which are strictly anaerobic bacteria, exceeds the total number of cells that make up the whole host. Whereas many of these organisms are incapable of surviving in the body because they are so susceptible to host defense mechanisms, others become pathogens if they are able to breach the mucosal barrier. Therefore, a healthy mucosal barrier is an important component of host defense. One way of appreciating this is to examine the consequences of altering mucosal cell turnover and replacement by the use of cytotoxic cancer chemotherapeutic agents. These agents often lead to ulcerations of the mucous membranes and increase the risk of systemic invasion by facultative Gram-negative bacilli that normally live in the gastrointestinal tract without causing harm, even in neutropenic patients.

Figure 2-17 Microbial response to acid production by the host.

Mucous membranes use several mechanisms to prevent microbial translocation. Some mucous membranes are the site of secretion of antibacterial proteins such as lysozyme, which hydrolyzes peptidoglycan and leads to the debility and death by lysis of Gram-positive organisms. The functional integrity of ciliated cells and mucus-secreting cells is another general mucosal host defense. Microbes can become embedded in balls of mucus, which are propeled to exit via a stoma by cilia in the upper respiratory tract or by peristalsis in the intestinal tract. Diseases that affect the function of cilia (e.g. viral infections) or the composition of mucus (e.g. cystic fibrosis) diminish the efficiency of this clearance mechanism and predispose to a variety of infections that a normal host would readily resist (Table 2.6).

Mucus itself is more interesting than its appearance as a slick and slippery substance. It is composed of a number of complex glycoconjugates expressing different antigenic epitopes, many of which may mimic receptors or microbial constituents and, by interacting with the host or pathogen surface, block the specific host-pathogen interaction that initiates infection. The mechanism by which breast milk protects the nursing infant from infection may depend on mimicry by the natural glycoconjugates present in colostrum and milk. By the same token, some micro-organisms use these interactions to establish colonization within the slime layers that overlay cells and use this niche to launch a more potent attack on host defenses, leading to systemic infectious diseases.

Initiation of the inflammatory response

Local and systemic manifestations of illness can be initiated by numerous mechanisms (see Chapter 56). For example, the LPS of Gram-negative organisms and the peptidoglycans of Gram-positive

Figure 2-18 Normal flora of the gastrointestinal tract.

organisms can initiate the production and release of proinflammatory cytokines such as IL-1ß and TNF-a. In the case of LPS, the biologic effects are mediated by the lipid A portion of the molecule, a hydrophobic domain in the outer monolayer of the outer microbial cell membrane.[52] Lipopolysaccharide polymers are solublized and converted to LPS monomers via LPS-binding protein (LBP), an acute-phase protein of 456 amino acids that is derived from hepatocytes.[53] It is the LPS-LBP complex that shuttles LPS monomers to CD14-bearing immune effector cells (e.g. neutrophils, monocytes and macrophages; Fig. 2.19).[54]

The identification of infectious agents by means of conserved structural features through pattern-recognition receptors initiates the innate immune response. The conserved components expressed by

THE TOLL-LIKE RECEPTORS AND THEIR LIGANDS	
Toll-like receptor	**Microbial ligands**
TLR1	Lipopeptide, lipoteichoic acid (in combination with TLR2)
TLR2	Peptidoglycan, lipopeptide, lipoarabinomannan, fungal cell wall components, lipopolysaccharide of leptospirosis
TLR3	Double-stranded viral RNA
TLR4	Lipopolysaccharide, respiratory syncytial virus proteins
TLR5	Flagellin from Gram-positive or Gram-negative bacteria
TLR6	Zymosan (fungal constituents) along with TLR2
TLR7	Imidazoquinoline antiviral compounds (natural ligand unknown)
TLR8	Imidazoquinoline antiviral compounds (natural ligand unknown)
TLR9	Unmethylated CpG motifs in prokaryotic DNA
TLR10	Natural ligand is currently unknown (may form heterodimers with TLR2 and possibly other TLRs)
Adapted from Opal and Huber[61] and Means et al.[62]	

microbial pathogens that trigger the immune response are termed pathogen-associated molecular patterns (PAMPs).[55] The Toll-like receptors (TLRs) along with CD14 and its accessory molecules are the major pattern recognition receptors that detect these PAMPs.[56] [57] The major microbial elements that are recognized by innate immune cells and their respective pattern recognition receptors are described in Table 2.7 .

Membrane-bound CD14, previously termed 'the endotoxin receptor', is a glycosyl-phosphatidyl-inositol (GPI)-anchored surface protein on myeloid cells. CD14 binds a wide array of microbial constituents in addition to bacterial endotoxin such as peptidoglycan, lipoteichoic acid, and even fungal antigens.[58] [59] [60] CD14 is therefore a prototypical pattern recognition receptor.[58] CD14 is anchored to the cell membrane by a single covalent bound via its GPI-linked tail that lacks a membrane-spanning domain and is incapable of directly transmitting an intracellular signal. The molecular nature of the actual signal transducing surface receptor was not known until its discovery in 1998 as the TLRs.[56]

There are a total of 10 TLRs identified in the human genome. These gene products contain a number of structural and functional similarities. All TLRs express a series of leucine-rich repeats in their ectodomain, a transmembrane domain and an intracellular domain that is homologous to the intracellular domain of the interleukin-1 type 1 receptor. This region of homology is known as the TIR (standing for the Toll-like receptor Interleukin-1 Receptor) domain. When macrophages are activated by LPS, a complex of membrane-bound CD14, an adapter protein known as MD2 and a TLR4 homodimer cluster on the cell surface to initiate an intracellular signal.[61] [62]

The TLRs have greater ligand specificity for the microbial structures than CD14 and they can discriminate between types of bacteria and their products. Gram-positive bacterial components such as peptidoglycan and lipopeptides are recognized by heterodimers consisting of TLR2[63] (in combination with TLR6 (for peptidoglycan) or TLR1 (for bacterial lipopeptides)).[60] [64] Most forms of Gram-negative bacterial LPS are specifically recognized by TLR4.[57] Toll-like receptors may detect additional microbial structures, including bacterial flagellin (TLR5),[63] prokaryotic unmethylated CpG motifs in bacterial DNA (TLR9),[65] mycobacterial lipoarabinomannan (TLR2),[66] fungal constituents (TLR6 and TLR2 heterodimers) [62] and double-stranded viral RNA (TLR3)[61] (Table 2.7).

There is another host protein in the PMNL composed of 456 amino acids, namely bactericidal permeability-increasing protein (BPI), which plays a different role in the host response from that of LPS.[67] The BPI is a very cationic protein, representing approximately 1% of the total protein content of the PMNL. It is produced only by immature PMNLs and it is stored in the primary granules of the cell; it is released when the cells are activated to degranulate, for example by LPS. It acts by forming complexes with LPS in the outer membrane of living Gram-negative organisms, resulting in the very rapid cessation of microbial replication. With time, BPI damages the inner membrane, resulting in a loss of viability of the organism (Fig. 2.20). Extracellular complexing of BPI and LPS inhibits the further cell signaling that is mediated by the LPS.[68] Antibodies to BPI block the microbicidal activity of PMN lysates and inflammatory secretions against Gram-negative bacteria, which suggest that BPI plays a role in PMNL mediated killing of these organisms.

Lipopolysaccaride-binding protein and BPI may compete for LPS binding in tissue sites where Gram-negative infections are present.[69] The opposing effects of BPI (LPS neutralization) and LBP (LPS delivery to monocyte-macrophage or neutrophil membranes) may contribute to the overall host response to LPS release in local infection. The *N*-terminal 199-amino-acid fragment of BPI is fully active in vitro and protects animals against lethal doses of LPS or Gram-negative bacteria. These properties have suggested a potential therapeutic use of this natural antimicrobial agent derived from the human host, and early clinical trials are currently being conducted.[70] Early results with the *N*-terminal portion of BPI in children with

meningococcemia suggest that this antiendotoxin binding protein may prove to be clinically useful[71] (see Chapter 56). It is interesting to note that the host is prepared to deal with Gram-negative bacteria

TABLE 2-8 -- Specificity and redundancy in host defenses.

by way of LBP and BPI, two related, small peptides: LBP binds LPS and allows it to transduce signals to phagocytic cells, resulting in degranulation and release of BPI. The BPI can complex with and neutralize the effects of LPS and bind to and ultimately kill the infecting organisms, thereby releasing the LPS, which again initiates the whole process. This is another example of the exquisite orchestration of host responses to micro-organisms. However, in the cat-and-mouse-like relationship between host defenses and microbial virulence, it is perhaps inevitable that some organisms will have become adept at turning this inflammatory response to their own benefit, as in the case of *Shigella* spp. described above.

Specific elicited (immunologic) responses

Immunologic responses may be defined as those in which microbial antigens elicit a host response that is specific for the structure that initiates the response. The regulation of these responses is rather complex and appears to be ever more complex as more factors involved in regulation are discovered. These factors include:[72]

- cells and secreted products, such as growth factors and signal-transducing mediators;
- soluble immune proteins that may be produced in the course of an immune response, such as antibodies; and
- activation of reaction cascades involving circulating proteins, which result in the formation of protein-protein complexes and the production of hydrolytic products with biologic activity, as occurs during the activation of the complement system.

Cells may interact with cells or proteins, or both, and proteins may interact with other proteins or non-protein constituents such as oligosaccharides or complex carbohydrates. The hallmark of immunologic reactions is specificity for the eliciting antigen of the pathogen, although non-specific or 'bystander' effects can occur and affect organisms other than the pathogen to which the response is directed (see below).

When the antimicrobial functions of these reactions are examined, they are often found to be redundant for certain organisms, to require interactions to be active against other organisms, or to be unique for other organisms. The fascination of this biologic system has never been greater than today, even though we know more about it than ever before, because the answer to one question is the genesis of a whole set of new questions. It is this deepening biologic complexity — along with the ingenuity and genetic plasticity of microbial pathogens, which leads to changes in virulence mechanisms

and new ways of interacting with the host — that makes infectious diseases one of the most vibrant of the disciplines of modern medicine, pediatrics and surgery.

Redundancy of defenses

If there were a single defense mechanism for each class of micro-organism, people with congenital defects in specific limbs of the immune system would be subject to disease with all possible classes of pathogens. This is not the case, and this fact is a major reason to believe that alternative defense mechanisms exist (Table 2.8). For example, if we consider congenital defects in the four major limbs of

Figure 2-21 Pathogenesis of AIDS. The pathogenesis begins with the binding of HIV to CD4 receptors on the regulatory cells of the immune system.

Figure 2-22 The process of phagocytosis.

the immune system (phagocytic cells, T cells, complement and antibody), it is clear that only certain pathogens commonly become problems for the affected host (see Chapter 98):

- defects in phagocytic cells diminish host defenses to certain bacteria and fungi, but not to viruses or protozoa;
- defects in T cells impair cell-mediated immunity to mycobacteria and facultative intracellular bacteria (such as *S. typhi*, *L. monocytogenes* and *L. pneumophila*, certain fungi, certain viruses and some protozoa) but not to pyogenic bacteria such as *S. aureus*;
- defects in complement may impair host defenses to encapsulated micro-organisms but not to fungi or viruses; and
- defects in antibody may impair host responses to encapsulated Gram-negative and Gram-positive bacterial pathogens but do not alter the host response to most viruses and fungi.

At the same time, vigorous immune responses may convey no protection at all and merely be a smoke-screen response elicited by pathogens that are wholly unaffected. Such is the case with malaria or infection with *Leishmania* spp., which elicit a polyclonal antibody response to antigens that do not mediate immune protection; the response consumes energy and amino acid substrates but offers little or no protection. Some micro-organisms, such as *Schistosoma* spp., shed their outer coats as antibodies are produced, thus evading immune recognition. Indeed, it seems that the higher the organism is in the evolutionary tree, the more elaborate its means of avoiding immune destruction. This is not to say that more primitive organisms, despite the relatively limited size of their genome, cannot possess intricate invasive properties. The foremost example of an eloquent evasion of host defences is HIV, with its attack on host immune regulatory cells bearing the CD4 determinant (Fig. 2.21). However, in biologic terms, this is a 'simple' mechanism, although it certainly leads to very complicated results because it disrupts the role of these cells as conductors of the immunologic orchestra (see Chapter 120).

Phagocytosis

Although micro-organisms can invade epithelial cells by inducing a process that appears very similar to phagocytosis, it is the PMNLs and the cells of the monocyte-macrophage line that, by and large, carry out the host function of microbial ingestion and destruction (Fig. 2.22). However, these cells are not very adept at phagocytosis and microbial killing unless they are instructed to do so (Fig. 2.23). This instruction often comes in the form of messages from activated T cells or macrophage antigen-presenting cells, or in the form of soluble proteins derived from complement or immunoglobulin that are able to signal the phagocyte to ingest and kill. Eosinophils are ordinarily considered to be largely restricted to their role in allergy, but they may also ingest very large macroscopic multiple-cell pathogens such as tissue nematodes.[73]

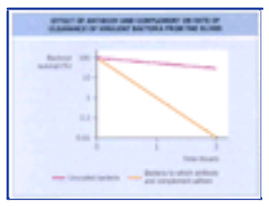

Figure 2-23 Effect of antibody and complement on the rate of clearance of virulent bacteria from the blood. Phagocytosis is greatly potentiated if the microbes are coated with antibody and complement.

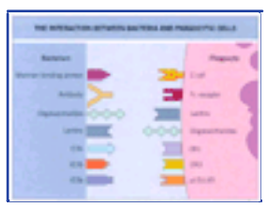

Figure 2-24 The interaction between bacteria and phagocytic cells. This is facilitated by a variety of molecules, the precise nature of which may determine whether uptake occurs and whether killing mechanisms are triggered.

Phagocytosis by PMNLs and the activation of intracellular microbicidal reactions is a multifactorial process that is dependent, in the first instance, on the deposition of activated complement fragments or immunoglobulin on the surface of the organisms, which renders them recognizable by receptors on the surface of the PMNL for C3b and the Fc fragment of immunoglobulin (Fig. 2.24). Subsequent ingestion requires complex signaling via protein phosphorylations that result in the rearrangement of the cytoskeleton, the ingestion of the organism within a vacuole made of host plasma membrane, and the subsequent fusion with primary and secondary granules to form phagolysosomes.[74] These granules contain a number of microbicidal proteins (e.g. BPI) and enzyme systems that are capable of generating reactive oxygen intermediates with microbicidal properties. [75]

To be effective, PMNLs must reach the site of infection. Chemical signals to attract these cells (chemotactic factors or chemoattractants) are produced during the initial host-pathogen interaction (Table 2.9). The ability of host defense cells to reach an infected

TABLE 2-9 -- Chemotactic molecules.

CHEMOTACTIC MOLECULES			
Factor	**Characteristic**	**Source**	**Action on**
C5a	77 amino-acid peptide	*N*-terminus of C5 a chain	Neutrophils, eosinophils, macrophages

Figure 2-25 Binding of selectins to carbohydrates expressed on various cells. HEV, high endothelial venules.

area involves the regulated and co-ordinated expression or activation both of leukocyte adhesion molecules and of endothelial cell adhesion molecules, which are called selectins (Fig. 2.25).[76] These adhesins mediate the cell-cell interactions that allow the initial sticking of PMNLs to the capillary endothelium and their subsequent migration across the capillary wall to the site of the infection (Fig. 2.26).[77] The importance of mechanisms of adherence and migration can be appreciated by considering the clinical problems experienced by people with the hyperimmunoglobulin E syndrome (also known as Job's syndrome).[78] Polymorphonuclear leukocytes can accumulate in subcutaneous tissues of these patients in response to microbial challenge, but their further migration is delayed and quantitatively diminished. Although the response is sufficient to prevent systemic spread of *S. aureus* from the skin, it is inadequate to prevent or clear the local subcutaneous lesions. These patients also have a deficiency in IgG and IgA antistaphylococcal antibodies and an excess of IgE, often with demonstrable specificity for *S. aureus* cell walls that, unfortunately, have little clinical importance. It is this

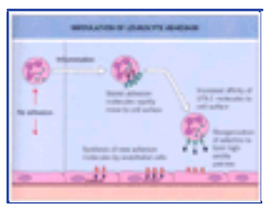

Figure 2-26 Modulation of leukocyte adhesion. There are four ways in which leukocyte binding to endothelium can be enhanced. LFA-1, lymphocyte function associated antigen-1.

finding, probably a reflection of lymphocyte abnormalities in the regulation of IgE production, that gives the syndrome its name.

Several genetic defects in PMNL function (see Chapter 98) confirm the importance of these cells for the defense against infection. These genetic defects include:

- chronic granulomatous disease, a defect in production of microbicidal reactive oxygen intermediates,[79] which renders the host susceptible to infection with *S. aureus* and to a lesser extent with *Aspergillus* spp. and *Candida* spp., *Chromobacterium violaceum*, *Burkholderia cepacia* and various Gram-negative Enterobacteriaceae; and
- Chédiak-Higashi syndrome, a defect in degranulation of lysosomes [80] with abnormal early kinetics for killing of ingested *S. aureus*.

Cyclic neutropenia results in periodic severe neutropenia that exposes the host to the same set of infections that occur in secondary neutropenia as caused, for example, by cancer chemotherapy. The result is increased susceptibility to infection with *S. aureus* and Gram-negative bacilli such as *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter cloacae* and *Pseudomonas aeruginosa*.

Humoral immunity

The best-known component of humoral immunity is antibody, comprising immunoglobulin proteins produced by B lymphocytes and having the property of recognizing unique antigenic molecular structures. Antibodies function in host defense against infection when they are directed to antigenic components of micro-organisms, whether these antigenic components are free in the tissues or present on whole organisms or on the surface of infected cells. For most infectious diseases, the host response depends on the processing of antigens by macrophage antigen-presenting cells, which results in the appearance of antigenic fragments in relation to major histocompatibility complex (MHC) locus determinants; this processing of antigens is regulated by T cells. [81] The repertoire of circulating antibodies generally shifts from an initial IgM to a subsequent IgG predominance (Fig. 2.27), associated with a change from low-affinity antibodies to high-affinity antibodies against specific antigens (Fig. 2.28); this is sometimes referred to as an increase in the 'quality' of the antibody response (or as 'antibody maturation'). The IgM response seems to have its value in being a rapid response to an infectious challenge, although the large size of the IgM molecule largely restricts its activity

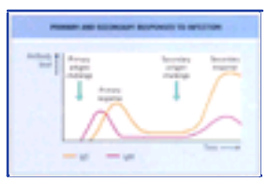

Figure 2-27 Primary and secondary responses to the same antigen during infection.

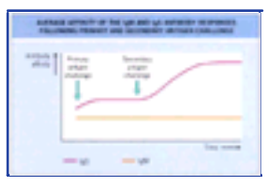

Figure 2-28 Affinity of the antibody responses following primary and secondary antigen challenge.

to the intravascular compartment. Immunoglobulin M is able to activate complement and generate the active byproducts of the classic pathway C3a (which acts as an opsonin) and C5a (which acts as an anaphylatoxin and chemoattractant) in order to facilitate phagocytosis via the C3a receptor of the phagocytic cell and to enhance leukocyte migration to the site of infection. In contrast, the IgG response is more specific and may be more effective as well as wider in distribution, assuming the host has survived the initial challenge. By binding to micro-organisms at the antibody combining site, IgG also acts as an opsonin because the phagocytes have receptors for the Fc portion of the immunoglobulin molecule. To some extent, IgG subclass antibodies act preferentially in certain infections. Thus, congenital IgG_2 subclass deficiency, which is often accompanied by a defect in IgG_4 or a deficiency in IgA, or both, is particularly associated with deficits in antibody to bacterial polysaccharide capsules and recurrent infections with encapsulated organisms.[82]

Recently, a host defense protein known as mannose-binding protein or mannose-binding lectin (MBL) has been characterized with antibody-like and complement-like properties. This lectin binds to mannose-terminated glycoprotein structures and other carbohydrate moieties found on the surface of microbial pathogens such as *N*-acetylglucosamine and fucose.[83] Mannose-binding lectin has a broad range of potential binding sites expressed on the surface of both Gram-positive and Gram-negative bacterial pathogens.[84] It can promote binding and phagocytosis by direct interactions with

pathogens and the CR1 receptor on phagocytic cells.[85] It also activates complement similar to the classical pathway by directly cleaving C3 by its own MBL-associated serine protease in the absence of C1q.[83]

Numerous polymorphisms of exon I of human MBL have been identified, with heterozygotes making up as much as 30% of the population.[86] [87] People who are homozygous or heterozygous for alleles that express low circulating MBL levels have an increased risk of respiratory tract infections,[88] [89] meningococcal disease[90] and infections during chemotherapy for cancer.[91]

In addition to circulating antibodies, the secretory IgA system produces a special dimeric form of IgA, in which the dimers are linked together by a joining peptide, the J piece, with an associated carrier peptide, the secretory component, which facilitates transport of the complete secretory IgA molecule across mucosal surfaces. Secretory IgA is able to act locally to impair microbial colonization and invasion at the mucosal surface, and it probably has many more functions. Although many people with congenital defects in secretory IgA production suffer from repeated infections, others remain clinically healthy, presumably because of the robust redundant response of various alternative defense systems.[62] For example, the introduction of the *Haemophilus influenzae* protein-polysaccharide vaccine to elicit circulating IgG anticapsular antibodies not only protects from invasive *H. influenzae* type b infection but also has shown that IgG can function on a mucosal surface as this has resulted in a marked decrease in upper airway colonization by the organism, which must be related to an effect of the antibody at the nasopharyngeal mucosal surface.[63] Interestingly, protein-energy malnutrition has a marked inhibitory effect on the secretory IgA response, and this is one likely reason why mucosal infections are so prominent in affected children, with respiratory disease predominating among the very young, and diarrheal diseases among those who are older.

Antibodies have highly specific very discrete functions, for example the neutralization of biologic products produced by the microorganism (Fig. 2.29). The oldest and best-known example is the antitoxin response to bacterial toxins, which was used to develop protective bacterial vaccines consisting of biologically inactivated but antigenic toxoids of tetanus and diphtheria toxins. This approach produced spectacular results, even though the natural infection may not lead to significant protection, presumably because so little toxin antigen is produced. It is now known that toxins are often synthesized as heterodimers, with separate A and B subunits mediating, respectively, the enzyme action of the toxin and its binding specificity. Antibody to either the A subunit or the B subunit can be protective, particularly when it is present before the toxin is introduced. Therefore, antitoxin antibody may be useful when it is elicited by a vaccine, although it may not be clinically effective when initiated during infection (as is the case with pertussis), because the pathophysiologic

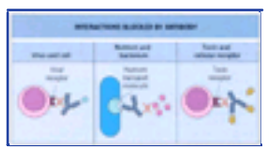

Figure 2-29 Examples of host-pathogen interactions blocked by antibody.

TABLE 2-10 -- Antiviral effects of antibody.

ANTIVIRAL EFFECTS OF ANTIBODY		
Target	**Agent**	**Mechanism**
Free virus	Antibody alone	Blocks binding to cell
		Blocks entry into cell
		Blocks uncoating of virus
	Antibody + complement	Damage to virus envelope
		Blockade of virus receptor
Virus-infected cells	Antibody + complement	Lysis of infected cell
		Opsonization of coated virus or infected cells for phagocytosis
	Antibody bound to infected cells	Antibody-dependent cell-mediated cytotoxicity by natural killer cells, macrophages and neutrophils
Antibody acts to neutralize virus or kill virus infected cells.		

events elicited by the toxin have already occurred by the time the response is mature and antibodies are detectable in situ.

Antibody to viral antigens can also be an effective host defense (Table 2.10). These antibodies may develop during the course of the infection and play a prominent role in the control of infection and clearance of the circulating virus. This occurs in infection with poliovirus and influenza A virus, in both of which virus-neutralizing antibodies develop. Killed parenteral polio vaccine or influenza A vaccine also elicit virus-neutralizing antibodies, which provide significant protection. How these antibodies work is not always clear, and there may be several different mechanisms involved at any one time:

- protection may be related to antibody-induced changes in viral surface charge or shape;
- protection may be due to aggregation and rapid clearance of virus released from cells, preventing viral replication; or
- protection may result in the lysis of infected cells, thus interrupting the life cycle of the virus.

The importance and specificity of antiviral antibody in the host response are shown by the predilection for some viral infections, but not all, in patients with congenital forms of agammaglobulinemia. The infections to which these patients are prone include poliovirus, echovirus and hepatitis B virus infection; the infections to which they are not abnormally prone include measles and rubella. The difference between these groups of viruses may relate to the extent to which cell-mediated immunity contributes to host defense.

Antibody can also function in a co-operative host defense mechanism: antibody-dependent cellular cytotoxicity (ADCC; Fig. 2.30). This is mediated by natural killer lymphocytes (NK cells), which possess high-affinity receptors for the Fc portion of the immunoglobulin molecule but lack markers of either T lymphocytes or B lymphocytes. As a result, they are capable of binding antibody by way of an interaction between the Fc portion of the IgG molecule and the Fc receptor. Antibody-dependent cellular cytotoxicity is distinguished from other cellular cytotoxicity responses by the fact that antigenic specificity is provided by the specificity of the antibody, rather than the cellular effector, and it is not restricted by the MHC locus.[85] In vitro, this mechanism occurs at physiologic concentrations of antibody, and therefore it could be expressed in vivo, especially at sites that are poor in complement activity, such as mucosal surfaces. However, there is as yet no convincing evidence for a role for ADCC in host defense against infection. A variant mechanism of ADCC

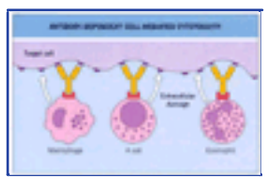

Figure 2-30 Antibody-dependent cell-mediated cytotoxicity. Different effector cells bind to the surface of the target cell via their receptor for antibody.

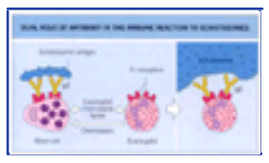

Figure 2-31 Dual role of antibody in the immune reaction to schistosomes. Following contact with the schistosome antigen, mast cells sensitized with anti-schistosome IgE release chemotactic factor, which attracts eosinophils. When the eosinophils arrive they are able to bind to the antibody-coated worm via their Fc receptors and damage the parasite.

involving eosinophils has also been described in vitro as a possible host defense to helminths.[86] These studies demonstrate that eosinophils, which are increased in number by many worm infections, adhere to and damage helminth larvae that have been coated with IgG, resulting in larval death (Fig. 2.31). This form of ADCC has been shown for *Schistosoma mansoni*, *Trichinella spiralis*, *Wuchereria bancrofti* and *Onchocerca volvulus.*

Cell-mediated host immunity

In contrast to humoral immunity resulting from the direct action of soluble host response molecules, such as antibody, cell-mediated immunity requires the action of intact cells of the mononuclear lineage, including macrophages or T cells, or both. This mechanism is dependent on specifically sensitized T cells, which have been activated by antigens of the micro-organism; indeed, in inbred mice, immunity can be adoptively transferred by injecting isolated cells from the spleen into a previously normal, uninfected animal. It is this phenomenon that led to the characterization of the immune response as cell-mediated, in contrast to immunity to pneumococci, which can be transferred by serum antibody alone. Tuberculosis is a particularly well-studied example of cell-mediated immunity (see Chapter 37),[87] in which infection induces clonal expansion of specific mycobacterial antigen-sensitized T cells, which in turn activate the mycobactericidal mechanisms of the macrophage. This event depends on the production

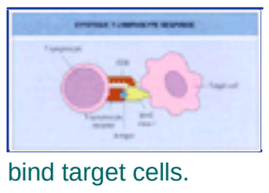

Figure 2-32 Cytotoxic T-lymphocyte response. Cytotoxic T lymphocytes expressing CD8 recognize antigen and major histocompatibility complex (MHC), enabling them to bind target cells.

and release of soluble mediators from the T cells, and it is enhanced by activation of cytokine production from the macrophage, for example IFN-?. Tuberculosis is also a classic example of granuloma formation, a cell-mediated response in which the organism is contained within a collection of macrophages surrounded by activated T cells. The granuloma is a recognizable pathologic unit that is present wherever the organism has spread (e.g. in lung or liver). It is granuloma formation that is initiated by the injection of tuberculin into the skin; indeed, the palpable reaction that characterizes a positive test is a focal granuloma induced by the injection of the antigen, which recruits macrophages and T cells to the site.

Granulomas also characterize the host response in schistosomiasis. It is the granulomatous response that results in the pathology of the infection. Measures that limit granuloma formation protect the host from the damage that results from the production by the granuloma of fibrogenic factors that induce the characteristic scarring of this disease (see Chapter 167).[88]

Another manifestation of cell-mediated immunity is represented by the ability of cytotoxic subpopulations of $CD8^+$ T cells to attack and lyse virus-infected target cells (Fig. 2.32). This cytotoxic lymphocyte response is more firmly established than ADCC and, in contrast to ADCC, it requires no antibody and is genetically restricted by the MHC locus. Congenital defects in this system lead to increased susceptibility to and severity of viral infections (e.g. infections with varicella-zoster virus and other herpesviruses, including cytomegalovirus) and infection with other intracellular pathogens (such as *M. tuberculosis* and *Pneumocystis carinii*). In influenza virus infection, although there is no doubt that vaccine-induced circulating antibody is protective, recovery from disease is best correlated with the appearance of an influenza-specific response by cytotoxic T lymphocytes. Experimental studies involving athymic nude mice and influenza virus have shown that antibody administration blocks shedding of virus for the duration of the treatment, whereas adoptive transfer of virus-specific cytotoxic T lymphocytes clears the virus from the lungs and cures the infection.[89] [90] These findings suggest that the two forms of specific immune response may work together in the response to influenza and presumably to other infections as well.

Natural killer cells

Although they were originally defined as a class of naturally occurring tumoricidal cells, NK cells have since been shown to be involved in the response to infection, especially virus infection. Natural killer cells are distinctive cells that are characterized as relatively large, low-density, granular cells that lack the T-cell receptor and surface immunoglobulin, although they do express a number of cell-surface receptors that are either unique or shared with other

immunologically active cells.[91] Natural killer cells do not require prior activation to function; however, their action is modulated by MHC class I determinants.[92] Cells expressing non-self MHC class I antigens (e.g. transplanted organs) or lacking MHC class I antigens ('loss of self'; e.g. some malignant cells) are subject to attack by NK cells.

The best evidence for the function of NK cells in host defense is in viral infections. Animal models have been extensively used for this purpose, and by depleting and adoptively transferring NK cells, a role in host defense against herpes simplex virus, murine cytomegalovirus and Coxsackie B4 virus infection has been shown, whereas there is no apparent effect of NK cells on lymphocytic choriomeningitis virus. The role of NK cells in humans remains to be clearly shown but a patient has been described with recurrent severe herpes viral infections with deficient NK cell populations.[93]

Interferons

It is now 40 years since the first IFN was described as a host-derived antiviral protein. The IFNs are now known to be a family of proteins, which — rather than being simply antiviral substances — are intimately involved in the regulation of the immune system and play an important role in tumor control. [94] There are, in fact, three classes of IFNs (Table 2.11):

- IFN-a (or leukocyte IFN),
- IFN-ß (or fibroblast IFN), and

¦ IFN-? (or immune IFN).

Interferons a and ß are acid-stable proteins produced in response to viral infections and double-stranded RNA and related polyanions; each of these IFNs is an antiviral protein. In contrast, IFN-?, an acidlabile protein, is made during antigen or mitogen activation of T cells and NK cells, primarily in response to IL-12 released from macrophages (Fig. 2.33). [95] Interferon-?, in turn, feeds back on macrophages to upregulate the expression of TNF-a, which, together with IFN-?, increases the expression of IL-12 and further drives the production of IFN-?. Interleukin-12 together with IFN-? favors the development of the T-helper-1 lymphocyte response, which:[96]

¦ activates macrophages to produce reactive oxygen intermediates such as superoxide and nitric oxide, and to express MHC and type II and Fc receptors;
¦ augments T-cell-mediated cytotoxicity; and
¦ induces NK cells.

TABLE 2-11 -- Human interferons.

HUMAN INTERFERONS			
	Interferon-a	**Interferon-ß**	**Interferon-?**
Alternative name	'Leukocyte' interferon	'Fibroblast' interferon	'Immune' interferon
Principal source	All cells	All cells	T cells
Inducing agent	Viral infection (or double-stranded RNA)	Viral infection (or double-stranded RNA)	Antigen (or mitogen)
Number of species	22	1	1
Chromosomal location of gene(s)	9	9	12
Antiviral activity	+++	+++	+
Immunoregulatory activity:			
Macrophage action	-	-	++
MHC class I upregulation	+	+	+
MHC class II upregulation	-	-	+
MHC, major histocompatibility complex.			

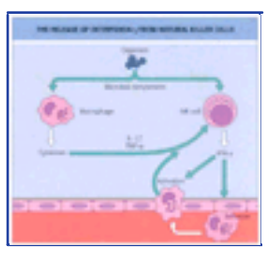

Figure 2-33 The release of interferon (IFN)-? from natural killer (NK) cells. IL, interleukin; TNF, tumor necrosis factor.

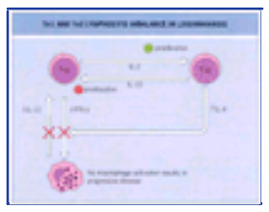

Figure 2-34 T-helper (Th)1 and Th2 lymphocyte imbalance in leishmaniasis. Leishmaniasis is characterized by deficient interferon (IFN)-? production and inhibition of its action. IL, interleukin.

In some intracellular infections of mononuclear cells, IFN-? production is reduced due to increased IL-10 production from activated T-helper-2 lymphocytes (e.g. in tuberculosis, leprosy and leishmaniasis), and this may be a major reason for the progression of these infections (Fig. 2.34). Successful therapy is associated with restoration of IFN-? production. Low levels of IFN-? are due to one of three abnormalities:

¦ abnormal IL-10 and/or IL-12 production,
¦ a deficiency of $CD4^+$ T cells, or
¦ a deficiency of IFN-? receptors.

Deficiency of IFN-? receptors has been identified in a small number of patients, and these patients have a prominent susceptibility to

nontuberculous mycobacterial infection but not to other infections, suggesting a unique function specificity for IFN-? in this infection.

Another cytokine has been identified, namely IL-18 (IFN-? releasing factor), which appears to have an upstream regulatory role in IFN-? regulation. Interleukin-18 is part of the IL-1-like family of cytokines that is activated by caspase 1 and binds to receptor with homology to IL-1 receptor and TLRs. [97] It promotes IFN-? production, induces NK cell cytotoxicity and promotes the T-lymphocyte T-helper-1 phenotype. Its relative role in IFN-? production and other immunologic activities in association with IL-12 are the focus of considerable research interest at the present time.

Interferon-? has been used with success in chronic granulomatous disease, for which it is licensed in several countries, and in the treatment of lepromatous leprosy, visceral and diffuse cutaneous leishmaniasis and disseminated mycobacterial infections. The use of IFN-a is also approved for the treatment of hairy cell leukemia, condyloma acuminatum, Kaposi's sarcoma and hepatitis B and C virus infection. It is likely that the utility of IFN therapy will increase as the number of disease indications in which it has an impact also increases, and the importance of providing the correct co-signal at the right time becomes better known.

Chapter 3 - Prevention

Natasha Crowcroft
Veronique Gibbons

INTRODUCTION

Prevention has been the greatest success in the field of infectious diseases. The largest impact in reducing human premature mortality has occurred through improved standards of living and the impact this has had on infection. However, the emergence of infections such as HIV and Ebola and the re-emergence of infections such as tuberculosis have been a stark reminder of the fact that new infections develop and old ones return if public health interventions lapse, behavior changes, social unrest or changes become prevalent, or various environmental interventions occur. Control of infectious disease is being challenged by development of resistance in bacteria, viruses and parasites such as malaria to both prophylactic and curative drugs. In some countries up to half of all etiologic agents of the most common forms of bacterial meningitis and pneumonia are now resistant to penicillin.[1] Infectious diseases do not respect administrative boundaries and a case of influenza in India does matter directly to someone living in the USA, because with the modern rates of global travel it takes very little time for a microbe to circumnavigate the planet. This was starkly illustrated by the rapid spread of the SARS (severe acute respiratory syndrome) epidemic that emerged in early 2003. Since 11th September 2001 the specter of smallpox is threatening us again after being eradicated from the world. Mass population movements have exacerbated the situation because refugees are vulnerable to infectious diseases and the circumstances in which they are mostly obliged to live are ideal for generating outbreaks.

Although great advances have been made, a considerable burden of morbidity and mortality from infectious diseases remains globally.[2] The majority of the nearly 14 million deaths that occurred in 2000 were preventable through low-cost health interventions that have existed for years to prevent or cure infectious disease[2] [3] (Table 3.1). Pneumonia, tuberculosis, diarrheal diseases, malaria, measles and HIV/AIDS account for half of all premature deaths, killing mostly children and young adults (Table 3.2). Apart from death they also cause long-term disability. Disability adjusted life years (DALYs) were developed to measure lost years of healthy life by a combination of lost years due to premature mortality and lost healthy years through disability.[2] In 2000, 26.8% of the global burden of disease in DALYs was directly attributable to communicable diseases[2] and six out of the leading 20 causes of DALYs were communicable diseases (Table 3.3).

A considerable further burden is from orphan or neglected diseases, which are left out of the priorities of pharmaceutical companies and private-public sector partnerships because there is insufficient market to justify the investment necessary to develop new treatments or vaccines.[4] Infectious diseases are the biggest killer of the young.[3] Measles, diarrhea and pneumonia, often in combination with malnutrition, together claim the lives of more than 5 million children under 5 years of age every year. [5] The impact of such diseases makes people poor and keeps them in poverty.[5] The long-term economic costs of such poverty are projected to be greater than the costs of the solutions. [5] Furthermore, as infectious diseases are

TABLE 3-1 -- Low cost interventions to prevent the global burden of infections.[j]

LOW COST INTERVENTIONS TO PREVENT THE GLOBAL BURDEN OF INFECTIONS	
Intervention	**Impact**
Integrated management of childhood illnesses	Combined therapy for common infectious diseases including oral rehydration and low-cost antibiotics could prevent up to 3 million deaths per year from pneumonia and diarrheal diseases alone
Childhood vaccinations — tuberculosis (TB)	More widespread use of low-cost vaccines could prevent an additional 1.6 million deaths per year
Directly observed therapy, short course (DOTS)	1–2 million TB deaths could be prevented through interventions such as DOTS, supported by the WHO STOP TB initiative
Impregnated bed nets	One in four deaths from malaria could be prevented if children at risk slept under bed nets at night
Availability of essential drugs	More than one-third of the world's population lack regular access to essential life-saving drugs
Prevention of HIV/AIDS	Cheap condoms, safe drug-injecting equipment, safe injection practice, treatment of other sexually transmitted diseases, counseling for HIV-infected mothers, and sex education at school and in the community could effectively reduce HIV transmission
Nutrition — vitamin and mineral supplements	Up to one in four child deaths from infectious diseases could be prevented by vitamin A supplements, and malaria deaths in children can be reduced by the use of iron supplements for anemia
Education	Education of women reduces infant mortality. Health education promotes safe sex, good nutrition and hygiene, immunization, and parents knowing what to do when their child is sick

j* *Adapted from WHO.* [3]

not constrained by administrative boundaries, controlling infections such as multiresistant tuberculosis in the poorest regions of the world where it has emerged has benefits for the whole world. Early intervention to contain epidemics may have dramatic effects and the World Health Organization (WHO) hopes, by taking earlier action, to prevent the HIV epidemic in Asia and Eastern Europe from developing to the same extent as it has in sub-Saharan Africa, where 70% of people with HIV/AIDS currently live.

An additional preventable burden arises from cancer, with up to 16% linked to infections: human papillomavirus infection is linked to cervical cancer; hepatitis B and C virus infection to liver cancer; *Helicobacter pylori* infection to stomach cancer; and schistosomiasis

TABLE 3-2 -- The continuing problem of infectious disease and targets for prevention.[*]

THE CONTINUING PROBLEM OF INFECTIOUS DISEASE AND TARGETS FOR PREVENTION				
Disease	**Deaths per year (millions)**	**New cases per year (millions)**	**% in developing countries**	**UN target**
HIV/AIDS	3	5.3	92	To reduce the number of newly infected young people by 25% by 2010
Tuberculosis	1.9	8.8	84	To halve deaths and prevalence by 2010
Malaria	>1	300	Nearly 100	To reduce disease burden by 50% by 2010
HIV/AIDS, tuberculosis and malaria.

to bladder cancer.[6] Hepatitis B virus vaccination programs effectively reduce mortality from hepatocellular carcinoma.[7]

Prevention of infectious diseases can be regarded as a social challenge. Diseases may be indicators of environmental quality as well as patterns of human behavior, and social, environmental or behavioral change may be the most effective intervention. Improvements in the quality of nutrition, the physical environment and provision of safe drinking water in the affluent world led to falls in mortality from practically all infectious diseases before antibiotics or vaccination programs were introduced. Cholera is hardly an infectious disease in a country with good sanitation; imported cases virtually never result in transmission.[8] The incidence of hepatitis A virus infection has fallen in every country with good sanitation and vaccination has played little part in eliminating this virus. The percentage of people with some form of improved water supply and sanitation has risen gradually, but at the beginning of 2000 one-sixth (1.1 billion) of the word's population was without access to improved water supply and two-fifths (2.4 billion) lacked access to improved sanitation.[9] Trends varied by region, with the poorest improved water access in Africa and the poorest sanitation in Asia (Fig. 3.1). Rural areas are generally less well served (Fig. 3.2).

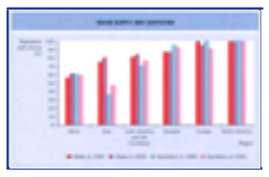

Figure 3-1 Water supply and sanitation. Coverage by region, 1990 and 2000. *Adapted from WHO*[9] .

HOST-MICROBE-ENVIRONMENT INTERACTIONS

Infectious diseases are the consequence of interaction of the infectious agent and the host. The environmental setting affects the likelihood that such an interaction will occur and the context in which it takes place (Fig. 3.3).[9] Therefore prevention efforts can be focused on each or any of these components, depending on the disease in question and the availability and acceptability of appropriate interventions.

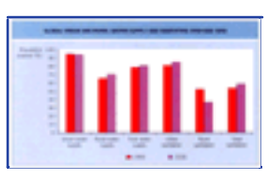

Figure 3-2 Global urban and rural water supply and sanitation, 1990 and 2000. *Adapted from WHO.*[9]

Figure 3-3 The host-agent-environment triad. *Adapted from WHO.*[9]

The specific characteristics of the host that increase the likelihood of exposure to an infectious agent or that predispose to infection, and the severity of the clinical course, are discussed in detail elsewhere in this book. However, there are several general features of the host that, alone or together, can influence the ultimate clinical response and offer the potential for intervention. Similarly, features of the infectious organism can also affect the likelihood that it will establish an infection in humans and subsequently develop into a clinical illness.

Severe malnutrition can precipitate a downward spiral. Weight loss and stunted growth may be the outward manifestations of underlying mucosal damage that exacerbates the state of malnutrition through malabsorption. The weakened mucosal barrier may also increase the success of invading micro-organisms and result in a blunted mucosal immune response. This can result in an increase in the incidence of disease in the population and an increase in the severity of disease in the affected

individual.

In addition to the effects of severe malnutrition, a growing body of evidence suggests that micronutrients such as vitamin A may also have substantial effects on immunity. This effect has been most striking among young children in developing countries when affected with the measles virus. It is estimated that nearly half of the world's children have an inadequate intake of vitamin A, putting them at a 23% higher risk of death from common diseases.[10] This recognition has led to the addition of vitamin A supplementation in infant immunization programs in many developing countries.[11] [12] [13]

There is also evidence that micronutrient supplementation with trace minerals such as zinc and selenium may have a protective effect against infections in malnourished children[14] [15] and institutionalized older people.[16] [17]

Advances in genetics are anticipated to have a great impact in increasing our understanding of the pathogenicity of infectious diseases through better knowledge of both host and pathogen. The human genome project is providing information about the human host, and sequencing of entire bacterial genomes of organisms such as *Mycobacterium tuberculosis*, with the possibility of comparing different related organisms, will provide insight into pathogenicity mechanisms.[18] [19]

The tools and knowledge to ease the burden of HIV/AIDS, tuberculosis and malaria already exist. World leaders have given political commitments and agreed upon United Nations (UN) agency targets for reductions in HIV/AIDS, tuberculosis and malaria (see Table 3.2). Political will at international, national and local levels as well as resources are necessary for success in the control of infectious diseases.[3] [5] Great progress has been made in the control of many diseases and seven have been targeted for eradication or elimination: poliovirus infection, measles, guinea worm disease, tetanus, leprosy, lymphatic filariasis and Chagas' disease.

PREVENTION METHODS

The aim of any control program can be defined by three levels — containment, elimination and eradication. Containment reduces the infection to an acceptable level although the disease remains endemic. Elimination means that there is no endemic transmission

and that imported infection leads only to isolated outbreaks. Eradication removes the disease from the world; smallpox is so far the only example.

Environmental change

Overcrowding in polluted urban environments contributes to the risk of infection. In 1999 more than 1 billion people were estimated to lack access to safe drinking water and around 800 million to lack any access to health services. Changes in land and water use such as deforestation, agricultural development, dams and irrigation schemes can trigger outbreaks of parasitic or other vector-borne diseases. Similar changes may bring people into contact with diseases such as Ebola. An increase in global warming of only 1–2°C over the next 50 years could increase the range of *Anopheles* mosquitoes and extend the range of malaria, dengue and lymphatic filiariasis.[3]

Vector control

By reducing the source of transmission, vector control efforts have had a substantial impact on disease incidence. An estimated 3% of the global burden of disease has been attributed to vector-borne diseases.[20] Malaria is a large component, causing 1.9 million deaths in 2000,[2] but other vector-borne diseases such as dengue fever are out of control in many regions. Roll Back Malaria is a global partnership founded in 1998 by the WHO, the United Nations Development Program (UNDP), the United Nations Children's Fund (UNICEF) and the World Bank. It has the goal of halving the world's malaria burden by 2010 — estimated to be more than 300 million acute illnesses and 1.9 million deaths per year. The Roll Back Malaria partnership includes national governments, civil society and nongovernmental organizations, research institutions, professional associations, UN and development agencies, development banks, the private sector and the media. It aims to expand the use of interventions that are already known to be effective in tackling malaria, including prompt access to effective treatment, promotion of insecticide-treated mosquito nets and improved vector control, prevention and management of malaria in pregnancy and improving the prevention of and response to malaria epidemics and malaria in complex emergencies, as well as supporting research into better drugs and insecticides, malaria vaccines and possibly genetically modified mosquitoes that will not transmit malaria.

Prevention guidelines

Beyond clean water, clean air and available sanitation, our enhanced understanding of microbial pathogenesis, disease transmission and host immunity now provides a number of options for intervention. This has resulted in an increasing number of prevention guidelines, which are updated as new information becomes available. These guidelines represent both primary prevention (a decrease in the likelihood

TABLE 3-4 -- Different categories of guidelines.

DIFFERENT CATEGORIES OF GUIDELINES	
Classification	**Example**
Medical condition	Absent or dysfunctional spleen
Target occupational group	Health care workers
Target professional group	Infection control officers
Organism	Control of hepatitis A virus
Mode of transmission	Sexually transmitted diseases, blood-borne viruses
Intervention	Immunization
Setting	Guidance on infection control in schools, nurseries and day care

of exposure and infection) and secondary prevention (a decrease in the likelihood of disease, given exposure). The details of the many guidelines that are available are far too wide-ranging to include in a single chapter.

Guidelines exist for a variety of purposes and are focused in a variety of ways (Table 3.4). They include pre-exposure and post-exposure protection, and guidance targeted at groups at high risk of exposure as well as groups at high risk from particular infections because of other medical conditions or because they are undergoing procedures (Table 3.5). They have been produced by groups and authorities at local, regional, national and international levels (Table 3.6). Guidelines vary greatly in quality, are different from country to country and vary in the extent to which they incorporate information on implementation or audit and to which they are locally adapted and implemented. They should be produced systematically[21] and undergo regular review to take account of new evidence or interventions and changing epidemiology, for example the emergence of antibiotic resistance or the development of a new antibiotic.

Increasingly, medical practice must be evaluated against standards, and standards should be based upon rigorously evaluated evidence. Evidence-based guidelines set a standard against which practice can be evaluated. As the evidence base for medical practice grows, so the

TABLE 3-5 -- Prevention guidelines — examples of topics.

PREVENTION GUIDELINES — EXAMPLES OF TOPICS	
Category of prevention	**Topic**
Pre-exposure	
At risk from an intervention	Health-care-associated infection — MRSA, nosocomial pneumonia
	Urinary tract infection
	Surgical procedures

Travelers	General advice (Yellow Book — WHO)
	Malaria
	Diarrhea
Underlying conditions at increased risk	Absent or dysfunctional spleen
	Heart disease — prevention of bacterial endocarditis
	Chronic pulmonary disease
	HIV infection — risk of opportunistic infection
	Peritonitis in patients with cirrhosis/ascites
	Sickle cell disease
	Immunosuppression
Postexposure	Hepatitis A
	Rabies
	HIV infection
	Hepatitis B
	Tetanus — wound prophylaxis
	Diphtheria
	Chickenpox
	Sexually transmitted diseases — following sexual assault
Community	Infection control in schools and nurseries
	Meningitis, meningococcal infection, *Haemophilus influenzae* type b infection
	Outbreak investigation and control
Pregnancy and neonates	Group B streptococcal carriage in mother
	RSV immunoglobulin for at-risk infants
	Rash contact (e.g. parvovirus B19 exposure) in pregnancy
	Hepatitis B virus carriage in mother
MRSA, methicillin-resistant *Staphylococcus aureus*; RSV, respiratory syncytial virus.

Examples of a global variety.		

task of producing such guidelines requires a multidisciplinary and dedicated resource. This has been provided by national bodies such as the Centers for Disease Control and Prevention (CDC) in the USA, organizations linked to professional bodies such as the Scottish Intercollegiate Guidelines Network (SIGN)[22] or networks concerned with evidence-based medicine such as the Cochrane collaboration [23] or the National Health Service Centre for Reviews and Dissemination in England, which has been involved in health technology assessment [24] (see Table 3.6). Even so, guidelines produced by such bodies may not always meet published standards.[25]

Surveillance

Early detection of outbreaks is a vital part of their prevention and surveillance is therefore an integral part of infectious disease control. Surveillance has been defined as the ongoing systematic collection, analysis and interpretation of outcome-specific data, closely integrated with the timely dissemination of these data to those responsible for preventing and controlling disease[26] or, more briefly, 'data for action'. Surveillance is carried out with the objectives of identifying changes and patterns to trigger investigation and timely intervention, to identify emerging and re-emerging diseases, and to evaluate, plan and prioritize health services and preventive interventions. To meet these objectives it needs to be simple, timely, accurate and analyzed regularly, and results should be communicated rapidly for appropriate control measures to be taken. Diverse data are used. Statutory notifications, laboratory reports and mortality statistics are most frequently analyzed, followed by

various sentinel systems such as the British Paediatric Surveillance Unit.[27] Reports are made in weekly bulletins in many countries.[28] [29] For vaccination programs, surveillance is also required postlicensure to determine the vaccine efficacy in field conditions, to monitor for changes in vaccine efficacy and to detect rare adverse events as well as vaccination coverage and population susceptibility. Surveillance and ad-hoc reports may lead to outbreak detection, an integral part of the public health role requiring the skills of field epidemiologists trained in programs such as the CDC Epidemic Intelligence Service in the USA[30] or the European Programme for Intervention Epidemiology Training.[31] Public health epidemiology provides the tools to identify potential control measures even before the causative organism is identified or fully characterized, for example in the cases of cholera[32] and HIV infection.[33]

A clear case definition is required for outbreak investigation and other epidemiologic studies and is also an integral part of a good surveillance system.[34] [35] The case definition contributes to the sensitivity and specificity of the surveillance system. When there is an effective intervention such as a vaccination program that has a dramatic impact on the incidence of disease, the positive predictive value of the case definition will change. Case definitions and surveillance systems may have to be adapted to the local epidemiology of the disease and its level of control, [36] and enhanced surveillance systems are often required for rarer diseases and those that are well controlled by vaccination.

In addition to surveillance of known diseases, methods have been developed to detect new and emerging infections and the WHO now has a Department of Communicable Disease Surveillance and Response that acts through partners in a Global Outbreak Alert and Response Network; it has been involved in various outbreaks, such as Ebola.[37] The WHO Influenza Surveillance Network ensures the rapid detection of new influenza viruses and helps to determine the composition of the next season's influenza vaccine, as well as being ready for the detection of pandemic influenza.

Mathematical modeling and health economics

Development of strategies to prevent infection requires a multidisciplinary approach involving clinicians, epidemiologists, public health

Figure 3-4 The basic reproductive number, R_0 — threshold for invasion. The left side shows R_0 = 3 and the right side R_0 = 1. *Modified from Begg and Gay.*[32]

specialists, field workers, mathematicians, modelers and health economists. Infections in populations have certain characteristics that require an understanding beyond the level of infections in individuals. Individual characteristics such as the mode of transmission, reservoirs of infection, the latent period, incubation period and total period of infectivity, the proportion of clinically apparent cases, duration of immunity and the influence of maternal antibody are vital parameters that must be understood for control measures to be appropriate. Infections that lead to life-long immunity, such as measles, tend to occur in regular epidemics, in contrast with diseases in which individuals become susceptible to reinfection on recovery (such as tetanus) or where a carrier state exists (such as hepatitis B virus infection). Other epidemiologic features are specific to particular populations or regions, accounting for different patterns of infection, such as meningococcal infection in Africa.

Modelers have developed approaches to explain the patterns observed to predict the impact of control measures. A fundamental idea is the basic reproduction number (R_0), a summary of these parameters that is specific for each disease. R_0 is defined as the number of secondary (infections) cases produced in a completely susceptible population by a typical infectious individual. The effective reproduction number (R) is the number of secondary cases produced by a typical infectious individual in a particular setting, and so depends upon the proportion of susceptible individuals in the population. Infection only persists in the population if infection is passed

TABLE 3-7 -- Measuring vaccination coverage.

MEASURING VACCINATION COVERAGE				
Type	**Method**	**Advantages**	**Disadvantage**	**Example**
Vaccine usage	Counts doses of vaccine used	Identifies major trends quickly, suitable for centrally distributed vaccine	No information on wasted doses; no information on incomplete courses; no information on vaccine recipients	AFIX, used in the USA for clinic or surgery-based immunization coverage — cannot be extrapolated to provide national coverage data
Sample population assessment	Sampling in different settings; can be done systematically or randomly	Can be a quick and cheap method	Problem with selection bias — may overestimate; pockets of low coverage may be missed	Used in New Zealand, based on immunization benefit claims (moving to total population assessment)
Total population assessment	Denominator: resident children; live births — numerator: completed courses; doses given	Data on primary care doses for age; long-term trends can be observed	Good records needed, migration/poor recording of doses given, may be delay in producing summary statistics	COVER, used in the UK; all infants are entered into the child health register at birth — can be extrapolated to provide national data
Examples of vaccine coverage used in the developing world. COVER, Coverage of Vaccination Evaluated Rapidly.				

to one or more individuals by each infectious person, or in other words if R_0 = 1. For diseases that show natural epidemic cycles, such as measles, pertussis and parvovirus B19, R oscillates around 1 as the proportion of the population that is susceptible oscillates around an equilibrium value.

The concept of reproduction number is directly related to herd immunity, the idea that an infection can be eliminated even if only a proportion of the population is immune, and that nonimmune individuals are thereby protected. A population is said to have herd immunity if on average an infection by a typical primary (infection) case produces less than one secondary infection (R_0 < 1; Fig. 3.4).[32] From such a simple idea, more complex modeling has developed involving both deterministic and stochastic approaches. In combination with health economics, modeling can be used to set health service priorities for preventive programs.[38]

Health economics of infectious disease prevention is a specialized field. For example, there is no standard for evaluating the cost-effectiveness of vaccination programs and many cost-effectiveness analyses are methodologically incorrect because they take no account of indirect protection (herd immunity). The gap between research and practice is large and vaccine efficacy estimated from clinical trials may be quite different from the observed effectiveness of a mass immunization program. Detailed observational studies are impracticable because of the large scale required, making them expensive, and the limitations in finding suitable control populations

Figure 3-5 Global polio incidence. Global and regional summaries of reported cases of poliomyelitis worldwide from 1990–2001. *Modified from WHO.*[43]

for comparison. Modeling allows the impact of mass vaccination to be predicted but still needs to be supported by post-implementation surveillance. Challenges for health economists include the fact that vaccine demand is derived and the 'market' is affected by uncertainty and imperfect information. Parents are generally risk adverse and may find the asymmetry of information between themselves and providers or agents threatening. Vaccination is a public good but the equity issues vary from other fields in that individuals can be protected indirectly through vaccination of others. These and other complex factors need to be incorporated into health economic analyses.

VACCINATION

Immunization has been the most successful medical intervention in reducing the incidence of disease and related deaths worldwide. Guidelines in the form of handbooks, such as the Pink Book in the USA and the Green Book in the UK, and international guidelines from the WHO, have disseminated a greater understanding of the

TABLE 3-8 -- Global measles strategic plan 1999.*

GLOBAL MEASLES STRATEGIC PLAN 1999			
Strategies for achieving sustainable reduction in measles mortality		**Strategies for achieving and maintaining interruption of indigenous measles transmission**	
•	Goal: Reduce the number of annual measles deaths by half by 2005	•	Goal: Achieve and maintain interruption of indigenous measles transmission in large geographic areas
1	Routine immunization — achieve >90% routine vaccination coverage (in each district and nationally) with at least one dose of measles vaccine administered at 9 months of age or shortly thereafter	1	Routine immunization — achieve very high (i.e. >95%) immunization coverage (in each district and nationally) with the first dose of measles vaccine administered through routine services
2	Second opportunity for measles vaccination — for all children through routine or supplemental activities	2	Second opportunity for measles vaccination — to maintain the number of susceptible population below the critical threshold for 'herd' immunity
3	Measles surveillance — establish effective surveillance for measles to report regularly the number, age and vaccination status of children contracting or dying from measles, to conduct outbreak investigations and to monitor immunization coverage	3	Measles surveillance — investigation and laboratory testing of all suspected measles cases (case-based surveillance). Isolation of measles virus should be attempted from all chains of transmission
4	Improve management of complicated cases — including vitamin A supplementation and adequate treatment of complications	4	Improve management of complicated cases — including vitamin A supplementation and adequate treatment of complications
Of all health interventions, measles immunization carries the highest health return for the money spent, saving more lives per unit cost.

epidemiology and prevention of vaccine-preventable diseases to a wider network of professionals.[39] [40]

An essential component of any effective immunization program is a system to measure performance. Vaccine coverage is often used as a surrogate for disease reduction and there are several ways of estimating this (Table 3.7). Assessing vaccine coverage through national, state or local methods is an essential component of any effective immunization program. In the USA, the National Vaccine Advisory Committee strongly encourages the development of community- or state-based immunization registry systems and recommends that vaccination providers participate in these registries whenever possible.[41] The AFIX system (Assessment, Feedback, Incentives and eXchange of information) developed by the CDC is a clinic- or surgery-based vaccine coverage assessment tool that can be used with or without computers. The aim of AFIX is not only to ensure that children are immunized on time but also to provide vaccine providers with feedback about their level of immunization performance in a timely manner. The AFIX system incorporates a mechanism to comment on reasons for low coverage and strategies a vaccine provider might use to improve immunization uptake. A 95% participation

REDUCTION IN VACCINE-PREVENTABLE DISEASES IN THE USA			
Disease	**Maximum no. reported cases during prevaccine era**	**Reported no. cases during 2001**	**% change in morbidity**
Diphtheria	206,939	2	-99.99
Measles	984,134	116	-99.99
Mumps	152,209	266	-99.83
Pertussis	265,269	7,580	-97.14
Polio (paralytic)	21,269	0	-100.00
Rubella	57,686	23	-99.96
Congenital rubella syndrome	20,000	3	-99.98
Tetanus	1,560	37	-97.63
Haemophilus influenzae type b/unknown (<5 years)	20,000	1,597	-92.01
The figures are reported for 2001 and the maximum number of reported cases during the prevaccine era is estimated for invasive congenital rubella syndrome and polio.			

** Modified from CDC.*[47]

of children aged less than 6 years in fully operational population-based registries is a national health objective for 2010.[42]

The example of smallpox eradication is a model on which other diseases and their eradication programs are drawn. The global smallpox eradication program began in 1967, initially using a 2-fold strategy of mass vaccination campaigns and surveillance systems to detect and contain cases and outbreaks. For example, in isolated pre-20th century populations, R_0 for smallpox was 3.5–6 (R_0 = 1). The persistence of smallpox in the presence of a highly vaccinated population showed that, by isolating people with smallpox and their contacts, outbreaks could be more rapidly contained, even in areas where vaccination coverage was low. This surveillance and containment strategy became a key element in the global eradication program.[39] The world's last indigenous case was in Somalia on 26 October 1977.

The synchronization of immunization among neighboring countries has become a model for eradicating diseases globally. Humans are the only known reservoir for many infections and therefore eradication is a distinct possibility. The success of smallpox eradication demonstrated the power of vaccines when coupled with appropriate strategies. In addition, smallpox had a low R_0 , was distinct and recognizable, and individuals were infectious from the time their earliest lesions were apparent.

In 1988 the World Health Assembly adopted the goal of global eradication of poliovirus by the year 2000. Although this goal has not been met, substantial progress has been made (Fig. 3.5). The Global Polio Eradication Initiative was launched in 1988.[43] Since then, three WHO regions have been certified polio-free: the Americas region (36 countries) in 1994, the Western Pacific region (37 countries, including China) in 2000 and the European region (51 countries) in 2002. Wildly endemic on five continents in 1988, polio is now only found in parts of Africa and South East Asia. The new polio eradication target date is 2005.

Measles is another leading cause of childhood deaths, mainly in developing countries. There were an estimated 30–40 million cases of measles in 2000, causing some 777,000 deaths. Measles accounts for nearly half of the 1.7 million annual deaths due to childhood vaccine-preventable diseases. The WHO and UNICEF have developed the Global Measles Strategic Plan together with the US CDC and numerous experts worldwide (Table 3.8).[44] Measles, unlike smallpox, is not always recognizable and individuals are infectious before the appearance of the erythematous maculopapular rash, leading to 'silent spreaders'. An R_0 of 15–20 means an

individual can infect a large proportion of other susceptible individuals before an index case has been identified. High levels of herd immunity and high vaccination coverage are required to control the infection. Factors in the success of smallpox eradication have not been found

TABLE 3-10 -- Licensed vaccines in the USA, October 1999.[†]

LICENSED VACCINES IN THE USA, OCTOBER 1999
• Adenovirus vaccine, live oral, type 4
• Adenovirus vaccine, live oral, type 7
• Anthrax vaccine, adsorbed
• BCG, live
• Botulinum toxin type A
• Cholera vaccine
• Diphtheria toxoid, adsorbed
• Diphtheria and tetanus toxoids and acellular pertussis vaccine, adsorbed
• Diphtheria and tetanus toxoids and pertussis vaccine, adsorbed and *Haemophilus influenzae* type b, conjugate vaccine
• Diphtheria and tetanus toxoids, adsorbed
• *Haemophilus influenzae* type b, conjugate vaccine
• Hepatitis A vaccine, inactivated
• Hepatitis B vaccine, recombinant
• Influenza virus vaccine, inactivated
• Japanese encephalitis virus vaccine, inactivated
• Lyme vaccine, recombinant vaccine
• Measles, mumps and rubella virus vaccine, live
• Measles and mumps virus vaccine, live
• Measles and rubella virus vaccine, live
• Measles vaccine, live
• Meningococcal polysaccharide vaccine group A
• Meningococcal polysaccharide vaccine group C
• Meningococcal polysaccharide vaccine groups A and C, combined
• Meningococcal polysaccharide vaccine groups A, C, Y and W-135, combined
• Mumps vaccine, live
• Pertussis vaccine, adsorbed
• Plague vaccine
• Pneumococcal vaccine (23-valent)
• Poliovirus vaccine, inactivated
• Poliovirus vaccine, live oral
• Rabies vaccine
• Rotavirus vaccine, live oral reassortant vaccine[*]
• Rubella and mumps vaccine, live
• Rubella vaccine, live
• Tetanus toxoid, adsorbed
• Tetanus and diphtheria toxoids, adsorbed (for adult use)
• Typhoid vaccine, live oral Ty21a
• Typhoid Vi polysaccharide vaccine
• Varicella vaccine, live
• Yellow fever vaccine

* On 15 October 1999, Wyeth Lederle Vaccines announced that it had withdrawn RotaShield® from the market.

TABLE 3-11 -- Immune globulins and antitoxins available in the USA and UK.[†]

IMMUNE GLOBULINS AND ANTITOXINS AVAILABLE IN THE USA AND UK				
Immunobiologic	**USA**	**UK**	**Type**	**Indication**
Botulinum antitoxin	?	?	Specific equine antibodies	Treatment of botulism
Cytomegalovirus intravenous immune globulin	?	?	Specific human antibodies	Prophylaxis for bone marrow and kidney transplant recipients
Diphtheria antitoxin	?	?	Specific equine antibodies	Treatment of respiratory diphtheria
Immune globulin	?	?	Pooled human antibodies	Hepatitis A pre-[*] and postexposure prophylaxis; measles postexposure prophylaxis
Intravenous immune globulin	?	?	Pooled human antibodies	Replacement therapy for antibody deficiency disorders; immune thrombocytopenic purpura; hypogammaglobulinemia in chronic lymphocytic leukemia; Kawasaki disease
Hepatitis B immune globulin	?	?	Specific human antibodies	Hepatitis B postexposure prophylaxis
Human rabies immune globulin	?	?	Specific human antibodies	Rabies postexposure management of people not previously immunized with rabies vaccine

Tetanus immune globulin	?	?	Specific human antibodies	Treatment of tetanus; postexposure prophylaxis of people not adequately immunized with tetanus toxoid
Vaccinia immune globulin	?	✗	Specific human antibodies	Treatment of eczema vaccinatum, vaccinia gangrenosa and ocular vaccinia
Varicella-zoster immune globulin	?	?	Specific human antibodies	Postexposure prophylaxis of susceptible immunocompromised people, certain susceptible pregnant women and perinatally exposed newborn infants
The type and indications of use are shown. Immune globulin preparations (called 'immunoglobulins' in the UK) and antitoxins are administered intramuscularly unless otherwise indicated; and human rabies immune globulin is administered around the wounds in addition to intramuscular injection.				

† *Modified from CDC.* [41] [49]
* Not used in the UK for pre-exposure prophylaxis. Hepatitis A vaccine only is offered for pre-exposure up to the day of travel.

to be as effective in the control of measles and no option other than mass immunization has emerged.

The WHO has recommended vaccine coverage to be achieved and maintained at 90% with all childhood vaccines.[45] In general, this target is sufficient to prevent the circulation of vaccine-preventable diseases. Mathematical modeling has shown that the herd immunity threshold, the mechanism by which an infection may be eradicated from a population, does not need to be 100%. The US Healthy People 2000 objective[46] has been consistent with the WHO target level. However, childhood immunization rates are still suboptimal; for example, in 2000 only 82% of children 19–35 months of age had received four doses of DTaP vaccine, down from 84% in 1998.[39] The reduction in vaccine-preventable diseases has had a dramatic effect on morbidity as compared with the prevaccine era in the USA. The most common childhood diseases have all been reduced by over 90% and in the case of paralytic polio by 100% (Table 3.9).[47]

Advances in vaccine technology have enabled development of new vaccines. Novel approaches for vaccine development include DNA vaccines and mucosal vaccines, including the prospect of 'edible' vaccines produced in transgenic plants and vaccines that can be administered by aerosol spray. Although not all vaccines in the process of development will be licensed, the list of vaccines, immune globulins and antitoxins continues to grow (Table 3.10 and Table 3.11). [48] [49] In 1998 the US Food and Drug Administration approved a vaccine using recombinant technology (RotaShield®) that was effective in preventing the serious complications of rotavirus gastroenteritis. In July 1999, the CDC postponed its use and in November 1999 the Advisory Committee on Immunization Practices (ACIP) withdrew its recommendations following reports through the Vaccine Adverse Events Reporting System of an increased risk of intussusception in the first 2 weeks after vaccination. The worldwide burden of rotavirus disease remains substantial and ACIP's decision therefore has implications regarding the risks and benefits of rotavirus vaccination in different settings. [50] At present, new rotavirus vaccines are under development.

The growing number of available vaccines has made the process of immunization increasingly complex. The current childhood schedule in the USA demonstrates the number of vaccines and immunizations required in the first years of life (Fig. 3.6), along with the complexities of catching up those who have uncertain or incomplete immunization status and those who need minimum visits to aid compliance (Table 3.12).[39] [41]

New vaccines for developing countries — the Children's Vaccine Initiative, the Global Alliance for Vaccines and Immunizations, and the Vaccine Fund

In contrast to the vast possibilities that modern technologies offer for vaccine development, the WHO's Expanded Program of Immunizations (EPI) is more limited. This was launched in 1974, following the impressive success of the smallpox eradication program; the WHO looked for other activities that could build on what had already been achieved. The six diseases chosen were tuberculosis, diphtheria, neonatal tetanus, whooping cough, poliomyelitis and measles. During this time, coverage for all EPI target diseases climbed steadily from 5% in developing countries to 80%, although this was not matched by a proportionate decrease in disease incidence. In 1999, serious limitations in global vaccine programs worldwide contributed to a fall in the average vaccination coverage of children under 5 years of age to 74%, and in many countries the infrastructure for vaccine delivery was deteriorating. This means that one child in four in the world remains unimmunized against the six target diseases.[51]

Vaccines available through EPI were further expanded in the 1990s to include yellow fever, hepatitis B and *Haemophilus influenzae* type b (Hib), to countries with high disease burdens from these infections. The aim is for hepatitis B vaccine to be given in all developing countries with adequate delivery systems by 2007 and for Hib

Figure 3-6 Recommended childhood immunization schedule for the USA, 2003. This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of 1 December 2002, for children through age 18 years. DTaP, diphtheria, tetanus, acellular pertussis; HepB, hepatitis B; Hib, *Haemophilus influenzae* type b; IPV, inactivated polio vaccine; MMR, measles, mumps, rubella; OPV, oral polio vaccine; PCV, pneumococcal conjugate vaccine; PPV, polysaccharide pneumococcal vaccine; Td, tetanus, low dose diphtheria; Var, varicella. *Redrawn with permission from CDC.*[39]

Modified from CDC.[41]						

* HbOC (HibTITER) and PRP-T (ActHib, OmniHib).
† PRP-OMP (PedvaxHiB).
c‡ If Hib1 given aged 7–11 months, give Hib3 at 12–15 months of age.
§ For infants 7–11 months of age: if unvaccinated, give PCV1 now, PCV2 at 4–8 weeks and PCV3 at 12–15 months.
¶ Overall there must be = 16 weeks between HepB1 and HepB3. Last dose in HepB series should not be given earlier than 6 months of age.
£ If DTaP4 is given before 4th birthday, wait at least 6 months for DTaP5; if DTaP4 is given after 4th birthday, DTaP5 is not needed.
¢ If IPV3 given before 4th birthday, give IPV4 at 4–6 years of age; if IPV3 given after 4th birthday, IPV4 is not needed. If a combination of OPV and IPV have been given, all four doses are needed.
$ For children =15 months and <5 years who have never received Hib vaccine, give only one dose. Not given = 5 years of age.
? For infants 12–23 months: if not previously vaccinated or only one previous dose before 12 months, give PCV1 and PCV2 8 weeks apart. If infant has previously had two doses of PCV, give booster dose 8 weeks or more after previous dose.
¥ If PPV23 is indicated following a course of PCV, allow = 8-week gap.
? Td given aged 11–12 if 5 years has elapsed since last dose. Td given every 10 years, thereafter.

vaccine to be given in 50% of the poorest countries with high disease burdens and adequate delivery systems by 2005. Although no target has been set for yellow fever vaccine, it is estimated that 200,000 yellow fever cases with 30,000 deaths occur each year, mostly in Saharan Africa.

The WHO has overall responsibility for the execution of the EPI program. Recognizing the need for global vaccine deployment and the search for new and improved vaccines, the Children's Vaccine Initiative was founded in 1990 — a collaboration involving UNICEF, UNDP, the World Bank, the Rockefeller Foundation and the WHO.

The impetus for these initiatives stems from the opportunities arising through innovative methods of vaccine production, coupled with an increasing commitment by the international community to prevent disease through vaccination.

To continue and build on the work of the Children's Vaccine Initiative, the Global Alliance for Vaccines and Immunization (GAVI) was launched in 1999. This coalition of international partners includes national governments, international organizations and the private sector. The pharmaceutical industry's participation as a full partner in GAVI is an innovation.

Alongside GAVI is the Global Fund for Children's Vaccines, a financially independent mechanism to raise new resources for immunization, which was launched to address the needs for vaccines and immunizations of the world's 71 poorest countries, those with a per capita GNP of less than US$1000. Funding decisions are based on recommendations of the GAVI board. To date, more than US$600 million of the vaccine fund's resources have been committed to 36 developing country immunization programs.

Vaccines and immunizations: definitions, principles, logistics and use

Vaccines both benefit the individuals who receive the vaccine directly, by preventing them from acquiring and spreading the disease, and in turn indirectly protect those who are unvaccinated or unprotected for any reason, such as age or immune deficiency. Vaccines are biologic agents capable of stimulating immune responses in the host and are called immunobiologics. The vaccines must be immunogenic, thus inducing a strong and measurable immune response in the host. The purpose of this is to provide artificial immunity by priming the recipient's immune system to recognize and attack the disease-causing organism if it is presented again. Immunobiologics are part of a larger grouping that includes antigenic substances (vaccines and toxoids) and antibody-containing products (globulins and antitoxins). Artificially acquired immunity can be either active or passive.

Immunity

A broad definition of immunity is 'a resistance developed in response to stimulus by an antigen and usually characterized by the host'.[52] Active immunity is produced by antibodies that develop in response to antigens (immune response) and can be naturally acquired (where immunity develops after infection or exposure to antigens in the environment) or acquired by active immunization (where immunity develops after administration of an antigen in order to prevent disease). Transfer of antibodies from another person produces passive immunity, and can be achieved either by passive immunization, conferred by administration of antibodies (e.g. immune globulin) to combat infection, or by natural passive immunity, conferred by transfer of maternal antibodies across the placenta.

Vaccine components

In addition to the vaccine antigen that provides a target for the immune response, vaccines may also contain other ingredients, including suspending fluids (e.g. sterile water, saline or fluids derived from the biologic system in which the vaccine is produced); preservatives, stabilizers and antibiotics to prevent bacterial contamination and to protect the antigen from degradation; and adjuvants (substances that enhance the immunologic response). In a patient with known allergies and sensitivities, each of these components should be considered before administration of any vaccine.[39]

Vaccine storage and handling

Each vaccine has its own specific storage and handling requirements. Knowledge of a vaccine's stability can be helpful in determining

Figure 3-7 Vaccine vial monitor showing stages of exposure. The information delivered by the vaccine vial monitor is simple. If the inner square is a lighter color than the outer reference ring than the vaccine can be used. If the inner square is the same color as the outer ring or darker than it, then the vaccine should not be used. *From WHO.*[53]

storage requirements. For example, oral poliovirus vaccine (OPV) and yellow fever vaccine are sensitive to heat and rapidly lose their potency at warm temperatures. In contrast, many vaccines are sensitive to freezing. These include diphtheria and tetanus toxoids, pertussis vaccine, inactivated poliovirus vaccine, Hib conjugate vaccines, hepatitis B vaccine, pneumococcal vaccine and influenza vaccine[53] (see Table 3.13). Maintaining the proper temperature of vaccines from their point of production to the vaccine recipient is referred to as the 'cold chain'. Because it may be difficult to distinguish a potent vaccine from one that has not been strictly maintained at the proper temperature, most vaccines are packed with temperature monitors during shipment. More recently, vaccine vial monitors, which measure exposure to heat, are time- and temperature-sensitive labels attached to vials of vaccine at the time of manufacture (Fig. 3.7).[53] Vaccine vial monitors comply with WHO requirements for heat stability and are being used extensively with the EPI program.

Route of administration

The route of administration is specific to each vaccine based on the process of development and testing for safety and efficacy. Vaccines should only be administered as recommended. In general, it is recommended that all injectable routine childhood vaccines given in the USA be administered by the deep subcutaneous or intramuscular routes.[40] [41] Vaccines containing adjuvants should be injected into muscles; local irritation, induration, skin discoloration, inflammation and granuloma formation are possible adverse events when given subcutaneously or intradermally. One important fact to consider is whether a vaccine is as effective when given at a different site. For example, antibody responses to rabies and hepatitis B vaccines have been shown to be lower when injected in the buttock as compared with intramuscularly into the deltoid. [54] [55] Needle length has been debated in recent studies,[56] [57] but there is insufficient evidence to advise any change in practice.[58] Currently, guidelines are based on age (Table 3.14).[41]

Vaccine schedules

Vaccines may not be effective in very young children with developing immune systems, or they may require several doses to be fully effective. Therefore, the timing sequence of immunizations affects the immune response. The administration of new vaccines is becoming increasingly complex; guidelines have been established for the spacing of vaccines and immune globulin preparations, which may be country- or schedule-specific (Table 3.15 and Table 3.16).[41]

TABLE 3-13 -- Stability of vaccines currently used in national immunization programs.*

STABILITY OF VACCINES CURRENTLY USED IN NATIONAL IMMUNIZATION PROGRAMS				
	Storage temperature (°C)			
Vaccine	**0–8**	**22–25**	**35–37**	**> 37**

Commonly used				
Diphtheria, tetanus and pertussis-containing vaccines (acellular pertussis components)	Will remain stable for 18–24 months in spite of continuous slow decrease in potency of the pertussis component	DT components stable for 4, possibly 6 months; the limiting factor is the pertussis component; some vaccines containing pertussis are stable for only 2 weeks at this temperature	DT components stable for weeks but stability of pertussis component varies with different vaccines; some vaccines containing pertussis lose 50% of potency during storage for 1 week	DT components are: At 45°C: stable for 2 weeks At 53°C: loss of potency after few days At 60–65°C: loss of potency after a few hours Pertussis component: about 10% loss of potency per day at 45°C; rapid loss in potency if stored at 50°C — pertussis component is the limiting factor
Hepatitis B vaccine	Stable for 2–4 years	Stable for 30 days	Stable for 1 week	At 45°C: stable for 3 days
Haemophilus influenzae type b containing vaccines	Stable until use-by date	Stable for at least 24 months when stored at 25°C	Information not available	Information not available
Polio (IPV): DO NOT FREEZE	Stable for up to 2 years	Loss of potency after 20 days	Unstable, discard	Information not available
Measles, mumps and rubella (freeze-dried or unconstituted vaccine) — diluent: DO NOT FREEZE	Stable for 2 years	Retains satisfactory potency for 1 month	Retains satisfactory potency for at least 1 week	50% loss of potency after 2–3 days at 41°C: 80% loss of potency after 1 day at 54°C
Measles, mumps and rubella (reconstituted with diluent): PROTECT FROM LIGHT	Should be used in one vaccination session (8h) if kept cool and protected from sunlight — if not, discard after 1h	Unstable: 50% loss of potency after 1h, 70% loss after 3h	Very unstable: titer may be below acceptable level after 2–7h	Inactivation within 1h
Varicella — Varilrix (freeze dried or unconstituted): MAY BE STORED BELOW 0°C — diluent: DO NOT FREEZE	Stable for 2 years. Protect from light	Information not available	Information not available	Information not available
Varicella — Varilrix (reconstituted with diluent): DO NOT FREEZE	Use promptly and within 90min	Information not available	Information not available	Information not available
Varicella — Varivax: STORE AT -15°C OR BELOW	Administer vaccine immediately after reconstitution; discard if not administered within 30min. Highly unstable — loses potency	Highly unstable — loses potency	Highly unstable — loses potency	Highly unstable — loses potency
Pneumococcal: DO NOT FREEZE	Stable until use by date	Information not available	Information not available	Information not available
Other vaccines				
Polio (OPV) (unopened vials)	Stable for 6–12 months	Unstable: 50% loss of potency after 3 weeks exposure	Very unstable. Loss of satisfactory titre in 1–3 days	Very unstable: At 41°C: 50% loss in 1 day At 50°C: loss of satisfactory titer after 1–3h exposure
BCG (freeze-dried or unconstituted form) — diluent: DO NOT FREEZE	Stable for 1 year. Do not expose to light	Stability varies: 20–30% loss of viability during 2-month exposure. Do not expose to light	Loses potency rapidly. Stability varies. 20% loss of viability during 3–14 days exposure. Do not expose to light	Rapid loss of potency. Up to 73% loss of potency at 3 days. At 70°C: 50% loss during 30min exposure. Do not expose to light
BCG (reconstituted with diluent): DO NOT FREEZE	Very unstable. Protect from light. Keep at 2°C to 8°C when vial is not in use. Discard all unused vaccine at the end of the vaccination session (6 hours)	Very unstable	Very unstable	Very unstable
The vaccines that are most unstable at room temperature are OPV, reconstituted MMR vaccine and reconstituted BCG vaccine. OPV, reconstituted BCG vaccine and reconstituted MMR vaccines must be protected from exposure to light.				

** Modified from WHO.*[53]

TABLE 3-14 -- Injection site and positioning.*

INJECTION SITE AND POSITIONING		
Intramuscular (im)		
Suitable for DTaP, DT, Td, Hib, Hep A, Hep B, influenza and PCV7 vaccine; IPV and PPV23 vaccine can be given im or sc		
Note: insert needle at an 80–90° angle		
Patient's age	**Site**	**Needle size**
Infants (birth to 12 months)	Vastus lateralis muscle in anterolateral aspect of middle upper thigh	7/8" to 1" needle, 23–25 gauge
Young children (12–36 months)	Vastus lateralis muscle preferred until deltoid muscle has developed adequate mass	7/8" to 1" needle, 23–25 gauge
Older children (>36 months) and adults	Thickest portion of deltoid muscle — above level of armpit and below acromion	1" to 2" needle, 23–25 gauge
Subcutaneous (sc)		
Suitable for MMR, varicella, and meningococcal vaccines		
Note: insert needle at 45° angle; make sure you pinch up sc tissue to avoid injecting into muscle		
Patient's age	**Site**	**Needle size**
Infants (birth to 12 months)	Fatty area of thigh	5/8" to 3/4" needle, 23–25 gauge
Young children (12–36 months)	Fatty area of thigh or outer aspect of upper arm	5/8" to 3/4" needle, 23–25 gauge
Older children (>36 months) and adults	Outer aspect of upper arm	5/8" to 3/4" needle, 23–25 gauge

Current guidelines for injection site, needles size and positioning based on age.

** Modified from CDC.[41]*

TABLE 3-15 -- Guidelines for spacing immune globulin preparations and vaccines.‡

GUIDELINES FOR SPACING IMMUNE GLOBULIN PREPARATIONS AND VACCINES		
Simultaneous administration		
Combination		**Minimum interval**
Immunoglobulin and inactivated vaccine		None; can be administered simultaneously at different sites or at any time between doses
Immunoglobulin and live vaccine		Should not be administered simultaneously* ; if unavoidable, administer at different sites and revaccinate or test for seroconversion
Nonsimultaneous administration		
Product administration		
First	**Second**	**Minimum interval**
Immune globulin	Inactivated vaccine	None
Inactivated vaccine	Immune globulin	None
Immune globulin	Live vaccine	Dose related* †
Live vaccine	Immune globulin	2 weeks
Immune globulin preparations include blood products containing large amounts of immune globulin, such as serum immune globulin, specific immune globulins (e.g. tetanus immune globulin and hepatitis B immune globulin), intravenous immune globulin, whole blood, packed red cells, plasma and platelet products.		

‡ *From CDC.[41]*
*Yellow fever and oral Ty21a typhoid vaccine are exceptions to the rule and can be administered at any time before, after or simultaneously with immunoglobulin without decreasing the response.
†The duration of interference of immune globulins on antibody response to measles-containing vaccines and possibly to varicella vaccine, is dose related (see Table 3.16).

Vaccines and schedules are not standardized worldwide and transferring patients on to the national schedule may require knowledge of schedules in other countries. The WHO vaccine preventable diseases monitoring system collects, compiles and disseminates data on immunization coverage and incidence of vaccine preventable diseases, as well as providing nationally recommended immunization schedules[59] (Table 3.17 and Table 3.18).

Vaccine contraindications and precautions

There are several contraindications and precautions to vaccination (Table 3.19).[41] With the exception of moderate or severe underlying illness, contraindications are specific to the vaccine. Among the factors to consider before administering a vaccine are:

- underlying allergies to animal proteins (eggs or chicken embryo), antibiotics (streptomycin or neomycin) or one of the stabilizers;
- immune deficiency; and
- pregnancy.

Some vaccines are prepared in eggs, but persons who are able to eat eggs or egg products without developing allergy should have no difficulty with the receipt of vaccines prepared in eggs or chicken embryos. A review of literature looking at evidence for egg as the agent responsible for allergic reactions to measles, mumps and rubella

TABLE 3-16 -- Suggested intervals between administration of selected immune globulin preparations and measles/varicella vaccine.‡

SUGGESTED INTERVALS BETWEEN ADMINISTRATION OF SELECTED IMMUNE GLOBULIN PREPARATIONS AND MEASLES/VARICELLA VACCINE		
Product indication	**Dose***	**Suggested interval before measles or varicella vaccination (months)**
Tetanus (TIG)	250 units (10mg IgG/kg) im	3
Hepatitis A		
Contact prophylaxis	0.02ml/kg (3.3mg IgG/kg) im	3
International travel*	0.06ml/kg (10mg IgG/kg) im	3
Hepatitis B Ig	0.06ml/kg (10mg IgG/kg) im	3
Rabies Ig	20 IU/kg (22mg IgG/kg) im	4
Varicella zoster Ig (VZIG)	125 units/10kg (20–40mg IgG/kg) im (maximum 625 units)	5
Measles prophylaxis Ig		
Standard	0.25ml/kg (40mg IgG/kg) im	5
Immunocompromised contact	0.50ml/kg (80mg IgG/kg) im	6
IGIV		
Replacement therapy for immune deficiencies†	300–400mg/kg iv	8
Immune thrombocytopenic purpura	400mg/kg iv daily for 5 consecutive days, or	8
Immune thrombocytopenic purpura	1000mg/kg iv daily for one or two consecutive days	10
Kawasaki disease	2g/kg iv	11
This table is not intended to show the correct indications and dosage for using immune globulin products. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80mg IgG/kg. Unvaccinated people may not be fully protected against measles and/or varicella during the entire suggested interval, and additional doses of immune globulin, vaccine or both may be indicated after exposure.		

‡ *Modified from CDC.[41]*
* Recommended for postexposure following travel if hepatitis A vaccine has not been given or if given within 1 month.
† Measles and rubella vaccination is recommended for children with asymptomatic or mildly symptomatic HIV infection but is contraindicated for persons with severe immunosuppression from HIV or

any other immunosuppressive disorder.

TABLE 3-17 -- Immunization schedule for infants recommended by the World Health Organization expanded program on immunization (EPI).[§]

IMMUNIZATION SCHEDULE FOR INFANTS RECOMMENDED BY THE WHO EXPANDED PROGRAM ON IMMUNIZATION			
		Hepatitis B vaccine[*]	
Age	**Vaccine**	**Scheme A**	**Scheme B**
Birth	BCG, OPV0[†]	HB1	
6 weeks	DPT1, OPV1	HB2	HB1
10 weeks	DPT2, OPV2		HB2
14 weeks	DPT3, OPV3	HB3	HB3
9 months	Measles, yellow fever[‡]		
The basis principle guiding the use of EPI vaccine is that protection against the EPI diseases should be achieved prior to the time that infants are at risk from these diseases. Immunization schedules should be designed to provide the first dose of vaccine as early as possible, consistent with the epidemiology of the disease and within the capacity of the vaccine delivery system.			

§ *From WHO.*[60]

* Scheme A is recommended in countries where newborns are at risk of being exposed to hepatitis B through their mothers; scheme B is recommended where this risk does not exist.
† OPV at birth (OPV0) is recommended in countries where poliomyelitis has not been controlled.
‡ Yellow fever vaccine is recommended in countries at risk for yellow fever.

(MMR) or measles vaccine found that MMR is as safe as any other vaccine, and an allergy to eggs should not delay measles vaccination.[61] Recommendations for children to be vaccinated in hospital are those with an allergy to eggs in whom previous exposure led to cardiorespiratory reactions and those with coexisting active, chronic asthma.

Adverse events following vaccination

Like any pharmaceutical product, no vaccine is 100% safe or effective. Almost all vaccines are associated with minor and self-limited

TABLE 3-18 -- Routine immunization schedules in the UK, Canada, Australia and New Zealand, 2002.

ROUTINE IMMUNIZATION SCHEDULES IN THE UK, CANADA, AUSTRALIA AND NEW ZEALAND, 2002	
Country	**Schedule**
UK	2, 3, 4 months: DTP, OPV, Men C, Hib
	12–15 months: MMR
	3.5–5 years: DTaP, MMR, OPV
	13 years: BCG
	15–18 years: Td, OPV
Canada	2, 4, 6 months: DTaP, IPV, Hib, Hep B, PC, Men C
	12 months: MMR, varicella, PC
	18 months: DTaP, IPV, Hib
	4–6 years: DTaP, IPV
	14–16 years: Td or TdaP
Australia	2, 4, 6 months: DTaP, Hib, Hep B, OPV
	12 months: MMR, Hib
	18 months: DTaP
	4 years: DTaP, MMR, OPV
	15–19 years: Td, OPV
New Zealand	6 weeks, 3 months: DTaP, IPV, Hib, Hep B
	5 months: DTaP, IPV, Hep B
	15 months: MMR, DTaP, Hib
	4 years: DTaP, IPV, MMR
	11 years: Td, IPV
Schedules differ from country to country. Awareness of schedules allows individuals to be transferred more easily on to the schedule of the country in which they now reside.	

adverse events, but some vaccines have been associated with very rare, but serious health effects. The paradox of vaccine effectiveness is the growing concern over vaccine safety. As the threat of disease

TABLE 3-19 -- Vaccination contraindications and precautions.[*]

VACCINATION CONTRAINDICATIONS AND PRECAUTIONS	
True contraindications and precautions	**Not contraindications (vaccines may be administered)**
General for all vaccines (DTP, DTaP, OPV, IPV, MMR, Hib, hepatitis B)	

Contraindications	Anaphylactic reaction to a vaccine contraindicates further doses of that vaccine	Mild to moderate local reaction (soreness, redness, swelling) following a dose of an injectable antigen
	Anaphylactic reaction to a vaccine constituent contraindicates the use of vaccines containing that substance	Mild acute illness with or without low-grade fever
	Moderate or severe illnesses with or without fever	Current antimicrobial therapy
		Convalescent phase of illnesses
		Prematurity (same dosage and indications as for normal full-term infants)
		Recent exposure to an infectious disease
		History of penicillin or other non-specific allergies, or family history of such allergies
DTP/DTaP		
Contraindications	Encephalopathy within 7 days of administration of previous dose of DTP	Temperature of <105°F (40.5°C) following previous dose of DTP
		Family history of convulsions
Precautions	Fever of =105°F (40.5°C) within 48h after vaccination with a prior dose of DTP	Family history of sudden infant death syndrome
	Collapse or shock-like state (hypotonic-hyporesponsive episode) within 48h of receiving a prior dose of DTP	Family history of an adverse event following DTP administration
	Seizures within 3 days of receiving a prior dose of DTP	
	Persistent, inconsolable crying lasting =3h within 48h of receiving a prior dose of DTP	
OPV		
Contraindications	Infection with HIV or a household contact with HIV	Breast-feeding
	Known altered immunodeficiency (hematologic and solid tumors; congenital immunodeficiency; long-term immunosuppressive therapy)	Current microbial therapy
	Immunodeficient household contact	Diarrhea
Precautions	Pregnancy	
IPV		
Contraindications	Anaphylactic reaction to neomycin or streptomycin	
Precautions	Pregnancy	
MMR		
Contraindications	Anaphylactic reactions to egg ingestion or to neomycin	Tuberculosis (TB) or positive purified protein derivative skin test
	Pregnancy	Simultaneous TB skin testing
	Known altered immunodeficiency (hematologic and solid tumors; congenital immunodeficiency; long-term immunosuppressive therapy)	Breast-feeding
		Pregnancy of mother of recipient
		Immunodeficient family member or household contact
		Infection with HIV
		Nonanaphylactic reactions to eggs or neomycin
Precautions	Recent immunoglobulin administration	
Hib		
Contraindication	None identified	History of Hib disease
Hepatitis B		
Contraindication	Anaphylactic reaction to common baker's yeast	Pregnancy
Varicella		
Contraindication	Anaphylactic reaction to neomycin	Pregnancy of recipient's mother or other close household contact
	Pregnancy	Immunodeficient family member or household contact
	Known altered immunodeficiency (hematologic and solid tumors; congenital immunodeficiency; long-term immunosuppressive therapy)	Asymptomatic or mildly symptomatic HIV infection
		Humoral immunodeficiency (e.g. agammaglobulinemia)
Precautions	Recent immunoglobulin administration	
	Moderate or severe illness with or without fever	
PCV		
Contraindication	Severe allergic reaction after a previous dose or vaccine component	
Precaution	Moderate or severe acute illness with or without fever	

Note that acetaminophen given before administering DTP and thereafter q4h for 24 hours should be considered for children with a personal or family history of convulsions in siblings or parents. DTP, diphtheria, tetanus, pertussis; DTaP, diphtheria, tetanus, acellular pertussis; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus vaccine; MMR, measles, mumps and rubella; OPV, oral poliovirus vaccine; PCV, pneumococcal conjugate vaccine.

* *From CDC.* [39]

disappears in a community, the risks attributed to vaccines, real and perceived, may achieve increased prominence.

In some countries, particularly in the UK, concern over vaccine safety focused on the whole-cell pertussis vaccine led to erosion of confidence and a decline in the use of vaccines. Without vaccine-induced protective immunity the enlarging pool of susceptible people led to pertussis epidemics.[62]

In the USA, similar concerns led to the creation of the National Childhood Vaccine Injury Act of 1986 and established a compensation program for persons injured by vaccines.[63] This 'no fault' program means that people filing claims are not required to prove negligence on the part of either the health care provider or the manufacturer to receive compensation. The vaccine injury table was created to separate those possibly injured by vaccines from unrelated

claims. The table is adjusted as more research on vaccine side-effects becomes available (Table 3.20).[64]

Adolescent and adult immunization

The focus of reducing the vaccine-preventable diseases of children has been a success around the world, as vaccines have become one of the foundations of routine pediatric care. However, despite the availability of safe and effective vaccines, approximately 50,000–70,000 adults die each year in the USA from complications of infections with *Streptococcus pneumoniae*, influenza virus and hepatitis B virus, infections for which vaccines are routinely recommended for many adults and the elderly. In contrast to the coverage rates of childhood vaccines in the USA (and around the world), current utilization in the USA of these vaccines in target adult populations for which these vaccines are recommended was estimated in 2000 to be 64% for an influenza vaccine in over-65-year-olds and only 53% of seniors had ever received pneumococcal vaccine.

Vaccination of children can have an impact on adolescent and adult populations by altering the epidemiology of disease. Studies have shown that the introduction of varicella vaccine in the USA might result in an increase in zoster cases in the unvaccinated population.[65] [66] Exposure to varicella provides a natural boost to individuals who have previously had chickenpox, thereby delaying or preventing the development of shingles. Reducing the incidence of varicella through vaccination will reduce the number of adults who receive this natural boost.

As new vaccines become available for adolescents and adults, it will be increasingly important to develop delivery systems that can efficiently and effectively administer the vaccines as recommended. It has been suggested that this can be accomplished in part by integrated adolescent and adult vaccinations with other routine preventive services (Table 3.21).[67]

Special populations and circumstances

Although general recommendations can be made for routine vaccination, several groups and circumstances merit additional consideration. This includes an assessment of a person's host factors (e.g. pregnancy or immunocompromising condition) and exposure factors (e.g. known contact with a person with a vaccine-preventable disease, persons living in chronic care facilities and occupations or behaviors that increase the chances of exposure to a vaccine-preventable disease). In general, persons who are immunocompromised should receive special consideration before immunization. [41] [68] Table 3.22 Table 3.23 Table 3.24 summarize the immunization recommendations for immunocompromised persons.

Immunization in pregnancy

Even though all vaccines may be administered safely to children or pregnant women and to breast-feeding mothers, because of the theoretic risk associated with vaccination during pregnancy many health practitioners are understandably cautious when assessing the need for an immunization for pregnant women or women likely to become pregnant during the first 3 months of immunization. The combined tetanus and diphtheria toxoids (Td) are the only vaccines that are routinely recommended for pregnant women, if they have not received a Td booster within the previous 10 years. Before administering hepatitis B vaccine or influenza vaccine, a realistic consideration of the risk of disease often determines the decision to vaccinate. Live virus vaccines are generally not recommended for women who are pregnant, unless the threat of infection and its consequences outweighs concern over a potential adverse event to the developing fetus. Table 3.25 provides a summary of recommendations for vaccination during pregnancy. [41] [69]

Health care workers

Given the potential for health care workers to be exposed to infectious diseases through contact with patients and clinical specimens, and the potential for health care workers to transmit infections to susceptible patients, maintaining immunity is an integral component of prevention and control of infectious diseases in health care settings. Recommendations for the immunization of health care workers have been established; these also take into account the immunization needs of health care workers with special conditions, such as pregnancy, immunosuppression, HIV infection, diabetes, alcoholism and cirrhosis, and renal failure (Table 3.26 and Table 3.27). [70]

TABLE 3-20 -- National vaccine injury compensation program — vaccine injury table.*

NATIONAL VACCINE INJURY COMPENSATION PROGRAM — VACCINE INJURY TABLE		
Vaccine	**Illness, disability, injury or condition covered**	**Time period for first symptom or manifestation of onset or of significant aggravation after vaccine administration**
I. Vaccines containing tetanus toxoid (e.g. DTaP, DTP, DT; Td, or TT)	A. Anaphylaxis or anaphylactic shock	4 hours
	B. Brachial neuritis	2–28 days
	C. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable
II. Vaccines containing whole-cell pertussis bacteria, extracted or partial cell pertussis bacteria, or specific pertussis antigen(s) (e.g. DTaP, DTP, P, DTP-Hib)	A. Anaphylaxis or anaphylactic shock	4 hours
	B. Encephalopathy (or encephalitis)	72 hours
	C. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable
III. Measles, mumps and rubella vaccine or any of its components (e.g. MMR, MR, M, R)	A. Anaphylaxis or anaphylactic shock	4 hours
	B. Encephalopathy (or encephalitis)	5–15 days (not less than 5 days and not more than 15 days) for measles, mumps, rubella or any vaccine containing any of the forgoing as a component
	C. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable
IV. Vaccines containing rubella virus (e.g. MMR, MR, R)	A. Chronic arthritis	7–42 days
	B. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable
V. Vaccines containing measles virus (e.g. MMR, MR, M)	A. Thrombocytopenic purpura	7–30 days
	B. Vaccine-strain viral infection in an immunodeficient recipient	6 months
	C. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable

VI. Vaccines containing polio live virus (OPV)	A. Paralytic polio	
	• in a non-immunodeficient recipient	30 days
	• in an immunodeficient recipient	6 months
	• in a vaccine-associated community case	Not applicable
	B. Vaccine-strain polio viral infection	
	• in a non-immunodeficient recipient	30 days
	• in an immunodeficient recipient	6 months
	• in a vaccine-associated community case	Not applicable
	C. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable
VII. Vaccines containing polio inactivated virus (e.g. IPV)	A. Anaphylaxis or anaphylactic shock	4 hours
	B. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable
VIII. Hepatitis B vaccines	A. Anaphylaxis or anaphylactic shock	4 hours
	B. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable
IX. *Haemophilus influenzae* type b polysaccharide vaccines (unconjugated, PRP vaccines)	A. Early onset Hib disease	7 days
	B. Any acute complication or sequela (including death) of an illness, disability, injury or condition arising within the time period prescribed	Not applicable
X. *Haemophilus influenzae* type b polysaccharide conjugate vaccines	No condition specified	Not applicable
XI. Varicella vaccine	No condition specified	Not applicable
XII. Rotavirus vaccine	No condition specified	Not applicable
XIII. Any new vaccine recommended by the CDC for routine administration to children, after publication by Secretary, HHS of a notice of coverage[†]	A. No condition specified for compensation	
	B. Events described in manufacturer's package insert as contraindications to additional doses of vaccine	Not applicable
Effective date 22 October 1998.		

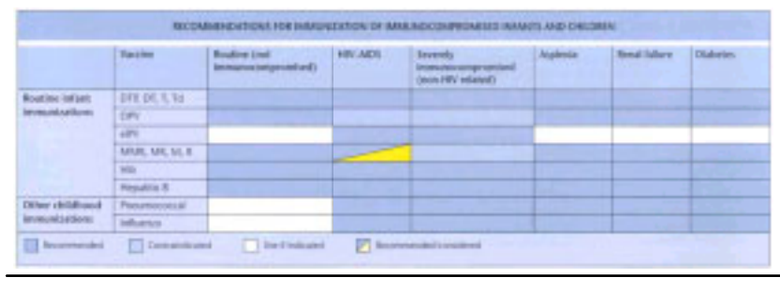
* With permission from US Department of Health and Human Services.[64]
† Pneumococcal conjugate vaccines are included in this category — on 22 May 2001 the secretary published a notice in the Federal Register announcing the addition of pneumococcal conjugate vaccines to the vaccine injury table under category XII.

TABLE 3-21 -- Recommended schedule of vaccinations for adolescents.*

RECOMMENDED SCHEDULE OF VACCINATIONS FOR ADOLESCENTS				
Immunobiologic	**Indications**	**Dose**	**Frequency**	**Route**
Hepatitis A vaccine	Increased risk of hepatitis A infection or its complications	720 EL U/0.5ml (HAVRIX)	A total of two doses at 0 and 6–12 months	im
		25U/0.5ml (VAQTA)	A total of two doses at 0 and 6–18 months	im
Hepatitis B vaccine	Not vaccinated previously for hepatitis B	5µg/0.5ml (Recombivax-HB)	A total of three doses at 0, 1–2 and 4–6 months	im
		10µg/0.5ml (Engerix-B)	A total of three doses at 0, 1–2 and 4–6 months	im
Influenza vaccine	Increased risk for complications caused by influenza or contact with persons at increased risk for these complications	0.5ml	Annually (September–December)	im
Measles, mumps and rubella vaccine	Not vaccinated previously with two doses of measles vaccine at =12 months of age	0.5ml	One dose	sc
Pneumococcal polysaccharide vaccine	Increased risk for pneumococcal disease or its complications	0.5ml	One dose	im or sc
Tetanus and diphtheria toxoids	Not vaccinated within the previous 5 years	0.5ml	Every 10 years	im
Varicella virus vaccine	Not vaccinated previously and no reliable history of chickenpox	0.5ml	One dose	sc
For the upper regimen for hepatitis A vaccine: an alternative dosage and schedule is 360 EL U/0.5ml, and a total of three doses administered at 0, 1 and 6–12 months. 0 Months represents the timing of the initial dose and subsequent numbers represent months after the initial dose. For varicella virus vaccine: adolescents = 13 years of age should be administered a total of two doses (0.5ml/dose) subcutaneously at 0 and 4–8 weeks. These recommendations apply to people aged 11–12 years. EL, enzyme-linked immunosorbent assay (ELISA) units.				

** From CDC.[67]*

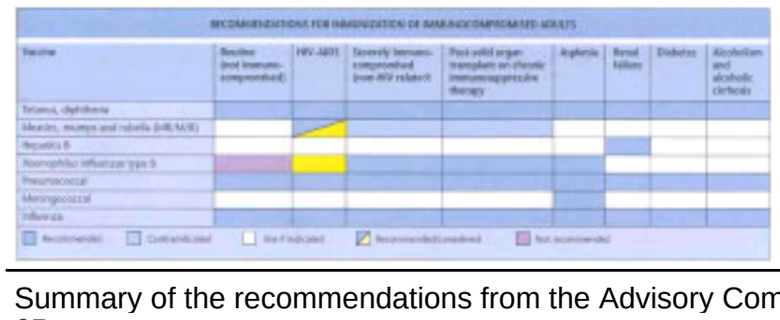
TABLE 3-22 -- Recommendations for immunization of immunocompromised infants and children.*



Summary of the recommendations from the Advisory Committee on Immunization Practices. Pneumococcal vaccine is recommended for those aged 2 years or more. Influenza vaccine is not recommended for children under 6 months of age. D, diphtheria; T, tetanus; P, pertussis; Td, tetanus and diphtheria toxoids; OPV, oral poliovirus vaccine; eIPV, enhanced-potency, inactivated poliovirus vaccine; MMR, measles, mumps and rubella; Hib, *Haemophilus influenzae* type b.

* *From CDC.* [68]

TABLE 3-23 -- Recommendations for immunization of immunocompromised adults.*



Summary of the recommendations from the Advisory Committee on Immunization Practices. Pneumococcal and influenza vaccines are recommended for those aged 65 years or over.

* *From CDC.* [68]

TABLE 3-24 -- Recommendations for the use of immune globulins in immunocompromised persons.*

RECOMMENDATIONS FOR THE USE OF IMMUNE GLOBULINS IN IMMUNOCOMPROMISED PERSONS			
Immune globulin	**Not immunocompromised**	**HIV infected**	**Severely immunocompromised**
Immune globulin	Recommended for infants and adults with contraindication to measles vaccine if exposed to measles	Recommended for symptomatic patients exposed to measles regardless of immunization status	Recommended for patients exposed to measles regardless of immunization status
		Recommended for persons with exposure to hepatitis A virus or who will travel to endemic areas	
Varicella-zoster	Recommended for newborns of mothers who develop chickenpox within 5 days before and 48 hours after delivery	Recommended for susceptible infants and adults after significant exposure to varicella-zoster	Recommended for susceptible infants and adults after significant exposure to varicella-zoster
	Recommended for exposed newborns (=28 weeks gestation) of susceptible mothers		
	Recommended for exposed pre-term (<28 weeks or <1000g body weight)		
	May be used for exposed, susceptible adults, exposed pregnant women, and infants <28 days		
Tetanus	Recommended for those with serious wounds who have received fewer than three doses of tetanus toxoid	Same as for not immunocompromised	Same as for not immunocompromised
Hepatitis B	Recommended for prophylaxis of infants born to hepatitis B surface antigen-positive mothers and susceptible persons with percutaneous, sexual or mucosal exposure to hepatitis B virus	Same as for not immunocompromised	Same as for not immunocompromised
Human rabies	Recommended for postexposure prophylaxis of persons not previously vaccinated against rabies	Same as for not immunocompromised	Same as for not immunocompromised
Summary of the recommendations from the Advisory Committee on Immunization Practices.			

* *From CDC.* [68]

TABLE 3-25 -- Vaccination during pregnancy.*

VACCINATION DURING PREGNANCY			
		Vaccine	**Indications for vaccination during pregnancy**
Live virus vaccines	Measles Mumps Rubella	Live-attenuated	Contraindicated
	Yellow fever	Live-attenuated	Contraindicated except if exposure to yellow fever virus is unavoidable
	Poliomyelitis	Trivalent live-attenuated (oral poliomyelitis vaccine)	Persons at substantial risk of exposure to polio

Inactivated virus vaccines	Hepatitis A	Killed virus	Data on safety in pregnancy are not available. Should weigh the theoretic risk of vaccination against the risk of disease
	Hepatitis B	Recombinant produced, purified hepatitis B surface antigen	Not contraindicated
	Influenza	Inactivated type A and type B virus vaccines	Recommended for women in 2nd and 3rd trimesters of pregnancy during the influenza season
	Japanese encephalitis	Killed virus	Should reflect actual risks of disease and probable benefits of vaccine
	Poliomyelitis	Killed virus (inactivated poliovirus vaccine)	Oral poliovirus vaccine preferred when immediate protection of pregnant females is needed; however, inactivated poliovirus vaccine is an alternative if complete vaccination series can be administered before exposure
	Rabies	Killed virus Rabies immunoglobulin	Should reflect actual risks of disease and probable benefits of vaccine
Live bacterial vaccines	Typhoid (Ty21a)	Live bacterial	Substantial risk of exposure
Inactivated bacterial vaccines	Cholera Typhoid	Killed bacterial	Should reflect actual risks of disease and probable benefits of vaccine
	Plague	Killed bacterial	Selective vaccination of exposed persons
	Meningococcal	Polysaccharide	Only in unusual outbreak situations
	Pneumococcal	Polysaccharide	Only for high-risk persons
	Haemophilus influenzae type b	Polysaccharide-protein conjugate	Only for high-risk persons
Toxoids	Tetanus-diphtheria	Combined tetanus-diphtheria toxoids (adult formulation)	Lack of primary series, or no booster within past 10 years
Immune globulins, pooled or hyperimmune		Immunoglobulin or specific globulin preparations	Exposure or anticipated unavoidable exposure to measles, hepatitis A, hepatitis B, rabies, or tetanus

** From CDC.*[68]

TABLE 3-26 -- Immunizing agents and immunization schedules for health care workers.*

IMMUNIZING AGENTS AND IMMUNIZATION SCHEDULES FOR HEALTH CARE WORKERS				
Generic name	**Primary schedule and booster(s)**	**Indications**	**Major precautions and contraindications**	**Special considerations**
Hepatitis A vaccine	Two doses of vaccine either 6–12 months apart or 6 months apart	Not routinely indicated in USA; recommended in those working with infected primates or with a laboratory researching hepatitis A virus	History of anaphylactic hypersensitivity to alum or 2-phenoxyethanol. The safety of the vaccine in pregnant women has not been determined — the risk associated with vaccination should be weighed against the risk for hepatitis A in women who may be at a high risk of exposure	
Meningococcal polysaccharide vaccine (tetravalent A, C, W135 and Y)	One dose in volume and by route specified by manufacturer; need for boosters unknown	Not routinely indicated in USA	The safety of the vaccine in pregnant women has not been evaluated; it should not be administered during pregnancy unless the risk of infection is high	
Typhoid vaccine, im, sc and po	im: one 0.5ml dose, booster 0.5ml every 2 years; sc: two 0.5ml doses, =4 weeks apart, booster 0.5ml sc or 0.1ml id every 3 years if exposure continues; po: four doses on alternate days The manufacturer recommends revaccination with the entire four-dose series every 5 years	Workers in microbiology laboratories who frequently work with *Salmonella typhi*	Severe local or systemic reactions to a previous dose. Ty21a (oral) vaccine should not be administered to immunocompromised persons or to persons receiving antimicrobial agents	Vaccination should not be considered an alternative to the use of proper procedures when handling specimens and cultures in the laboratory
Vaccinia vaccine (smallpox)	One dose administered with a bifurcated needle; boosters administered every 10 years	Laboratory workers who directly handle cultures with vaccinia, recombinant vaccinia viruses or orthopox viruses that infect humans	Contraindicated in pregnancy, in persons with eczema or a history of eczema, and in immunocompromised persons and their household contacts	Vaccination may be considered for those who have direct contact with contaminated dressings or other infectious material from volunteers in clinical studies involving recombinant vaccinia virus
Other vaccine-preventable diseases				
Tetanus and diphtheria toxoids	Two im doses 4 weeks apart; third dose 6–12 months after second dose; booster every 10 years	All adults	Except in the first trimester, pregnancy is not a precaution. History of a neurologic reaction or immediate hypersensitivity reaction after a previous dose History of severe local (arthus-type) reaction after a previous dose — these people should not receive further routine or emergency doses for 10 years	

Pneumococcal polysaccharide vaccine (23-valent)	One dose, 0.5ml, im or sc; revaccination recommended for those at highest risk 5 or more years after the first dose	Adults who are at increased risk of pneumococcal disease and its complications because of underlying health conditions; older adults, especially those who are aged 65 years or older and who are healthy	The safety of vaccine in pregnant women has not been evaluated; it should not be administered during pregnancy unless the risk of infection is high	Previous recipients of any type of pneumococcal polysaccharide vaccine who are at highest risk of fatal infection or antibody loss may be revaccinated 5 years or more after the first dose
Rubella live-virus vaccine	One dose sc; no booster	Indicated for both men and women with no documentation of prior vaccination on or after their first birthday or laboratory evidence of immunity; people born before 1957, except women who can become pregnant, can be considered immune	Pregnancy Immunocompromised persons Those with a history of anaphylactic reaction after administration of neomycin	The risk for rubella vaccine-associated malformations in the offspring of women pregnant when vaccinated or who become pregnant within 3 months after vaccination is negligible; such women should be counseled about the theoretic basis of concern for the fetus Measles, mumps and rubella vaccine is the vaccine of choice if recipients are likely to be susceptible to measles or mumps as well as to rubella
Varicella-zoster live-virus vaccine	Two 0.5ml doses sc 4–8 weeks apart if 13 years of age or older	Indicated if no reliable history of varicella or no serologic evidence of immunity	Pregnancy Immunocompromised persons History of anaphylactic reaction following receipt of neomycin or gelatin Avoid salicylate use for 6 weeks after vaccination	Vaccine is available from the manufacturer for certain patients with acute lymphocytic leukemia in remission Because 71–93% of persons without a history of varicella are immune, serologic testing before vaccination is likely to be cost-effective
Varicella-zoster immune globulin	If <50kg: 125U/10kg im; if =50kg: 625U	Indicated for those known or likely to be susceptible if at high risk of complications, (e.g. pregnant women) following close and prolonged exposure		Serologic testing may help in assessing whether to administer; if use prevents varicella disease, patient should be vaccinated subsequently
BCG	One percutaneous dose of 0.3ml; no booster dose recommended	Consider only when drug-resistant tuberculosis is prevalent, infection likely and tuberculosis control efforts less than optimal	Should not be administered to immunocompromised persons, pregnant women	In the USA, tuberculosis-control efforts are directed toward early identification, treatment of cases and preventive therapy
Other immunobiologics that are or may be indicated for health care workers				
Immunoglobulin (hepatitis A)	Postexposure: one im dose of 0.02ml/kg given 2 weeks or sooner after exposure	Indicated for those exposed to feces of infectious patients	Contraindicated in persons with IgA deficiency; do not administer within 2 weeks after measles, mumps and rubella vaccine, or 3 weeks after varicella vaccine Delay administration of mumps, measles and rubella vaccine for 3 months or more and varicella vaccine for 5 months or more	Administer in large muscle mass (deltoid, gluteal)
Immunizing agents strongly recommended for health care workers				
Hepatitis B recombinant vaccine	Two doses im 4 weeks apart; third dose 5 months after second; no booster	Those at risk of exposure to blood or body fluids	On the basis of limited data, no risk of adverse effects to developing fetuses is apparent Pregnancy should not be considered a contraindication to vaccination of women Previous anaphylactic reaction to common baker's yeast is a contraindication to vaccination	Prevaccination serologic screening is not indicated for persons being vaccinated because of occupational risk Those who have contact with patients or blood should be tested 1–2 months after vaccination to determine serologic response
Hepatitis B immune globulin	0.06ml/kg im as soon as possible, but no later than 7 days after exposure; a second dose should be administered 1 month later if the hepatitis B vaccine series has not been started	For persons exposed to blood or body fluids containing hepatitis B surface antigen and who are not immune to HBV infection		
Influenza vaccine (inactivated whole-virus and split-virus vaccines)	Annual im vaccination with current vaccine	Those who have contact with patients at high risk for influenza or its complications; those who work in chronic care facilities; those with high-risk medical conditions; those aged 65 years or more	History of anaphylactic hypersensitivity to egg ingestion	No evidence exists of risk to mother or fetus when the vaccine is administered to a pregnant woman with an underlying high-risk condition; influenza vaccination is recommended during second and third trimesters of pregnancy
Measles live-virus vaccine	One dose sc: second dose at least 1 month later	For persons born after 1957 without documentation of physician-diagnosed measles, serologic evidence of immunity or receipt of two doses of live-attenuated vaccine on or after the first birthday. Consider immunization for all health care workers without proof of immunity, even if born before 1957	Pregnancy Immunocompromised persons, including HIV-infected persons who have evidence of severe immunosuppression, anaphylaxis after gelatin ingestion or administration of neomycin Recent administration of immunoglobulin	Measles, mumps and rubella vaccine is the vaccine of choice if recipients are likely to be susceptible to rubella or mumps as well as to measles Persons vaccinated during 1963–1967 with a killed measles vaccine alone, killed vaccine followed by live vaccine, or with a vaccine of unknown type should be revaccinated with two doses of live measles virus vaccine

Mumps live-virus vaccine	One dose sc: no booster	Those believed to be susceptible can be vaccinated; those born before 1957 can be considered immune	Pregnancy Immunocompromised persons History of anaphylactic reaction after gelatin ingestion or administration of neomycin	Measles, mumps and rubella vaccine is the vaccine of choice if recipients are likely to be susceptible to measles and rubella as well as to mumps

TABLE 3-27 -- Recommendations for immunization of health care workers with special needs.*

RECOMMENDATIONS FOR IMMUNIZATION OF HEALTH CARE WORKERS WITH SPECIAL NEEDS							
Vaccine	**Pregnancy**	**HIV infection**	**Severe immunosuppression**	**Asplenia**	**Renal failure**	**Diabetes**	**Alcoholism and alcoholic cirrhosis**
BCG	Contraindicated	Contraindicated	Contraindicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated
Hepatitis A	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Recommended
Hepatitis B	Recommended	Recommended	Recommended	Recommended	Recommended	Recommended	Recommended
Influenza	Recommended	Recommended	Recommended	Recommended	Recommended	Recommended	Recommended
Measles, mumps and rubella	Contraindicated	Recommended	Contraindicated	Recommended	Recommended	Recommended	Recommended
Meningococcus	Use if indicated	Use if indicated	Use if indicated	Recommended	Use if indicated	Use if indicated	Use if indicated
Poliovirus vaccine (inactivated)	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated
Poliovirus vaccine (live, oral)	Use if indicated	Contraindicated	Contraindicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated
Pneumococcus	Use if indicated	Recommended	Recommended	Recommended	Recommended	Recommended	Recommended
Rabies	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated
Tetanus and diphtheria	Recommended	Recommended	Recommended	Recommended	Recommended	Recommended	Recommended
Typhoid (inactivated and Vi)	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated
Typhoid (Ty21a)	Use if indicated	Contraindicated	Contraindicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated
Varicella	Contraindicated	Contraindicated	Contraindicated	Recommended	Recommended	Recommended	Recommended
Vaccinia	Contraindicated	Contraindicated	Contraindicated	Use if indicated	Use if indicated	Use if indicated	Use if indicated
Summary of the recommendations from the Advisory Committee on Immunization Practices. The recommendations for pneumococcus vaccine is based on the person's underlying condition rather than the occupation. Influenza vaccine is recommended for pregnant women who will be in the second or third trimester during the influenza season. Measles, mumps and rubella vaccination is contraindicated in HIV-infected persons who have evidence of severe immunosuppression. Polio vaccination is recommended for unvaccinated health care workers who have close contact with patients who may be excreting wild polioviruses. Primary vaccination with inactivated poliovirus vaccine (IPV) is recommended because the risk for vaccine-associated paralysis after administration of oral live poliovirus vaccine (OPV) is higher among adults than among children. Health care workers who have had a primary series of OPV or IPV and who are directly involved in the provision of care to patients who may be excreting poliovirus may receive another dose of either OPV or IPV. Any suspected case of poliomyelitis should be investigated immediately. If evidence suggests transmission of wild poliovirus, control measures to prevent further transmission should be instituted immediately, including an OPV vaccination campaign.

Chapter 4 - Emerging and Re-emerging Pathogens and Diseases

Alexandra M Levitt
Ali S Khan
James M Hughes

INTRODUCTION

Humans and microbes have been engaged in a complex struggle for survival since human life began. Rapid microbial evolution allows bacteria, viruses and parasites to overcome human defenses (e.g. physiologic mechanisms and manmade drugs) and exploit human behaviors (e.g. sexual practices and methods of food preparation). Moreover, some zoonotic microbes have 'jumped' from animals to humans to evolve into major human pathogens. The ancestors of smallpox virus and malaria parasites, for example, probably became human pathogens 10,000 years ago when humans began to cultivate animals in settlements that were large enough to sustain human-to-human transmission. In recent times the AIDS virus, one of the most destructive pathogens in human history, is thought to have evolved from a virus carried by a nonhuman primate. [1]

Human evolution, though far slower and more difficult to observe, has in turn been influenced by microbes. Some pathogens have apparently been sufficiently virulent and widespread over the course of human history to affect the make-up of the human genome. The best evidence for this concerns malaria parasites, which are less likely to kill individuals who have globin gene alleles that make their red blood cells poor hosts for intracellular parasites (e.g. sickle hemoglobin and a- and ß-thalassemias).[2] Moreover, most or all components of the human immune system probably evolved to prevent

Figure 4-1 Interactions among humans, disease vectors and the environment that contribute to disease emergence. *Source: Institute of Medicine. Emerging infections: microbial threats to health in the United States. Washington DC: National Academy Press; 1992.[3] (In March 2003, the Institute of Medicine published a successor to this report, entitled Microbial threats to health: emergence, detection, and response.)*

disease agents from using human cellular machinery for microbial gene expression and reproduction.

Today, the increasing complexity of human behavior coupled with our ability to change our natural environment has hastened the pace of disease emergence and re-emergence (Fig. 4.1). Many modern human activities facilitate microbial transmission (e.g. air travel and the globalization of the food supply; see Table 4.1),[3] even while others have decreased it (e.g. improvements in sanitation, antimicrobial drug treatments, vaccines and disease eradication programs). Looking ahead, the most significant risk factor for disease emergence in the 21st century is likely to be population growth and urbanization, leading to the creation of megacities (a city with >10 million inhabitants)[4] throughout the developing world. Between 1990 and 2025, the number of people living in urban areas is expected to double to more than 5 billion, with 90% of the increase occurring in the poverty-ridden cities of Asia, Africa and Latin America.[5] By 2007, the number of urban dwellers will equal the number of rural dwellers and by 2015, the number of megacities will have grown from five in 1975 (three in the developing world) to 23 (19 in the developing world).[4] These population increases will be associated with further stresses on natural habitats and resources including clean air, water and food.

TABLE 4-1 -- Factors in the emergence of infectious diseases.

FACTORS IN THE EMERGENCE OF INFECTIOUS DISEASES
Modern demographic and environmental conditions that favor the spread of infectious diseases include:
• global travel;
• globalization of the food supply and centralized processing of food;
• population growth and increased urbanization and crowding;
• population movements due to civil wars, famines and other manmade or natural disasters;
• irrigation, deforestation and reforestation projects that alter the habitats of disease-carrying insects and animals;
• human behaviors, such as intravenous drug use and risky sexual behavior;
• increased use of antimicrobial agents and pesticides, hastening the development of resistance;
• increased human contact with tropical rainforests and other wilderness habitats that are reservoirs for insects and animals that harbor unknown infectious agents;
• deteriorating public health infrastructures in many parts of the world.
Adapted from references[3] [13]

New and re-emerging infectious diseases

Over the past 30 years, more than 40 new pathogens have been identified and characterized, often by using serological and molecular methods (Table 4.2). Some of these microbes cause diseases of global importance (e.g. HIV/AIDS, hepatitis C and rotavirus diarrheal disease). Others appear to be limited (thus far) to particular countries or continents (e.g. Ebola hemorrhagic fever in central Africa (although simian Ebola has also been identified in the Philippines); Argentinian, Bolivian, Venezuelan and Sabia-associated hemorrhagic fevers in South America; hantavirus pulmonary syndrome in the Americas; and new variant Creutzfeldt-Jakob disease in Europe). The most recent example is the outbreak of severe acute respiratory virus syndrome (SARS), almost certainly associated with a novel corona virus. This first emerged in Guangdong province in China but quickly spread through SE Asia. Air travel resulted in its rapid dissemination, most notably to Toronto, Canada. In addition to these newly identified diseases, several 'old' threats have re-emerged in new or drug-resistant forms (Table 4.3). Year-by-year examples of major outbreaks since 1993 are listed in Table 4.4 .

The essential role of the clinician in disease detection and reporting

Physicians are in the best possible position to observe and report unusual illnesses, syndromes and disease risk factors. In 1993, for example, an Indian health service physician reported a cluster of fatal cases of unexplained respiratory disease on Navajo land that proved to be a previously unrecognized disease (hantavirus pulmonary disease). In 1999, the first US outbreak of West Nile encephalitis was identified when an infectious disease physician reported unusual neurologic disease in three elderly people who lived in the same area (Fig. 4.2).[6] West Nile encephalitis-whose causative agent is carried by migratory birds in Asia, Africa and Europe and

transmitted to humans by mosquito bite — had never before been reported in the Western hemisphere. In 2000, physicians in New York, London and Toronto helped identify an international outbreak of leptospirosis among athletes returning home from a competition in Malaysian Borneo. These physicians reported their findings to Geosentinel, the surveillance network of the International Society of Travel Medicine, which alerted travel clinics in 11 countries.[7] An astute clinician was also responsible for reporting the first cases of a multistate outbreak of *Cyclospora* infection that was associated with imported raspberries.[8] Later cases were detected in 20 states, the District of Columbia and two Canadian provinces.

The US anthrax attacks in autumn 2001 also highlighted the crucial role of clinicians in monitoring unusual and dangerous diseases. Six of eight anthrax cases (one inhalational and seven cutaneous) that occurred in New York City were reported to city health authorities by alert physicians. Three were diagnosed by infectious disease physicians (including the inhalational case), one by a dermatologist, one by a public health doctor and one by an emergency room physician. Physicians also reported anthrax cases in Washington DC and New Jersey.

As these examples illustrate, the vigilance of physicians and other health care providers remains the most important factor in infectious disease surveillance and control.

Linkages between animal and human disease surveillance

Most emerging and many re-emerging infectious diseases of human health importance are zoonotic (i.e. animal diseases that can infect humans). The intimate relationship between animal and human health is illustrated by the 1999 outbreak of West Nile encephalitis, which was preceded by die-offs of crows; the 1999 Nipah encephalitis outbreak, which was preceded by illness in pigs; and the 1996 outbreak of new variant Creutzfeldt-Jakob disease, which was preceded by the recognition of an epidemic of bovine spongiform encephalopathy (BSE) among cows.

At the present time, formal mechanisms are being developed to link public health disease monitoring with surveillance for diseases in agricultural animals, migrating birds and wild animals. For example, the Centers for Disease Control and Prevention (CDC) and the US Department of Agriculture (USDA) are working in partnership with zoos across the nation to establish surveillance for West Nile encephalitis among zoo animals. Efforts are also under way to monitor outbreaks of animal influenza (e.g. in chickens and pigs) that might give rise to a new human pandemic strain, as well as to monitor antimicrobial resistance in zoonotic bacteria (e.g. *Salmonella* and *Campylobacter*) that infect agricultural animals. In the future, animal disease surveillance efforts must be expanded to include such potential bioterrorist agents as anthrax, plague, tularemia and Q fever.

In addition to protecting human health, rapid detection and control of animal diseases will benefit agriculture, help preserve wildlife species and avert economic losses due to expensive disease control measures (Table 4.5).

Molecular diagnostics and outbreak detection

To ensure optimal medical care, clinical diagnosis of unusual diseases must be confirmed by laboratory tests. Today's advances in microbial genomics, molecular immunology and bio-informatics are facilitating the development of accurate, rapid and sensitive diagnostics based on detection of microbe-specific or strain-specific nucleic acids or proteins. In the future, advances in human genomics may also allow the identification of individuals with increased genetic susceptibility to certain diseases or to severe manifestations of those diseases (Table 4.6).[9]

Molecular testing has the potential not only to confirm clinical diagnoses but also to facilitate the detection of outbreaks. This function may be especially important when individual cases are not related geographically or by other easily identifiable risk factors. Examples include:

¦ food-borne pathogens transmitted simultaneously to many localities when a contaminated product is shipped to supermarkets or restaurants in several states or countries;

¦ disease agents dispersed by international travelers, like the leptospirosis outbreak in Malaysian Borneo;

¦ an unannounced and undetected (covert) release of a bioterrorist agent in a public place.

TABLE 4-2 -- New microbes

NEW MICROBES			
	Microbe	**Type**	**Disease**
1973	Rotavirus	Virus	Major cause of infantile diarrhea worldwide
1975	Parvovirus B19	Virus	Aplastic crisis in chronic hemolytic anemia
1976	*Cryptosporidium parvum*	Parasite	Acute and chronic diarrhea
1977	Ebola virus	Virus	Ebola hemorrhagic fever
1977	Hantaan virus	Virus	Hemorrhagic fever with renal syndrome (HFRS)
1977	*Legionella pneumophila*	Bacterium	Legionnaires' disease
1977	*Campylobacter jejuni*	Bacterium	Enteric pathogens distributed globally
1980	Human T-lymphotropic virus type I (HTLV-I)	Virus	T-cell lymphoma-leukemia
1981	Toxin-producing strains of *Staphylococcus aureus*	Bacterium	Toxic shock syndrome
1982	*Escherichia coli* 0157:H7	Bacterium	Hemorrhagic colitis; hemolytic uremic syndrome
1982	Human T-lymphotropic virus type II (HTLV-II)	Virus	Hairy cell leukemia
1982	*Borrelia burgdorferi*	Bacterium	Lyme disease
1983	Human immunodeficiency virus (HIV)	Virus	Acquired immunodeficiency syndrome (AIDS)
1985	*Helicobacter pylori*	Bacterium	Peptic ulcer disease
1985	*Enterocytozoon bieneusi*	Parasite	Persistent diarrhea
1986	*Cyclospora cayetanensis*	Parasite	Persistent diarrhea
1988	Human herpesvirus 6 (HHV-6)	Virus	Exanthema subitum
1988	Hepatitis E	Virus	Enterically transmitted non-A, non-B hepatitis
1989	*Ehrlichia chafeensis*	Bacterium	Human ehrlichiosis
1989	Hepatitis C	Virus	Parenterally transmitted non-A, non-B hepatitis
1991	Guanarito virus	Virus	Venezuelan hemorrhagic fever
1991	*Encephalitozoon hellem*	Parasite	Conjunctivitis, disseminated disease
1991	New species of *Babesia*	Parasite	Atypical babesiosis
1992	*Bartonella henselae*	Bacterium	Cat-scratch disease; bacillary angiomatosis
1993	Sin Nombre virus	Virus	Hantavirus pulmonary syndrome (HPS)
1993	*Encephalitozoon cuniculi*	Parasite	Disseminated disease
1994	Sabia virus	Virus	Brazilian hemorrhagic fever
1994	Hendra virus	Virus	Encephalitic disease transmitted from horses to humans

1995	Human herpesvirus 8 (HHV-8)	Virus	Associated with Kaposi's sarcoma in AIDS patients
1996	New variant Creutzfeldt-Jakob disease agent	Prion	Progressive degenerative neurologic disease
1997	H5N1 strain of avian influenza	Virus	Influenza transmitted from chickens to humans; often fatal
1999	Nipah virus	Virus	Encephalitic disease transmitted from pigs to humans
2001	Human metapneumovirus	Virus	Acute respiratory infections
2002	Vancomycin-resistant *Staphylococcus aureus*	Bacterium	First vancomycin-resistant *Staph. aureus* strain identified in the United States
Updated from WHO. World Health Report, 1996. Fighting disease: fostering development. Geneva: WHO; 1996.			

Public health tools are already in place in Europe and the United States to identify and trace the source of geographically dispersed food-borne outbreaks by comparing molecular fingerprinting data from clinical and public health laboratories. This is the operating principle behind PulseNET,[10] a molecular subtyping network that has been used to detect several major multistate food-borne outbreaks (Table 4.7). In 1999, for example, PulseNET was used to detect an outbreak of *Salmonella* Newport infections by comparing the molecular fingerprints of 78 *Salmonella* cases from 22 states.

This technology has been shared with Canada, several Pacific Island nations and the European Union. Advances in genome sequencing and bio-informatics will allow this network and molecular epidemiology in general to use increasingly sophisticated typing methods to discover novel disease risk factors and linkages between cases.

In the future, molecular testing may also become a routine part of local efforts to detect intentionally caused outbreaks, for example, by applying environmental sensors that use automated molecular diagnostic tests to detect biologic agents that cause smallpox, anthrax and plague. Once these sensors are in operation, it may become possible to rapidly analyze the genetic make-up of bioterrorist agents (including antibiotic susceptibilities) before symptomatic cases of disease appear.

Being prepared for the unexpected

Infectious pathogens are extraordinarily resilient and have a remarkable ability to evolve, adapt and develop resistance to drugs in an unpredictable and dynamic fashion. Because we do not know what

TABLE 4-3 -- Resurging diseases

RESURGING DISEASES	
Disease or agent	**Factors in re-emergence**
Viral	
Rabies	Breakdown in public health measures; changes in land use; travel
Dengue and dengue hemorrhagic fever	Transportation; travel and migration; urbanization
Yellow fever	Favorable conditions for growth of the mosquito vector
Rift Valley fever	Infected humans, animals or mosquitoes traveled across East Africa to Saudi Arabia and Yemen
Parasitic	
Malaria	Drug and insecticide resistance; civil strife; lack of economic resources
Schistosomiasis	Dam construction, improved irrigation and ecological changes favorable to the snail host
Neurocysticercosis	Immigration
Acanthamebiasis	Introduction of soft contact lenses
Visceral leishmaniasis	War; population displacement; immigrations; habitat changes favorable to the insect vector; and increase in immunocompromised human hosts
Toxoplasmosis	Increase in immunocompromised human hosts
Giardiasis	Increased use of child-care facilities
Echinococcosis	Ecological changes that affect the habitats of the intermediate (animal) hosts
Trypanosomiasis (African sleeping sickness)	Breakdown in public health infrastructure
Bacterial	
Tuberculosis	Human demographics and behavior; industry and technology; international commerce and travel; breakdown of public health measures; microbial adaptation; the HIV/AIDS pandemic
Group A streptococcus	Uncertain
Trench fever	Breakdown of public health measures
Plague	Economic development; land use
Diphtheria	Interruption of immunization programs due to political changes
Pertussis	Refusal to vaccinate in some countries because of belief that pertussis vaccines are not safe
Salmonella	Industry and technology; human demographics and behavior; microbial adaptation; changes in food production
Pneumococcus	Human demographics; microbial adaptation; international travel and commerce; misuse and overuse of antibiotics
Cholera	International travel; introduced to South America from Asia by ship, with spread facilitated by reduced water chlorination and by contaminated food
Adapted from Lorber B. Are all diseases infectious? Ann Intern Med 1996;125;844–51.	

TABLE 4-4 -- Infectious disease challenges, 1993–2003.

INFECTIOUS DISEASE CHALLENGES, 1993–2003	
1993	Hantavirus pulmonary syndrome (United States)
1994	Plague (India)
1995	Ebola fever (Zaire)
1996	New variant Creutzfeldt-Jakob disease (United Kingdom)
1997	H5N1 influenza (Hong Kong); vancomycin-intermediate resistant *Staphylococcus aureus* (Japan, United States)
1998	Nipah virus encephalitis (Malaysia, Singapore)
1999	West Nile encephalitis (Russia, United States)

2000	Rift Valley fever (Kenya, Saudi Arabia, Yemen); Ebola fever (Uganda)
2001	Anthrax (United States); foot and mouth disease (United Kingdom)
2002	Vancomycin-resistant *Staphylococcus aureus* (United States)
2003	Severe acute respiratory syndrome (SARS)

new diseases will arise, we must always be prepared for the unexpected (see Table 4.4). In 1997, for example, an avian strain of influenza that had never before infected humans began to kill previously healthy people (see below). In 2002, the first vancomycin-resistant *Staphylococcus aureus* strain was identified in the United States.[11] Moreover, in 2001, the United States experienced a bioterrorist attack, a multistate outbreak of anthrax that necessitated antibiotic prophylaxis for more than 30,000 people. Rapid medical and public health action limited the outbreak to 11 inhalational cases, 11 cutaneous cases and five deaths.

These examples of unforeseen outbreaks, both naturally occurring and intentional, underscore the need to maintain a strong public health system that is supported by a well-informed and vigilant medical community.

Shifts in view of infectious disease in the past 50 years

Over the past 50 years, there have been significant shifts in how infectious diseases are viewed by the medical and scientific world and by the public. In the years following World War II, it was widely believed that humans were winning the war against infectious microbes. Vaccines and antibiotics, coupled with earlier improvements in urban sanitation and water quality, had dramatically lowered the incidence of infectious diseases. Therefore, it became possible to imagine a world in which infectious pathogens would no longer prey upon humanity. In 1962, the Australian Nobel prize winner Frank Macfarlane Burnet stated:

Figure 4-2 Spread of West Nile virus in the United States. In the 4 years since West Nile virus was first reported in the USA (in New York City), it has been detected in 44 states. *Source: National Center for Infectious Diseases, Centers for Disease Control and Prevention.*

> One can think of the middle of the twentieth century as the end of one of the most important social revolutions in history, the virtual elimination of the infectious disease as an important factor in social life.[12]

Five years later, Surgeon General William H Stewart expressed the views of many US doctors and health experts when he stated that it was time to 'close the book on infectious illnesses', as long as we continued to prevent disease through vaccination. He encouraged the public health community to turn its attention to chronic diseases. Over the following years, biomedical research in the USA became increasingly focused on heart disease, stroke and the 'war on cancer', which was declared by President Richard Nixon in 1971. Local and federal programs aimed at monitoring and studying infectious diseases were greatly reduced or abolished.

New diseases continue to emerge and re-emerge

In spite of optimistic predictions, infectious diseases continued to cause serious problems. As early as the 1950s, certain bacteria, such as *Staphylococcus aureus*, began to develop resistance to penicillin. In 1957 and 1968, new strains of influenza emerged in China and Hong Kong, respectively, and spread rapidly around the globe and in the 1970s there was a resurgence of sexually transmitted diseases in the United States (perhaps due in part to changes in human sexual behaviors and to the importation of antibiotic-resistant strains of gonorrhea by infected soldiers returning from Vietnam). The final blows to our complacent attitude toward infectious diseases came in the 1980s, with the appearance of AIDS and the re-emergence of tuberculosis, including multidrug-resistant strains.

By the early 1990s, many health experts no longer believed that the threat of infectious diseases was receding in the United States and the developed world. Growing concern about the threat of emerging infectious diseases was cogently expressed in a 1992 report issued by the Institute of Medicine (IOM) of the National Academies. The report, *Emerging infections: microbial threats to health in the United States*, emphasized the intimate links between US health and international health.[3] It described the major factors that contribute to disease emergence, including societal changes and microbial evolution (see Table 4.1). The report concluded that emerging infectious diseases are a major threat to US health and it challenged the US government to take action.

In 1994, the CDC answered the challenge by launching a national effort to revitalize the US capacity to protect the public from infectious diseases. This ongoing effort is described in *Preventing emerging infectious diseases: a strategy for the 21st century*.[13]

Looking back to the 1950s and 1960s it is useful to remember that very little was then known about how microbes evolve or develop drug resistance. In the 1970s and 1980s, with the development of molecular biology, biologists learned how resistance genes are carried on plasmids and transmitted from one bacterium to another. They also learned how quickly viruses can evolve by generating mutations with each round of replication, as well as by reassorting gene segments or jumping species barriers. As molecular tools became available, many new viruses (pathogenic and nonpathogenic) were discovered in humans, animals and plants.

Infectious diseases are a national security threat

Before 2001, US concerns about the impact of health issues on national security were focused primarily on events overseas[14] (Table 4.8). During the 1990s, security experts expressed particular concern about the destabilizing effects of HIV/AIDS in poor countries where high death rates among young adults have damaged economic, social, political, military and educational infrastructures and created vast numbers of orphans. In July 2000, the Group of Eight Industrialized Nations pledged to reduce deaths from HIV/AIDS, malaria, tuberculosis and vaccine-preventable diseases by supporting global health initiatives launched by the World Health Organization and other international groups (Table 4.9). These ongoing efforts (including the Global Fund to Fight AIDS, Tuberculosis, and Malaria (GFATM)) reflect a growing consensus that global health security must be a shared responsibility.

Since the autumn of 2001, domestic security concerns have taken center stage. The anthrax attacks illustrated that the United States is vulnerable to bioterrorist weapons. The medical and health care communities must therefore reorient themselves to be prepared for intentional as well as naturally occurring outbreaks.[15]

Physicians are one of the three cornerstones of the 'golden triangle' for bioterrorism preparedness, along with the health care delivery

TABLE 4-5 -- Agricultural costs of controlling diseases carried by food animals.

AGRICULTURAL COSTS OF CONTROLLING DISEASES CARRIED BY FOOD ANIMALS
When a dangerous animal-borne disease threatens human health or food safety, a government may be forced to slaughter large numbers of food animals as a control measure, despite considerable economic costs. Recent examples include two zoonotic diseases (Nipah encephalitis and H5N1 influenza) and two veterinary diseases (foot and mouth disease and bovine spongiform encephalopathy (BSE; also called mad cow disease)). Ingestion of beef containing the causative agent of BSE (a prion) may result in the development of a fatal human neurodegenerative illness (new variant Creutzfeldt-Jakob disease) many years later.
• *Nipah encephalitis.* In 1999 Malaysian health authorities were faced with an outbreak of encephalitis among farm workers, which had a nearly 50% mortality rate. The cause was a previously unknown paramyxovirus called the Nipah virus, which is carried by bats. To control the outbreak, millions of pigs were slaughtered within a few weeks, severely harming the Malaysian meat industry.
• *Avian influenza (strain H5N1).* In 1997, a similar precautionary measure was taken by the government of Hong Kong, which arranged the culling of all 1.6 million chickens on Hong Kong Island and the New Territories to prevent chicken-to-human transmission of a virulent avian form of influenza.

• *Bovine spongiform encephalopathy.* The European Union has temporarily banned the export of live cattle and cattle products (other than milk) from the United Kingdom and trade in these products has been affected on a global basis. Government officials have come under fire and consumers across Europe have changed their eating habits because of concern over the spread of BSE. Control measures, including the slaughter of affected cows, have thus far cost the UK government an estimated £3.5 billion sterling (about US$5 billion).
• *Foot and mouth disease.* The costs of controlling the 2001 outbreak of foot and mouth disease in the United Kingdom and continental Europe dwarfed those of the BSE outbreak and devastated the centuries-old British livestock industry. (Foot and mouth disease does not infect humans but can be spread by travelers who have contaminated soil on their shoes or clothing or who carry contaminated food products.) The St Patrick's Day parade in Ireland was cancelled due to concerns about spreading the virus and the British army was drafted to help bury the carcasses of animals slaughtered because of potential exposure to the disease. Officials credit high-quality animal health surveillance and importation restrictions for the absence of foot and mouth disease in the United States.

TABLE 4-6 -- Examples of genetic factors that influence susceptibility to disease or disease progression.

EXAMPLES OF GENETIC FACTORS THAT INFLUENCE SUSCEPTIBILITY TO DISEASE OR DISEASE PROGRESSION
• Alleles of the chemokine receptor gene CCR5 confer partial protection against HIV infection and the development of AIDS
• Globin gene alleles (e.g. sickle globin and a- and ß-thalassemias) confer partial protection against malaria
• Lack of the Duffy blood group on red cells (due to a mutation in a chemokine receptor gene) confers complete protection against *Plasmodium vivax* malaria
• The tt vitamin D receptor (VDR) genotype may reduce the risk of developing clinical tuberculosis
• Blood group O is associated with severe cholera
• Mutations in the cystic fibrosis gene may confer some protection against cholera
• HLA alleles may influence susceptibility to — or course of infection of — HIV/AIDS, hepatitis B, measles, hantavirus pulmonary syndrome, malaria, tuberculosis, human papillomavirus infection and coccidioidomycosis

system and public health officials.[16] All clinicians, regardless of their specialty, must have basic information about the clinical manifestations of such bioterrorist agents as variola virus (smallpox), *Yersinia pestis* (plague) and *Bacillus anthracis* (anthrax). They must have a high index of suspicion and know how to recognize unusual diseases and report them to local public health and law enforcement officials. The expertise and full engagement of the medical community are essential to the national effort to preserve health security. For further discussion of issues related to bioterrorism, see Chapter 6 .

CATEGORIES OF EMERGING AND RE-EMERGING INFECTIOUS DISEASES

For the purposes of this discussion, emerging and re-emerging threats may be grouped into five (sometimes overlapping) categories:[7]

- drug-resistant diseases;
- food-borne and water-borne diseases;
- zoonotic and vector-borne diseases;
- diseases transmitted through blood transfusions or blood products;
- chronic diseases caused by infectious agents.

Drug-resistant diseases

Drug-resistant pathogens are a growing menace to all people, regardless of age, sex or socio-economic background. They endanger people in affluent, industrial societies like the United States, as well as in less developed nations. Examples of clinically important microbes that are rapidly developing resistance to available antimicrobial agents include bacteria that cause pneumonia, ear infections and meningitis (e.g. *Streptococcus pneumoniae*), skin, bone and bloodstream infections (e.g. *Staphylococcus aureus*), urinary tract infections (e.g. *Escherichia coli*), food-borne infections (e.g. *Salmonella*) and infections transmitted in health care settings (e.g. enterococci) (Table 4.10). Many other pathogens — including the bacteria that cause tuberculosis and gonorrhea; the virus that causes AIDS; the fungi that cause *Candida* infections; and the parasites that cause malaria — are also becoming resistant to standard therapies. If we do not act to address the problem of antimicrobial resistance, it will become impossible to take for granted quick and reliable treatment of infections that have been a manageable problem since the late 1940s. Drug choices for the treatment of common infections will become increasingly limited and expensive and, in some cases, nonexistent.

Reasons for the rapid development of antibiotic resistance include the natural tendency of organisms to mutate and share genetic material. However, this process has been facilitated by:

- inappropriate prescription practices by physicians and veterinarians;
- unrealistic patient expectations that lead to requests for antibiotic treatment of nonbacterial infections;
- overuse of antibiotics by the agricultural industry;
- the economics of pharmaceutical sales;
- increased use of sophisticated medical interventions that require the administration of large quantities of antibiotics (e.g. transplant surgery and immunosuppressive and cytotoxic drug therapy).

Growing antibiotic resistance poses a substantial threat to modern gains in infectious disease control. About 70% of bacteria that cause infections in hospitals in many countries, including the US, are resistant to at least one of the drugs most commonly used to treat infections. The medical community must therefore join with patients and members of the agricultural and pharmaceutical industries in a common effort to promote appropriate use of antibiotics to safeguard their effectiveness for future generations. Steps to be taken by the European Union and the US government to facilitate this process are outlined in the Copenhagen Recommendations[52] and in A Public Health Action Plan to Combat Antimicrobial Resistance respectively. [17]

TABLE 4-7 -- Examples of multistate food-borne outbreaks in the United States, 1994–2002.

EXAMPLES OF MULTISTATE FOOD-BORNE OUTBREAKS IN THE UNITED STATES, 1994–2002			
Year	**Outbreak**	**Number of states**	**Food source**
1994	*Shigella flexneri*	2	Green onions, probably contaminated in Mexico
1994	*Listeria monocytogenes*	3	Milk, contaminated after pasteurization. The milk was consumed in one state, but two of the case patients traveled to other states before becoming ill
1995	*Salmonella enteriditis*	41	Ice-cream premix hauled in trucks that had previously carried raw eggs
1996	*Cyclospora cayetanensis*	20	Raspberries from Guatemala, mode of contamination unclear. Cases were also reported in the District of Columbia and two Canadian provinces
1996	*Escherichia coli* 0157:H7	3	Unpasteurized apple juice, probably contaminated during harvest
1996	Norwalk-like virus	5	Oysters, contaminated before harvest
1997	*Salmonella infantis*	2	Alfalfa sprouts, probably contaminated during sprouting
1997	*Cyclospora cayetanensis*	18	Raspberries imported from Guatemala, mesclun lettuce and products containing basil. Cases were also reported in the District of Columbia and two Canadian provinces
1997	Hepatitis A virus	4	Strawberries from Mexico distributed through the USDA Commodity Program for use in school lunches

1998	*Vibrio parahaemolyticus*	13	Raw oysters, contaminated before harvest
1998	*Shigella sonnei*	4	Imported parsley, probably contaminated during washing after harvest
1999	*Listeria monocytogenes*	22	Hot dogs, probably contaminated at plant after cooking
1999	*Salmonella* Muenchen	20	Unpasteurized orange juice
2000	Hepatitis A virus	2	Green onions or tomatoes served at two outlets of the same fast food chain
2000	*Salmonella* Newport	10	Imported manges, likely contaminated during treatment to kill fruit flies
2000	*Listeria monocytogenes*	8	Deli turkey, contaminated at the plant after cooking
2000	Norwalk-like virus	13	Salads in a 'boxed banquet' sent to several car dealerships in the US
2001	*Salmonella* Poona	16	Imported cantaloupe, probably contaminated in the field or shortly after harvest
2002	*Salmonella* Newport	5	Ground beef from a large commercial grinder
2002	*Escherichia coli* 0157:H7	6	Ground beef from a large commercial grinder
Update from reference[13] .			

TABLE 4-8 -- Biologic national security issues.

BIOLOGIC NATIONAL SECURITY ISSUES
• Diseases that spread across borders, crossing countries and continents (e.g. cholera, bacterial meningitis and measles)
• The emergence of new and antibiotic-resistant diseases that arise in one region and spread throughout the world (e.g. AIDS and drug-resistant TB)
• Environmental issues that may have global effects (e.g. pollution, loss of biodiversity, and global warming, which may affect the growth rate of insect vectors of disease)
• Population overgrowth that may lead to disease, war, famine and political instability
• Bioterrorism: the deliberate release of infectious agents by a terrorist or rogue nation
Adapted from Goldberg J. Our Africa problem. New York Times, March 2, 1997.

Food-borne and water-borne diseases

Twentieth-century improvements in sanitation, food sterilization and processing, and water treatment have greatly reduced the burden of food-borne and water-borne illnesses in developed countries, nearly eliminating many diseases that remain major killers in the developing world (e.g. typhoid fever, cholera and dysentery). Now, in the 21st century, however, there is growing evidence that modern factors such as centralized food processing and the appearance of new types of industrial chemicals may pose challenges to food safety and healthy water.

Food-borne diseases

Food-borne diseases cause an estimated 76 million illnesses, 325,000 hospitalizations and 5000 deaths in the United States each year.[18] As noted above, food-borne pathogens such as *Salmonella, Shigella, Cyclospora, Campylobacter* and *E. coli* 0157:H7 can be transmitted via commercial products that are processed in large quantities and shipped to different states or nations. Although techniques for sterile processing are very advanced, when contamination does occur it can affect many people in many different localities (see Table 4.7). A recent example is an outbreak of *E. coli* 0157:H7 (transmitted via hamburger meat) that affected people in 21 states and led to the recall of 18 tons of beef.[19]

Water-borne diseases

Microbial contamination of water can occur when animal or human sewage contaminates source water that is not adequately disinfected by filtration, chlorination or other methods. In addition, some parasites are resistant to routine water treatment methods. These include *Cryptosporidium*, the causative agent of a major disease outbreak in the Milwaukee drinking water system in 1993 that affected more than 400,000 people.[20] Moreover, some bacteria, viruses and parasites live in 'biofilms' — coatings on pipes and tubing — that may shield them from disinfection.[21] Microbes that live in biofilms in medical devices such as catheters and dialysis machines may be responsible for a significant proportion of health care-associated infections.

Associations between illness and water contaminants are often difficult to evaluate, since most people drink water every day, often from more than one source. Another complicating factor in estimating the national burden of water-related illness is the diversity of US

TABLE 4-9 -- Global health initiatives.

GLOBAL HEALTH INITIATIVES	
Four major global health initiatives were launched between 1998 and 2000.	
• ***Roll Back Malaria***, a global strategy to reduce deaths from malaria by increasing access to prompt and effective treatment (including protective intermittent therapy for pregnant women) and prevention tools (including insecticide-treated bednets); by facilitating rapid response to malaria outbreaks; and by developing new products for the prevention and treatment of malaria.	
• ***Stop TB***, a global strategy to stop the spread of TB around the world. One of its objectives is to promote implementation of the directly observed therapy short-course strategy (DOTS). The effective implementation of DOTS in NYC, in response to the epidemic in the late 1980s and early 1990s, has served as a model in the USA and around the world.	
• ***International Partnership Against AIDS in Africa***, a UNAIDS-led effort to mitigate the effects of the growing HIV/AIDS epidemic. In 1999, as part of this effort, the USA government launched the Leadership and Investment for Fighting an Epidemic (LIFE) Initiative, which provides support to the hardest-hit countries for reducing HIV transmission, improving treatment of HIV/AIDS and opportunistic infections, and strengthening national capacities to collect disease surveillance data and manage national HIV/AIDS programs. The Global AIDS Program is the CDC component of the LIFE Initiative.	
• ***Global Alliance for Vaccines and Immunization (GAVI)***, a global effort to strengthen childhood immunization programs and bring a new generation of recently licensed vaccines into use in developing countries. These include vaccines against hepatitis B, childhood meningitis, yellow fever and respiratory infections, which are the leading cause of death in children under age 5. Substantial resources for this purpose have been pledged by the Bill and Melinda Gates Foundation and the governments of Norway, the Netherlands and the United States. This initiative could save as many as 3 million lives every year.	
Targets for disease reduction	
These targets for disease reduction were endorsed at the Group of Eight Industrialized Nations Summit in Okinawa in July 2000.	
HIV/AIDS:	25% reduction in prevalence in young people by 2010
TB:	50% reduction in deaths by 2010
Malaria:	50% reduction in deaths by 2010

Adapted from reference[40]

source water systems, treatment systems, and distribution systems. Two recent trials [22] [23] found that tap water from selected municipal surface water systems may cause up to 40% of endemic cases of diarrheal illness. Full-scale studies to evaluate the safety of public drinking water systems are underway as part of the Congressionally mandated National Estimate of Waterborne Diease[24] , which will include information on the severity and economic impact of diarrheal illness associated with tap water.

Zoonotic and vector-borne diseases

Zoonotic pathogens

Many of the novel pathogens identified over the past decade are carried by animals. For example, Sin Nombre virus, which is carried by rodents, was identified in 1993 in the USA as the cause of hantavirus pulmonary syndrome. Hendra virus, carried by fruit bats, was identified in Australia in 1994 as a cause of encephalitis in humans and horses.[25] Nipah virus, which is also carried by fruit bats, was identified in 1999 in Malaysia as a cause of encephalitis in humans and swine.[26] Like Sin Nombre virus (a hantavirus), the Nipah and Hendra viruses (paramyxoviruses) are highly dangerous and there are as yet no drugs or vaccines for their treatment or prevention.

TABLE 4-10 -- Examples of emerging resistance in bacterial pathogens.

EXAMPLES OF EMERGING RESISTANCE IN BACTERIAL PATHOGENS
Gram-positive cocci
Methicillin-resistant Staphylococcus aureus
Vancomycin-resistant *Staphylococcus aureus*
Coagulase-negative staphylococci
Penicillin-resistant pneumococci
Macrolide-resistant streptococci
Vancomycin-resistant enterococci
Gram-negative cocci
Penicillin-resistant meningococci
Quinolone-resistant gonococci
Gram-negative bacilli
Enterobacter spp. and other Enterobacteriaceae with chromosomal ß-lactamases
Multidrug-resistant *Pseudomonas aeruginosa*
Stenotrophomonas maltophila
Acinetobacter spp. with novel ß-lactamases, aminoglycoside-modifying enzymes and other resistance mechanisms
Enterobacteriaceae with extended-spectrum ß-lactamases
Multidrug-resistant diarrheal pathogens (*Shigella* spp., *Salmonella* spp., *Escherichia coli*, *Campylobacter* spp.)
Acid-fact bacilli
Multidrug-resistant *Mycobacterium tuberculosis*
Multidrug-resistant *Mycobacterium avium* complex

Zoonotic agents can become established in any geographic area that has a suitable animal reservoir. The arenavirus that causes lymphocytic choriomeningitis (first isolated in 1933) was probably introduced into the New World at the same time as its vector, *Mus musculus*, the common house mouse. Plague (which is both animal-borne and vectorborne) was introduced into the United States in the early 1900s, via infected rats and fleas in ships that arrived at port cities. It quickly became established in the North American prairie ecosystem, infecting a wide range of animals, including native rodents and their fleas, which have been the most frequent sources of human infection. Like plague, newly emergent disease agents that are able to infect many animal species (e.g. Nipah and Hendra viruses) have the potential to spread worldwide.

Zoonotic pathogens are an important public health concern not only because of the illnesses they cause but also because new human diseases can arise from animal reservoirs. Pandemic strains of influenza can emerge from avian and swine reservoirs[27] and many experts believe that Ebola and Marburg hemorrhagic fever viruses are maintained in an animal host. As mentioned above, the AIDS virus probably evolved from a virus carried by a nonhuman primate (e.g. the chimpanzee *Pan troglodytes troglodytes*). [1]

Disease dispersion via insect vectors

Diseases that are carried by insect vectors (i.e. mosquitoes, fleas, ticks and other arthropods) can also spread into new geographical areas and infect new human populations. In 1999, for example, mosquito-borne transmission of three nonendemic diseases — malaria, dengue and West Nile fever — was reported in the United States. West Nile encephalitis may have entered New York City via an imported or migrating bird, an infected person or a mosquito that 'hitch-hiked' on an airplane; dengue fever most likely arrived in Texas via both people and mosquitoes. Asian tiger mosquitoes (*Aedes albopictus*) that can transmit dengue arrived in the United States in Houston in 1987 in imported used-tire casings[28] and more

recently appeared in California, in commercial shipments of a Chinese ornamental indoor plant called 'lucky bamboo'.[29]

While many cases of 'airport malaria' have been reported in Europe and North America (presumably involving small numbers of traveling mosquitoes), locally acquired malaria cases have also been identified that apparently involved at least one cycle of human-to-mosquito transmission. For example, a cluster of non-airport malaria cases was detected in Virginia in 2002, in a community that included a significant number of immigrants from malarious countries who might have asymptomatic malaria infections.[30] Another example of vector-borne disease spread is the recent identification of Rift Valley fever (previously seen only in Africa) in the Middle East.[31] Competent mosquito vectors for Rift Valley fever, a febrile hepatitis associated with encephalitis, retinitis and hemorrhagic fever (among both humans and animals), are present throughout the world.

Without ongoing public health attention, vector-borne diseases may continue to become established (e.g. Japanese encephalitis) or re-established (e.g. malaria or yellow fever) in developed countries in the future.

These concerns are underscored by studies on the effects of global warming in Alaska, which suggest that mosquito populations may grow larger as the area becomes warmer and wetter, increasing the risk of transmission of malaria parasites and encephalitis viruses if these disease agents are introduced into the state.[32]

Diseases transmitted through blood transfusions or blood products

Improvements in donor screening, serologic testing and transfusion practices have made the US blood supply one of the safest in the world, despite its size and complexity. However, because blood is a human tissue, it is a natural vehicle for transmission of infectious agents. During the 1980s, HIV was transmitted through clotting factor and blood transfusions, and during the 1990s, hepatitis C virus was transmitted via intravenous immunoglobulin. More recently, transmissions of Chagas'

disease trypanosomes[33] and West Nile virus[34] have been reported in surgical patients who received organ transplants or blood from infected persons.

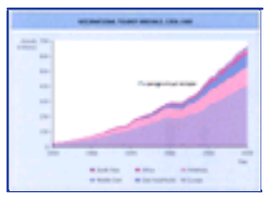

Figure 4-3 International tourist arrivals, 1950–99. International travel has increased by 160 million tourist arrivals since 1990, from 500 million to more than 660 million in 1999. In 1950, 15 countries received nearly 100% of the 25 million international tourist arrivals. In 1999, at least 70 countries and territories each received more than one million international tourist arrivals. The rate of growth in international arrivals in Africa alone was 7.8%, nearly twice the world average. ('Tourism' in these statistics includes business travel.) *Source: World Tourism Organization. WTO tourism highlights 2000, August 2000.*

TABLE 4-11 -- Infectious agents that cause or contribute to neoplastic diseases in humans.

INFECTIOUS AGENTS THAT CAUSE OR CONTRIBUTE TO NEOPLASTIC DISEASES IN HUMANS	
Epstein-Barr virus	Nasopharyngeal carcinoma (undifferentiated)
	Burkitt's lymphoma
	Post-transplant lymphoproliferative disease
	B-cell lymphoma
Hepatitis B and C viruses	Hepatocellular carcinoma
Human immunodeficiency virus	Lymphoma
Human herpesvirus 8	Kaposi's sarcoma
Human T-cell leukemia virus	Adult T-cell leukemia
Human papillomavirus	Cervical carcinoma
Helicobacter pylori	Gastric carcinoma
	Mucosa-associated lymphoid tissue lymphoma
Schistosoma haematobium	Bladder carcinoma
Liver flukes	Cholangiocarcinoma
Adapted from reference[13]	

Infectious diseases also have implications for the availability of blood and blood products, because people who have traveled in countries where they may have been exposed to blood-borne diseases are often excluded as blood donors. Examples include individuals who have recently visited malaria-endemic countries and people who have stayed for 6 months or more in the United Kingdom, where they might have ingested beef from cows with BSE and acquired new variant Creutzfeldt-Jakob disease.

Although research on artificial blood substitutes is under way, it is unlikely that they will be available in the near future. Therefore, continued vigilance is required to ensure the safety of the blood supply. As part of this effort, new blood screening tests must be developed and applied by blood banks as new blood-borne diseases are recognized.

Chronic diseases caused or exacerbated by infectious agents

Several chronic diseases once attributed to lifestyle or environmental factors (such as some forms of cancer, diabetes, heart disease and ulcers) are actually caused by or exacerbated by an infectious agent.[35] [36] Three of the six major causes of cancer death in the world are caused by infectious agents: hepatocellular carcinoma by hepatitis B and C viruses, cervical cancer by human papillomavirus and stomach cancer by *Helicobacter pylori* bacteria (see also Table 4.11). Hepatitis B and C are also major causes of cirrhosis and end-stage liver disease, while *H. pylori* causes peptic ulcer disease in addition to stomach cancer. Moreover, Epstein-Barr virus is associated with nasopharyngeal carinoma, Burkitt's lymphoma, B-cell lymphoma and post-transplant lymphoproliferative disease.

Current research suggests that some chronic cardiovascular, intestinal and pulmonary diseases may also have an infectious etiology. For example, Whipple's disease is caused by a bacterial infection (*Tropheryma whipplei*) [37] and tropical spastic paraparesis is caused by a viral infection (HTLV-I).[38] Potential associations are being investigated for many other illnesses and syndromes, including coronary artery disease (chlamydia infection);[39] Paget's disease (paramyxoviridae infection);[40] and Crohn's disease (mycobacterial infection).[41] There are also preliminary data suggesting that Wegener's granulomatosis responds to antibiotic therapy.[42] These findings raise the possibility that some chronic conditions, including cancer, asthma, arthritis and heart disease, may someday be treated with antimicrobial drugs or prevented by vaccines.

INFECTIOUS DISEASES AND THE GLOBAL VILLAGE

As stressed in the 1992 IOM report, US health and global health are inextricably linked.[3] [43] Modern factors that connect us culturally, commercially and physically such as air travel (Fig. 4.3) and the globalization of the food supply (Table 4.7) put us at risk of exposure to microbes that are endemic in other countries, whether we live in large cities or small rural hamlets. As the HIV/AIDS epidemic has illustrated, a disease that emerges or re-emerges anywhere in the world can spread far and wide.

Several diseases of global public health importance — including epidemic-prone diseases, newly emerging or re-emerging diseases, vaccine-preventable diseases and diseases slated for regional

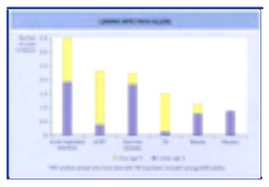

Figure 4-4 Leading infectious killers. *Source: World Health Organization. Overcoming antimicrobial resistance. Geneva: WHO.*

TABLE 4-12 -- Infectious diseases do not recognize borders.

INFECTIOUS DISEASES DO NOT RECOGNIZE BORDERS
From a public health point of view, domestic and international health are inextricably linked. Examples of disease spread from continent to continent include the following:
• *HIV/AIDS.* The AIDS virus apparently emerged in central Africa in the 1950s or earlier[1] and spread through most of Africa, Asia, Europe and the Americas during the 1970s and 1980s.
• *Tuberculosis.* This age-old scourge re-emerged in the 1980s (sometimes in a multidrug-resistant form) in cities around the world, including in the United States. By 2000, approximately 46% of newly identified US TB cases originated in other countries.

• *Malaria.* Although malaria was eliminated in the USA by the 1960s (through swamp-draining and vector control programs), approximately 1500 cases of malaria are reported in the USA each year. One-half occur in US travelers to malaria-endemic countries and the other half occur among foreign nationals who enter the USA already infected.
• *Vibrio cholerae 01, El Tor biotype.* This virulent strain of cholera has caused an ongoing pandemic that has lasted 40 years and affected more than 75 countries. Beginning in 1961, it spread from Indonesia through most of Asia into eastern Europe and Africa. From North Africa it spread to the Iberian peninsula and into Italy in 1973. Small outbreaks occurred in Japan and in the South Pacific in the late 1970s. In January 1991, epidemic cholera appeared in Peru and spread rapidly through most of Latin America, causing more than 1,000,000 cases by 1994. This was the first time in 100 years that a cholera pandemic had reached the New World.
• *Measles.* Fifty-six of the 87 cases of measles identified in the USA in 2000 were traced to importations of the virus from other countries. Twenty-six were direct importations, 18 were secondary cases and eight involved viruses whose DNA sequences suggested a foreign origin.
• *Influenza spread on cruise ships.* A 1997 outbreak of the A/Sydney strain of influenza occurred among people on a cruise that made stops in Canada and New England. The A/Sydney strain had been isolated in Australia too late in the year to be included in the vaccine formulated for the fall/winter flu season in the Northern hemisphere.
• *Polio.* Eliminated from the Western hemisphere since 1991, paralytic polio reappeared in Central America in 2000 (in Haiti and the Dominican Republic) and was attributed to waning immunization coverage rates in those countries.

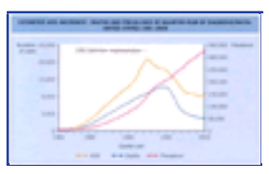

Figure 4-5 Estimated AIDS incidence (*adjusted for reporting delays), deaths and prevalence, by quarter-year of diagnosis/death — United States, 1981–2000. AIDS incidence increased rapidly through the 1980s, peaked in the early 1990s and then declined. The peak of new diagnoses was associated with the expansion of the AIDS surveillance case definition in 1993 (CDC. HIV/AIDS surveillance report, 2000;1 2[1]). As of 1996, sharp declines were reported in AIDS incidence and deaths. From 1998 through June 2000, AIDS incidence and deaths leveled off and AIDS prevalence continued to increase. Throughout the epidemic, approximately 85% of persons diagnosed with AIDS were aged 20–49 years. *Source: Centers for Disease Control and Prevention. HIV and AIDS — United States, 1981–2000. MMWR 2001;50(21);430–4.*

Figure 4-6 Adults and children estimated to be living with HIV/AIDS at the end of 2001. *Source: UNAIDS and World Health Organization, 2001 (http://www.unaids.org/barcelona/presskit/epigraphics/epicore_en4_0602.GIF).*

elimination or worldwide eradication — have resurged in recent years, spreading across countries and (sometimes) continents (Table 4.12). HIV/AIDS, tuberculosis, malaria and measles continue to be major infectious causes of death worldwide, along with acute respiratory infections and diarrheal diseases (Fig. 4.4). Globally important diseases that are of special domestic concern to the United States and other developed countries include HIV/AIDS, tuberculosis and pandemic influenza.

HIV/AIDS

HIV/AIDS incidence in the United States increased rapidly through the 1980s and early 1990s (Fig. 4.5), with the peak of new diagnoses occurring after the expansion of the AIDS surveillance case definition in 1993.[44] After 1996, with the introduction of effective combination antiretroviral therapies, sharp declines were reported in AIDS incidence and deaths, while AIDS prevalence continued to increase. At the present time, US disease prevention efforts are

targeted to young men who have sex with men, the group that currently exhibits the highest incidence nationally.[45]

Worldwide, an estimated 40 million people are living with HIV/AIDS (Fig. 4.6). In 2001 alone, there were 3 million HIV-related deaths and approximately 5 million new infections.

Tuberculosis

Tuberculosis is the attributable cause of one-third of all adult deaths in developing nations.[46] It is also a leading killer of young women. Once thought to be eliminated in Western countries, tuberculosis has reemerged in Europe and the United States, where multidrug-resistant *Mycobacterium tuberculosis* has been reported in 45 of the 50 states.[47] HIV infection confers the greatest known risk for the development of the disease, stimulating both the activation of latent infection and progression to primary disease. UNAIDS estimates that approximately 30% of all AIDS deaths result directly from tuberculosis.[48]

Pandemic influenza

New strains of influenza viruses can emerge unpredictably and spread rapidly and pervasively through susceptible populations, sometimes causing worldwide epidemics. This is due in large part to two features of the influenza virus: its ability to exchange genetic information between strains and its ability to occasionally 'jump' species barriers between mammalian and avian hosts. Experts agree that future pandemics of influenza are inevitable. In the United States alone, preliminary estimates indicate that an influenza pandemic would cause between 88,000 and 227,000 deaths and the economic impact would range from 71 to 166 billion dollars. [49]

The sudden and unpredictable emergence of potential pandemic strains of influenza was illustrated in 1997 by an outbreak of avian influenza A[H5N1] in Hong Kong, which raised the specter of a worldwide epidemic similar to the one that killed 20–50 million people (including 500,000 Americans) in 1918. Epidemiological studies conducted in consultation with the CDC suggested that the H5N1 virus was transmitted from chickens to people and only poorly (if at all) from person to person. Nevertheless, it was feared that the virus might recombine with a human influenza virus during the winter influenza season, creating a virulent strain capable of air-borne human-to-human transmission. To ensure that the H5N1 virus would have no opportunity to evolve, the Hong Kong government authorized the culling of all 1.6 million chickens in Hong Kong (see Table 4.5).

BIOTERRORISM PREPAREDNESS AND RESPONSE

Today, because of recent experiences with bioterrorism, the public health effort to address emerging infections has acquired a new dimension. The medical community must be ready to diagnose and treat not only naturally occurring illnesses but also a wide range of diseases that might be caused by agents engineered for deliberate dissemination.[50]

Instructions for preparing many 'homemade' threat agents are readily available and reports of arsenals of military bioweapons[51] raise the possibility that some terrorists may have access to highly dangerous agents that are engineered for mass dissemination as small-particle aerosols. Some of these agents (like variola virus) are highly contagious and often fatal. There is also concern that bioweapons may be altered physically or genetically to increase their ease of dispersion, change their modes of transmission or render them drug or vaccine resistant.

Responding to outbreaks caused by such agents will require the rapid mobilization of the health care system. There may be a large volume of patients (including both infected people and the 'worried well') and a corresponding need for large quantities of medical supplies, diagnostic tests and hospital beds. Efforts to mitigate illness

and death due to acts of bioterrorism therefore depend on the expertise and full engagement of physicians and other health care providers across the nations. The most likely way in which the next bioterrorist attack will be detected is through the vigilance of an astute clinician who reports something unusual to public health authorities. Rapid treatment of patients and chemotherapeutic prophylaxis or vaccination of exposed persons will also depend on coordinated action by clinicians. Once again, since political and geographic boundaries pose no barrier to the dissemination of these agents, it will be important to think of domestic preparedness in a global context to improve our health security.

Now more than ever, global health and well-being depend on the vigilance of concerned and well-informed clinicians. Each and every clinician plays a critical role in the public health early warning system for unusual infectious diseases, as well as in the public health response to bioterrorism (see Chapter 6).

Acknowledgment

We would like to thank Curtis Hendrickson of the National Center for Infectious Disease, Centers for Disease Control and Prevention, for his help in preparing the figures and Robin Moseley for proof-reading the manuscript.

Chapter 5 - Diseases of Unknown Etiology: The Role of Infectious Agents

David N Fredricks

INTRODUCTION

'A fool knows everything. A wise man knows his own ignorance.'
(Anon)

We do not understand what causes many diseases. Although risk factors, genetic susceptibility and pathologic manifestations are defined for many diseases, the proximate causes are elusive. Even for a disease such as schizophrenia, with a clear genetic component, environmental factors play a critical role as evidenced by concordance rates of only 30% for monozygotic twins. What are the environmental triggers in these diseases? Among the numerous exogenous factors, infectious agents have several characteristics that make them good candidates for producing occult disease. Microbes can replicate, induce direct tissue damage, promote inflammation and be transmitted to new susceptible hosts. Many microbes are difficult to detect and propagate in the laboratory, so the failure to isolate a pathogen from diseased tissue does not exclude an infectious cause.

Why look for infectious triggers in unexplained diseases? Identification of infectious agents that cause or contribute to disease would create new opportunities for better diagnosis, prevention and treatment.[1] Recent history is replete with instances where novel pathogens have been shown to cause diseases that were previously considered idiopathic. Table 5.1 lists some microbes detected since 1980 and the diseases they cause. These successes provide the impetus to search for occult infectious causes of other unexplained diseases.

The list of diseases with uncertain causation is long and includes many common chronic diseases. Chronic diseases account for 70% of all deaths and 400 billion dollars in annual health care costs in the USA. These chronic diseases include atherosclerosis, cancer and diabetes, all of which have been linked to infectious agents. Table 5.2 provides a partial list of idiopathic diseases for which an infectious cause has been proposed.

NEW MICROBE-DISEASE ASSOCIATIONS: LESSONS LEARNED

The discovery of Lyme arthritis as an infectious disease illustrates the impediments to forming microbe-disease links. In 1975 there was a cluster of cases of oligoarticular arthritis in children from Lyme, Connecticut, that was at first attributed to juvenile rheumatoid arthritis.[2] However, the high attack rate in the community was not consistent with the diagnosis of juvenile rheumatoid arthritis. After prompting by concerned mothers, public health authorities initiated an investigation that eventually resulted in the description of a new disease syndrome, Lyme arthritis. Although evidence suggested that ticks transmit Lyme disease and antibacterial therapy is curative, identification of the causative bacterium was delayed by several years. *Borrelia burgdorferi* was isolated from *Ixodes* ticks in 1982 and identified as the cause of erythema migrans rash, arthritis and other manifestations of Lyme disease.[3] Thus, even with strong evidence implicating a bacterial infection in Lyme disease, identification of the infectious agent was difficult.

Was Lyme disease a new disease? *Borrelia burgdorferi* was detected in a mouse specimen from Massachusetts collected in 1894[4] and ticks from Long Island collected in the 1940s,[5] suggesting that the agent of Lyme disease has been present in the environment for many years. Illness compatible with Lyme disease was described in Europe in the early 1900s. Lyme disease is currently the most common tick-borne illness in the USA. It is hard to believe that Lyme disease was not present in our more bucolic ancestors. It is likely that *Borrelia burgdorferi* has been producing human disease for many decades, if not centuries.

The failure to identify the infectious nature of Lyme disease prior to 1975 reflects at least two problems. The first is inadequate disease surveillance. If the rates of arthritis, pneumonia or encephalitis are not tracked in a community, then we will miss spikes in disease that may represent outbreaks of infectious disease and therefore we will miss the opportunity to identify novel infectious agents. The second problem is our failure to consider the hypothesis of infection. If clinical patterns do not fit our preconceived notions of an infectious disease, we tend to dismiss them as noninfectious and a search for infectious agents is not pursued.

Hantavirus pulmonary syndrome is another disease that has been linked to a recently described infectious agent. A cluster of unexplained respiratory deaths in previously healthy adults was noted in the Four Corners area of the western USA in 1993.[6] Since these patients had a febrile prodrome, an infectious disease was suspected. The US Centers for Disease Control and Prevention initiated an investigation after being alerted by physicians in the Indian health service. Sera from affected patients were screened to detect antibodies to known respiratory pathogens, but no seroreactivity was noted. However, patients' sera did have antibodies that targeted hantavirus antigens. Reverse transcriptase polymerase chain reaction (PCR) using primers complementary to conserved hantavirus RNA sequences identified a novel hantavirus, later named Sin Nombre virus (SNV), as the cause of this respiratory syndrome. A climate-related expansion in the deer mouse population that harbors SNV is believed to have increased contact between mice and humans, resulting in the outbreak. Subsequent investigations have revealed that hantaviruses capable of producing hantavirus pulmonary syndrome are found throughout the Americas.

The etiologic agents of Lyme disease and hantavirus pulmonary syndrome were identified after disease outbreaks with unique clinical syndromes in small, well-circumscribed communities. It is clear that these microbes produced human disease long before their identification as pathogens. Why were these microbes undiscovered for so long? If a novel microbe causes sporadic disease, disease with unremarkable clinical features or only affects a few individuals in a large population, then there may be insufficient evidence to prompt a search for an infectious cause. If the deer mouse population of the Four Corners area of the USA had not increased in 1993, would we know about hantavirus pulmonary syndrome today? What other infectious agents lurk beneath our radar screen for detection?

TABLE 5-1 -- Infectious agents identified since 1980 and the diseases they cause.

INFECTIOUS AGENTS IDENTIFIED SINCE 1980 AND THE DISEASES THEY CAUSE	
Microbe	**Disease**
Helicobacter pylori	Peptic ulcer disease, gastric adenocarcinoma
Borrelia burgdorferi	Lyme disease
Tropheryma whipplei	Whipple's disease
Campylobacter cinaedi	Proctitis
Streptococcus iniae	Cellulitis
Bartonella henselae	Cat scratch disease, bacillary angiomatosis
Escherichia coli 0157:H7	Hemolytic-uremic syndrome
Campylobacter	Guillain-Barré syndrome
Anaplasma phagocytophaga	Human granulocytic 'ehrlichiosis'
Ehrlichia chaffeensis	Human monocytic ehrlichiosis

Rickettsia japonica	Spotted fever
Mycoplasma fermentans	Arthritis
Mycobacterium genavense	Disseminated mycobacteriosis in AIDS
HIV	AIDS
Human herpesvirus 6	Roseola infantum
Human herpesvirus 7	Unknown
Human herpesvirus 8	Kaposi's sarcoma
Human metapneumovirus	Respiratory tract infection
Nipah virus	Encephalitis
Hendra virus	Encephalitis
Hepatitis C virus	Hepatitis, hepatocellular carcinoma
Hepatitis E virus	Hepatitis
Cyclospora cayetanensis	Diarrhea
SARS coronavirus	Severe acute respiratory syndrome (SARS)

TABLE 5-2 -- Diseases of unknown etiology suspected to be caused by infectious agents.

DISEASES OF UNKNOWN ETIOLOGY SUSPECTED TO BE CAUSED BY INFECTIOUS AGENTS
Crohn's disease
Ulcerative colitis
Sprue
Necrotizing enterocolitis of newborns
Sclerosing cholangitis
Primary biliary cirrhosis
Cholelithiasis
Brainerd diarrhea
Scleroderma
Ankylosing spondylitis
Seal finger
Polymyositis
Polyarteritis nodosa
Rheumatoid arthritis
Systemic lupus erythematosus
Wegener's granulomatosus
Behçet's syndrome
Goodpasture's syndrome
Takayasu's arteritis
Eosinophilic pustular folliculitis
Sweet's syndrome
Psoriasis
Kawasaki's disease
Sarcoidosis
Kikuchi's disease
Multiple sclerosis
Schizophrenia
Obsessive-compulsive personality disorder
Diabetes mellitus
Cancer
Chronic fatigue syndrome
Atherosclerosis
Idiopathic pulmonary fibrosis
Bronchiolitis obliterans with organizing pneumonia
Idiopathic pneumonia syndrome
Still's disease
Malakoplakia
Bacterial vaginosis
Nephrolithiasis
Chronic culture-negative prostatitis

A novel paramyxovirus, human metapneumovirus, has been linked to respiratory tract infections in children.[7] The illness resembles respiratory syncytial virus infection and is caused by a phylogenetically closely related virus. Serologic evidence suggests that most people are infected with this virus at an early age. Thus, even though human metapneumovirus infection appears to be ubiquitous, the virus was only recently identified. Another novel paramyxovirus, Nipah virus, was recently linked to encephalitis and respiratory tract infections in pig farmers in Malaysia and Singapore.[8] Japanese encephalitis virus was initially suspected in the outbreak, but this hypothesis proved wrong. A syncytium-forming virus was eventually isolated from cell cultures of cerebrospinal fluid and the infection was identified as a porcine zoonosis. If novel microbes produce disease that mimics other well-known and endemic infectious agents, then their discovery may be impeded. When we encounter a patient with pneumonia or encephalitis who has a negative evaluation for infection, we virtually never push to find novel infectious agents but rather label the illness as idiopathic and move to our next case.

Helicobacter pylori and peptic ulcer disease: a new microbe for an old disease

Another barrier to the identification of microbial triggers of disease is the intellectual inertia that derives from entrenched theories of pathophysiology. Until the 1980s, peptic ulcer disease (PUD) was thought to be caused primarily by excessive gastric acid secretion. Interventions were thus aimed at reducing acid secretion by pharmacologic or surgical means. Although these interventions were usually successful, there was a high rate of disease relapse. In 1984 Marshall and Warren reported finding a unique spiral bacterium in a high percentage of patients with PUD.[9] The association of a novel bacterium with PUD was initially met with great skepticism. Although *H. pylori* was detected in most patients with PUD, it was also detected in patients without PUD, raising questions about the specificity of the association between bacterium and disease. The most compelling argument that *H. pylori* causes PUD comes from antibiotic treatment trials showing that eradication of *H. pylori* eliminates PUD, while bacterial persistence is associated with disease relapse. The shift in therapeutic focus from antiacid to antibacterial interventions has radically changed the diagnosis and management of PUD. Peptic ulcer disease is now curable with antibiotic therapy, and elective surgeries such as vagotomy, antrectomy and gastrectomy for PUD are now virtually obsolete.

Why was the association between *H. pylori* and PUD missed for so many years? *Helicobacter pylori* infection does not behave like other infectious diseases that are more familiar. Patients with *H. pylori* infection lack a prominent acute inflammatory response and the infection typically has a chronic course. If patients with *H. pylori* infection developed high fever, intense leukocytosis and abscess formation, then the infectious nature of PUD would have been more apparent. The fact that a bacterium can produce a chronic, subtle, stable infection emphasizes the need to expand our definition of what syndromes may constitute infectious diseases. *Helicobacter pylori* can be easily visualized in stomach tissue with light microscopy and conventional tissue stains and cultivated in the laboratory using conventional culture media in a micro-aerophilic environment. As noted by Martin Blaser, 'pathologists who now easily identify these organisms using such stains did not previously (before 1983) report and probably did not even see these organisms in histologic sections. Dogma dulls the senses ...'.[10] If a microbe such as *H. pylori* can escape our detection, then it may not be surprising that other more stealthy microbes associated with idiopathic diseases may also escape detection.

Elusive associations and hidden pathogens

If microbes cause some idiopathic diseases, why do they remain concealed? There are several reasons why microbe-disease associations may be missed. The first reason is the failure to consider the

hypothesis of infection. If a disease has metabolic or autoimmune features, then an infectious trigger may not be sought. As evidenced by *H. pylori* and PUD, we need to at least consider the possibility that diseases have an infectious cause, even when we think we understand the pathophysiology.

Second, microbes may initiate an inflammatory cascade but be absent when disease is manifest — a 'hit and run' model of disease causation. Rheumatic heart disease arising from group A streptococcal pharyngitis is an example. The hypothesis of molecular mimicry poses that antibodies directed against bacterial antigens also bind to tissue in the myocardium and heart valves, resulting in myocarditis or valvular heart disease. Disease may occur after *Streptococcus pyogenes* is cleared from the pharynx and is thought to be mediated by ongoing antigenic stimulation from shared epitopes. Trying to detect *S. pyogenes* bacteria in patients with old rheumatic heart disease would thus not be a successful strategy. When microbes have fled the scene of the crime, an immunologic 'fingerprint' may be the only evidence establishing a connection between microbe and disease.

Third, epidemiologic features of disease may mask associations with infectious agents. It is easiest to make an association between an uncommon microbe and a rare but unique clinical syndrome that occurs in all infected patients, such as seen with rabies virus infection and rabies encephalitis. In this setting, all patients who are infected develop disease (high infection 'penetrance'), and all patients who lack infection are free of disease. In contrast, when common microbes cause uncommon diseases, the association between microbe and disease may be obscured. For instance, about 90% of adults are seropositive for Epstein-Barr virus (EBV), but only a small fraction of patients with EBV infection develop EBV-associated malignancies such as nasopharyngeal carcinoma, Burkitt's lymphoma or Hodgkin's malignancy. Being seropositive for EBV does not substantially increase a person's risk for malignancy over that found in the general population because the background seroprevalence is so high. The rarity of these tumors suggests that genetic or additional environmental factors are also required for carcinogenesis. Infection with EBV may be necessary but not sufficient for tumor formation. Identifying rare outcomes associated with common infections thus presents a challenge.

In a similar fashion, the causal relationship between a common infection and a common disease may also be obscured. How would we determine whether human herpesvirus (HHV)-6 causes dementia — an entirely hypothetical proposition? It would be difficult to determine the causal relationship between this common, latent viral infection and a common neurodegenerative condition of the elderly.

Fourth, diseases may result from pathogenic microbial communities. Failure to identify all co-pathogens in the community will lead to spurious conclusions about disease causation. We are familiar with the paradigm in which each disease is caused by a single microbe. What if disease required the interaction of several microbes? In this setting, identification of a single pathogen may not reliably predict disease. The synergistic interaction between hepatitis D virus and hepatitis B virus is an example of this interaction. Hepatitis D virus is a defective virus that requires hepatitis B surface antigen for infectivity. Patients who have chronic stable hepatitis B infection can develop fulminant hepatitis after co-infection with hepatitis D. Bacterial communities may also cause disease. Periodontitis is a disease that has been linked to particular assemblages of pathogenic bacteria at the tooth surface. Some gastrointestinal diseases may be caused by aberrant microbial communities, including ulcerative colitis and Crohn's disease.

Fifth, conventional microbial detection technologies may miss unconventional microbes. Microbes are most likely to be associated with disease when they are present in high numbers, are visible with conventional stains, are large enough to be seen with light microscopy or are cultivated using conventional media. Novel microbes associated with still unexplained diseases likely do not possess these characteristics; the low-hanging fruit has been picked and the remaining fruit will require more work and some technical innovation to grasp a more elusive harvest. When colony-forming units of bacteria are compared with directly observed bacterial counts in environmental niches, only about 1% of bacteria are amenable to laboratory cultivation.[11] When the cultivated bacteria present in human associated niches such as the gut and mouth are compared with the representation of bacteria detected by analysis of bacterial nucleic acid sequences, a large percentage of uncultivated and previously undescribed bacteria are detected with sequence-based methods.[12] [13] These findings underscore the limitations of conventional methods of microbial detection and point the way toward finding novel microbes.

METHODS FOR NOVEL PATHOGEN DISCOVERY

For most idiopathic diseases, the application of conventional microbial detection methods such as cultivation, serology and microscopy has failed to reveal a microbial culprit. If microbes cause some idiopathic diseases, then their discovery will likely necessitate the use of unconventional methods, such as those relying on the detection of microbial nucleic acid sequences.[14] There are several advantages to the nucleic acid approach. All known infectious agents contain nucleic acids (with the possible exception of prions) and thus it should be possible to detect all pathogens. Each unique microbe has a unique complement of nucleic acid so it is possible to distinguish between microbes on the basis of these distinctive sequences and to identify novel microbes based on phylogenetic relationships inferred from shared nucleic acid sequences. Amplification methods, such as PCR, can be used to detect extremely small quantities of microbial nucleic acid, resulting in highly sensitive assays.

Several sequence-based methods have successfully been used to discover novel pathogens. Consensus sequence PCR was used to identify the cultivation-resistant bacterium that causes Whipple's disease (see below). Representational difference analysis was used to identify Kaposi's sarcoma-associated herpesvirus or HHV-8, the cause of Kaposi's sarcoma.[15] This method employs subtractive hybridization and PCR amplification to isolate nucleic acid sequences that are preferentially found in diseased tissue as compared with normal tissue. Microbial nucleic acid sequences can be enriched with this process, although the resulting nucleic acid sequences may not be phylogenetically informative or even derive from a microbe. Hepatitis C virus was discovered by screening cDNA expression libraries with serum from an affected patient.[16] Viral particles were concentrated from the blood of a chimpanzee experimentally infected with the non-A non-B hepatitis agent. Nucleic acid was extracted, cloned into an expression library and then probed with immune serum. From one million clones screened, a single reactive clone was identified and the sequence of this clone was used to identify other overlapping clones and to assemble the genome of hepatitis C, a member of the Flaviviridae.

Other methods for pathogen discovery will likely emerge based on the differential expression of microbial or host nucleic acid sequences in diseased tissue, or on the simultaneous detection of thousands of signature microbial nucleic acid sequences using microarrays (hybridization to high-density nucleic acids anchored to solid supports) or Luminex beads (hybridization to nucleic acids attached to coded beads in solution).

Pitfalls of pathogen discovery

Nucleic acid amplification methods can detect a single molecule of nucleic acid in a reaction. This strength is also a weakness. If billions

of molecules are created in a PCR reaction and a single molecule can produce a positive result, then there is great potential for contamination unless rigorous laboratory procedures are employed to prevent PCR product carry over. Laboratory contamination can also arise from other tissue samples, reagents or equipment. Although reagents and solutions may be sterile, these same solutions frequently contain microbial nucleic acid sequences. Even blood culture bottles contain bacterial and fungal nucleic acids that are likely derived from the media components.[17] Thus, laboratories employing methods for the detection of microbial nucleic acid sequences must adopt stringent measures to control contamination and should confirm results to avoid erroneous conclusions.

The challenge of making new microbe-disease links is illustrated by the association between HHV-8 and sarcoidosis. Sarcoidosis is a systemic inflammatory disease of unknown etiology that is suspected to have an infectious cause. Human herpesvirus-8 is a recently discovered human herpesvirus that causes Kaposi's sarcoma, but may cause other diseases. In 1997 a research team reported finding evidence of HHV-8 DNA in 97% of tissue samples from patients with sarcoidosis, but only 6% of tissue samples from subjects without sarcoidosis.[18] This association was highly statistically significant, with a p value of <0.0001. A nested PCR assay was used to detect HHV-8, a protocol that is prone to contamination from previously amplified PCR products. At first glance, this study gives compelling evidence that HHV-8 is associated with sarcoidosis. Many control samples were processed and found to be negative by HHV-8 PCR and results of the first PCR assay were mostly confirmed in a second PCR assay employing a different HHV-8 gene target. Nevertheless, at least seven laboratories from different countries were not able to confirm the association between HHV-8 and sarcoidosis.[19] Multiple PCR and serologic assays were used to assess HHV-8 infection in sarcoid tissues/sera and the results were strikingly negative. The association between HHV-8 infection and sarcoidosis thus appears to be spurious. This saga demonstrates the potential for rounding up the wrong suspects in our search for etiologic agents of disease. To build a strong case for causation, data should be collected using Hill's criteria for causal association as a guide and results should be reproducible in other laboratories.[14]

MULTIFACTORIAL CAUSATION AND INFECTIOUS DISEASES

For many diseases, our understanding of the causal factors is incomplete. In order to investigate the elements that may contribute to disease production, various measurable risk factors are analyzed to determine whether there is a relationship between exposure to the risk factor and disease. When a risk factor is identified, intervention measures are proposed to reduce its impact. Unfortunately, risk factors may have little or nothing to do with causation. In the case of infectious diseases, easily measured risk factors may overlook occult infectious agents. For example, several studies showed that use of the recreational drug amyl nitrate (poppers) was a risk factor for the development of AIDS. Does amyl nitrate cause AIDS? No, but amyl nitrate use may facilitate risk-taking behaviors that lead to transmission of HIV, which causes AIDS. If intervention studies rely only on risk factor analysis and do not attempt to interrupt the proximate causes of disease, then our efforts at prevention and treatment will be hobbled.

The same caveat is true for atherosclerotic coronary artery disease (CAD). Conventional risk factors associated with CAD include hypertension, smoking, diabetes, hyperlipidemia and family history, but do these factors cause CAD or are they like amyl nitrate and fail to identify the proximate cause of disease? Infectious agents such as *Chlamydia pneumoniae* and cytomegalovirus have been proposed to cause or contribute to CAD (see below). The presence of conventional risk factors for CAD in no way undercuts the validity of the infectious hypothesis.

Many infectious diseases have a swift onset, a short course and a single microbial cause. In contrast, we tend to think of chronic diseases as having a slow onset, a prolonged course and multifactorial causation. These differences are reflected in the different approaches to the epidemiology of infectious versus chronic diseases. For many people, the fact that a disease has multifactorial causation implies that a disease is not infectious. Lewis Kuller wrote, 'The concept of multifactorial etiology of many chronic diseases may be a measure of our ignorance of causality rather than a biological principle'.[20] In fact, all infectious diseases have multifactorial causation. Infectious diseases require a pathogenic microbe, a susceptible host, a suitable environment for transmission and for some diseases a vector. If any of these elements are lacking, disease will not occur.

Whipple's disease: knowing the unknown

The scientific evolution of Whipple's disease from a metabolic disorder to an infectious disease is informative. Whipple's disease is named after the pathologist George Whipple who described a peculiar wasting illness in 1907. [21] The patient was a 36-year-old physician who presented to Johns Hopkins Hospital with complaints of weight loss, abdominal pain, bloating, diarrhea, cough and arthritis. The illness started 5 years prior to presentation with arthritis that affected large joints, causing pain, redness and swelling. These attacks were transient (<24 hours), recurrent and affected almost every joint in succession. In hospital, the patient was noted to have a low-grade fever, abdominal swelling, arthritis and steatorrhea. Tuberculosis or cancer was suspected. He underwent an exploratory laparotomy that revealed mesenteric adenopathy and he died without a diagnosis 2 days later. At autopsy, Whipple noted foamy histiocytes and fat deposits in tissue sections, concluded that the illness results from a derangement in fat metabolism and named it intestinal lipodystrophy. However, upon examination of a silver-stained section of lymph node, Whipple also noted 'great numbers of a rod-shaped organism (?) which, with this stain, is about the diameter of the spirochete of syphilis ...'.[21] Attempts to culture the bacterium failed and the observation of these bacillary structures was ignored for almost 50 years.

Steroid treatment was noted to provide some relief from symptoms of Whipple's disease, but this treatment did not appear to change the ultimate fatal outcome. In 1952, Paulley published a report describing the successful treatment of intestinal lipodystrophy with chloramphenicol.[22] The introduction of antibiotic therapy turned Whipple's disease from an invariably fatal metabolic illness into a frequently curable infectious disease. In the 1960s, electron microscopic studies of Whipple's disease tissues demonstrated small monomorphic bacterial structures inside phagocytes and free in the extracellular spaces. Attempts to culture this bacterium failed.

How can one identify a bacterium when it resists attempts at laboratory propagation? The bacillus of Whipple's disease was identified in the 1990s by molecular phylogenetic analysis of its DNA.[23] Oligonucleotide primers that anneal to highly conserved sequence targets in the bacterial 16S rRNA gene were used in a PCR to amplify bacterial rDNA from infected tissue. The amplified rDNA sequence included regions that are highly polymorphic among the bacteria and allow one to infer evolutionary relationships. Whipple's disease tissues contained a unique 16S rDNA sequence from a novel bacterium and phylogenetic analysis grouped this organism with the actinobacteria. The Whipple bacillus has been named *Tropheryma whipplei*. Fluorescence in-situ hybridization has been used to show that a probe targeting the Whipple bacillus rRNA localizes to bacterial structures in affected tissue and most bacteria are found in the

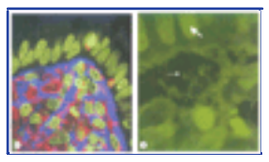

Figure 5-1 Fluorescence micrographs of a formalin fixed intestinal biopsy from a patient with Whipple's disease. (a) Confocal micrograph demonstrating hybridization of a fluorescent *Tropheryma whipplei* rDNA probe (blue) to bacterial rRNA in a small intestine biopsy from a patient with Whipple's disease. Yo-pro dye (green) highlights cell nuclei and an anti-vimentin antibody (red) labels the cytoskeletal protein of human mesenchymal cells. Bacteria localize to the lamina propria and appear abundant in the extracellular spaces. Macrophages and polymorphonuclear leukocytes infiltrate the lamina propria of this enlarged villus. (b) Confocal micrograph of Whipple's disease intestine showing clumps of small bacillary bodies in the lamina propria stained with Yo-pro nucleic acid dye in green (small arrow), and a human epithelial cell nucleus (large arrow). The extremely small size of the Whipple bacillus makes detection difficult using standard methods.

extracellular spaces of the intestinal lamina propria (Fig. 5.1).[24] Over 90 years after George Whipple's description of bacteria in tissue, *T. whipplei* was successfully propagated in the laboratory by co-cultivation with human cells. The remarkably slow doubling time of this bacterium makes routine cultivation impractical and growth on axenic media has not been reported.[25]

Whipple's disease has much to teach us about the infectious causes of idiopathic diseases. The first manifestation of Whipple's disease is frequently a migratory polyarthritis that waxes and wanes. These arthritic symptoms may precede the other manifestations of Whipple's disease by decades. Some infectious diseases may have a prolonged disease course. Whipple's disease can affect any organ and produces a multiplicity of presentations, from isolated gastrointestinal symptoms to isolated neuropsychiatric symptoms or multisystem disease. Some infectious diseases are protean. Although patients with Whipple's disease may improve with steroid treatment, cure is not achieved. A response to steroid medications does not mean a disease is noninfectious. Patients with Whipple's disease usually require a year of antibiotic treatment and relapse is common. Conventional antibiotic courses do not easily eradicate some slow-growing microbes.

EVIDENCE OF MICROBIAL CULPABILITY IN UNEXPLAINED DISEASE: ATHEROSCLEROSIS

Atherosclerosis is the leading cause of mortality in developed countries. Conventional risk factors such as hyperlipidemia and smoking only account for about 50% of atherosclerosis cases. Infectious agents have been proposed as factors that may account for the remaining cases of disease. Recent studies have demonstrated that patients with CAD have circulating markers of inflammation, including elevated levels of C-reactive protein, interleukin-6, tumor necrosis factor a and other cytokines and chemokines.[26] [27] It is believed that the anti-inflammatory properties of aspirin may be responsible for some of its benefits in CAD treatment. If CAD is an inflammatory disease, what is causing this inflammation?

The role of infectious agents in atherosclerosis and the attendant vascular inflammation is a controversial and active area of investigation. Several microbes have been implicated in atherogenesis, including *Chlamydia pneumoniae*, cytomegalovirus and *Helicobacter pylori*, among others. Evidence that *C. pneumoniae* plays a role in atherosclerosis is the most compelling. The first evidence that CAD was linked to *C. pneumoniae* infection came from studies showing that patients with CAD were more likely to have serologic evidence of infection than controls without disease.[28] *Chlamydia pneumoniae* has been detected in atherosclerotic plaque by immunohistochemistry, electron microscopy, PCR, in-situ hybridization and culture. Unfortunately, there is great variability in the reported success rates for detecting *C. pneumoniae* in diseased vascular tissue samples, with rates between 0% and 100% noted. A study of PCR for the detection of *C. pneumoniae* found discrepant results from different laboratories when the same samples were tested. [29] Thus, results are difficult to interpret and compare without standardized diagnostic methods.[30]

In-vitro studies have shown that *C. pneumoniae* can promote adherence of monocytes to vascular endothelium, increase the expression of inflammatory cytokines/chemokines, induce foam cell formation and promote low-density lipoprotein oxidation — all features of atherosclerosis. Animal models of atherosclerosis have yielded additional data supporting a causal role for *C. pneumoniae*. For instance, in a rabbit model, *C. pneumoniae* infected vascular endothelial cells and fostered the release of platelet-derived growth factor.[31] These events were associated with vascular smooth muscle cell proliferation and intimal thickening — histologic hallmarks of atherosclerosis. Early treatment of rabbits with antimicrobial agents active against *C. pneumoniae* can reduce the incidence and extent of atherosclerosis.

The best evidence that *C. pneumoniae* causes atherosclerosis would come from intervention trials showing that the prevention or treatment of *C. pneumoniae* infection reduces the incidence and severity of atherosclerosis in humans. Several small trials have demonstrated some moderate benefit from antibiotic treatment. For instance, a trial comparing 28 days of treatment with roxithromycin versus placebo in men seropositive for *C. pneumoniae* who had peripheral arterial occlusive disease found that antibiotic-treated patients required fewer revascularization procedures, had greater exercise tolerance and experienced reductions in the size of carotid plaques.[32] Some small studies of macrolide therapy in patients with CAD have demonstrated reductions in coronary events for patients treated with antibiotics, but other studies have not been as convincing. Larger trials such as the WIZARD and ACES studies are

underway and may provide the statistical power to determine whether antibiotic therapy is useful in CAD.[33]

There are several caveats to the interpretation of antibiotic intervention trials for atherosclerosis. It may be unreasonable to assume that antibiotic treatment will reduce vascular events in patients with long-standing and advanced disease. If *C. pneumoniae* plays a role in atherogenesis, then eradication of viable bacteria at this stage of disease may not reverse years of smooth muscle proliferation, intimal thickening, calcification and vessel obstruction. The greatest effect from antibiotics is likely to be realized when administered to patients with evidence of early *C. pneumoniae* infection and multiple risk factors for atherosclerosis.

In addition, atherosclerosis is a disease with some autoimmune features. One hypothesis suggests that the immune response to *C. pneumoniae* heat shock protein 60 may induce cross-reactive immune responses to human heat shock proteins in vascular endothelium. Indeed, a study found that antibodies to both *C. pneumoniae* and heat shock protein 60 conferred a relative risk of 82 for the development of CAD.[34] In contrast, individual conventional risk factors for CAD confer relative risks for disease that are generally below 10. Thus, elimination of bacteria may not be sufficient to quench inflammation if human epitopes continue to fan the flames (microbial 'hit and run' — see above).

Finally, conventional courses of antibiotic therapy may not be optimal for eradication of *C. pneumoniae* in atherosclerotic lesions. For instance, an in-vitro study showed that a 30-day treatment course with azithromycin, clarithromycin or levofloxacin did not eliminate bacteria from *C. pneumoniae*-infected cells.[35] Accordingly, one should not be surprised if antibiotic treatment regimens employing short courses of antibiotics fail to impact on atherogenesis. Antibiotic treatment courses designed for acute infections may not be successful in the setting of chronic infections. We need to study which antibiotics (or combinations of antibiotics), doses, intervals and durations are most effective in eradicating chronic *C. pneumoniae* infection before we can conclude that antibiotic therapy is not effective in atherosclerosis.

CONCLUSION

Some diseases that were previously considered to be metabolic, neoplastic, autoimmune or idiopathic have been linked to specific pathogens and reclassified as infectious diseases. There remain many unexplained diseases that may be caused by infectious agents. If we are to identify occult infectious causes of disease, then we must be open to the hypothesis of infection, while demanding rigorous evidence of microbial complicity. Although the search for microbial triggers of disease presents significant challenges, it also provides unmatched opportunities for improved diagnosis, prevention and treatment. Not all diseases are infectious, but only a fool would think that we have discovered all infectious diseases.

Chapter 6 - Bioterrorism and Biodefense

Andrew W Artenstein

INTRODUCTION

Bioterrorism can be broadly defined as the deliberate use of microbial agents or their toxins as weapons against noncombatants outside the setting of armed conflict. The broad scope and mounting boldness of worldwide terrorism, exemplified by the massive attacks on New York City and Washington DC on 11 September 2001, coupled with recent revelations regarding the apparent willingness of terrorist organizations to acquire and deploy biological weapons, constitute ample evidence that the specter of bioterrorism will pose a persistent global threat.

Biological weapons have been used against both military and civilian targets throughout history. In the 14th century, Tatars attempted to use epidemic disease against the defenders of Kaffa by catapulting plague-infected corpses into the city.[1] British forces gave Native American tribespeople blankets from a smallpox hospital in an attempt to affect the balance of power in the Ohio River Valley in the 18th century.[1] In addition to their well-described use of chemical weapons, German forces purportedly infected livestock with anthrax and glanders to weaken Allied initiatives during World War I. Perhaps the most egregious period in the history of biological weaponry involved the Japanese program in Manchuria from 1932 to 1945. Based on survivor accounts and confessions of Japanese participants, thousands died as a result of experimental infection with a multitude of virulent pathogens at Unit 731, the code name for the biological weapons facility there.[2]

The USA maintained an active program for the development and testing of offensive biological weapons from the early 1940s until 1969, when the program was terminated by executive order of then President Nixon, although efforts continue with regard to countermeasures against biological weapons. The Convention on the Prohibition of the Development, Production, and Stockpiling of Biological and Toxin Weapons and on Their Destruction (Biological Weapons Convention; BWC), which was ratified in 1972, formally banned the development or use of biological weapons, with enforcement the responsibility of the United Nations.[1] Unfortunately, the BWC has not been effective in its stated goals; multiple signatories, including the former Soviet Union and Iraq, have violated the terms and spirit of the agreement. The accidental release of aerosolized anthrax spores from a military plant in Sverdlovsk in 1979, with at least 68 human deaths from inhalational anthrax reported downwind, was proved years later to have occurred in the context of Soviet offensive weapons production.

ASSESSMENT OF THREAT

Biological agents are considered weapons of mass destruction (WMD) because, as with certain conventional weapons, chemical weapons and nuclear weapons, their use may result in large-scale morbidity and mortality. In a World Health Organization (WHO) assessment model of the hypothetical effects of the release of 50g of aerosolized anthrax spores upwind from a population center of 500,000, it was estimated that the agent would concentrate in excess of 20km downwind and that nearly 85,000 people would be killed or incapacitated by the event.[3] Biological weapons also possess unique properties among WMD. Unlike other forms of WMD, biological agents are associated with a clinical latency period, in most cases, of days to weeks, during which time early detection is quite difficult. In addition, specific antimicrobial therapy and, in select circumstances, vaccines are available for the treatment and prevention of illness caused by biological weapons. In contrast, casualties from other forms of WMD can be treated only by decontamination, trauma mitigation and supportive care.

Nations adhering to democratic principles are vulnerable to bioterrorism because of the inherent freedoms that their citizens and visitors enjoy. Freedom of movement and access to public and private institutions can be exploited by rogue nations, terrorist organizations or malicious people acting individually and intent on untoward acts. This, coupled with worldwide cultural tensions, geopolitical conflicts and economic instability, provides fertile ground for terrorism.

Recent events have established bioterrorism as a credible and ubiquitous threat. The intentional contamination of restaurant salad bars with *Salmonella* spp. by a religious cult trying to influence a local election in The Dalles, Oregon in 1984,[4] the revelations that Aum Shinrikyo (the Japanese cult that released sarin nerve agent in the Tokyo subway system in 1995) had unsuccessfully experimented on multiple occasions with spraying anthrax from downtown rooftops before their successful chemical attack, and the findings of the United Nations weapons inspectors of massive quantities of weaponized biological weapons in Iraq during the GulfWar and its aftermath[5] served as sentinel warnings of a shift in terrorism trends. The anthrax attacks in the USA in October and November 2001, following the catastrophic events of 11 September, elevated bioterrorism to the fore of the international dialogue.

The aims of bioterrorism are those of terrorism in general: morbidity and mortality among civilian populations, disruption of the societal fabric and exhaustion or diversion of resources. A 'successful' outcome, from a terrorist standpoint, may be achieved without furthering all of these aims. The anthrax attacks in 2001 evoked fear and anxiety and diverted resources from other critical activities despite the limited number of casualties. Biological weapons offer other, significant advantages to terrorists: they are relatively inexpensive compared with conventional or nuclear weaponry; they can be deployed in a stealth fashion, owing to a variable clinical latency period, thus allowing the perpetrator an opportunity to escape if desired; and they clearly evoke anxiety and panic that is, in some instances, out of proportion to their physical effects. From a rogue government's standpoint, the technology for bioterrorism is 'dual use' in that it can serve legitimate functions, such as the production of vaccine or pharmaceutical agents, as readily as it can serve the production of biological weapons, thus making detection by inspectors all the more difficult.

To be employed in large-scale bioterrorism, biological agents must undergo complex processes of production, cultivation, chemical modification and weaponization. For these reasons, state sponsorship

or direct support from governments or organizations with significant resources, contacts and infrastructure would predictably be required in large-scale events. However, recent revelations have suggested that some agents may be available on the worldwide black market and in other illicit settings,[6] thus obviating the need for the production process. Although an efficient mode of delivery has traditionally been felt to be necessary, the anthrax attacks in the USA in late 2001 illustrated the devastating results that can be achieved with relatively primitive delivery methods such as high-speed mail sorting equipment and mailed letters.

Numerous attributes contribute to the selection of a pathogen as a biological weapon, including availability or ease of large-scale production, ease of dissemination (usually by the aerosol route), stability of the product in storage, in weapons and in the environment (biological entities differ in their physical properties), cost and clinical virulence. Clinical virulence refers to the reliability with which the pathogen causes high mortality, morbidity or social disruption. The Centers for Disease Control and Prevention (CDC) have prioritized biological agent threats on the basis of the characteristics mentioned above,[7] and this has influenced current preparedness strategies (Table 6.1). Category A agents are associated with high mortality and the greatest potential for major impact on public health. Category B agents are considered 'incapacitating' because of their potential for moderate morbidity but relatively low mortality. Most of the category A and B agents have been experimentally weaponized in the past and thus of proven feasibility. Category C agents include emerging threats and pathogens that may be available for development.

Another factor that must be addressed in assessing future bioterrorism risk is the historic track record of experimentation with specific pathogens, an area that has been informed from the corroborated claims of various high-level Soviet defectors and data released from the former offensive weapons programs of the USA and the UK.[1] [6] [8] It is apparent, from these sources combined with the burgeoning fields of molecular biology and genomics, that future risk scenarios may have to contend with genetically altered and 'designer' pathogens. To this end a miscellaneous grouping of potential threat agents to the extant CDC categories can be added (see Table 6.1). The most cautious approach to assessing risk may be to remain open to additional, novel possibilities.

BIOTERRORISM RECOGNITION

By definition bioterrorism is insidious. In the absence of an advance warning or specific intelligence information, clinical illness will manifest itself before the circumstances of a release event are known. For this reason, health care providers are likely to be the first responders to this form of terrorism. This is in contrast to the more familiar scenarios in which police, firefighters, paramedics and other emergency personnel are deployed to the scene of an attack by conventional weaponry or a natural disaster. Physicians and other health care workers must therefore maintain a high index of suspicion of bioterrorism and recognize suggestive epidemiologic clues and clinical features to enhance early recognition and to guide initial management of casualties. This remains the most effective way of minimizing the deleterious effects of bioterrorism on individual patients and on public health.

Early recognition is hampered for multiple reasons. It is likely that the circumstances of any event will only be known in retrospect, and therefore it may prove problematic to discern the extent of exposure immediately. Terrorists have an unlimited number of targets in most open, democratic societies and it is unrealistic to expect that, without detailed intelligence data, all of these can be secured at all times. Certain sites, such as government institutions,

TABLE 6-1 -- Agents of concern for use in bioterrorism.

AGENTS OF CONCERN FOR USE IN BIOTERRORISM	
Highest priority (category A)	
Microbe or toxin	**Disease**
Bacillus anthracis	Anthrax
Variola virus	Smallpox
Yersinia pestis	Plague
Clostridium botulinum	Botulism
Francisella tularensis	Tularemia
Filoviruses	Ebola hemorrhagic fevers, Marburg disease
Arenaviruses	Lassa fever, South American hemorrhagic fevers
Bunyaviruses	Rift Valley fever, Congo-Crimean hemorrhagic fevers
Moderately high priority (category B)	
Microbe or toxin	**Disease**
Coxiella burnetti	Q fever
Brucella spp.	Brucellosis
Burkholderia mallei	Glanders
Alphaviruses	Viral encephalitides
Ricin	Ricin intoxication
Staphylococcus aureus enterotoxin B	Staphylococcal toxin illness
Salmonella spp., *Shigella dysenteriae*, *Escherichia coli* O 157:H7, *Vibrio cholerae*, *Cryptosporidium parvum*	Foods and water-borne gastroenteritis
Category C	
Microbe or toxin	**Disease**
Hantaviruses	Viral hemorrhagic fevers
Flaviviruses	Yellow fever
Mycobacterium tuberculosis	Multidrug resistant tuberculosis
Miscellaneous	
Genetically engineered vaccine- and/or antimicrobial-resistant category	
A or B agents	
HIV-1	
Adenoviruses	
Influenza	
Rotaviruses	
Hybrid pathogens (e.g. smallpox-plague, smallpox-ebola)	

historic landmarks or large public events, may be predictable targets, but there are other, less predictable possibilities. Metropolitan areas are considered vulnerable, but owing to the expansion of suburbs and the increased number of commuters, and also to the clinical latency period between exposure and symptoms inherent with biological agents, casualties of bioterrorism are likely to present for medical attention in diverse locations and at varying times after a common exposure. An event in New York City on a Wednesday morning may result in clinically ill people presenting over the ensuing weekend to a variety of emergency rooms within a 60-mile radius. Additionally, modern modes of transportation ensure that there will also be affected people thousands of miles away at both

national and international locations. This adds layers of complexity to an already complicated setting and illustrates the critical importance of surveillance and real-time communication in this setting.

Further hindrance to the early recognition of bioterrorism comes from the fact that initial symptoms may be nondiagnostic. In the absence of a known exposure, many symptomatic people may not seek medical attention early on or may be misdiagnosed as having a flu-like illness. Once beyond the early stages many of these illnesses progress quite rapidly and treatment may be less successful. Most of the diseases caused by agents of bioterrorism are rarely, if ever, seen in clinical practice. Physicians are, therefore, likely to be inexperienced with their clinical presentation. Additionally, these agents, by definition, will have been laboratory-manipulated and may not present with the classic clinical features of naturally occurring infection. This was dramatically illustrated by some of the inhalational anthrax cases in the USA in October 2001.[9]

Early recognition of bioterrorism is facilitated by the recognition of epidemiologic and clinical clues. Clustering of patients with common symptoms and signs, especially if these are unusual or characteristic of bioterrorism agents, is suggestive and should prompt expeditious notification of local public health authorities. This approach will also lead to the recognition of outbreaks of naturally occurring disease or emerging pathogens. The recognition of a single case of a rare or nonendemic infection, in the absence of a travel history or other potential natural exposure, should raise the specter of bioterrorism and should prompt notification of public health authorities. Finally, unusual patterns of disease, such as concurrent illness in human and animal populations, should raise suspicions of bioterrorism or another form of emerging infection.

Infectious diseases specialists are uniquely suited to play pivotal roles in the recognition, investigation and mitigation of bioterrorism. This role is based on an understanding of epidemiologic principles and risk assessment, expertise in specific threat agents and their clinical presentations and diagnostic approaches, knowledge of communicability and infection control principles, and an understanding of the tenets of infection treatment and prophylaxis. Nonetheless, an effective response to bioterrorism requires co-ordination of the medical system at all levels, from the community physician to the tertiary care center, with public health, emergency management and law enforcement infrastructures all playing a part.

THREAT AGENTS

This section covers the biological threat agents felt to be of major current concern, largely the CDC category A agents. Extensive

TABLE 6-2 -- Infection control issues for selected agents of bioterrorism.

INFECTION CONTROL ISSUES FOR SELECTED AGENTS OF BIOTERRORISM			
Disease	**Incubation period (days)**	**Person-to-person transmission**	**Infection control precautions**
Inhalational anthrax (see Chapter 185)	2–43*	No	Standard
Botulism (see Chapter 25)	12–72 hours	No	Standard
Primary pneumonic plague (see Chapter 176)	1–6	Yes	Droplet
Smallpox (see Chapter 151)	7–17	Yes	Contact and airborne
Tularemia (see Chapter 177)	1–14	No	Standard
Viral hemorrhagic fevers (see Chapter 183)	2–21	Yes	Contact and airborne
Viral encephalitides (see Chapter 23)	2–14	No	Standard
Q fever (see Chapter 235)	2–14	No	Standard
Brucellosis (see Chapter 180)	5–60	No	Standard
Glanders	10–14	No	Standard

* Based on limited data from human outbreaks; experimental animal data support clinical latency periods of up to 100 days

coverage of specific pathogens can be found in related chapters in this text (cross-referenced in Table 6.2) and in other sources.[10] Data concerning clinical incubation periods, transmission characteristics and infection control procedures for agents of bioterrorism are provided in Table 6.2 . Syndromic differential diagnoses for select clinical presentations are detailed in Table 6.3 .

Anthrax

Anthrax results from infection with *Bacillus anthracis*, a Gram-positive, spore-forming, rod-shaped organism that exists in its host as a vegetative bacillus and in the environment as a spore (see chapter 185 and chapter 226). In nature, anthrax is a zoonotic disease of herbivores that is prevalent in many geographic regions; sporadic human disease results from environmental or occupational contact with endospore-contaminated animal products.[11] The cutaneous form of anthrax is the most common presentation; gastrointestinal and inhalational forms are exceedingly rare in naturally acquired disease. Cutaneous anthrax occurred regularly in the first half of the 20th century, in association with contaminated hides and wools used in the garment industry, but it is uncommonly seen in current-day industrialized countries, owing to import restrictions. The last known case of naturally occurring inhalational anthrax in the USA occurred in 1976.[12]

It was previously hypothesized that large-scale bioterrorism with anthrax would involve aerosolized endospores with resultant inhalational disease, but the recent attacks in the USA illustrate the difficulties in predicting modes and outcomes in bioterrorism; the attacks were on a relatively small scale and nearly 40% of the confirmed cases were of the cutaneous variety.[13] The serious morbidity and mortality, however, were related to inhalational disease, as was the case in the Sverdlovsk outbreak in 1979. Therefore, planning for larger scale events with aerosolized agent seems warranted.

The lesion of cutaneous anthrax may be similar in appearance to other lesions, including cutaneous forms of other agents of bioterrorism; however, it may be distinguished by epidemiologic as well as certain clinical features (see Table 6.3). Anthrax is traditionally a painless lesion, unless secondarily infected, and it is associated with significant local edema. The bite of *Loxosceles reclusa*, the brown recluse spider, shares many of the local and systemic features of anthrax but is typically painful from the outset and lacks significant edema.[14] Cutaneous anthrax is associated with systemic disease, and the mortality is up to 20% of untreated cases, although with appropriate antimicrobial therapy the mortality is less than 1%.[13]

Once the inhaled endospores reach the terminal alveoli of the lungs, generally requiring particle sizes of 1–5µm, they are phagocytosed by macrophages and transported to regional lymph

TABLE 6-3 -- Clinical presentations and syndromic differential diagnoses of selected agents of bioterrorism.

PRESENTATIONS AND DIFFERENTIAL DIAGNOSES OF BIOTERRORISM AGENTS		
Clinical presentation	**Disease**	**Differential diagnosis**
Non-specific 'flu-like' symptoms with nausea, emesis, cough with or without chest discomfort, without coryza or rhinorrhea, leading to abrupt onset of respiratory distress with or without shock, mental status changes, with chest radiograph abnormalities (wide mediastinum, infiltrates, pleural effusions)	Inhalational anthrax	Bacterial mediastinitis, tularemia, Q fever, psittacosis, Legionnaires' disease, influenza, *Pneumocystis carinii* pneumonia, viral pneumonia, ruptured aortic aneurysm, superior vena cava syndrome, histoplasmosis, coccidioidomycosis, sarcoidosis
Pruritic, painless papule, leading to vesicle(s), leading to ulcer, leading to edematous black eschar with or without massive local edema and regional adenopathy and fever, evolving over 3–7 days	Cutaneous anthrax	Recluse spider bite, plague, staphylococcal lesion, atypical Lyme disease, orf, glanders, tularemia, rat-bite fever, ecthyma gangrenosum, rickettsialpox, atypical mycobacteria, diphtheria
Rapidly progressive respiratory illness with cough, fever, rigors, dyspnea, chest pain, hemoptysis, possible gastrointestinal symptoms, lung consolidation with or without shock	Primary pneumonic plague	Severe community-acquired bacterial or viral pneumonia, inhalational anthrax, inhalational tularemia, pulmonary infarct, pulmonary hemorrhage
Sepsis, disseminated intravascular coagulation, purpura, acral gangrene	Septicemic plague	Meningococcemia; Gram-negative, streptococcal, pneumococcal or staphylococcal bacteremia with shock; overwhelming postsplenectomy sepsis; acute leukemia; Rocky Mountain spotted fever; hemorrhagic smallpox; hemorrhagic varicella (in immunocompromised patients)
Fever, malaise, prostration, headache, myalgias followed by development of synchronous, progressive papular leading to vesicular and then pustular rash on face, mucous membranes (extremities more than the trunk); the rash may become generalized, with a hemorrhagic component and systemic toxicity	Smallpox	Varicella, drug eruption, Stevens-Johnson syndrome, measles, secondary syphilis, erythema multiforme, severe acne, meningococcemia, monkeypox (with African travel history), generalized vaccinia, insect bites, Coxsackie virus infection, vaccine reaction
Non-specific flu-like, febrile illness with pleuropneumonitis, bronchiolitis with or without hilar lymphadenopathy; variable progression to respiratory failure	Inhalational tularemia	Inhalational anthrax, pneumonic plague, influenza, mycoplasma pneumonia, Legionnaire's disease, Q fever, bacterial pneumonia
Acute onset of afebrile, symmetric, descending flaccid paralysis that begins in bulbar muscles, dilated pupils, diplopia or blurred vision, dysphagia, dysarthria, ptosis, dry mucous membranes, leading to airway obstruction with respiratory muscle paralysis. Clear sensorium and absence of sensory changes	Botulism	Myasthenia gravis, brain stem cerebrovascular accident, polio, Guillain-Barré syndrome variant, tick paralysis, chemical intoxication

Acute onset fevers, malaise, prostration, myalgias, headache, gastrointestinal symptoms, mucosal hemorrhage, altered vascular permeability, disseminated intravascular coagulation, hypotension, leading to shock, with or without hepatitis and neurologic findings	Viral hemorrhagic fever	Malaria, meningococcemia, leptospirosis, rickettsial infection, typhoid fever, borrelioses, fulminant hepatitis, hemorrhagic smallpox, acute leukemia, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, systemic lupus erythematosus

nodes, where they germinate into vegetative bacteria and, subsequently, disseminate hematogenously.[12] Spores may remain latent in the host for extended periods of time — up to 100 days in experimental animal exposures.[11] This has translated into prolonged clinical incubation periods following exposure to endospores. Cases of inhalational anthrax occurred up to 43 days after exposure in the Sverdlovsk experience, although the average incubation period is 2–10 days, perhaps influenced by exposure dose.[11] [12]

Before the anthrax attacks on the USA in October 2001, most of the clinical data concerning inhalational anthrax derived from Sverdlovsk, the largest recorded outbreak. More detailed data are available from the recent experience in the USA. There were 11 confirmed cases of inhalational anthrax, five (45%) of whom died. Although this contrasts with a case-fatality rate of more than 85% reported from Sverdlovsk, the reliability of reported data from that outbreak are questionable. [11] Patients almost uniformly present an average of 3.3 days after symptom onset with fevers, chills, malaise, myalgias, nonproductive cough, chest discomfort, dyspnea, nausea or vomiting, tachycardia, peripheral neutrophilia and liver enzyme elevations.[9] [15] Many of these findings are nondiagnostic and overlap considerably with those of influenza and other common viral respiratory tract infections (see Table 6.3). Recently compiled data suggest that shortness of breath, nausea and vomiting are significantly more common in anthrax whereas rhinorrhea is uncommon but is noted in the majority of viral respiratory infections.[16]

Other common clinical manifestations of inhalational anthrax include abdominal pain, headache, mental status abnormalities and hypoxemia. Abnormalities on chest radiography appear to be universally present, although these may be identified only retrospectively in some cases. Pleural effusions are the most common abnormality; infiltrates, consolidation and mediastinal adenopathy or widening are noted in the majority (Fig. 6.1). Mediastinal abnormality is felt to be an early indicator of disease, but computerized tomography appears to provide greater sensitivity than chest radiographs for this finding.

The clinical manifestations of inhalational anthrax generally evolve to a fulminant septic picture with progressive respiratory failure. *Bacillus anthracis* is routinely isolated in blood cultures if

Figure 6-1 Imaging abnormalities associated with anthrax. (a) Chest radiograph demonstrating widened mediastinum due to inhalational anthrax. *Courtesy CDC and Dr PS Brachman.*

the blood is obtained before the initiation of antimicrobial agents (Fig. 6.2). Pleural fluid is typically hemorrhagic; the bacteria can either be isolated in culture or documented by antigen-specific immunohistochemical stains of this material in the majority of patients.[9] In the five fatalities in the USA series, the average time from hospitalization until death was 3 days (range 1–5 days), consistent with other reports of the clinical virulence of this infection. Autopsy data typically reveal hemorrhagic mediastinal lymphadenitis and disseminated, metastatic infection. Pathology data from the Sverdlovsk outbreak confirm meningeal involvement, typically hemorrhagic meningitis, in 50% of cases.[17]

The diagnosis of inhalational anthrax should be entertained in the setting of a consistent clinical presentation in the context of a known exposure, a possible exposure or epidemiologic factors suggesting bioterrorism (e.g. clustered cases of a rapidly progressive illness). The diagnosis should also be considered in a single patient with a consistent or suggestive clinical illness in the absence of another etiology. The early recognition and treatment of inhalational anthrax is likely to be associated with a survival advantage.[9] Therefore, prompt empiric antimicrobial therapy should be initiated if infection is clinically suspected. Combination parenteral therapy is appropriate in the ill patient for a number of reasons:[9]

- to cover the possibility of antimicrobial resistance;
- to target specific bacterial functions (e.g. the theoretical effect of clindamycin on toxin production);
- to ensure adequate drug penetration into the central nervous system; and
- to have a possibly favorable effect on survival.

In the future it is likely that novel therapies, such as toxin inhibitors or receptor antagonists, will be available to treat anthrax.[18] Detailed therapeutic and postexposure prophylaxis recommendations for adults, children and special groups have been recently reviewed elsewhere.[12] Anthrax vaccine has been proven to be effective in preventing cutaneous anthrax in human clinical trials and in preventing inhalational disease after aerosol challenge in nonhuman primates.[19] The vaccine has generally been found to be safe but requires six doses over 18 months with the need for frequent boosting. Its availability is currently limited; it is hoped that second-generation anthrax vaccines will prove effective.

Smallpox

The last known naturally acquired case of smallpox occurred in Somalia in 1977. The disease was officially certified as having been eradicated in 1980, the culmination of a 12-year, intensive campaign by the WHO.[20] However, because of concerns that variola virus stocks may have either been removed from or sequestered outside their officially designated repositories, smallpox is considered to be a potential agent of bioterrorism. Multiple features make smallpox an attractive biological weapon and ensure that its re-introduction into human populations would be a global public health catastrophe: it is stable in aerosol form with a low infective dose; case fatality rates are historically high, approaching 30%; secondary attack rates among unvaccinated close contacts is 37–88% and are amplified; and much of the world's population is susceptible because routine civilian vaccination was terminated more than two decades ago, vaccine-induced immunity wanes over time, and there is no virus circulating in the environment to provide low-level, booster exposures.[21] Additionally, vaccine supplies are currently limited, although this problem has begun to be addressed, and there are currently no antiviral therapies of proven effectiveness against this pathogen.

After an incubation period of 7–17 days (average 10–12 days), the patient experiences the acute onset of a prostrating prodrome of fever, rigors, headache and backache that may last 2–3 days. This is followed by a centrifugally distributed eruption that generalizes as it evolves through macular, papular, vesicular and pustular stages in synchronous fashion over approximately 8 days, with umbilication in the latter stages (Fig 6.3 Fig 6.4 Fig 6.5 Fig 6.6). Enanthema in the oropharynx typically precede the exanthem by a day or two. The rash typically involves the palms and soles early on. The pustules begin crusting during the second week of the eruption; separation of scabs is usually complete by the end of the third week. The differential diagnosis of smallpox is delineated in Table 6.3 . Historically, varicella and drug reactions posed the most diagnostic dilemmas.[21]

Smallpox is transmitted from person to person by respiratory droplet nuclei and, less commonly, by contact with lesions or contaminated fomites. Airborne transmission by fine-particle aerosols has, in certain conditions, been documented. [21] The virus is communicable from the onset of the enanthema until all of the scabs have separated, although patients are felt to be most contagious during the first week of the rash, owing to high titers of replicating virus in the oropharynx. Household

members, other face-to-face contacts and health care workers have traditionally been at highest risk

Figure 6-3 Third day of rash in smallpox. Additional lesions continue to appear and some of the papules are becoming obviously vesicular. *From Fenner et al.,*[20] *with permission of the World Health Organization.*

Figure 6-4 Fifth day of rash in smallpox. Almost all the papules have now become vesicular or pustular, the truly 'vesicular' stage usually being very brief. Some of the lesions on the upper arm show early umbilication. *From Fenner et al.,*[20] *with permission of the World Health Organization.*

of secondary transmission. Thus, hospitalized cases are placed in negative-pressure rooms with contact and airborne precautions to minimize this risk, and those not requiring hospital-level care should remain isolated at home in order to avoid infecting others.

Issues related to the diagnosis and the initial approach to the management and containment of suspected smallpox cases are discussed in detail in Chapter 96d . The suspicion of a single smallpox case should prompt immediate notification of local public health authorities and the hospital epidemiologist. Containment of smallpox is predicated on isolating cases and the 'ring vaccination' strategy, which was successfully deployed in the WHO global eradication campaign and mandates the identification and immunization of all directly exposed people, including close contacts, health care workers and laboratory personnel. Vaccination, if deployed within 4 days of infection during the early incubation period, can significantly attenuate or prevent disease and may have a favorable impact on secondary transmission.[21] Because the occurrence of even a single case of smallpox would be tantamount to bioterrorism, an epidemiologic investigation would be necessary to ascertain the perimeter of the initial release, so that tracing of those initially exposed can be accomplished.

Botulism

Botulism, an acute neurologic disease resulting from intoxication with *Clostridium botulinum* toxin, occurs sporadically and in focal outbreaks throughout the world in relation to wound contamination by the bacterium or ingestion of food-borne toxin. A detailed discussion of botulism is found in Chapter 25 . Aerosol forms of the toxin, a rare mode of acquisition in nature, have been used in weapons designed for use in bioterrorism.[5] Botulinum toxin is considered

Figure 6-5 Eighth day of rash in smallpox. This case is now clearly classified as discrete ordinary-type smallpox. In the confluent subtype of ordinary-type smallpox the lesions would have been confluent on the face and forearms: in the semiconfluent subtype they would have been confluent on the face but not on the forearms. *From Fenner et al.,*[20] *with permission of the World Health Organization.*

Figure 6-6 Twentieth day of rash in smallpox. The scabs have separated except on the palms of the hands and the soles of the feet, leaving depigmented areas. *From Fenner et al.,* [20] *with permission of the World Health Organization.*

to be the most toxic microbial molecule known; it is lethal to humans in minute quantities. It blocks the release of the neurotransmitter acetylcholine from presynaptic vesicles, thereby inhibiting muscle contraction.[22]

Botulism presents as an acute, afebrile, symmetric, descending, flaccid paralysis. The disease manifests initially in the bulbar musculature and is unassociated with mental status or sensory changes. Fatigue, dizziness, dysphagia, dysarthria, diplopia, dry mouth, dyspnea, ptosis, ophthalmoparesis, tongue weakness and facial muscle paresis are early findings seen in more than 75% of cases. Progressive muscular involvement leading to respiratory failure ensures. The clinical presentations of food-borne and inhalational botulism are indistinguishable in experimental animals. [22]

The diagnosis of botulism is largely based on epidemiologic and clinical features and the exclusion of other possibilities (see Table 6.3). Clinicians should recognize that any single case of botulism could be the result of bioterrorism or could herald a larger scale 'natural' outbreak. A large number of epidemiologically unrelated, multifocal cases should be clues to an intentional release of the agent, either in food or water supplies or as an aerosol.

The mortality from food-borne botulism has declined from 60% to 6% over the past four decades, probably as a result of improvements in supportive care, including mechanical ventilation. Because the need for mechanical ventilation may be prolonged, the limited availability of ventilators would be likely to be exceeded in the event of a large-scale bioterrorism event. Treatment with an equine antitoxin, available in limited supply from the national public health laboratories (the CDC in the USA), may ameliorate disease if given early.

Plague

Plague, the disease caused by the Gram-negative pathogen *Yersinia pestis*, presents in a variety of forms in naturally acquired disease (see Chapter 176). Plague is endemic in parts of South East Asia, Africa and the western USA. Aerosolized preparations of the agent, the expected vehicle in bioterrorism, would be predicted to result in cases of primary pneumonic plague outside endemic areas. As was the case with the anthrax attacks in the USA in 2001, however, additional forms of the disease, such as bubonic and septicemic plague, might also occur.

Primary pneumonic plague classically presents as an acute, febrile, pneumonic illness with prominent respiratory and systemic symptoms; gastrointestinal symptoms, purulent sputum production or hemoptysis occur variably.[23] Chest radiographs typically show

patchy, bilateral, multilobar infiltrates or consolidations. In the absence of appropriate treatment there may be rapid progression to respiratory failure, vascular collapse, purpuric skin lesions, necrotic digits and death. The differential diagnosis is largely that of rapidly progressive pneumonia (see Table 6.3). The diagnosis may be suggested by the characteristic small Gram-negative coccobacilli forms in stained sputum specimens with bipolar ('safety-pin') uptake of Giemsa or Wright stain.[24]

Confirmation by culture is necessary to confirm the diagnosis; the microbiology laboratory should be notified in advance if plague is suspected because special techniques and precautions must be employed.

Treatment recommendations for plague have been reviewed elsewhere. [24] Pneumonic plague can be transmitted from person to person by respiratory droplet nuclei, thus placing close contacts, other patients and health care workers at risk. Prompt recognition and treatment of this disease, appropriate deployment of postexposure prophylaxis and early institution of droplet precautions will interrupt secondary transmission.

Tularemia

Francisella tularensis, the causative agent of tularemia, is a small Gram-negative coccobacillus that would probably cause primary pneumonia if delivered as an aerosol agent of bioterrorism. Inhalational tularemia presents with the abrupt onset of a febrile, systemic illness with prominent upper respiratory symptoms, pleuritic chest pain, and the variable development of pneumonia, hilar adenopathy and progression to respiratory failure and death in more than 30% of those who do not receive appropriate therapy.[25] The diagnosis is generally based on clinical features, after ruling out other agents; laboratory personnel should be notified in advance if tularemia is suspected, because the organism can be very infectious under culture conditions. This agent is discussed in depth in Chapter 177 .

Viral hemorrhagic fevers

The agents of viral hemorrhagic fevers are members of four distinct families of RNA viruses that cause clinical syndromes with overlapping features: fever, malaise, headache, myalgias, prostration, mucosal hemorrhage and other signs of increased vascular permeability and circulatory dysregulation, leading to shock and multiorgan system failure in advanced cases.[26] Specific agents are also associated with specific target organ effects. These pathogens include the agents of Ebola hemorrhagic fever, Marburg disease, Lassa fever, Rift Valley fever and Congo-Crimean hemorrhagic fever (see Chapter 183).

Hemorrhagic fever viruses have been viewed as emerging infections in nature, owing to their sporadic occurrence in focal outbreaks throughout the world, thought to be the results of human intrusion into a viral ecologic niche. They are, however, potential weapons of bioterrorism because they are highly infectious in aerosol form, are transmissible in health care settings, cause high morbidity and mortality and are purported to have been successfully used in weaponry.[8] Blood and other body fluids from infected patients are extremely infectious, and person-to-person air borne transmission may occur; therefore, strict contact and air borne precautions should be instituted.[26]

Treatment is largely supportive and includes the early use of vasopressors as needed. Ribavirin is effective against some forms of viral hemorrhagic fevers but not those caused by Ebola virus and Marburg virus. Nonetheless, this drug should be initiated empirically in patients presenting with a syndrome consistent with viral hemorrhagic fever until the etiology is confirmed.

ASSOCIATED ISSUES AND SEQUELAE OF BIOTERRORISM

Quarantine

Quarantine, the physical separation and geographic restriction of groups of uninfected people potentially exposed to a communicable illness, has been variably considered to be one form of management strategy following bioterrorism. The potential effectiveness, feasibility, legality and consequences of quarantine have recently been reviewed.[27] The logistics of this approach are complex and impractical, and it can be associated with adverse consequences, such as increased risk of disease transmission among a quarantined group and an increased risk of riots. It seems clear that there are only limited scenarios in which the potential public health benefits of the imposition of quarantine may outweigh the potential problems engendered by this approach; these largely revolve around highly transmissible, lethal agents. In most situations a disease-specific containment strategy, based on transmission epidemiology and disease prevention approaches, is preferable.

Management of special patient populations

The approach to the management of diseases of bioterrorism must be broadened to include children, pregnant women and immunocompromised people. Specific recommendations for treatment and prophylaxis of these special patient groups for selected bioterrorism agents have recently been reviewed.[13] [24] [25] A general approach requires an assessment of the risk of certain drugs or products in select populations versus the potential risk of the infection in question, accounting for extent of exposure and agent involved. The issue extends to immunization because certain vaccines, such as smallpox, pose a higher risk to these special groups than to others. This will impact on mass vaccination strategies.

Psychosocial morbidity

An often overlooked but vitally important issue in bioterrorism is that of psychosocial sequelae. These may take the form of acute anxiety reactions and exacerbations of chronic psychiatric illness during the stress of the event, or post-traumatic stress disorder (PTSD) in its aftermath. Nearly half of the emergency department visits during the Gulf War missile attacks in Israel in 1991 were related to acute psychologic illness or exacerbations of underlying problems.[28] Data from recent acts of terrorism in the USA suggest that PTSD may develop in as many as 35% of those affected by the events.[29] In the early period after the 11 September attacks in New York, PTSD and depression were nearly twice as prevalent as in historical controls.[30] Although there were direct correlations between close proximity to the events and PTSD and between personal loss and depression, there was a substantial burden of morbidity among those indirectly involved. The psychologic impact of these events and of the ongoing international concern over terrorism can be expected to be significant and sustained for society as a whole.

CONCLUSION

The response to bioterrorism is unique among WMD because it necessitates the consequential management that is common to all disasters as well as the application of basic infectious diseases principles: disease surveillance, infection control, antimicrobial therapy and prophylaxis, and vaccine prevention. For these reasons physicians, specifically infectious diseases specialists, are likely first responders to bioterrorism and are expected to be reliable sources of information for their patients, colleagues and public health authorities.[31]

Chapter 7 - Microbial Genomes

E Richard Moxon
Jay CD Hinton
Derek Hood

INTRODUCTION

In the 1940s, Avery and his colleagues made an astounding and, at the time, controversial discovery. Heritable traits of the pneumococcus, specifically capsular serotype, could be transferred through the donation of DNA from one bacterial cell to another. In the 1950s, the structure of DNA was resolved by Watson and Crick, and with it was proposed a plausible (and as it turned out correct) basis by which heritable information could be accurately retained and transmitted to progeny cells. The genetic code by which DNA determines the order and specificity of the amino acids making up a particular polypeptide was solved. So began the era of molecular biology, a discipline that rapidly became a dominant force in biology. A biochemical method for establishing the order and content of the nucleic acids making up entire genes, even the entire genetic complement of viruses or free-living cells, was developed by Sanger. This opened up the possibility of determining the DNA sequence of complete genomes, the most ambitious project being the Human Genome Project. At this time, the only complete genome sequences were those of a few viruses (e.g. vaccinia in 1990 and cytomegalovirus in 1991). The first genome to be completed using automated technology was that of variola in 1993. However, at this time, there were no complete genome sequences of free-living organisms, including pathogenic bacteria, fungi and macroparasites.

A MILESTONE IN MICROBIOLOGY

The obvious single cell for which to obtain a complete genome sequence was *Escherichia coli*, but this project was languishing

Figure 7-1 The microbial revolution of the 1990s: bacterial genome sequencing. (1) Construction of a random gene library. (2) Random sequencing of thousands of clones. (3) Closure phase (which can be very labour-intensive). (4) Collation and annotation of the final sequence *(reproduced from Moxon[30] with permission from The Lancet)*

when, to the surprise of many, the Institute for Genome Research announced the completion of the entire genome sequence of a strain (Rd) of the bacterium *Haemophilus influenzae*.[1] This was immediately recognized as a conceptual and technical breakthrough of immense significance. It literally changed the face of microbiology and had a revolutionary impact on infectious diseases. This milestone was made possible, in part, through important technical innovations. Whole genome DNA was sheared into small fragments, each of which was cloned and sequenced (often referred to as shot-gun sequencing). Sophisticated computational methods, rather than methods that depended on the construction of physical genetic maps, were used to assemble the sequence. The approach relied on sequencing enough clones with unique DNA fragments to have a high probability that every nucleotide of the genome had been sampled. This posed an enormous challenge — the assembly of hundreds of thousands of overlapping partial DNA fragments of 300–500 nucleotides. A final step involved identifying and sequencing a relatively few remaining gaps in the sequence (closure; Fig. 7.1).

Once sequencing had been achieved for *H. influenzae*, numerous other bacterial genomes were sequenced using similar methods and more than 80 complete genome sequences have now been completed.[2] Of these, 38 strains represent pathogens (obligate, facultative and opportunistic) including the causative agents of important human diseases (pneumonia, meningitis and gastroenteritis) and agents of historically important pandemics and recurrent epidemics (plague, cholera, typhoid, typhus and meningococcal disease). Other completed genome sequences include the etiologic agents of nosocomial and community-acquired infections (*Staphylococcus*

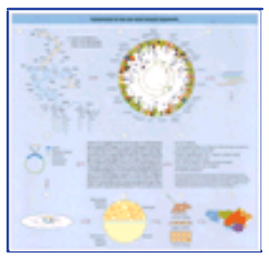

Figure 7-2 How a whole-genome sequence of a pathogenic microbe can be used to develop a candidate vaccine. (1) Representation of lipopolysaccharide (LPS), a major surface antigen of *H. influenzae* and a potential vaccine candidate. The lipid A (endotoxin) is inserted into the cell envelope of the bacterium to which are attached inner and outer core saccharides (uppermost in figure). These oligosaccharides are important in the interactions of the bacterium with host cells. (2) Whole-genome sequence of *H. influenzae* Rd that includes all of the genes involved in the biosynthesis of *H. influenzae* LPS of this strain (reproduced with permission from Fleischmann et al[1]). (3) DNA sequences (or their deduced amino-acid sequences), publicly available in databases (e.g. GenBank, EMBL), are used as probesto search and identify homologues (candidate LPS genes) in the *H. influenzae* complete genome sequence. (4) These candidate *H. influenzae* LPS genes can be further investigated to confirm or reject their role in LPS biosynthesis through appropriate experimental methods. (5) Oligonucleotide primers can be constructed to obtain multiple copies of each of the candidate LPS genes using polymerase chain reaction (PCR). (6) The PCR amplified candidate LPS genes are cloned into a suitable plasmid vector and mutations are constructed. In this example, the candidate LPS gene has been disrupted by an insertion of a cassette of DNA containing a gene for kanamycin resistance; this also acts as a selectable marker. (7) The cloned mutant gene is introduced into *H. influenzae* by transformation (allelic replacement); the phenotype of the parent strain and its mutant can then be compared to determine whether there are differences in LPS phenotype. (8) Immunoblotting is used to compare the reactivity of a monoclonal antibody (specific for LPS) in the parent and mutant strains; in this example, the LPS of the mutant has lost its capacity to bind to the monoclonal antibody, whereas colonies of the parent strain bind this antibody. This provides strong evidence in support of a function for this gene in LPS biosynthesis. (9) Further tests of biological function on parent and mutant can be done to further characterise the role of LPS, for example, its role in virulence. (10) Information on the many genes involved in LPS biosynthesis provides detailed information on the structure and its potential for use in vaccine development. *(Reproduced from Moxon[30] with permission from The Lancet.)*

aureus) and opportunistic infections (*Pseudomonas aeruginosa*). Importantly, complete genome sequences have become available for pathogenic bacteria, such as *Treponema pallidum* and *Chlamydia* spp., that could not be grown in vitro and for which few if any classical genetic methodologies are available. Ignited by the successes achieved in pathogenic bacteria, the entire genome sequence of all 14 chromosomes of the parasite *Plasmodium falciparum* have been sequenced,[3] a milestone in the quest to understand and control one of the most important causes of death and disability in the developing world.

IMPACT OF COMPLETE GENOME SEQUENCES

Complete genome sequences represent the most economical approach (less than 30 cents/base) to obtaining a vast body of information with which to investigate the biology of pathogenic microbes. However, the successful exploitation of these data is still dependent on the classical biologic methods of the pregenomic era. Indeed, many disciplines that had languished, such as microbial physiology, have been rejuvenated because of the wealth of information that can now be downloaded from a personal computer in minutes.

Complete genome sequences have not eroded any of the established fundamental tenets of biology. Our conceptual framework of the cell and its essential mechanisms, ranging from replication, genetic exchange and DNA repair to the complexities of commensal and virulence behavior of pathogens, remain unchanged. However, genome sequences have allowed a previously unattainable appreciation of genome content and of the very large number of distinct, even species-specific,

genes that exist. Many are of completely unknown function and these afford potentially completely novel approaches to understanding the biology of microbes, as well as opportunities for developing new diagnostics, therapeutics and vaccines. A critical aspect is the completeness of the information provided by genome sequences. This allows a comprehensive approach to determining which genes are essential to pathogenic or commensal behavior and whether they are deployed in colonizing, transmission, obtaining essential nutrients, evading host clearance mechanisms or damaging tissues. All the metabolic pathways available to the organism are apparent and these in turn can provide major clues as to the basis of the niche-specificity and tissue tropism of pathogens and facilitate the analysis of macromolecules (e.g. lipopolysaccharide)[4] of importance to virulence and the development of vaccines (Fig. 7.2). The nucleotide content (i.e. the ratio of adenine and thymidine to cytidine and guanine of a genome) is for the most part highly characteristic, and so it allows immediate identification of sequences within the genome that are foreign — DNA acquired by horizontal transfer, a mechanism responsible for conferring the genetic basis of antibiotic resistance or virulence. Examples of this kind of DNA include so-called pathogenicity islands (because they contain a whole suite of genes that are essential to causing disease) and large mobile resistance elements that confer multiple different resistances to antibiotics. Repetitive DNA (microsatellites), previously not considered a feature of prokaryotes, has been found in a number of major bacterial pathogens (*H. influenzae*, *Neisseria meningitidis* and *Neisseria gonorrhoeae*) and is responsible for antigenic variation.

INFORMATION CONTENT OF COMPLETE GENOME SEQUENCES (ANNOTATION)

Any microbial genome sequence contains an extremely significant amount of information — the complete genetic blueprint for that organism. To make that information of use and easily accessible to researchers, a major task for bioinformaticians is the annotation of a genome sequence to identify the genes, their relative position and their likely function. An annotated genome constitutes a primary interface for researchers to access the information encoded within it.

Genome annotation requires coupling of the processes of identification of open reading frames (ORFs) and other genome features with prediction of function. Most genes in any genome have not been experimentally investigated, so the expedient method of determining the function of encoded proteins is through inference from genes of known or proposed function, on the basis of sequence similarity (Table 7.1). A majority of microbial genomes have been annotated using an ORF-based method of analysis. Open reading frames are first identified in a sequence defined by the predicted start and stop codons. As an example, the program currently available from The Institute for Genomic Research (TIGR) website,[2] GLIMMER (standing for gene locator and interpolated markov models), identifies coding regions and distinguishes them from noncoding DNA using interpolated Markov models. [5] A lower size limit must be assigned to reduce the number of spurious reading frames included for analysis. A derivative version, GLIMMERM, has been developed particularly for small eukaryotic genomes. Gene functions are then assigned after homology comparisons by automated searching of ORFs from the new genome (query sequence) against databanks of sequenced and published genes and other genome sequences. Various search algorithms are used, a majority of which are based on the BLAST and FASTA search programs. The best matches for each ORF are noted and a judgment is then made to assign a predicted function to a query gene sequence. Some more recent genome sequencing projects, such as that for *N. meningitidis* serogroup B strain, used GLIMMER in conjunction with a non-ORF based method.[6] This latter method searches database sequences using large tracts of genomic DNA and aligns homologies independent of reading frame. Start and stop codons can then be overlaid on the results of the search, which are viewed via a graphical interface, such as ACEDB, which runs on a UNIX platform.[7] This allows the operator to select the most appropriate reading frame in the genome sequence. This method is particularly valuable for identifying translational frameshifts, which are often found associated with phase variable genes and pseudogenes. Pseudogenes (genes not expressed because of the presence of stop codons or frameshifts that interrupt the translated reading frame) are found in many genome sequences. A further program, ARTEMIS (a JAVA-based tool) allows viewing of sequence and sequence features via a graphical interface.[8] It is generally considered that detailed interpretation of the raw output from an annotation procedure by researchers with an intimate knowledge of the relevant organism is the most appropriate means of resolving the many problems posed by annotation of any given genome.

CATEGORIZING AND ACCESSING INFORMATION (DATA-MINING)

The gene pool contains all of the genes required for the existence of the free-living organism. Riley has proposed a system to catalog genes into broad functional groups.[9] These 12 groups have proved useful as a framework for classifying genes and they allow researchers to access the DNA sequence information in a directed and informative manner relevant to any particular research interest. For many microbial genome sequences, around 60% of genes can be assigned to these broad functional categories. Importantly, typically about 40% of the ORFs at the time of annotation remain unassigned with respect to function by homology comparisons alone. The ORFs that appear only within one genome and that have no sequence similarity to other sequences in the databases are termed 'hypothetical' or 'function unknown' (FUN),[10] whereas those of unknown function but present in more than one genome are classified as 'conserved

hypothetical'. The number of FUN genes has decreased as the number of completed sequencing projects increases and homologous FUN genes are identified in other organisms. An important consideration following any genome annotation procedure, based solely upon homology comparisons, is that some gene functions listed in that genome database may remain erroneous. Homology predictions alone do not provide rigorous evidence for the biologic function of genes and their products. Existing data bank sequences upon which predictions are based may have putative, probable or confirmed functions, and each will be given equal weighting by most annotation teams. Good quality partial matches and lower quality more extensive matches may not always be distinguished but could be crucial in deciding likely gene function. When analyzing and comparing between genomes, useful terms for considering genes of comparable function are paralogs (homologous genes in the same organism whose products perform related but not identical functions) and orthologs (homologous gene functions from different organisms). Orthologs are likely to have the same function whereas paralogs are more likely to have diverged in their function.

For investigators, most microbial genome databases allow both the searching of the genome sequence annotation using key words and the genome sequence by a search algorithm (e.g. GRASTA for TIGR genome sequences). To permit more detailed analyses on the investigator's own computer system, the complete genome sequence can be downloaded, usually in a FASTA format, using the instructions at the appropriate website. Once downloaded, the sequence can be investigated or manipulated as required and viewed via a graphical interface using programs such as ACEDB and ARTEMIS, described above. Two widely used software packages are freely available for sequence searching — stand-alone BLAST[11] and FASTA.[12] Both packages contain a number of programs (or 'flavors') that are used, depending on the nature of the query and the database sequences. Each package has user information in an associated 'README' file. In general, comparative protein sequence searches are the most informative for homology comparison. The output from homology searches include an expectation (E) value for each match, a statistical estimate of the significance of the particular comparison against that expected purely by chance. This is important information for deciding the homology of a query sequence; the smaller the value the greater the confidence of a true match. Typically, E values of 10^{-5} to 10^{-6} are considered as the threshold for homology assignment.

Other useful programs for comparing sequence information are:

- PSI-BLAST (position-specific iterative BLAST) program,[13] which uses successive BLASTP searches of a database to identify distantly related sequence function;
- ProDom (protein domain),[14] Prosite[15] and Pfam (protein family)[16] for analysis of families of proteins of related structure and/or function — each of these databases contains proteins grouped by homologous domains using different automated searches; and
- the Expasy website,[17] which locates any putative enzyme function in a biochemical pathway by Enzyme Commission (EC) number and provides links to other

useful information on function.

COMPARING AND CONTRASTING INFORMATION ON PATHOGENS

The bias in the selection of micro-organisms of clinical significance for genome sequencing projects exists because of our need to understand and control infection. As the number of available microbial genome sequences has increased, many studies have focused on comparative genomics, comparing whole genome sequences from related bacteria with their different pathogenic potential or host ranges. This has the potential to identify genes associated with expression of particular disease traits. As examples, studies have compared hypervirulent and carrier isolates of *N. meningitidis* and *N. gonorrhoeae*, pathogenic and nonpathogenic *Listeria* spp., and the human gastric tumorigenic pathogen *Helicobacter pylori* with *Helicobacter hepaticus* (which is a cause of liver cancer in mice). A particular emphasis in comparative studies of microbial pathogens has been placed on identifying pathogenicity islands, regions of DNA normally containing clusters of virulence-related genes. These may be mobile and when acquired are sometimes all that is apparently required to convert a bacterium to a virulent phenotype.[18] Such 'foreign' DNA can often be identified by a divergence in DNA base (percentage of guanine plus cytidine) composition or the characteristic prevalence of particular nucleotides, the so-called dinucleotide signature. Innovative strategies to identify novel candidate virulence genes through computational approaches are continually being developed.

Analysis of genome sequences has led to an increase in our understanding of the population biology of some pathogenic bacteria. The availability of complete genome sequences has facilitated multilocus sequence typing methods for epidemiologic studies. Limited analysis of DNA sequence at multiple sites in the genome permits comparison of the relatedness of large numbers of strains for any organism. Such studies have advanced our understanding of the dynamics of the genome and the population structure of micro-organisms. *Streptococcus pneumoniae* and *N. meningitidis* are characterized by high rates of interstrain recombination whereas, in *S. aureus* and *Mycobacterium tuberculosis*, the major driving force for population variability within these species is mutation.

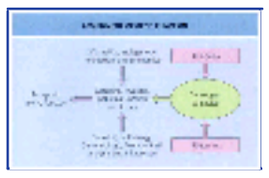

Figure 7-3 Assignment of gene function.

ADJUNCT METHODOLOGIES: MICROARRAYS AND PROTEOMICS

The assignment of gene function relies on a combination of sophisticated bioinformatic tools with the results of careful biologic experimentation (Fig. 7.3). Until the mid-1990s bacterial molecular biology was based on reductionist experiments designed to give information about individual genes. The genome sequence of the gastrointestinal commensal *Escherichia coli* was published in 1997 and revealed the limitations of these approaches. *E. coli* is the best understood of all organisms and detailed functions have been assigned to many of its genes. However, despite more than 60 years of research, it was found that one-third of the genome was made up of FUN genes.[10] Evidently, the development of functional understanding from genomic information posed a significant challenge. The necessity of looking at thousands of genes or proteins in a single experiment has spurred the development of 'functional genomics'. This methodology is largely based on identifying and characterizing messenger RNA (mRNA; transcriptomics) and translated peptides (proteomics) of individual genes.

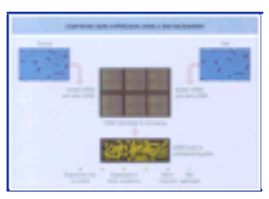

Figure 7-4 Comparing gene expression using a DNA microarray. The color of each spot relates to the level of expression of every gene on the microarray. *Further details can be obtained from http://www.ifr.ac.uk/safety/microarrays*

The transcriptome is the complement of mRNA species expressed in a bacterial cell under a particular condition, and it can be visualized with DNA microarrays (Fig. 7.4). Microarrays are microscope slides that have been spotted with DNA representing each of the gene sequences of a bacterium. They can be used to identify the activity of genes in a microbe, the so-called expression profile. To detect the changes in gene activity that occur when bacteria adapt to new environments, organisms are grown under different conditions, and the mRNA is extracted, fluorescently labelled and placed on the microarray. The degree of hybridization to specific genes reflects the abundance of mRNA and provides an indication of the level of gene expression. Microarray technology was originally developed to study eukaryotic RNA, which is extremely stable and easy to purify. In contrast, bacterial mRNA is very labile and this short half-life (as brief as 1 minute in some cases) poses technical challenges in recovering adequate amounts of mRNA to perform an analysis. These difficulties have been largely overcome, and reproducible gene expression profiles can now be obtained. Interpretation of these results has required the development of dedicated computer software methods to perform multivariate analyses so as to obtain data on bacterial gene expression from extremely large data sets.

Microarrays were first used to obtain gene expression profiles from in-vitro cultures of *M. tuberculosis* and *E. coli* in 1999. Subsequently, bacteria have been grown under defined conditions to determine the effect of factors such as acidity, anaerobicity, salinity and temperature on gene expression. Whole-genome expression studies can be used to identify genes differentially regulated in the host.[19] For example, it has been established that modulation of the heat shock response of *M. tuberculosis* promotes survival of the pathogen during the chronic phase of infection. Microarrays have been used to identify the effector regulatory genes (regulons).[20] These could be targets for the development of novel drugs.

Microarrays have been used to explain why *Vibrio cholerae* becomes more infectious during passage through the human gut; this has been done by isolating RNA from human stool samples and comparing it with RNA from laboratory-grown bacteria. Forty-four genes were more active and 193 were less active in the stool-derived sample. These findings provide new insights into the pathogenesis and transmission of cholera. In another example, gene expression

profiles showed significant changes in transcription during infection of murine macrophages with *Salmonella typhimurium*. One-quarter of the genome (919 genes), including many virulence genes and genes that respond to DNA damage (SOS response genes), had altered expression profiles.[21]

Microarrays are beginning to be used as a tool to study differences in the complement of virulence genes between bacterial strains of the same or related species. This 'genomic indexing' approach is based on analysis of chromosomal DNA rather than mRNA, and it gives information about the presence or absence of genes using microarray hybridization. It has already been used to determine the presence or absence of the major virulence determinants in a collection of strains of *Salmonella* spp.,[22] and in a range of other bacterial pathogens including *Campylobacter jejuni*, *H. pylori*, *M. tuberculosis*, *S. aureus* and *V. cholerae*. Genomic indexing could be the ideal way to assess the level of horizontal gene transfer between bacteria.

Much regulation occurs at the post-transcriptional, translational or post-translational levels; changes in mRNA transcription do not always lead to concomitant changes in protein expression. Consequently, the entire bacterial protein complement, the proteome, must be studied in parallel with the transcriptome. Current approaches for proteome analysis rely on a variety of two-dimensional polyacrylamide gel electrophoresis techniques. Proteins are separated according to their isoelectric point and their molecular weight. Mass spectrometry is then used to obtain partial peptide sequence, and information from comprehensive databases is then used to interrogate the relevant genome so as to identify the appropriate protein of interest.[23]

Most studies of bacterial proteomes have focused on the growth of particular pathogens in vitro. A large-scale study of *H. pylori* in which the bacteria were cultured on agar plates identified 175 proteins among which was the urease virulence factor.[24] Proteomic technology offers the hope of recognizing the proteins that are produced by bacteria during infection of mammalian cells, and two-dimensional gels have been used to show that the profile of bacterial proteins changes during infection. These approaches have generally relied on differential labelling methods to reveal the pathogenencoded proteins. Six abundant proteins that are expressed by *M. tuberculosis* during infection of human macrophages have been identified; they include two major chaperone proteins (GroEL-1 and GroEL-2) as well as two proteins that are components of the cell wall of *M. tuberculosis*. [25] However, this technology has been successfully only for the direct identification of bacterial proteins from infection of cultured cells in vitro; it is not currently applicable to whole-animal models because of the limited quantities of protein that can be obtained ex vivo.

One important and innovative application of immunoproteomics is the identification of subsets of bacterial proteins that are expressed during natural human infections.

This approach uses sera obtained from infected patients. The sera are used to probe two-dimensional gels comprising the proteome of the infecting pathogen. In one study, 310 antigenic proteins of *H. pylori* were identified and characterized by routine mass spectrometry.[26] Because these proteins raised an immune response, they were known to be expressed during infection and are therefore candidates for the development of specific diagnostic assays.

THE DISCOVERY OF NOVEL AGENTS FOR CONTROLLING INFECTIONS

The availability of complete genome sequences has dramatically changed the opportunities for developing new and improved vaccines or antimicrobial agents by facilitating the discovery of novel molecules and increasing the efficiency and rapidity of their development. Complete genomic databases provide an inclusive catalog of all potential candidate vaccines and drug targets. In conjunction with adjunct technologies, including bioinformatics, random mutagenesis, microarrays and proteomics, a systematic and comprehensive approach can be undertaken. Genomics must be used in conjunction with population biology to ensure that the vaccine or drug can target all pathogenic strains of a species. On a more cautious note, the genomic revolution has brought to the fore the immense difficulties inherent in evaluating the large number of potential candidates emanating from complete genome sequence data. How to arrive at a judicious decision on which of many candidates to take forward into human trials is an immense challenge. The costs of taking a new product from concept to market are huge (millions to billions of dollars) and the process lengthy (5–10 years). Given that genomic screens may yield scores, even hundreds, of candidates, there is a need to reduce to a handful the number of molecules that are taken forward into clinical testing.

Genomics and vaccines

Ideally, a vaccine should be effective against all pathogenic strains of a species because host immune responses to cell surface-exposed epitopes, through natural selection, result in both intra- and interstrain genetic diversity (diversifying selection). This is most effectively achieved by selecting strains that are representative of the genetic diversity within the natural population of that species through the use of, for example, ribotyping multilocus enzyme electrophoresis or multilocus sequence typing[27] [28] and determining its presence or absence and, if present, the degree of amino-acid variability. This amalgamation of population biology and genomics is critical because complete bacterial genome sequences are typically available for only one strain or a very few strains of a pathogen. Basing a genomic screen for vaccine antigen discovery on one or two strains of the species runs the risk of identifying candidate genes or epitopes that are absent in other genetically distinct pathogenic strains of the species. However, if a gene is present in some strains of the species but is absent from the genome of the sequenced strain, this is not a serious flaw in that any robust vaccine candidate should be present in all strains.

A proof in principle of the utility of genomics is provided by the recent exploitation of the complete genome sequence of *N. meningitidis* group B.[6] [28] This important pathogen is a major cause of meningitis and septicemia. Although group-specific capsular polysaccharide vaccines can prevent disease caused by most meningococcal strains, this approach is not easily applicable to the development of vaccines against group B strains.[29] As a result, there has been a substantial research effort over many years to identify alternative noncapsular antigens. This has proved to be a frustrating and costly process and one that has proved unable to deliver any convincing vaccine candidates suitable for routine immunization of infants. The availability of the complete genome sequence of *N. meningitidis* group B provided an opportunity to take a different, genomic-based, approach. Primary screening of the complete genome sequence for coding capacity was carried out using database and computer programs to exclude proteins with cytoplasmic functions and identify surface exposed or secreted proteins. This search identified 570 such ORFs, and the sequences of these predicted genes were amplified using polymerase chain reaction and then cloned into *E. coli* to express each polypeptide. Successful expression was achieved in the majority (61%) and included lipoproteins, inner membrane proteins, periplasmic proteins and outer membrane proteins. The recombinant proteins were used to immunize mice and the postimmunization sera were analyzed to verify the specific reactivity with, and surface localization of, each polypeptide. Out of 85 proteins that showed convincing evidence of surface localization, 22 also showed activity using the bactericidal

assay that has been shown to correlate with protection in humans. Several of these proteins are currently being prepared for testing in phase 1 human studies.

Perspective

The past 8 years have seen dramatic changes in the scientific approach to infectious diseases as the result of complete genome sequences, especially those of bacterial pathogens. This has revolutionized the study of individual microbes and pathogenesis of infectious diseases. Over 80 complete bacterial genomes have been published, half of which belong to strains that cause disease. Many more, probably hundreds of genomes are in draft form or are in the process of being sequenced,[19] and many of these are held privately. Increasingly, publications of complete genome sequences include innovative uses of sequence data, such as high-throughput experimental analyses (e.g. microarray studies). There will undoubtedly be an explosion of papers of this kind in the next few years.

The ability to integrate information derived from genomes with other sources of information will be central to our future ability to exploit bacterial genomes. The sequencing of pathogen genomes has proved beyond doubt the value of using genomes to discover new determinants of virulence. It has also proved the power of using genomes to elucidate the molecular basis of physiology, adaptation to niche, and the mechanisms by which genomes change over both short and long evolutionary time spans. In order to build upon this knowledge we must:

- find new ways to characterize the vast number of genes without known function, especially those conserved between organisms;
- continue to look for global patterns that help to define unusual features of specific sequences, strains and species;
- more effectively translate the results of genome sequence into hypotheses that can be tested by experiment;
- explore the extent and significance of population-level genetic diversity; and
- place each genome into its proper 'organismal' context by understanding its specific ecology and evolution.

Perhaps most importantly, this heterogeneous and complex information must be captured in next-generation databases that will improve the scope, quality and interconnectivity of our current invaluable electronic resources. By combining a sound knowledge of clinical manifestations of disease, classical microbiology and genome sequences, we will understand in more detail than ever before 'what makes a pathogen'.

Chapter 8 - Viral Exanthems

Barbara A Bannister

INTRODUCTION

This chapter discusses those infections characterized by the eruption of widespread skin lesions (an exanthem). Although their etiologies differ, they share a number of features:

- many are highly infectious by the airborne route;
- the viral agents are shed in oropharyngeal secretions;
- exposure and infection usually occur in childhood;
- epidemics and large outbreaks are common in susceptible groups;
- infections in adults tend to be more severe, with complications; and
- infections in pregnancy can be detrimental to the fetus.

In spite of these similarities, each disease is discussed individually because each has its own etiology and clinical behavior.

MEASLES (RUBEOLA)

EPIDEMIOLOGY

Measles is highly infectious. In most populations, 95% or more of adults are seropositive. Transmission is usually by airborne droplet spread, which is important in hospitals and other institutions. As with other paramyxoviruses, including respiratory syncytial virus, transmission can also occur by direct transfer of infectious secretions, such as saliva, on hands, toys or other fomites. Viruses are shed from the respiratory mucosa during the prodrome and evolution of the rash; in adults excretion can persist for 6 days after the rash begins.

In nonimmune communities, large epidemics occur in the spring and early summer of alternate years. Maternally derived immunity is effective up to age 6–9 months. The peak age of infection is about 4 years. In small and isolated communities, epidemics occur at less frequent intervals; they affect a wider age range and result in a higher mortality.

Death occurs in approximately 1 in 4000 cases in developed countries, usually in debilitated or immunocompromised individuals. In malnourished populations fatality rates reach 10–15%, mainly as a result of bacterial complications.

PATHOGENESIS AND PATHOLOGY

Measles virus is a member of the Paramyxoviridae, a family of enveloped, negative single-stranded RNA viruses. Human signaling lymphocyte activation molecule (SLAM, or CDw150) acts as the major receptor for measles virus. SLAM is expressed on lymphocytes and dendritic cells and is important in T-cell and cytotoxic natural-killer-cell activation.[1] The involvement of SLAM may help to explain the significant immunosuppression that accompanies measles infection. The Edmonston strain of measles virus, progenitor of some commonly used vaccines, will also bind to CD46. Viral ribonucleocapsids are assembled in the host cell nucleus and accumulate as inclusion bodies in the cytoplasm. Virions acquire matrix protein and leave the host cell by budding, deriving their envelope from the host cell membrane. Infected host cells often coalesce to form multinucleate giant cells.

Once the virus has replicated in respiratory mucosal cells, it invades the local lymph nodes. Within 4–6 days it is detectable in the plasma and in blood mononuclear cells, particularly lymphocytes. By about 8 days the virus is detectable in the liver, spleen, lung, respiratory epithelia and eye, and has more recently been demonstrated in endothelium in the central nervous system. The rash reflects viral invasion of the skin, with accumulation of immune complexes and mononuclear cell infiltration.

In measles inclusion body encephalitis (MIBE) and subacute sclerosing panencephalitis (SSPE), virus ribonucleocapsids are seen in neurons but the virus is replication-deficient; hemagglutinin is often absent, and membrane and fusion proteins are undetectable.[2] No virus release occurs and giant cells do not develop. In the laboratory these defects are rectified in the presence of interferon-a and the neuronal infection regains the ability to produce virus.[3]

PREVENTION

Pre-exposure prophylaxis

Live attenuated measles vaccines, and measles/mumps/rubella (MMR) vaccines, based on the Edmonston, Schwartz or Moraten virus strains, were introduced in the 1960s and 1970s. They rapidly controlled epidemic disease, including the rare neurological manifestations (Fig. 8.1). However, immunization before the age of 9–12 months produces short-lasting immunity, whereas immunization at the age of 1 year or more leaves a window of susceptibility between the loss of maternally derived protection and vaccine-induced protection; furthermore, vaccine uptake rates of over 95% are needed to prevent the spread of measles, emphasizing the need for effective immunization policies.[4]

A two-dose immunization program is used: the first dose at the age of 12–15 months (or at 6–9 months in developing countries in which measles threatens young infants), followed by a booster at 3–5 years of age. About 96% of recipients seroconvert satisfactorily. Outbreak investigations show that approximately 4% of exposed vaccinees suffer from clinical measles.

Common adverse effects of immunization include:

- a mild febrile illness, rarely with a transient rash ('mini-measles') after 7 days, in approximately 10% of first immunizations; and
- mild allergic reactions such as urticaria or other rashes (anaphylaxis is exceptionally rare).

All other adverse effects are rare. Although live vaccines are generally contraindicated in immunosuppressed individuals, measles vaccine has safely been given to children who had both asymptomatic and symptomatic HIV infection. There is some evidence that survival from severe measles infection is better in previously immunized HIV infected patients. However, in severe immunosuppression ($CD4^+$ cell count < 500) there is an increased risk of disseminated, pneumonic or neurological infections caused by the vaccine viruses,

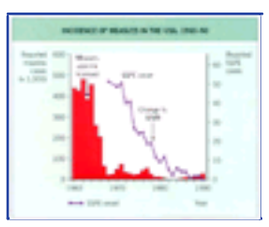

Figure 8-1 Incidence of measles in the USA 1960–90. The effect of measles and measles/mumps/rubella immunization on the incidence of measles and of SSPE in the USA, showing that both are prevented by the live attenuated vaccines.

and it is now recommended that immunization should be avoided in these cases.

Inactivated vaccine, available in the 1950s, was less effective; some recipients developed measles and suffered modified disease, with severe lung involvement and/or exfoliation. Other, highly immunogenic vaccines have been developed, and are effective at the age of 2–3 months, but there are concerns that their immunomodulatory effects may predispose recipients to other severe childhood infections.

Postexposure prophylaxis

Human normal immunoglobulin is effective in preventing measles. It should be given early, preferably within 3 days of exposure. Since universal immunization against measles, levels of protective antibody in pooled immunoglobulin products may have tended to decline. In a study from Japan, commercial products gave less than 50% protection. The recommended intramuscular doses for immunoglobulin to prevent an attack of measles are as follows:

- age under 1 year — 250mg immunoglobulin;
- age 1–2 years — 500mg immunoglobulin; and
- age 3 years and over — 750mg immunoglobulin.

All commercially available intravenous immunoglobulin preparations contain high levels of antibodies against measles.

CLINICAL FEATURES

The prodromal illness

After an incubation period of 9–11 days illness begins abruptly with high, swinging fever, irritability, nasal and conjunctival discharge, repetitive 'croupy' cough and, often, loose stools. Febrile convulsions are common in young children. Chest auscultation reveals many moist sounds but impaired respiratory function is rare.

Koplik's spots are pathognomonic of prodromal measles. They appear in the buccal mucosa, usually opposite the upper premolars, but may affect the whole inner cheek. White and irregular, their size varies from 'salt grains' to 'small breadcrumbs' and they are superimposed on a highly inflamed mucosa. They disappear by the second day of the rash and may be absent in the vaccinated individual.

Figure 8-2 The acute rash of measles. Marked conjunctivitis accompanied the maculopapular skin lesions in this unimmunized adult.

Evolution of the rash

The rash begins on the third to fifth day of fever. It is maculopapular, extending downward from the ears and hairline, reaching the hips by the next day and the lower legs by the day after that (Fig. 8.2). After 4 days, it changes from pink to purplish and the fever abates quickly, marking the end of viremia. The rash fades without desquamation in 4–7 days.

In dark-skinned patients the rash may be invisible but the papular element causes a 'gooseflesh' appearance. In severe measles (which is more common in adults than in children) or in immunosuppressed patients there may be a hemorrhagic component, with desquamation on healing.

Other features

There is often mild neutropenia, with a white cell count of 3–4 × 10^9 /l.[5] Significant thrombocytopenia is rare. Liver transaminases and pancreatic amylase may be elevated, particularly in adults, although frank jaundice and pancreatitis are rare. More severe hematological and biochemical abnormalities indicate more severe disease.

Marked suppression of cell-mediated immunity occurs during the illness and for weeks afterward, with negative recall skin-test reactions.

Complications

Secondary bacterial infections

These are common and often severe. Acute suppurative otitis media and pyogenic bronchopneumonia are the most frequent. In addition to *Streptococcus pneumoniae* and *Haemophilus influenzae*, *Staphylococcus aureus* is an important secondary invader (Fig. 8.3). Rare cases of pyogenic mediastinitis are reported.

When poor hygiene, crowding or malnourishment exist, severe, destructive infection of macerated perioral or perinasal skin (noma, or cancrum oris) may be caused by pyogenic organisms, often accompanied by herpes simplex and/or anaerobic mouth flora (Fig. 8.4). A cloudy or punctate keratopathy with secondary bacterial keratoconjunctivitis may threaten sight. Tuberculosis may be unmasked or contracted during the immunosuppressed phase.

Measles is a dangerous infection in patients who have cell-mediated immunosuppression. Koplik's spots are often absent; the rash may be atypical and up to 30% of cases have no rash. Neutropenic patients have up to 70% mortality, and those who have severe HIV about 40%.[6]

Postinfectious encephalitis

Postinfectious encephalitis occurs in approximately 1 in 800–1600 cases and has a mortality of 12–15%. Up to 50% of survivors have neurologic sequelae of varying severity (see Chapter 27).

Measles inclusion body encephalitis

Measles inclusion body encephalitis, or subacute measles encephalitis, [7] is described most often in immunosuppressed children, with onset 1–7 months after acute measles. Occasional reports exist of cases with no known history of acute infection, and in one case a

Figure 8-3 Secondary invasion by *Staphylococcus aureus* in measles. Ill-defined basal opacities were seen in a patient who had moderate respiratory failure; *S. aureus* was isolated from sputum (same patient as in Fig. 8.2).

Figure 8-4 Secondary infections complicating measles. Perioral infection and paranasal herpes simplex lesion in a 2-year-old girl.

measles vaccine strain was identified in neural tissue.[8] Fever, loss of cerebral function and focal seizures develop progressively over 3 or more weeks. Fatality rates are about 75% and neurological sequelae are common in survivors.

Subacute sclerosing panencephalitis

Subacute sclerosing panencephalitis occurs in approximately 1 in 1,000,000 cases, particularly if the original measles infection occurred before the age of 2 years. After a 3- to 10-year interval, clumsiness and poor school performance herald the onset of myoclonic spasms with typical electroencephalographic changes; decerebration and death occur within 2 years.

Other associations of measles virus

Measles virus RNA has been demonstrated in the ossicles of patients who have otosclerosis. There is evidence that the age of onset of otosclerosis symptoms has increased since the availability of immunization for measles, suggesting that immunization may be protecting younger age cohorts and supporting measles as an etiological factor in otosclerosis. Paramyxovirus-like inclusions, which react with antibodies to measles virus, have been found in osteoclasts of patients who have Paget's disease.

In the 1980s a group of bowel specialists suggested that wild or vaccine strains of measles virus were an etiological factor in Crohn's disease. However, it is now known that the apparent presence of viral antigenic reactions in bowel mucosa was due to a cross-reaction with host protein and that the reaction was not specific to any particular type of inflammatory condition.[9] More recently, a further hypothesis — that measles vaccine virus, in the MMR formulation but not alone, could precipitate features of autism — has not been supported by epidemiological studies from several countries.[10]

DIAGNOSIS

Although the clinical features are often typical, the diagnosis should be confirmed by laboratory tests, particularly during measles eradication programs.

Measles virus is difficult to recover from cell cultures, although it will grow in primary primate or human cell lines. Serodiagnosis is sensitive using IgM enzyme-linked immunosorbent assay (ELISA) in serum or saliva samples. Positive results are obtained at presentation in approximately 70% of cases, and up to 100% are positive by the end of the first week. In SSPE there are very high levels of IgG antibodies, with evidence of local production in the cerebrospinal fluid (CSF), and measles nucleoprotein and genome are detectable in brain biopsy. In MIBE, CSF antibodies are not a reliable test; electron microscopy, antigen detection or genome detection must be performed on brain tissue. Bronchial lavage may demonstrate multinucleate giant cells, intracytoplasmic inclusion bodies and measles capsid antigen, which is helpful in detecting measles pneumonitis in immunosuppressed patients. High levels of measles-specific IgG are found in the perilymph in otosclerosis.

MANAGEMENT

Vitamin A

Measles mortality is inversely related to serum retinol concentrations. Children from developing countries or those from crowded urban areas of Western countries where health care and nutrition are suboptimal should receive oral vitamin A 10,000IU (age 1 year) or 20,000IU (age 1 year plus) at diagnosis.[11] Children who have keratoconjunctivitis should have further doses 1 day and 1 month later.

High-dose vitamin A can be given with measles vaccine, although there is some evidence of reduced seroconversion, possibly

because vitamin-induced immune enhancement reduces vaccine virus replication.

Antibiotics

The commonest febrile complications of measles are due to pyogenic bacterial infection. Empiric treatment for these should include antibiotics effective against common respiratory pathogens plus *S. aureus*. Co-amoxiclav, second-generation cephalosporins or trimethoprim-sulfamethoxazole are suitable choices. Treatment may be modified if necessary when laboratory results are available.

Antiviral drugs

Measles in the immunocompetent rarely demands specific treatment, although a single randomized, double-blind trial of ribavirin (tribavirin) therapy suggested that the course of the disease was slightly shortened and the occurrence of complications reduced in the treatment group.[12] Inhibitory levels of ribavirin can be demonstrated in serum and CSF during intravenous dosing. Reports of attempted treatment for severe or complicated measles are based on small numbers of cases. Although few adverse effects of ribavirin are reported in these cases, dose-related hemolysis, as well as nausea, malaise and agitation, are acknowledged adverse effects, which may limit longer courses of treatment.

Inhaled and intravenous (20–35mg/kg/day) ribavirin has been used successfully in patients who have severe viral pneumonitis.[13] However, experience suggests that specific therapy must be started early to derive significant benefit, preferably within 5 days. In the immunosuppressed, a 1-week course of intravenous ribavirin is usually given; if recrudescence occurs, this may respond to a further course.

Measles inclusion body encephalitis has also been treated with intravenous ribavirin, given in courses of 2 or 3 months.[7] An early fall in fever was seen in many cases, but treatment started later than 1 or 2 weeks after onset did not usually prevent severe or fatal disease.

Intrathecal interferon-a may significantly delay deterioration in SSPE but must be given intraventricularly in doses of around 3MIU, up to twice weekly. Sustained responses and some improvement in neurological deficit have been reported after the combined use of interferon and ribavirin.[14] However, the treatment is demanding and must be continued indefinitely to maintain its effectiveness.

Intravenous immunoglobulin has been used in conjunction with ribavirin in a few reported cases of severe pneumonitis and of disseminated measles. It is not possible to determine whether it contributed to a positive outcome.

RUBELLA

EPIDEMIOLOGY

Rubella virus (Rubivirus), a member of the Togaviridae, is transmitted from person to person by the airborne route and is only slightly less infectious than measles. An increase in cases occurs every 4–10 years, with larger epidemics every 10–20 years (Fig. 8.5). In susceptible populations the peak age of infection is between 5 and 9 years. In Western countries before the advent of immunization, 15–20% of individuals remained susceptible beyond the age of 20 years. In some tropical countries up to 40% of adults are susceptible.

Although rubella is mild in children and nonpregnant adults, in pregnant women the infection commonly causes severe disease and long-term damage to the developing fetus (see Chapter 65).

Recognition of rubella can be difficult, as it is often trivial, subclinical or atypical, mimicking other infections.[15]

Figure 8-5 Incidence of rubella in England and Wales. The effects of different immunization programs are shown. *Data from Bannister et al. Infectious disease, 2nd ed. Oxford: Blackwell Science; 2000: 234.*

PATHOGENESIS AND PATHOLOGY

Togaviridae are enveloped RNA viruses with cubical symmetry. Humans are the only known hosts of Rubivirus and only one serotype is recognized. Culture is possible in a variety of cell lines but rarely produces a cytopathic effect. Positive cell cultures are identified by immunofluorescence, antigen-detecting ELISA or interference with infection by other viruses such as enteroviruses.

The virus attaches to and invades upper respiratory and pharyngeal mucosal cells. Viral construction and assembly occurs in the cytoplasm, and virions bud into intracytoplasmic vesicles, acquiring their envelope from the host cell membrane. Viral hemagglutinin molecules are inserted into the envelope. Viremia and pharyngeal shedding are detectable 9 or 10 days after infection, and virus excretion continues for 14–21 days.

Most body tissues can be invaded, including lymphocytes, conjunctiva, synovium, uterine cervix and lymph nodes. Virus is excreted from the nasopharynx and in the stools and urine. The appearance of the rash marks the end of viremia and the production of neutralizing antibodies. Interestingly, men produce earlier and larger antibody responses than do women to several rubella antigens, but only women seem to produce antibodies to the second envelope protein E2.[16] Capsid antigens are important in eliciting cytotoxic cell-mediated immunity.[17]

PREVENTION

Live attenuated rubella vaccines became available in the late 1960s. About 95% of recipients seroconvert and develop hemagglutination-inhibiting antibodies (HI antibodies), which correlate with neutralizing antibody function. Vaccine virus is briefly excreted from the pharynx in the 4 weeks after immunization but transmission to close

Figure 8-6 Rubella. This patient had a typical early maculopapular rash, irritating conjunctivitis and painful occipital lymphadenopathy.

contacts does not occur. Other members of a family may therefore be immunized even if a household member is pregnant.

Although HI antibodies decline over 10–16 years after immunization, resistance to re-infection by wild strains wanes little, indicating that vaccine-induced immunity is as durable as that which follows natural infection.[18] Between 1.5% and 4% of vaccinated individuals become re-infected (usually asymptomatically) and exhibit an IgM response after exposure to wild virus. Viremia is transient or absent during most re-infections. Congenital rubella rarely follows re-infection in naturally immune or vaccinated women. Effective immunization, vigilance and readily available screening and diagnostic testing are important in controlling outbreaks and protecting pregnant women.

Postexposure prophylaxis with human normal immunoglobulin has been attempted but even high doses have not been reliably effective.

CLINICAL FEATURES

Postnatally acquired rubella is usually mild, and in most studies about one-half of seroconversions are asymptomatic. The incubation period is about 15 days (range 14–21 days). The clinical features may appear in any combination, usually developing simultaneously, although joint involvement often follows after 4–7 days.

Rash

This usually coincides with fever, although adults may suffer 1 or 2 days' prodrome. The rash spreads from the face and chest (Fig. 8.6) to the peripheries over 1 or 2 days. It is maculopapular or macular, with small elements, often fading to a 'peach-bloom' appearance after the first day. It rarely lasts more than 3 or 4 days. It mimics the rashes of parvovirus infection (see below), echovirus infections and mild scarlet fever or early Kawasaki disease, although it does not desquamate on healing. Conjunctival itching, soreness and reddening often occur at the onset of illness.

Lymphadenopathy

Large, tender lymph nodes high in the occipital region are typical of rubella, although minor cervical lymphadenopathy may also occur. The patient may complain of localized head or neck pain. The nodes are hard and usually immobile, as they are tightly confined by the cervical fascia.

Arthralgia and arthritis

Many adults and some older children complain of marked joint pain late in the illness. There is also an increased incidence of arthropathy following rubella immunization. The proximal finger joints and wrists are most often affected. Frank arthritis with effusions, soft tissue swelling and erythema can occur; larger joints may

also be involved and women are affected more often than men.[19] In some individuals acute polyarthritis resembles rheumatoid arthritis but subsides over weeks or months. Some workers have found evidence of persisting rubella RNA in blood or peripheral blood mononuclear cells of patients who have arthropathy but others have failed to confirm this.[20] An auto-immune etiology is suggested by the increased prevalence of HLA-DR2 and DR5[21] in those affected, and by the interaction of cellular rubella-associated proteins with autoantigens such as Ro and La.[22]

Complications

Thrombocytopenia

A modest reduction in the platelet count is common and occasionally causes thrombocytopenic purpura, even if the original infection was subclinical. Severe bleeding is rare but may occur late in the course of the rash. The platelet count recovers completely within a few weeks. Thrombocytopenia rarely follows immunization with MMR vaccine but does not recur with further doses. Arthralgia may follow immunization in older girls and adults.

Encephalitis

Encephalitis is a rare complication, affecting approximately 1 in 5000 patients. It can occur up to 1 week after the appearance of the rash but very rarely before it. The onset is abrupt, with irritability, headache and, often, stiff neck. Lumbar puncture reveals lymphocytes and mildly elevated CSF protein. The electroencephalogram shows widespread slow-wave abnormalities. Convulsions, altered consciousness or neurologic signs may follow, with varying severity. Polyradiculitis occurs rarely.[23] Almost all patients recover fully within 1 week or so, although fatalities and a chronic SSPE-like syndrome have occasionally been reported.

Individual reports exist of rubella-associated cases of hepatitis, pancreatitis and retinal vasculitis. Rubella antigens have been demonstrated in the chondrocytes of patients who have Paget's disease.[24]

DIAGNOSIS

Rapid diagnosis depends on the detection of IgM antibodies, using antibody capture or sandwich ELISA tests and particle agglutination techniques. Immunoglobulin M antibodies are detectable very early in infection and are also useful in diagnosing re-infection in those already immunized. Many polymerase chain reaction (PCR)-based tests are under investigation but most laboratories still rely on serological tests.

Screening tests for immunity are important, especially in antenatal care. Radial diffusion precipitin or radial hemolysis tests are the most frequently used techniques.

MANAGEMENT

Management is symptomatic. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in treating arthralgia and arthritis but should be substituted with simple analgesics if there is symptomatic thrombocytopenia.

Severe thrombocytopenia may be treated with prednisone (prednisolone), or intravenous immunoglobulin followed by a brief reducing course of prednisone.

Neither corticosteroids nor antiviral agents influence the course of rubella encephalitis.

PARVOVIRUS B19 INFECTION AND ERYTHEMA INFECTIOSUM

EPIDEMIOLOGY

Parvovirus B19, or human serum parvovirus, is the only member of the Parvoviridae pathogenic to humans. The Parvoviridae are small, icosahedral, nonenveloped viruses whose genome is a single 5kd strand of DNA. The family includes the adeno-associated viruses, which replicate only in the presence of co-infection with a helper virus. Serologic evidence suggests that some can infect humans asymptomatically. Parvovirus-like structures (small round viruses or small round featureless viruses) can be seen in the stools of patients who have acute gastroenteritis and have also been identified in some foods, but these have not been speciated.

Parvovirus B19 is common worldwide and is highly transmissible from person to person via respiratory tract secretions; it has an incubation period of 6–10 days. Epidemics occur, peaking in the spring, every 3–5 years, with smaller outbreaks in intervening years. Infection is commonest between the ages of 4 and 10 years and usually manifests as erythema infectiosum (fifth disease or slapped cheek syndrome). In those who have disorders causing short red blood cell survival, transient aplastic anemia occurs; in countries in which sickle-cell disease is common epidemics of aplasia occur. The high level of viremia in parvovirus infection means that transfusion-transmitted disease can occur. Infection probably confers lifelong immunity.

PATHOGENESIS AND PATHOLOGY

Viruses are adsorbed on to protein receptors of the host mucosa and are transported to the nucleus, where they uncoat. DNA replication can only occur if the host cell is in the S phase of mitosis. In the mature host, infection therefore affects rapidly replicating tissues, such as the bone marrow, reticuloendothelial system and, particularly, red-cell progenitors. The erythrocyte P-antigen acts as a virus receptor.[25] In the fetus, early infection may cause widespread damage and death of the conceptus, whereas later infections affect red-cell precursors (see Chapter 65).

Viral replication and assembly takes place in the host-cell nucleus; virions are released by lysis of the nuclear and cytoplasmic membranes. Virus is detectable in throat washings up to 1 week after infection, and an intense viremia (10^{10} –10^{12} virus particles/ml serum) occurs at the same time.

Infection of erythrocyte precursors causes a profound reticulocytopenia during the second week, whereas the total leukocyte count falls to a lesser extent. Between days 10 and 14, IgM antibodies to capsid antigens appear, terminating the viremia. They remain detectable for 2–3 months. Between the third and fourth week IgG antibody levels rise; these decline slowly over a number of years.

PREVENTION

Parvovirus B19 is extremely difficult to cultivate in the laboratory and this has delayed vaccine development. Attempts to engineer antigens, for instance in baculovirus systems, hold promise. Quarantine is not an effective means of interrupting transmission, as many infections are subclinical and the infectious period is over by the time typical clinical features develop.

Attempts at prevention by the use of intramuscular immunoglobulin have not been reported. Intravenous immunoglobulin preparations contain high levels of antibody to parvovirus B19 and might be effective in prophylaxis if the exposure was recognized.

CLINICAL FEATURES

At least 50% of parvovirus infections are unrecognized. Most recognized infections present with combinations of rash, anemia and arthritis but any feature can occur alone.[26]

Rash (erythema infectiosum)

After 2–4 days of malaise, fever and sweating, erythema of the cheeks appears, often with a slightly raised margin, as though the patient had been slapped (hence the name 'slapped cheek syndrome'). A macular rash appears 1 or 2 days later, spreading from the neck and shoulders to the peripheries in 2–3 days. Clear areas appear in the rash; these cause a reticulate pattern that can persist for 10–14 days, fading to violet and fluctuating with the skin temperature.

Other bizarre rashes may complicate the feverish, viremic phase of illness. Childhood papular-purpuric gloves and socks syndrome (PPGSS) is well described, consisting of a mildly itchy, confluent erythema with a marked purpuric element that sometimes resembles a large bruise. The author has seen similar rashes affecting the buttocks, perineum and thighs. Despite their intensity, these rashes resolve spontaneously in 4–6 days.

Arthropathy and arthritis

The incidence of arthritis is uncertain, as it can occur in the absence of rash or other features. In known cases it ranges from 10% to 33%, being highest in women and lowest in children. The commonest manifestation is polyarthralgia, with particular involvement of the wrists and proximal interphalangeal joints. Monoarthralgia and monoarthritis are also seen and may cause concern when they manifest as pseudopalsy in a child. Young women may suffer acute polyarthralgia or polyarthritis, with or without rash but usually with noticeable preceding fever. Although most individuals recover in 1–2 weeks, pain and stiffness can persist for several months. Evidence of parvovirus infection can be found in some cases of patients who have undifferentiated mono- and oligo-arthritis.[27]

Blood and bone marrow disorders

Stem-cell and erythrocyte infection profoundly affect erythropoiesis during the viremic phase. The reticulocyte count is usually negligible or undetectable for 4–6 days, and bone marrow examination shows cessation of red cell maturation and the presence of giant proerythroblasts. In normal patients, over 80% may exhibit mild anemia, but in patients who have sickle-cell disease, hereditary spherocytosis or severe nutritional anemias, there is transient, profound aplastic anemia. In tropical countries, epidemics of 'aplastic crises' can occur.

Other elements of the blood are less commonly affected; however, mild neutropenia and thrombocytopenia are common. Reticulocyte, platelet and neutrophil counts often rebound to levels well above normal in the 10 days after the fever.

Other clinical features

Individual reports of acute endocapillary proliferative nephritis have described parvovirus-containing immune complex deposits in the mesangium.[28] Meningoencephalitis has been described. Reports of hepatitis, myocarditis and systemic vasculitis have not been unequivocally attributed to parvovirus infection. Reports exist of systemic lupus erythematosus, apparently precipitated by acute parvovirus infection.

Complications

The most important complications are those affecting pregnancy, which include second-trimester fetal loss or hydrops fetalis (see Chapter 65)

Hemophagocytic syndrome has been reported to complicate acute parvovirus infection.

Persistent aplastic anemia can occur when an immunocompromised patient fails to clear replicating virus from the bone marrow stem cells.

Polyarticular juvenile arthritis and refractory rheumatoid arthritis have been associated with an increased likelihood of seropositivity to parvovirus B19.

DIAGNOSIS

The presence of fever plus cytopenias or a very low reticulocyte count should arouse suspicion of parvovirus infection, especially if a rash or arthralgia also exists.

In the febrile phase, high titers of virus in the blood permit confirmation by ELISA or immunofluorescence methods of antigen detection or by PCR and identification of parvovirus DNA.

Immunoglobulin M antibodies become detectable at about the onset of the rash, allowing a reliable serologic diagnosis by the sixth to 10th day of illness.

MANAGEMENT

There is no specific antiviral treatment. Most individuals recover without sequelae in 1–2 weeks with symptomatic treatment alone. NSAIDs are helpful in persisting arthralgia and arthritis.

High-dose intravenous immunoglobulin has been successful in treating immunosuppressed patients who have persisting aplastic anemia associated with parvovirus infection.

VARICELLA-ZOSTER VIRUS INFECTIONS (CHICKENPOX AND HERPES ZOSTER)

EPIDEMIOLOGY

Varicella-zoster virus (VZV) is an enveloped a-herpesvirus, with icosahedral symmetry and a linear, double-stranded DNA genome. Like other herpesviruses, it causes a primary infection (varicella or chickenpox) with seroconversion and subsequent lifelong latency. Reactivation causes localized neurologic disease with an associated skin eruption (herpes zoster or shingles). Both primary and reactivation diseases are infectious, although there is less virus shedding from the rash of herpes zoster.

VARICELLA

In developed countries varicella causes winter and spring epidemics, mainly affecting schoolchildren, with a peak incidence traditionally at the age of 5–9 years. In developed countries, there has been a downward shift in age prevalence from school age to pre-school age, which is likely related to an increase in attendance at out-of-home childcare increasing exposure at an earlier age. Maternally derived antibodies protect infants up to the age of 6–9 months. Likewise, about 90% of adults are seropositive and immune. By contrast, in the tropics, varicella is less common in children and seronegativity varies from 20% to 50% in adults. In the USA, introduction of varicella vaccine has been associated with a dramatic reduction in the incidence of varicella disease.[29]

Varicella-zoster virus is easily transmitted by respiratory secretions, on children's hands or by droplet spread. It also spreads along air currents in buildings such as hospitals.[30] In developed countries, exposure at home carries approximately an 80% risk of infection; in hospital or day care centers the risk is about 40–60%. The incubation period varies from 10–25 days, averaging 15 days.

The incidence of adult varicella is apparently increasing in several countries. In the UK reports of adult cases doubled between the 1970s and 1990s but have now stabilized. This is important, as the disease is more severe in adults and infection in pregnancy may cause fetal loss or damage (see Chapter 65). The fatality rate for varicella in the UK is about 1 per 6000 cases but this rises to approximately 1 per 600 for those aged over 55 years. In spite of the apparent increased severity in adults, it should be noted that children aged <15 yrs account for 90–95% of all cases of chickenpox, 80–90% of physician visits, 60–80% of hospital admissions and 25–45% of fatalities due to chickenpox.

HERPES ZOSTER

Herpes zoster reflects infection of a sensory nerve ganglion, its neurologic connections and associated dermatome. It complicates waning immunity and therefore affects elderly, debilitated and immunocompromised individuals. It may be precipitated by such stresses as another illness, trauma or bereavement, or by immunodeficiency as a result of HIV infection, malignancy or immunosuppressive chemotherapy. There is usually an interval of years between the occurrence of varicella and the eruption of herpes zoster, although varicella in a fetus or infant may be followed by neonatal or childhood zoster. Investigations into the cost of morbidity and mortality from VZV infections shows that the major cost to society is caused by herpes zoster.[31]

Close contact with a patient who has herpes zoster can lead to varicella in a seronegative person. It is possible that immunity is boosted throughout life by repeated exposure to varicella and zoster in the community.[32]

PATHOGENESIS AND PATHOLOGY

Varicella-zoster virus first infects the respiratory mucosa, where it replicates and invades the lymphatics, leading to asymptomatic primary viremia about 7 days after infection. Further viral replication occurs in most tissues; VZV DNA appears in the peripheral blood mononuclear cells and polymorphs at this stage. Virus replication and assembly takes place in the nucleus of affected cells, producing characteristic 'type A' intranuclear inclusions. Syncytium and giant cell formation occurs. In the skin, large, balloon-shaped 'Tzanck' cells, with typical nuclear inclusions, are seen in scrapings from vesicular skin lesions. VZV is strongly cell-associated and is more readily demonstrated by antigen detection in respiratory or skin specimens than by culture of secretions or vesicle fluid.

Clinical disease begins with a secondary viremia about 15 days after infection. Focal lesions develop, containing giant cells with intranuclear inclusions. Organs infected include the skin, lungs, gut, reticuloendothelial system and occasionally the brain, retina or joint synovia. In the skin, cell damage and fluid collection separate the layers of the epidermis to produce blistering, at the base of which Tzanck cells are found. Giant-cell vasculitis may play a part in rare neurologic events that precede or follow the classic illness.

Humoral immunity is demonstrable by fluorescence labeling of antibodies against membrane-associated antigens. These rise progressively in titer throughout the illness, and no clear cut-off predicts susceptibility rather than immunity. ELISA tests are now used to detect IgM and IgG antibodies.[33] Varicella-zoster virus can be cultured, with cytopathic effects in human embryo cell lines.

In spite of cellular and humoral immunity, VZV persists in the body after primary infection. Unlike herpes simplex, it is not detectable by the presence of DNA 'latency sequences'.[34] Messenger

ribonucleic acid has been demonstrated in trigeminal ganglion tissue. During reactivation, virus replication and assembly begins in sensory ganglion neurons, subsequently appears in glial cells and is accompanied by intense inflammation. Virus migrates along the dorsal root connections to the central nervous system, causing inflammation and nerve fiber degeneration, and along axons to the skin, where typical VZV skin lesions occur. Local meningeal inflammation surrounds the affected spinal segment and may proceed to a general, viral-type meningitis.

PREVENTION

Pre-exposure prophylaxis

Live attenuated varicella vaccine is derived from the Oka strain of VZV. It is immunogenic in 98–99% of children after a single dose and 94–99% of adolescents and adults when given in two doses 4–8 weeks apart. Breakthrough disease after exposure to wild varicella occurs in 12–20% of vaccinees 5–10 years after immunization, causing a similar secondary infection rate in immunized household contacts. However, the disease is mild, with a median of 20–40 vesicles. [35] A few recipients develop a sparse vesicular rash and may then infect close contacts with the vaccine strain.

The vaccine can be given to selected immunocompromised individuals, for example children in remission from steroid-responsive nephritic syndrome or from leukemia, or in the intervals between pulsed chemotherapy courses. The vaccine virus exhibits latency and can cause herpes zoster, earlier and more commonly in the immunosuppressed. Long-term follow-up will quantify the likelihood of later vaccine-related herpes zoster.

The vaccine is licensed for childhood use in some countries (including the USA), and in others for use in nonimmunes from special groups, including health care workers and household contacts of the immunosuppressed, or in immunosuppressed individuals.

Universal childhood immunization reduces the incidence of varicella in both immunized and nonimmunized children. Experience in the USA attests to its safety and effectiveness in reducing the incidence of varicella disease and morbidity. [29] [36] There is a concern that the resulting reduced circulation of wild virus may increase the susceptibility of the elderly to herpes zoster, by reducing the frequent boosting of immunity derived from exposure to varicella.[32] This remains to be confirmed clinically.

Postexposure prophylaxis

Human immunoglobulin derived from the plasma of individuals with high VZV antibody levels (usually after recent varicella or herpes zoster) is used to prevent or modify varicella after exposure. Varicella-zoster immune globulin is the product available in North America: zoster immunoglobulin (ZIG) is available in the UK. It prevents or modifies varicella even when given 7–10 days after exposure.[37] However, for maximum benefit, VZIG must be administered within 96 hours of exposure, and preferably within 72 hours. Immunoprophylaxis with VZIG may not prevent infection, but does effectively reduce disease severity. It also may prolong the incubation period a week, from 21 days to 28 days at the upper end. Zoster immunoglobulin is recommended for:

- immunosuppressed individuals exposed to varicella or disseminated herpes zoster;
- nonimmune pregnant women who have been exposed to varicella or disseminated herpes zoster; and
- the neonate whose mother developed varicella between 7 days before and 7 days after delivery.

The recommended dosages for intramuscular ZIG are as follows:

- age 0–5 years — 250mg;
- age 6–10 years — 500mg;
- age 11–14 years — 750mg;
- age 15 years and over — 1000mg.

VZIG is administered at a dosage of 125 units/10kg body weight to maximum dose of 625 units. If ZIG cannot be given, particularly if intramuscular injection is contraindicated, there is evidence that intravenous immunoglobulin contains sufficient antibody to prevent infection.[38]

Varicella can occur after immunoglobulin prophylaxis. In neonates about 30% of these infections are severe and in the immunosuppressed all infections are a threat. Antiviral chemotherapy should therefore be given to those who have breakthrough infections, especially those at risk for severe disease (ie newborns whose mothers rash onset 5 days before to 2 days after delivery, and immunocompromised patients). Such patients need to be treated at the first onset of rash, regardless of whether or not VZIG was given.

Varicella vaccine has been proven effective as post-exposure prophylaxis if given within 5 days of exposure and is recommended for such use in both Canada and the United States provided there are not contraindications to receipt of vaccine. [39]

Aciclovir alone has been given prophylactically, in household and institutional settings. A 10-day course prevented clinical disease in both, but larger studies are required to define the effective dose and duration of prophylaxis. [40]

CLINICAL FEATURES

Varicella

Childhood varicella is often first recognized when the rash appears. Adults more often have a 1–3 days' prodromal, influenza-like illness.

Rash

Lesions begin as papules but progress within hours to superficial, clear vesicles surrounded by a variable halo of erythema. Vesicles are often oval, with the long axis parallel to skin creases, and are commonly pruritic. New lesions appear progressively over 5–7 days. The head and upper trunk are affected first and most densely, whereas the limbs have fewer lesions and these appear later. The rash is exaggerated and appears earlier in hot areas of skin, for instance under a diaper or occlusive dressing.

The vesicular fluid opacifies and in 2 or 3 days a central dimple appears. A crust then forms from this center outward and falls away after about 5 days (Fig. 8.7). Unless secondary infection has occurred, scarring is limited to faint, pale outlines. The rash is accompanied by variable fever. Secondary cases in households are often more severely ill than the index case.

The density of the rash indicates the severity of varicella. Indicators of severe disease include confluence of the rash, multiple lesions in the mouth, pharynx and genital mucosae, and retrosternal or epigastric pain (presumably caused by tracheal and esophageal lesions).

Patients are infectious from the prodromal period until the skin lesions scab, although virus rapidly becomes undetectable after the sixth day of uncomplicated illness.

Varicella pneumonitis

Varicella is always accompanied by a giant-cell pneumonitis but this is not usually clinically significant. Cigarette smokers, women in late pregnancy and the immunosuppressed are at increased risk of respiratory disease. The first sign is a drop in arterial oxygen saturation (Fig. 8.8), followed within hours by respiratory symptoms, or abnormal sounds on auscultation. Pneumonitis varies widely in severity. In patients who have severe pneumonitis there is cough with mucoid or bloodstained sputum and respiratory failure, which may prove fatal. Co-existing bacterial infection must always be suspected. The chest

Figure 8-7 The lesions of varicella. Papules, vesicles and pustules, some of which are beginning to crust from the center, are seen.

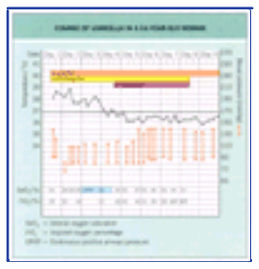

Figure 8-8 Course of varicella in a 54-year-old woman. Low arterial oxygen saturation precedes respiratory and hemodynamic failure.

radiograph may show ground-glass changes, widespread nodular opacities (chickenpox lung) or segmental shadows. However, reliance on chest radiographs will over-diagnose clinically relevant pneumonia, and they should not be obtained routinely, but reserved for those wih clinical respiratory distress.

Hepatitis

Elevation of transaminase levels to three times the upper limit or more is most often seen in adults, particularly men. Although transaminitis is common, clinically significant hepatitis or jaundice is rare.

Thrombocytopenia

Mild thrombocytopenia is common in adults, particularly men, and may cause a petechial rash and hematuria. The skin vesicles are then hemorrhagic. In severe

varicella, platelet and vascular damage may lead to disseminated intravascular coagulation.

Rare features of varicella

Rare features of varicella include:

- ¦ transient cerebellar disturbance with ataxia and vertigo; this occurs in convalescence in about 1 in 4000 cases and mostly affects males;
- ¦ encephalitis, which may be of rapid onset with focal signs, seizures or coma; most patients recover, although a few, often those who have imaging evidence of cerebral infarcts, suffer permanent sequelae; and
- ¦ retinitis, which can occur immediately or after several weeks' delay, is often severe or necrotizing and may be associated with lasting visual impairment.

Occasionally, cerebral or retinal disease precedes the rash or occurs alone. Since the availability of PCR-based tests in CSF, it is now recognized that VZV is among the common causes of meningitis and encephalitis, and is more common than herpes simplex virus in individuals of all ages.[41] VZV has also been linked with stroke-syndromes in healthy children and adults as well as HIV patients; rash is not always seen in such cases.[42]

Neonatal varicella

Neonatal varicella affects neonates born to seronegative mothers who therefore lack maternally derived immunity. The source of varicella is often the perinatally infected mother. The infant will not acquire adequate antibody levels until the mother is 7 days into her clinical illness. Babies born before this, or exposed in the first week of life, require varicella prophylaxis.

If acquired from exposure to their mother whose rash onsets from 7 days before to 2 days after delivery, it is a severe, multisystem disease with lung, kidney, bone marrow and brain involvement, and a resulting case-fatality rate of 25–40%. However, for infants exposed for the first time to infection more than 2 days after delivery, disease is often mild to inapparent. Premature infants who are considered at risk for severe disease throughout the first month of life. The risk of severe disease rapidly decreases: after 4 weeks of age varicella is no longer as dangerous; however, although most cases in the first year of life are mild-moderate in severity, disease can be severe as shown by a fatality rate (8/100000) that is 4 fold higher than for children aged >1 yrs, and ~¼ of that in adults.[43] Clinicians should consider iv aciclovir for infants whose rash is rapidly spreading and/or in whom complications other than secondary skin infections become apparent early in the course of disease.

Herpes zoster

Herpes zoster is heralded by pain in the dermatome served by the affected sensory root, which sometimes resembles pleurisy or abdominal pathology. Occasionally in children it manifests as a viral meningitis with increased lymphocytes in the CSF.

Groups of papules then appear at the sites where cutaneous nerves reach the skin. In a spinal nerve this is just lateral to the spine, in the midaxillary line and just lateral to the linea alba. This may not progress further; however, in adults it usually extends to fill the dermatome unilaterally. Some dermatomes, such as those of the supraclavicular and lumbar regions, are more often affected, while the arms are rarely involved, possibly reflecting the denser areas of the preceding varicella rash.

The papules progress to vesicles, pustules and crusts but, unlike varicella, lesions may become confluent and form large, flaccid bullae (Fig 8.9) that rupture to leave weeping bare areas. Uncomplicated

Figure 8-9 The rash of herpes zoster. It can be seen that the lesions occur in groups, with coalescence of lesions in the larger groups.

lesions can heal in 4–6 days but severe rashes may take 3–5 weeks. Nevertheless, altered skin pigmentation is often the only sequela. Scarring is rare.

Ophthalmic herpes zoster

The commonest cranial dermatome affected is the ophthalmic branch of the trigeminal nerve. The conjunctiva is usually inflamed and swollen, with associated edema of the eyelid; in severe cases, keratoconjunctivitis can cause prolonged blurred vision and, rarely, corneal scarring. Nasociliary involvement (evidenced by vesicles on the tip of the nose) indicates inflammation of the uveal tract, with pain, blurred vision and the risk of synechiae of the iris.

Geniculate herpes zoster (Ramsay Hunt syndrome)

In this rare syndrome the geniculate nucleus of the facial nerve is involved, affecting sensory neurons that serve the skin in the external auditory meatus. Vesicles are often seen in the ear, but inflammation and swelling also compress the facial and auditory nerves. There is unilateral facial palsy, deafness and severe vertigo, often with prostration and vomiting. If the chorda tympani is involved, there is also loss of taste sensation on the anterior two-thirds of the tongue.

Zoster-associated pain and post-herpetic neuralgia

The burning, tingling pain of herpes zoster recedes with healing, but older patients are at risk of persisting pain. This is often distressing, causalgic (not related in quality to the mild stimulus that causes it) and severe. Its average duration in those aged over 60 years is about 60 days, but it can last much longer and, rarely, persists permanently. This pain has been called post-herpetic neuralgia and has been given various definitions, for example pain after rash healing, or pain continuing more than 1 month after herpes zoster. It is now more correctly included in the whole continuum of pain caused by herpes zoster and is called zoster-associated pain (ZAP).

COMPLICATIONS

Secondary bacterial skin infection

Secondary bacterial skin infection is the commonest complication of varicella. Children are twice as likely as adults to have significant skin infection, particularly severe or toxin-mediated disease (Fig. 8.10). Eczema does not predispose individuals to more severe varicella or to worse secondary infection.

Bacterial infection of individual spots causes pain, induration and often abscess formation. The usual pathogens are *S. aureus* or *Streptococcus pyogenes*. Local extension can cause cellulitis or erysipelas. Bacteremia occasionally co-exists. Children are particularly prone to staphylococcal or streptococcal toxic shock

syndromes, perhaps because they lack antibodies to the exotoxins. Necrotizing fasciitis is rare and affects adults or children. Nevertheless, children with varicella are at much higher risk of severe infection with group A *streptococcus*.[44]

Secondary bacterial infection can also complicate herpes zoster, especially when severe and in the elderly. In ophthalmic herpes zoster, bacterial conjunctivitis or keratoconjunctivitis can occur.

Bacterial lung infections

These can exist alone or complicate varicella pneumonitis. They are less important than skin infections in children, even in those who have a history of asthma, but are more common in adults.

Staphylococcus aureus is the commonest pathogen, but other chest pathogens occasionally occur. It is difficult to distinguish bacterial or mixed infection from viral pneumonia, especially as staphylococcal infection does not always cause an early neutrophilia. If doubt exists, bacterial infection should be assumed.

Motor paralysis in herpes zoster

Herpes zoster is occasionally associated with paralysis of muscle groups innervated from the affected dermatome. The quadriceps may be affected in lumbar zoster; diaphragmatic paralysis is sometimes seen in supraclavicular zoster. Transient paralytic ileus can occur in dorsal zoster. Electromyographic studies of affected muscles show evidence of axonal dysfunction. Gradual recovery is usual, but some residual weakness may persist.

Ascending myeloencephalitis

This is an exceptionally rare complication of herpes zoster, which is more common in immunosuppressed individuals. Successive involvement of higher spinal and cerebral levels first causes transverse myelitis, with pain, sensory and motor 'level's, and long-tract signs. These extend until cerebral irritability and coma supervene. There is a significant chance of recovery with vigorous antiviral treatment, depending on the severity of any underlying disease.

Varicella-zoster infection in the immunosuppressed

Cell-mediated immunosuppression predisposes individuals to severe VZV infections that result in progressive multisystem disease, often with a deceptively indolent onset. Herpes zoster is also recognized as one of the earlier opportunistic infections seen in patients who have AIDS (see Chapter 125). In severe immunosuppression, abnormal hemorrhagic lesions may develop without becoming vesicular, although the rash is distributed normally. Rarely, pneumonitis can exist without the rash, or retinitis occurs long after infection. Systemic corticosteroids during the incubation and prodrome are thought to predispose individuals to severe primary disease. A necrotizing cerebritis can appear in severely immunocompromised hosts, resulting in a syndrome resembling a brain abscess. A biopsy is necessary to establish the diagnosis.

Herpes zoster occurs earlier, more frequently and more severely in the immunosuppressed, often with deep, scarring lesions. Dissemination may occur, leading to varicella-like disease (Fig 8.11).

MANAGEMENT

Varicella

The nucleoside analogue aciclovir is licensed for the treatment of varicella. The oral dose is 800mg five times daily for 5–7 days but, even with this maximum dose, predose troughs below the mean

Figure 8-11 Varicella-zoster virus infection. Infection in a patient who had a history of varicella in childhood, had recently had a thymectomy and was taking high-dose prednisone (prednisolone): initially localized lesions on the neck were quickly followed by an extensive, varicella-type rash.

inhibitory concentration for VZV often occur. Valaciclovir, a prodrug of aciclovir, has much enhanced bioavailability, being well absorbed by the gut mucosa. It is hydrolyzed to release aciclovir. Famciclovir is similarly well absorbed and hydrolyzed to release penciclovir. Both prodrugs are licensed for the treatment of herpes zoster but as yet not for varicella.

Antiviral treatment has minimal impact on mild childhood infections and is not universally recommended (although it is cost-effective if loss of parental working time is included in the calculation). In adolescents and in uncomplicated adult disease, oral aciclovir reduces the severity of the rash and shortens the duration of illness by up to 1 day. It may reduce the risk of complications. Treatment commencing more than 1 or 2 days after the onset of rash is unlikely to influence the course of uncomplicated disease.

Intravenous aciclovir is the treatment of choice for severe or complicated VZV infections. A dose of 5–10mg/kg q8h is given by intravenous infusion over at least 1 hour. This avoids high peak blood levels and consequent renal impairment. Aciclovir is excreted by the kidney, and doses or dosing intervals must be altered if the creatinine clearance is below 60ml/min. Other side effects are mild and include nausea and occasional rashes. The dose may be increased to 15mg/kg in urgent cases, but renal function must be closely monitored.

Herpes zoster

In herpes zoster of the middle-aged and elderly, treatment started in the first 48 hours after the onset of the rash reduces the duration of the rash and the duration of ZAP. Recommended dosages are:

- aciclovir: 800mg five times daily orally for 1 week or 5mg/kg by intravenous infusion over 1 hour, q8h (may be increased to 10mg/kg in severe infection or in case of immunosuppression);
- valaciclovir: 1.0g orally q8h for 7 days; and
- famciclovir: *either* 250mg orally q8h *or* 750mg orally once daily, for 7 days.

Ophthalmic and geniculate herpes zoster should always be treated in order to reduce the risk of severe eye inflammation or permanent facial or vestibular nerve damage. Prednisone 0.5% eye drops 4–6 times daily are often added when there is evidence of uveitis. Atropine 2.5% eye drops may be used daily to dilate the pupil and avoid the development of synechiae, but carry a small risk of precipitating acute angle-closure glaucoma or atropine toxicity in the elderly, even at this low dosage.

Some immunosuppressed patients, particularly those who have had previous treatment with aciclovir, become infected with aciclovir-resistant VZV, which has an altered viral thymidine kinase. Ganciclovir (5mg/kg by intravenous infusion q12h for 14–21 days), which is activated by a different kinase, and foscarnet (60mg/kg by intravenous infusion q8h for 14–21 days) are useful in this setting. Valganciclovir is a prodrug of ganciclovir that is well absorbed and is hydrolyzed to release ganciclovir with much higher bioavailability than oral ganciclovir. It may reduce the need for regular injections in longer term therapy.

Ganciclovir has significant gastrointestinal and bone-marrow toxicity as well as a range of less frequent adverse effects, and foscarnet is nephrotoxic. Neither drug is therefore appropriate for the treatment of sensitive VZV infections. The use of corticosteroids with antiviral therapy is associated with a moderate acceleration in the

resolution of skin lesions and alleviation of acute pain.[45] Corticosteroids have no effect on the incidence or duration of ZAP.

Varicella retinitis

Varicella retinitis, with outer retinal necrosis, more often seen in HIV-infected patients and lymphoma sufferers, responds poorly to

aciclovir treatment. Case-series studies have shown that patients have a better long term visual outcome after treatment with ganciclovir or the combination of ganciclovir and foscarnet.[46]

Secondary bacterial infections

Secondary bacterial infections should be promptly treated. Skin lesions often respond to oral penicillins active against penicillinase-producing *Staph. aureus* or cefaclor. Severely painful or necrotic skin lesions need inpatient treatment with intravenous penicillins active against penicillinase-producing *Staph. aureus* for suspected staphylococcal infection. If streptococcal infection is suspected, then benzylpenicillin 2.4g q4h or q6h is appropriate; for necrotizing lesions, metronidazole 500mg q8h may be added or clindamycin substituted, and early surgery should be considered.

Mild chest infections in children may respond to oral flucloxacillin (or dicloxacillin) but infection in adults usually requires parenteral treatment. If a penicillin alone is not effective, an early change to a broad-spectrum cephalosporin such as cefuroxime or ceftriaxone should be considered.

Zoster-associated pain

In acute herpes zoster simple analgesics are often effective. Opiates should not be withheld if pain is severe, although nausea and confusion may limit their use in the elderly. Late, causalgic pain responds poorly to any analgesic but is often helped by gabapentin (300mg on day 1; 300mg q12h on day 2; 300mg q8h on day 3; then increased according to response as q8h doses up to a maximum of 1.8g daily) or amitriptyline (up to 25mg q8h). There is some evidence that this limits the duration of ZAP if given early. Antiviral agents have no proven benefit on chronic post-herpetic neuralgia.

HUMAN HERPESVIRUS TYPE 6 AND ROSEOLA (EXANTHEM SUBITUM)

Human herpesvirus type 6 (HHV-6) was recovered from B cells by cocultivation. It exists as two variants, HHV-6A and HHV-6B;[47] both can infect humans but only HHV-6B has been definitely associated with clinical disease. The virus is closely related to cytomegalovirus; a mononucleosis-like infection has occasionally been described. Infants are protected by maternally derived antibody detectable up to the age of 4–6 months. The virus can be found in the saliva of seropositive adults, suggesting that latent infection exists.

Almost all humans acquire infection and seroconvert in early childhood. Up to 60% of infected children develop roseola, in which 4–5 days of fever is followed by the sudden appearance of a macular or maculopapular rash, which quickly spreads across the neck, trunk and proximal limbs. The lesions fade in 1–2 days. Mild neutropenia is common in established infection. Occasional epidemics are recognized. The incubation period is about 10 days (range 5–15 days). Complications are few; febrile convulsions may accompany the high fever; occasional cases with encephalopathy or hepatic inflammation are described, rarely with lasting sequelae.[48] Some work suggests that the virus may be involved in the pathogenesis of multiple sclerosis.[49]

Treatment is symptomatic although the illness is usually trivial and self-limiting. Susceptibility to antiviral agents is similar to that of cytomegalovirus. Antipyretic medication is useful if the fever causes convulsions or other adverse effects.

HAND, FOOT AND MOUTH DISEASE

This is a systemic infection of young children that often occurs in local or household outbreaks and occasionally also affects adults. It is caused by Coxsackie viruses, most commonly type A16, although recent epidemics caused by enterovirus type 71 have occurred in eastern Asia.

After an incubation period of about 10 days, fever and mild generalized lymphadenopathy occur, followed after 2–3 days by the eruption of tense, clear vesicles on the palmar surfaces of the hands and feet (Fig. 8.12). Lesions also affect the mouth, tongue and pharynx. There is a papular or maculopapular rash on the buttocks and, rarely, on the back or thighs.

The illness is usually mild and self-limiting. Occasional cases, especially those caused by enterovirus 71, develop severe systemic disease with respiratory and/or encephalitic features and a significant mortality.

Specific treatment is not available. Skin lesions can be painful or tender and simple analgesics may help this. Prototype antiviral drugs directed at attachment proteins on the viral surface have not yet progressed beyond trials but may have a place in future in the treatment of systemic complications.

Figure 8-12 Hand, foot and mouth disease. Typical vesicles are seen on the foot of a 3-year-old child.

Chapter 9 - Cellulitis, Pyoderma, Abscesses and Other Skin and Subcutaneous Infections

Dennis L Stevens

INTRODUCTION

Infections of the skin and/or subcutaneous tissues are highly diverse in respect to etiologic organisms, incidence, clinical manifestations, severity and complications. They may occur as single or recurrent episodes. Many cases are mild or self-limited, but some progress to cause scarring, loss of digits or limbs, or even death.

The terminology can be confusing because several different names, which are often not precisely defined, may be used to describe the same condition. Nomenclature for the most common infections is summarized in Table 9.1 .

When a patient presents with soft tissue infection, the clinician faces the challenge of establishing a specific diagnosis and prescribing definitive treatment. Important points in diagnosis are:

¦ the patient's symptoms;
¦ the general appearance of the infected site;
¦ historic clues such as contact with insects or animals, especially involving bites, travel to specific geographic areas, occupation or use of a hot tub (see Folliculitis, furuncles and carbuncles, below);
¦ the immune status of the host;
¦ chronicity; and
¦ anatomic distribution.

TABLE 9-1 -- Nomenclature, location and etiology of some common skin and subcutaneous infections.

NOMENCLATURE, LOCATION AND ETIOLOGY OF SOME COMMON SKIN AND SUBCUTANEOUS INFECTIONS			
Terminology	**Subgroups**	**Location**	**Etiology**
Pyoderma	Impetigo (impetigo contagiosa)	Skin	*Streptococcus pyogenes, Staphylococcus aureus*
	Bullous impetigo	Skin	*Staph. aureus* with group II phage
	Folliculitis (pustulosis)	Skin, hair follicles	*Staph. aureus*
	Folliculitis (sycosis) barbae	Skin, hair follicles of the beard	*Strep. pyogenes, Staph. aureus*
	Hot tub folliculitis	Skin	*Pseudomonas aeruginosa*
Abscesses	Furuncle (boil, subcutaneous abscess)	Subcutaneous tissue	*Staph. aureus*
	Hydradenitis suppurativa	Multiple furuncles in sweat glands: axilla, groins	*Staph. aureus* and other bacteria, including Gram-negative bacilli and anaerobes
	Carbuncle	Dense group of furuncles in areas of thick skin: back of neck, shoulders, buttocks	*Staph. aureus*
Cellulitis		Skin and subcutaneous tissue	*Staph. aureus, Strep. pyogenes*, Group C and G streptococci, *P. aeruginosa, Haemophilus influenzae* or Gram-negative bacilli; fungi can cause cellulitis in immunocompromised hosts
	Erysipelas	Skin	*Strep. pyogenes*
Ecthyma		Skin and subcutaneous tissue	*Strep. pyogenes, Staph aureus* or both; other bacteria *P. aeruginosa*
	Ecthyma gangrenosum	Skin and subcutaneous tissue in neutropenic patients	

If the diagnosis cannot be established based upon the history, symptoms and signs, then needle aspiration, biopsy or surgical exploration may be necessary to obtain specimens for appropriate staining and culture.

As the antimicrobial susceptibility of these microbes varies greatly, treatment (particularly for severe infections) should be based upon the results of microscopy, Gram stain and culture whenever possible.

EPIDEMIOLOGY

Although the exact incidence of these infections in the general population is unknown, they are among the most common infections occurring in all age groups. Some are age-related, for example impetigo is more common in children, erysipelas is more common in older adults.

Infections of the skin and soft tissues can be caused by bacteria (including rickettsiae), fungi, viruses, parasites and spirochetes.

TABLE 9-2 -- Probable etiology of soft tissue infections associated with some specific risk factor or setting.

PROBABLE ETIOLOGY OF SOFT TISSUE INFECTIONS ASSOCIATED WITH SOME SPECIFIC RISK FACTOR OR SETTING	
Risk factor or setting	**Likely etiologic agent**
Cat bite	*Pasteurella multocida*
Dog bite	*P. multocida, Capnocytophaga canimorsus* (DF-2), *Staphylococcus intermedius*
Tick bite followed by erythema chronicum migrans rash	*Borrelia burgdorferi*

Hot tub exposure	*Pseudomonas aeruginosa*
Diabetes mellitus or peripheral vascular disease	Group B streptococci
Periorbital cellulitis (children)	*Haemophilus influenzae*
Saphenous vein donor site cellulitis	Groups C and G streptococci
Fresh water laceration	*Aeromonas hydrophila*
Sea water exposure, cirrhosis, raw oysters	*Vibrio vulnificus*
Cellulitis associated with stasis dermatitis	Groups A, C and G streptococci
Lymphedema	Groups A, C and G streptococci
Cat scratch	*Bartonella henselae, B. quintana*
HIV-positive patient with bacillary angiomatosis	*B. henselae, B. quintana*
Fishmongering, bone rendering	*Erysipelothrix rhusiopathiae*
Fish tank exposure	*Mycobacterium marinum*
Compromised host with ecthyma gangrenosum	*P. aeuruginosa*
Human bite	*Eikenella corrodens, Fusobacterium* spp., *Prevotella* spp., *Porphorymonas* spp., *Streptococcus pyogenes*

TABLE 9-3 -- Differential diagnosis of bullous skin lesions.

DIFFERENTIAL DIAGNOSIS OF BULLOUS SKIN LESIONS	
Clinical condition	**Etiology**
Bullous impetigo	*Staphylococcus aureus* carrying group II phage
Erysipelas	*Streptococcus pyogenes*
Staphylococcal scalded skin syndrome	*Staph. aureus* producing exfoliative toxin
Necrotizing fasciitis	Type I: mixed aerobic and anaerobic bacteria
	Type II: *Strep. pyogenes*
Gas gangrene	*Clostridium perfringens, C. septicum*
Halophilic vibrio sepsis	*Vibrio vulnificus*
Pemphigoid	Immune-mediated
Toxic epidermal necrolysis	Drug-induced

TABLE 9-4 -- Differential diagnosis of crusted skin lesions.

DIFFERENTIAL DIAGNOSIS OF CRUSTED SKIN LESIONS	
Clinical condition	**Etiology**
Impetigo	*Staphylococcus aureus, Streptococcus pyogenes* or both
Ringworm	Dermatophytic fungi (e.g. *Tinea rubrum*)
Systemic fungal infections	*Histoplasma capsulatum*
	Coccidioides immitis
	Blastomyces dermatitidis
Cutaneous mycobacterial infection	*Mycobacterium tuberculosis*
	M. marinum
Cutaneous leishmaniasis	*Leishmania tropica*
Nocardiosis	*Nocardia asteroides*

Although there are hundreds of possible etiologic agents (Table 9.1 Table 9.2 Table 9.3 Table 9.4), two common species of Gram-positive cocci are the predominant causes of skin and soft tissue infections — *Staphylococcus aureus* and *Streptococcus pyogenes*. Skin and soft tissue infections caused by newly recognized or previously rarely encountered microbes are continually being described in immunocompromised patients, especially those who have AIDS.

Several noninfectious diseases can mimic infection of the soft tissues. For example, patients who have contact dermatitis, pyoderma gangrenosum, gout, psoriatic arthritis with distal dactylitis, Reiter's syndrome, relapsing polychondritis or mixed cryoglobulinemia secondary to immune complex disease from chronic hepatitis C or B virus infection may present with erythematous rashes, with or without fever.

PATHOGENESIS

The integument is an organ that reacts to noxious, infectious, external and internal stimuli in a limited number of ways. It is therefore

not surprising that infection can be mimicked by noninfectious inflammatory conditions. The rich plexus of capillaries beneath the dermal papillae provides nutrition to the stratum germinativum and the dermatocytes, which are bound together by tight junctions and form the barrier to microbial invasion. Once microbes have penetrated this barrier through a hair follicle, cut or bite, the dermal plexus of capillaries delivers the components of the host's defense — oxygen, complement, immunoglobulins, macrophages, lymphocytes and granulocytes — to the site of infection.

Perhaps the first clue available to the immune system to the presence of foreign material in the deep tissues is provided by the organisms themselves. Virtually all bacteria are comprised of proteins whose *N*-terminal amino acid sequence begins with an *N*-formylmethionine group and these proteins are chemoattractive to phagocytes such as macrophages and granulocytes. Other microbial cell wall components such as zymosan of yeast, endotoxins of Gram-negative bacteria and peptidoglycans of Gram-positive bacteria activate the alternative complement pathway,[1] yielding serumderived chemotactic factors. Chemotactic factors are therefore promptly produced at the site of infection by multiple mechanisms.

The efflux or diapedesis of phagocytes through endothelial cell junctions is dependent upon the orchestrated sequential expression of adherence molecules on the surface of the polymorphonuclear leukocyte (PMNL)[2] [3] such as L-selectin and CD11b/CD18 in association with counter-receptors (adhesins) on the endothelial surface.[4] *In vivo*, surface expression of these molecules results first in 'rolling' of PMNLs along the endothelial surface, followed by tethering, and finally firm adhesion of the PMNLs onto the surface of endothelial cells. Phagocytes actually leave the capillary through endothelial cell interstices bound by peripheral endothelial cell adherence molecules, which are found only at these junctional sites.

Once diapedesis has occurred, the PMNL follows the gradient of chemotactic factors derived from the bacteria and serum to the site of active infection. Recent studies suggest that the activated endothelial cells also produce chemotactic cytokines, such as interleukin (IL)-8. Finally, activated granulocytes synthesize leukotriene B_4 from

arachidonic acid, and this too is a potent chemoattractant for leukocytes.

Production of proinflammatory cytokines such as IL-1, tumor necrosis factor a, and IL-6 results in an augmentation of the immune functions described above. These cytokines induce fever, prime neutrophils, and increase antibody production and the synthesis of acute phase reactants, such as C-reactive protein.[5] [6] Cytokine-driven stimulation of endothelial cells also results in the generation of nitric oxide and prostaglandins, both of which cause vasodilation. The net physiologic effect is greater bloodflow to the tissue. These processes result in the cardinal manifestations of inflammation:

- heat,
- swelling,
- erythema, and
- tenderness or pain.

At some locations, factors such as pressure, thrombosis or drugs may reduce or stop bloodflow, resulting in inadequate oxygenation. Compounds such as corticosteroids, which inhibit phospholipase A_2 activity (necessary for releasing arachidonic acid from cell membranes), and nonsteroidal anti-inflammatory agents, which inhibit cyclo-oxygenase (the endogenous enzyme necessary for the synthesis of prostaglandins from arachidonic acid), reduce local bloodflow to tissues. These drugs are therefore useful in the treatment of noninfectious inflammatory conditions because they reduce pain and swelling. However, if the inflammation is secondary to undiagnosed bacterial infection, these drugs may predispose the patient to more severe infection or mask the clinical signs, so delaying the correct diagnosis.

If tissue perfusion is moderately attenuated, tissues may remain viable, but the threshold for progression of infection may be lowered. Predisposing conditions in this category include:

- peripheral vascular disease affecting large arteries,
- diabetes mellitus causing microvascular disease, and
- chronic venous stasis causing postcapillary obstruction.

Necrosis of the skin and deeper tissue may occur if there is severe hypoxia. Two examples are:

- pressure necrosis resulting in decubitus ulcers, and
- compartment syndromes resulting in hypoxia and then necrosis in muscles confined within tight fascial bundles.

When the host is physiologically, structurally and immunologically normal, only certain pathogens such as *Staph. aureus* and group A streptococci are able to cause disease by virtue of their potent virulence factors, such as toxins, capsules or dermonecrotic enzymes, which confer ability to withstand the barrage of host defenses and to induce clinical disease. This statement is supported by the observation that normal skin, although constantly exposed to many indigenous and exogenous microbes, rarely becomes infected.

In contrast, patients who have compromised skin integrity (e.g. patients with burns), vascular defects (e.g. those who have diabetes mellitus or pressure ulceration) or immunologic deficits may become infected with either virulent organisms (e.g. staphylococci or streptococci) or microbes that are usually saprophytic, such as *Pseudomonas aeruginosa, Escherichia coli,* enterococci or *Fusarium* spp. Other defects such as complement deficiency, immunoglobulin deficiencies or neutropenia attenuate the host response to the invading pathogen and predispose to infection.

PREVENTION

Avoidance of cuts, scratches and other forms of trauma that disrupt the natural barrier function of the skin helps to prevent skin and soft tissue infections. For example, stopping shaving may prevent recurrent folliculitis in the beard area (sycosis barbae). Prompt cleansing, debridement and disinfection of such lesions are important for preventing infection, particularly in the case of bite wounds. Treatment of eczema reduces the risk of secondary bacterial superinfection.

Prevention of recurrent folliculitis or furunculosis is difficult to achieve, but there has been some success using intranasal applications of bacitracin or mupirocin ointment. pHisohex (hexachloraphene) baths may be tried to eliminate or reduce staphylococcal carriage in adults.[7] Prophylaxis with systemic antibiotics is of doubtful efficacy and can result in the emergence of resistant strains; it should be tried only for severe cases (see Folliculitis, furuncules and carbuncles, below).

Recurrent bacterial cellulitis of the lower extremities can often be prevented by topical antifungal treatment for dermatophyte infections such as tinea pedis because even minor or inapparent superficial fungal infection can serve as a portal of entry for Gram-positive cocci.

CLINICAL FEATURES, DIAGNOSIS AND MANAGEMENT OF SPECIFIC SOFT TISSUE INFECTIONS

Folliculitis, furuncles and carbuncles

Pustules or abscesses can develop when organisms permanently or transiently resident on the skin surfaces are introduced into deeper tissues (Fig. 9.1). Pathogens can also seed the skin from hematogenous sources such as bacteremias, for example associated with staphylococcal endocarditis (Fig. 9.2) or by contiguous spread from infectious foci in the lung or gastrointestinal tract. Most commonly, small focal abscesses develop in the superficial layers of the skin,

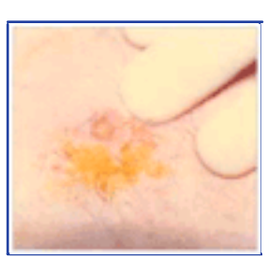

Figure 9-1 Cutaneous infection at the previous insertion site of an intravenous catheter. Organisms from the skin were likely introduced into the dermis and subcutaneous tissue at the time of catheter insertion. Many of these infections remain superficial, but in this patient suppurative thrombophlebitis with bacteremia ensued.

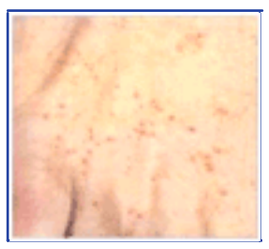

Figure 9-2 Diffuse skin involvement. Petechial lesions in a patient with *Staphylococcus aureus* bacteremia, endocarditis and acute aortic insufficiency.

Figure 9-3 Carbuncle of the buttock caused by *Staphylococcus aureus.* This large carbuncle developed over the course of 7–10 days and required surgical drainage plus treatment with antibiotics. The patient had previously experienced numerous episodes of *Staph. aureus* cutaneous abscesses. He carried the staphylococci in his anterior nares.

where hair follicles serve as the portal of entry. Such lesions are called folliculitis. *Staphylococcus aureus* accounts for most of these infections, but many different

bacterial species can occasionally cause localized folliculitis.

Folliculitis can progress to form subcutaneous abscesses, called furuncles or boils, which usually drain and resolve spontaneously, but may progress to form a large, exquisitely painful group of contiguous furuncles, called a carbuncle (Fig. 9.3). Carbuncles require surgical drainage as well as antibiotic treatment.[6]

Recurrent furunculosis

Certain individuals seem to be predisposed to recurrent *Staph. aureus* skin infections (recurrent furunculosis). Although it has been suggested that diabetic patients are especially prone to boils and carbuncles,

Figure 9-4 Staphylococcal nasal carriage. This patient had a small staphylococcal abscess beneath the mucosa of the nose, illustrating how *Staphylococcus aureus*, which colonizes the nares, can infect skin and submucosa. Intact mucosa is highly resistant to infection; such infections usually occur as a result of defects in the mucosal membranes or via hair follicles inside the nose.

few data support this concept. In contrast, it is well established that patients with Job's syndrome, who have eosinophilia and high levels of serum IgE antibody, are strongly predisposed to these focal *Staph. aureus* infections. However, most patients do not have immunologic or metabolic abnormalities, and the greatest predisposing factor has been the colonization of the anterior nares with *Staph. aureus* (Fig. 9.4). Thus, touching the nose or nasal secretions and then rubbing or scratching the skin results in autoinoculation and abscess formation. Breaking the cycle can be useful to prevent recurrences; however, it is important to document nasal colonization by appropriate techniques. Administration of intranasal mupuricin or bacitracin ointment for the first 5 days of each month has been shown to decrease colonization and reduce the frequency of recurrent infection by about 50%.[8] Treatment of recurrent furunculosis may also require surgical incision and drainage as well as antistaphylococcal antibiotics such as oral dicloxacillin or parenteral nafcillin.

Predisposing factors

Superficial dermal trauma such as insect bites or abrasions can result in cutaneous abscesses. Eczema may also serve as a portal of entry. Superinfected eczema may be difficult to distinguish from eczema itself because both result in crusted lesions, exudation and cutaneous erythema. The presence of lymphangitis, pustules or fever suggests infection. Because *Staph. aureus* is the most common cause of infected eczema, treatment with an oral antistaphylococcal antibiotic such as dicloxacillin is warranted.

Sebaceous glands empty into hair follicles; if the ducts become blocked they form sebaceous cysts, which may resemble staphylococcal abscess or become secondarily infected. Chronic folliculitis is uncommon except in acne vulgaris in which normal flora (e.g. *Propionibacterium acnes*) may play a role.

Recurrent folliculitis is most common in black males and associated with trauma from shaving (folliculitis barbae). Hidradenitis suppurativa occurs in either acute or chronic forms and can lead to recurrent axillary or pudendal abscesses.

Diffuse folliculitis

Diffuse folliculitis occurs in two distinct settings. The first, 'hot tub folliculitis' is associated with water maintained at a temperature between 98.6 and 104°F (37 and 40°C) that is insufficiently chlorinated and is caused by *P. aeruginosa*. The infection is usually self-limited, although serious complications of bacteremia and shock have occasionally been reported.

The second form of diffuse folliculitis, swimmer's itch (Fig. 9.5), occurs when the skin is exposed to water infected with avian freshwater

Figure 9-5 Swimmer's itch. Diffuse folliculitis can be caused by *Pseudomonas aeruginosa* (hot tub folliculitis), schistosomes (swimmer's itch) or *Staphylococcus aureus* (folliculitis). This young man had been fishing in an alkaline lake in the western part of the USA. He had been fishing from a 'float tube' and had exposed only his hands and arms to the water. The rash was associated with severe itching. Although his white blood count was not elevated 35% of the white cells were eosinophils.

Figure 9-6 Staphylococcal scalded skin syndrome. Flaccid bullae occur as single or multiple lesions. Examination of a frozen tissue section reveals that the cleavage plane is at the stratum corneum. This disease must be distinguished from toxic epidermal necrolysis (see Fig. 9.7).

Figure 9-7 Toxic epidermal necrolysis. This picture shows a skin slough (Nikolsky's sign), which resulted when lateral pressure was applied by the thumb in a plane parallel to the skin surface. This disorder is more common in adults, has a high mortality rate and is usually caused by medications.

schistosomes. Warm water temperatures and alkaline pH are suitable for mollusks, which are the intermediate host between birds and humans. Free-swimming cercariae readily penetrate human hair follicles or pores, but quickly die. This triggers a brisk allergic reaction, causing intense itching and erythema. The infestation is self-limited, secondary infection is uncommon and antipruritics and topical corticosteroid cream promptly relieve the symptoms.

Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome has been described in all age groups, but it is usually seen in children under 5 years of age, including neonates. [9] The characteristic features are a faint erythematous rash with the formation of flaccid bullae (Fig. 9.6). *Staphylococcus aureus* of phage group II is the causative organism. These organisms produce the toxin exfoliatin, which appears to affect the cell junctions of young dermal cells. Specifically, there is intraepidermal cleavage at the level of the stratum corneum. A classic clinical feature is Nikolsky's sign, in which lateral pressure on the skin results in shearing off of the top layer of skin (Fig. 9.7). The

mortality of staphylococcal scalded skin syndrome is low, and fluid loss from the skin is minimal. Appropriate antibiotic therapy is the main component of treatment.

Staphylococcal scalded skin syndrome must be distinguished from toxic epidermal necrolysis, a condition that is more common in adults, is usually secondary to a drug reaction and is associated with high mortality rate (see Fig. 9.7). Frozen section examination of a punch biopsy readily distinguishes these two entities:

- staphylococcal scalded skin syndrome shows a cleavage at the level of the stratum corneum; and
- toxic epidermal necrolysis shows deeper cleavage, at the stratum germinativum.

Impetigo

Impetigo contagiosa is a form of superficial pyoderma caused by streptococci and/or staphylococci. Currently, about half of impetigo cases are caused by *Staph. aureus*.[9] Staphylococci and group A streptococci can be co-isolated from impetiginous lesions in many cases. Group A streptococci alone currently cause less than half the cases. Staphylococcal impetigo tends to occur sporadically, whereas epidemics of impetigo caused by group A streptococci have been well described. Epidemics occur throughout the year in tropical areas or during the summer months in more temperate climates. Impetigo caused by group A streptococci is sometimes complicated by the development of poststreptococcal glomerulonephritis. This important nonsuppurative complication is more likely to occur during epidemics of impetigo caused by certain M types such as M type 49 (see Chapter 225).

Impetigo is characterized by thick-crusted lesions with rounded or irregular margins, often located on the face (Fig. 9.8a).[10] Streptococcal pyoderma frequently has a golden brown or honey color, resembling a plaque of dried serum. Children between 2 and 10 years of age are most commonly infected. Impetigo is often associated with poor socioeconomic conditions and poor hygiene.

Initially, colonization of unbroken skin occurs either exogenously from other infected persons (hence the term impetigo contagiosa) or endogenously by contamination of the skin with organisms carried in the anterior nares or oropharynx. The development of impetiginous lesions takes 10–14 days and likely is initiated through lesions such as minor abrasions and insect bites, which serve as a means of intradermal inoculation. Initially, impetigo may appear as vesicular lesions, which then evolve into crusts (Fig. 9.8b).

Patients should receive penicillin treatment, particularly when numerous sites of the skin are involved, although treatment may not prevent poststreptococcal glomerulonephritis. Topical treatment with an agent effective against Gram-positive bacteria, such as bacitracin or mupirocin is also effective.

Bullous impetigo

Bullous impetigo is caused by strains of *Staph. aureus* harboring a group II bacteriophage that contains genetic elements coding for a

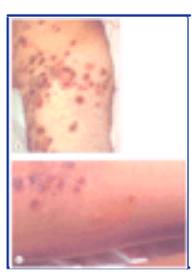

Figure 9-8 Impetigo. (a) Impetigo in a homeless man. Both *Staphylococcus aureus* and group A streptococci were cultured from these lesions. (b) Impetigo, with initial vesicles changing to crusts.

toxin, which causes cleavage in the epidermis. This results in separation of the cellular planes at the level of the stratum corneum and this is responsible for the superficial flaccid bullae that characterize this condition. Several of these lesions may coalesce and spread to form large reddish plaques, usually involving the neck, face or chin. The superficial flaccid bullae are easily ruptured and may not be apparent at the time when the patient is first seen. Because of the superficial nature of these infections, scarring does not occur. Appropriate treatment is an antistaphylococcal antibiotic, which may be given orally.

Ecthyma, paronychia and blistering distal dactylitis

Ecthyma, like impetigo, is characterized by dry crusted lesions of the skin and may be caused by *Staph. aureus*, group A streptococci or both. Unlike impetigo, this lesion extends into the dermis and may therefore lead to post-treatment scarring.[9]

Paronychia is an infection between the nail plate of a digit and the cuticle. It is associated with sucking of the fingers and occupations or hobbies involving prolonged immersion of the hands in water. Paronychia may occur in some immunocompromised patients. Staphylococci are the most common etiologic agents, although oral anaerobes and streptococci may also be isolated. Fungi such as *Fusarium* spp. may be isolated from paronychias in immunocompromised patients. Drainage is best accomplished between the nail-plate and the cuticle. Antimicrobial agents are rarely needed in otherwise healthy individuals.

Blistering distal dactylitis is characterized by painful blisters on the fingerpads of digits. It is most common in children. *Streptococcus*

Figure 9-9 Erysipelas. This form of cellulitis is caused by *Streptococcus pyogenes* and is most common in the elderly. Unique characteristics include a fiery red or salmon color, well-demarcated edges, desquamation after 5–7 days and location on the face or lower extemities. This picture was taken 48 hours after treatment with penicillin when the brilliant red salmon color had evolved to a reddish blue color. On the second day of treatment patients usually have less pain and fever subsides, but swelling may be more extensive.

pyogenes is the most common organism isolated, although *Staph. aureus* can cause a similar lesion. Incision and drainage may be useful, in conjunction with an antibiotic appropriate for *Staph. aureus* or *Strep. pyogenes*.

Erysipelas

Erysipelas is a specific variant of cellulitis caused by *Strep. pyogenes,* and occasionally by streptococci of groups B, C and D.[11] [12] It is characterized by an abrupt onset of fiery red swelling of the face or extremities. Distinctive features are well-defined margins, particularly along the nasolabial fold, rapid progression and intense pain (Fig. 9.9). Flaccid superficial bullae may develop during the second to third day of the illness, but extension to deeper soft tissues is rare.

Surgical debridement is rarely necessary, and treatment with penicillin is effective. Swelling may progress for a time despite appropriate treatment, even while fever, pain and the intense red color are diminishing. Desquamation of the involved skin occurs after 5–10 days.

Erysipelas is most common in elderly adults, and the severity of systemic toxicity can vary from region to region. It seems to be less common and less severe now than in the past.

Cellulitis

The term 'cellulitis' is commonly used by physicians, but is not well defined in the literature. It is a localized area of soft tissue inflammation characterized by:

- leukocytic infiltration of the dermis,
- capillary dilatation, and
- proliferation of bacteria.

Clinically cellulitis is recognized as an acute inflammatory condition of the skin characterized by localized pain, erythema, swelling and heat.[6] The area of erythema is a paler pink than the flaming red of erysipelas, and has indistinct margins (Fig. 9.10).

Cellulitis caused by Staphylococcus aureus and Streptococcus pyogenes

Cellulitis is most commonly caused by indigenous flora such as *Staph. aureus* and *Strep. pyogenes,* which colonize the skin and appendages. Bacteria may gain access to the epidermis through cracks in the skin, abrasions, cuts, burns, insect bites, surgical incisions and intravenous catheters.

Figure 9-10 Cellulitis. In contrast to erysipelas, cellulitis is a pink color rather than brilliant red and has indistinct margins. *Staphylococcus aureus* and group A, C and G streptococci are the most common etiologies. Many other bacteria may cause cellulitis (see Table 9.1).

Figure 9-11 Cellulitis. (a) This case was caused by *Staphylococcus aureus* and is spreading centripetally from a central localized focus of infection. The redness and swelling characteristic of cellulitis are apparent over the upper eyelid. (b) The cellulitis has developed from a localized staphylococcal abscess formed in a meibomian gland (chalazion).

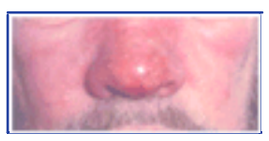

Figure 9-12 *Staphylococcus aureus* cellulitis of the nose. The focal lesion began in a hair follicle inside the nose, with redness, swelling and pain. Rarely, such lesions on the nose are complicated by extension into the cavernous sinus via veins draining the central part of the face.

Cellulitis caused by *Staph. aureus* spreads centripetally from a central localized infection such as an abscess (Fig. 9.11 and Fig. 9.12), folliculitis or foreign body (e.g. a sliver, prosthetic device or intravascular catheter).

Figure 9-13 Lymphangitis. Cellulitis caused by group A streptococci began below the knee and rapidly spread; about 4 hours later lymphangitis had spread up the inner aspect of the thigh.

Figure 9-14 Cellulitis of the lower leg associated with chronic venous insufficiency. Streptococci of groups A, B, C and G are the most common isolates. Group B streptococci seldom cause cellulitis in previously healthy hosts, but should be considered in people who have peripheral vascular disease or diabetes mellitus.

In contrast, cellulitis due to *Strep. pyogenes* is a more rapidly spreading diffuse process, frequently associated with lymphangitis (Fig. 9.13) and fever.[13]

Recurrent cellulitis

Recurrent streptococcal cellulitis of the lower extremities may be caused by group A, C or G streptococci in association with skin lesions such as chronic venous stasis (Fig. 9.14), saphenous venectomy for coronary artery bypass surgery,[14] or healed burns, especially if the skin is colonized by dermatophyte fungi. Streptococci also cause recurrent cellulitis among patients with chronic lymphedema resulting from irradiation, lymph node dissection, Milroy's disease or elephantiasis.

Recurrent staphylococcal cutaneous infections occur in individuals who have eosinophilia and elevated serum levels of immunoglobulin E (Job's syndrome) and among chronic nasal carriers of staphylococci.

Cellulitis associated with predisposing conditions

A number of other conditions predispose to infection by endogenous or exogenous pathogens (see Table 9.2). For example:

- *Streptococcus agalactiae* cellulitis occurs in people who have diabetes mellitus or peripheral vascular disease; and[15]
- *Haemophilus influenzae* causes periorbital cellulitis in children in association with sinusitis, otitis media or epiglottitis and will presumably become less common, as has *Haemophilus* meningitis, due to the impressive efficacy of the *H. influenzae* type b vaccine.

Cellulitis associated with bites

Many other species of bacteria can cause cellulitis. These often occur in special settings, and the history can provide useful clues to the diagnosis (see Table 9.2). Bites of various types may introduce specific organisms into the deeper tissues, resulting in soft tissue infections. For example, cellulitis associated with cat bites and, to a lesser degree, dog bites is commonly caused by *Pasteurella multocida*, although in the latter case *Staphylococcus intermedius* and *Capnocytophaga canimorsus* (DF-2) must also be considered. Cellulitis and abscesses associated with dog and human bites also contain a variety of anaerobic organisms.[16] *Pasteurella multocida* is resistant to dicloxacillin and nafcillin, but sensitive to all other ß-lactam antimicrobials as well as quinolones, tetracycline and erythromycin. Ampicillin-clavulanate, ampicillin-sulbactam or cefoxitin are good choices for treating animal or human bite infections.

Soft tissue infections may result from the bites of mosquitoes, horse flies and spiders; usually they cause only local allergic reactions with itching, swelling and

erythema. Similarly, brown recluse spider bites may resemble acute infection at first, but later there is primary tissue destruction and central necrosis due to the action of dermonecrotic toxins. These infections may resemble pyoderma gangrenosum or may become secondarily infected with skin organisms. Mosquito bites may serve as a portals of entry for skin organisms such as *Staph. aureus* or *Strep. pyogenes*. Such infections are not uncommon in clinical practice, but given the number of individuals bitten by insects, infection is a relatively rare complication.

Cellulitis associated with water exposure

Aeromonas hydrophila causes a highly aggressive form of cellulitis in tissues surrounding lacerations that were sustained in fresh water lakes, rivers and streams. This organism is sensitive to aminoglycosides, fluoroquinolones, chloramphenicol, trimethoprim-sulfamethoxazole (co-trimoxazole) and third-generation cephalosporins, but is resistant to ampicilllin.

Fish food containing the water fleas of the genus *Daphnia* can be contaminated with *Mycobacterium marinum,* which may cause cellulitis or granulomas on skin surfaces exposed to the water in aquariums or following injuries in swimming pools. Rifampin (rifampicin) plus ethambutol has been an effective treatment for some, although no comprehensive studies have been carried out. In addition, some strains of *M. marinum* are susceptible to tetracycline or trimethoprim-sulfamethoxazole.

Pseudomonas aeruginosa causes four types of soft tissue Cellulitis caused by *Pseudomonas aeruginosa* and other Gram-negative bacteria infections:

- ecthyma gangrenosum in neutropenic patients,
- hot tub folliculitis,
- burn wound sepsis, and
- cellulitis following penetrating injury.

TABLE 9-5 -- Differential diagnosis of ulcerative skin lesions.

DIFFERENTIAL DIAGNOSIS OF ULCERATIVE SKIN LESIONS	
Clinical condition	**Etiology**
Anthrax	*Bacillus anthracis*
Cutaneous diphtheria	*Corynebacterium diphtheriae*
Ulceroglandular tularemia	*Francisella tularensis*
Bubonic plague	*Yersinia pestis*
Buruli ulcer	*Mycobacterium ulcerans*
Primary syphilis	*Treponema pallidum*
Chancroid	*Haemophilus ducreyi*
Lucio's phenomenon	*Mycobacterium leprae*
Decubitus (pressure) ulcer	Mixed aerobic and anaerobic bacteria
Leishmaniasis	*Leishmania tropica*
Ecthyma gangrenosum	*Pseudomonas aeruginosa*
Tropical ulcer	Idiopathic and nonspecific; mixed bacterial species

In the last of these *P. aeruginosa* is often introduced into the deep tissues by stepping on a nail, a scenario referred to as the 'sweaty tennis shoe syndrome'.

Treatment includes surgical inspection and drainage, particularly if the injury also involves bone or joint capsule. Choices for empiric treatment pending antimicrobial susceptibility data include aminoglycosides, third-generation cephalosporins such as ceftazidime, cefoperazone or cefotaxime, semisynthetic penicillins such as ticarcillin, mezlocillin or piperacillin, or fluoroquinolones. (The quinolones are not approved in children under 13 years of age.)

Cellulitis caused by Gram-negative bacilli, including *P. aeruginosa* as described above, is most common in hospitalized immunocompromised hosts. Recently, *Stenotrophomonas maltophilia* has emerged as an important cause of nosocomial cellulitis in patients who have cancer. [17] The bacterium has been isolated from incubators, nebulizers, humidifiers and tap water in hospitals. The cellulitis may be related to intravenous catheters and in some circumstances may be metastatic via the bloodstream.

Trimethoprim-sulfamethoxazole, or ticarcillin-clavulanic acid, with or without ciprofloxacin are reasonable treatment choices, although cultures and sensitivities are important because of the high prevalence of antibiotic-resistant organisms in the health care environment.

Other causes of cellulitis

The Gram-positive aerobic rod, *Erysipelothrix rhusiopathiae,* which causes cellulitis in bone renderers and fishmongers, remains susceptible to erythromycin, clindamycin, tetracycline and cephalosporins, but is resistant to sulfonamides and chloramphenicol.

Differential diagnosis

The etiology of cellulitis can be suspected on the basis of the epidemiologic data supplied above. If there is drainage, an open wound or an obvious portal of entry, Gram stain and culture can often provide a definitive diagnosis (Table 9.5). In the absence of these findings, the bacterial etiology of cellulitis may be difficult to establish. Even with needle aspiration from the leading edge or punch biopsy of the cellulitis itself, cultures are positive in only 20% of cases.[18] This suggests that relatively low numbers of bacteria may cause cellulitis and that the expanding area of erythema within the skin may be the direct result of extracellular toxins or the soluble mediators of inflammation elicited by the host.

Antibiotic treatment

Because many different microbes can cause cellulitis, the choice of initial empiric antibiotic therapy depends upon the clinical features described above. Once cultures and sensitivities are available, the

choice is easier and more specific. The physician must first decide whether the patient's illness is severe enough to require parenteral treatment, either in hospital or on an outpatient basis.

Presumed streptococcal or staphylococcal cellulitis

For presumed streptococcal or staphylococcal cellulitis, nafcillin, cephalothin, cefuroxime, vancomycin, or erythromycin are good choices. Cefazolin and ceftriaxone have less activity against *Staph. aureus* than cephalothin, although clinical trials have shown a high degree of efficacy. Ceftriaxone is a useful choice for outpatient treatment because it can be given once daily. Similarly, teicoplanin, like vancomycin, has excellent activity against *Strep. pyogenes* and both *Staph. aureus* and *Staph. epidermidis* and may be given once daily by intravenous or intramuscular injection. Because methicillin-resistant *Staph. aureus* has recently increased in prevalence throughout much of the world, vancomycin or linezolid should be used empirically in patients with severe soft tissue infections who are toxic or in those who have recently been hospitalized or received antibiotics.[19]

For patients being treated with oral antibiotics, dicloxacillin, cefuroxime axetil, cefpodoxime, erythromycin, clarithromycin or azithromycin are all effective treatments.

For known group A, B, C or G streptococcal infections, penicillin or erythromycin should be used orally or parenterally. For serious group A streptococcal infections such as necrotizing fasciitis or streptococcal toxic shock syndrome, clindamycin is more efficacious than penicillin.[20] This is probably because in this type of infection where there are large numbers of bacteria, streptococci are in a stationary growth phase and do not express a full complement of penicillin-binding proteins.[21] In contrast, the activity of clindamycin is not affected by inoculum size or growth phase. In addition, clindamycin suppresses the synthesis of many streptococcal exotoxins and surface proteins.[22] [23]

Other types of cellulitis

For cellulitis associated with *Eikenella corrodens* useful antibiotics are penicillin, ceftriaxone, sulfamethoxazole-trimethoprim, tetracyclines and fluoroquinolones. Interestingly, this organism is resistant to oxacillin, cefazolin, clindamycin and erythromycin.

Cellulitis associated with cat bites may fail to respond to treatment with oral cephalosporins, erythromycins and dicloxacillin. Reasons for failure include resistance of *P. multocida* to oxacillin and dicloxacillin and the inadequate serum and tissue levels attained with older oral cephalosporins and erythromycins.

Cutaneous ulcers

Infectious ulceration of the skin results from either:

- direct destruction of dermal cells by bacterial products, or
- an intense inflammatory reaction.

Cutaneous anthrax

This is an example of direct destruction of dermal cells by toxins produced by *Bacillus anthracis* (see Table 9.5). This disease is traditionally contracted by direct inoculation of the skin of animal handlers, especially goat and sheep herders or hide processors, [24] but recent cases have occurred as the result of deliberate bioterrorism (see Chapter 6). The lesion begins as a papule, which evolves into a bulla and then ulcerates. Sepsis may occur. The diagnosis is established by aspiration of the leading edge of the lesion, Gram stain and culture. Penicillin is appropriate therapy.

Cutaneous diphtheria

Since 1980 cutaneous diphtheria has been recognized in homeless individuals who present with chronic nonhealing ulcers with an overlying dirty gray membrane. These lesions may mimic those of psoriasis, eczema or impetigo, but have a deeper base. Appropriate cultures of the ulcer are mandatory because organisms growing from routine cultures may be misidentified as diphtheroids.[25]

Cutaneous tularemia (ulceroglandular tularemia)

Cutaneous tularemia occurs following a tick bite or handling of infected rodents or lagomorphs (rabbits). It most commonly presents with regional lymphadenopathy associated with suppuration and fever, although pneumonic, oculoglandular, oropharyngeal and typhoidal forms have also been described. The characteristic lesion is a small ulceration with an eschar, which develops 2–10 days after exposure. Treatment with streptomycin or gentamycin has been successful, and doxycycline, chloramphenicol or a fluoroquinolone are alternatives.

Buruli ulcer

Buruli ulcer is caused by *Mycobacterium ulcerans*. It presents as a shallow ulcer, which slowly expands centripetally. It is uncommon in the USA and Europe, but is endemic in tropical climates, particularly Africa. Diagnosis is easily established by biopsy, acid-fast staining or culture. The organism is susceptible to isoniazid, rifampin and *para*-amino salicylic acid (PAS). Oral treatment with isoniazid and rifampin for 2–3 months is usually successful.

Leishmaniasis

Leishmaniasis also presents as shallow ulcers with an expanding margin. Diagnosis should be suspected in patients residing in or returning from Central or South America. A biopsy from the raised edge stained with Giemsa or Wright's stain demonstrates the amastigote stage of *Leishmania tropica*. Treatment with antimony compounds is effective, but requires prolonged administration over 4–6 months.

Other causes of cutaneous ulcers

The differential diagnosis of cutaneous ulcers in genital areas should include:

- syphilis,
- chancroid,
- lymphogranuloma venereum, and
- herpes simplex virus infection.

Noninfectious causes of cutaneous ulceration include:

- Behçet's syndrome,
- cutaneous vasculitis, including lupus erythematosus,
- toxic epidermal necrolysis,
- pressure necrosis, and
- brown recluse spider bites.

Solitary shallow ulcers of skin and mucous membranes have also been described in disseminated histoplasmosis.

Herpes simplex can cause primary or recurrent cutaneous infections of the digits (herpetic whitlow) or head and neck. This viral infection is often misdiagnosed and mistreated as a bacterial condition, and occurs in those who are exposed to inoculation of the skin from oral secretions, such as from dentists, dental hygienists, nurses, anesthesiologists and wrestlers.

Orf is caused by a DNA virus similar to smallpox. It causes development of shallow ulcers (in general only one lesion) on the digits of animal handlers working with sheep or goats that harbor open mucous membrane lesions.[24]

Bacillary angiomatosis (see also Chapter 132)

Bacillary angiomatosis is a primary infection of endothelial cells that has important cutaneous manifestations.[26] The lesions may appear as purple nodules resembling Kaposi's sarcoma. They may also appear as scaly or ulcerated lesions and may have the appearance of superficial pink papules or plaques in black people. This disease usually occurs in people who have HIV infection and is caused by *Bartonella henselae* or *B. quintana*. The organisms can be acquired from cat bites and scratches or from cat fleas. The course and extent

Figure 9-15 Gram stain of purulent material demonstrating *Staphylococcus aureus.* The microbial etiology of cellulitis may be suspected based upon signs, symptoms and history; however, definitive diagnosis requires Gram stain and culture. If there is no portal of entry, aspiration or even punch biopsy of cellulitic skin yields a positive culture in only 20% of cases.

Figure 9-16 Cellulitis at the elbow associated with olecranon bursitis. (a) Pale pink erythema on the inner aspect of the elbow. (b) Careful inspection demonstrates a focal infection over the point of the elbow. Fluid aspirated from the olecranon bursa yielded a pure culture of *Staphylococcus aureus*.

Figure 9-17 Erythema and swelling of the face due to a tooth abscess. (a) Swelling of the face, on inspection resembling periorbital cellulitis. (b) Further inspection reveals a gingival abscess above the patient's left upper canine tooth.

of infection is highly variable and depends upon the host's immune status.

Histopathology reveals capillary proliferation. The organisms can be visualized using Warthin-Starry silver stain or electron microscopy. Bacteriologic identification requires a special culture technique: lysed blood centrifugate or digested tissue is plated onto chocolate or Columbia agar and incubated for 10–14 days at 95°F (35°C) in 5–7% carbon dioxide. Small dry adherent oxidase-negative colonies of Gram-negative curved rods with twitching motility can be identified as *Bartonella* spp. by fluorescent antibody, gas-liquid chromatography or biochemical tests.[27]

Resistance to penicillin, cephalosporins, sulfonamides and vancomycin has been described. The recommended therapy is erythromycin 500mg q6h.[23]

Cutaneous manifestations of infections of deep soft tissues

Staphylococcal infections of deeper tissues may also cause superficial redness, warmth and swelling of the skin, even though the skin itself is not infected (Fig. 9.15). Examples include olecranon bursitis (Fig. 9.16), septic arthritis, osteomyelitis, staphylococcal parotitis and other deep infections of the head and neck, such as anaerobic infections, actinomycosis and tooth abscesses (Fig. 9.17).

Chapter 10 - Necrotizing Fasciitis, Gas Gangrene, Myositis and Myonecrosis

Dennis L Stevens

INTRODUCTION

The spectrum of infections of the deep soft tissues ranges from localized bacterial, viral and parasitic lesions to rapidly spreading, tissue-destructive infections such as necrotizing fasciitis and myonecrosis. For example, pyomyositis, which is common in the tropics but rare in temperate zones, is a focal infection of skeletal muscle that is usually caused by *Staphylococcus aureus*; it generally remains localized and rarely causes systemic complications. In contrast, necrotizing fasciitis and myonecrosis may be caused by single or multiple pathogens and often give rise to extensive tissue loss, bacteremia, organ failure, shock and death. Even the experienced clinician may have difficulty distinguishing between the different forms of deep soft tissue infection during the early stages. Finally, despite early diagnosis and appropriate treatment, some patients will lose tissue, even limbs, whereas others will succumb to systemic complications. This chapter emphasizes the clinical clues that help to make early, specific diagnoses.

EPIDEMIOLOGY

Until the middle of the 20th century, wartime injuries were commonly complicated by gas gangrene caused by *Clostridium* spp. During the Civil War in the USA, nearly 50% of soldiers who sustained gunshot wounds developed infection and many of these developed gas gangrene. Clostridial gangrene is typically a sporadic infection but during the Civil War apparent epidemics of 'hospital gangrene' were described. Contributing factors included severe trauma, grossly contaminated wounds, crowded and dirty conditions, application of soiled dressings (often recycled from patients who had just died of infection) and primitive surgical techniques for debridement and fixation of open fractures. Group A streptococci undoubtedly caused some of these infections but other major bacterial pathogens, including *Clostridium perfringens*, Gram-negative bacteria and mixed aerobic-anaerobic bacteria, also contributed.

Gas gangrene was also common during the First World War, particularly in the European theater, where the soil was rich and well fertilized with animal feces containing large numbers of vegetative spores of clostridia. In contrast, in North Africa, cases of gangrene following gunshot wounds were far less common, presumably because the desert sand contained few clostridial spores.[1] Gas gangrene has become uncommon in modern warfare because wounded soldiers are evacuated rapidly to well-equipped hospitals for surgical intervention, arterial reconstruction and antibiotic treatment, all of which have greatly reduced the prevalence of this feared disease.

In modern times, these serious deep soft tissue infections have become less common. Sporadic cases in the general population most often occur as occasional complications of penetrating trauma, compound fractures or septic abortions. For the first time in history, spontaneous gas gangrene caused by *Clostridium septicum* may be more common than trauma-associated gas gangrene caused by *C. perfringens*, *C. histolyticum* or other *Clostridium* spp. (see Chapter 232). Recently, severe soft tissue infections caused by *C. perfringens*, *C. sordellii* and *C. novyi* have been described among intradermal ('skin popping') and intravenous drug users.[2] [3]

Necrotizing fasciitis is a life-threatening form of soft tissue infection. It can occur in association with gas gangrene as a part of generalized tissue necrosis or as a separate clinical entity.[4] Two types of necrotizing fasciitis, types I and II, are recognized. Type I necrotizing fasciitis occurs in patients who have diabetes mellitus or severe peripheral vascular disease, or both;[5] it is usually caused by mixed aerobic and anaerobic bacteria. Although the risk for an individual diabetic patient is low, this type of deep soft tissue infection is the most common form of necrotizing fasciitis in the general population, because the total number of people who have diabetes is large.

Type II necrotizing fasciitis, formerly called streptococcal gangrene, is caused by group A streptococci. Since the mid-1980s, this disease has been recognized with increasing frequency in many parts of the world, at a current annual incidence of 5–10 cases per 100,000.[6]

Morbidity and mortality

Before the availability of antibiotics, gas gangrene was usually fatal. Since then, mortality rates from gas gangrene caused by *C. perfringens* have improved, owing to aggressive antibiotic therapy, aggressive surgical therapy employing better surgical techniques, and hyperbaric oxygen therapy. The most important factors in determining outcome, reducing the need for amputations and preventing shock have been early recognition and aggressive treatment.

The mortality and morbidity of group A streptococcal necrotizing fasciitis has evolved differently. In the pre-antibiotic era this infection carried a mortality rate of about 25% when treated with surgery (such as 'bear claw' fasciotomies) alone.[7] In modern times, mortality due to group A streptococcal necrotizing fasciitis has not decreased and continues to range from 30% to 70% despite antibiotics, appropriate surgical debridement and intensive supportive care. This suggests that more virulent strains must be responsible.

CLINICAL FEATURES

Pain, either generalized or localized, is the most common reason for patients who have deep-seated infection to seek medical care (Fig. 10.1). Although myalgia may occur with any febrile illness as part of the systemic immune response, in certain infectious diseases myalgia may provide an invaluable clinical clue. For example, diffuse myalgia is one of the cardinal manifestations of influenza. Severe, localized pain in a febrile patient is a common presentation for deep-seated bacterial infection. Early in the course of necrotizing fasciitis caused by group A streptococci, patients may have a viral-like prodrome with nausea, vomiting, diarrhea and fever; however, later in the course of the disease, patients seek medical assistance because of increasingly severe localized pain with continuing fever.

A portal of entry can be defined in the majority of cases of deep bacterial soft tissue infections such as type I necrotizing fasciitis and

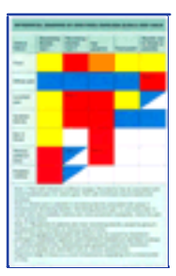

Figure 10-1 Differential diagnosis of infections involving muscle and fascia. Red, severe; orange, moderate; yellow, mild-to-moderate; blue, mild; white, none.

traumatic gas gangrene. In type I necrotizing fasciitis, infection begins at the site of a surgical incision, at a mucosal tear or at sites of skin breakdown in patients who have diabetes mellitus or peripheral vascular disease. Similarly, traumatic gas gangrene occurs at the site of major trauma such as crush injuries or penetrating injuries severe enough to cause arterial damage. In these cases, the clinician has reason to suspect infection as a cause of fever or increasing pain. In contrast, patients who have either type II necrotizing fasciitis or spontaneous gas gangrene may have no apparent portal of entry.[8] Early in the course of infection in such patients, the only physical signs of infection may be fever and localized tenderness. Fever and localized pain are the cardinal clues to this diagnosis but in some cases evidence of localized infection may not become apparent until after the development of systemic signs such as hypotension or organ failure.

Early in the course of deep infection associated with a defined portal of entry there is generally evidence of localized inflammation such as swelling, redness, warmth and tenderness. At that point the process may resemble simple cellulitis, which can be caused by any of a multitude of bacteria (see Chapter 9). In type I necrotizing

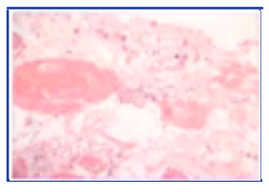

Figure 10-2 Histopathologic examination of tissue from a patient who has necrotizing fasciitis with extension into the underlying musculature. Note the absence of acute inflammatory cells in the area of muscle necrosis. When present, infiltrating granulocytes can be seen at the interface between normal and necrotic tissue and are often massed within small postcapillary venules.

fasciitis there is generally gas in the tissue, as there is in gas gangrene. Where there is no apparent portal of entry, the leading diagnoses to be considered are infection with group A streptococci (type II necrotizing fasciitis), *C. septicum* (spontaneous gangrene) or *Vibrio vulnificus*. The presence of gas in the tissue favors clostridial infection.

Gas may be detected by physical examination (crepitus) or by imaging (radiography, magnetic resonance imaging (MRI) or computerized tomography (CT) scan). Group A streptococci should be suspected if there is fever and severe pain and a history of blunt trauma or muscle strain. *Vibrio vulnificus* should be suspected in a patient who has cirrhosis of the liver, a history of ingestion of raw oysters or exposure to seawater in the south-east Atlantic Ocean or the Caribbean Sea.[9] Later, erythema is superceded by violaceous bullous lesions, massive local swelling becomes apparent and signs of systemic toxicity develop rapidly (see Chapter 230).

SPECIFIC TYPES OF DEEP SOFT TISSUE INFECTION

Necrotizing infections

Necrotizing infections of the skin and underlying soft tissues share the features of fulminant destruction of tissue and severe systemic signs of toxicity associated with high mortality (see Fig 10.1). Few areas of infectious diseases have a more confusing nomenclature. This is partly because authors have named necrotizing infections on the basis of clinical features, whereas these diagnoses should be based on surgical or pathologic findings. Thus, many different names have been used to describe processes that share common pathologic features:

- extensive tissue destruction;
- thrombosis of blood vessels;
- abundant bacteria spreading along fascial planes; and
- relatively few acute inflammatory cells, although small collections of polymorphonuclear leukocytes or microabscesses have been described (Fig. 10.2).

For patients who have evidence of an aggressive localized soft tissue infection, prompt surgical exploration of that site is of extreme importance to determine whether a necrotizing process is present. The same is true for patients who have milder local features associated

with severe systemic toxicity. In addition, although the clinical entity referred to as necrotizing fasciitis may occur alone, there is commonly also evidence of necrosis extending up to the dermis and down to underlying muscle (myonecrosis). Despite these common features, it is worth reviewing the many different types of necrotizing soft tissue infections that have been described in the literature because this may point to clinical clues leading to earlier surgical intervention and therefore an earlier diagnosis.

Necrotizing fasciitis

Necrotizing fasciitis is a deep-seated infection of the subcutaneous tissue that results in progressive destruction of fascia and fat, although it may spare the skin itself.[10] Two clinical types exist.

Type I necrotizing fasciitis

Type I necrotizing fasciitis is a mixed infection caused by aerobic and anaerobic bacteria. It occurs most commonly after surgical procedures, in diabetic patients or in those who have peripheral vascular disease (see Fig. 10.1). Non-clostridial anaerobic cellulitis and synergistic necrotizing cellulitis are both variants of the same syndrome. It may not be important to distinguish these entities from one another because all occur in diabetic patients and are caused by mixed anaerobic and aerobic bacteria.

Clinical features

These infections most commonly occur on or about the feet, with rapid extension along the fascia into the leg. Although cellulitis also occurs commonly in diabetic patients, necrotizing fasciitis should be considered in those who have cellulitis and systemic signs of infection such as tachycardia, leukocytosis, acidosis or marked hyperglycemia. In addition to its spontaneous occurrence in diabetic patients, type I necrotizing fasciitis may also develop as a result of a breach in the integrity of mucous membranes from surgery or instrumentation. In the head and neck region, bacterial penetration into the fascial compartments can result in a related syndrome known as Ludwig's angina (Fig. 10.3) or it may develop into necrotizing fasciitis. Group A streptococci may cause necrotizing fasciitis or a peritonsillar abscess, which can extend into the deep structures of the neck (Fig. 10.4).

Figure 10-3 Ludwig's angina. Infection begins with a break in the mucosal lining in the oropharynx; oral bacterial flora invade the soft tissues at the base of the tongue and penetrate through the floor of the mouth and into soft tissue of the neck. The floor of the mouth is elevated and patients talk as though they have a 'hot potato' in their mouth. Potential airway obstruction is a major concern. Although patients usually respond to penicillin, surgical consultation should be obtained and CT or MRI scans are useful for determining whether a necrotizing process is present.

Diagnostic tests

The first goal of management is to determine the depth and extent of the infection. Computerized tomography or MRI scans are invaluable in this regard to determine whether the infection is localized or spreading along fascial planes. The second goal is to determine whether surgical intervention is necessary. Because of the proximity to vital structures of the neck, surgical consultation is of major importance because exploration, drainage and debridement may be necessary to prevent airway obstruction, to determine the level of soft tissue involvement and to establish which bacteria are involved.

Treatment

Both Ludwig's angina and necrotizing fasciitis of the head and neck are usually caused by mouth anaerobes such as *Fusobacterium* spp. anaerobic streptococci, *Bacteroides* spp. and spirochetes. Either penicillin or clindamycin is effective treatment largely because the Gram-positive aerobic cocci and anaerobes of the oropharynx are generally susceptible to both. In contrast, type I necrotizing fasciitis below the diaphragm requires ampicillin plus clindamycin and a fluoroquinalone to cover the *Bacteroides* spp. and enterobacteriacea.

Type II necrotizing fasciitis

Type II necrotizing fasciitis is caused by group A streptococci and was previously called streptococcal gangrene.[5] In recent years, there has been a dramatic increase in the number of invasive infections, including necrotizing fasciitis, caused by group A streptococci. In contrast to type I necrotizing fasciitis, type II may occur in any age group and among patients who do not have complicated medical illnesses. Predisposing factors include:

- a history of blunt trauma,
- muscle strain,

- childbirth,
- chickenpox,
- non steroidal anti-inflammatory agents,[11]
- intravenous drug abuse, or
- penetrating injury such as caused by a laceration or a surgical procedure.

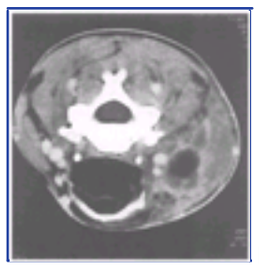

Figure 10-4 Computerized tomography of a soft tissue infection of the neck. This infection is caused by group A streptococci, which invaded as a rare complication of a previous 'strep throat'. Surgical drainage yielded a pure culture of group A streptococci and established a diagnosis. The patient was treated with intravenous penicillin for 10 days and made a good recovery.

In penetrating injuries, it is the skin rather than the mucous membranes that serve as the portal of entry for the streptococci. In contrast, among patients who do not have a defined portal of entry, hematogenous translocation of group A streptococci from the throat (asymptomatic or symptomatic pharyngitis) to the site of blunt trauma or muscle strain probably occurs.[12] The only other possibility, which is of course highly conjectural, is that group A streptococci reside in a dormant state in the deep tissue and trauma of various types reactivates their growth.

Group A streptococci are contagious microbes that in the past have caused epidemics of pharyngitis and scarlet fever in schools, rheumatic fever in military recruits and surgical wound infections in hospitalized patients. Thus, close contacts of a patient who has type II necrotizing fasciitis have a high likelihood of becoming colonized with a virulent strain. Clearly, the risk of developing a secondary case of fulminant necrotizing fasciitis is very low, but it is probably 50-fold higher than it is in the general population. In evaluating the risk to family members and hospital workers, the physician should consider the degree of exposure and the susceptibility of the host. Those contacts with conditions such as open wounds or chickenpox, as well as those family members and health care workers with frequent or continuous contact with a case of necrotizing streptococcal infection, should be treated with an agent to which the strain is sensitive (e.g. penicillin).

Pathogenesis

Pyrogenic exotoxins possess the unique ability to bind simultaneously to the MHC (major histocompatibility complex) class II portion of antigen-presenting cells, such as macrophage and specific Vß (variable part of ß chain) segments of the T-cell receptor in the absence of classic antigen processing by the macrophage. [13] Thus, pyrogenic exotoxins are superantigens that can cause rapid proliferation of T cells bearing specific Vß repertoires (see Chapter 2 and Chapter 56). Such stimulation of the host's immune cells is associated with production of both monokines (tumor necrosis factor (TNF)-a), interleukin (IL)-1 and IL-6)) and the lymphokines (IL-2, interferon and TNF-ß).[14] Expression of these cytokines in vivo probably contributes to shock, organ failure and tissue destruction.[15]

Clinical features

Necrotizing fasciitis exhibits a remarkably rapid progression from an inapparent process to one associated with extensive destruction of tissue, systemic toxicity, loss of limb or death.[8] [12] [16] Unexplained pain that increases rapidly over time may be the first manifestation of infection.[8] [12] The early signs and symptoms of infection may not be apparent, particularly in patients who have postsurgical infection, gunshot or knife wounds, or diabetes. In patients who have diabetes, the absence of pain may be related to neuropathy and anesthesia at the site of infection. In surgical patients, patients who have traumatic injuries and postpartum patients, the increasing pain may be assumed to be part of the normal convalescence rather than to be due to acute infection. Such a delay in diagnosis may allow the disease to progress to later stages before appropriate antibiotics and surgical invention are initiated.

In addition to pain, there may also be fever, malaise, myalgias, diarrhea and anorexia during the first 24 hours; erythema, which may be diffuse or local, may also be present. However, in most patients excruciating pain in the absence of any cutaneous findings

Figure 10-5 Type II necrotizing fasciitis caused by group A streptococci. (a) This patient was a 60-year-old man who had type II diabetes mellitus and who had a 3-day history of malaise, diffuse myalgia and low-grade fever. Over the course of 2–3 hours the pain became excruciating and was localized to the calf. During this time the calf swelled. Note that the skin over the anterior shin looks relatively normal, but that two small purple bullae are present. (b) Extensive necrotizing fasciitis was present on surgical exploration. In addition, myonecrosis was present beneath the fascia. The patient developed profound hypotension, acute respiratory distress syndrome and renal failure. He died despite aggressive surgical and medical management. There was no definable portal of entry, yet group A streptococci were grown from deep cultures and from blood.

may be the only clue of infection. Within 24–48 hours, erythema may develop or darken to a reddish-purple color, frequently with associated blisters and bullae. Conversely, erythema may be absent and the characteristic bullae may develop in skin of normal appearance. The bullae are initially filled with clear fluid and rapidly take on a blue or maroon appearance (Fig. 10.5). When the bullous stage is observed, there is already extensive necrotizing fasciitis (Fig. 10.5) and patients usually exhibit fever and systemic toxicity.

Although many different M-types of group A streptococci have been associated with necrotizing fasciitis in the past, M type I and 3 have been the strains most commonly isolated from patients throughout the world.[12] These strains can produce one or more of the pyrogenic exotoxins A, B and C.[8] [17] Necrotizing fasciitis caused by these strains is frequently associated with 'streptococcal toxic-shock syndrome'.[8] The hallmarks of this syndrome are the early onset of shock and multiple organ failure (see Chapter 225).

Diagnosis

Laboratory tests such as creatine phosphokinase, aspartate aminotransferase and serum creatinine usually show elevated levels and, together with leukocytosis with marked left shift, these findings should be sufficient to prompt surgical exploration. [8] Some experts have advocated punch biopsy and frozen section to establish the diagnosis; however, there may be false-negative findings if the deep tissue is not adequately sampled. Routine soft tissue radiographs, CT scans and MRI scans show soft tissue swelling.[18] Gas is not present and abscess formation is not apparent. These radiographic abnormalities

Figure 10-6 Postpartum sepsis due to group A streptococci. The patient was a 24-year-old woman who delivered a normal child. Thirty-six hours after delivery she developed fever, leukocytosis with marked left shift and increasing low abdominal pain. This MRI demonstrates swelling of the uterus, although not out of proportion for a recent delivery. There was no gas in the tissue. An emergency laparotomy revealed necrosis of the mucosa of the uterus, necrotizing fasciitis and myonecrosis of the uterus.

are not unusual in uninfected patients who have trauma or in postsurgical or postpartum patients (Fig. 10.6). In such cases, direct surgical exploration will determine whether necrotizing fasciitis is present, accomplish debridement of necrotic tissue and obtain material suitable for Gram stains and culture.

Management

The three main themes in treatment are surgical debridement, appropriate antibiotics and intensive supportive care. Some patients require mechanical ventilation and others need hemodialysis. Because of intractable hypotension and diffuse capillary leak, massive amounts of intravenous fluids (10–20 liters per day) are often necessary, although anasarca is a common complication. In some patients blood pressure improves with intravenous fluid alone. Pressors such as dopamine may be useful, but there is little controlled information from clinical or experimental studies in this specific infection. Although potent vasoconstrictors such as epinephrine (adrenaline) may improve blood pressure, symmetric gangrene may ensue, partly as a result of the drug and partly as a result of poor perfusion caused by the bacteria, toxins and endogenous mediators.

Antibiotic selection is difficult in patients who have rapidly progressing infection. Recent studies suggest that clindamycin is superior to penicillin for treatment of experimental necrotizing fasciitis or myonecrosis caused by group A streptococci.[19] This corroborates studies done by Eagle more than 40 years ago, which demonstrated the failure of penicillin in this setting.[20] It seems likely that penicillin failure is due to the reduced expression of critical penicillin-binding proteins during the stationary phase of bacterial growth.[21] Clindamycin may be more efficacious because:

- it is not affected by inoculum size or stage of growth,
- it suppresses toxin production,
- it facilitates phagocytosis of *Streptococcus pyogenes* by inhibiting M-protein synthesis,
- it suppresses the production of regulatory elements that control cell wall synthesis, and
- it has a long postantibiotic effect.[22]

Neutralization of circulating streptococcal toxins is a desirable therapeutic goal and is advocated by some experts.[23] [24] [25] [26] There seems little question that some batches of intravenous gammaglobulin contain neutralizing antibodies against some streptococcal toxins.[25] On

Figure 10-7 Type I necrotizing fasciitis. A 24-year-old man had been in good health but was awakened with severe perineal pain. (a) This photograph was taken 3 hours later. Note the massive swelling of the scrotum. (b) Soft tissue radiograph shows gas in the tissues of the thigh, buttocks, scrotum and anterior abdominal wall. Surgical inspection revealed brownish fluid in the scrotum, with gray, dull-colored, friable fascia but normal underlying musculature. Cultures grew *Enterococcus faecalis*, *Bacteroides fragilis*, *Escherichia coli* and anaerobic streptococci. The patient was treated with ampicillin, clindamycin and gentamicin for 3 weeks and surgical drains were placed in the scrotum, buttocks, thigh and anterior abdominal wall. There was an excellent clinical response. In some cases, surgery of a more radical nature may be necessary.

the basis of two case reports[23] [24] and a report of a non-randomized clinical trial, there is a suggestion that this treatment may affect the mortality and morbidity of this fulminant infection.[26]

Fournier's gangrene

In the perineal area, penetration of the gastrointestinal or urethral mucosa by bacteria may cause 'Fournier's gangrene', an aggressive infection caused by aerobic Gram-negative bacteria, enterococci and anaerobic bacteria such as *Bacteroides* spp. and peptostreptococci. These infections begin abruptly with severe pain and may spread rapidly to the anterior abdominal wall and the gluteal muscles; in males, infection frequently extends to the scrotum and penis (Fig. 10.7).

Surgical inspection, placement of drains and appropriate surgical debridement are necessary for both diagnosis and treatment. Antibiotic treatment should be based upon Gram stain, culture and sensitivity information when available. An appropriate empiric regimen would be either ampicillin or ampicillin and sulbactam combined with either clindamycin or metronidazole. Alternatively, broader Gram-negative coverage might be advisable if the patient has had prior hospitalization or if antibiotics have been used recently. This could be accomplished by substituting ticarcillin-clavulanic acid or piperacillin-tazobactam for ampicillin or by adding a fluorinated quinolone or an aminoglycoside.

Meleney's synergistic gangrene

This rare variant occurs in postsurgical patients. The lesion is a slowly expanding, indolent ulceration that is confined to the superficial fascia. It results from a synergistic interaction between *Staph. aureus* and microaerophilic streptococci. As in other forms of necrotizing infection, antibiotic therapy together with surgical debridement are the mainstays of treatment.

Non-clostridial anaerobic cellulitis

In non-clostridial anaerobic cellulitis, infection is associated with mixed anaerobic and aerobic organisms that produce gas in tissues. Unlike clostridial cellulitis, this type of infection is usually associated with diabetes mellitus and it often produces a foul odor. Surgical exploration is required to distinguish this condition from necrotizing cellulitis, myonecrosis and necrotizing fasciitis by *Clostridium* spp.

Clostridial cellulitis

In clostridial cellulitis, infection is usually preceded by local trauma or recent surgery. *Clostridium perfringens* is the most common species causing this entity. Gas is invariably found in the skin; the fascia and deep muscle are spared. Although clostridial cellulitis differs from clostridial myonecrosis in that there is less systemic toxicity, it is mandatory that thorough surgical exploration and debridement be performed to distinguish these entities. Magnetic resonance imaging or CT scans as well as a serum creatinine phosphokinase assay may also be useful for determining whether muscle tissue is involved. Treatment is discussed below under gas gangrene.

Clostridial gas gangrene

Three types of clostridial soft tissue infections have been defined: [1]

- simple wound contamination or colonization,
- anaerobic cellulitis, and
- clostridial gas gangrene.

The first type, simple wound contamination or colonization, does not progress to true infection for various reasons (e.g. there may be insufficient devitalized tissue to

promote infection or there may be effective host responses or effective medical and surgical management). Contamination is a very common occurrence; 30–80% of open traumatic wounds contain clostridial species.[27]

The second type, anaerobic cellulitis, occurs when there is devitalized tissue in a wound, sufficient for growth of *C. perfringens* or other strains. Although gas is produced locally and extends along fascial planes, bacteremia and invasion of healthy tissue do not occur. Appropriate medical and surgical management, including prompt removal of the devitalized tissue, is all that is necessary for cure and mortality is generally nil.[1]

The third type is clostridial gas gangrene or myonecrosis. This is defined as an acute invasion of healthy living muscle that is undamaged by previous trauma or ischemia.[27] It is divided into three different subtypes:

- traumatic gas gangrene,
- spontaneous or non-traumatic gas gangrene, and
- recurrent gas gangrene caused by *C. perfringens*.

Traumatic gas gangrene is the most common subtype. It develops when a deep, penetrating injury that compromises the blood supply (e.g. knife or gunshot wounds, crush injury or car accident) creates an anaerobic environment that is ideal for clostridial proliferation. This type of trauma accounts for about 70% of cases of gas gangrene. *Clostridium perfringens* is found in about 80% of such infections;[1] the remaining cases are caused by *C. septicum, C. novyi, C. histolyticum, C. bifermentans, C. tertium* and *C. fallax*. Other conditions associated with traumatic gas gangrene are bowel and biliary tract surgery, intramuscular injection of adrenaline, illegal abortion, retained placenta, prolonged rupture of the membranes and intrauterine fetal demise or missed abortion in postpartum patients.

Spontaneous or non-traumatic gas gangrene is less common. This is often caused by the more aerotolerant species *C. septicum*. As described below, most of these cases occur in patients who have a gastrointestinal portal of entry such as adenocarcinoma.

Third, and least common, is recurrent gas gangrene caused by *C. perfringens*. This has been described in people who have non-penetrating injuries at sites of previous gas gangrene; residual spores of *C. perfringens* may remain quiescent in tissue for periods of up to 20 years, and then germinate when minor trauma provides anaerobic conditions suitable for growth. [28]

Traumatic gas gangrene

Pathogensis

The initiating trauma introduces organisms (either vegetative forms or spores) into the deep tissues and produces an anaerobic niche with a sufficiently low redox potential and acid pH for optimal clostridial growth.[1] [27] Necrosis progresses within hours. At the junction of necrotic and normal tissues few polymorphonuclear leukocytes are present, yet pavementing of these cells along the endothelium is apparent within capillaries and in small arterioles and postcapillary venules.[29] [30] Later in the course of the illness there is leukostasis within larger vessels. Thus, the histopathology of clostridial gas gangrene is opposite to that seen in soft tissue infections caused by pyogenic organisms such as *Staph. aureus*, in which an early luxuriant influx of polymorphonuculear leukocytes localizes the infection without adjacent tissue or vascular destruction. Recent studies suggest that s-toxin (Fig. 10.8), when elaborated in high concentrations at the site of infection, destroys host tissues and inflammatory cells.[31] As the toxin diffuses into surrounding tissues or enters the systemic circulation, s-toxin promotes dysregulated adhesive interactions between polymorphonuclear leukocytes and endothelial cells and primes leukocytes for increased respiratory burst activity. [31] These actions lead to vascular leukostasis, endothelial cell injury and regional tissue hypoxia. Such perfusion deficits expand the anaerobic environment and contribute to the rapidly advancing margins of tissue destruction that are characteristic of clostridial gangrene.[1]

Figure 10-8 Colonies of *Clostridium perfringens* growing on an anaerobic blood agar plate. Theta toxin causes the clear zone of hemolysis closest to the colony. A second area of partial hemolysis is caused by a-toxin, an enzyme with phospholipase C activity.

Shock associated with gas gangrene may be attributable, in part, to direct and indirect effects of toxins. Alpha toxin (see Fig. 10.8), a phospholipase C, directly suppresses myocardial contractility ex vivo[32] and may contribute to profound hypotension via a sudden reduction in cardiac output.[33] In experimental models, theta toxin (a cholesterol-binding cytolysin) causes 'warm shock', defined as a markedly reduced systemic vascular resistance combined with a markedly increased cardiac output.[32] [33] It is clear that theta toxin accomplishes this indirectly by inducing endogenous mediators that cause relaxation of blood vessel wall tension, such as the lipid autacoids prostacyclin or platelet-activating factor.[34] Reduced vascular tone develops rapidly and, in order to maintain adequate tissue perfusion, a compensatory host response is required; this either increases cardiac output or rapidly expands the intravascular blood volume. Patients who have Gram-negative sepsis compensate for hypotension by markedly increasing cardiac output; however, this adaptive mechanism may not be possible in shock induced by *C. perfringens* due to direct suppression of myocardial contractility by alpha toxin.[32] The role of other endogenous mediators such as cytokines (e.g. TNF, IL-1, IL-6) as well as the potent endogenous vasodilator bradykinin have not been elucidated.

Prevention

Aggressive debridement of devitalized tissue and rapid repair of compromised vascular supply greatly reduce the frequency of gas gangrene in contaminated deep wounds. Intramuscular adrenaline, prolonged application of tourniquets and surgical closure of traumatic wounds should be avoided. Patients who have compound fractures are at particular risk of gas gangrene if the wound is surgically closed. Patients who have contaminated wounds should receive prophylactic antibiotics.

Clinical findings

The first symptom is usually the sudden onset of severe pain at the site of recent surgery or trauma.[2] [25] The mean incubation period is less than 24 hours, but it ranges from 6–8 hours to several days, probably depending on the degree of soil contamination or bowel contents spillage and the extent of vascular compromise.

The skin may initially appear pale, but it quickly changes to bronze then purplish red, becoming tense and exquisitely tender (Fig. 10.9). Bullae develop; they may be clear, red, blue or purple.

Gas in tissue may be obvious from physical examination, soft tissue radiographs, CT scan or MRI. Interestingly, none of these radiographic procedures have proved to be more specific or more sensitive than the physical finding of crepitus in the soft tissue.[10] However, radiographic procedures are particularly helpful for demonstrating gas in deeper tissue such as the uterus.

Signs of systemic toxicity develop rapidly; these include tachycardia, fever and diaphoresis, followed by shock and multiple organ failure. Shock is present in 50% of patients at the time they present to the hospital.[35] Bacteremia occurs in 15% of patients and may be associated with brisk hemolysis. In one patient, the hematocrit fell from 37% to 0% over a 24-hour period.[36] Subsequently, despite transfusion with 10 units of packed red blood cells over 4 hours, the hematocrit never exceeded 7.2%.[36] Based on my studies using recombinant alpha and theta toxins, it is clear that both toxins contribute to this marked intravascular hemolysis (unpublished). Not all cases of *C. perfringens* bacteremia have been associated with gas gangrene[37] but 90% of *C. perfringens* and 100% of *C. septicum* isolates from blood were associated with clinically significant infection.[38]

Additional complications of clostridial myonecrosis include jaundice, renal failure, hypotension and liver necrosis. Renal failure is largely due to hemoglobinuria and myoglobinuria, but it may be a

Figure 10-9 Extensive gas gangrene of the arm due to *Clostridium perfringens.* A 35-year-old man sustained a knife wound to the forearm. He did not seek medical care, but 36 hours later experienced severe pain in the upper arm and came to the emergency room. There was extreme tenderness of the arm and crepitus was easily demonstrated. A radiograph also demonstrated gas in the deep soft tissues. Surgical debridement and antibiotics were instituted, but later amputation at the level of the shoulder was necessary. A pure culture of *C. perfringens* was grown from the deep tissues.

result of acute tubular necrosis caused by hypotension. Renal tubular cells are probably directly affected by toxins, but this has not been proved.

Diagnosis

Increasing pain at a site of previous injury or surgery, together with signs of systemic toxicity and gas in the tissues, support the diagnosis. Definitive diagnosis rests on demonstrating large, Gram-variable rods at the affected site (Fig. 10.10). Note that although clostridia stain Gram positive when obtained from bacteriologic media, when visualized from infected tissues they often appear both Gram positive and Gram negative. In fresh specimens *C. perfringens* may appear to be encapsulated,[39] although this was not corroborated in gas gangrene associated with wartime trauma. [40] Surgical exploration is essential. The exposed muscle appears edematous, may be an abnormal reddish-blue to black color and does not bleed or contract when stimulated. Usually, some degree of necrotizing fasciitis and cutaneous necrosis are also present. Microscopic evaluation of biopsy material (see Fig. 10.10) demonstrates organisms among degenerating muscle bundles and characteristically an absence of acute inflammatory cells.[27] [41]

Management

Penicillin, clindamycin, tetracycline, chloramphenicol, metronidazole and a number of cephalosporins have excellent in vitro activity against *C. perfringens* and other clostridia. No controlled clinical trials have ever been conducted to compare the efficacy of these agents in humans. Based strictly on in-vitro susceptibility data, most textbooks state that penicillin is the drug of choice.[42] [43] However, experimental studies in mice suggest that clindamycin has the greatest efficacy and penicillin the least.[44] [45] Other agents with greater efficacy than penicillin include erythromycin, rifampin (rifampicin), tetracycline, chloramphenicol and metronidazole.[44] [45] Slightly greater survival was observed in animals receiving both clindamycin and penicillin; in contrast, antagonism was observed with penicillin plus metronidazole.[45] Because between 2% and 5% of strains are resistant to clindamycin, a combination of penicillin and clindamycin is

Figure 10-10 *Clostridium perfringens* in a patient who has extensive gas gangrene. (a) Tissue Gram stain of tissue removed from the arm of the patient described in Figure 10.9 . Note that the bacteria are rod shaped but gram variable. Note also that there are few if any acute inflammatory cells at the site of infection. (b) Transmission electron micrograph of *C. perfringens*. Note the endospores.

warranted. Based on his experimental studies and his vast clinical experience with gas gangrene, the late Dr William Altemeier recommended tetracycline and penicillin. [46] Thus, given an absence of efficacy data from a clinical trial in humans, the best treatment would appear to be clindamycin or tetracycline combined with penicillin. The failure of penicillin in experimental clostridial myonecrosis may be related to continued toxin production and filament formation rather than lysis.[47] In contrast, the efficacy of clindamycin and tetracycline may be related to their ability to inhibit toxin synthesis rapidly.[47]

Aggressive and thorough surgical debridement is mandatory to improve survival, preserve limbs and prevent complications.[42] [43] The use of hyperbaric oxygen (HBO) is controversial, although some non-randomized studies have reported good results with HBO therapy when combined with antibiotics and surgical debridement.[35] [48] [49] Experimental studies in animals have demonstrated that HBO alone can be effective treatment if the inoculum is small and treatment is begun immediately.[50] In contrast, other studies have demonstrated that HBO was only of slight benefit when combined with penicillin.[51] However, survival was better with clindamycin alone than with either HBO alone, penicillin alone or HBO plus penicillin together.[51] The benefit of HBO, at least theoretically, is to inhibit bacterial growth,[52] to preserve marginally perfused tissue and to inhibit toxin production.[53] Interestingly, Altemeier did not use HBO and was able to realize a mortality rate of less than 15% using surgical debridement and antibiotics (tetracycline plus penicillin) alone.[46]

Therapeutic strategies directed against toxin expression in vivo, such as neutralization with specific antitoxin antibody or inhibition of toxin synthesis, may be valuable adjuncts to traditional antimicrobial regimens. Currently, antitoxin is no longer available. Future strategies may target endogenous proadhesive molecules such that toxin-induced vascular leukostasis and resultant tissue injury are attenuated.

Prognosis

Patients presenting with gas gangrene of an extremity have a better prognosis than those who have truncal or intra-abdominal gas gangrene, largely because it is difficult to debride such lesions adequately.[42] [43] [54] Hyperbaric oxygen could be useful in such patients, yet there are few data on this subject. In addition to truncal gangrene, patients who have associated bacteremia and intravascular hemolysis have the greatest likelihood of progressing to shock and death. In one study, of those patients who developed shock at some point in their hospitalization, 40% died, compared with 20% mortality in the group as a whole.[35] In another study, those who were in shock at the time of diagnosis had the highest mortality.[54]

Spontaneous, non-traumatic gas gangrene due to *Clostridium septicum*

Pathogenesis

Predisposing factors include:[54] [55] [56]

- colonic carcinoma,
- diverticulitis,
- gastrointestinal surgery,
- leukemia,
- lymphoproliferative disorders,
- cancer chemotherapy,
- radiation therapy, and
- AIDS.

Cyclic or other forms of neutropenia are also associated with spontaneous gas gangrene due to *C. septicum* and in such cases necrotizing enterocolitis, cecitis or distal ileitis are commonly found. These gastrointestinal pathologies permit bacterial access to the bloodstream; consequently, the aerotolerant *C. septicum* can become established in normal tissues. [1]

Clostridium septicum produces four toxins:

- a-toxin (lethal, hemolytic, necrotizing activity),
- ß-toxin (deoxyribonuclease),
- ?-toxin (hyaluronidase), and
- ?-toxin (septicolysin, an oxygen labile hemolysin).

Clostridium septicum also produces a protease and a neuraminidase.[1]

The *C. septicum* a-toxin does not possess phospholipase activity and is thus distinct from the a-toxin of *C. perfringens*. Active immunization against a-toxin significantly protects against challenge with viable *C. septicum*. [57] The mechanism by which a-toxin contributes to *C. septicum* pathogenesis is unknown; however, the recent

cloning and sequencing of this toxin should facilitate studies in this area (see Chapter 232).

Figure 10-11 Spontaneous necrotizing fasciitis due to *Clostridium septicum.* This patient developed the sudden onset of severe pain in the forearm. Swelling rapidly ensued and he sought medical treatment. Crepitus was present on physical examination and gas in the soft tissue was verified with routine radiographs. Immediate surgical debridement revealed necrotizing fasciitis but sparing of the muscle. Note the purple-violaceous appearance of the skin. See also Figure 10.12 .

Clinical features

The onset of disease is abrupt, often with excruciating pain, although the patient may sense only heaviness or numbness.[1] [27] [54] [55] [56] The first symptom may be confusion or malaise. Extremely rapid progression of gangrene follows. Swelling advances and bullae appear; these are filled with clear, cloudy, hemorrhagic or purplish fluid. The skin around such bullae also has a purple hue (Fig. 10.11), perhaps reflecting vascular compromise resulting from bacterial toxins diffusing into surrounding tissues.[54] Histopathology of muscle and connective tissues includes cell lysis and gas formation; inflammatory cells are notably absent.[54]

Diagnosis

Unlike the situation in traumatic gas gangrene, bacteremia precedes cutaneous manifestations by several hours. In the absence of the usual cutaneous manifestations of gas gangrene, other causes of fever and extremity pain such as deep vein thrombophlebitis or cellulitis are naturally considered first, delaying appropriate diagnosis and treatment and as a consequence, increasing mortality.

Management

No comparative human trials have evaluated the efficacy of antibiotics or HBO for treating clinical cases of spontaneous gas gangrene. In-vitro data indicate that *C. septicum* is uniformly susceptible to penicillin, tetracycline, erythromycin, clindamycin, chloramphenicol and metronidazole. The aerotolerance of *C. septicum* may reduce the likelihood that HBO therapy would be effective.[52]

Prognosis

The mortality of spontaneous clinical gangrene ranges from 67% to 100%, with the majority of deaths occurring within 24 hours of onset. Unfavorable factors include underlying malignancy and compromised immune status. All patients who survive bacteremia or spontaneous gangrene caused by *C. septicum* should have appropriate diagnostic studies of the gastrointestinal tract (Fig. 10.12). Occasionally, this has led to detection and cure of an unsuspected malignancy that might otherwise have been fatal.[54]

Clostridium sordellii infections

Patients who have *C. sordellii* infection present with unique clinical features including edema, absence of fever, leukemoid reaction, hemoconcentration

Figure 10-12 Colonic carcinoma in a patient who has spontaneous gas gangrene caused by *Clostridium septicum.* The patient described in Figure 10.11 was found to have a mass in the colon. Surgical resection revealed an adenocarcinoma, which probably served as a portal of entry for the *Clostridium septicum* bacillus. Hematogenous seeding of the forearm resulted in spontaneous gas gangrene.

and later shock and multiple organ failure.[43] Often *C. sordellii* infections develop after childbirth or after gynecologic procedures[58] and most represent endometrial infection. Rarely, other cases have occurred at sites of minor trauma such as lacerations of the soft tissues of an extremity. Recently, outbreaks of *C. sordellii* and *C. novyi* infections have been described among intravenous drug users in Scotland, Ireland and England. Patients have presented with severe soft tissue infections with shock with a case fatality rate of 20–30%.[3] Unlike *C. perfringens* and *C. septicum* infections, pain may not be a prominent feature of *C. sordellii* infections. The absence of fever and the paucity of signs and symptoms of local infection make early diagnosis difficult.[43] The mechanisms of diffuse capillary leak, massive edema and hemoconcentration are not well established but clearly are related to elaboration of a potent toxin or toxins. Hematocrits of 75–80% have been described and leukocytosis of 50,000–100,000 cells/mm^3 with a left shift is common.[41] [58]

Clostridium tertium infections

Clostridium tertium has been associated with spontaneous myonecrosis; however, it more commonly causes bacteremia in compromised hosts who have received long courses of antibiotics. Bacteremia probably arises from bowel sources, and the presence of the organism in the bowel may be partly related to its relative resistance to penicillin, cephalosporins and clindamycin. *Clostridium tertium* is, however, usually quite sensitive to chloramphenicol, vancomycin and metronidazole. Because this organism can grow aerobically, it may be mistakenly disregarded as a contaminant such as a diphtheroid or a *Bacillus* sp.[42] [43]

Pyomyositis

Most cases of pyomyositis occur in tropical areas. Local trauma is a common predisposing factor. Initially, seeding of traumatized muscle occurs and physical findings are not usually helpful. Within 10–20 days, fever, chills, muscle pain and tenderness are manifest (see Fig. 10.1). Most patients seek medical care at this stage and a diagnosis can be established by appropriate imaging

Figure 10-13 MRI scan showing high signal STIR sequence (consistent with marked edema) in the adductor muscles of the patient's left leg in a patient with *Staphylococcus aureus* bacteremia (arrow). At operation, necrotic and infected muscle was decompressed and debrided. This represents the 'woody' stage, prior to muscle liquefaction and the formation of frank abscesses.

studies (Fig. 10.13), needle aspiration or exploration. Patients in whom a diagnosis has not been made may progress to shock and organ failure, though these complications are uncommon. *Staphylococcus aureus* is the most common cause of pyomyositis in tropical and non-tropical areas, and among HIV-positive patients. Hospitalized immunocompromised patients who are HIV negative occasionally develop pyomyositis caused by Gramnegative bacteria.

Surgical drainage of the abscess and empiric administration of parenteral antibiotics such as nafcillin or cephalosporins are reasonable treatments since most cases

are caused by *Staph. aureus*. Definitive treatment can then be established based on cultures and sensitivities. Due to an increase in the prevalence of methicillin-resistant *Staph. aureus*, it may be necessary to use vancomycin or linezolid empirically pending sensitivity results.[59]

Chapter 11 - Ectoparasites

Peter J Moss
Nick J Beeching

INTRODUCTION

Parasites depend on their hosts for sustenance; an ectoparasite is a parasite that lives or feeds on the surface of that host. Most ectoparasites of vertebrates are hematophagous, but a few feed on skin and tissue debris. Some spend their entire life on the host, others move from host to host as they develop and many simply alight on the host to feed. The definition of 'ectoparasite' is usually extended to include those parasites that burrow into the epidermis as well as those that remain on the surface.

Humans are the preferred or only host of some ectoparasites, but the majority are catholic in their choice or turn to humans only when their primary host is unavailable. Ectoparasites can cause local skin disease as a direct result of their bites, as a result of secondary infection or as a result of hypersensitivity reaction. They can cause systemic disease by inducing an allergic response or by toxin release and they can act as vectors for a large number of viral, bacterial and parasitic infections.

This chapter reviews the clinical syndromes caused by ectoparasites, outlining the key features associated with each family.

SKIN PROBLEMS

Transient ectoparasites

Clinical and pathologic features

The most common feature of ectoparasite infection is local reaction to the bite of a blood-feeding arthropod. Numerous species of insects and arachnids rely on blood meals from vertebrate hosts. Although the behavior and feeding methods differ by species, most uncomplicated arthropod bites produce a similar local reaction.

Initial contact in an unsensitized person may produce little or no response. After repeated bites typical raised pruritic lesions (papular urticaria) appear within 24–48 hours (Fig. 11.1), although delays of more than 1 week have been reported. Occasionally, these lesions are bullous. With further exposure and increased sensitization, an immediate weal skin response may be seen, followed after some hours by papular urticaria. Some hypersensitive people may develop a pronounced immediate reaction with large areas of superficial edema. After prolonged and frequent biting, the delayed reaction often diminishes and eventually there is no response to further bites. The term papular urticaria is also used to describe a condition (usually seen in children) in which widespread papular lesions occur distant from but temporally related to insect bites; this may represent reactivation of previously sensitized bite sites.

The lesions of papular urticaria consist of pruritic papules, often with a central puncture marking the site of the bite. Superficial erosion and ulceration resulting from scratching is common. Unlike most other types of urticaria, papular lesions may persist for several days, although this period tends to decrease with regular exposure. Histologically there is intense inflammatory infiltrate with a predominance of T cells; the response is thought to be a type 1 IgE-mediated reaction. [1] A variety of vasodilators, anticoagulants and other substances have been isolated from arthropod saliva; in some species a specific allergen has been identified as the cause of local hypersensitivity, but in others the stimulus remains obscure.

Treatment of uncomplicated bites is usually unnecessary, although severe pruritus may be relieved by systemic antihistamines. (Caution is needed with terfenadine and astemizole, which can cause prolongation of the cardiographic QT interval and have a synergistic cardiotoxic effect with certain antimalarial drugs.) Secondary bacterial infection is common in hot moist climates (Fig. 11.2) and this may require antibiotic therapy; infection is usually due to Gram-positive cocci. Local lesions caused by various blood-feeding arthropods are usually indistinguishable, and diagnosis of the precise cause relies either on epidemiologic knowledge or on detection and identification of the parasite. This may sometimes be necessary in order to eradicate the source of infection.

The major types of transient-feeding ectoparasites responsible for this type of bite are discussed below.

Flies

The most common cause of local reactions are biting flies of the order Diptera. Mosquitoes, blackflies, horseflies, sandflies and midges are ubiquitous, whereas tsetse flies are essentially tropical. Only certain species of each family tend to attack humans, and in all except the tsetse fly only the females are blood feeders. Culicid mosquitoes usually feed by inserting their proboscis directly into the capillary, whereas other species feed by inflicting local tissue damage and sucking the resultant blood (pool feeding). This may explain the relatively more severe irritation that complicates bites by some species, although host factors also play a significant part.

Fleas

Fleas occur worldwide and are a common cause of pruritic bites in humans. They are free living, only approaching their host in order to feed. The human flea, *Pulex irritans*, is found mainly in crowded and unhygienic living conditions and is relatively uncommon in the developed world. However, many species of animal and bird fleas will also feed on humans, and household infestations with cat and dog fleas (*Ctenocephalides felis* and *C. canis*) are increasing in frequency.

Flea bites provoke typical papular urticaria, although there may be a more severe reaction with bulla formation. The distribution of the lesions reflects the source of the infestation; for example, bites on the lower leg are usually due to cat and dog fleas, at least in adults. Diagnosis can be difficult; fleas are rarely seen on the human victim and excoriation may mask the original nature of the lesions. If flea bites are suspected, careful inspection of the home environment is needed, although other sources of exposure (e.g. school, the workplace) should be considered. Household pets and their bedding should be checked thoroughly for fleas and droppings. Flea bites need no specific treatment unless there is secondary infection. Prevention depends on identifying the source of the infestation; in

Figure 11-1 Typical lesions of papular urticaria, caused in this case by bedbug bites.

Figure 11-2 Mosquito bites with secondary staphylococcal and streptococcal infection.

the case of pets, insecticides must be applied to both the animal and its environment.

Tungiasis, caused by the flea *Tunga penetrans*, is described in Chapter 155 .

Bugs

Many members of the order Hemiptera (bugs) are blood feeders, but only two families include significant ectoparasites of humans. The Reduviidae cause relatively little local irritation, although hypersensitivity can develop with prolonged exposure; they are important principally as vectors of South American trypanosomiasis (see Chapter 173). Cimicidae (bedbugs) are voracious feeders and cause intense reactions. Bedbugs live and reproduce in crevices in walls and furniture, only approaching the host to feed (usually at night). They are found worldwide, the tropical bedbug (*Cimex hemipterus*) parasitizing humans in hot climates and the common bedbug (*C. lectularius*) in other areas. Bites cause papular lesions similar to those of other arthropods, but in unhygienic conditions infestations can be very heavy and secondary iron deficiency anemia has been reported. Personal insect repellants and permethrin-impregnated bed nets provide some protection, but decontamination of the environment with residual insecticides may be necessary.

Ticks

Ticks are cosmopolitan ectoparasites of mammals, birds and reptiles. All stages of tick (larva, one or more nymphal instars and adults)

Figure 11-3 Ixodid tick after feeding on the host for several days.

Figure 11-4 Tick-bite eschar associated with African tick typhus.

attach to vertebrate hosts to feed; some species spend their entire life cycle on a single animal (one-host ticks), while others drop off before moulting and then seek out a new host (multihost ticks). Although ticks are relatively host specific, most will attack humans in the appropriate circumstances. Worldwide, hard ticks (family Ixodidae) are the more important parasites of humans, but soft ticks (family Argasidae) can cause similar problems.

Most adult and immature ixodid ticks remain attached to the host for several days unless removed; argasid ticks feed more rapidly and may detach themselves after a few hours. The bite is often not irritating and passes unnoticed, especially in the early stages of attachment, which is an important factor in the role of the tick as a vector. Larval ticks are very small (<1mm in length) and are easily missed. In some cases, however (presumably when the host has been presensitized), tick bites can cause itchy papular lesions with evidence of a type 1 hypersensitivity reaction. Elevated levels of specific IgE against tick saliva can be demonstrated in such people.[2] Local skin reactions may occur when tick attachment is prolonged (Fig. 11.3). Hypersensitive people may experience more generalized urticarial skin reactions and even systemic features of anaphylaxis (see below).

A characteristic necrotic lesion may be seen when the tick bite is associated with the transmission of certain rickettsial infections — the so-called eschar or *tâche noire* (Fig. 11.4 ; see Chapter 235).

Avoidance and management of tick bites

Ticks usually prefer certain specific types of vegetation and most species are more commonly found during the spring and summer. In adults, ticks are generally found on the lower body, while children are often bitten on the head, neck and axillae. Some species of tick also have preferential sites of attachment. A knowledge of

the epidemiology of local tick species, as well as the wearing of long trousers and the use of permethrin-impregnated clothing, can decrease the incidence of tick bites and their complications.

Most ectoparasite vectors of infection feed rapidly, and length of time on the host probably does not influence the likelihood of infection. Ixodid ticks, by contrast, can spend many days feeding and the risk of transmission of some infections appears to be directly related to the duration of the bite. Tick paralysis is also dependent on prolonged feeding and both infectious agents and toxins may be inoculated into the host by careless removal, which can also leave the barbed mouthparts embedded in the skin. As well as predisposing to bacterial infection this can also generate a chronic granulomatous response; in some cases local surgical excision is needed to relieve the symptoms. Early detection and appropriate detachment of ticks is therefore essential, especially in regions where tick-borne diseases are endemic. The ideal method of removal is to grasp the tick mouthparts as close to the skin as possible with fine forceps or tweezers and gently lever the creature off. The body should not be squeezed, in order to prevent further inoculation. Any retained fragments should not be dug out, but the site cleaned and antiseptic applied. This method of removal is associated with a significantly lower incidence of rickettsial and borrelial infection following tick bites.[3] [4]

In the particular case of Lyme disease, early antibiotic therapy after infection with *Borrelia burgdorferi* may provide some protection against the development of disease. Tick bites are very common, and even in areas where the majority of vector species are infected the rate of human infection is very low.[4] Routine antibiotic prophylaxis following tick bites is not justified even in these areas. However, risk of infection rises dramatically once the tick has been feeding for more than 72 hours (from about 3% at <72 hours to 18–25% at >72 hours).[5] The approximate duration of attachment of the tick can be estimated from an index of tick engorgment (the scutal index), and antibiotics may be justified in cases where the tick had been feeding for more than 72 hours. Other attempts at predicting high-risk groups following tick bites (e.g. by testing the tick for *B. burgdorferi* infection) have not proved successful.[5] There is no evidence that empiric antibiotic prophylaxis following tick bites has a role in the prevention of rickettsial infections such as Rocky Mountain spotted fever.[6]

Mites

The majority of mites that parasitize humans are not blood feeders, but feed on tissue fluids and cell debris. However, the effect of their bites is similar to those of other transient feeders.

Trombiculid mites ('chiggers') are found worldwide. The adult and nymphal stages are free-living predators, but the larvae parasitize many animals, including humans. The mites inhabit areas of transitional vegetation (hence the alternative name of 'scrub mite'), often forming localized 'mite islands' in areas inhabited by a host species. Larval mites climb on to a human host who is passing through the vegetation and crawl over the host's body to find a suitable area of skin to bite, such as the axillae or groins or areas of skin that are constricted by clothing. They feed for several days if undisturbed and then drop to the ground. The resulting lesions are similar to those

caused by tick bites; the methods of prevention are similar.

Pyemotid mites are primarily predators of insects and their larvae, but they bite humans that come into contact with the grain or straw in which the mites live. The resulting papular urticarial rash, usually found on exposed surfaces or areas of thinner skin, goes under a number of occupational names, including 'straw itch', 'barley itch' and 'grain-shoveler's itch'.[7]

Cheyletiellid mites are ubiquitous tissue-feeding parasites of domestic dogs and cats. Bites follow close contact with infected animals and lesions are usually seen on the thighs and abdomen after a pet has sat on someone's lap. Itchy papules similar to other arthropod bites result and the diagnosis is made by finding mites on the animal. Some hematophagous animal mites also attack humans, causing typical lesions in areas that depend on the form of contact with the animal. Poultry, cage birds, wild and domestic rodents and snakes have all been incriminated. [7] In all these cases management is by removal or treatment of the principal animal host, with environmental acaricide if necessary.

Scabies and other resident mites are described below.

Infestations of resident hematophagous parasites

Head and body lice

Epidemiology

Head lice (*Pediculus humanus capitis*) and body lice (*Pediculus humanus corporis*) are morphologically almost indistinguishable from each other, but they each tend to keep within their own territory on the host. The latter species clings to and deposits eggs on clothing fibers rather than hair shafts. It parasitizes those who do not change or wash clothing, unlike the head louse, which is not associated with poor hygiene alone. Children are more commonly infected with head lice than adults and women are more frequently infected than men (at least in Western cultures). This is because the vast majority of infections are acquired by direct head-to-head contact, which is more likely in these groups. Overcrowding is also an important risk factor, but hair length is not. Head lice are more common in late summer, which probably reflects the need for high ambient temperature to hatch eggs. The role of fomites in transmission is controversial; there is little evidence that hats and brushes are important.

Clinical features

The main feature of head louse infestation is scalp itching, although secondary bacterial infection is not uncommon, and louse infection should be looked for in cases of scalp impetigo. Chronic infection can produce cervical lymphadenopathy. The diagnosis is made by finding empty egg-cases ('nits') stuck to the base of hair follicles; the highest concentration is usually in the occipital and parietal regions. In heavy infestations, developing eggs, nymphs and adult lice may be seen.

Management

The efficacy of traditional wet combing remains unproven and although some experts recommend dry combing, both methods are very time consuming and require good technique to be of any benefit.[8] Several insecticides are available for the treatment of head lice (Table 11.1).[9] The acetylcholinesterase inhibitors malathion and carbaryl both have reasonable ovicidal and pediculicidal activity, although some resistance has been seen. Malathion, unlike carbaryl, has a residual action of several weeks, but two applications 10 days apart are necessary whichever agent is used. The synthetic pyrethroids, such as permethrin, also have good activity, although there are concerns about the rapid development of resistance to these compounds. Topical ivermectin has also been used with good effect, although there is little evidence to suggest that it is preferable to other agents.

Malathion and carbaryl need to remain on the scalp for 8–12 hours before they are washed off and they are degraded by high temperatures (e.g. as occurs during the use of a hair dryer). Pyrethroids need only a short application. Lotion or mousse preparations are generally preferable to shampoos. Although there are numerous trials comparing different drugs and preparations, it is very difficult to draw general conclusions.[10] Resistance patterns vary from region to region and there are many different formulations and preparations of drugs available. If possible, the choice of therapy should be based on a local policy designed to take into account existing resistance patterns and to prevent the development of resistance.

TABLE 11-1 -- Commonly used topical preparations for the treatment of ectoparasite infestations.

COMMONLY USED TOPICAL PREPARATIONS FOR THE TREATMENT OF ECTOPARASITE INFESTATIONS				
Class	**Agent**	**Uses**	**Toxicity**	**Comments**
Acetylcholinesterase inhibitors	Malathion	Scabies		Good residual protection
		Head lice		Recommended for public lice infestation of eyelashes; safe in pregnancy
		Public lice		
	Carbaryl	Head lice	Carcinogenic in animals; minimal risk to humans in therapeutic doses	Prescription only in the UK
		Pubic lice		
Organochlorines	Lindane	Head lice	Neurotoxic (potential for systemic absorption)	Increasing resistance; no longer available in the UK
		Public lice		
Natural pyrethroids	Pyrethrin	Head lice		Less evidence of efficacy than synthetic pyrethroids
	Phenothrin	Public lice		
Synthetic pyrethroids	Permethrin	Scabies	Rarely rash and local edema	Probably safe in pregnancy and breast-feeding (limited data)
		Head lice		
		Public lice		
Others	Benzyl benzoate	Scabies	Skin irritation	Limited safety data in pregnancy; avoid in breast-feeding
	Ivermectin	Head lice		Available for topical and systemic use
		Scabies		
	Crotamiton	Head lice		Relatively poor efficacy
		Scabies		Avoid in pregnancy
	Mercury preparations	Head lice	Contact dermatitis	Available over the counter in some European countries
			Systemic toxicity	
	Monosulfiram	Scabies	'Antabuse' effect (alcohol should be avoided)	No longer available in the UK
	Sulfur ointment	Scabies	Skin irritation	Cheap, safe, reasonably effective

Systemic therapy has occasionally been used to treat head lice. Trimethoprim-sulfamethoxazole and ivermectin have been reported to be effective, although repeated doses are necessary because they affect only the feeding stages of the parasite. In most cases topical treatment should be adequate. Older drugs, such as organochlorines and mercury-based preparations, are less effective and more toxic.

Body lice are associated with poor hygiene and unwashed clothing and are principally parasites of vagrants and refugees. They can be found worldwide, but they are particularly found in cooler climates where clothing is rarely removed. Transmission is by direct body-to-body spread or by sharing infected clothing. Initially the bites are similar to those of other hematophagous ectoparasites, but the prolonged and persistent nature of the infestation leads to widespread excoriation and secondary infection and eventually to the hyperpigmented chronic skin condition known as 'vagabond's disease' or morbus errorum.

The diagnosis is made by finding lice and eggs in the clothing (particularly along seams), and treatment should be directed at the clothing rather than the patient. High-temperature washing, tumble-drying and malathion dusting powder are all effective at clearing garments of lice; permethrin-treated clothing may be protective for those at risk of infestation.

Pubic lice

Pthirus pubis (often written as *Phthirus pubis*) is morphologically different from *Pediculus humanus* and is unique to humans. Infection is usually confined to the pubic region, although lice and eggs are sometimes found in axillary and facial hair, eyelashes, eyebrows and (especially in children) the scalp. Infection is transmitted by close, usually sexual, contact and may be associated with other sexually transmitted diseases.

The main symptom is itching of the affected area, especially at night, although there may be few visible skin lesions. Close inspection may reveal eggs that are attached to the hair shafts, with adult lice clinging on close to the skin. Treatment is with the same insecticides as for head lice, with the proviso that alcohol-based preparations may irritate sensitive skin and mucous membranes. This is particularly true for the eyes, and eyelash infestations should always be treated with an aqueous formulation. It is usually advisable to treat the whole trunk and limbs in view of the possible spread to other hairy areas; where appropriate, sexual contacts should also be treated.

Other ectoparasite infestations

Scabies

Clinical features

Some infesting arthropod ectoparasites do not feed on blood at all, but cause disease in other ways. The most important of these is *Sarcoptes scabei*, the human scabies mite, which is found worldwide in conditions of poor hygiene. This skin-burrowing mite is not a blood feeder, but ingests predigested dermal cells as it tunnels through the epithelium. Female mites live in small burrows in the skin, which they extend by 2–3mm daily, leaving a trail of eggs and feces behind them. The burrows are intensely itchy and are responsible for the features of scabies. They are usually found around the wrists, web spaces, toes and genitalia, although they may be more widespread; small papules are sometimes seen at the distal end adjacent to the female mite. Infestations are relatively light, with an average of 12 adult females found on an infected patient. Crusted scabies, in which there is heavy mite infestation and gross hyperkeratosis, may be seen in immunocompromised and institutionalized patients.

Management

Diagnosis based on history and clinical features alone can be difficult and should be confirmed whenever possible by identification of mites. This is usually done by extracting parasites with a needle or in skin scrapings, but these techniques require operator experience and visible burrows. Newer methods of diagnosis include high-magnification videodermatoscopy, epiluminescence microscopy and polymerase chain reaction but none of these is widely available. Treatment should be given if scabies is suspected, even if the diagnosis cannot be confirmed.

Scabies is usually treated with topical acaricides (see Table 11.1). Comparative trials suggest that 5% permethrin is the most effective treatment, with 0.5% malathion the second choice; permethrin is considerably more expensive.[11] Oral ivermectin has been increasingly used in recent years, especially in crusted or recurrent infections. It is well tolerated and appears to be highly effective, although a second dose may be needed one week after the first. Although unlicenced, oral ivermectin is probably the treatment of choice in recurrent cases, institutional outbreaks and crusted scabies; combining systemic treatment with a topical preparation may give the best results in hyperkeratotic disease.[12] [13] Crusted scabies is highly contagious, and bedding and clothing should be boil-washed or treated.

Pseudoscabies

Sarcoptid mites are relatively host specific and mites acquired from animals do not usually cause prolonged infestations of humans. However, people in close contact with infected livestock (notably pigs, cows and dogs) may acquire temporary infestation, causing pruritic lesions but lacking the typical burrows of human scabies. In most cases no treatment is required except for avoidance of the source of infection.

Demodicidosis

Demodex folliculorum, the follicle mite, is a human ectoparasite that lives in the pilosebaceous follicles, where it feeds on cell contents. The mites are found in areas of high sebum production; the forehead, cheeks, nose and nasolabial folds. The role of follicle mites in skin disease is controversial; they are very common and unless they are present in large numbers do not appear to cause problems. However, they have been described as a cause of papulopustular eruptions in children and immunocompromised subjects, and they have been implicated in the pathogenesis of other skin conditions such as pityriasis folliculorum and rosacea.[14]

Storage mites

The so-called storage mites include a number of mite species that live in stored products (e.g. flour, grain, straw, dried meat, dried fruit and cheese). When a person handles infested stock, mites crawl onto exposed areas and migrate under the horny layer of the skin. Here they can cause an acute dermatitis, with erythema and small papulovesicles, which is known by a number of occupational names, for example 'grocer's itch', 'baker's itch' and 'copra itch'.[7] It is uncertain whether the mites actually feed on skin cells, so they may not be true ectoparasites of humans.

Skin lesions due to myiatic larvae

These parasites are covered in Chapter 155 .

NONINFECTIVE SYSTEMIC PROBLEMS

Tick paralysis/toxicosis

Epidemiology

Paralysis and death of domestic animals and occasionally humans following tick bites has been documented in Australia and South Africa since the end of the 19th century and more recently it has been observed in North America and Europe. This syndrome is not, as once thought, an infective process, but is caused by a toxin in the saliva of the pregnant females of certain ixodid species. Children are more often affected than adults and the condition is most commonly seen in spring and early summer.

Clinical features

Tick paralysis almost always results from bites on the head, typically behind the ear where the tick may not be noticed. Symptoms appear only after the tick has been feeding for at least 48 hours. The usual presentation is an ascending flaccid paralysis, frequently with cranial nerve involvement, although atypical features such as isolated nerve lesions and cerebellar signs are occasionally seen. There is no sensory loss or decrease in consciousness, but if the condition is untreated death from respiratory failure can supervene. In the North American form the paralysis starts to improve within a few hours of removing the tick, but in the Australian form of the disease deterioration may continue for a further 24–48 hours.[15]

Management

The neurotoxin involved probably varies between different tick species. It has not been fully characterized, but there are many clinical and neurophysiologic similarities to the effects of botulinum toxin.[15] The essential treatment is to remove the tick carefully to prevent further transfer of toxin, followed by supportive care until the neurologic signs resolve. Although rare, the diagnosis should be considered in any progressive flaccid paralysis in an endemic area.

Tick anaphylaxis

The local allergic urticarial reactions to tick bites have already been discussed. Rarely, in hypersensitive people, anaphylaxis can follow a bite, with bronchospasm, edema and hypotension. This is an IgE-mediated response to tick salivary antigens, which can occur soon after the tick first bites or following careless removal.[16] Treatment is as for any form of anaphylactic reaction and sensitive people in tick-infested areas may benefit from carrying epinephrine (adrenaline) for inhalation or self-injection.

Mite allergy

House dust mites (*Dermatophagoides* spp.) are cosmopolitan, free-living mites that feed principally on animal and human skin detritus. Although they are sometimes found on the skin surface they usually consume skin that has already been shed and are thus not true parasites. Their main medical importance is as a cause of allergic rhinitis and bronchial constriction.

ECTOPARASITES AS VECTORS OF INFECTION

The principal importance of many human ectoparasites is their potential for transmitting a wide variety of viral, bacterial and protozoal infections. Table 11.2 lists the major vector-borne human infections (see also Chapter 155).

Bedbugs do not appear in the table; their role as potential vectors of infection remains controversial. Viable infective hepatitis B virus and other pathogens have been found in the gut of bedbugs weeks after their last blood meal. However, community-based studies have failed to confirm that bedbugs have a significant role in hepatitis B transmission[17] and attempts at transmitting infection among a group of chimpanzees using bedbugs were unsuccessful when the bugs fed normally.[18] Although HIV has been isolated from bedbugs up to 8 days after feeding on heavily infected blood under experimental conditions, there is no evidence to suggest transmission to humans by this route.[19]

TABLE 11-2 -- Important ectoparasite vectors of human disease.

IMPORTANT ECTOPARASITE VECTORS OF HUMAN DISEASE				
Ectoparasite	**Vector**	**Infective organism**	**Disease**	**Distribution**
Flies (Diptera)				
Mosquitoes	*Anopheles* spp.	*Plasmodium* spp.	Malaria	Tropics and subtropics
	Anopheles spp. *Culex* spp. *Aedes* spp.	*Wuchereria bancrofti*	Lymphatic filariasis	Tropics
	Anopheles spp. *Mansonia* spp. *Aedes* spp.	*Brugia* spp.	Lymphatic filariasis	Southern Asia
	Aedes spp. *Culex* spp. *Anopheles* spp.	Arboviruses	Dengue, yellow fever Japanese encephalitis, West Nile virus St Louis encephalitis	Specific to each disease
Blackflies (Simuliidae)		*Onchocerca volvulus*	Onchocerciasis	Sub-Saharan Africa, Central and South America
		Mansonella ozzardi	Mansonelliasis	Amazon basin
Sandflies		*Leishmania* spp.	Visceral and cutaneous leishmaniasis	Sub-Saharan Africa, Asia and Mediterranean Europe
	Phlebotomus spp.	Bunyaviridae	Sandfly fever	Central Asia, Mediterranean and North Africa
		Leishmania spp.	Visceral and cutaneous leishmaniasis	Central and South America
	Lutzomyia spp.	*Bartonella bacilliformis*	Bartonellosis (Oroya fever, Carrion's disease, verruga peruana)	South America
Midges	*Culicoides* spp.	*Mansonella perstans*	Mansonelliasis	Sub-Saharan Africa
		Mansonella ozzardi	Mansonelliasis	Amazon basin
Tsetse flies (Glossinidae)		*Trypanosoma* spp.	African trypanosomiasis	Sub-Saharan Africa
Deer flies (*Chrysops* spp.)		*Loa loa*	Loiasis	West Africa
		Francisella tularensis	Tularemia	Western USA
Fleas (Siphonaptera)	Various species	*Yersinia pestis*	Plague	Worldwide (patchy)
	Various species	*Rickettsia mooseri*	Murine typhus	Worldwide (patchy)
Bugs (Hemiptera)	Reduviidae	*Trypanosoma cruzi*	South American trypanosomiasis	Central and South America

Lice	Body louse (*Pediculus humanus corporis*)	*Rickettsia prowazeki*	Epidemic typhus	Worldwide (patchy)
		Bartonella quintana	Trench fever	Worldwide
	Body louse (*Pediculus humanus corporis*) and head louse (*Pediculus humanus capitis*)	*Borrelia recurrentis*	Louse-borne relapsing fever	Worldwide (patchy)
Ticks				
Ixodidae	Numerous hard tick (ixodid) species	*Rickettsia* spp.	Tick typhus and various rickettsial spotted fevers	Worldwide
		Borrelia burgdorferi	Lyme disease	USA, Europe, Eastern Asia, Australia
		Francisella tularensis	Tularemia	USA, Europe, Japan
		Babesia spp.	Babesiosis	USA, Europe
		Arboviruses	Tick-borne encephalitis, Congo-Crimea hemorrhagic fever and other arbovirus infections	
		Ehrlichia spp.	Ehrlichiosis	USA, Europe, North Africa, Eastern Asia
Argasidae	*Ornithodoros* spp.	*Borrellia* spp.	Tick-borne relapsing fever	Africa, Central Asia, North and South America
Mites	*Leptotrombidium* spp.	*Rickettsia tsutsugamushi*	Scrub typhus	South East Asia, Pacific and (rarely) West Africa
	Liponyssoides sanguineus	*Rickettsia akari*	Rickettsialpox	USA, South Africa, Eastern Asia

Chapter 12 - Dermatologic Manifestations of Systemic Infections

Anthony C Chu
Edward D Seaton

INTRODUCTION

The skin is the largest and most visible organ of the body. In addition to its role as a barrier separating the body from the external environment and its role in temperature regulation, the skin has a complex immune system that recognizes and attacks foreign antigens and microbes, but that also reacts to systemic disease to give characteristic clinical changes.

The skin may be affected by systemic infections in three ways:

- by direct involvement by the infectious agent,
- by specific reaction to an infection, and
- by non-specific reaction to an infection.

In addition, there are a number of inflammatory dermatoses that can mimic skin infections.

DIRECT INVOLVEMENT OF THE SKIN BY AN INFECTIOUS AGENT DURING A SYSTEMIC INFECTION

Viral infections

Chickenpox

Viral infection of the skin as part of a systemic infection is well demonstrated by chickenpox (see Chapter 8). After an incubation period of 14–21 days the patient develops 1–2 days of fever and malaise. This is followed by crops of unilocular vesicles, which quickly become pustular, appearing over 2–4 days (see Chapter 8). After the acute infection the virus persists in dorsal root nerve ganglion cells and on reactivation of the residual latent virus, herpes zoster or shingles develops.

Hand, foot and mouth disease

Hand, foot and mouth disease is caused by Coxsackie viruses A16, A5 and A10, and enterovirus 71[1] (see Chapter 8 and Chapter 213). It occurs predominantly in children. After an incubation period of 5–7 days the patient develops painful stomatitis with oral vesicles that ulcerate. A more variable feature is that of small, thin-walled vesicles on the fingers and toes (see Chapter 8 , Fig. 8.12). An uncommon feature is onychomadesis[2] due to nail matrix arrest leading to nail shedding from the proximal portion. Disease related to Coxsackie virus infection is generally mild and self-limiting. Cardiac and pulmonary involvement with enterovirus 71 hand, foot and mouth disease is associated with high mortality. Viral particles can be identified in the vesicles on electron microscopy.

Bacterial infections

Gonococcal infection

In disseminated gonococcal infection caused by *Neisseria gonorrhoeae*, characteristic skin lesions (called septic gonococcal dermatitis) may be observed. One or more crops of three or four macules or papules develop often over the extremities; these then become pustular or bullous. Gonococci can occasionally be cultured from the skin lesions.

Tuberculosis

In tuberculosis, skin involvement may occur as the result of contiguous involvement of the skin from underlying lymph nodes, joints or bones, a condition called scrofuloderma.[3] A bluish-red nodule develops over the affected bone, joint (Fig. 12.1) or lymph node and multiple fistulae develop. Diagnosis must be confirmed by biopsy, which shows tuberculous granulation tissue. *Mycobacterium tuberculosis* can often be isolated from involved tissue.

Skin involvement in tuberculosis may also occur secondary to hematogenous dissemination. In miliary tuberculosis, hematogenous dissemination can produce severe systemic symptoms and profuse crops of bluish papules, which become vesicular and then pustular. These often become necrotic, leading to ulceration of the skin.

Chronic hematogenous dissemination of tubercle bacilli in patients who have moderate or high degrees of immunity may present as one of the tuberculides:

- papulonecrotic tuberculid, in which there are symmetric crops of necrotic papules predominantly affecting the extremities;
- lichen scrofulosum, in which minute lichenoid papules appear predominantly on the limbs rather than on the trunk; and
- erythema induratum (or Bazin's disease), in which persistent or recurrent nodular lesions appear in the calves of the legs and may lead to ulceration (Fig. 12.2); these nodular areas are very well defined and are generally asymptomatic. [4]

The tuberculides respond rapidly to antituberculous therapy (see Chapter 202).

Spirochetal infections

Disease caused by spirochetes tends to affect the skin as part of the primary manifestation, but it may also involve the skin during subsequent, disseminated disease.

Syphilis

In syphilis, the primary lesion or primary chancre is often cutaneous or mucosal. Secondary syphilis starts approximately 3 months after the primary infection and gives rise to non-irritating, coppery red symmetric lesions, which start as macules and become papular (see Chapter 75 , Fig. 75.5). Secondary syphilis is the 'great pretender'[5] and lesions of secondary syphilis can mimic acne, psoriasis and a number of other non-specific dermatoses. Characteristically, the palms and soles are affected. When mucosal surfaces are involved, 'snail track' ulcers may develop. Later, condylomata may occur perianally and on the vulva or penis. Patchy hair loss is a characteristic sign of secondary syphilis, giving rise to a moth-eaten appearance of the scalp.

Late or tertiary syphilis occurs after a latent period of up to 20 years. Both skin and mucous membranes may be affected. Nodular syphilides present as nodular subcutaneous lesions appearing in groups and tending to develop a circinate arrangement. These are more common on the extensor surfaces of the arms, the back and the face (Fig. 12.3), but they may occur in the oral cavity. Gummas are masses of syphilitic granulomatous tissue; they may originate in the subcutis, underlying bone or muscle. These masses ulcerate to produce punched-out ulcers.

Figure 12-1 Scrofuloderma in a 60-year-old patient. A biopsy confirmed tuberculoid granulation tissue and the patient responded very well to antituberculous therapy.

Figure 12-2 Erythema induratum on the back of the leg of a 45-year-old woman.

Yaws

Yaws is a disease caused by the spirochete *Treponema pertenue*. The primary lesion of yaws produces a cutaneous erythematous papule, which becomes papillomatous and resembles a raspberry, giving rise to its name, 'frambesia'. After 2–4 months the secondary eruption of yaws occurs, with multiple small papules developing into exudative papillomas (Fig. 12.4). Mucosal involvement does not occur in yaws. After 6 months to 3 years tertiary yaws occurs; this is characterized by ulcerated nodular and tuberous cutaneous lesions and keratoderma of the palms and soles.

Pinta

Pinta is caused by the spirochete *Treponema carateum*. The initial eruption starts in the skin as multiple erythematous papules and plaques. This is followed after months or years by generalized cutaneous lesions, where the skin becomes pale, pigmented or erythematosquamous. The late phase occurs 2–5 years after primary infection with irregular pigmentation, which can be grayish, steely or bluish in color. Areas of leukoderma, particularly around the elbows, knees, ankles and wrists, may develop. Hyperkeratosis occurs, particularly on the legs and arms, and is associated with areas of atrophy, particularly around the large joints (see Chapter 156 , Chapter 230).

Figure 12-3 Tertiary syphilis on the face of a 56-year-old woman.

Figure 12-4 Secondary yaws showing papular and rather vegetative lesions on the anterior chest wall.

Lyme disease

In infections with *Borrelia burgdorferi*, the primary lesion occurs at the site of the Ixodes tick bite, with a characteristic eruption: erythema chronicum migrans.[6] The macular erythema starts up to 36 days after the bite and slowly increases in size by several centimeters each week (see Fig. 54.3 , Chapter 54). Subsequent dissemination leads to Lyme disease with involvement of the nervous system, heart and joints. One year or longer after the original infection, a late cutaneous manifestation may occur: acrodermatitis chronica atrophicans (see Chapter 54).[7] As this name suggests, this typically affects the hands and feet, but the elbows and knees may also be affected. Erythematous plaques develop and these slowly enlarge and become atrophic. *Borrelia burgdorferi* can be cultured from skin biopsies in this condition although often with difficulty. Hence, diagnosis relies on clinical features and serologic testing.

Fungal infections

A number of deep fungal infections may have cutaneous involvement in the course of systemic disease. These fungal infections include blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis, paracoccidioidomycosis and disseminated candidiasis.

Cutaneous lesions in these deep fungal infections tend to be nonspecific, with papules, nodules and ulcers developing on different parts of the skin. In disseminated blastomycosis cutaneous lesions start as papules or nodules, which then ulcerate and evolve into serpiginous lesions with raised warty borders.

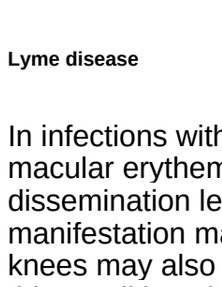

Figure 12-5 Cutaneous cryptococcosis in a renal transplant patient. These lesions started as nodules that then rapidly ulcerated. Computerized tomography of the patient's brain showed no abnormality but *Cryptococcus neoformans* was grown from the cerebrospinal fluid.

Disseminated coccidioidomycosis may result in cutaneous abscesses and granulomas and discharging sinuses. Disseminated cutaneous cryptococcosis is observed in patients on long-term immunosuppression. It presents as erythematous papules and nodules, which become exudative and eventually ulcerate (Fig. 12.5). Disseminated cutaneous cryptococcosis is seen most often in patients who have AIDS. The cutaneous lesions tend to be non-specific, but molluscum contagiosum-like lesions are a recognized feature of this disease. These typically occur around the nose and mouth and eventually ulcerate to leave punched-out, rolled edged ulcers.

SPECIFIC SKIN REACTIONS RESULTING FROM SYSTEMIC INFECTIONS

Systemic infections with viruses and bacteria can occasionally cause specific cutaneous reactions. These skin reactions can establish the diagnosis of the specific systemic infections and it is thus very important to recognize them.

Viruses

Roseola infantum and pityriasis rosea

Infection with human herpesvirus 6 in the first 3 years of life gives rise to a specific dermatitis: roseola infantum (exanthem subitum) (see Chapter 8). After an incubation period of 10–15 days, fever starts abruptly and lasts for 3–5 days.[8] As the fever subsides a maculopapular eruption, which is characteristically rose pink in color, develops on the neck and trunk. This later spreads to the arms, face and legs. The eruption subsides after 1–2 days, leaving no pigmentation or scaling of the skin. In common with other herpesviruses, human herpesvirus 6 is capable of establishing lifelong latent infection of its host.[9] Reactivation in the immunocompromised host is linked to various diseases, including encephalitis.

A similar eruption is observed in adults; this is called pityriasis rosea. There is generally no prodromal syndrome but patients develop a single erythematous macular lesion, which may reach several centimeters in diameter, most commonly on the trunk, thigh or upper arm. The macule has a characteristic collarette of fine scales. This herald patch is followed after 5–15 days by a widespread eruption of small erythematous, scaly macules, which typically form a Christmas-tree pattern on the trunk and eventually spread down the limbs, to subside after 6 weeks. Recent studies have implicated human herpesvirus 7 in pityriasis rosea[10] but these finding have been challenged by a number of studies that have failed to demonstrate an association between the disease and human herpesvirus 6 or 7.[11]

Figure 12-6 Kaposi's sarcoma in a 20-year-old man who had AIDS. One lesion on the patient's back had been treated with radiotherapy, resulting in disfiguring pigmentation at the site of treatment.

Cutaneous changes associated with HIV infection

Infection with HIV is associated with a number of cutaneous changes. Some of these are characteristic enough to alert the physician to the possibility of infection with HIV. Kaposi's sarcoma is seen in about 34% of patients who have AIDS. The great majority of these patients are homosexual or bisexual men in developed countries (see Chapter 130 and Chapter 132).

Kaposi's sarcoma is a multicentric endothelial cell neoplasm that often starts in the skin but may become disseminated to affect multiple organs.[12] It is associated with human herpesvirus 8 infection. Skin lesions range in color from red to purple-brown and may be macules, papules, nodules or plaques. Cutaneous Kaposi's sarcoma in those who have AIDS is often multiple and very disfiguring (Fig. 12.6).

Oral hairy leukoplakia presents as asymptomatic white plaques on the lateral borders of the tongue.[13] These may spread to involve the oral mucosa. Oral hairy leukoplakia is now considered to be due to a proliferation of Epstein-Barr virus within the epithelium of the tongue.

A common dermatosis in HIV-positive patients is a papulopruritic eruption or itchy folliculitis.[14] Small erythematous or skin-colored papules develop on the head, neck and trunk, and these are extremely pruritic. No infectious cause has been found for this and histologic examination shows only a non-specific perifollicular mixed cell infiltrate. This eruption does not respond well to topical corticosteroids, antihistamines or antimicrobials, but it may respond to ultraviolet light therapy.[15]

Another itchy papular eruption observed in HIV-positive patients is eosinophilic pustular folliculitis.[16] This condition starts as itchy erythematous papules on the head, neck, trunk and limbs and may develop into plaques with a papular or vesicular border. Histology shows an eosinophil-rich perifollicular infiltrate. No infectious cause has been found for this condition. As with the itchy folliculitis, topical therapies and antihistamines tend to be ineffective but the condition often responds well to ultraviolet light.

Bacillary angiomatosis presents as small angioma-like lesions affecting both the skin and the internal organs.[17] In the skin, lesions start as pin-point red papules, which then enlarge to become nodular. Although seen mainly in HIV-positive patients, bacillary angiomatosis has also been described in other immunodeficient patients and is now known to be caused by *Bartonella* spp (see Chapter 128 and Chapter 132 .

Bacterial infections

Specific bacterial infections may cause a variety of cutaneous syndromes as a result of toxin production.

Scarlet fever

Scarlet fever complicates acute infections by *Streptococcus pyogenes* strains that produce a pyrogenic exotoxin and *Staphylococcus aureus* strains that produce enterotoxins. Production of the exotoxin by *Strep. pyogenes* appears to depend on the presence of a temperate bacteriophage and is exclusive to the group A streptococci. Three antigenically distinct exotoxins can be produced: types A, B and C. Specific strains of *Strep. pyogenes* may produce one or more of these toxins.[18] After an incubation period of 2–5 days, fever develops with localized signs at the portal of entry (e.g. tonsillitis and lymphadenopathy or tenderness at a wound site).

The eruption of scarlet fever occurs on the second day of infection. It begins on the upper trunk with a punctuate erythema that becomes generalized over a few hours to 3–4 days. A characteristic sign is the development of transverse red streaks at the sites of skinfolds, owing to capillary damage; these are known as Pastia's lines. The face is erythematous but with a characteristic perioral pallor. After 7–10 days the eruption subsides with desquamation of the palms and soles.

Lyell's syndrome

Staphylococcal scalded skin syndrome, otherwise known as Lyell's syndrome, is caused by strains of *Staph. aureus* that produce a specific epidermolytic toxin. Phage group 2 staphylococci predominate, but other phage groups have been implicated.

The epidermolytic toxin cleaves the epidermis just below the granular cell layer, resulting in the typical scalded skin appearance. The eruption usually starts suddenly with erythema and tenderness of the skin. Flaccid blistering occurs, which often rubs off, leaving raw exudative areas. Staphylococci can usually be isolated from involved skin. This syndrome usually carries an excellent prognosis with resolution in 7–14 days.

The disease is one of infants and children. In the few reports of adults who have staphylococcal scaled skin syndrome there is generally an underlying medical problem, such as renal failure or immunosuppression, and it is thought that reduced clearance of the toxin by the kidneys in these patients may be important in the development of the disease.[19]

Toxic shock syndrome

The toxic shock syndrome is recognized as a complication of toxic shock toxin-1 production by selected strains of *Staph. aureus*. These have been incriminated in a variety of circumstances including tampon use, surgical or traumatic skin wounds and burns. Involvement of the skin, oral mucosa and conjunctiva is common. Dermatologic manifestations include diffuse erythema, punctate lesions, petechiae with subsequent desquamation and occasional nail loss.

Rheumatic fever

Group A ß-hemolytic streptococci are implicated in the pathogenesis of rheumatic fever. A specific (although now rare) cutaneous manifestation of rheumatic fever is erythema marginatum rheumaticum.[20] This consists of rings or arcs of pale or dull red erythema, which are either macular or slightly thickened. The rings make a discrete or enlarged polycyclic pattern. These rings characteristically fade over a few hours or days and appear in recurrent crops, usually at different sites, over many weeks.

Sepsis

Sepsis caused by a variety of different bacteria can cause disseminated intravascular coagulation. This results in hemorrhagic skin lesions, particularly of dependent

areas, followed by purpura and possibly ulceration of the skin. In acute meningococcal sepsis, 40–90% of patients develop these characteristic purpuric lesions, which are important diagnostic signs of this rapidly progressing infection.[21]

Henoch-Schönlein purpura

Henoch-Schönlein purpura has in the past been strongly associated with streptococcal infections but the link has become less impressive in recent years; other infectious agents, such as upper respiratory viruses, have been suggested. Henoch-Schönlein purpura has a characteristic appearance, with palpable purpuric papules developing on the lower legs and buttocks. This may be associated with arthritis, gastrointestinal syndromes and renal disease. Histologically, there is a leukocytoclastic vasculitis and characteristic deposition of IgA within the walls of affected blood vessels.[22]

Leprosy

Mycobacterium leprae affects the skin in all forms of leprosy. In tuberculoid leprosy the skin lesions tend to be few or solitary (see Chapter 154 , Fig. 154.2). They are often hypopigmented but they may have a rather indurated coppery color or a purple border. These patches tend to be hypoesthetic and dry with loss of hairs, and they show a negative histamine provocation test.

In lepromatous leprosy, multiple small macules, papules and nodules develop in a symmetric manner in all sites apart from the hairy scalp, the axillae and the groins, where the temperature tends to be higher. Patients often develop leonine facies because of diffuse involvement of the facial skin (Fig. 12.7). Borderline types of leprosy have clinical features between these extremes of immunologic reaction to the causative agent.

Three types of inflammatory reactions can occur during the course of leprosy. Type I leprae reaction occurs in borderline disease and is associated with upgrading of the condition. Existing skin lesions become more inflamed and painful or may ulcerate and new lesions may appear. This is associated with acute or insidious pain and tenderness of affected nerves.

Type II leprae reactions occur in patients who have lepromatous leprosy and borderline leprosy. These reactions may occur spontaneously or in response to treatment. The most common cutaneous manifestation is that of erythema nodosum leprosum, in which painful red nodules occur in the skin, most commonly on the face and extensor surfaces of the limbs.[23] Individual lesions are painful,

Figure 12-7 Lepromatous leprosy, with multiple symmetric lesions on the face, giving a leonine facies.

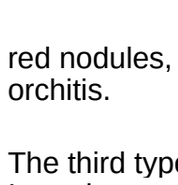

Figure 12-8 Erythema multiforme showing target lesions and bullous lesions on the palms of the hands.

red nodules, but they may ultimately ulcerate. Erythema nodosum leprosum may be accompanied by uveitis, myositis, lymphadenitis, neuritis, dactylitis, arthritis and orchitis.

The third type of reaction seen in leprosy is the so-called Lucio phenomenon.[24] This is due to deep cutaneous vasculitis leading to infarction of the overlying skin. Irregular erythematous patches develop and these may necrose to leave deep painful ulcers.

NON-SPECIFIC CUTANEOUS SIGNS OF SYSTEMIC INFECTIONS

Erythema multiforme

Erythema multiforme may occur at any age. The lesions are usually asymptomatic and start as dull red macules and papules that occur on acral sites (particularly the hands) and then spread more centrally. Typical target lesions occur; these have a central purpuric area and a raised, rather edematous border (Fig. 12.8). Less commonly, the feet, elbows, knees, face, neck and trunk are affected.

In severe eruptions, bullae may develop over the individual lesions. In the most severe form of the disease the oral mucosa shows extensive bullous formation with erosions affecting the lips and buccal mucosa. Genital lesions may also occur. This form is called the Stevens-Johnson syndrome. A variety of infectious agents have been implicated in causing erythema multiforme (Table 12.1).[25] The most common infectious cause of erythema multiforme is herpes simplex infection.

Erythema nodosum

Erythema nodosum is an acute type IV reaction to a number of different stimuli. The skin and subcutaneous fat are affected with a septal panniculitis. Clinically, there is a short prodrome of mild fever, myalgia and malaise. Erythematous nodules develop on the shins and more rarely on the arms, face and neck; these vary in diameter from 1cm to several centimeters (Fig. 12.9). The hallmark of erythema nodosum is pain and exquisite tenderness of the lesions. Initially, the lesions are bright red but as they subside over the next 3 weeks or so they undergo a bruise-like change from dusky purple-yellow and green before leaving mild scaling of the skin.

A number of infectious agents have been implicated in the etiology of erythema nodosum (Table 12.2). [26] These vary with the age of the patient and the country of residence. The most common infectious cause is an upper respiratory viral infection. Streptococcal sore throats are also a common cause in children and tuberculosis is still a common cause in children where the disease is prevalent. Infections with *Chlamydia psittaci* have been responsible for small outbreaks of erythema nodosum in adults in the UK,

Tularemia
Upper respiratory tract viruses
Yersiniosis

Figure 12-9 Erythema nodosum on the lower legs. On investigation this patient was found to have a negative Mantoux even at 1 in 100 but the erythema nodosum subsided when the patient was started on antituberculous therapy.

where contact with birds and poultry may be an important clue in identifying the cause of the reaction. Infections with *Yersinia* spp. are a common cause of erythema nodosum in France and Finland but are rare in other countries. Recent reports have shown that gonorrhea is a relatively common cause of erythema nodosum in Singapore.[27]

Erythema nodosum may be related to inflammatory tinea capitis in children, particularly in association with kerion formation. Deep fungal infection, particularly coccidioidomycosis, blastomycosis and histoplasmosis, has been associated with erythema nodosum. More rarely, erythema nodosum has been reported in association with tularemia, salmonellosis, *Campylobacter* spp. infection and leptospirosis.

Cutaneous vasculitis

The clinical features of cutaneous vasculitis depend on the size of the blood vessels affected and on whether the vasculitis is acute or chronic. Acute leukocytoclastic vasculitis is caused by immune complex deposition in cutaneous blood vessels with complement fixation and damage caused by polymorphonuclear leukocyte infiltration and activation. The targeted blood vessels tend to be small, superficial vessels and the clinical signs are of a purpuric macular or papular eruption on the lower legs and dependent areas; these eruptions may become bullous and ulcerate (Fig. 12.10). The most common bacterial infection associated with cutaneous vasculitis is a streptococcal sore throat,[28] [29] which precedes the vasculitis by 1–3 weeks.

Subacute and chronic cutaneous vasculitis is associated with chronic foci of infection such as dental abscesses or asymptomatic chronic pyelonephritis.[28] In nodular vasculitis, tuberculosis has been blamed for the reaction; leprosy and syphilis should also be considered. *Neisseria gonorrhoeae*, *Mycoplasma pneumoniae* and *Rickettsia* spp. may also cause an acute vasculitis (Table 12.3).

Viruses can cause endothelial cell damage, platelet agglutination and immune complex formation. The best studied causes of viral vasculitis are influenza vaccines, hepatitis B virus[30] and the Bunyaviridae-induced hemorrhagic fever. Hepatitis C virus should also be considered in any vasculitis work-up. Herpes simplex infection[31] and enterovirus infections[32] have also been implicated in cutaneous vasculitis.

Figure 12-10 Acute leukocytoclastic vasculitis showing bullous lesions on the lower leg. This patient was found to have a high antistreptolysin titer.

TABLE 12-3 -- Infections associated with cutaneous vasculitis.

INFECTIONS ASSOCIATED WITH CUTANEOUS VASCULITIS
Streptococci
Dental abscesses
Chronic *Escherichia coli* infections
Tuberculosis
Leprosy
Syphilis
Gonorrhea
Hepatitis B virus
Hepatitis C virus
Enteroviruses
Hemorrhagic fever
Herpes simplex
Mycoplasma pneumoniae
Rickettsia spp.
Candidiasis
Cryptococcosis

Less commonly, fungal infections (including those with *Candida albicans*) have been reported in association with vascular damage and cutaneous vasculitis. Cryptococcosis may present with a widespread nodular vasculitis when complicating HIV infection.

Gianotti-Crosti syndrome

Gianotti-Crosti syndrome is a cutaneous reaction to virus infection, characteristically seen in children aged between 6 months and 12 years. The majority of cases are associated with hepatitis B virus infection, usually with subtype ayw. [33] More recently, a number of other viruses have been causally linked with this syndrome, including Epstein-Barr virus, Coxsackie viruses A16, B4 and B5, echoviruses 7 and 9, poliovirus, cytomegalovirus, respiratory syncytial virus, hepatitis A virus and parainfluenza virus.[34] [35]

The eruption presents acutely with dull red papules of 5–10mm diameter. These develop over 3–4 days, starting on the buttocks and thighs and spreading to the arms and face. The papules may become purpuric. In cases that are related to hepatitis B virus, the papules are not itchy, unlike those linked to other viruses. Lymphadenopathy of the axillae and groins is often present and may persist for several months after the eruption has settled, which generally occurs within 2–8 weeks to leave mild scaling but no scarring.

Kawasaki disease

Kawasaki disease is a diffuse vasculitic disease of unknown cause. A number of infectious agents have been implicated in its pathogenesis, including streptococci,[36] staphylococci,[37] *Leptospira* spp.,[38] *Pseudomonas* spp., *Rickettsia* spp., and Epstein-Barr virus and other viruses. In most cases no agent is identified. The disease generally affects children under the age of 4 years and although it most commonly occurs in Japan it has been reported throughout the world.

The disease is acute in onset with a remittent fever. The conjunctivae become infected and the lips and tongue are red. At the onset of fever, a generalized polymorphic eruption develops on the trunk and proximal limbs; this is associated with redness and induration of the palms and soles. Cervical lymphadenopathy develops in 50–80% of patients. The fever lasts for more than 5 days and as this subsides the skin scales and the patient may develop arthralgias and arthropathy. Cardiac involvement develops at this stage of the illness in 20% of patients, with myocarditis, aneurysm, stenosis and obstruction of the coronary arteries, which is usually responsible for the 1% mortality seen in this disease.

INFLAMMATORY DERMATOSES MIMICKING INFECTION

Acute febrile neutrophilic dermatosis (Sweet's syndrome)

Acute febrile neutrophilic dermatosis was first described by Sweet in 1964.[39] It is characterized by an explosive cutaneous eruption of raised violaceous plaques in association with constitutional symptoms and fever. Although the original series described a preceding upper respiratory infection in some patients, the majority of cases apparently are not associated with underlying infection. Approximately 50% of cases are associated with underlying malignancy, particularly myeloproliferative disorders and acute myelogenous leukemia. [40] Other reported associations include vaccination, endocrine disturbances (such as thyrotoxicosis and pregnancy), autoimmune diseases and inflammatory bowel disease. Women are more commonly affected.

Clinical presentation is an acute eruption of dull red elevated inflammatory nodules and plaques, which may pustulate in later stages or clear centrally to give an annular appearance. The majority of patients have a persistent fever and neutrophilia with elevated erythrocyte sedimentation rate and C-reactive protein. Diagnosis may be confirmed by cutaneous biopsy, which reveals a florid dermal polymorphonuclear cell infiltrate. Cases respond rapidly to systemic corticosteroid therapy, which is usually required for several weeks.

Toxic epidermal necrolysis

Toxic epidermal necrolysis (TEN) is a serious drug-induced skin disorder, which clinically may be difficult to distinguish from staphylococcal scalded skin syndrome (SSSS). Both conditions are characterized by an acute and widespread cutaneous erythema with sloughing and loss of the epidermis in sheets. As described, SSSS occurs mainly in childhood and is caused by staphylococcal toxin-mediated superficial cleavage of the epidermis below the granular layer. It has an excellent prognosis if appropriately treated. In comparison TEN is usually a drug-induced phenomenon causing full-thickness necrosis of the epidermis, with subsequent impairment of cutaneous barrier function and a high mortality (30%).[41] The precise pathogenesis is poorly understood, although increased circulating levels of fasL, a ligand for the fas (CD 95) keratinocyte death receptor, have been identified in patients with TEN.[42]

The most commonly implicated drugs are antibiotics, particularly sulfonamides, anticonvulsants, allopurinol and nonsteroidal anti-inflammatory drugs. Toxic epidermal necrolysis may be distinguished from SSSS by histologic examination of biopsied skin, allowing assessment of the level of epidermal splitting and identification of the presence or absence of micro-organisms. Treatment outcome is improved by intensive nursing in a specialist burns unit and by prompt withdrawal of all potential

precipitants. Corticosteroids do not appear to improve outcome and possibly increase mortality. Experimental evidence indicates that pooled human immunoglobulin inhibits fasL-CD95 interaction in vitro and beneficial clinical responses have been observed. [42]

Oral ulceration

Oral ulceration is a common clinical finding, with a wide differential diagnosis including infectious disease. It may be seen at any stage of syphilis, but affects up to one-third of patients with secondary disease. Ulcers are usually painless, shallow and may occur at any mucosal site.

Primary herpes simplex infection usually occurs in early childhood, producing a gingivostomatitis. Patients develop fever, malaise and restlessness followed by the development of a painful vesicular eruption on the lips, buccal mucosa, tongue and palate, with associated tender regional lymphadenopathy.

Aphthous ulceration is common, painful and occurs in a variety of clinical patterns. Crops of lesions typically occur. Minor aphthous ulcers are 2–4mm in diameter with a gray-white surface and a red margin. These are commonest on the lips, buccal mucosa or floor of the mouth and rarely occur on the gingiva, palate or dorsal tongue. Major aphthous ulcers may exceed 1cm in diameter and occur anywhere in the mouth. These are more painful, last longer than minor aphthous ulcers and may heal with scarring. Herpetiform aphthous ulceration produces very painful vesicles and multiple tiny ulcers less than 2mm in diameter. These may coalesce to produce larger lesions and tend to recur frequently. The syndrome closely resembles herpetic gingivostomatitis, although there is no evidence of viral etiology.

Behçet's syndrome is characterized by the presence of recurrent aphthous ulcers in association with genital ulcers, eye disease (particularly relapsing iridocyclitis), central nervous system disease (e.g. meningoencephalitis), arthropathy, skin lesions (e.g. pustules, pathergy, erythema nodosum) and other systemic manifestations. [43] Oral lesions in Behçet's syndrome start as small erythematous papules or pustules, which erode to form small ulcers. Pain is a variable feature. Recurrent ulceration may predate the syndrome by months or years.

Pemphigus vulgaris affects the oral mucosa in almost all patients and is the presenting feature in 50–70%. Bullae are fragile and therefore rarely seen. Ruptured bullae form painful large irregular erosions on any part of the oral mucosa. Most patients will also go on to develop flaccid cutaneous bullae which rupture easily.[44]

Eosinophilic cellulitis (Wells' syndrome)

Eosinophilic cellulitis is a rare syndrome, first described by Wells, which may closely mimic bacterial cellulitis.[45] Etiology is unknown. It is characterized by the development of indurated inflammatory areas of erythema, usually on a distal limb, which may be single or multiple. Systemic illness is unusual, although associated fever has been reported and peripheral eosinophilia is common. Early lesions are often pruritic and infiltrated but then flatten and resolve without scarring within a few weeks. Diagnosis is suggested on skin pathology by the demonstration of marked dermal eosinophilia with areas of granulomatous change surrounding aggregates of eosinophilic material, known as 'flame figures'. The condition responds to oral corticosteroid therapy.

Chapter 13 - Superficial Fungal Infections

David W Warnock

INTRODUCTION

This chapter reviews the different fungal diseases of the skin, nails and hair. The most common of these diseases are dermatophytosis, candidiasis and pityriasis versicolor. Other, less frequent infections of the skin and hair include tinea nigra and piedra. In addition, there are a number of non-dermatophytic molds that can cause nail disease (onychomycosis). Superficial fungal infections, such as dermatophytosis and onychomycosis, have become an important problem in persons infected with HIV and other immunocompromised host groups. The diagnosis of these infections can be difficult because of atypical clinical manifestations. Furthermore, in such patients, skin and nail infections can be difficult to treat because the disease is often more extensive and severe.

EPIDEMIOLOGY

The organisms that cause dermatophytosis are molds belonging to the genera *Trichophyton*, *Microsporum* and *Epidermophyton*.[1] Many of the 40 or so species that are recognized at present are worldwide in distribution, but others are confined to particular regions.[2] About 10 species are common human pathogens. The dermatophytes can be split into three ecologic groups depending on whether their usual natural habitat is the soil (geophilic species), animals (zoophilic species) or humans (anthropophilic species). Members of all three groups can cause human infections, but their different natural reservoirs have important implications in relation to the acquisition, site and spread of the disease. Infections originating from the soil are the least common. Infections having animal origins are more frequent and particular species are often associated with particular animal hosts. Anthropophilic dermatophytes account for most human infections; these species are contagious and are readily transmitted from person to person.

Tinea capitis (dermatophytosis of the scalp) is a common infection in children. The predominant etiologic agents differ from continent to continent, but the anthropophilic species *Trichophyton tonsurans* has replaced *Microsporum audouinii* as the dominant cause of this disease among urban populations in North, Central and South America. [3] Infections with this organism have also become much more common in the UK, particularly among black African or black Caribbean school children in London. The cause of this rise in anthropophilic infection rates is difficult to ascertain, but it is possible that it is associated with increased migration. In France, and in particular Paris, the main anthropophilic dermatophytes associated with tinea capitis are those that originate from Africa, particularly *Trichophyton soudanense*. Other less common causes of tinea capitis include the animal species *Microsporum canis* and *Trichophyton verrucosum*. Tinea pedis (dermatophytosis of the feet) is a contagious condition and is easily spread from person to person. The predominant agent is the anthropophilic species *Trichophyton rubrum*, but this disease can also be caused by *Trichophyton mentagrophytes* var. *interdigitale*. Transfer within households has been reported, but the main spread occurs in communal baths and showers.[4]

Cutaneous candidiasis is a less common disease than dermatophytosis. *Candida albicans*, the predominant etiologic agent, is a commensal organism found in the mouth and gastrointestinal tract of a significant proportion of the normal population. It is seldom recovered from normal skin, being much less prevalent than *Candida parapsilosis*, but it is a frequent colonizer of moist or damaged skin and nails.

Malassezia furfur is a common commensal organism that colonizes the normal skin of the head and trunk during late childhood.[5] In certain circumstances, such as hot humid climatic conditions, this lipophilic organism produces the disease pityriasis versicolor. In the tropics, up to 50% of the population may be affected. *Malassezia furfur* can be transmitted from person to person, either through direct contact or through contaminated clothing or bedding. In practice, however, infection is endogenous in most cases and spread between individuals is uncommon.

Tinea nigra is a chronic infection of the palms and soles. The disease is rare but has a worldwide distribution, although it is more common in the tropics and subtropics. The etiologic agent, *Phaeoannellomyces werneckii*, is a saprobic mold that is found in the soil and in decomposing vegetation. Human infection is thought to follow traumatic inoculation.

Black piedra is an uncommon hair infection that occurs in humid tropical regions. The natural habitat of the etiologic agent, *Piedraia hortae*, has not been identified. There are some reports of familial infection. White piedra is less common than black piedra. It is found worldwide, but it is more prevalent in the tropics and subtropics. The etiologic agent, *Trichosporon asahii*, has a widespread natural distribution and is sometimes found on normal skin.

Onychomycosis is a non-specific term used to describe fungal disease of the nails; tinea unguium is a more specific term used to describe dermatophyte nail infection. At least 80% of fungal nail infections and 90% of toenail infections are due to dermatophytes, in particular *Trichophyton rubrum*. [6] Between 5% and 10% of nail infections are due to *Candida* spp. and the remainder are attributable to non-dermatophytic molds. Most prominent among these are *Scopulariopsis brevicaulis*, *Scytalidium dimidiatum* (*Hendersonula toruloidea*), *Aspergillus* spp. and *Fusarium* spp.[6] Unlike the dermatophytes, these molds are not contagious. Onychomycosis is more prevalent in older people and men are more commonly affected than women. Toenails are more frequently involved than fingernails.

PATHOGENESIS AND PATHOLOGY

The dermatophytes are keratinophilic fungi that are normally found growing only in the dead keratinized tissue of the stratum corneum, within and around hair shafts, and in the nail-plate and keratinized nail-bed. The clinical appearances of dermatophyte infections are the result of a combination of direct damage to the tissue by the fungus (mainly in the case of hair and nail infections) and of the immune

response of the host. The damage to tissue is due to a combination of mechanical forces and enzymatic activities. Dermatophytes produce a number of keratinolytic proteinases that function best at an acidic pH and these have been recognized as important virulence factors.[1]

The immune response to dermatophytes has been studied in human infections as well as in animal models.[7] The humoral response does not appear to help in the elimination of infection; the highest levels of antibodies are often found in patients with chronic dermatophytosis. Rather, it is the cell-mediated response that is important in ridding the stratum corneum of the infection.[8] Dermatophytes vary in their host interactions. Zoophilic species, such as *Trichophyton verrucosum*, often elicit intense inflammation in humans. This leads to enhanced epidermal proliferation and can result in spontaneous cure.[9] In contrast, anthropophilic species such as *Trichophyton rubrum* often produce chronic or recurrent lesions. Chronic dermatophytosis in otherwise healthy people may be mediated by fungal cell wall components, such as mannan, that diminish the local immune response.[9]

Except for neonatal infections, most cases of superficial candidasis result from infection of the host from his or her own commensal flora. This shift in the host-fungus relationship results from a number of influences, of which host factors appear to be the most important. Local tissue damage is a critical factor in the pathogenesis of cutaneous candidiasis; most infections occur in moist, occluded sites and follow maceration of the tissue. Chronic mucocutaneous candidiasis is a rare condition that results from inherited defects in the cell-mediated immune response.[10]

Malassezia furfur is present on the normal skin from late childhood. Hot, humid environmental conditions are among the factors that predispose to the development of the cutaneous lesions of pityriasis versicolor.

PREVENTION

Prevention of dermatophytosis must take into account the site of the infection, the etiologic agent and the source of the infection.

Anthropophilic tinea capitis is a common fungal infection in children. It is easily spread from child to child, both in the home and at school. To prevent this, contacts of children infected with *Microsporum audouinii* can be examined for infected fluorescent hairs with Wood's light (a source of ultraviolet light filtered through nickel oxide glass). In the more common non-fluorescent infection with *Trichophyton tonsurans*, detection is more difficult, but the scalp brush sampling method is often helpful in detecting subclinical disease. [11] All those found to be infected must be treated and the importance of good personal hygiene should be stressed. It is seldom practical to exclude infected children from school.

In the case of tinea capitis and tinea corporis caused by zoophilic species, such as *Microsporum canis* and *Trichophyton*

TABLE 13-1 -- Some characteristics of common dermatophytes causing scalp infection.

SOME CHARACTERISTICS OF COMMON DERMATOPHYTES CAUSING SCALP INFECTION			
Organism	**Arthrospore size**	**Arthrospore arrangement**	**Fluorescence under Wood's light**
Microsporum audouinii	Small (2–3µm)	Ectothrix	Yes
Microsporum canis	Small (2–3µm)	Ectothrix	Yes
Trichophyton mentagrophytes	Small (3–5µm)	Ectothrix	No
Trichophyton soudanense	Large (4–8µm)	Endothrix	No
Trichophyton tonsurans	Large (4–8µm)	Endothrix	No
Trichophyton verrucosum	Large (5–10µm)	Ectothrix	No
Trichophyton violaceum	Large (4–8µm)	Endothrix	No

verrucosum, it is important to locate the animal source. *Microsporum canis* infection of cats and dogs can often be detected with Wood's light examination. The subsequent course of action will depend upon the value placed on the infected animal. It is more difficult to detect and eliminate *Trichophyton verrucosum* infection in cattle, because infected hairs are not fluorescent and because the fungus can survive for long periods on hairs and scales that have been deposited on the walls of buildings and gates. Fungicidal washes have sometimes been effective in controlling this infection.

Tinea pedis is a contagious condition and is easily spread from person to person. Transfer within households has been reported, but the main spread occurs in communal baths and showers.[4] Educating infected people not to expose others to their infection by not walking barefoot on the floors of communal changing rooms and by avoiding public baths and showers can help to reduce the spread of this disease. Frequent hosing of the floors of public baths and antifungal foot dips near communal baths are helpful preventive measures. Prompt treatment of tinea pedis and the use of separate towels are sensible measures that can help to prevent tinea cruris, tinea manuum and tinea unguium.

Intertriginous candidiasis of the fingernails is often seen in people whose occupation necessitates frequent wetting of the hands. Wearing protective gloves can help to prevent this infection.

Good personal hygiene is important in preventing the spread of piedra. Infected people should not share hair brushes or combs with others.

CLINICAL FEATURES

The dermatophytes are the predominant causal organisms of fungal disease of the scalp, toe clefts, soles, palms and nails. In the temperate, developed countries, tinea pedis is the most common form of dermatophytosis. By contrast, in the tropics, tinea capitis and tinea corporis are the most prevalent.

Tinea capitis

The clinical manifestations of tinea capitis are varied and depend on the species of dermatophyte involved and the degree of host response (Table 13.1). The appearance of the lesions can range from mild scaling and hair loss with minimal inflammation to severe inflammation with kerion formation.

In *Microsporum audouinii* infection the lesions consist of well-demarcated patches of partial alopecia. Inflammation is minimal, but fine scaling is characteristic. Most of the hairs in these lesions are broken off near the surface of the scalp. In *Microsporum canis* infection the picture is similar, but there is usually more inflammation. In both these infections the hair surface is coated with small arthrospores (ectothrix infection). The affected hairs show green fluorescence under Wood's light.

In *Trichophyton tonsurans* and *Trichophyton violaceum* infections the lesions are often inconspicuous and inflammation may be minimal. The typical lesions are irregular patches of scaling. The affected hairs often break off at the surface of the scalp, giving a 'black-dot' appearance. The hairs are filled with arthrospores (endothrix infection) and do not fluoresce under Wood's light.

The most florid form of tinea capitis is a kerion. A kerion is a painful inflammatory mass in which the hairs that remain are loose. Thick crusting with matting of adjacent hairs is common. Pus may be discharged from one or more points. A kerion may be limited in extent, but a large confluent lesion may develop (a severe form of kerion) that involves most of the scalp. In most cases this violent reaction results from infection with an animal dermatophyte such as *Trichophyton verrucosum* or *Trichophyton mentagrophytes* var. *mentagrophytes*. However, geophilic or anthropophilic organisms are sometimes involved. In *Trichophyton verrucosum* infections the hairs are covered with chains of large arthrospores but they do not fluoresce under Wood's light.

Favus is now rare, but it is still a distinctive form of fungal scalp infection. The causal organism is *Trichophyton schoenleinii*, an anthropophilic dermatophyte noted for its persistence. Favus presents with hair loss and the formation of cup-shaped crusts known as scutula. These give off a fetid odor and can amalgamate to form dense mats on part or all of the scalp. Long-standing favus can lead to permanent patches of cicatricial alopecia. Infected hairs give off a dull green fluorescence under Wood's light.

Tinea capitis must be distinguished from seborrheic dermatitis, psoriasis, bacterial folliculitis and cicatricial alopecia.

Tinea barbae

The animal species *Trichophyton verrucosum* and *Trichophyton mentagrophytes* var. *mentagrophytes* are the principal causes of dermatophyte infection of the beard and moustache areas of the face. *Microsporum canis* is a less common cause. The characteristic appearance is of a highly inflammatory pustular folliculitis (Fig. 13.1). Some infections are less severe and consist of circular, erythematous, scaling lesions.

Tinea faciei

The more common causes of dermatophyte infection of the face are *Trichophyton rubrum* and *Trichophyton mentagrophytes* var. *mentagrophytes*, but many other species may be involved, including *Trichophyton tonsurans* and *Microsporum canis*. The typical annular lesions are erythematous, but scaling is often absent. The lesions are often pruritic and exacerbation after exposure to the sun is common.

Tinea corporis

The clinical manifestations of tinea corporis are varied and often depend on the species of the infective organism. The disease often

Figure 13-1 Tinea barbae due to *Trichophyton verrucosum.*

follows contact with infected animals, but occasional cases result from contact with contaminated soil. *Microsporum canis* is a frequent cause of human infection and *Trichophyton verrucosum* infection is common in rural districts. Infections with anthropophilic species, such as *Trichophyton rubrum*, often follow spread from another site, such as the feet. Infections with *Trichophyton tonsurans* are sometimes seen in children with tinea capitis.

The characteristic lesion is an annular scaling plaque with a raised erythematous border and central clearing. In their most florid form the lesions can become indurated and pustular (Fig. 13.2). This is more common in infections with zoophilic organisms. The differential diagnosis includes discoid eczema, impetigo, psoriasis and discoid lupus erythematosus.

Tinea cruris

Infection of the groin and the perianal and perineal regions is more common in men. The predominant causes are the anthropophilic species *Trichophyton rubrum* and *Epidermophyton floccosum*. The infection often follows spread from another site in the same person, but person-to-person spread (e.g. through contaminated clothing) is not uncommon.

In color, the lesions are erythematous to brown. They have raised scaling margins and radiate from the groin down the inner border of the thigh. Patients often complain of intense pruritus. The differential diagnosis includes intertriginous *Candida* spp. infection, bacterial intertrigo, psoriasis and seborrheic dermatitis.

Tinea imbricata

This is a chronic infection that is characterized by the development of homogeneous sheets or concentric rings of scaling that can spread to cover large parts of the affected person. Most reports of tinea imbricata have come from the Pacific Islands and Melanesia but there have been occasional reports from South East Asia and Central and South America. The etiologic agent is the anthropophilic species *Trichophyton concentricum*.

Tinea pedis

Infection of the feet is the most common form of dermatophytosis in the UK and North America. The main organisms involved are the anthropophilic species *Trichophyton rubrum* and, less commonly, *Trichophyton mentagrophytes* var. *interdigitale*.

The most common clinical presentation is interdigital maceration, peeling and fissuring, mostly in the spaces between the fourth and fifth toes. Itching is a common symptom.

Figure 13-2 Tinea corporis due to *Trichophyton mentagrophytes* var. *mentagrophytes.*

Figure 13-3 Moccasin tinea pedis due to *Trichophyton rubrum.*

Another common presentation associated with *Trichophyton rubrum* is hyperkeratosis of the soles, heels and sides of the feet. The affected sites are pink and covered with fine, white scales. This form of the disease is often chronic and resistant to treatment. If there is extensive involvement of the foot, then the term 'moccasin tinea pedis' is often applied (Fig. 13.3).

A third form of tinea pedis, associated with *Trichophyton mentagrophytes* var. *interdigitale*, is an acute vesicular infection of the soles. This severe form of the disease may resolve without treatment, but exacerbations tend to occur under hot humid conditions. There is often associated hyperhidrosis.

Tinea pedis can be difficult to distinguish from other infectious causes of toe web infection, such as *Candida* intertrigo and erythrasma. Noninfectious conditions that mimic tinea pedis of the soles include psoriasis and contact dermatitis.

Tinea manuum

Tinea manuum is usually unilateral, the right hand being more commonly affected than the left. Lesions on the dorsum of the hand appear similar to those of tinea corporis, with a distinct border and central clearing. Infection of the palms is more common. This presents as a diffuse scaling hyperkeratosis, with accentuation of the fissuring in the palmar creases. *Trichophyton rubrum* is the most common cause of tinea manuum. The differential diagnosis includes contact dermatitis, eczema and psoriasis.

Tinea unguium

The most common causes of dermatophyte infection of the nails are *Trichophyton rubrum* and *Trichophyton mentagrophytes* var. *interdigitale*, but many other species may be involved. Three clinical forms of tinea unguium are recognized. Distal (or lateral) subungual disease is the most common presentation (Fig. 13.4). This usually begins as a discoloration and thickening of the nail and it can result in destruction of the entire nail-plate and separation of the nail from the nail-bed (Fig. 13.5). In superficial white onychomycosis, crumbling white lesions are evident on the nail surface, particularly the toenails. This condition is most commonly caused by *Trichophyton mentagrophytes* var. *interdigitale*. Proximal subungual disease is the least common presentation of dermatophyte nail infection. In the USA *Trichophyton rubrum* is the principal cause of proximal subungual onychomycosis.

The differential diagnosis includes eczema, lichen planus, onychogryphosis and lichen planus. Unlike dermatophytosis, *Candida* infections of the nails often begin in the proximal nail-plate and are associated with nail-fold infection.

Candidiasis

The lesions of cutaneous candidiasis (intertrigo) tend to develop in warm, moist sites such as the folds of the skin under the breasts and the groin. The infection is more common in overweight or diabetic people. The initial lesions are papules or vesicopustules that later enlarge and become confluent. The larger lesions are erythematous

Figure 13-4 Patterns of fungal nail disease.

Figure 13-5 Total dystrophic onychomycosis due to *Trichophyton rubrum.*

and have an irregular margin. Smaller, satellite lesions are often present. Soreness and itching are usual. The differential diagnosis includes dermatophytosis, seborrheic dermatitis, bacterial intertrigo and psoriasis.

Infection of the skin between the fingers or toes can also occur. Infection of the webs of the fingers presents as a macerated, erythematous lesion (Fig. 13.6). It is often uncomfortable and may be painful. This condition is usually seen in people whose occupations necessitate frequent immersion of the hands in water. Infection of the webs of the toes mimics tinea pedis and many cases do occur in conjunction with this form of dermatophytosis.

Chronic mucocutaneous candidiasis is a rare condition that affects people with underlying endocrinologic or immunologic disorders. The disease often develops during the first 3 years of life. The mouth is usually the first site to be affected, but lesions then appear on the

Figure 13-6 Interdigital candidiasis.

Figure 13-7 Pityriasis versicolor showing depigmented lesions.

scalp, hands, feet and nails. In some patients, disfiguring hyperkeratotic lesions develop on the scalp and face.

Three forms of *Candida* nail infection are recognized: infection of the nail-folds (paronychia), distal nail infection and total dystrophic onychomycosis. The last is a manifestation of chronic mucocutaneous candidiasis. Infection of the nail-folds is more common in women than in men. The periungual skin is raised and painful and a prominent gap develops between the fold and the nail-plate. White pus may be discharged. The infection usually starts in the proximal nail-fold, but the lateral margins are sometimes the first site to be affected. The nail-plate may be invaded.

Distal *Candida* nail infection presents as onycholysis and subungual hyperkeratosis. It is often difficult to distinguish from dermatophytosis, but candidasis tends to affect the fingernails rather than the toenails. In patients with chronic mucocutaneous candidiasis, the nail-plate is invaded from the outset, causing gross thickening and hyperkeratosis.

Pityriasis versicolor

Pityriasis versicolor is a disfiguring but otherwise harmless condition. The characteristic lesions consist of patches of fine brown scaling that are found particularly on the upper trunk, neck, upper arms and abdomen. In light-skinned people the affected skin may appear darker than normal. The lesions are light pink in color but grow darker, turning a pale brown shade. In dark-skinned or tanned people, the affected skin becomes depigmented (Fig. 13.7).

Hyperpigmented lesions must be distinguished from erythrasma, seborrheic dermatitis, pityriasis rosea and tinea corporis. Hypopigmented lesions can be confused with pityriasis alba and vitiligo.

Tinea nigra

The lesions of tinea nigra, which are found on the palm or sole, consist of one or more flat, dark brown or black, non-scaling patches with a well-defined edge. Inflammation is absent. The lesions, which are small at first, expand and become confluent. The disease is asymptomatic and may remain undiagnosed for long periods. Tinea nigra must be distinguished from malignant melanoma and chemical stains.

Figure 13-8 Onychomycosis due to *Scytalidium dimidiatum* (*Hendersonula toruloidea*).

Piedra

Black piedra is most often seen on the scalp hair. Small, brown or black, hard nodules, which are difficult to remove, are formed on the distal hair shafts. The appearance of white piedra is similar, but the nodules are softer and pale in color. This condition affects the hairs of the beard and moustache. Less commonly, it involves the scalp or pubic hair.

Onychomycosis

Up to 5% of cases of onychomycosis are due to non-dermatophyte molds. With the exception of *Scytalidium dimidiatum*, these molds usually affect nails that have previously been diseased or damaged. This may account for the fact that these infections often affect only one nail. There is nothing specific about the clinical appearance of the lesions (Fig. 13.8). Distal subungual hyperkeratosis with onycholysis of the distal nail-plate is common (see Fig. 13.4). Superficial white lesions are

another presentation.

Superficial fungal infections in immunocompromised patients

In general, fungal infections, such as dermatophytosis and onychomycosis, are no more common in immunocompromised persons than in immunocompetent individuals. [12] [13]

The clinical manifestations of dermatophytosis in the immunocompromised patient are often similar to those seen in normal individuals. However, the clinical presentation can be atypical, particularly in patients with T-cell defects, such as organ transplant recipients and persons who have AIDS. The major features of dermatophytosis in these groups are loss of obvious lesions, minimal scaling and the presence of follicular papules or pustules. In addition, the lesions can be more extensive than normal.

Tinea pedis has been described in both organ transplant recipients and persons who have AIDS. The lesions are often indistinguishable from those seen in normal individuals but can be extensive, with involvement of the dorsum of the foot. In tinea corporis and tinea cruris, the lesions can be extensive but the inflammation is mild and the margin is indistinct. Facial dermatophytosis has been noted in persons who have AIDS, where it can be confused with seborrheic dermatitis. This is because the rash is diffuse and can spread across both cheeks.

Although proximal subungual onychomycosis is the most infrequent form of fungal nail disease in the general population, it is common in persons who have AIDS and has been considered a useful clinical marker of HIV infection.[14] Infection of the toenails is much more frequent than fingernail infection. *Trichophyton rubrum* is the usual etiologic agent. In AIDS patients, it can spread rapidly from the proximal margin and superior surface of the nail to produce gross white discoloration of the plate without obvious thickening.

Malassezia furfur infections of the skin can take a number of different clinical forms in immunocompromised persons, including pityriasis versicolor, *Malassezia* folliculitis and seborrheic dermatitis.[12] [13] The clinical manifestations of pityriasis versicolor in immunocompromised persons are similar to those seen in normal individuals. However, the lesions are usually more erythematous and may appear raised. *Malassezia furfur* can also cause folliculitis in immunosuppressed individuals. This is characterized by scattered itching follicular papules and pustules on the chest and back.

Seborrheic dermatitis is chronic relapsing scaling dermatosis of the face, scalp and trunk. It is the commonest cause of dandruff (scalp scaling). The role of *Malassezia furfur* in the pathogenesis of seborrheic dermatitis is controversial and is based on the fact that most cases respond to azole antifungal treatment. Improvement is associated with disappearance of the organisms and relapse with recolonization. Seborrheic dermatitis is a common and troublesome problem, estimated to occur in up to 80% of persons with HIV infection. The lesions take the form of an erythematous scaling rash on the scalp, face, ears, chest and upper back. Scaling of the eyelid margins and around the nasal folds is a common presentation. The rash is often more extensive than in other individuals.

DIAGNOSIS

Superficial fungal infections often present with characteristic lesions but where this is not the case, mycologic investigation can assist in diagnosis. Material should be collected from cutaneous lesions by scraping outward from the margin. Cleansing the site with 70% alcohol before sampling will increase the likelihood of detecting fungus on direct microscopic examination. Nail specimens should be taken from discolored or dystrophic parts of the nail and should include the full thickness of the nail. If distal subungual lesions are present, debris should be collected from underneath the nail. If there is superficial nail-plate involvement, the scrapings should be taken from the nail surface. Specimens from the scalp should include hair roots and skin scales. Wood's light can sometimes be useful for the selection of sites of active infection, especially if the lesions are inconspicuous or atypical.

Direct microscopic examination of skin and nail material is often sufficient for the diagnosis of a dermatophyte infection, but it gives no indication as to which species is involved. With hair specimens, the size and disposition of the arthrospores can give some indication as to the etiologic agent (see Table 13.1 ; Chapter 240).

Culture is a more reliable method of diagnosis than microscopic examination. It permits the species of dermatophyte to be determined and this can aid the selection of the most appropriate form of treatment. If possible, both microscopic examination and culture should be performed on all specimens. If, however, there is insufficient material for both, microscopic examination should be performed.

Cutaneous candidiasis is often difficult to diagnose if the lesions are other than typical in appearance. Isolation of *Candida albicans* from scrapings is of doubtful significance because the organism is a common colonizer of cutaneous lesions in moist sites. Microscopic demonstration of the organism in scrapings is much more significant. Isolation of *Candida albicans* from nails is seldom significant unless the organism is seen on direct microscopic examination.

Microscopic examination of scrapings from lesions will permit the diagnosis of pityriasis versicolor if there are clusters of round or oval cells together with short broad filaments (which are seldom branched). Because this appearance is pathognomonic for pityriasis versicolor, and because *Malassezia furfur* is part of the normal skin flora, its isolation in culture is not helpful. Direct microscopic examination and culture of scrapings or epilated hairs will permit the diagnosis of tinea nigra and piedra.

It is not unusual to isolate molds other than dermatophytes from abnormal nails cultured on media from which cycloheximide has been omitted. In many cases, these molds are casual, transient contaminants and direct microscopic examination of the material is negative. However, if filaments are seen on microscopic examination but no dermatophyte is isolated, it is possible that the mold is the cause of the infection.

MANAGEMENT

There is now a good selection of topical and systemic agents for the treatment of superficial fungal infections. The choice of treatment and its duration depends on the causative organism, the site of infection and the extent of the disease, as well as on other factors for each individual patient, such as concurrent disease and medication. Topical agents can be used for localized skin infections, but they are seldom successful for sites with a thick keratin layer. The palms and soles and certainly the nails and hair often require systemic antifungal treatment. Although they respond well to many topical and systemic antifungal agents, persons who have AIDS often suffer from recurrent episodes of superficial fungal infections. If the disease is chronic and extensive, systemic treatment is required.

Tinea capitis

Topical treatment is ineffective on its own in tinea capitis. Terbinafine 250mg/day and itraconazole 100mg/day are both effective oral treatments for scalp infection. In adults, either agent should be given for 2–4 weeks. Terbinafine is licensed in some countries for use in children and it appears to be a safe and effective agent in this group.[15] In other countries, the older drug griseofulvin must still be used in children. The recommended dose is 10mg/kg/day for at least 6–8 weeks.

Tinea corporis and tinea cruris

The choice of topical or systemic treatment in these conditions depends on the extent of the disease. Localized lesions can be treated with topical antifungal preparations. Numerous imidazoles and allylamines are available in different formulations. These agents should be applied morning and evening for 2–4 weeks. To prevent relapse, treatment should be continued for at least 1 week after the lesions have cleared.

If the disease is widespread or the patient fails to respond to topical preparations, oral treatment is usually indicated. Terbinafine 250mg/day for 2–4 weeks and itraconazole 100mg/day for 2 weeks are more effective than griseofulvin 10mg/kg/day for 4–6 weeks. Unlike itraconazole, oral terbinafine has a low potential for drug interactions, making it a useful agent for the treatment of dermatophytosis in persons who have AIDS and other immunocompromised individuals. Terbinafine has been reported to be a safe and effective drug for tinea corporis and cruris in these patient groups.[16] [17]

Tinea pedis

Tinea pedis is a chronic infection that seldom clears if left untreated. Infection of the webs of the toes will often respond to topical terbinafine, applied morning and evening for 1–2 weeks. Topical imidazoles can also be used, but they are less effective and must be applied for at least 4 weeks.[18] The recurrence rate following

topical treatment is quite high and it is not uncommon for chronic infection to persist despite treatment.

If the disease involves the soles or if there is acute inflammation, oral treatment should be given. Terbinafine 250mg/day for 2 weeks has been shown to be effective in tinea pedis. Itraconazole 100mg/day is an alternative, but it must be given for 4 weeks.[19] Chronic tinea pedis is often associated with nail infection. Inadequate treatment of onychomycosis may result in reinfection of

the feet. Terbinafine has been reported to be a safe and effective drug for tinea pedis in persons who have AIDS.[16] [17]

Tinea manuum

Local treatment with an imidazole or an allylamine will often suffice to clear tinea manuum. In cases that fail to respond to topical preparations, oral treatment is usually indicated. Infections of the palms are difficult to clear with griseofulvin, but oral terbinafine 250mg/day for 2–6 weeks has been shown to be highly effective.[20] Itraconazole 100mg/day for 4 weeks is an alternative.

Candidiasis

Most patients with cutaneous candidiasis will respond to topical treatment with terbinafine or an imidazole such as clotrimazole or micronazole, applied for 2–4 weeks. However, relapse is common if any underlying problem is not controlled. If the infection is associated with an underlying skin disease, such as flexural eczema or diaper dermatitis, treatment with a combination preparation containing an azole agent together with hydrocortisone is often helpful.

Long-term treatment with itraconazole or fluconazole has helped many patients with chronic mucocutaneous candidiasis. However, protracted treatment has led to the development of azole-resistant stains of *Candida albicans* in some cases.[21]

Pityriasis versicolor

If left untreated, pityriasis versicolor will persist for long periods. Most patients with this disease respond to topical treatment with terbinafine, azole agents or selenium sulfide shampoo, but more than half relapse within 12 months. Oral treatment with itraconazole 200mg/day for 1 week is indicated for extensive or recalcitrant lesions. Oral terbinafine and griseofulvin are ineffective.

Seborrheic dermatitis

This is a difficult condition to treat in persons who have AIDS. Milder forms can often be managed with topical ketoconazole 2% cream with or without a topical corticosteroid. Terbinafine cream may also be effective. Patients with inflamed lesions often benefit from topical application of combined hydrocortisone 1% and antifungal drugs. However, relapse is common once treatment is discontinued.

Tinea nigra

Benzoic acid compound ointment or 10% thiabendazole solution can be applied morning and evening for 3–4 weeks. Topical imidazoles are also effective.

Piedra

Black piedra can be treated with a topical salicylic acid preparation or an imidazole cream. However, relapse is common. Shaving or clipping the affected hairs is often sufficient to clear white piedra. To help prevent recurrence, an imidazole lotion can be applied to the scalp after shampooing.

Onychomycosis

Topical agents should only be used where the infection is confined to the distal ends of the nails. Topical applications of tioconazole or amorolfine should be continued for at least 6 months for fingernails and 12 months or longer for toenails.

Oral terbinafine 250mg/day is the treatment of choice for proven dermatophyte infections of the nail (tinea unguium).[22] However, it is not appropriate for *Candida* infections, non-dermatophytic mold infections or mixed infections.[23] The optimum treatment period is 6–12 weeks for fingernails and 3–6 months for toenails. Treatment with terbinafine will also clear any associated skin infection without the need for additional topical treatment. Terbinafine 250mg/day for 3 months has been proven to be effective in the treatment of dermatophyte infections of the nail in persons who have AIDS. No drug interactions or significant adverse effects related to the drug have been reported.[24]

Itraconazole is also licensed for the oral treatment of nail infections at a dose of 200mg/day for 3–6 months. Pulsed treatment with itraconazole (in which 1 week of treatment is alternated with 3 weeks without treatment for 3–4 months) has also been advocated. It is at least as effective as continuous treatment while offering potential improvements in patient compliance and cost-effectiveness. Itraconazole has a broader spectrum than terbinafine and is more appropriate for patients who present with non-dermatophyte or mixed nail infections.[23] However, itraconazole interacts with a number of other drugs and this can limit its usefulness in certain situations. It is not recommended for simultaneous use with protease inhibitors in persons who have AIDS. Fluconazole is not licensed for use in fungal nail disease, but it is sometimes useful in severe *Candida* nail infections.

Oral griseofulvin is only effective in dermatophytosis. It is no longer regarded as a first-line choice for toenail infections, but it works quite well in fingernail infections if given over a 6–9 month period. It must be taken until the affected nail has fully grown out. It should be borne in mind that it has a number of side-effects and can interact with other medications.

Other interventions include chemical dissolution of the nail using 40% urea paste and, in rare instances, surgical removal of the nail. Surgical removal is a painful and disfiguring procedure that should be reserved for cases where there are either contraindications to the use of systemic antifungal agents or a drug-resistant fungus is present.

Chapter 14 - Spotted Fever due to Rickettsiae

Florence Fenollar
Didier Raoult

INTRODUCTION

Rickettsioses are caused by bacteria of the order Rickettsiales, which are Gram-negative micro-organisms that grow only in association with eukaryotic cells.[1] Molecular phylogenic studies based on 16S rRNA analysis have helped to provide a basis for the reclassification of these bacteria. All rickettsiae belong to the family Rickettsiaceae. The genus *Rickettsia* is subdivided into the typhus group, whose members are *Rickettsia typhi* and *Rickettsia prowazekii*; the spotted fever group (SFG), which comprises about 15 different species of bacteria pathogenic for humans; and the scrub typhus group, whose only member is *Orientia tsutsugamushi*, the agent of scrub typhus.[1] The SFG comprises principally *Rickettsia rickettsii*, the agent of Rocky Mountain spotted fever, and *Rickettsia conorii*, the agent of Mediterranean spotted fever.

Rickettsiae are associated with arthropods and are transmitted to humans principally by the bite of infected arthropods or by infected feces. Ixodid or hard ticks are the vectors of most SFG rickettsiae, mites are vectors of *Rickettsia akari* and fleas are the vectors of *Rickettsia felis*. [1] Prior to 1984, only eight rickettsioses were recognized and in the subsequent 13 years, seven new rickettsioses were described. [2] Strains of unknown pathogenicity and new rickettsiae strains have been isolated from arthropods, particularly in ticks, and their roles as human pathogens have yet to be determined.

The four main symptoms that may be observed during spotted fever due to rickettsiae include fever, a rash that is usually maculopapular but can be purpuric or sometimes vesicular, an inoculation black eschar, named 'tache noire', at the site of the arthropod bite, and lymphadenopathies draining this lesion or more generalized.

HISTORY

The Rocky Mountain spotted fever caused by *Rickettsia rickettsii*[2] was first recognized in the 19th century by American Indians in the Bitter Root Valley of western Montana. [3] At the beginning of the 20th century, Ricketts proved that the wood tick, *Dermacentor andersoni*, was involved in the transmission of this disease.

The first case of Mediterranean spotted fever (MSF) was reported in 1910, in Tunisia.[3] In 1925, the inoculation eschar at the site of the tick bite was reported in Marseilles (France). In 1930, the role of *Rhipicephalus sanguineus* was established. In 1932, the causative agent *Rickettsia conorii* was described by Brumpt.[3]

EPIDEMIOLOGY

The main characteristics of spotted fever due to rickettsiae are presented in Table 14.1 .

Rocky Mountain spotted fever (RMSF) is due to *Rickettsia rickettsii*.[1] [4] Most cases are diagnosed during late spring and summer in America. Two to 14 days after a tick bite, the patient presents with high fever, headaches and unspecific symptoms such as nausea, vomiting, anorexia, diarrhea and myalgia. The classic triad of fever, headache and rash is present in only 44% of confirmed cases. The inoculation eschar is very rarely observed. The rash, which is absent in 34% of cases, is macular. The disease can be associated with general manifestations related to increased vascular permeability and can lead to a multiple organ dysfunction syndrome (MODS). This malignant form is particularly observed in old people, in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, and in alcoholics. The clue to the diagnosis is unexplained fever in a patient with a history of tick exposure, in an endemic area. Untreated patients worsen progressively with a high level of mortality (20–25%) when treatment is delayed.

Rickettsia conorii has different but related serotypes; the strain Malish is the most common (Europe and Africa) and the other serotypes are Israel (Israel and southern Europe), Astrakhan (on the Caspian sea) and Indian (India). Many names are given to the infection caused by *R. conorii*, including Mediterranean spotted fever, boutonneuse fever, Marseilles fever, Astrakhan fever, Israeli spotted fever, Indian tick typhus and Kenya tick typhus.

Mediterranean spotted fever is due to *Rickettsia conorii sensu stricto* and is transmitted by the dog tick *Rhipicephalus sanguineus* (Fig. 14.1), which seldom bites humans.[1] Most cases are observed in summer in the Mediterranean area. Approximately 7 days after a tick bite, the typical clinical presentation is that of a patient with fever, a rash and a single inoculation eschar at the site of the tick bite. Rash is observed in 97–99% of cases. It is clearly papular (Fig. 14.2). The inoculation eschar is found in 50–80% of cases. The spontaneous evolution is milder than in RMSF, but a fatality rate of 1% of diagnosed patients is still observed. The malignant form of the disease with shock and MODS occurs in 6–7% of patients. This form is particularly observed in old people, in patients with G6PD deficiency and in alcoholics. Israeli spotted fever, due to *Rickettsia conorii* serotype Israel, is transmitted by *Rhipicephalus sanguineus*. It is clinically very similar to MSF but the inoculation eschar is more rarely observed.[1] The disease, which occurs in Israel, is mild. Astrakhan fever, due to *Rickettsia conorii* serotype Astrakhan, is transmitted by *Rhipicephalus pumilio*. This disease, which occurs in Astrakhan, is very similar to MSF[1] but the inoculation eschar is rarely observed. The spontaneous evolution is mild. Indian tick typhus, due to *Rickettsia conorii* serotype Indian, is transmitted by *Rhipicephalus sanguineus*. This disease has been described in India[5] and is similar to MSF. The rash is frequently purpuric but an inoculation eschar at the bite site is rarely found. The disease is mild to moderately severe.

African tick bite fever, due to *Rickettsia africae*, is transmitted in sub-Saharan Africa by *Amblyomma* spp. It is characterized by a rash in 46% of patients after 1–10 days of incubation. [1] [2] [6] The rash is vesicular in half of the cases. Nearly all patients have an inoculation eschar and 54% have multiple eschars (Fig. 14.3). Eschars are frequently found on lower limbs. The tick vector, typically *Amblyomma*, attacks humans in groups, which explains why grouped cases and multiple eschars are observed. The evolution is much milder than that in MSF. Fever is often absent but draining lymphadenopathy in the groin is frequently observed.

TABLE 14-1 -- Main characteristics of spotted fever due to rickettsiae.

MAIN CHARACTERISTICS OF SPOTTED FEVER DUE TO RICKETTSIAE									
Bacteria	**Disease**	**Vectors**	**Geographic distribution**	**Spotted exanthema**	**Rash specificity**	**Inoculation eschar**	**Multiple eschars**	**Draining adenopathy**	**Current mortality %**
R. rickettsii	Rocky mountain spotted fever	*Dermacentor andersoni Dermacentor variabilis*	North, Central and South America	Yes	Purpuric (half of cases)	Very rare	No	No	2–5%
R. conorii sensu stricto	Mediterranean spotted fever	*Rhipicephaleus sanguineus*	South Europe, Africa, Georgia, Central Asia	Yes	Purpuric (rarely)	Yes	No	Rare	1
R. conorii (Israel)	Israeli spotted fever	*Rhipicephalus sanguineus*	Israel, Italy, Portugal	Yes	Rarely purpuric	No	No	No	<1

R. conorii (Astrakhan)	Astrakhan fever	*Rhipicephalus pumilio*	Caspian Sea	Yes	No	Rare	No	No	No
R. conorii (Indian)	Indian tick typhus	*Rhipicephalus sanguineus*	Indian subcontinent	Yes	May be purpuric	Rare	No	No	Low
R. africae	African tick-bite fever	*Amblyomma variegatum Amblyomma haebraeum*	Sub-Saharan Africa, West Indies	Rare (less than half)	Vesicular	Yes	Yes	Yes	Very low
							(Half of cases)		
R. slovaca	Spotted fever	*Dermacentor marginatus*	Europe	No	-	Yes	No	Yes	No
R. aeschlimannii	Spotted fever	*Hyalomma marginatum*	Africa	Yes	-	Yes	No	Yes	?
R. sibirica	Siberian tick typhus or North Asian tick typhus	*Dermacentor marginatus Haemophysalis concinna*	Central Asia, China	Yes	No	Yes	No	Yes	Low
R. australis	Queensland tick fever	*Ixodes holocyclus*	Australia	Yes	Vesicular	Half of cases	No	Yes	Low
R. honei	Flinders Island tick typhus	Unknown	Thailand, Australia	Yes	-	Yes	No	Yes	Low
R. japonica	Japanese or Oriental spotted fever	*Haemophylasis longicornis, Dermacentor taiwanensis*	Japan, China	Yes	No	Yes	No	No	Low
'R. mongolotimonae'	Spotted fever	*Hyalomma asiaticum*	China, Europe, Africa	Yes	Few spots	Yes	No	Yes	No
R. felis	Flea-borne spotted fever	*Ctenocephalides felis*	USA, Mexico, Europe, Africa	Yes	-	Yes	Possible	Maybe	?
R. akari	Rickettsialpox	*Allodermanyssus sanguineus*	USA, Korea, Eastern Europe	Yes	Vesicular	Yes	Yes	Yes	Low

Spotted fever due to *Rickettsia slovaca*, also named TIBOLA (TIck BOrne LymphAdenopathy), is apparently common in Europe.[1] [2] [7] [8] Its tick vectors, *Dermacentor marginatus* (Fig. 14.4) and *Dermacentor reticulatus*, bite preferentially in cold months and on the scalp as the vectors prefer hairy prey. The disease is more prevalent in children and women, contrary to the other tick-borne rickettsioses. The incubation period is usually 1 week. The inoculation eschar is an erythematous lesion ranging from 2 to 8cm in diameter associated with a neck adenopathy that may be painful (Fig. 14.5). Fever and rash are rarely present. Postinfectious asthenia and residual alopecia at the site of the tick bite have been reported.

Queensland tick typhus, due to *Rickettsia australis*, presents with fever, headache and myalgia.[1] [9] It is transmitted by *Ixodes holocyclus* in Australia. The patients develop a rash, which can be vesicular 10 days after the onset of symptoms. An inoculation eschar is frequently noticed. It is usually mild. Japanese or Oriental spotted fever, due to *Rickettsia japonica*, is transmitted by *Haemophylasis longicornis* and *Dermacentor taiwensis* in Japan but also probably in eastern China. The patient presents with fever, headache, inoculation eschar and a maculopapulous rash.[1] [2] Flinders Island spotted fever, due to *Rickettsia honei*, is a febrile illness associated with an erythematous rash. An inoculation eschar is observed in 25% of cases and locoregional adenopathy in 55%.[1] [2] This disease may also be observed in continental eastern Australia.

Siberian tick typhus is due to *Rickettsia sibirica*, which is transmitted by *Dermacentor marginatus* and *Haemophylasis concinna*. It is found in Siberia and China. After an incubation period of 4–7 days after the tick bite, an ulcerated necrotic lesion appears at

Figure 14-1 Adult *Rhipicephalus sanguineus.*

Figure 14-2 Maculopapular rash in Mediterranean spotted fever.

the inoculation site, often accompanied by regional lymphadenopathy.[1] Fever, headache and myalgias occur and can last for 6–10 days without treatment. The central nervous system is sometimes affected. *Rickettsia mongolotimonae*, related to *Rickettsia sibirica*, is prevalent in *Hyalomma asiaticum* ticks from inner Mongolia (China) and sub-Saharan Africa. Cases of spotted fever caused by this rickettsia have been seen in Marseilles (France). Patients show a discrete rash, an inoculation eschar and satellite lymphadenopathy.[2] [10] [11]

Rickettsia aeschlimannii has been isolated from *Hyalomma marginatum* ticks from Africa. [12] The first human case was recently reported. [12] The disease was described as a typical *Rickettsia conorii* infection in a patient who had traveled to Morocco.

Rickettsialpox or smallpox rickettsia is due to *Rickettsia akari*, which is transmitted by *Allodermanyssus sanguineus*. [1] Seven to 10 days after the mite bite, a vesiculous rash and a painless red papula appear at the inoculation site and become vesicular over the following days. Fever and myalgia are present at the beginning of the disease. A rash appears after 3 days. Even untreated, patients recover spontaneously in 1–3 weeks with no sequelae.

Flea-borne spotted fever is due to *Rickettsia felis*, which is transmitted by cat fleas. *Rickettsia felis* was first detected by molecular biology techniques in 1990 as the ELB agent from the midgut epithelial cells of cat fleas (*Ctenocephalides felis*). The bacterium was isolated in 2000, allowing the development of serologic tests.[13] *Rickettsia felis* has been observed in fleas or patients in the USA, Mexico, Brazil, Ethiopia, Spain, France and Germany. The disease is characterized by fever, rash, headache and central nervous system involvement.[13] [14] [15]

Figure 14-5 Eschar inoculation on the scalp of a patient who presented with *Rickettsia slovaca* infection.

DIAGNOSIS

Clinical features

The usual clinical manifestations of spotted fever are fever, rash and eschar inoculation. The epidemiology is important, with a history of tick or flea bite in an endemic area. Transmission is unlikely when a tick feeds for less than 20 hours. The differential diagnosis of spotted fever includes diseases caused by closely related organisms (*Rickettsia typhi, Rickettsia prowazekii, Orientia tsutsugamushi* and *Ehrlichia*), other bacteria, viruses, parasites (*Toxoplasma gondi*i) or fungi (*Penicillium marneffei*).

Laboratory diagnosis

The leukocyte count is usually normal but leukopenia and leukocytosis can be observed.[3] Thrombocytopenia occurs in 30–50% of cases.[3] Acute phase proteins (C-reactive protein, fibrinogen) are increased. Hepatic enzyme levels (ASAT and ALAT) can be raised.[3] Coagulopathy with a decrease in clotting factors can be responsible for bleeding.

Serology

Currently, the laboratory diagnosis of rickettsioses is based on serology. Two serum samples should be tested (early and convalescent). Samples can be obtained by using blood dried on blotting paper.[16]

The indirect immunofluorescence assay (IFA) is the reference test of choice, and is useful both for diagnosis of acute cases and for seroepidemiology. [17] It can simultaneously detect antibodies to several rickettsial antigens with the same drop of serum in a single well containing multiple dots. The IFA allows the detection of IgG and IgM anti-bodies and is highly specific and sensitive, but requires a fluorescence microscope. This is the reference technique in most laboratories. The early serum is often negative. A cut-off value of 1/64 for total immunoglobulins and 1/32 for IgM is usually required for the diagnosis. Cross-reactive antibodies have been observed with infections caused by the other rickettsioses, *Ehrlichia, Bartonella, Legionella* and *Proteus*. These cross-reacting antibodies, observed between species, appear to be directed against lipopolysaccharide. False positives, including those for IgM, have also been reported when rheumatoid factor is present and in patients with viral infection generating non-specific lymphocyte B proliferation (cytomegalovirus, Epstein-Barr virus) in the serum.

Latex agglutination is a simple and commercially available test that can be used in a non-equipped laboratory but the kit is expensive.[17] Enzyme-linked immunosorbent assay (ELISA) is both specific and sensitive and is useful for seroepidemiology.[17] The immunoperoxidase assay is specific and sensitive, and does not require a fluorescence microscope. [17] It may be used as an alternative to IFA and allows permanent slide records. The Western immunoblot assay, with sodium dodecyl sulfate gel electrophoresed and electroblotted antigens, is especially useful in differentiating true-positive from false-positive results created by cross-reacting antibodies.[17] This technique is the most specific and sensitive serologic test, allowing detection of the earliest antibodies. However, it is time consuming and lacks reproducibility.

Cross-absorption is used to discriminate cross-reacting antibodies between two or more antigens.[17] This technique is performed by mixing separately the serum studied with the bacteria involved in the cross-reaction. The homologous and heterologous antibodies both disappear when absorption is performed with the bacterium responsible for the disease, whereas disappearance of only homologous antibodies is observed when absorption is performed with the antigen responsible for the cross-reaction. This technique is limited by the large amount of antigen needed.

Techniques such as the complement fixation test, which lacks sensitivity, and the Weil Felix test, which lacks specificity, should not be used.

Immunodetection of Rickettsia[1] [17]

In skin biopsies, the bacteria can be detected prior to seroconversion. Biopsy specimens of the skin, preferably petechial lesions and 'tache noire', may be tested using the immunofluorescence and immunoperoxidase techniques performed on frozen or fixed, paraffin-embedded material, allowing a retrospective diagnosis. A positive result can be obtained 2 days after sampling, even for patients with prior antibiotic therapy.

Genomic amplification by polymerase chain reaction

In our laboratory, amplification of the gene encoding outer membrane protein A (*ompA*) and the gene encoding citrate-synthase (*gltA*) is used for the polymerase chain reaction (PCR). Several samples are suitable for use in PCR amplification of rickettsial DNA including skin biopsy specimens and peripheral white blood cells. Suspected arthropods should also be sampled and can be tested by PCR. Skin biopsy testing is probably the best method for early diagnosis before seroconversion. The blood may be collected in tubes containing EDTA or sodium citrate. Sera can also be tested. For this purpose, we recently introduced suicide PCR, which corresponds to a nested PCR using single-use primers.[6] Testing was done in a blinded fashion with one negative control used for every seven samples. All positive PCR products were sequenced for the identification of the pathogenic rickettsiae.

Culture

Culture is restricted to specialized laboratories with biohazard facilities. Currently, cell culture is the method used for isolating rickettsiae from samples.[17] This can be performed from human samples (decanted plasma or skin biopsies) and hemolymph from arthropods. The best sample is a biopsy from the inoculation eschar. Usually, culture of rickettsiae takes 3–7 days. This technique is essential for the identification of new rickettsial pathogens.

TREATMENT

Doxycyline is the treatment of choice for rickettsioses.[18] It can be prescribed in both adults and children[19] but not in pregnant women and allergic patients. Prognosis

depends on early antibiotic treatment and it should be prescribed in any suspected cases. The usual dosage is 100mg twice a day. The treatment should be given orally. The exact treatment duration is not fully determined but treatment should continue for 2–3 days after defervescence. In MSF, a single dose of 200mg of doxycycline is adequate. In pregnant women, chloramphenicol is the only available treatment for RMSF and the macrolide josamycin has been used successfully for MSF. Several antibiotics are effective in vitro against *Rickettsia rickettsii*, including rifampin (rifampicin), fluoroquinolones and new macrolides (except erythromycin) but clinical experience is lacking except for MSF, where quinolones and newer macrolides give results comparable to those with doxycycline but with longer regimens.[20] ß-Lactams, antibiotics, aminoglycosides and trimethoprim-sulfamethoxazole are ineffective in vitro and in vivo.

PREVENTION

Prevention is based on the avoidance of tick and flea bites. Repellents and/or protective garments can be used. After a possible exposure, people could be checked for ticks, with careful examination of axilla, groin and scalp. The tick can be removed by forceps followed by skin disinfection.

CONCLUSION

The diagnosis of rickettsioses must be suspected on the basis of clinical symptoms and epidemiology. The current diagnosis is frequently based on serology. The only exception is infection due to *Rickettsia slovaca* in which the serologic response is weak, perhaps because it does not cause a general infection. Polymerase chain reaction of a skin lesion or a lymph node aspirate gives an earlier positive test. The appropriate treatment should be started without waiting for laboratory confirmation.

Chapter 15 - Practice Points

15.a Approach to the acutely febrile patient who has a generalized rash

Edmund L Ong

Introduction

In assessing patients who have fever and rash, the following four points are essential.

¦ Is the patient well enough to give a further history?
¦ Is immediate cardiorespiratory support required?
¦ From the nature of the rash, does the patient require isolation precautions?
¦ Is immediate empiric antimicrobial therapy required?

The history obtained should give the following information:

¦ drugs taken within the past month,
¦ geographic itinerary of travel,
¦ immunizations,
¦ occupational exposure,
¦ sexually transmitted disease exposure and risk factors for HIV,
¦ the immunologic status of the patient,
¦ whether the female patient is pregnant
¦ any history of valvular heart disease,
¦ recent exposure to other ill febrile patients,
¦ exposure to wild or rural habitats and wild animals,
¦ exposure to domestic animals,
¦ prior medical history including allergies, and
¦ sun exposure.

Pathogenesis

Virtually any class of microbe can induce a local skin rash with fever if the microbes are allowed to penetrate the stratum corneum. The systemic effects of micro-organisms on the skin, however, can also produce cutaneous eruptions by:

¦ multiplying in the skin,
¦ toxin-mediated effects,
¦ inflammatory responses, and
¦ altering the vasculature of skin.

Microbiology

The range of organisms causing systemic infections with prominent cutaneous manifestations is described in Table 15a.1 (see Chapter 8 , Chapter 9 , Chapter 12 and Chapter 14). There are other noninfectious causes of fever with a generalized rash and these need to be borne in mind.

Clinical features

Physical examination should include the following:

¦ vital signs,
¦ general appearance,
¦ signs of toxicity,
¦ evidence of adenopathy,
¦ presence of mucosal, genital or conjunctival lesions,
¦ presence of hepatosplenomegaly,
¦ evidence of arthropathy, and
¦ signs of meningismus or neurologic dysfunction.

The rash should be assessed with regard to:

¦ its distribution,
¦ its pattern of progression,
¦ the timing of its development relative to the onset of illness and fever (Table 15a.2), and
¦ its characteristics.

The morphology of skin lesions includes macules, papules, plaques, nodules, vesicles, bullae and pustules. Skin lesions are also characterized by their color and particularly by the presence or absence of hemorrhage. Lesions may also be hyperpigmented or hypopigmented. Blanching erythematous lesions are due to vasodilation, whereas nonblanching erythemas may be due to extravasation of blood. Purpuric lesions are hemorrhages into the skin and they may be small, petechial or large and ecchymotic. Lesions of erythema multiforme usually begin as round or oval macules and papules that vary in size and have central erythema surrounded by a narrow ring of normal skin, which is also surrounded by another thin ring of erythema to form target lesions. Most cases are idiopathic, but the common infective causes are shown in Table 15a.3 . The lesions of erythema nodosum are characterized by tender, erythematous nodules that vary in diameter from 1cm to several centimeters. Infectious agents are a major cause of this lesion (Table 15a.4).

Investigations

Establishing the microbiologic diagnosis is of great importance in managing the patient. Blood cultures should form part of the essential investigations, along with full blood count and differential white cell count, liver function tests and renal function tests. Skin lesion aspirates or biopsy should be considered, particularly for the identification of meningococcal, staphylococcal and gonococcal infections. A punch biopsy of the maculopapular skin lesion of disseminated candidemia is sometimes diagnostic. Occasionally, a Gram stain of a routine buffy coat may reveal the responsible organisms (e.g. staphylococci, meningococci or *Candida* spp.) in a

septic patient. Isolation of the causative organisms may be difficult, particularly with viruses and some bacteria. Serologic methods (e.g. serologic test for syphilis, paired viral complement fixation tests), molecular techniques (e.g. polymerase chain reaction for dengue fever virus, cytomegalovirus and HIV) and immunofluorescence microscopy are useful methods for establishing the difficult culturable organisms.

15.b Management of foot ulcer

Sanjeev Handa

Introduction

Foot ulceration is a relatively common problem in clinical practice and one that sometimes poses difficult diagnostic and therapeutic dilemmas. Major complications are infection and, in more severe cases, the development of dry and wet gangrene. In certain cases making a determination of superinfection versus colonization can try even the most astute clinician.

Pathogenesis

The pathogenesis depends on the type and etiology of foot ulcer. The differential diagnosis includes:

¦ ischemic arterial ulceration;
¦ venous ulceration, due to increased venous hydrostatic pressure causing local edema, with its low exchange of oxygen and metabolites; edematous tissue, particularly skin, is more vulnerable to trauma than healthy tissue and is far less able to combat infection;
¦ neuropathic ulcers caused by diabetes, tabes dorsalis, leprosy, syringomyelia or hereditary sensory (radicular) neuropathy; the protective pain sensation is ablated, resulting in loss of awareness of trauma, which can cause further deterioration of the ulcer;
¦ vasculitis; and
¦ infection, including acute pyogenic infections, tuberculous infections, tropical ulcer (chronic phagedenic ulcer secondary to Vincent's organisms), syphilis and yaws.

Clinical features

The ischemic arterial ulcer is typically located on the toes, heel, dorsum of the foot or lower third of the leg. The pain is severe and

persistent and worsens at night. The ulcer is generally 'punched out' with a pale or necrotic base.

Venous ulcers are located in the 'gaiter' distribution around the ankle, especially around the medial malleoli. They are less painful, more diffuse and shallow and usually have some evidence of granulation tissue at the base.

Diabetic ulcers are usually located in the plantar or lateral aspect of the foot. They resemble arterial ulcers morphologically but are characteristically painless. Diabetic neuropathy (sensory, motor and autonomic), microvascular and macrovascular lesions, and diminished neutrophil function all conspire to generate diabetic foot ulcers.

Diabetic foot ulcers may be classified under Wagner's grades as follows.

```
Grade 0     No ulcer in a high-risk foot
Grade 1     Superficial ulcer involving the full skin thickness but
            not the underlying tissues
Grade 2     Deep ulcer, penetrating down to the ligaments and
            muscle but not involving the bone and no formation
            of an abscess
Grade 3     Deep ulcer with cellulitis or abscess formation, often
            with osteomyelitis
Grade 4     Localized gangrene
Grade 5     Extensive gangrene involving the whole foot
```

All ulcers may become secondarily infected. Features of infection range from minimal cellulitis with lack of systemic toxicity to extensive cellulitis with associated lymphangitis, purulent drainage, sinus tract formation, osteomyelitis, septic arthritis, abscess formation and sometimes the development of gangrene. Systemic signs and symptoms often occur late and suggest severe infection.

Infected ulcer — diagnosis

A peripheral blood count may demonstrate a leukocytosis (this may be absent in severe cases, especially in diabetes); the erythrocyte sedimentation rate is usually raised. Blood cultures may be positive, especially if the patient is febrile and has not received prior antibiotic treatment.

Obtaining a swab culture of the ulcer itself is an unreliable means of establishing the causative organism(s) in superinfected ulcerations. Ulcers are typically colonized by a multitude of organisms that may or may not be pathogenic. Deep tissue cultures that avoid contact with the ulcer surface or other draining lesions are preferable. In osteomyelitis, bone cultures obtained by percutaneous biopsy or surgical excision are the best specimens for determining the etiology provided the incision site is away from the ulceration itself.

Plain radiographs of the affected area are useful in determining the presence of foreign bodies or air in the soft tissues, which may suggest the presence of gas-forming bacteria. Computerized tomography scanning and magnetic resonance imaging are useful for looking for abscesses as well as early osteomyelitis. The performance of technetium bone scanning for the diagnosis of osteomyelitis in the impaired foot is poor and a 24-hour indium-111 leukocyte scan is more sensitive than a bone scan in diagnosing osteomyelitis associated with a diabetic foot. However, this test is expensive and it may be difficult to interpret in the presence of local soft tissue inflammation (Chapter 52).

Microbiology

Mild ulcers may be infected by single organisms. Organisms frequently involved include:

¦ *Staphylococcus aureus*,
¦ *Streptococcus pyogenes*, and
¦ facultative Gram-negative bacilli and anaerobic organisms (which are isolated infrequently).

Severe ulcers, especially the diabetic foot, are usually polymicrobial with aerobic and anaerobic bacterial isolates, including:

¦ *Staph. aureus*,
¦ coagulase-negative staphylococci,
¦ aerobic streptococci and enterococci,
¦ Enterobacteriaceae (e.g. *Escherichia coli, Klebsiella* spp. and *Proteus* spp.),

- *Pseudomonas* spp.,
- *Corynebacterium* spp.,
- *Bacteroides* spp., and
- *Clostridium* spp.

Therapy

Antibiotics are the mainstay of treatment (Chapter 9) and are recommended in the presence of a surrounding cellulitis, a foul-smelling lesion, fever or deep tissue infection. Empiric antibiotics are necessary until culture results are available (see Table 15b.1).

The optimal duration of therapy is unclear; however, for infections that are limited to soft tissue, intravenous therapy may be administered for 7–10 days followed by oral therapy for an additional 14 days. For those in whom osteomyelitis is identified, a minimum of 6–8 weeks' parenteral therapy is recommended if the offending tissue is not removed in its entirety (Chapter 52). Limb-threatening infections require immediate hospitalization, bed rest and a strict non-weight-bearing regimen, even if signs and symptoms of systemic infection are absent. Although medical stabilization, metabolic and glycemic control (in diabetic patients) and antimicrobial therapy are important, debridement should not be delayed. Failure to debride necrotic, infected tissue and to drain purulent collections increases the risk of amputation. The initial debridement must be performed

TABLE 15.b-1 -- Selected empiric antimicrobial regimens for infected foot ulcers.

SELECTED EMPIRIC ANTIMICROBIAL REGIMENS FOR INFECTED FOOT ULCERS	
Non-limb-threatening infection	
Oral regimen	Cephalexin
	Clindamycin
	Dicloxacillin/flucloxacillin
	Amoxicillin-clavulanate
	Quinolones
	Metronidazole
Parenteral regimens	Cefazolin
	Oxacillin or nafcillin
Limb-threatening infection	
Oral regimen	Clindamycin or metronidazole with a quinolone
Parenteral regimens	Ampicillin-sulbactam with or without an oral quinolone or aminoglycoside
	Ticarcillin-clavulanate with an oral or parenteral quinolone or aminoglycoside
	Piperacillin-tazobactam with an oral or parenteral quinolone or aminoglycoside
Life-threatening infection	
Parenteral regimens	Imipenem-cilastatin
	Meropenem
	Ertapenem
	Vancomycin, metronidazole with either aztreonam or quinolone
	Piperacillin-tazobactam with an oral or parenteral quinolone or aminoglycoside
Note that if methicillin-resistant *Staphylococcus aureus* is a concern, then vancomycin or linezoid should be included in the regimen.	

independently of the status of the arterial circulation and revascularization should be postponed until sepsis is controlled (Chapter 10).

It should be noted that definitive management of the ulcer will require treatment of the underlying cause. For example, up to 60% of diabetic patients with nonhealing ulcers have associated arterial insufficiency. Therefore, the arterial circulation must be critically evaluated in all diabetics presenting with a foot ulcer. Once the ulcer has healed, a lifelong program of proper footwear, education and close follow-up for routine callus and nail care must be maintained. In addition, the tetanus vaccination status must be ascertained in all patients presenting with ulceration or infection.

15.c Role of hyperbaric oxygen in the management of gas gangrene

Athena Stoupis

Introduction

Gas gangrene (clostridial myonecrosis) is one of the most serious limb-threatening and possibly life-threatening infectious diseases (see Chapter 10). It may occur as a complication of surgery or trauma or it may occur spontaneously. Rapid surgical decompression and excision of necrotic tissue along with antibiotic therapy have been the mainstay of treatment. Over the past 30 years, the use of hyperbaric oxygen (HBO; 100% oxygen at two to three times the atmospheric pressure at sea level) as an adjunct therapy has demonstrated diminished mortality rates and diminished tissue loss. However, its use remains controversial, given the paucity of controlled clinical trials that have examined the specific efficacy of this modality.

Pathogenesis

Clostridial myonecrosis occurs when the oxygen tension (PO_2) of a necrotic wound is low, allowing the germination of clostridial spores and subsequent release of lethal toxins, which initiate the fulminant phase of hemolysis, loss of local host defenses and tissue necrosis.

Over 20 exotoxins are produced by *Clostridium perfringens*. The most virulent toxin appears to be the a-toxin. A tissue PO_2 of 250mmHg inhibits the production of a-toxin in vitro. Tissue oxygen levels of 300–400mmHg have been measured in patients during HBO therapy at two atmospheres. Once toxin production is halted, the disease cycle is broken and clinical improvement follows. Some investigators have shown direct inhibition of *Clostridium perfringens* in vitro by HBO therapy.

In addition, HBO increases the oxygen supply to the surrounding tissues of the wound, allowing normal phagocytosis and free radical formation by granulocytes, further assisting in the tissue repair process.

Low tissue oxygen tension levels reduce collagen synthesis. An increased oxygen supply enhances the rate of collagen synthesis and wound healing. Finally, although hyperoxia initially reduces the rate of capillary growth, a sharp increase in angiogenesis follows within the first 24 hours of oxygen therapy, allowing migration of cells into the previously hypoxic areas and further tissue proliferation.

Microbiology

Clostridium spp. are Gram-positive, obligate anaerobic organisms. They are widespread in the environment and can be cultured from soil, clothing and the intestinal flora of humans.

Clostridium perfringens is the most commonly isolated organism in gas gangrene (80–95%). Other organisms less commonly implicated as the cause of gas gangrene include *Clostridium novyi* (10–40%) and *Clostridium septicum* (5–20%; Chapter 232).

Clinical features

The incubation period of gas gangrene is usually less than 24 hours. The most significant clinical sign is intense pain that is out of proportion to the pain usually associated with the preceding injury or surgical procedure (Table 15c.1). The patient rapidly becomes ill with fever, tachycardia, hemodynamic compromise and change in mental status.

Tense 'woody hard' edema in the vicinity of the wound develops. Bullae and vesicles may appear. Putrid serosanguinous drainage may develop in the overlying skin blebs and often drains from open wounds. Crepitus may develop, but is a late sign of true gas gangrene.

Investigations

Early diagnosis is critical and is usually based on the clinical appearance of the patient. Demonstration of Gram-positive rods in the wound exudate gives rapid microbiologic identification that can be confirmed on subsequent anaerobic wound cultures. Blood cultures are usually negative and may not be helpful in establishing the diagnosis. Computerized tomography scanning may show involvement of muscle and fascial planes.

Management

Early initiation of antibiotic therapy and rapid surgical decompression and removal of necrotic tissue are essential for a favorable outcome.

There is no consensus over the timing of adjuvant HBO therapy in relation to surgical intervention. The paucity of controlled randomized clinical trials for the use of HBO in gas gangrene has created controversy among investigators. Several studies have indicated that the combination of surgery, antibiotics and antecedent HBO therapy have reduced morbidity and mortality rates from 80–90% to 20–30% in both human and animal models.

In one study, a dog model of clinical gas gangrene infection was used. All of the infected controls and dogs randomized to surgery alone or HBO therapy alone died. Survival was 50% with antibiotics alone, 70% with antibiotics and surgery, and 95% with the combination of antibiotics, HBO therapy and surgery.

TABLE 15.c-1 -- Clinical findings in acute gas gangrene.

CLINICAL FINDINGS IN ACUTE GAS GANGRENE
Severe soft tissue pain
Disproportionate tachycardia
Skin changes (bullae, bronze discoloration)
Gram-positive rods found on tissue smears
Demonstrable myonecrosis and gas formation in imaging studies

However, in human studies, the efficacy of HBO therapy was often determined retrospectively and the inclusion criteria for some of the cases were variable. Some investigators also argue that the large medical centers that have HBO chambers readily available also provide aggressive surgical and intensive care support, which may have an impact on morbidity and mortality rate.

However, most investigators advocate that HBO therapy before surgery because of the following potential benefits:

- clearer demarcation of the borders between viable tissue and devitalized tissue, permitting more conservative tissue debridement; and
- substantial improvement and stabilization of the severely ill patient before surgery, with inhibition of toxin production.

Others advocate that surgery is indicated before HBO therapy, given the fulminant, life-threatening course of gas gangrene and the need for rapid debridement of necrotic tissue. Most clinical experience is weighted toward antecedent HBO therapy.

Surgical debridement should not be delayed when a HBO chamber is not readily available. Arrangements should be made for transfer to the appropriate institution that can provide HBO therapy after initial surgical debridement. If fasciotomy is indicated for relief of compartment syndrome, then it should be performed before HBO therapy.

To be effective, HBO must be inhaled directly through the atmosphere, through an endotracheal tube in a monochamber, or through tight-fitting masks or hoods or endotracheal tubes in a multiple occupancy chamber. For HBO, pressure is expressed in multiples of the atmospheric pressure at sea level, which is 1 atmosphere (760mmHg).

The standard HBO therapy protocol consists of multiple early treatment sessions administered at 3 atmospheres for 90 minutes or 2.5 atmospheres for 120 minutes. Three treatments are given during the first 24 hours, then 2 treatments per day for an average of 7 chamber treatments.

Complications of hyperbaric oxygen therapy

The most common complaint during HBO treatment is the experience of ear or sinus pain (Table 15c.2). Persistent pain may require myringotomy. Patients who have sinus infection also require nasal decongestants to avoid barotrauma.

Generalized seizures have also occurred with oxygen toxicity and are usually controlled with anticonvulsants. During the immediate seizure episode removal of the oxygen mask may promptly terminate seizures. Patients may also develop transient myopia, the cause of

TABLE 15.c-2 -- Complications of hyperbaric oxygen therapy.

COMPLICATIONS OF HBO THERAPY
Air embolism
Combustion
Confinement anxiety
Ear or sinus pain
Generalized tonic-clonic seizures
Pneumothorax
Transient myopia
Tympanic membrane rupture

which is unknown. It is usually reversible within 2 months of completing therapy.

Another significant side-effect is the development of tension pneumothorax secondary to barotrauma. Immediate recompression with the placement of a chest tube is required.

Claustrophobia is also a common side-effect. Many patients require tranquilizers for relief of their confinement anxiety.

Complications of HBO therapy used for gas gangrene treatment are fortunately rare with the use of relatively low oxygen pressures (2–3 atmospheres) and with the short duration of HBO treatments.

15.d Managing the patient with recurring skin infections

Stephen T Green
Ravi Gowda
Ben Clark

Background

Skin infections come in many forms. Most commonly, troublesome skin infections is synonymous with cellulitis, an entity that perfectly illustrates the cardinal signs of inflammation. Cellulitis is therefore an acute, usually noncontagious inflammation of the connective tissue of the skin, resulting from bacterial infection and characterized by localized warmth, erythema, pain and tenderness, swelling and reluctance to mobilize the affected area (Fig. 15d.1). When such a problem is recurrent, this can become extremely tiresome and even disabling for the afflicted individual.

Cellulitis is usually consequent upon a break developing in the skin surface or its appendages, such as a laceration, cut, fissure, puncture wound, insect bite, animal or human bite, scratch, abrasion, blisters or friction burn, such as might occur with shoes that are too tight. Organisms normally confined to the skin surface are admitted to the dermis where they proliferate and lead to cellulitis.

Recurrent cellulitis

Recurrent cellulitis implies that factors facilitate the recurrent entry of organisms into the dermis. Effective management of recurrent cellulitis involves identifying these factors and, if possible, remedying them. Recurrent cellulitis may cause local persistent lymphedema, resulting in permanent hypertrophic fibrosis.

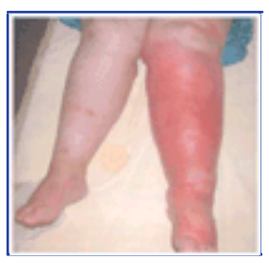

Figure 15.d-1 Severe recurrent cellulitis associated with obesity.

With respect to location, most often it is the lower limbs that are involved in recurrent cellulitis. The site may be the arm if, for example, the patient has received radiotherapy to the axillary area as part of breast cancer treatment. Other sites, such as the vulva and perianal region (sometimes in association with *Enterobius vermicularis*) can also be problematic.

To make matters more complex, cellulitis of the lower extremities is more likely to be complicated by thrombophlebitis in elderly patients, which in turn can encourage recurrence of cellulitis.

A number of clinical scenarios and risk activities render patients particularly vulnerable to recurrent episodes of cellulitis. These include:

¦ tinea pedis or onychomycosis;
¦ diabetes mellitus — there may be a family history;
¦ peripheral vascular (arterial) disease — there may be a history of smoking, angina pectoris or hypertension;
¦ ischemic or venous ulceration of the skin (including sickle cell disease);
¦ post-deep venous thrombosis;
¦ eczema and dermatitis;
¦ immunodeficiency states, for example patients with HIV infection (who may be more prone to recurrent staphylococcal skin sepsis), neutropenia (granulocytopenia), Job's syndrome (hyper IgE syndrome with recurrent staphylococcal cellulitis) or use of immunosuppressive or corticosteroid drugs — always establish the medication history;
¦ lymphatic obstruction, for example post-radiotherapy (e.g. post-mastectomy), post-block dissection of lymph nodes for cancer (Fig. 15d.2), elephantiasis (e.g. due to infections *by Wuchereria bancroftii*, *Brugia malayi*, *Onchocerca volvulus*) or Milroy's disease;
¦ scar cellulitis (e.g. previous burn or skin graft sites and in areas from which veins were harvested for coronary artery bypass grafting);
¦ trauma related, for example cosmetic piercings (studs, rings), injecting drug users, recurrent localized trauma, self-harm or Munchausen's syndrome;
¦ nasal carriage of staphylococci;
¦ lepromatous leprosy;
¦ underlying occult osteomyelitis;
¦ very poor personal hygiene (e.g. associated with alcoholism); and
¦ morbid obesity — largely associated with recurrent lower limb cellulitis (Fig. 15d.1).

Figure 15.d-2 Severe recurrent cellulitis in a lymphedematous leg following radical surgery for rhabdomyosarcoma.

Microbiology

In immunocompetent individuals, cellulitis is usually the result of Gram-positive aerobic cocci, particularly *Staphylococcus aureus* and *Streptococcus pyogenes*, or sometimes a combination of both. It can be clinically difficult to decide which of them is causing the problem.

Non-group A streptococci, particularly groups B, C and G, are sometimes implicated in cellulitis, occurring in patients with lymphatic obstruction, or post-vein harvesting for coronary artery bypass grafting.

Recurrent cellulitis due to streptococci may be seen in association with chronic lymphedema (e.g. from lymph node dissection, post-irradiation, Milroy's disease, elephantiasis).

Neutropenic patients may develop cellulitis due to other organisms, such as Gram-negative bacilli (e.g. *Proteus, Serratia, Enterobacter* spp.) and fungi (e.g. *Cryptococcus neoformans*).

Other organisms may be involved as part of a mixed picture, depending upon the source of the organisms. Incontinent patients may contaminate their lower limbs with urine and feces while injecting drug users can inoculate their own tissues (Fig. 15d.3) with a variety of organisms from contaminated needles. Patients whose cellulitis

is the result of deliberate self-harm may also yield multiple organisms on culture — this is an extremely difficult diagnosis to make and requires the highest levels of clinical acumen. For example self-inoculation with milk has been reported as the cause of recurrent cellulitis.

Figure 15.d-3 Injecting drug user with severe recurrent cellulitis of the left arm.

Is it really cellulitis?

Sometimes the apparent recurrent cellulitis problem may not in fact be cellulitis, and the following should be considered:

- acute gout can resemble recurrent cellulitis and certain diuretics may predispose to gout;
- recurrent deep venous thrombosis;
- migratory necrolytic erythema associated with underlying neoplasia, particularly glucagonoma of the pancreas;
- inflammatory carcinoma of the breast, which produces a picture of localized cellulitis unresponsive to antibiotics;
- herpes zoster, which can cause recurrent rash that may be complicated by superinfection;
- erythema nodosum, especially if it recurs;
- palmoplantar pustulosis and pyoderma gangrenosum, such as that associated with inflammatory bowel disease, can be mistaken for cellulitis;
- scurvy and pellagra; and
- fixed drug eruptions.

Assessment and diagnosis

Unless pus has formed or an open wound is present, it is often difficult to isolate the responsible organism from a case of cellulitis. Aspiration of material from the advancing edge of the lesion, skin biopsy and blood cultures yield potential pathogens in only about 25% of cases. The etiology of most cases of cellulitis will usually be *Staphylococcus aureus* and *Streptococcus pyogenes*.

In unusual circumstances, such as patients who are immunocompromised or those not responding to empiric therapy, or indeed whenever the clinical history points toward other infective or noninfective diagnostic options, further investigations may be warranted. This may become particularly important where the patient is suffering recurrent attacks. For example, among those with peripheral vascular disease or diabetes mellitus, minor injuries or cracked skin in the feet or toes can serve as an entry point for recurrent infection.

Attention should accordingly be directed toward establishing the presence or absence of factors that might be supporting the development of recurrent cellulitis and might be amenable to correction. The following range of tests can be applied selectively according to circumstances:

- microbiologic — samples for microscopy, Gram staining, culture and sensitivity, swabs from areas of abscess or bullae formation, needle aspiration of the advancing edge of cellulitis, full skin biopsy, interdigital skin and/or nail scrapings (especially where tinea pedis is present), blood culture (positive in only a few patients), nasal swabs (especially for *S. aureus* carriage, including methicillin-resistant *S. aureus* (MRSA)), perianal cellophane tape (for *Enterobius* ova), throat swab (for *S. pyogenes* in those with erythema nodosum) and bullous fluid (for immunofluorescence antibody test for varicella zoster);
- imaging — tissue scanning (plain radiographs, ultrasound, computerized tomography scanning, magnetic resonance imaging and indium leukocyte scanning) may identify collections of pus meriting drainage, foreign bodies or underlying osteomyelitis (if gas is seen in the tissues, the differential diagnosis then includes gangrene and fasciitis, which are generally considered to be surgical emergencies), Doppler scans (which may assist in identifying deep venous thrombosis or peripheral arterial disease);
- hematologic and immunologic — blood films (macrocytosis associated with alcohol excess and microfilaria in suspected filariasis), differential white cell count (to identify neutropenia, eosinophilia, e.g. in filariasis), hemoglobin electrophoresis in sickle-cell disease, immunoglobulin levels and subsets, complement levels, T-cell subsets;
- serology — HIV-1 and HIV-2, antistreptolysin titer (may point toward erythema nodosum as the diagnosis), hepatitis C, hepatitis B (may point toward occult injecting drug abuse), filariasis, onchocerciasis if patient is at risk;
- biochemistry — blood glucose studies (to exclude diabetes mellitus including hemoglobin A_{1C}), urate levels, liver function tests; and
- skin biopsy — may help with rarer causes of cellulitis.

Management

Managing the acute phase of recurrences

Tissue penetration sufficient to achieve adequate local antibiotic concentrations can be problematic. For acute exacerbations, intravenous therapy may therefore be necessary. Useful combinations include (flucl)oxacillin-benzylpenicillin, (flucl)oxacillin-amoxicillin and clindamycin-ciprofloxacin.

Other antibiotics may be indicated, depending upon the clinical scenario:

- where allergy to ß-lactam drugs is an issue — macrolides, levofloxacin, or moxifloxacin;
- where MRSA is an issue — doxycycline, rifampin (rifampicin), linezolid, or vancomycin; and
- where anaerobes are an issue — metronidazole or clindamycin-dalfopristin.

Surgical care includes debridement of devitalized tissue. Incision and drainage may be indicated if suppuration occurs. Treat the local effects of the cellulitis by elevating the affected limb.

Prevent recurrences

Adequate patient education and training are essential.

Skin and foot care for tinea pedis and onychomycosis includes:

- patient training regarding proper skin hygiene and suitable footwear;
- treating affected toe webs or feet with topical antifungals;
- consideration of oral antifungals such as itraconazole or terbinafine for severe chronic tinea pedis or onychomycoses; and
- expert podiatry — cuts and fissures should be washed and kept clean while healing.

For cases caused by edema treat any underlying cause (e.g. cardiac failure) and relieve edema using support stockings, specialized bandaging and nocturnal elevation of the affected area. Diuretics may have a role.

There is no convincing evidence for the value of antibiotic prophylaxis and there is a risk of antibiotic resistance. Penicillin, erythromycin and clindamycin have all been

advocated. Early institution of antibiotics may help in cellulitis of the lower extremities. The patient must be trained to spot the early signs of a recurrence, and given a supply of antibiotics (such as amoxicillin or flucloxacillin) to take. They should be advised to seek medical advice as soon as possible.

Nasal carriage of *S. aureus* can be treated with mupiricin if it is thought to be associated with recurrent disease.

Conclusion

Recurrent cellulitis is responsible for much morbidity. Diagnosis is not always straightforward and it presents a significant management challenge.

Chapter 16 - Generalized and Regional Lymphadenopathy

Bina Rubinovitch
Itzchak Levi
Ethan Rubinstein

INTRODUCTION

The lymph nodes are major components of the body's surveillance system against foreign invaders; they function as a filter to trap micro-organisms, cancerous cells and immune complexes. The lymphoid system grows rapidly during childhood and achieves twice the adult size by early adolescence. Although lymphoid tissue begins to regress during mid-adolescence, it does not reach adult maturity until the age of 20–25 years. Peripheral lymphadenopathy, therefore, is a common finding throughout late childhood, adolescence and young adulthood.[1] Lymphadenopathy (i.e. disease of lymph nodes) may be due to primary lymphoproliferative diseases as well as to secondary reactive (infectious and noninfectious) or infiltrative diseases. Table 16.1 summarizes the differential diagnosis of lymphadenopathy. Lymphadenopathy occurring in returning travellers is discussed in Chapter 152 .

EPIDEMIOLOGY

In children, the cause of lymphadenopathy is clinically apparent in most cases. In approximately 80% of cases it is benign, reactive and most commonly due to an infectious cause. In contrast, lymphadenopathy in adults more often reflects serious disease. The probability of neoplasm affecting enlarged peripheral lymph nodes increases steadily with age; in those older than 50 years, more than 60% of cases of lymphadenopathy are due to malignancy.[2] [3] In tropical and subtropical parts of the world, lymphadenopathy requires other considerations.

PATHOGENESIS AND PATHOLOGY

Lymph nodes are widely distributed throughout the body, especially at potential portals of entry into the body (Fig. 16.1). The normal lymph node is an oval, encapsulated, soft structure; the size ranges from 1cm to 2cm in diameter. The node contains a reticular network packed with lymphocytes, macrophages and dendritic cells. A single lymph node weighs about 1g and contains approximately 2000 million lymphocytes. The lymph node is a dynamic structure and the exchange rate of lymphocytes between blood and the node is extremely high; lymphocytes equivalent to approximately three times the weight of the lymph node pass into the lymph each hour.[4]

Histologically, the lymph node can be divided into three regions (Fig. 16.2):[5]

- the cortex, which is the outermost layer and is composed mainly of B lymphocytes and macrophages arranged in primary follicles;
- the paracortical region, below the cortex, which is composed mainly of T lymphocytes and dendritic cells; and
- the medulla, which is the innermost region and has fewer lymphocytes than the other regions but more plasma cells that actively secrete antibodies.

Afferent lymphatic vessels empty the lymph drained from the tissues into the subcapsular sinus; from there the lymph flows through the cortex, paracortex and medulla, allowing phagocytic and dendritic cells to trap any foreign material. The efferent lymphatic vessels carry lymph enriched in lymphocytes and antibodies; this lymph reenters the circulatory system.

The lymph node has two main functions:

- it acts as a defensive barrier; and
- it serves as a factory for lymphocyte maturation and differentiation and for antibody production during antigenic challenge.

After antigenic stimulation, the primary follicle enlarges into a secondary follicle, which contains a germinal center in which large proliferating lymphoblasts and plasma cells are interspersed with macrophages and dendritic cells surrounded by packed lymphocytes. The germinal center is a site where B lymphocytes are intensively activated and differentiated into plasma and memory cells. The dendritic cells in the paracortex are rich in major histocompatibility class II molecules and act as antigen presenting cells to T-helper cells, which in turn activate B lymphocytes.

Lymphadenitis

Lymphadenitis (Table 16.2) represents inflammation of the lymph node. The initial response to acute inflammation consists of swelling and hyperplasia of the sinusoidal lining cells and infiltration by leukocytes. The process may progress to abscess formation depending on the micro-organism involved and the host response.

Acutely inflamed nodes are most commonly caused by local trapping of microbes; acute inflammation commonly affects the cervical nodes in association with infections of the teeth or tonsils or the axillary or inguinal nodes in association with infections in the limbs. Generalized acute lymphadenopathy is characteristic of viral infections, bacteremias or diseased caused by exotoxins, as well as a variety of other noninfectious diseases. In acute lymphadenitis the lymph node becomes enlarged owing to cellular infiltration and edema. As a consequence of distension of the capsule, the node becomes tender. Abscess formation causes the node to become fluctuant. Penetration of the infection through the overlying subcutis and skin surface may produce draining sinuses, particularly when nodes have undergone suppurative necrosis. Control of the infection with resolution of the inflammatory changes leads to shrinkage of the node. Nodes resume their former macroscopic and microscopic appearance if the infection has not caused extensive tissue destruction. If severe scarring and fibrosis ensue, nodes may remain firm and palpable.

Chronic lymphadenitis is typically a proliferative response, with either follicular hyperplasia or paracortical lymphoid hyperplasia, depending on the cause of inflammation. Characteristically, the nodes are not tender.[6]

CLINICAL FEATURES

Regional lymphadenopathy

Acute suppurative lymphadenitis

Acute suppurative lymphadenitis is commonly caused by a pyogenic infection. The inflammatory neutrophilic reaction arises due to

TABLE 16-1 -- Differential diagnosis of lymphadenopathy.

DIFFERENTIAL DIAGNOSIS OF LYMPHADENOPATHY

Reactive	**Infectious diseases**
	Viral (e.g. infectious mononucleosis syndrome, rubella)
	Bacterial (e.g. pyogenic, cat-scratch disease)
	Mycobacterial (*Mycobacterium tuberculosis*, atypical mycobacteria)
	Spirochetal (e.g. syphilis, leptospirosis)
	Chlamydial (e.g. lymphogranuloma venereum)
	Fungal (e.g. coccidioidomycosis)
	Parasitic (e.g. toxoplasmosis)
	Noninfectious diseases
	Sarcoidosis
	Connective tissue diseases (e.g. systemic lupus erythematosus)
	Kawasaki's disease
	Rosai-Dorfman disease
	Kikuchi's disease
	Castleman's disease
	Drug hypersensitivity (e.g. to phenytoin)
	Silicone breast implantation
Infiltrative	**Malignant diseases**
	Metastatic carcinoma
	Metastatic melanoma, germ cell tumor
	Leukemia
	Nonmalignant diseases
	Lipid storage diseases (e.g. Gaucher's disease, Niemann-Pick disease)
	Amyloidosis
Primary lymphoproliferative diseases	Lymphoma (e.g. Hodgkin's, non-Hodgkin's)
	Angioimmunoblastic lymphadenopathy
	Lymphomatoid granulomatosis
	Malignant histiocytosis

drainage of bacteria — *Staphylococcus aureus* or group A streptococci — from an infected site. The most common sites of involvement are the submandibular, cervical, inguinal and axillary lymph nodes. The affected lymph node is extremely tender and firm, although it may be fluctuant, and the overlying skin may be red and warm. There are usually systemic manifestations. Acute cervical lymphadenitis due to a pyogenic infection is more common in children than adults. In both children and adults it is commonly due to staphylococcal infections of the face or neck and, uncommonly, it may be a complication of streptococcal pharyngitis. [7] In adults, anaerobic bacteria, of which the predominant species are *Prevotella* spp., *Peptostreptococcus* spp., *Propionibacterium acnes* and *Fusobacterium* spp., are recovered in 30% of cervical lymphadenitis, 13% are anaerobes alone and 17% are mixed anaerobic-aerob bacteria.[8] Acute pyogenic cervical lymphadenitis is unilateral. In contrast, acute bilateral cervical lymphadenitis is commonly due to viral upper respiratory infection, infectious mononucleosis, streptococcal pharyngitis or localized periodontal infections. Acute suppurative axillary lymphadenitis is a severe infection with prominent systemic manifestations and axillary pain that radiates to the shoulder and down to the arm. The axilla, arm, shoulder and supraclavicular and pectoral areas are markedly

Figure 16-1 The human lymphatic system.

Figure 16-2 The lymph node.

TABLE 16-2 -- General histologic correlates of some diseases that cause lymphadenitis.

GENERAL HISTOLOGIC CORRELATES OF SOME DISEASES THAT CAUSE LYMPHADENITIS	
Histologic feature	**Type of disease and examples of causative organism**
Acute suppurative lymphadenitis	Pyogenic infections (*Streptococcus pyogenes*, *Staphylococcus aureus*, *Yersinia pestis*)
Lymphadenitis with caseating necrosis	Tuberculosis (*Mycobacterium tuberculosis*)
	Atypical mycobacteria
Necrotizing granulomatous lymphadenitis	Cat-scratch disease (*Bartonella henselae*)
	Tularemia (*Francisella tularensis*)
	Leishmaniasis (*Leishmania braziliensis*, *L. major*)
	Lymphogranuloma venereum (*Chlamydia trachomatis*)
Non-necrotizing granulomatous lymphadenitis	Histoplasmosis (*Histoplasma capsulatum*)
	Coccidioidomycosis (*Coccidioides immitis*)
	Sarcoidosis

Necrotizing nongranulomatous lymphadenitis	Kikuchi's syndrome
	Systemic lupus erythematosus

edematous, but there are no signs of skin infection or lymphangitis. The portal of entry of the infecting bacteria (group A streptococci or *S. aureus*) is often a traumatic lesion of the arm.[9] Acute suppurative inguinal lymphadenitis due to group A streptococci has been reported in patients infected with HIV with or without chronic lymphadenopathy. Rapidly enlarging lymph nodes may be accompanied by systemic manifestations, including toxic shock syndrome, without obvious genital or skin lesions.[10] [11]

Patients who have chronic granulomatous disease experience recurrent pyogenic infections, of which the most common manifestations are lower respiratory tract infections, suppurative lymphadenitis, subcutaneous abscesses and hepatic abscesses. [12] The infecting pathogens are catalase-positive organisms such as *S. aureus*, *Serratia marcescens*, *Burkholderia* (*Pseudomonas*) *cepacia* and *Aspergillus* spp. The histologic appearance of the lymph node is one of inflammation with granuloma formation and necrosis.[12] [13]

Cat-scratch disease

Cat-scratch disease typically manifests after a cat scratch or bite as regional lymphadenopathy distal to the involved lymph node. The mode of transmission is presumably direct contact with the causative agent, primarily *Bartonella henselae*. The disease occurs worldwide, with healthy children and adolescents being most frequently affected.[14] A history of a trivial cat scratch or a bite by a kitten can

TABLE 16-3 -- Oculoglandular syndromes.

OCULOGLANDULAR SYNDROMES		
Disease	**Infecting organism**	**Features**
Cat-scratch disease	*Bartonella henselae*	Parinaud's sign in 3%
		Conjunctivitis in 6%
Tularemia	*Francisella tularensis*	Parinaud's sign in 5%
Lymphogranuloma venereum	*Chlamydia trachomatis*	Parinaud's sign in <1%
Pharyngoconjunctival fever	Adenovirus 3, 7	Common in children
Epidemic keratoconjunctivitis	Adenovirus 8, 19, 37	Occasionally seen in adults
Chagas' disease	*Trypanosoma cruzi*	Romaña's sign

be elicited in most cases.[15] Rarely, a dog or monkey is implicated. Occasionally, typical cat-scratch disease case can be caused by other pathogenic *Bartonella* sp. (i.e. *Bartonella claridgeiae*).[16]

Tender lymphadenopathy develops within 1–3 weeks after inoculation. Commonly, an erythematous papule at the site of inoculation precedes the development of lymphadenopathy and may last for several weeks. Regional lymph node enlargement is the sole manifestation in one-half of the patients. Most commonly the cervical, axillary or epitrochlear lymph nodes are involved, but any peripheral nodes at multiple sites may be enlarged. In one-third of the patients, low grade fever is present, and about 15% have systemic manifestations such as malaise, headache, splenomegaly and sore throat. Unusual clinical manifestations occur in 10% of patients; the most frequent of these is the oculoglandular syndrome of Parinaud,[15] [17] which is conjunctivitis with ipsilateral preauricular lymphadenitis (Table 16.3). The adenopathy subsides spontaneously within several months. Occasionally, aspiration of a suppurative lymph node is needed to relieve pain.

The diagnosis is based on epidemiologic exposure and can be confirmed by detection of serum antibody to *B. henselae*.[15] Occasional cat-scratch disease cases caused by other pathogenic *Bartonella* may, however, he serologically negative.[16]

In atypical presentations or whenever a neoplastic or mycobacterial process is suspected, a lymph node biopsy or aspirate may be needed. Early in the course of the infection the involved lymph node shows lymphoid hyperplasia; later, granuloma formation with central areas of necrosis give the distinctive histopathologic appearance of necrotizing granulomatous lymphadenitis. The histologic reaction cannot differentiate cat-scratch disease from diseases such as tularemia, lymphogranuloma venereum and fungal and mycobacterial infections. Sometimes, small pleomorphic bacteria can be visualized with the Warthin-Starry silver stain in necrotic foci of early-stage microabscesses. A polymerase chain reaction (PCR) assay for detecting *B. henselae* DNA in clinical specimens has been found to be a sensitive and specific tool,[18] but it is not widely available.

Toxoplasmosis

Acute acquired infection with *Toxoplasma gondii* is common worldwide. The prevalence of seropositivity by the fourth decade of life in the USA is 30–50%, and higher than 90% in certain areas of western Europe.[19] [20] Acute infection occurs primarily in patients in the second to fourth decades of life. In the immunocompetent host the infection is most often asymptomatic. In 10–20% of patients the infection is self-limited, with lymphadenopathy being the most frequent clinical manifestation. In 90% of patients who have clinically apparent infection, regional lymphadenopathy, usually of the head and neck, is the sole manifestation. A single node is usually involved, most commonly a posterior cervical, anterior cervical, axillary or

suboccipital node; occasionally an inguinal node is involved. Retroperitoneal or mesenteric lymphadenopathy may occur and can cause abdominal pain. Cases of toxoplasma hilar lymphadenopathy and unusual sites of lymph nodes such as intramammary,[21] parotid[22] and chest wall (our experience) have also been reported.

On palpation, the lymph nodes are discrete, of varying firmness and may or may not be tender; they rarely suppurate and they do not ulcerate. The histologic appearance is distinctive but may sometimes be confused with lymphoma, cat-scratch disease or Kikuchi's lymphadenitis. Lymphadenopathy is associated with fever, headache, sore throat and myalgia in approximately 15% of patients. Toxoplasmosis may rarely cause a syndrome resembling mononucleosis. In uncommon situations lymphadenopathy may persist or recur for months and pose a diagnostic challenge.[19]

Toxoplasmosis has been estimated to cause between 3% and 7% of clinically significant lymphadenopathy. Of major importance is the diagnosis of infection in pregnant women and the subsequent management of the fetus, and the need to differentiate toxoplasmosis from neoplasia (Hodgkin's and non-Hodgkin's lymphoma and carcinoma). Failure to consider toxoplasmosis in the differential diagnosis frequently results in unnecessary surgical biopsies.[19]

In the immunocompetent host, serologic testing is sufficient for the diagnosis of toxoplasmic lymphadenitis because it occurs almost exclusively as a manifestation of the acute acquired infection. A negative result in the Sabin-Feldman dye test or a comparable test for detecting *Toxoplasma* IgG in the first 3 months practically excludes the diagnosis. Acute infection is likely if elevated IgM antibody titer on enzyme-linked immunosorbent assay is present. In patients who have equivocal IgM antibody results (after 3 months), detection of IgA or IgE antibodies or an acute pattern in the differential agglutination titers may be helpful.[20]

Mycobacterial lymphadenitis

Tuberculous lymphadenitis is the most frequent form of extrapulmonary tuberculosis and in Western countries it accounts for 5% of cases of tuberculosis. [23] In areas where both AIDS and tuberculosis are endemic (e.g. in central Africa), tuberculous lymphadenitis is the presenting sign of tuberculosis in 50% of young children and is often associated with intrathoracic disease; a contact with an index case is often apparent.[24] In the past, *Mycobacterium bovis* was a common cause of cervical lymphadenitis in countries with a high incidence of bovine tuberculosis. [9] Currently, most cases of mycobacterial cervical lymphadenitis are caused by *Mycobacterium tuberculosis* or by atypical mycobacteria, especially *Mycobacterium scrofulaceum* and *Mycobacterium avium* complex (MAC). In the USA an abrupt change in the predominant etiologic agents from *M. scrofulaceum* to MAC was noted in the 1970s.[25] The latter is also seen in children in areas where *M. bovis* has been eradicated and *M. tuberculosis* is rare. Recent reports have documented rare cases of childhood lymphadenitis caused by other mycobacteria (*Mycobacterium interjectum* or *Mycobacterium malmoense*).[26] [27] [28]

Tuberculous cervical lymphadenitis (scrofula) is caused by spread of the infection from the lung, usually by the hematogenous or lymphatic route. When the source of

infection is milk contaminated with *M. bovis*, the primary focus is in the tonsils or the pharynx.

Scrofula most often presents as a unilateral firm, red, painless mass located along the upper border of the sternocleidomastoid muscle or in the supraclavicular area.[27] Occasionally, tuberculous lymphadenitis may be found in the axilla (Fig. 16.3). The process progresses indolently and is usually not accompanied by systemic symptoms. Miliary tuberculosis should be suspected when the lymphadenopathy is generalized, localized outside the cervical chain or accompanied by systemic symptoms.

Figure 16-3 Tuberculous lymphadenitis of the axilla.

In HIV-infected or otherwise immunocompromised patients, the course of the disease is severe, with bilateral lymphadenopathy and systemic symptoms such as fever, night sweats and weight loss. Patients infected with HIV are more likely to develop extrapulmonary disease, often in conjunction with pulmonary tuberculosis. [29]

The diagnosis of mycobacterial lymphadenitis is confirmed by lymph node histology and bacteriology examinations. Fine-needle aspiration reveals the presence of granuloma but only rarely yields positive smears or cultures.[26] Bacteriology and histopathology examinations are complementary diagnostic tools, because *M. tuberculosis* has been cultured from lymph nodes without caseating granuloma and atypical mycobacteria have been cultured from lymph nodes with classic histopathologic appearance for tubercu-losis. Acid-fast bacilli are only rarely seen in smears except in HIV-positive patients, in whom positive smear results are much more frequent because of the high density of organisms. Therefore, a specific culture of aspirated lymph node should be performed routinely. New diagnostic tools such as PCR and hybridization and blotting techniques hold promise for rapid and precise diagnosis (see Chapter 37).

Inguinal lymphadenopathy

Sexually transmitted diseases (STDs) and metastatic genital neoplastic disease are the most common causes of inguinal lymphadenopathy. The differential diagnosis of infectious inguinal lymphadenopathy is shown in Table 16.4 .

Chancroid

Chancroid is caused by *Haemophilus ducreyi* and in some parts of the world (e.g. Thailand) it is one of the most common causes of genital ulcer with inguinal lymphadenopathy. The chancroid ulcer is a painful, nonindurated lesion that appears 1 day to several weeks after inoculation. Inguinal lymphadenitis occurs in between one-third and one-half of untreated cases. The lymph nodes are enlarged, painful and tender. The process is most commonly unilateral and, without treatment, can progress to suppuration with periadenitis and involvement of the overlying skin (bubo). Coinfection

TABLE 16-4 -- Differential diagnosis of infectious inguinal lymphadenopathy.

DIFFERENTIAL DIAGNOSIS OF INFECTIOUS INGUINAL LYMPHADENOPATHY	
Sexually transmitted diseases	**Other diseases**
Syphilis	Pyogenic infections
Lymphogranuloma venereum	Cellulitis
Chancroid	Plague
Genital herpes	Filariasis
Granuloma inguinale	Onchocerciasis

Figure 16-4 Groove sign of lymphogranuloma venereum. There is cleavage of extensive lymphadenopathy by the inguinal ligament.

with other organisms (e.g. herpes simplex virus (HSV) or *Chlamydia trachomatis*) is not uncommon. The differential diagnosis includes other STDs, especially syphilis, herpes simplex and lymphogranuloma venereum, secondary pyogenic infections of traumatic lesions and neoplasia.

Culture provides the definitive diagnosis; however, *H. ducreyi* is a fastidious organism and immediate direct inoculation into specific culture media is required for bacterial growth and isolation. Chemotherapy is sufficient in most uncomplicated cases but abscesses that are more than 5cm in diameter may need surgical drainage.[30] (See also Chapter 78).

Lymphogranuloma venereum

Lymphogranuloma venereum is a rare STD caused by *C. trachomatis* serovars L1, L2 and L3. The typical vesicular lesions appear 1–2 weeks after inoculation but the incubation period varies between 5 and 20 days. The lesions often go unnoticed by the patient. Inguinal lymphadenopathy appears 1–6 weeks after the vesicles disappear. The lymphadenopathy is most commonly unilateral but is bilateral in 30–40% of patients. The nodes are painful and the groove sign (cleavage of the enlarged nodes by the inguinal ligament) is seen in 25% of patients (Fig. 16.4). The involved lymph nodes frequently coalesce to form a bubo. If untreated, the nodes, which are filled with bacteria, rupture and a nonhealing fistula is formed. The anorectal syndrome, which occurs mainly in women and homosexual men, results from involvement of the pelvic lymph nodes. In the male, abscess formation may occur in the dorsal lymphatic of the penis and cause tissue destruction and elephantiasis of the penis. *Chlamydia trachomatis* can be isolated from both blood and aspirates of lymph nodes in approximately 30% of cases. Incision of the bubo is not warranted for diagnosis and positive serologic tests (complement fixation antibody test or microimmunofluorescence test) in the appropriate clinical setting are highly sensitive and specific for the diagnosis.[31] (See Chapter 78).

Syphilis

The lymphadenopathy of primary syphilis is easily differentiated from chancroid and lymphogranuloma venereum because nodes involved in syphilis are firm, only moderately enlarged, nonsuppurative and painless. The classic primary chancre appears 14–30 days after inoculation and is a nonexudative, painless ulcer. In the immunocompetent patient only one chancre appears but in the immunocompromised patient, especially in patients who have AIDS, multiple chancres may be seen. In women and homosexual men, the chancre may be located in the perianal region or in the anal canal. Regional painless lymphadenopathy is characteristic at this stage of disease. The chancre usually heals and disappears after 3–6 weeks, but the lymphadenopathy may persist for longer. The symptoms of secondary syphilis appear 2–8 weeks after the chancre has healed, with generalized lymphadenopathy and various skin lesions in the majority of patients. Epitrochlear lymphadenopathy suggests the diagnosis.[32]

Genital herpes

The typical vesicles associated with inguinal lymphadenopathy usually suggest the correct diagnosis. Rarely, lymph node enlargement may appear before the rash

develops.[33] Herpes simplex virus is the most common cause of genital ulcers in the Western world. The incidence of genital herpes rose in the pre-AIDS era but has been stable in the past decade. Women are reported to have higher rates of infection than men. Both HSV-1 and HSV-2 can cause genital herpes but from epidemiologic studies it is estimated that HSV-2 causes more than 90% of genital herpes. The distinction between the two types of the virus is significant because HSV-1 infection is less severe and is less prone to recur than infection with HSV-2.

Primary herpes genitalis infection is usually more severe than recurrent attacks. Genital lesions begin as macules and papules, followed by vesicles and ulcers that may appear and last for 2–3 weeks. Occasionally, primary infection is accompanied by systemic manifestations such as fever, malaise, aseptic meningitis (in 10% of patients) and extragenital lesions as well as dysuria and painful lymphadenopathy. In women, primary lesions appear on the vulva, with involvement of the cervix. Lesions can also appear in the perineum, vagina, buttocks and perianal region. Urinary retention has been described in 15% of women. In males, the lesions are vesicular and are superimposed on an erythematous base. In homosexual men the lesions may appear on the buttocks and in the anal and perianal areas.

The lymphadenopathy associated with primary herpes is either unilateral or bilateral and in severe cases generalized lymphadenopathy may also occur. Genital lesions and lymphadenopathy are common in genital herpes in the immunocompetent host; however, massive lymphadenitis is frequently seen in the immunocompromised patient. The diagnosis is based on isolation of HSV from a skin lesion, preferably from a vesicle.[34]

Granuloma inguinale

Granuloma inguinale (donovanosis) is caused by *Calymmatobacterium granulomatis*. The disease is rare in the Western world but is a major cause of genital ulcer in southeast India, Brazil and some parts of Africa. The penile papules of granuloma inguinale appear within days of inoculation and rapidly ulcerate to form a red, granulomatous, painless ulcer with a characteristic surface that bleeds easily on contact. Subcutaneous spread into the inguinal region results in swellings (pseudobubos) that are not a true adenitis. Lymphedema and elephantiasis occasionally result from scarring and blockage of the lymphatics. Granuloma inguinale should be differentiated from other genital ulcerative lesions with inguinal lymphadenopathy. The diagnosis is established through the demonstration of the typical intracellular Donovan bodies in stained smears obtained from the lesions.[35] (See Chapter 78 and Chapter 229).

Plague and tularemia

Plague and tularemia are both zoonotic infections that produce similar diseases, mostly fever and regional lymphadenitis.[36] These infections have regained interest after the events of 11 September 2001 as airborne transmission is considered to be a potential biologic weapon.[37] [38]

Plague is caused by *Yersinia pestis*. It is distributed worldwide (with the exception of Europe and Australia). Most human plague is of the bubonic form and is transmitted by the bite of infected fleas. After an incubation period of 2–8 days, patients are affected

by the sudden onset of fever, chills, malaise and headache. Usually at the same time or after a few hours, a painfully swollen regional lymph node appears in the draining area of the inoculation site, commonly in the axilla, neck or groin. The primary lesion is occasionally found at the bite site and may later develop into extensive cellulitis or abscess. Over the next few days, the discrete nodes become matted together to form the characteristic bubo (Fig. 16.5). If untreated, infection spreads hematogenously and results in a 'septic' phase with organ involvement, including secondary pneumonic plague (see Chapter 176).

Diagnosis of plague should be suspected in an acutely ill patient who has an extremely tender cluster of lymph nodes when there has been the appropriate epidemiologic exposure. Isolation of *Y. pestis* from bubo aspirate, blood and any other involved organ is possible but growth is slow and rapid identification of the bacteria is possible by Gram stain or Wayson stain. A patient suspected of having plague should be isolated and treatment should begin immediately. The prognosis is favorable in patients who are treated early.

Tularemia is restricted to the northern hemisphere. Over 80% of infections are acquired by handling infected animals or by tick or deer fly bites. In the USA, cases are mostly sporadic or occur in small clusters; in Eurasia, waterborne, arthropod-borne and airborne outbreaks involving hundreds of persons have been reported. [37]
Infection commonly manifests as ulceroglandular syndrome. The most common portal of entry is the skin, with an ulcer or pustule developing 1–10 days after exposure; regional lymphadenopathy, usually axillary or epitrochlear, follows. The lymph nodes may suppurate. Systemic manifestations are common, but severe endotoxemia as seen in plague is uncommon. The oculoglandular syndrome is seen when the portal of entry is the conjunctiva (as happens when the eyes are contaminated with infected fluids). Conjunctivitis, conjunctival ulcerations and papules on the eyelids appear, and lymph nodes of the head and neck become inflamed. Diagnosis of typical ulceroglandular tularemia in a patient who has the appropriate epidemiologic exposure is made on clinical grounds. In other less obvious settings, diagnosis relies on serologic studies (see Chapter 177).

Filariasis and onchocerciasis should also be considered in the differential diagnosis of inguinal bubo formation; these are discussed below (see Lymphadenopathy of presumed tropical origin).

Figure 16-5 Bubonic plague. Femoral lymph nodes matted together to form the classic bubo.

Mediastinal and hilar lymphadenopathy

Mediastinal or hilar lymph node enlargement may be detected because it causes symptoms (e.g. cough, dyspnea, hoarseness caused by recurrent laryngeal nerve compression, superior vena cava syndrome caused compression of the superior vena cava); on other occasions it is detected during routine chest radiographic screening. The presence of mediastinal lymphadenopathy is usually indicative of a significant disease and is frequently seen in lymphoma. In contrast, bilateral hilar lymphadenopathy is more often benign and is seen in tuberculosis, sarcoidosis and endemic mycoses. [39]

Tuberculosis

Isolated mediastinal or hilar lymphadenopathy is an uncommon manifestation of tuberculosis, although tuberculosis should be considered, especially in high-risk patients such as those infected with HIV or people from Asia or Africa. Mediastinal and hilar lymphadenopathy can be a manifestation of primary disease or of reactivation of tuberculosis (Fig. 16.6). Isolated lymphadenopathy is relatively rare in postprimary tuberculosis.[40] Associated ipsilateral hilar or mediastinal adenopathy is almost universal in children who have primary tuberculosis but is less common in adults. In patients infected with HIV, mediastinal or hilar lymphadenopathy are usually present in tuberculosis even in the advanced stages of immunosuppression (see Chapter 129).

Anthrax

Inhalational anthrax is characterized by mediastinal lymphadenopathy. On CE 02 X-rays of suspected cases this may be the earliest diagnostic clue, appearing in 100% of the cases. Histology discloses diffuse hemorrhagic lympadenitis.

Endemic mycoses (also see Chapter 39)

Histoplasmosis

Histoplasmosis is a fungal infection acquired through inhalation. It is endemic in the USA in the great river valleys of the Mississippi and Ohio. More than 90% of the primary infections are asymptomatic or only mildly symptomatic, although sudden enlargement of the hilar lymph nodes may cause substernal pain. Non-specific

systemic symptoms such as fever, headache, malaise and anorexia are common. Most patients recover within 2–6 weeks.

Typical findings on chest radiography in symptomatic patients include patchy pneumonic infiltrates. Mediastinal and hilar lymphadenopathy

Figure 16-6 Pulmonary tuberculosis.

is common in patients with or without parenchymal involvement. At times, extension of the infection from the pulmonary parenchyma to the adjacent mediastinal lymph nodes causes central caseating necrosis and granuloma formation with multinucleated giant cells. Resolution causes fibrosis of the affected nodes, which usually causes no symptoms. Rarely, the fibrotic lymph nodes invade mediastinal structures, resulting in esophageal stricture or compromise to the mediastinal blood or lymph vessels (fibrosing mediastinitis).[41]

Coccidioidomycosis

Coccidioidomycosis is endemic in the south west USA, Mexico and Central and South America. The lymph nodes most commonly involved are the mediastinal and hilar lymph nodes. When there is involvement of the scalene or supraclavicular nodes, the organism can be isolated from these sites.[42]

Paracoccidioidomycosis

Paracoccidioidomycosis is endemic in Mexico and Central and South America. Most primary infections are asymptomatic. In 10% of patients there is lymphadenopathy, especially of the cervical, axillary and mediastinal nodes, with or without fistula formation. Characteristic budding yeasts may be demonstrated in aspirated material from lymph nodes.[43]

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disease of unknown etiology. Bilateral symmetric hilar lymphadenopathy, usually with paratracheal adenopathy, is characteristic. Peripheral lymphadenopathy is rare. In the mild form of the disease (radiologic grading stage 1) mediastinal or hilar lymphadenopathy is usually discovered inadvertently in asymptomatic persons undergoing a chest radiography for an unrelated cause. Computerized tomography scanning can detect anterior mediastinal and subcarinal lymph nodes that are undetected by chest radiography. Biopsy of lung tissue, even without radiologic findings, is superior for histopathologic diagnosis to lymph node biopsy because it has a higher specificity. The lymph node often shows only non-specific granuloma and therefore has a low diagnostic yield.[44]

Abdominal and retroperitoneal lymphadenopathy

Abdominal and retroperitoneal lymphadenopathy are not usually inflammatory in origin but are frequently due to neoplasia. In the patient who has HIV infection abdominal or retroperitoneal lymphadenopathy is commonly due to persistent generalized lymphadenopathy, disseminated MAC infection or lymphoma. Fever, night sweats and an elevated alkaline phosphatase serum level suggest disseminated MAC infection, whereas an elevated lactic dehydrogenase serum level is more suggestive of the presence of lymphoma.

Mesenteric lymphadenitis is frequently caused by *Yersinia enterocolitica*; some cases have been described with *Yersinia pseudotuberculosis*. The disease needs to be differentiated from appendicitis because it is manifested by right iliac fossa pain. In a 10-year follow-up study of 458 patients who had *Y. enterocolitica* infection [45] it was found that the majority of cases had diarrhea and abdominal pain; vomiting and weight loss were also common. Mesenteric lymphadenitis was diagnosed in 43 of 56 patients who had undergone laparotomy for severe right iliac fossa pain. The histologic appearance of resected mesenteric lymph node may vary from non-specific changes of inflammation and microabscesses to frank granulomatous changes.

Other causes of mesenteric lymphadenitis are talcum powder spread during abdominal surgery, viral diseases in children and adolescents, and inflammatory bowel disease.

Generalized lymphadenopathy

Generalized lymphadenopathy is identified whenever three or more anatomically discrete groups of nodes are involved. Numerous infectious and noninfectious diseases cause generalized lymphadenopathy. Viral diseases predominate but systemic bacterial diseases, including tuberculosis, typhoid fever, brucellosis and leptospirosis, are not uncommon causes of generalized lymphadenopathy. The clinical setting is important in the differential diagnosis. The age of the patient, epidemiologic factors, accompanying physical findings (e.g. rash, organomegaly) or laboratory findings (e.g. atypical lymphocytes, eosinophilia) usually guide further diagnostic investigations.

In intestinal anthrax the lymphnodes draining the ileocecal valve and caecum are also enlarged.

Infectious mononucleosis

Infectious mononucleosis is a syndrome that appears most commonly in children and young adolescents. It is classically characterized by the acute onset of fever, tonsillopharyngitis, lymphadenopathy, splenomegaly and the appearance of atypical lymphocytes in peripheral blood.[46] In children and adolescents, Epstein-Barr virus (EBV) is the most frequent cause (80–90%), followed by cytomegalovirus (CMV; 8–16%).[47] It is usually a benign and self-limited process. Patients may exhibit generalized lymphadenopathy, localized lymph node enlargement in unusual sites (e.g. the inguinal nodes) and lymphadenopathy without systemic manifestations. Rarely, a progressive, fatal disease develops in patients who have X-linked lymphoproliferative disorder and in other immunocompromised patients.[46]

Complete recovery generally occurs within 1–26 weeks after onset of disease, although postinfectious asthenia is not an uncommon complication. Serious complications, sequelae and death are exceedingly rare, occurring in fewer than one case in 3000. Other complications are meningoencephalitis with seizures, splenic rupture, upper airway obstruction, interstitial pneumonitis with hypoxemia and severe hepatitis with liver failure.

Lymphadenopathy is present in the vast majority of children and young adults but in only 45% of patients older than 40 years.[46] Lymph nodes are usually moderately enlarged throughout the body, principally in the posterior cervical, axillary and groin region. They are usually nontender or only minimally tender (Fig. 16.7). Lymph node histology demonstrates paracortical immunoblastic proliferation, as seen in most viral infections.[48]

Mononucleosis-like syndrome may occasionally be caused by *T. gondii* (1% of infectious mononucleosis cases)[19] and by other viruses, such as hepatitis A virus, HSV, rubella, adenovirus and human herpes virus type 6; it may also be caused by allergic reactions to various drugs. [46] Acute retroviral syndrome caused by HIV

Figure 16-7 Posterior cervical lymphadenopathy in infectious mononucleosis.

TABLE 16-5 -- Lymphadenopathy in patients infected with HIV.

LYMPHADENOPATHY IN PATIENTS INFECTED WITH HIV	
Generalized lymphadenopathy	
HIV associated	Acute retroviral syndrome
	Persistent generalized lymphadenopathy
Opportunistic infections	*Mycobacterium avium* complex
	Cytomegalovirus
	Tuberculosis
	Toxoplasmosis
	Cryptococcosis
	Bartonellosis
Malignancy	Lymphoma
	Kaposi's sarcoma
Drugs	Phenytoin
	Pyrimethamine
	Sulfonamides
	Abacavir
Others	Multicentric Castleman's disease
Localized lymphadenopathy	
Infections	Tuberculosis
	Cryptococcosis
	Syphilis
	Lymphogranuloma venereum
	Chancroid
	Other localized infection
Malignancy	Kaposi's sarcoma
	Lymphoma
	Metastasis

infection may manifest as mononucleosis-like syndrome and is discussed below.

Lymphadenopathy in HIV disease

Lymphadenopathy associated with HIV disease may have a multitude of origins, including lymphadenopathy related to HIV infection itself, opportunistic infections, STDs, malignancies and drugs (Table 16.5).

Lymphadenopathy related to HIV infection

Since key pathogenesis events and most viral replication take place in lymphoid tissues, it is not surprising that lymphadenopathy is common in patients who have HIV. Up to 90% of patients who become infected with HIV develop an initial mononucleosis-like illness, referred to as primary HIV infection or acute retroviral syndrome.[49] Illness typically occurs between 1 and 4 weeks after infection. Lymphadenopathy is common, usually appears in the second week of illness and most often involves posterior cervical, anterior cervical, occipital, submandibular and axillary groups. Enlarged nodes are symmetric and painless, with a diameter of 2cm or less.[49] [50] Following seroconversion, lymphadenopathy gradually declines but enlarged nodes may persist throughout the course of disease. Persistent glandular lymphadenopathy, once considered a marker of disease progression, apparently has no prognostic value.[51] In later stages of disease, lymph node architecture is disrupted, germinal centers involute and lymphadenopathy becomes less prominent.[52]

At times, a patient who has AIDS develops lymphadenopathy caused by a neoplastic disease (e.g. lymphoma or Kaposi's sarcoma) or an opportunistic infection. Sudden enlargement, pain or tenderness of a lymph node warrants aspiration or biopsy. Enlarged mesenteric or retroperitoneal lymph nodes can be part of the persistent lymph nodes enlargement seen during HIV disease, but if nodes are large or if there are symptoms such as fever, abdominal pain or diarrhea then a mycobacterial disease or lymphoma should be suspected. Mediastinal or hilar lymphadenopathy is usually not part of the syndrome of persistent generalized lymphadenopathy, and whenever isolated intrathoracic lymphadenopathy is detected a thorough investigation for mycobacterial disease is recommended. In such cases tuberculosis is found in more than half of the patients.[53]

Fine-needle aspiration cytology in HIV-positive patients is most useful in the diagnosis of opportunistic infections, obviating the need for tissue biopsy and allowing prompt initiation of treatment.[54] Whenever lymphoma is suspected biopsy with appropriate studies is preferred over fine-needle aspiration cytology.

Human T-lymphocyte leukemia virus 1

Lymphadenopathy is the most common finding in patients who have adult T-lymphocyte leukemia or lymphoma caused by human T-lymphocyte leukemia virus (HTLV)-1. Other characteristic findings include skin lesions, hepatomegaly, splenomegaly, hypercalcemia, lymphocytosis with abnormal circulating lymphocytes, hyperimmunoglobulinemia and rapid clinical deterioration. Histologic diagnosis of the disease requires immunophenotypic analysis, and these high-grade tumors often show loss of pan-T antigens.[55] Peripheral lymphadenopathy may also be observed in association with tropical spastic paraparesis and myelopathy caused by HTLV-1, which is endemic in some tropical areas. [56] (See Chapter 29).

Lymphadenopathy of presumed tropical origin

Leishmaniasis

Enlarged lymph nodes (mean diameter 3.6cm and up to 10.5cm) occur in 77% of patients who have parasitologically confirmed cutaneous leishmaniasis in South

America and in patients who have *Leishmania major* infection in equatorial Africa.[57] [58] Lymphadenopathy precedes the skin lesion by some 2 weeks in two-thirds of cases. Cultures of the enlarged lymph nodes for *Leishmania* spp. are more frequently positive (86%) than cultures of the skin. Lymph node histology frequently shows necrotizing or suppurative granulomas, sometimes with discharging sinuses. Patients who have leishmanial lymphadenopathy often have fever, hepatomegaly, splenomegaly and more intense leishmanin skin reactions and lymphocyte proliferation in response to antigenic stimulation, but fewer previous infections. Therefore, in endemic areas unexplained lymphadenopathy should prompt a search for leishmaniasis.

Leptospirosis (see Chapter 181)

Lymphadenopathy may appear in up to one-third of patients who have leptospirosis. Other common signs of this infection include fever, headache, myalgia and the classic clinical findings of conjunctival irritation, jaundice and impairment of renal function.[59]

Filariasis (see Chapter 170)

The most common symptomatic manifestations of filarial infection are recurrent episodes of high fever, occasionally with shaking chills, accompanied by lymphadenitis and a distinctive lymphangitis extending retrogradely from the lymph node where the filaria resides to the periphery. The attacks may last for 3–7 days and occur between six and 12 times a year. The attacks subside spontaneously without any specific therapy. The affected lymph nodes are characteristically enlarged and painful and the lymphatic vessels around them appear inflamed and indurated. Sometime local lymphedema appears as well. Occasionally, local thrombophlebitis may also occur. With infection by *Brugia malayi*, an abscess of the entire local lymphatic apparatus may develop with characteristic scars. The involved area is most commonly in the inguinal region.

With the continuation of lymphangitis and lymphadenitis, pitting edema of the skin develops; this is transformed into brawny edema of the involved area, resulting in thickening of the subcutaneous tissue and hyper-keratosis. There is coarsening of the skin, with deep fissuring and nodular and papillomatous hyperplastic changes. The damage to the lymphatic vessels leads to the development of elephantiasis, particularly in the legs but also in the lower arms and breasts.[60]

Onchocerciasis

The major manifestations of onchocerciasis are dermatitis, onchocercomas, lymphadenitis and visual impairment or blindness. The frequency and distribution of these symptoms vary according to the duration of exposure and the age and geographic location of the patient. Mild to moderate lymphadenopathy is common, particularly in the inguinal and femoral areas. Involved nodes are firm and nontender; at times they may reach gigantic proportions and be associated with local lymphatic obstruction and elephantiasis ('hanging groin'). In a recent survey of 770 patients in Uganda, [60] the most common manifestations of onchocerciasis were troublesome skin itching, chronic papular onchodermatitis and depigmentation; lymphadenopathy appeared only in conjunction with bacterially infected skin lesions associated with the itch.

Wuchereria bancrofti *infection*

In contrast to the situation in onchocerciasis, lymphadenopathy may be a striking feature of infection with *Wuchereria bancrofti*. Filaria are frequently present in the lymph nodes. The histology of the lymph node may not show the intense eosinophilia present in the peripheral blood smear or in other invaded organs. At times the genitalia may also be involved, with funiculitis, epididymitis, scrotal pain and anatomic disfiguration of the penis and scrotum. Scrotal lymphedema, hydrocele and elephantiasis may ensue. In addition, characteristic swelling of the leg below the knee and of the arm below the elbow develop as a result of lymphatic involvement and subsequent elephantiasis. Occasionally, obstruction of the retroperitoneal lymphatics occurs, leading to rupture of lymphatic vessels into the kidneys and the appearance of chyluria.

African trypanosomiasis (see Chapter 157)

Lymphadenopathy is observed in up to 80% of patients who have African trypanosomiasis. The supraclavicular or posterior cervical lymph nodes are the most frequently involved. The nodes are usually soft, rubbery, discrete, painless and nontender. They appear at the second stage of the disease. The skin chancre, the hallmark of the first stage of the disease, appears 1 week after the bite and lasts for 2–3 weeks; the skin chancre disappears without leaving a scar. During the second stage, when enlarged lymph nodes are present, pyrexial episodes lasting 1–6 days occur and alternate with afebrile intervals lasting several weeks. Anemia, monocytosis, elevated serum IgM and involvement of the central nervous system with elevated protein and immunoglobulins in the cerebrospinal fluid are characteristic of African trypanosomiasis in endemic areas. In light-skinned travelers to endemic areas, a characteristic extensive erythematous skin rash with circinate patches on the chest or back may appear and disappear several times and therefore suggest the correct diagnosis.[61]

American trypanosomiasis (Chagas' disease) (see Chapter 173)

Lymphadenopathy is an integral part of the first two stages of American trypanosomiasis, which is caused by *Trypanosoma cruzi*. The initial cutaneous lesion (the so-called 'inoculation chagoma'), which consists of a small raised reddish tender nodule with an indurated base, is accompanied by swelling of the regional lymph nodes.

Figure 16-8 Romaña's sign in acute Chagas' disease. There is unilateral edema of the eyelid accompanied by conjunctivitis and auricular lymphadenopathy.

Symptomatic acute Chagas' disease, which usually affects children and adolescents, is manifested by a lesion at the portal of entry in 50% of vector-infected patients. Regional lymphadenitis (iliac, axillary or cervical) may occur. Romaña's sign (Fig. 16.8) is a painless, unilateral indurated erythematous edema of the eyelids, accompanied by conjunctivitis and auricular lymphadenopathy. Local symptoms may be accompanied by rash, mild fever, hepatomegaly and acute myocarditis.

Occasionally, fatal meningoencephalitis occurs in young infants. Generalized enlargement of the lymph nodes, liver and spleen begins to develop during the second week of the infection, with accompanying subcutaneous edema of the face, legs and feet. The lymph nodes are usually isolated and discrete, nontender, nonadherent and painless. During this stage, myocarditis ensues; this is the hallmark of the disease and manifests itself with sinus tachycardia and a variety of conduction defects. [62]

Noninfectious causes of lymphadenopathy

Postvaccination lymphadenopathy

Postvaccination lymphadenopathy is rare nowadays. In the past, smallpox (vaccinia) vaccination was the most common cause of postvaccination lymphadenopathy. Regional lymphadenopathy may occur from several days up to 2 weeks after measles vaccination; it is not usually accompanied by systemic manifestations. The histopathologic findings of an excised node are similar to primary viral lymphadenitis[63] and characteristic Warthin-Finkeldey multinucleated giant cells can be seen. An outbreak of axillary lymphadenitis has been documented in children receiving bacillus Calmette-Guérin (BCG) vaccination. *Mycobacterium bovis* was isolated from a minority of these patients.[64]

Drug-induced lymphadenopathy

Certain drugs are known to cause hypersensitivity reactions associated with lymphadenopathy associated with fever, rash, arthralgia and eosinophilia. Liver enzyme abnormalities and pancytopenia are occasionally seen as well.[65] Phenytoin is the most common drug responsible for such cases.[65] [66] Moreover, some anticonvulsants (e.g. phenytoin and carbamazepine) can cause a pseudolymphoma syndrome, which is characterized by fever, erythematous rash, marked lymphadenopathy and organomegaly.[67] Most patients have taken the implicated drug for only a short time, usually less than 3–4 months, but in some patients many months elapse between initiation of the drug and the appearance of the clinical syndrome. In most patients lymphadenopathy spontaneously regresses 1–2 weeks after stopping the drug.

Lymphadenopathy and autoimmune disease

Generalized lymphadenopathy is common in some autoimmune disease. Studies have shown that lymphadenopathy occurs in up to 75% of patients who have rheumatoid arthritis, 43% of patients who have juvenile rheumatoid arthritis and up to 65% of patients who have active systemic lupus erythematosus.[48]

Kawasaki disease (mucocutaneous lymph node syndrome)

Kawasaki disease is an acute inflammation of small and medium-sized arteries that affects young children. The clinical manifestations include fever, conjunctivitis, oral mucositis, skin rash and cardiac involvement. Lymphadenopathy occurs in 75% of the patients, most frequently in the cervical area.[68] The most devastating complications of this disease include coronary artery aneurysm, coronary thrombosis and myocarditis. The histopathologic features of the lymph nodes are not characteristic; there are scattered necrotic foci associated with thrombi of the adjacent microvasculature.[48] The diagnosis is made on clinical grounds and at least five features should be present. The differential diagnosis of Kawasaki disease includes staphylococcal scalded skin syndrome, scarlet fever and hypersensitivity reactions. The presence of lymphadenopathy, however, suggests Kawasaki disease.

Rosai-Dorfman disease

Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy) is a rare, idiopathic and generally benign, self-limited disease that affects children and adolescents. Massive lymphadenopathy, most commonly involving the cervical nodes, is the hallmark of the disease. Nearly 50% of the patients have some extranodal involvement, most of them occurring in the head and neck where they involve the nose, paranasal sinuses and parotid gland. About 10% of the patients have an associated immunologic disorder.

The involved lymph nodes show a marked sinus expansion by numerous histiocytes with abundant clear cytoplasm containing engulfed small lymphocytes and a small bland nucleus. The clinical setting is usually a child or adolescent presenting with marked cervical adenopathy associated with fever, neutrophilic leukocytosis, elevated erythrocyte sedimentation rate and polyclonal hypergammaglobulinemia. Although the disease is usually self-limited, the prognosis is unfavorable in patients who have immunologic disorders.[48] [69]

Kikuchi's disease

Kikuchi's disease is a histiocytic necrotizing lymphadenitis that was first described in 1972 in Japan as a benign lymphadenopathy of the neck.[70] Kikuchi's disease affects women more often than men and, owing to its association with systemic lupus erythematosus and Still's disease, it is suspected of being an autoimmune disorder. The clinical features of Kikuchi's disease include fever and lymphadenopathy, which is usually cervical.[71] The differential diagnosis includes infectious disease and malignant disease. Biopsy is important for diagnosis and exclusion of lymphoma.

Castleman's disease

This condition, originally called angiofollicular lymph node hyperplasia, was first described as a rare cause of a mediastinal mass seen on chest radiography. It causes mild systemic symptoms of fever and night sweats, and is associated with an elevated erythrocyte sedimentation rate. More recently a variant has been described in which there is generalized lymphadenopathy and more systemic signs. There may be an association with the so-called POEMS syndrome: peripheral neuropathy, organomegaly, endocrinopathy a monoclonal paraprotein and skin lesions. The etiology of Castleman's disease has recently been linked to infection with HHV8 (human herpesvirus 8). Severe cases may require corticosteroid therapy.

Infiltrative lymphadenopathy

Inborn errors of metabolism (Gaucher's disease, Niemann-Pick disease), amyloidosis, histiocytosis X and metastatic malignancy cause infiltration of various organs, including the lymph nodes. The nodes in these cases are characteristically firm and nontender; they may constitute the first clue to a systemic infiltrative process.

Lymphadenopathy and silicone breast implant

In recent years, there has been a growing body of evidence concerning the immune response to silicone and its breakdown products. In women who have silicone breast implants, leakage of silicone causes axillary lymph node enlargement. The histopathology is characteristic for foreign body reaction.[72]

MANAGEMENT

Lymphadenopathy may be the presenting sign in many diseases. Techniques for palpation and assessment of lymph nodes are essential for providing the physician with useful information on which diagnostic and therapeutic decisions can be based. In adults, small lymph nodes can normally be palpated in the inguinal area and in children in the suboccipital area. Enlarged supraclavicular, scalenal, axillary and epitrochlear lymph nodes are usually pathologic and require appropriate investigation with possible aspiration or biopsy of the node. The investigation of lymphadenopathy can be organized according to the following categorizations:

- the mode of presentation (an acutely ill, chronically ill or asymptomatic patient, and any pertinent associated clinical manifestation);
- the patient's age, epidemiologic exposure and immune status;
- the physical characteristic of the enlarged node or nodes; and
- the location of the lymphadenopathy.

Mode of presentation

In acutely ill patients who have a tender, enlarged lymph node a pyogenic bacterial infection is most commonly found. A search for skin and soft tissue infection in the region drained by the involved lymph node is indicated. A thorough ear, nose and throat examination is mandatory if the adenitis is in the head and neck area. Fluctuant abscesses should be aspirated, Gram stained and cultured, and appropriate antibiotic treatment be instituted. Group A streptococcal and *S. aureus* infections cannot be differentiated on the basis of clinical presentation. In endemic regions plague should be suspected and treated promptly. The acutely ill patient who is found to have generalized lymphadenopathy should be evaluated for systemic infections such as streptococcal and staphylococcal bacteremia, infectious mononucleosis, typhoid fever, rickettsiosis, leptospirosis, miliary tuberculosis and reactive noninfectious diseases, depending on any associated clinical features. In the asymptomatic or mildly symptomatic young patient who has generalized lymphadenopathy and no localizing clinical features, the most plausible etiology is a viral disease, usually caused by EBV, CMV or HIV; appropriate serologic or culture studies are called for.

In the elderly, acute EBV or CMV infections cause lymphadenopathy less frequently than they do in younger patients. The differential diagnosis includes primary lymphoproliferative and metastatic disease as well as reactive processes.

Table 16.6 summarizes the clinical presentation of infectious lymphadenitis.

Disease progression

Lymphadenopathy of long duration mandates further evaluation. Although lymphadenopathy due to cat-scratch disease or toxoplasmosis may persist for months, a presumptive diagnosis of toxoplasmic

TABLE 16-6 -- Clinical presentation of infectious lymphadenitis.

CLINICAL PRESENTATION OF INFECTIOUS LYMPHADENITIS					
Disease		**Infecting organism**	**Lymphadenopathy**		**Systemic manifestations**
			Regional	**Generalized**	
Bacterial	Pyogenic	Group A streptococci	Yes	No	Prominent
		Staphylococcus aureus			
	Cat-scratch disease	*Bartonella henselae*	Yes	No	Occasional, mild
	Scrofula	*Mycobacterium tuberculosis*, nontuberculous mycobacteria	Yes	No	No, unless AIDS is present
	Miliary tuberculosis	*Mycobacterium tuberculosis*	No	Yes	Prominent
	Syphilis	*Treponema pallidum*	Yes	Yes	Variable
	Plague	*Yersinia pestis*	Yes	No	Prominent
	Tularemia	*Francisella tularensis*	Yes	No	Common, mild to moderate
	Chancroid	*Haemophilus ducreyi*	Yes	No	No
	Leptospirosis	Leptospira	No	Yes	Prominent
Viral	Infectious mononucleosis	Epstein-Barr virus, cytomegalovirus, HIV	Yes	Yes	Common, mild to moderate
	Rubella	Rubella virus	Yes	Yes	Common, mild
	Genital herpes (primary infection)	Herpes simplex virus 2	Yes	No	Common, mild to moderate
	Persistent generalized lymphadenopathy	HIV	Yes	Yes	Variable
	Pharyngoconjunctival fever	Adenovirus 3, 7	Yes	No	Common, mild
	Epidemic keratoconjunctivitis	Adenovirus 8, 19, 37	Yes	No	Occasional, mild
Chlamydial	Lymphogranuloma venereum	*Chlamydia trachomatis*	Yes	No	Common, moderate
Rickettsial	Spotted fever	*Rickettsia rickettsii*, *R. conori*	No	Yes	Prominent
Fungal	Histoplasmosis	*Histoplasma capsulatum*	Yes	Yes	Uncommon
	Coccidioidomycosis	*Coccidioides immitis*	Yes	No	Uncommon
Protozoan	Toxoplasmosis	*Toxoplasma gondii*	Yes	No	Uncommon
	Chagas' disease	*Trypanosoma cruzi*	Yes	Yes	Common, mild to moderate
	African trypanosomiasis	*Trypanosoma brucei*	Yes	No	Common, mild to moderate
	Leishmaniasis	*Leishmania* spp.	Yes	No	Variable

		Wuchereria bancrofti	Yes	No	No
	Onchocerciasis	*Onchocerca vulvulus*	Yes	No	No

lymphadenitis should be questioned if adenopathy persists longer than 6 months, and lymph node biopsy or aspiration should be performed. Fine-needle aspiration is suitable for diagnosing infection or metastatic disease but a lymph node biopsy is required for the diagnosis of lymphoma. Analysis of biopsied lymph node yields a diagnosis in 50–60% of patients. Among patients in whom a diagnosis is not established by biopsy, 25% will develop a definable disease, mostly lymphoma, within a year. Therefore, close follow-up and repeated biopsies should be performed in patients who have a nondiagnostic initial biopsy.

Age

Lymphadenopathy is common in the pediatric age group and represents a benign process in approximately 80% of cases. Therefore, in a child who has lymphadenopathy and other features suggesting a possible bacterial infection, a trial of antibiotic may be appropriate. In adults, especially in patients older than 50 years, any finding of lymphadenopathy requires a thorough evaluation and consideration of a lymph node biopsy.

Physical characteristics of the enlarged lymph node

The size, consistency and relation to underlying tissue are important clues to the etiology of the enlarged nodes. Lymph nodes involved by an infective process tend to be large, soft and tender. Signs of local inflammation may be present, and draining sinuses are commonly seen in mycobacterial lymphadenitis. This presentation may be mistaken for orocervicofacial actinomycosis, which seldom spreads to the lymphatic vessels to cause lymphadenopathy. Nodes involved in lymphomas are rubbery, matted together and nontender. Metastatic lymph nodes due to carcinomas are usually firm, non-tender and fixed to the underlying tissues.

Location

Specific locations of enlarged lymph nodes are associated with specific etiologies (Table 16.7). Intra-abdominal or intrathoracic lymphadenopathy is not accessible to palpation, and imaging should be undertaken whenever it is suspected. Suggested investigations for regional lymphadenopathy are discussed below according to site.

TABLE 16-7 -- Correlation between the site of lymphadenopathy and disease

CORRELATION BETWEEN THE SITE OF LYMPHADENOPATHY AND DISEASE	
Enlarged lymph node	**Associated disease or condition**
Occipital	Scalp infections, insect bites, head lice
Posterior auricular	Rubella, ear piercing, HIV
Anterior auricular	Eye or conjunctival infections
Posterior cervical	Toxoplasmosis
Submental	Dental infections
Anterior cervical or submandibular	Oral cavity infections, Epstein-Barr virus, HIV, tuberculosis
Supraclavicular	Neoplasia
Mediastinal	Sarcoidosis, tuberculosis, histoplasmosis, neoplasia (Hodgkin's or non-Hodgkin's lymphoma, metastases), anthrax

Axillary	Cat-scratch disease, pyogenic infection of the upper arm, neoplasia (breast, lymphoma)
Epitrochlear	Viral diseases, cat-scratch disease, tularemia, hand infection, secondary syphilis
Abdominal/retroperitoneal	Tuberculosis, neoplasia, yersiniosis
Inguinal	Genital herpes, syphilis, lymphogranuloma venereum, filariasis, neoplasia

Head and neck lymphadenopathy

Any lymph node enlargement in the head and neck region should stimulate a thorough search for an infection in the oropharyngeal and nasal cavities. Symmetric lymph node enlargement usually suggests self-limited viral disease, and unilateral node enlargement may be viral in origin but evokes a broader differential diagnosis, including cat-scratch disease, toxoplasmosis and neoplasia. Unilateral enlarged tender lymph nodes usually indicate an acute infection but may be due to a rapidly proliferating process. If asymptomatic cer-vical node enlargement persists and serologic testing for toxoplasmosis is negative, a lymph node biopsy or aspiration should be performed. An abnormal chest radiograph in children and young adults who have cervical lymphadenopathy has been found strongly associated with malignant neoplasm, mostly lymphoma. Furthermore, 80% of patients who have cervical lymphadenopathy, abnormal chest radiograph and nondiagnostic lymph node biopsy are subsequently found to have malignant or granulomatous disease. We recommend a lymph node biopsy, and not aspiration, as the diagnostic procedure of choice when asymptomatic cervical lymphadenopathy persists in the presence of an abnormal chest radiograph. Supraclavicular lymphadenopathy without any other enlarged nodes, particularly in adults, is often of neoplastic origin and should therefore be biopsied.

In children and adolescents other causes of lumps in the neck, such as epidermoid thyroglossal or branchial cysts and parotid gland enlargement, should be differentiated from cervical lymphadenopathy.

Axillary lymphadenopathy

Infectious causes of unilateral axillary lymphadenopathy include local infectious processes of the arm and hand, hidradenitis suppurativa, streptococcal and staphylococcal lymphadenitis, cat-scratch disease, toxoplasmosis and tularemia. Conventional bacteria are easily differentiated from cat-scratch disease and toxoplasmosis on clinical grounds and should be treated accordingly. Asymptomatic unilateral axillary lymphadenopathy should be evaluated for neoplasia in both adults and adolescents. In the younger age group, however, a serologic test for the presence of *Toxoplasma* antibodies should precede the biopsy. Bilateral axillary lymphadenopathy can by caused by a variety of viral and bacterial infections as well as by neoplasms and immunologic disorders.

Thoracic lymphadenopathy

The principal differential diagnosis of intrathoracic lymphadenopathy includes neoplasia, tuberculosis, anthrax sarcoidosis and endemic mycoses. Unilateral or bilateral mediastinal lymphadenopathy in children without additional findings is the characteristic feature of primary tuberculosis. However, malignant lymphoma in the pediatric age group may also manifest in this way. Therefore, if a tuberculin skin test is found to be strongly reactive in such circumstances, antituberculous therapy should be started. However, if the tuberculin skin test is nondiagnostic or nonreactive and remains so on retesting 10–14 days later, an invasive diagnostic procedure is indicated.

Mediastinal lymphadenopathy in adults who have no accompanying complaints or findings is usually indicative of a neoplasm requiring an invasive diagnostic procedure. An exception to this is the patient who has HIV infection or one who arrives from an endemic area, in whom tuberculosis may be as frequent as a neoplasia. In the appropriate epidemiologic settings, endemic mycosis is also a diagnostic possibility requiring specific tests.

These considerations also apply to patients who have unilateral hilar lymphadenopathy. Bilateral hilar lymphadenopathy in the asymptomatic young patient is commonly caused by sarcoidosis. In patients who have parenchymal infiltration on radiography in addition to intrathoracic lymphadenopathy, bronchoscopy should be performed if sputum smear for *M. tuberculosis* is negative, regardless of age.

In the future, it is possible that new laboratory procedures such as PCR may reduce the need for invasive procedures. In patients who have no lung parenchymal involvement the diagnostic yield of sputum examination is low. Bronchoscopy increases the diagnostic yield of tuberculosis to 50–75%, especially if mucosal biopsy specimens are taken from ulcerating granuloma seen during the procedure.[54] Video-assisted thoracic surgery and mediastinotomy increase the diagnosis to 100% of patients, whereas mediastinoscopy supports the diagnosis of tuberculosis in 85–90%. [54]

Abdominal lymphadenopathy

Abdominal lymphadenopathy may be detected as an isolated finding during the investigation of abdominal complaints. In such cases, etiology of lymph node enlargement lies in the abdominal organs that drain into the enlarged nodes. The appropriate diagnostic approach should be directed at investigating and, if appropriate, biopsying a particular organ. Exceptions to this recommendation are intraabdominal lymphoma and abdominal tuberculosis (mesenteric lymphadenitis), in which the abdominal lymph nodes may be the primary site involved. In cases with abdominal lymphadenopathy, a careful search for peripheral lymph node enlargement is mandatory.

Inguinal lymphadenopathy

The main causes of inguinal lymphadenopathy include infectious diseases (STDs and others) and neoplasm (lymphoma or metastatic carcinoma). If an STD is suspected or a genital ulcer is detected, serologic tests (e.g. Venereal Disease Research Laboratory, complement fixation test, microimmunofluorescence test for *Chlamydia* spp.), bacteriologic investigations (dark field, immediate culture) and virologic investigations (herpesvirus culture) should be performed. According to epidemiologic considerations, the presence of one STD could indicate the possibility of another STD. Therefore, it is recommended that multiple infectious etiologies such as HIV and hepatitis B virus be ruled out.

PRACTICAL SUMMARY

¦ The size of an enlarged peripheral lymph node is often not helpful in determining the cause of lymphadenopathy or the need for biopsy.
¦ Empiric antibiotic treatment for suspected supperative lymphadenitis is indicated and should be primarily directed toward *Streptococcus pyogenes* and *Staphylococcus aureus*.
¦ In immunosuppressed patients (e.g. patients who have acute leukemia) or in diabetic patients who have foot ulcers and inguinal lymphadenitis, aspiration of pus from the involved node should be performed and therapy modified accordingly.
¦ Do not attempt drainage of a scrofula; this may cause fistula formation. Total excision is the treatment of choice in such cases. If in doubt, excision is the preferred approach.
¦ Consult a hematologist before processing an excised lymph node. It is essential that the biopsy material be handled properly to allow possible ancillary tests, such as immunoperoxidase staining, cytogenetic analysis and molecular clonality studies.
¦ Aspirated or excised material should be of sufficient amount to ensure recovery of suspected organisms.
¦ Specimens for bacterial and fungal diagnosis should be processed for Gram stain, acid-fast stain, Giemsa or Wright stain and methenamine silver stain.
¦ Specimens for parasitic diseases should be fixed in 100% alcohol and not in formalin.
¦ Specimens for viral cultures should be transported in appropriate transport media.
¦ For PCR assays, consult the local laboratory.
¦ The patient who has acute HIV infection manifesting as mononucleosis-like syndrome is typically HIV-antibody-negative. In order to rule out the possibility of acute retroviral syndrome, a negative serum p24 antigen or HIV PCR are required.
¦ In suspected tropical lymphadenitis or lymphadenopathy, appropriate serologic tests are mandatory and tissue specimens should be processed accordingly.
¦ Lymphadenopathy caused by dual infections or by an infectious process and a noninfectious one has been described; if, for example, lymphadenopathy attributed to toxoplasmosis on the basis of serologic investigations persists for more than 6–8 months, lymph node biopsy should be performed to exclude other diagnoses.

Chapter 17 - Practice Point

Management of the solitary enlarged lymph node

Martin Dedicoat
Martin J Wood

Pathogenesis

Enlargement of a lymph node may result from:

- infiltration by metastatic malignancy;
- acute inflammation secondary to infectious agents being filtered from afferent lymphatics or blood; or
- proliferation of lymphocytes and other mononuclear cells in response to antigenic stimuli or due to a primary lymphoproliferative disorder.

In certain infections there is nonspecific abscess formation and suppuration, whereas in others there is a more distinctive histologic

TABLE 17-1 -- Infectious causes of a solitary enlarged lymph node.

INFECTIOUS CAUSES OF A SOLITARY LYMPH NODE			
Infecting agent		**Site**	**Comments**
Viruses	Herpes simplex virus, type 2	Inguinal	Not always associated with mucocutaneous lesions
	Adenoviruses	Cervical or preauricular	Associated with pharyngitis or conjunctivitis
Bacteria	Group A streptococci	Cervical	Tender, may suppurate
	Staphylococcus aureus	Regional	Search for skin focus
	Mycobacterium tuberculosis	Regional (particularly cervical)	Particularly in certain ethnic groups and in people who have HIV infection
	Atypical mycobacteria	Cervical	Scrofula; particularly in children
	Treponema pallidum (syphilis)	Inguinal	In primary disease; painless lymphadenitis; search for chancre
	Haemophilus ducreyi (chancroid)	Inguinal	Painful papules and suppurative nodes
	Yersinia pestis (plague)	Inguinal or lemoral	Extremely tender node and acute systemic illness; exposure to rodents or fleas
	Francisella tularensis (tularemia)	Regional	Painful ulcer at site of inoculation; tender node; exposure to rodents
	Bartonella henselae (cat-scratch disease)	Regional (usually axillary, epitrochlear or cervical)	History of cat scratch or bite; skin lesion may have healed; not usually systemically ill; node moderately tender
Rickettsia/chlamydia	*Rickettsia tsutsugamushi* (scrub typhus)	Regional	Travel to Asia or Australasia; history of mite bite with eschar at site
	Rickettsia akari (rickettsialpox)	Regional	Travel to South Africa, Korea or North America; papule at site of mite bite and generalized vesicular rash
	Rickettsia aricae		
	Chlamydia trachomatis (lymphogranuloma venereum)	Inguinal	Fixed, tender, matted nodes above and below inguinal ligament (groove sign); foci of suppuration and fistulas
Fungi	*Histoplasma capsulatum* var. duboisii	Regional	West Africa; cutaneous lesion
	Paracoccidioides brasiliensis (paracoccidioidomycosis)	Cervical	Central and South America: usually chronic mucocutaneous lesions present
Protozoa	*Toxoplasma gondii*	Cervical	Mononucleosis-like illness; often generalized lymphadenopathy
	Trypanosoma brucei (African trypanosomiasis)	Cervical	African travel or residence; often generalized lymphadenopathy

appearance. Caseation necrosis suggests mycobacterial (or occasionally fungal) infection; a granulomatous reaction with or without stellate necrosis is typical of sarcoidosis, cat-scratch disease, tularemia, lymphogranuloma venereum and Kikuchi's disease; and follicular hyperplasia with epithelioid histiocytes is seen in toxoplasmosis. In other cases it is usually not possible to determine the infecting organism from the histologic appearances.

Microbiology

Many infections can result in a solitary enlarged lymph node, but most (particularly viral and protozoal infections) are much more

TABLE 17-2 -- Noninfectious causes of a solitary enlarged lymph node.

NONINFECTIOUS CAUSES OF A SOLITARY ENLARGED LYMPH NODE	
Immunologic	Rheumatoid arthritis (Felty's syndrome)
	Systemic lupus erythematosus
Malignant	Leukemia
	Lymphoma
	Metastatic malignancy

Miscellaneous	Sarcoidosis
	Drugs (carbamazepine, phenytoin)
	Castleman's disease (possibly related to human herpesvirus-8)
	Kikuchi's disease (histiocytic necrotizing lymphadenitis; possibly an infectious etiology)
	Histiocytosis X
	Kaposi's sarcoma

likely to cause a generalized lymphadenitis. The organisms listed in Table 17.1 are those that need particular consideration. Causes of lymphadenopathy other than infection are listed in Table 17.2 .

Clinical features

A patient may present with an enlarged lymph node or it may be a chance finding. Palpable lymph nodes do not always have a pathologic cause; a submandibular or cervical node less than 1cm in diameter or an inguinal node less than 2cm in diameter in an adult may be considered to be normal. Solitary nodes in other areas are more likely to have a pathologic cause. Evaluation requires an assessment of the duration and progression of the enlargement and any associated systemic or local (related to the area drained by the enlarged lymph node) symptoms or signs. The patient's occupation, exposure to animals, sexual behavior and travel history will indicate whether diseases listed in Table 17.1 and Table 17.2 can be excluded or should be considered more seriously.

Examination of the mass should first focus on ensuring that it is a lymph node (Table 17.3) and an enlarged node should be assessed for its size, texture, tenderness and any discharge. An acutely enlarged, very tender (perhaps fluctuant), cervical, submandibular, axillary or epitrochlear node with overlying skin erythema and fever, particularly in a child, suggests a streptococcal or staphylococcal etiology. Suppurative iliac lymphadenitis in a child is also usually caused by *Staphylococcus aureus*, but in an adult several sexually transmitted diseases, particularly lymphogranuloma venereum, also need to be considered. In an appropriate geographic location and with animal

TABLE 17-3 -- Masses often confused with enlarged lymph nodes.

MASSES OFTEN CONFUSED WITH ENLARGED LYMPH NODES		
Name of mass	**Usual site**	**Comment**
Branchial cyst	Over the midpoint of the sternomastoid muscle	Contains sterile pus and many cholesterol crystals
Dermoid cyst	In the midline at any line of embryologic fusion	Fluctuant mass containing cheesy epithelial debris
Thyroid nodule	In region of the thyroid gland	Moves on swallowing
Thyroglossal cyst	In midline of throat	Moves on protruding the tongue
Onchocercal nodule	Associated with bony prominence such as the iliac crest or occiput	Travel or residence in Africa or Latin America; may be associated skin changes or visual problems
Femoral hernia	Below inguinal ligament	Cough impulse; reducible

exposure, plague and tularemia should be considered in an acutely ill person who has inguinal buboes.

In the absence of fever and tenderness, an indolent suppurative painless lymphadenitis, particularly in the cervical or submandibular region, suggests mycobacterial infection. In children this is is often caused by atypical mycobacteria such as *Mycobacterium scrofulaceum* or *M. avium-intracellulare*. Peripheral tuberculous lymphadenitis occurs particularly in young adult women immigrants from areas where tuberculosis is endemic. Similar slowly progressive regional lymphadenitis is a feature of cat-scratch disease, which is caused by *Bartonella henselae*, and most patients who have this infection have been scratched or bitten by a cat. Hard immobile nodes are suggestive of malignancy and rubbery painless nodes may indicate a lymphoproliferative process. The area drained by any enlarged node should be examined for signs of skin inflammation or malignancy. Careful genital examination for mucosal ulcers and urethral discharge are indicated if the node is in the inguinal region.

For people who have HIV infection, especially those who originate or who have spent time outside Europe and North America, there should be a high index of suspicion for tuberculosis. Kaposi's sarcoma should also be considered, even in the absence of cutaneous lesions.

Investigations

Investigations should be tailored to the clinical findings. Basic tests include a full blood count and blood film and an antibody test for mononucleosis. Swabs should be taken from the throat (for cervical nodes), and any ulcerative lesions or sinus tracts. A fluctuant node can be aspirated and the pus stained with Gram and Ziehl-Neelsen stains and cultured for bacteria, including mycobacteria, and fungi. Any material from a submandibular swelling can also be sent for cytology because this may be helpful in differentiating a submandibular node from a branchial cyst containing cholesterol crystals. If the patient is febrile blood cultures should be obtained. A chest radiograph is useful if the node is supraclavicular because it may show a pulmonary infiltrate, mediastinal or other masses, or hilar adenopathy due to sarcoidosis. Patients who have an enlarged cervical node without a visible cause should have a thorough ear, nose and throat examination and any suspicious mucosal lesions should be biopsied. For an inguinal node in an adult a full sexually transmitted infection (STI) screen should be offered, including counseling for HIV testing if any risk factors are identified. It should be remembered that STIs can be asymptomatic.

Serologic tests can be helpful in supporting a diagnosis of streptococcal, viral or rickettsial infection, toxoplasmosis and cat-scratch disease. Immunologic tests such as antinuclear antibody, double-stranded DNA and rheumatoid factor may be indicated if systemic lupus erythematosus or rheumatoid arthritis are thought likely. A tuberculin test (Mantoux or Heaf) can suggest tuberculosis as a cause, but needs to be interpreted carefully, particularly for patients who have lived in Asia and other countries where the disease is endemic and previous infection is likely, and in those who have had previous bacille Calmette-Guérin (BCG) immunization. It is often falsely negative in patients who have HIV infection.

Other investigations such as computed tomography should be guided by clinical suspicion. A single stony-hard supraclavicular node suggests an intra-abdominal malignancy.

Management

If a cause for the enlarged node is found on examination or after initial investigations (including microscopy) of any purulent material obtained after aspiration, the management is usually straightforward and directed at the underlying disease. An acutely ill patient who has

suppurative lymphadenitis or an enlarged node accompanied by lymphangitis can be treated with a penicillinase-resistant penicillin such as oxacillin or flucloxacillin. Cervical nodes secondary to presumed pharyngotonsillar infection can be treated with penicillin, which may need to be given intravenously at first until the patient is able to swallow. More chronic suppurative lymphadenitis might be treated empirically as tuberculosis, an atypical mycobacterial infection or cat-scratch disease, depending upon the epidemiologic features. A single lymph node infected by atypical mycobacteria is usually treated by surgical excision alone.

If no specific diagnosis is suggested by the history and initial investigation a decision has to be made about performing an excision biopsy. If a node is less than 1cm in diameter and there are no suspicious features (hard, fixed, painless node or supraclavicular location) in an otherwise well patient under 40 years of age it can usually be observed on a regular basis every few weeks and in many cases will regress or the disease process will manifest itself. Biopsy is indicated for:

- nodes that fail to regress or have enlarged despite empiric antibiotic therapy directed at the disease thought to be the most likely cause;
- a node over 2cm in diameter; and
- a progressively enlarging hard node or one with associated local symptoms or signs (e.g hoarseness, nasal obstruction or mucocutaneous ulceration and

induration).

It needs to be stressed, however, that if an enlarged node is thought to due to metastastic malignancy the patient needs a thorough evaluation for the primary before any lymph node biopsy.

Chapter 18 - Conjunctivitis, Keratitis and Infections of Periorbital Structures

Luke Herbert

CONJUNCTIVITIS

Conjunctivitis is inflammation of the conjunctiva. It is not a diagnosis but a description of a clinical syndrome. There may be redness, dilated blood vessels, follicles, papillae and a watery-to-purulent discharge. Follicles are germinal centers of conjunctival lymphoid tissue and are predominant in viral conjunctivitis. They are small (typically <1mm) pale bumps under the tarsal conjunctiva and sometimes the limbal conjunctiva. Small papillae are non-specific and give the tarsal conjunctiva a velvety appearance. Giant papillae are a sign of chronic inflammation, give the upper tarsal conjunctiva a cobblestone appearance and may lead to reticular scarring on resolution.

Decreased vision or photophobia are associated with keratitis or uveitis, which can accompany conjunctivitis.

NONINFECTIVE CONJUNCTIVITIS

Endogenous causes of noninfectious conjunctivitis include dry eye and acute and chronic inflammatory conditions of the conjunctiva such as Stevens-Johnson syndrome or mucous membrane pemphigoid. Exogenous causes include pollution and medication (conjunctivitis medicamentosa). Rarely conjunctival or eyelid tumors can cause conjunctivitis (masquerade syndrome). Molluscum contagiosum lesions near the eye can shed viral particles into the eye and cause a reactive follicular conjunctivitis, without evidence of conjunctival infection. This is more common in children than in adults. Large crops of periocular molluscum lesion can be seen in patients with AIDS.

The distinction between noninfective and infectious causes is usually clear from the history. Except for chlamydial conjunctivitis, infectious conjunctivitis rarely lasts longer than 3 weeks, beginning to resolve after 10 days. Conjunctivitis medicamentosa can be a difficult condition to diagnose and may follow an infectious conjunctivitis. Clues include a history of initial improvement on starting a new type of eye-drop followed by worsening and complaints that the eye-drops sting. Thorough history taking is necessary because patients may not recall all the different eye-drops that they have been using during an episode of conjunctivitis. Withdrawal of all topical medication and reassessment 2 or 3 days later is helpful.

In allergic conjunctivitis there is often a history of atopy and chronic mucus discharge, and giant papillae are seen.

INFECTIOUS CONJUNCTIVITIS

Bacterial conjunctivitis

Epidemiology

Bacterial conjunctivitis is ubiquitous and is more common in warmer months and regions. It is transmitted by contact with ocular or upper respiratory tract discharges of people who have the infection, fomites, medical equipment or shared cosmetics. In some areas insect vectors are involved.

Clinical features

Tearing, irritation and sticky discharge without preauricular lymphadenopathy are early clinical features. The conjunctiva is pink (not red). The lids may be stuck together by a mucopurulent exudate on awakening.

Diagnosis

Microbiologic investigation is necessary only in neonatal, hyperacute, severe, unusual or chronic cases. Microscopy of conjunctival smears can be useful, and conjunctival swabs on blood agar and (especially in children) chocolate agar are used. *Haemophilus influenzae* biogroup *aegyptius* and *Streptococcus pneumoniae* are common causes. *Haemophilus influenzae* type b and *Moraxella* and *Branhamella* spp., *Neisseria meningitidis* and *Corynebacterium diphtheriae* are also involved. In infants the main organisms are *H. influenzae* biogroup *aegyptius*, *Neisseria gonorrhoeae*, *S. pneumoniae*, viridans streptococci, enterococci and rarely *Pseudomonas aeruginosa*.[1] [2]

Management

Topical broad-spectrum antibiotic drops are used 2-hourly until the symptoms subside, which should occur rapidly. In Europe, chloramphenicol is used; in the USA, neomycin, polymyxin and bacitracin are used. Gentamicin and tobramycin are useful against Gramnegative organisms, but cause a higher rate of local toxic reactions. Erythromycin or the quinolones may also be used.

Hyperacute conjunctivitis

Hyperacute conjunctivitis is characterized by copious discharge, chemosis and lid swelling. Membranes may form on the tarsal conjunctiva and there may be a tender preauricular lymphadenopathy. Corneal involvement is common and severe, and corneal perforation can occur within 24 hours. It is caused by *N. gonorrhoeae* and *N. meningitidis*.

Management

The drug of choice is an extended-spectrum cephalosporin such as ceftriaxone 1g (25–40mg/kg) every 12 hours for 3 days. Repeated irrigation of the conjunctival sac is recommended to reduce inflammatory microbial mediators to the cornea.

Brazilian purpuric fever

This is caused by a rare invasive clone of *H. influenzae* biogroup *aegyptius*. Systemic disease occurs in children 1–3 weeks after an episode of conjunctivitis. It is seen over a widespread area in Brazil and there is a case mortality of 70%. The clinical picture is similar to that of meningococcal sepsis.

Management

The Brazilian purpuric fever clone of *H. influenzae* biogroup *aegyptius* is resistant to trimethoprim but is sensitive to chloramphenicol and ampicillin. During epidemics systemic rifampin (rifampicin) (20mg/kg/day for 2 days) may be used as prophylaxis against Brazilian purpuric fever for children who have conjunctivitis.

Ophthalmia neonatorum

Ophthalmia neonatorum is any conjunctivitis in the first 3 weeks of life. The most serious cause is gonococcal conjunctivitis, which can be life-threatening. More common causes are *Chlamydia trachomatis*, chemical irritation and herpes simplex virus.

Epidemiology

Ophthalmia neonatorum occurs worldwide, but is uncommon where there is adequate infant eye prophylaxis. Globally gonococcal ophthalmia neonatorum is an important cause of blindness. The risk of ophthalmia neonatorum for a child born to an infected mother is 30–50% for gonorrhea[3] and 15–35% for chlamydial infection.[4] Transmission usually occurs in the birth canal.

Prevention

Topical prophylaxis was described in 1881 by Credé. His silver nitrate eye drops substantially reduced the incidence of gonococcal conjunctivitis; however, they are inactive against chlamydia, and toxicity is common. Recently, 2.5% aqueous povidone-iodine has been shown to be safer, cheaper and more effective. [5] [6] Maternal treatment before birth is the best prevention.

Clinical features

Gonococcal conjunctivitis presents 24–48 hours after birth and earlier after premature rupture of membranes. Lid edema, chemosis and a discharge, which is serosanguineous and rapidly becomes purulent, progress to corneal ulceration. Perforation can occur soon afterward.

Chlamydial conjunctivitis presents 5–12 days after birth with a watery discharge, which becomes purulent more slowly. Follicles are absent because the conjunctival lymphoid tissue in infants is immature. Untreated the condition usually resolves in 3–4 weeks, but can take 1 year. Rarely membranes and micropannus form, resulting in significant stromal scarring in later life. Pneumonitis, rhinitis, vaginitis and otitis can follow the conjunctivitis.

Diagnosis

Cultures on blood and chocolate agar for gonococci, and viral culture and immunofluorescent testing, enzyme immunoassay or DNA probing for chlamydial antigen should be performed.

Management

Neonates who have a purulent discharge are presumed to have gonococcal infection and are treated with ceftriaxone 25–50mg/kg intramuscularly or intravenously to a maximum of 125mg. Frequent irrigation removes bacteria and microbial products. A single intramuscular dose of 125mg of ceftriaxone is effective therapy for gonococcal ophthalmia neonatorum.[7] Parents should be screened for sexually transmitted diseases.

Treatment of chlamydial ophthalmia neonatorum comprises 2 weeks of erythromycin 10mg/kg q12h for the first week and q8h for the second week of life.

Chlamydial conjunctivitis: trachoma

Chlamydial infection results in three distinct clinical pictures. Trachoma is a scarring condition of the conjunctiva and cornea in adults caused by recurrent childhood infection with *C. trachomatis*. Adult inclusion conjunctivitis is an acute condition associated with sexually transmitted chlamydial infection. Neonatal chlamydial conjunctivitis is described above.

Epidemiology

Trachoma occurs worldwide and is endemic in poorer rural areas of developing countries. Blindness due to trachoma is still common in parts of the Middle East, northern and sub-Saharan Africa, parts of the Indian subcontinent, South East Asia and China. There are pockets of infection in South America, among Australian Aborigines, in the Pacific islands and in native American reservations in southwest USA.

Prevention

The infection is transmitted by contact with ocular or nasopharyngeal secretions, either directly through fomites or insect vectors (the flies *Musca sorbens* in Africa and the Middle East and *Hippelates* spp. in the Americas). Untreated active lesions can be infectious for years. Prevention of transmission is the most important public health measure.[8] Education about personal hygiene and regular washing of the face is very important, and these hygiene measures require only a tiny amount of water. There has been mass treatment of the population with topical tetracycline or erythromycin in hyperendemic areas.

Clinical features

The acute conjunctivitis is characterized by a diffuse follicular reaction in the conjunctiva of the superior tarsal plate and at the limbus with soft follicles. Papillary hypertrophy is a non-specific sign. With resolution of the follicles there is subconjunctival scarring and a loss of conjunctival mucin-producing goblet cells. Blinding complications result from chronic re-infection,[9] severe dry eyes and entropion leading to corneal scarring, bacterial superinfection and ulceration.

Diagnosis

The diagnosis is made on clinical grounds in endemic areas.
Expressed follicles have a characteristic microscopic appearance involving macrophages (Leber's cells), plasma cells and lymphoblasts.

Chlamydia trachomatis types A–C are involved. Secondary bacterial superinfection is common and causes severe disease. Antibodies to *C. trachomatis* can be demonstrated in the tears and serum.

Management

Prevention of the chronic sequelae by treatment in childhood is a public health priority. Once scarring has occurred management is with lubricants and surgery.

Chlamydial conjunctivitis: adult inclusion conjunctivitis

Clinical features

The conjunctivitis presents with a mucopurulent discharge after a 4- to 12-day incubation period. It is often monocular and develops into a chronic follicular conjunctivitis, often with epithelial keratitis and limbal follicles. Tender preauricular lymphadenopathy is common. Untreated the disease has a chronic course and may progress to keratitis and possibly iritis.

Diagnosis

Enzyme-linked immunoassay or immunofluorescent monoclonal antibody stains of conjunctival scrapings are rapid and convenient ways to make the diagnosis. [10]

Management

Treatment is with 3 weeks of systemic doxycycline 100mg q12h or erythromycin stearate 500mg q6h. Topical treatment is relatively ineffective.

VIRAL CONJUNCTIVITIS

Epidemiology

Viral conjunctivitis is common and occurs worldwide. Epidemics frequently occur and may be propagated by eye clinics. Transmission is

by direct or indirect contact with ocular or upper respiratory tract secretions. Airborne transmission occurs. Viral particles can remain infectious on surfaces for more than 1 month.

The incubation period is from 2 days to 2 weeks, and infected people remain contagious for up to 2 weeks after the symptoms begin.

Prevention

Control of epidemics associated with eye clinics involves setting up a triage system for those suspected of viral conjunctivitis.[11]

These patients are seen in a separate room with dedicated personnel. I strongly recommend the use of gloves and noncontact examination techniques. Staff infected with viral conjunctivitis should be furloughed until 2 weeks after the start of symptoms, by which time they are considered to be no longer contagious.

Clinical features

The main patterns of viral conjunctivitis are:

- epidemic keratoconjunctivitis (EKC),
- pharyngoconjunctival fever (PCF), and
- acute hemorrhagic conjunctivitis (AHC).

The symptoms and signs of these patterns of infection are similar, but vary in degree. All of these patterns present as an acute follicular conjunctivitis, with watering, grittiness, redness, ecchymosis and lid edema, often with flu-like symptoms. Preauricular lymphadenopathy and bilateral involvement are common.

In EKC most patients have some focal epitheliopathy and photophobia by 2 weeks. Subepithelial opacities appear after 2 weeks in 50% of patients and occasionally impair vision. These lesions cause occasional recurrences of grittiness. The natural history is of slow resolution, which can take more than 1 year.

In PCF there is a similar ophthalmic picture, but the systemic features are more pronounced.

In AHC ecchymosis is more prominent and the onset of symptoms more rapid. Rarely a polio-like radiculopathy follows AHC.

Diagnosis

Several methods are available for typing the viruses that cause acute conjunctivitis; most of these methods are time-consuming and expensive. More recently, polymerase chain reaction (PCR) and restriction fragment length polymorphism analysis have allowed faster diagnosis. Immunochromatography promises almost instant results.[12] These tests will be useful for epidemiology.

Most epidemics of viral conjunctivitis are caused by adenoviruses, commonly serotypes 8, 19 and 37 for EKC, and types 3 and 8 for PCF. Picornaviruses such as enterovirus type 70 and Coxsackie virus type A24 cause AHC. Conjunctivitis can be a feature of many other viral diseases, including influenza, rubella, rubeola, chickenpox and glandular fever.

Management

The management of viral conjunctivitis is supportive, with warm or cold compresses reducing symptoms of itch, plus lubrication and cycloplegics if there is an element of keratitis (see below). Antibacterial prophylaxis is probably unnecessary and can cause an allergic or toxic conjunctivitis.

KERATITIS

Keratitis is an inflammation of the cornea. Microbial keratitis is suppurative inflammation of the cornea produced by a replicating micro-organism. It carries a high risk of visual loss and can be caused by bacteria, fungi, viruses or parasites. A large variety of bacteria and fungi can infect the cornea.[13]

Figure 18-1 Typical microbial keratitis. Note accumulation of inflammatory cells at the dependent part of the anterior chamber of the eye (hypopyon) and mid-corneal defect. *Courtesy of Myron Yanoff.*

Typical acute microbial keratitis is the major syndrome. Patients present with a corneal epithelial defect and a stromal infiltrate (Fig. 18.1). The other main clinical problems are herpesvirus infections, with recurrent inflammation leading to scarring, and infection in a 'compromised' cornea (i.e. after local or systemic immunosuppression, injury or chronic disease). *Acanthamoeba* keratitis, which used to be rare, is a problem in contact lens wearers. Noninfectious keratitis is important in that it can be confused with infectious keratitis.

Algorithms for the initial division of keratitis into the main clinical situations are shown in Figure 18.2 .

INFECTIOUS KERATITIS

Typical acute microbial keratitis

Epidemiology

Microbial keratitis is responsible for 30% of cases of blindness in some developing countries. In hot climates fungal infection is more frequent, although bacterial keratitis still accounts for 60% of cases.[14]

The wearing of contact lenses increases the risk of developing bacterial keratitis.[15] The annual incidence is 5/10,000 for daily wear of soft lenses and 20/10,000 for overnight wear of soft lenses, although estimates 10-fold higher than this have been made. It has been estimated that over 65% of all new cases of keratitis in London, UK are due to the wearing of contact lenses.[16] The largest risk factor is the overnight wearing of soft lenses. This increases the risk 5-fold compared with the daytime wearing of lenses and 20-fold compared with the wearing of rigid lenses.[17]

Surgery, particularly corneal grafts and corneal sutures, and concomitant use of topical corticosteroids increase the risk of infection. Other than vitamin A deficiency, systemic predisposing conditions are relatively unimportant clinically. Vitamin A deficiency is particularly important in children who are malnourished and who have a concomitant infection, especially measles, in which keratomalacia (corneal melting) can occur suddenly.

Pathogenesis and pathology

Four principal groups of bacterial pathogens are responsible for most cases of infective keratitis. Micrococci (*Staphylococcus* and *Micrococcus* spp.), *Streptococcus* and *Pseudomonas* spp. and the Enterobacteriaceae (*Citrobacter*, *Klebsiella*, *Enterobacter*, *Serratia* and *Proteus* spp.) accounted for 87% of cases of bacterial keratitis in one series.[18]

Pseudomonas infection is recognized for its swift suppurative course to perforation secondary to proteolytic enzyme release. It is particularly common in contact lens wearers (hard and soft). *Serratia marcescens* corneal ulcers have been associated with the wearing of contact lenses and with contaminated eye drops. *Neisseria gonorrhoeae*, *C. diphtheriae* and *Haemophilus* and *Listeria* spp. are

Figure 18-2 Diagnosis of keratitis.

capable of penetrating an intact corneal epithelium. Other bacteria and fungi produce disease only after a loss of corneal epithelial integrity.

Following invasion by micro-organisms, several chemotactic substances are released, leading to an inflammatory cell infiltrate and consequent phagocytosis, cell death, release of proteolytic enzymes and corneal stromal damage.

Clinical features

The clinical appearance is not pathognomonic for any particular infecting organism, although some patterns are characteristic. Stromal ring infiltrates imply a massive immune response characteristic of infection by *Bacillus* and *Pseudomonas* spp. They are also seen in infections by *Streptococcus*, *Listeria*, *Proteus* and *Acanthamoeba* spp.

Staphylococcal infection can present early without an infiltrate but with pain, localized edema and a ring of keratic precipitates (inflammatory cells adherent to the endothelium). Developing ulcers caused by *Staphylococcus aureus* infection are round or oval and tend to progress in depth rather than area.

Diagnosis

Diagnosis is by microscopy and culture of a corneal scrape. In contact lens wearers the lenses and the lens case should be cultured.

In some parts of the world broad-spectrum therapy is used without initial investigation and it has been suggested that this practice could be extended. [19] If microbiologic services are not available there is little choice. However, the current high success rates of this treatment may not continue and in some areas antibiotic resistance is developing. Corneal scraping also debrides the ulcer, allows antibiotics to enter the base of the ulcer and provides microbiologic data (provided that antimicrobial therapy has not been given within the previous 24 hours).

The cornea is anesthetized with nonpreserved amethocaine 1%, five or six drops at 2-minute intervals. Using a slit-lamp, necrotic material is removed from the center of the ulcer. A 23 gauge needle tip is scraped parallel to the cornea to remove infected tissue. A fresh needle is used for each specimen. If a slit-lamp is not available scraping with a scalpel blade is safer than using a needle. The diagnostic yield is greater from the sides of the ulcer than from necrotic areas.

Slides should be made for Gram stain and Giesma stain, and appropriate bacterial cultures (and fungal cultures if suspected) should be prepared directly from the needle. Bending the tip of the needle before use facilitates this. The sharp side is used to scrape the cornea and the smooth surface used to plate out the specimen without penetrating the surface of the agar.

Management

Either gentamicin 1.5% with cefuroxime 5% or the fluoroquinolones ofloxacin 0.3% or ciprofloxacin 0.3% are effective against 90% of expected isolates in most clinical settings.[20] [21]

Aminoglycosides are toxic to the epithelium in moderate doses and quinolones are preferred as monotherapy. In cases in which streptococci are likely (e.g. chronic ocular surface disease, children) there may be quinolone resistance, and combination with cefuroxime 5% is recommended. There are increasing reports of quinolone resistance in some settings.[22]

Initial treatment is with drops every hour day and night for 2 days, followed by review.[23] If the clinical picture has improved or not worsened, treatment is then reduced to drops every hour by day for 3 days. After this time the ulcer should be sterile. Treatment is reduced to prophylactic levels q6h until the epithelium has healed. One trap for the inexperienced is that intensive treatment with ciprofloxacin 0.3% can cause a white ciprofloxacin precipitate to form in the corneal stroma adjacent to an epithelial defect. This may be confused with progression of the infection.

If the clinical picture progresses after 2 days of treatment the patient should be admitted to hospital for supervised treatment. If after the first week there is no response to therapy, consider stopping therapy and reculturing or switching to a different antibiotic guided by antibiotic sensitivity testing.

Fungal keratitis

Fungal infections are seen in two distinct clinical settings. In hotter climates the cornea is inoculated with infected vegetable matter as a result of agricultural or other trauma. Infection can then occur in otherwise healthy eyes. In temperate climates infection most often occurs in association with chronic ocular surface disease or prolonged corticosteroid use.

The septate filamentous fungal species, especially *Fusarium* and *Aspergillus* spp., are the most common cause of fungal keratitis. With increasing distance from the equator the relative incidence of candidal infection increases. Dematiaceous filamentous fungi such as *Curvularia* spp. are of low virulence and cause indolent infections.

Prevention

The main cause of fungal keratitis worldwide is trauma. In the developed world risk factors include protracted epithelial ulceration, therapeutic wearing of soft contact lenses, corneal transplant and topical corticosteroid therapy. Patients who have exposure keratitis and a history of previous herpes simplex or herpes zoster keratitis are at risk.

Clinical features

Fungal keratitis usually presents as a typical microbial keratitis. It is not possible to diagnose the type of infection on clinical grounds. Clinical context is the most important guide to appropriate investigation and therapy. In filamentary fungus keratitis the corneal surface is gray or dull. Satellite lesions are common in the surrounding stroma and may be seen with an intact epithelium (Fig. 18.3).

Figure 18-3 Fungal keratitis. The corneal surface looks rough, and there are several satellite lesions best seen here at the periphery on the left side of the cornea. *Courtesy of Myron Yanoff.*

Candidal lesions appear in corneas that are already abnormal. They are often quite localized at first with a collar button configuration.

Diagnosis

Diagnosis is by culture of corneal scrapes. In indolent cases corneal biopsy is indicated.

Management

Historic data are the best guide to selecting antifungal therapy. [24] The greatest experience in the use of antifungals for keratitis comes from India. However, this experience may not apply to situations where there is a local or systemic disorder of immunity.

No currently available antifungal agent has a favorable profile of activity and toxicity. Response to antifungal treatment is poor compared with that to antibacterial treatment. Surgical management (corneal transplant) may be necessary.

Combined topical and systemic therapy is often used and is usually prolonged. Corneal drug penetration is helped by daily scraping of the epithelium and necrotic stroma.

The choice of antifungal agent is often dictated by availability. Most topical antifungal agents must be made locally from tablets or intravenous preparations.

Among the polyenes, amphotericin B is fungicidal, but is toxic to the eye in high concentrations. It is used diluted in sterile water at 0.1–0.15% two to four times every hour for the first 1–2 days. Natamycin 5% has poor corneal penetration, but is useful for superficial filamentary fungal infections.

Among the pyrimidines, flucytosine 1% can be prepared from a commercially available intravenous or tablet form and is used in combination only (early resistance occurs) with amphotericin B for candidal keratitis. Concomitant systemic use may be helpful.

Among the imidazoles, miconazole 10mg/ml in polyethoxylated castor oil (intravenous preparation) was effective in more than 60% of cases in a prospective trial in India[25] when used topically every 2 hours. Ketoconazole 2% prepared as an aqueous solution from tablets is probably effective against *Aspergillus flavus*, but not *Aspergillus fumigatus* or *Fusarium* spp. Systemic and topical administration is often combined. Econazole 1% is used topically in combination with systemic itraconazole, and clotrimazole 1% vaginal cream has also been used. Fluconazole is given systemically or as a 0.2–0.5% topical aqueous solution. Itraconazole used orally has an some activity against filamentous fungi (see Chapter 208). It has poor tissue penetration, but a good clinical response when used against candidal infections. *Fusarium* spp. respond less well.

Silver sulfadiazine 1% is used for antibiotic prophylaxis in patients who have burns. It has moderate antifungal activity in vitro, but has been widely used in developing countries as a topical antifungal with good rates of success, particularly against *Fusarium* spp.

Chlorhexidine gluconate 0.2% solution is at least as effective as natamycin in treating fungal infections and is suggested as an inexpensive agent for use in the

developing world.[26]

Initial treatment for fungal keratitis depends upon local experience. In London, UK we use topical econazole 1% (or amphotericin B 0.15 or 0.3%) hourly for 48 hours, then 2 hourly for 72 hours and then reduce the dosage depending upon the initial response. Long-term treatment is required. Systemic treatment is used as an adjunct: itraconazole 200mg daily initially, reduced to 100mg for longer term use, or fluconazole 200mg daily for *Candida* infections. If surgical debridement is performed, a 2mm clear margin is advised. The inflammatory reaction results from live organisms and fungal debris. Because most antifungal agents are fungistatic, reduction of inflammation also depresses local immunity so that the organisms are not killed. Concomitant corticosteroid use is therefore not recommended for fungal keratitis.

Acanthamoeba keratitis

Epidemiology

Acanthamoeba histolytica was not recognized as a cause of keratitis until the 1970s, and the incidence has increased since. *Acanthamoeba histolytica* live in soil and water, including swimming pools, water storage tanks and contact lens cases (see Chapter 244).[27] Approximately 10–15% of cases are associated with agricultural and other trauma, but most are associated with contact lens use. The annual incidence in 1985–7 was estimated at 1.65–2.01/million contact lens wearers.[28] Poor lens hygiene by soft contact lens wearers and the use of homemade saline- or chlorine-based disinfection systems are risk factors. Disposable lens wearers have a particularly high risk, although this may be related to care systems used with the lenses.[29]

In the UK the use of tank-stored water by contact lens wearers to rinse lenses or lens cases may have introduced *A. histolytica* into their lens care systems.[30] The free-living protozoa have been seen grazing on bacterial slime on the bottom of contact lens cases.

Acanthamoeba histolytica can also cause scleritis and chorioretinitis.

Prevention

Good lens hygiene, the use of hydrogen peroxide 3% for at least 3 hours[31] and avoidance of tap water in contact lens care are important preventive measures.

Clinical features

In early epithelial disease there may be punctate keratopathy, pseudodendrites, epithelial wrinkling, diffuse or focal subepithelial infiltrates and radial perineural infiltrates. Ring infiltrates and corneal ulceration may present later.[32] [33] Pain out of proportion to the clinical signs is common, but not constant. The clinical picture may resemble herpetic or fungal keratitis, and a high index of suspicion is warranted in contact lens wearers who have apparent herpetic disease. Bacterial coinfection or superinfection in late disease occurs in around 10% of cases and causes an atypical presentation.

The clinical course of *A. histolytica* keratitis is prolonged. Early diagnosis is important, but treatment started before proper diagnostic tests are carried out only confuses the clinical picture. Unlike bacterial keratitis there is no justification for starting therapy without investigation. A delay of a 1–2 days while a patient is referred for expert opinion and investigation is less harmful than early inappropriate therapy. The grave prognosis of *A. histolytica* keratitis in the past was due to the slow inexorable progression of disease rather than fulminant corneal destruction.

Diagnosis

Diagnosis is made by microbiologic and histopathologic examination of tissue specimens. The epithelium is removed for examination by epithelial biopsy. In cases in which only the stroma appears to be involved corneal biopsy (described above) is necessary. If culture is negative, tear fluid PCR has been suggested as an adjunctive investigation.[34]

For microbiologic analysis, specimens[35] can be plated on nonnutrient agar, which is later overlain with *Escherichia coli* in the laboratory. Tracks of bacterial clearing show where the amebae have been grazing. Bacterial and fungal cultures should also be obtained.

Microscopy techniques vary. Fluorescent microscopy can be carried out using calcofluor white, which stains the walls of cysts, with acridine orange or with an immunofluorescent antibody. An immunoperoxidase test is used in some laboratories. Confocal microscopy of a wet preparation can be used to identify motile trophozoites, which have a large karyosome and a contractile vacuole.

Biopsy specimens should also be stained with hematoxylin and eosin, periodic acid-Schiff and methenamine silver to demonstrate *A. histolytica* cysts.

Sensitivity testing, although useful in screening for amebicides, is less useful in the management of individual cases,[36] [37] perhaps because *A. histolytica* encysts in infected tissues.

Management

The diamidines, propamidine isethionate 0.1% and hexamidine 0.1% and the cationic antiseptics, polyhexamethyl biguanide (PHMB) 0.02% and chlorhexidine 0.02% are probably the most effective medications,[33] [38] although availability can be a problem. Local manufacture of chlorhexidine or PHMB may be possible from 20% disinfectant preparations. The azoles (clotrimazole, fluconazole, ketoconazole and miconazole) have also been suggested for use as a third agent.

Initial treatment starts immediately after the epithelium is debrided using a cationic antiseptic and a diamidine, each hour day and night for 48 hours, then hourly by day for 3 days. Dosage is then reduced to 3-hourly to reduce local toxicity. If toxicity is suspected the frequency of the diamidine should be reduced.

It may take 2 weeks to achieve a response to treatment. Pain relief with systemic nonsteroidal anti-inflammatory agents and cycloplegia is very important.

The use of corticosteroids in controlling inflammation is controversial. Some authorities say that they are contraindicated at any stage. Others advocate the use of a weak topical corticosteroid to control inflammation after at least 2 weeks of antiamebic therapy, emphasizing the importance of continued antiamebic therapy until several weeks after the corticosteroid is stopped.

Viral keratitis: herpes simplex virus type 1 or 2

Epidemiology

Herpes simplex keratitis has an annual incidence of new cases of 8/10,000. The incidence peaks at ages 5–10 years and 35–40 years. Males are affected twice as often as females. Approximately 50% of patients have a history of herpes labialis. Primary ocular infection occurs in 5%.[39]

Corneal infection is usually with herpes simplex virus type 1 (in 98% of cases), except in neonatal herpes infection, when 80% of cases are due to herpes simplex virus type 2.

Pathogenesis and pathology

The pattern of dendritic ulcers is caused by direct infection of corneal epithelium. It is thought that delayed-type hypersensitivity to viral antigens causes the inflammation that leads to disciform keratitis.[40]

Clinical features

Primary ocular infection is usually asymptomatic, although a vesicular reaction may be seen. Occasionally there is a follicular conjunctivitis. Corneal damage is caused by recurrent disease.

Recurrence occurs in around 10% of cases at 1 year and 50% by 20 years. Triggers include fever, trauma and ultraviolet light. Recurrence is a consequence of latency.[41] Latency develops as virus spreads to a sensory ganglion and remains dormant there. It is thought that infection can spread across a ganglion, for instance from the mandibular to the ophthalmic division of the trigeminal nerve, and hence from lip to eye. Spread from eye to eye is uncommon except in atopic patients in whom delayed-type hypersensitivity is impaired. These patients are at risk of bilateral disease, larger geographic ulcers and disseminated infection.

With each recurrence corneal scarring increases, and it is thought that viral particles remaining within the cornea cause the continuing inflammation and edema seen in disciform keratitis.

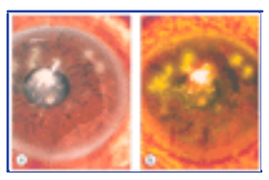

Figure 18-4 Herpes simplex virus dendritic keratitis, showing branching epithelial lesions seen (a) without staining and (b) with rose bengal staining. Rose bengal stains the devitalized cells at the edges of the dendritic lesions. *Courtesy of Myron Yanoff.*

Diagnosis

Viral culture or immunofluorescence[42] can be used to confirm infection, but in practice the diagnosis is clinical. In epithelial disease there is a characteristic dendritic ulcer (Fig. 18.4). Corneal sensation is often impaired, and there is usually a history of similar attacks in the past.

Management

Untreated herpes simplex keratitis usually resolves within 1–2 weeks, but it can progress, resulting in the development of geographic ulcers. Resolution is more rapid if the dendritic ulcer is debrided. Antiviral treatment also speeds up resolution, and no benefit has been shown for a combination of debridement and antiviral agents when compared with the use of antiviral agents alone. The choice of antiviral agent depends on availability. In Europe aciclovir 3% ophthalmic ointment five times a day is almost universally preferred because it is effective and has a low incidence of toxicity.[43] In the USA, trifluridine 1% 2-hourly is used.

Oral aciclovir or famciclovir is effective but comparatively expensive. It may be useful when there is a desire to reduce corneal exposure to topical agents. Systemic antiviral treatment is recommended as prophylaxis against encephalitis for infants who have primary infection.

Prophylactic treatment with oral aciclovir 400mg q12h reduces the recurrence rate of stromal (severe) disease from 28 to 14%.[44]

The management of the chronic sequelae of herpes simplex keratitis may require topical corticosteroid therapy under close ophthalmic supervision. Topical antiviral treatment reduces recurrence rates in these patients.[45]

Viral keratitis: herpes zoster ophthalmicus

Epidemiology

The varicella-zoster virus is a herpesvirus that causes chickenpox as a primary infection and shingles on recurrence. Around 90% of adults are seropositive for varicella-zoster virus. The rate of recurrence increases with age, and second recurrences can occur in those who have impaired immunity.

Pathogenesis and pathology

Reactivated virus replicates in the ganglion, producing local inflammation and premonitory pain before it travels down peripheral nerves to the skin or eye. A perineuritis and vasculitis occurs, and in the eye a disciform keratitis, iritis and cyclitis are common manifestations.

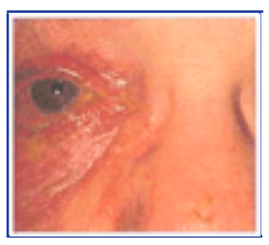

Figure 18-5 Herpes zoster ophthalmicus. Inflamed right periorbital skin, with conjunctivitis and a lesion on the nose. *Courtesy of Myron Yanoff.*

Clinical features

The clinical appearance is typical. Symptoms of eye involvement include photophobia and decreased vision. Hutchinson's sign, a rash on the side of the nose, is associated with ocular inflammation (Fig. 18.5).

Management

Oral aciclovir 800mg five times a day for 7 days accelerates skin healing and reduces the incidence of episcleritis, keratitis, iritis, postherpetic neuralgia and probably acute pain.[46] The newer antivirals famciclovir and valaciclovir have improved bioavailability and are increasingly used instead of aciclovir. There is little role for topical antivirals.

Systemic corticosteroids used with antiviral therapy have some benefit in shortening the clinical syndrome, but they do not reduce the incidence of postherpetic neuralgia.[47] There is no clinical consensus on whether the benefits of treatment outweigh the risks (see Chapter 8).

Disciform keratitis, iritis and cyclitis respond to conventional topical corticosteroid treatment, but prolonged therapy, sometimes for years, is required.

AIDS: varicella-zoster epithelial keratitis

A chronic, painful epithelial keratitis has been described in patients with AIDS and severe immunodeficiency ($CD4^+$ T cell counts of less than 0.1×10^9 /l). Clinically characterized by a variable dendrite-like keratitis, the associated severe, burning pain is the most dramatic feature. Response to treatment is variable; some patients have responded to oral or topical aciclovir, but such patients tend to relapse when treatment stops. [48]

INFECTIONS OF PERIORBITAL STRUCTURES

PERIORBITAL CELLULITIS

The orbit is the bony structure surrounding the eye. Infection of the contents of the bony orbit is called orbital cellulitis. Orbital infection commonly occurs as a result of contiguous spread from adjacent structures. Periorbital cellulitis is divided into preseptal or postseptal (orbital) depending on the site of infection. Orbital cellulitis is sight-threatening and occasionally life-threatening. Preseptal cellulitis is five to 10 times more common than orbital cellulitis in infants and toddlers and is not sight-threatening or life-threatening, but it can, rarely, spread to become orbital cellulitis. It is commonly caused by *H. influenzae* or *Streptococcus* spp. and follows an upper respiratory tract infection. In adults it is most often seen after minor trauma such as an infected bite or scratch.

The source and agents of infection causing orbital cellulitis vary with age. The paranasal sinuses (the ethmoid, maxillary and frontal sinuses) are the main sources. Orbital cellulitis is uncommon in neonates, but when it occurs it is usually secondary to conjunctivitis or a developmental abnormality such as a ruptured dacryocele. In infants respiratory tract infections may cause preseptal cellulitis. In older children and adults dental abscesses and trauma become important causes. Endogenous orbital cellulitis is rare.

Clinical features

In adults there is frequently a history of sinusitis, headache or recent tooth extraction or abscess. Children often have an antecedent upper respiratory tract infection.

Preseptal cellulitis is characterized by eyelid swelling and edema, which is usually unilateral mainly involves the upper lids. Lower lid swelling occurs when the cellulitis is secondary to dacryocystitis. Edematous conjunctiva can prolapse between the lids.

In orbital cellulitis features of preseptal cellulitis are variably present, but there is also proptosis, decreased ocular mobility and even decreased vision or a relative afferent pupil defect. These signs are caused by increased intraorbital pressure due to edema or abscess. If a subperiosteal abscess forms there may be nonaxial displacement of the globe and a palpable fluctuant mass in the orbit. Headache, fever and leukocytosis are common.

Diagnosis

Blood and local cultures are mandatory. A computerized tomography (CT) scan can distinguish between preseptal and orbital cellulitis and show the site of an orbital or subperiosteal abscess:[49]

- preseptal cellulitis produces edema of the lids and tissues anterior to the orbital septum, and
- orbital cellulitis produces edema of the orbital tissues and proptosis.

Orbital cellulitis is often associated with signs of primary or secondary sinus disease.

Staphylococcus and *Streptococcus* spp. and, in those under 4 years of age, *H. influenzae* are the main pathogens that cause preseptal and orbital cellulitis in children. In subperiosteal abscesses in children over 9 years of age and adults there is often a mixed infection of aerobes and anaerobes[50] from extending sinus or dental infections.

Management

Preseptal cellulitis responds well to systemic antibiotics. One or more broad-spectrum agents that cover *Staphylococcus* and *Streptococcus* spp. and *H. influenzae* should be used. A response is usual within 24 hours.

Orbital cellulitis requires prompt diagnosis and inpatient treatment with intravenous antibiotics. Monitoring of vision, pupillary reaction, extraocular movements and central nervous system function should be carried out during the first 1–2 days until the infection begins to resolve. If a subperiosteal abscess or sinusitis is identified and the clinical picture is not improving after 24 hours, surgical management is required. Orbital or brain abscesses are less common and should be drained immediately.

LACRIMAL SYSTEM INFECTIONS

Dacryoadenitis

Dacryoadenitis is usually due to a viral infection of the lacrimal gland. Patients present with adenopathy, fever, malaise and leukocytosis. The causes include infectious mononucleosis, herpes zoster, mumps, trachoma, syphilis, tuberculosis and sarcoidosis. Dacryoadenitis occasionally occurs in dehydrated patients as an ascending staphylococcal infection associated with a purulent discharge. On CT scanning there is diffuse lacrimal gland swelling without bony defects.

Diagnosis

The condition is usually self-limiting. Investigation other than CT scanning is reserved for chronic dacryoadenitis, and such patients should be referred for specialist investigation to exclude neoplasia.

Management

Treatment is generally symptomatic. Corticosteroids can help speed up resolution. It can be difficult to distinguish dacryoadenitis from idiopathic lacrimal gland inflammation (pseudotumor), although the presence of enlarged preauricular lymph nodes makes a viral diagnosis more likely.

Canaliculitis

There are chronic and acute forms. Acute dacryoadenitis may be caused by herpes simplex or herpes zoster and is often unrecognized except as a conjunctivitis and by its sequelae: scarred closed canaliculi and a punctum.

Chronic canaliculitis is usually unilateral and is characterized by pain or tenderness at the inner canthus. A chronic conjunctivitis may mask the more specific signs. The lacrimal punctum may pout and 'sulfur granules' may be expressed. These sulfur granules are pathognomonic of infection with *Actinomyces israelii*, an anaerobic Gram-positive branching filamentous bacterium. Less common causes are *Aspergillus* and *Candida* spp.

Treatment is by incision of the infected canaliculus and wash-out of all 'sulfur' material, usually with a penicillin-containing irrigation fluid.

Dacryocystitis

Pathogenesis and pathology

This condition occurs in chronic and acute forms. In infants it is usually an indolent condition resulting from incomplete development of the lacrimal drainage system. There is a mucopurulent discharge and recurrent conjunctivitis. Colonization is usual with *H. influenzae*, *Streptococcus pneumoniae*, staphylococci and *Klebsiella* and *Pseudomonas* spp.

In adults an acquired blockage of the lacrimal drainage system can cause an acute or chronic infection. An acute infection can be precipitated by instrumentation for investigation of a suspected blocked lacrimal duct. For this reason, mucoceles or chronic dacryocystitis should not be probed or syringed. Acute dacrocystitis presents with a painful swelling over the lacrimal sac.

Treatment is with warm compresses and systemic antibiotics. A large abscess should be drained by a stab through the skin or inferior fornix conjunctiva. A dacryocystorhinostomy will prevent recurrence.

Chapter 19 - Endophthalmitis

Michael Whitby

Endophthalmitis is fortunately an uncommon condition; however, it may result in severe visual impairment or loss of an eye.

EPIDEMIOLOGY

Definition and nomenclature

Endophthalmitis is an infection within the vitreous and may involve the cornea and, in severe cases, the sclera (panophthalmitis). A number of classifications of this condition have been published but from a practical point of view, categorization by the clinical setting, taking into account such factors as the events preceding infection and the time to diagnosis, is most appropriate. Categories include postoperative endophthalmitis (acute (within 2 weeks of operation), delayed onset (more than 2 weeks after operation), conjunctival filtering bleb associated), post-traumatic endophthalmitis and endogenous endophthalmitis. Each of these subtypes may have characteristic clinical features and a spectrum of common causative pathogens (Table 19.1).

Incidence and prevalence of endophthalmitis

Although recent eye surgery is the most common cause of endophthalmitis, accounting for more than 70% of cases, the incidence of infection after cataract extraction, the most commonly performed eye surgery, continues to decline. Reported infection rates over the past few decades after extracapsular cataract extraction, with or without intraocular lens implantation, are very low, at 0.07–0.25%. [1] Endophthalmitis may occur after any other form of ocular surgery, but appears to be more common after glaucoma filtering procedures.

Endophthalmitis after penetrating ocular trauma is common, representing 7–30% of all endophthalmitis cases; 3–26% of penetrating eye injuries develop infection. It is more common when trauma is associated with a retained intraocular foreign body or when the injury is contaminated with vegetable matter.[2] The leading organisms in this setting are staphylococci, especially *Staphylococcus aureus*, and *Bacillus* spp.

Endogenous bacterial and fungal endophthalmitis are the least common forms, accounting for less than 2–8% of cases; they usually follow bloodstream spread of organisms and are commonly associated with a number of chronic medical conditions, such as diabetes mellitus, chronic renal failure, chronic immunosuppression, invasive medical procedures (including urinary catheterization and intravascular central lines) and intravenous drug abuse.

PATHOGENESIS AND PATHOLOGY

Although a broad range of organisms can cause endophthalmitis, the most common causative infectious agents are bacteria. Virtually any bacterium, including those usually accepted as saprophytes, can cause infection, although members of the normal ocular microflora are the most commonly implicated.

Acute postoperative endophthalmitis

In over 70% of cases, the pathogenic organism is a Gram-positive bacterium. *Staphylococcus epidermidis* and other coagulase-negative staphylococci are now the most frequently isolated bacteria from postsurgical endophthalmitis, representing 50–55% of all culture-positive cases. [3] *Staphylococcus aureus* and *Streptococcus* spp. are cultured from 10–30% of postoperative infections, whereas Gram-negative organisms, including *Pseudomonas* spp., *Proteus* spp. and *Citrobacter* spp., are implicated in only 7–20%. The change in prevalence of *Staph. epidermidis* probably represents, at least in part, a past failure to recognize coagulase-negative staphylococci as potential ocular pathogens.

Infecting organisms are usually introduced into the eye via incisions at the time of surgery. Nosocomial outbreaks of endophthalmitis caused by contaminated irrigation fluids, intraocular lenses and donor corneas have been recognized. Infiltration of pathogens in the immediate postoperative period may be associated with inadequately buried sutures, suture removal or the presence of vitreous wicks.

Delayed-onset postoperative endophthalmitis

Delayed-onset endophthalmitis is often caused by less aggressive organisms, including *Staph. epidermidis*, *Corynebacterium* spp. and *Candida* spp. A specific syndrome of chronic localized infection may occur with *Propionobacterium acnes*.

Filtering bleb endophthalmitis

Filtering bleb endophthalmitis is frequently caused by streptococci (60%) and *Haemophilus influenzae* (20%), although *Staph. aureus* remains a prominent pathogen.[4]

Post-traumatic endophthalmitis

Post-traumatic infection may be polymicrobial (10–40%), particularly in rural settings. Rarely, although more commonly than seen in postoperative infection, it can be caused by anaerobic organisms, especially *Clostridium* spp. *Staph. aureus* remains a common agent, although saprophytes such as *Bacillus* spp., especially associated with intraocular foreign bodies, may induce fulminating endophthalmitis.[5] Spread of organisms through corneal abrasions and penetrating corneal ulcers, particularly those involving *Staph. aureus* or *Pseudomonas aeruginosa*, may lead to endophthalmitis.

Endogenous endophthalmitis

Endogenous infection may be associated with a recognizable infective focus elsewhere in the body and this may provide an indication as to the likely causative organism. Ocular involvement, however, may also be the first and only manifestation of systemic infection. Two to three decades ago, the most commonly associated bacteria were meningococci and pneumococci related to meningitis and infective endocarditis, respectively; more recently, *Streptococcus* spp. other than *Strep. pneumoniae*, *Staph. aureus* and Enterobacteriaceae from gastrointestinal sources have become more prominent.[6] Intravenous drug use may be associated with infection with *Candida* spp., *Aspergillus* spp. and *Bacillus cereus*, although more common pathogens, including *Staph. aureus*, may be involved.

TABLE 19-1 -- Microbial etiology of endophthalmitis.

MICROBIAL ETIOLOGY OF ENDOPHTHALMITIS	
Category of endophtalmitis	**Common causative organisms**

Postoperative	Acute	Coagulase-negative staphylococcus
		Staphylococcus aureus
		Streptococcus spp.
		Gram-negative bacilli
		Pseudomonas spp.
	Delayed	*Staphylococcus epidermidis*
		Propionobacterium acnes
		Candida spp.
	Filtering bleb	*Streptococcus* spp.
		Haemophilus influenzae
		Staphylococcus aureus
Post-traumatic	Bacterial	*Staphylococcus aureus*; other staph spp.
		Bacillus spp.
		Pseudomonas spp.
		Other Gram-negative bacilli; anaerobes; corynebacteria; streptococci
	Fungal	*Penicillium* spp.; *Fusarium* spp.; *Acremonium* spp; other filamentous fungi
Endogenous	Bacterial	Enteric Gram-negative bacilli
		Fungi (including *Candida albicans*, *Aspergillus* spp.)
		Streptococcus spp.
	Fungal	Yeasts (*Candida albicans*, *Cryptococcus* spp.)
		Filamentous fungi (*Aspergillus* spp., *Acremonium* spp., *Fusarium* spp., *Paecilomyces* spp.)

Fungal endophthalmitis

Fungal endophthalmitis may occur as exogenous or endogenous infection. Postoperative fungal infection is fortunately exceedingly rare; however, after trauma, fungal endophthalmitis may represent up to 10% of cases, particularly if penetration with vegetable matter has occurred.[7] Extension of a fungal corneal ulcer may also lead to endophthalmitis. Fungi most commonly identified in this situation are usually saprophytic and may include *Aspergillus* spp., *Fusarium* spp., *Acremonium* spp. and *Paecilomyces* spp. Endogenous fungal endophthalmitis has been seen with increasing frequency over the past two decades, concurrent with an increased recognition of systemic fungal infections. *Candida albicans* is the most frequently reported causative agent after hematogenous dissemination from other infected body sites, particularly infected central venous catheters, and often in immunocompromised patients.[8] Direct intravenous inoculation as a result of narcotic abuse or contaminated infusion solutions has also been reported. Other fungi less commonly implicated in endogenous fungal endophthalmitis include *Cryptococcus neoformans*, *Aspergillus* spp. and *Paecilomyces* spp.

PREVENTION

The prevention of endophthalmitis is based on identification and pre-treatment of high-risk patients, and reduction in the conjunctival commensal flora.

Preoperative precautions

High-risk patients

Host factors that lower resistance to infection, such as chronic immunosuppression or diabetes mellitus, have been reported as significant risk factors for postoperative endophthalmitis. Reduction in immunosuppressive medications, when possible, and optimal control of blood glucose are essential in such groups. Pre-existing infection of external ocular tissue, for example chronic blepharitis, conjunctivitis and lacrimal outflow obstruction, should be identified and treated with appropriate topical antibiotics.

Antimicrobial prophylaxis

The aim of preventive treatment is to reduce eyelid and ocular surface microflora; this may be achieved by using topical antibiotics, topical antiseptic agents or subconjunctival antibiotics at the time of surgery.

Topical antibiotics

Although there is no consensus as to the optimal use of preoperative topical antibiotics in intraocular surgery, several studies have demonstrated significant falls in bacterial colonization of the conjunctiva with the application of topical antibiotics and have thus suggested a reduction in the incidence of postoperative endophthalmitis with the use of such antibiotics preoperatively. Topical antibiotics have been reported to be most effective in decreasing conjunctival bacterial colony counts when administered 2 hours before surgery.[9] Until the early 1980s, gentamicin (3mg/ml) was consistently found to be the most effective antibiotic in this situation compared with other agents such as chloramphenicol (5mg/ml), bacitracin (10mg/ml), neomycin (5mg/ml) and polymixin (2.5mg/ml).[10] However, the increase in gentamicin resistance among *Staph. epidermidis*, now the most common cause of postoperative endophthalmitis, suggests that it may no longer be the optimal agent for prophylaxis.[11] Vancomycin, when used prophylactically, has been shown to be active against staphylococci, but the potential risk of emerging resistance in enterococci and to a lesser extent in methicillin-resistant *Staph. aureus* has led some authorities to discourage this practice. Although no specific recommendations have been developed for ophthalmology, it seems appropriate to restrict the use of vancomycin to the treatment of, for example, serious keratitis, endophthalmitis or orbital cellulitis caused by ß-lactam resistant Gram-positive organisms or alternatively to the treatment of enterococci and *Staph. aureus* in patients unable to tolerate ß-lactam antibiotics. More recently, fluoroquinolones (all compounded at a concentration of 3mg/ml), for example ciprofloxacin, norfloxacin and ofloxacin, have been shown to be very effective in reducing conjunctival and eyelid bacterial flora when used preoperatively.[12]

Subconjunctival antimicrobials

Subconjunctival antibiotics can be administered after intraocular surgery based on the rationale that, at the completion of the ocular procedure, it is appropriate to inhibit growth of any bacteria that may have gained entry into the eye during surgery. During routine cataract surgery, aqueous fluid samples have been demonstrated to be culture positive in up to 43% of cases.[13] Conflicting results as to the value of this modality have been reported and penetration into the vitreous is relatively poor.

Topical antiseptics

Application of 5% aqueous povidone-iodine solution alone has been shown to be nontoxic and to decrease perioperative conjunctival bacterial colony counts and reduce the incidence of postoperative endophthalmitis significantly. In combination with topical antibiotics, povidone-iodine has been found to sterilize the conjunctiva in more than 80% of treated patients.[14]

Intraoperative precautions

Although the judicious use of preoperative antibiotics can reduce infection rates considerably, they do not replace meticulous aseptic technique in intraocular procedures. An appropriate operating room

environment, with efficient ventilation to reduce bacterial contamination, is essential; surgical techniques should be modified to minimize entry of ocular surface microbes into the eye during the surgical procedure, and adhesive-backed plastic drapes to isolate the eyelids and lashes from the operative field are recommended.

Implantation of intraocular lenses with prolene haptics appears to increase the risk of endophthalmitis, probably because coagulase-negative staphylococci bind well to this particular plastic. Binding to polymethylmethacrylate material is less, and therefore its use may reduce risk.[15] Care must be taken to minimize contact with the external eye during insertion of an intraocular lens to prevent contamination with conjunctival flora. A foldable lens insertion device has been developed to facilitate this. There is always the threat of infection from personnel and equipment in the operating room, and from contaminated irrigation solutions.

CLINICAL FEATURES

Clinical signs of endophthalmitis vary greatly depending on the preceding events, the nature of the infecting organism, the degree of tissue inflammation and the duration of disease. Early diagnosis requires the maintenance of a high index of suspicion as classic features of infection may be absent.

Acute postoperative endophthalmitis

Acute postoperative endophthalmitis usually occurs within 2 weeks of surgery, whereas the presentation of infection after penetrating trauma will often be more rapid. As a general principle, the more rapid the onset of symptoms, the more virulent the organism, with *Staph. aureus*, *Streptococcus pyogenes*, *Bacillus* spp. and Gram-negative bacilli being implicated in very rapid onset of infection within 24–72 hours of surgery. This presentation is characterized by marked anterior chamber inflammation, by the rapid development of a fibrinous anterior chamber exudate with hypopyon (which produces severe pain, more prominent than general postoperative discomfort) and by a progressive decrease in visual acuity. A marked vitreous inflammatory reaction, often obscuring visualization of the retina, frequently follows (Fig 19.1 , Fig 19.2 and Fig 19.3). Associated features may include marked conjunctival, lid and corneal edema, but systemic features are virtually never seen.

Delayed-onset postoperative endophthalmitis

Delayed-onset endophthalmitis has a more insidious course and frequently overlaps with acute postoperative endophthalmitis if less virulent organisms are implicated. Symptoms may not manifest until weeks or even months after surgery, although early mild clinical features with progressive worsening over time are not uncommon (Fig. 19.4). When delayed-onset endophthalmitis is caused by *P. acnes*, it usually develops months after cataract extraction; patients will often have a history of corticosteroid-responsive postoperative inflammation with a fluctuating course over many months. The

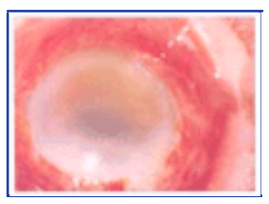

Figure 19-1 Corneal edema and fibrinous anterior chamber exudate in a traumatic foreign body-induced endophthalmitis. Any posterior vitreal or retinal view is obscured by the anterior corneal and aqueous haze.

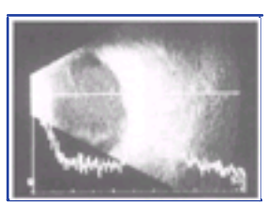

Figure 19-2 B-scan ultrasound of the eye showing total vitreous opacity of a severe endophthalmitis in patient seen in Figure 19.1 . This horizontal 'cut' through the eye shows the normally 'transparent' vitreous cavity to be filled with inflammatory debris, but there is no obvious retinal detachment.

Figure 19-3 A dense vitreous abscess in advanced endophthalmitis. This partially treated postoperative endophthalmitis has vitreous cellular and protein deposits obscuring the retinal view.

Figure 19-4 The typical posterior capsular opacities seen in a late-onset *Staphylococcus epidermidis* endophthalmitis. These deposits are actual coccal colonies, which are frequently removed at subsequent vitrectomy surgery to open up the capsular bag to intraocular antibiotics.

Figure 19-5 A 'quiet' endogenous fungal endophthalmitis with small hypopyon. This eye is relatively quiet with little chemosis, injection and pain, but has a small hypopyon and some small fungal 'balls' on the temporal iris.

most common clinical signs are posterior capsular deposits and chronic iridocyclitis. [16]

Fungal infection may also have a delayed clinical onset. Anterior chamber reaction is seen with progressive white infiltrates often adherent to the iris and posterior corneal surface (Fig 19.5 and Fig 19.6). Fluffy white fungal ball infiltrates ('string of pearls') occurring in the vitreous are characteristic (Fig. 19.7). Patients who have chronic postoperative endophthalmitis caused by coagulase-negative staphylococci may present with a hypopyon and diffuse vitritis, which occasionally obscures the view of the fundus. Visual loss is usually more severe than that in endophthalmitis caused by *P. acnes* or fungi.

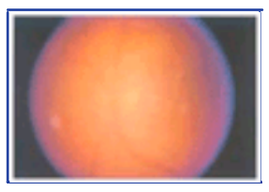

Figure 19-6 The degraded ophthalmoscopic retinal view obtained in patient seen in Figure 19.5 . The corneal edema and anterior chamber activity make vitreous and retinal observation difficult.

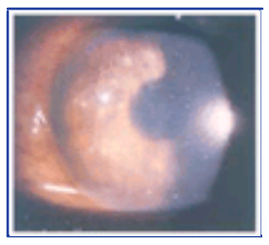

Figure 19-7 Fungal 'fluff balls' on the iris seen in a fungal endophthalmitis. Although these are not pathognomonic, their appearance raises the real possibility that the infection is of fungal origin.

Filtering bleb endophthalmitis

A conjunctival filtering bleb is a collection of fluid under the conjunctiva resulting from the formation of a fistula at operation through the sclera from the anterior chamber in an endeavor to reduce pressure in the anterior chamber. Endophthalmitis associated with a conjunctival filtering bleb is actually an acute presentation of endophthalmitis, but may occur months to years after the operation with rapid development of symptoms. Intraocular spread occurs from an initial bacterial penetration through the mucosa of the bleb, often in association with bacterial conjunctivitis. Infection is often associated with late bleb leakage and is facilitated by antimetabolites (e.g. 5-FU or mitomycin) used to ensure bleb survival.[2] A purulent discharge and an injected bleb are commonly seen, ultimately in association with typical signs of endophthalmitis. Viridans streptococci, *H. influenzae* and *Staph. aureus* are commonly implicated.

Post-traumatic endophthalmitis

Presentation will vary depending on the nature and severity of the ocular trauma or the type of retained foreign body, for example steel or vegetable matter, and the virulence and concentration of the organism initially deposited into the intraocular tissues (Fig. 19.8). The more virulent this organism, including *Staph. aureus* and *B. cereus*, the more rapid the onset of pain and associated ophthalmic features of infection. *Bacillus cereus*, fungi and to a lesser extent Nocardia spp. and atypical mycobacteria should be considered when injury to the eye is related to plant or vegetable matter.[17]

Endogenous endophthalmitis

Endogenous endophthalmitis usually has an insidious onset with a slow decrease in visual acuity caused by vitritis and localized areas of chorioretinitis. It may be suspected when other systemic symptoms of infection are present or in certain groups of patients, including those in whom bacteremia or fungemia is common, such as those with infective endocarditis and those with intravascular or urinary catheters, or patients who abuse intravenous drugs. Rarely, a fungal endophthalmitis, with a predilection for *Paecilomyces* infection, may occur in otherwise healthy individuals with no antecedent trauma.[18]

Figure 19-8 Horizontal computerized tomography scan section of eye seen in Figure 19.1 and Figure 19.2 revealing metallic intraocular foreign body in vitreous cavity (arrow). This CT scan demonstrates that the vitreous opacity seen by ultrasound is 'invisible' to this investigation.

Differential diagnosis

The differential diagnosis of postoperative inflammation includes sterile uveitis related to retained lens cortex; operative complications such as vitreous loss, hemorrhage and iris trauma; pre-existing uveitis; and toxicity of foreign material such as irrigation solutions introduced during surgery. These presentations are often difficult to distinguish from similar symptoms caused by infective endophthalmitis and careful sequential monitoring of such eyes or intraocular sampling for culture is appropriate to facilitate early diagnosis and treatment.

DIAGNOSIS

Microbiologic investigations in endophthalmitis

Confirmation of the diagnosis of infective endophthalmitis is essential to rational management. Because most postoperative infections are caused by normal ocular flora, there is some correlation between the results of external swabs of the eyelid margins and conjunctivae with intraocular isolates.[19] These should not be used to determine causative pathogens; routine preoperative cultures have a low predictive value and are not recommended. The optimal specimen for laboratory processing in endophthalmitis is an intraocular aspirate; aqueous and vitreous specimens should be obtained, although the latter appears the most reliable, as some 30–55% of concomitant aqueous specimens are negative in the presence of positive vitreous isolates.[20] In the case of late endophthalmitis, aqueous vitreous and some capsule material should also be cultured. Foreign bodies should be processed in traumatic endophthalmitis, whereas a swab of the bleb may assist in bleb-associated infections.

Because specimen volumes are often very limited, the traditional approach of direct inoculation onto culture media for aerobic and anaerobic bacteria, and fungi, remains important. Direct inoculation of specimens into blood culture bottles is of more limited value, but is useful in circumstances in which appropriate media are not readily accessible. Molecular diagnostic techniques are increasingly reported, but require further study of their utility and are not yet widely available. Rapid results by microscopy of Gram stains are useful, with positive results occurring in some 50–70% of well-collected vitreous aspirates.[21] An appropriate clinical history should accompany specimens to the laboratory so that culture can be prolonged for fastidious organisms and so that skin commensals such as *P. acnes* are not routinely discarded as contaminants.

MANAGEMENT

Antibiotic chemotherapy

Early institution of antimicrobial therapy is essential to optimal outcome in the management of infective endophthalmitis. Controversy continues as to the best therapeutic approach.

Intravitreal antibiotics

Intravitreal injection of antibiotics is the most effective way of rapidly achieving high intraocular antibiotic levels. Direct intravitreal injections of nonpreserved (i.e. intravenous) formulations of antibiotics are now the recommended route of administration in endophthalmitis treatment. The rationale of such therapy is that, although antibiotics when administered topically, subconjunctivally or systemically may attain therapeutic concentrations in the anterior chamber, concentrations in the vitreous are much lower. Intravitreal injections may produce significant retinal toxicity, although single injections have been shown to be safe and effective.

The optimal combination of antibiotics in empiric therapy normally covers Gram-positive and Gram-negative organisms. Over recent years, vancomycin has replaced first-generation cephalosporins for Gram-positive activity because of the increasing incidence of *Staph. epidermidis* infection resistant to methicillin and other ß-lactam drugs. Reports of retinal toxicity caused by gentamicin led to the use of amikacin to cover Gram-negative organisms, as this later antibiotic was believed to be less toxic. Amikacin has now been used widely in controlled and uncontrolled clinical situations. However, more recently, gentamicin and amikacin have been associated with macular infarction[22] and this has led to increased use of other broad-spectrum Gram-negative antimicrobial agents, particularly ceftazidime. An initial single injection of 0.2mg vancomycin maintains therapeutic concentration for at least 3 days and a repeat injection at that time for at least 4 days.[23] Repeat injections of aminoglycosides should be avoided, except in severe cases. Intravitreal amphotericin B injections (1–5µg) can be utilized in fungal endophthalmitis, with a single repeat inoculation after 72–96 hours in progressive infection; again, however, toxicity limits longer duration of therapy.

Subconjunctival antibiotics

The data regarding subconjunctival antibiotic penetration is conflicting, possibly because of varying degrees of inflammation in the eye or poor and variable sampling techniques. Penetration is affected by the transcleral and transcorneal permeability of the agent, but high aqueous levels can be achieved with vancomycin, gentamicin and ß-lactam antibiotics for up to 4 hours; however, vitreous concentrations are generally poor. Subconjunctival injections are an irritant and are painful, thus limiting duration of this form of therapy to a few days.

Topical antibiotic therapy

The efficacy of topical antibacterial applications in endophthalmitis is not well studied, although significant concentrations of antibiotics in the anterior segment can be obtained with frequent administration of highly concentrated (fortified) solutions. A combination of vancomycin and fortified gentamicin, e.g. 1.5%, provides a broad-spectrum cover, but solutions must be prepared by a qualified pharmacist as they are not commercially available. Third-generation cephalosporins, such as cefotaxime and ceftazidime, and fluoroquinolones, such as ciprofloxacin, may be used to replace gentamicin to provide appropriate Gram-negative cover. The use of collagen shields to produce frequent topical application of antibiotic solutions has been explored, but is limited by potential corneal toxicity. Iontophoresis also increases anterior chamber concentrations, but its efficacy remains unproved.

Systemic antibiotics

In humans, intraocular penetration of systemically administered antibiotics is generally poor. However, intravenous antibiotics are a common adjunctive therapy in endophthalmitis, justified in that they may enhance concentrations of antibiotics achieved with intravitreal agents and extend the duration of therapeutic activity. Intraocular inflammation and/or performance of a vitrectomy may alter the blood-retina barrier to allow improved intraocular penetration.

Posterior chamber concentrations of newer and broad-spectrum agents, including ceftazidime, imipenem and ciprofloxacin, appear improved, particularly in terms of efficacy against Gram-negative bacilli such as *Pseudomonas* spp. However, none is reliably active against *Staph. epidermidis*, the most common cause of postoperative endophthalmitis, and resistance may develop rapidly.

A multicenter randomized trial, the Endophthalmitis Vitrectomy Study (EVS), sponsored by the National Eye Institute of the National Institutes of Health, followed a cohort of 420 patients who had clinical evidence of endophthalmitis within 6 weeks after cataract surgery or secondary intraocular lens implantation. [24] Patients were randomly assigned to therapy, with or without pars plana vitrectomy and with or without systemic antibiotics (ceftazidime and amikacin), but each patient underwent intravitreal injection of vancomycin and amikacin. When outcome was assessed 9–12 months after the operation, no difference in final visual acuity or media clouding between groups with and without systemic antibiotics could be determined. Well conducted as this study was, a number of questions remain unanswered, particularly in relation to generalization of the results. Do the results, for example, extrapolate to Gram-negative infection or to other categories of ocular surgery? Moreover, a significant percentage of coagulase-negative staphylococci and *Streptococcus* spp., the most common Gram-positive pathogens, are resistant to ceftazidime and amikacin, although vancomycin was active against all.

Duration of therapy is very variable. In spite of the presence of an ocular foreign body such as an intraocular lens, endophthalmitis caused by *Staph. epidermidis* will settle rapidly with appropriate management. Length of therapy can be assessed by a reduction in cellular activity in both the anterior and posterior chambers and by improvement in visual acuity.

Fungal endophthalmitis poses a particular problem. [25] Itraconazole, a lipophilic antifungal imidazole, has been shown to be efficacious in *Aspergillus* endophthalmitis. Fluconazole, a hydrophilic imidazole, achieves useful concentrations in intraocular tissue and has also proved successful in *Candida* endophthalmitis. A newer imidazole, voriconazole, shows promise in fungal endophthalmitis, though further experience is needed. Amphotericin B, often the only available therapy in filamentous fungal infections other than those caused by *Aspergillus* spp., does not achieve significant concentrations in intraocular tissue. Nevertheless, it is widely used in both conventional and liposomal formulations, in fungal endophthalmitis with some evidence of success.

Specific recommendations

Endophthalmitis may cause irreparable visual loss within 24–48 hours. Initial therapy must frequently be empiric, because of the low sensitivity of Gram stain film and the 24–48 hour delay until culture results become available. Antibiotic therapy should be chosen to cover the spectrum of pathogens likely to be implicated. In this situation classification of endophthalmitis by clinical setting provides useful information. Suggested initial antibiotic therapy for acute postoperative, filtering bleb and post-traumatic endophthalmitis is illustrated in Table 19.2 .

Localized bleb infection without endophthalmitis can usually initially be managed with topical therapy. Because of the increased prevalence of *H. influenzae* in this infection, a combination of antibiotics

TABLE 19-2 -- Initial empiric recommendations for antimicrobial therapy of endophthalmitis.

INITIAL EMPIRIC RECOMMENDATIONS FOR ANTIMICROBIAL THERAPY OF ENDOPHTHALMITIS				
Category of endophthalmitis		**Antimicrobial therapy**		
		Topical	**Intravitreal**	**Systemic**
Postoperative	Acute	Cefazolin (5mg/ml) + gentamicin (8–15mg/ml) or amikacin (25–50mg/ml)	Cefazolin (2.25mg) + amikacin (400mg)	Cefazolin (2g q8h) + gentamicin (4–5mg/kg q24h)* or amikacin (15mg/kg q24h)*
		Vancomycin (50mg/ml) + gentamicin or amikacin or ceftazidime (5mg/ml) or ciprofloxacin (3mg/ml)	Vancomycin (1mg) + amikacin or ceftazidime (2.25mg)	Vancomycin + gentamicin or amikacin or ceftazidime (2g q8h) or ciprofloxacin (400mg q12h)
	Delayed	Vancomycin + gentamicin or amikacin or ceftazidime or ciprofloxacin	Vancomycin + amikacin or ceftazidime	Vancomycin + gentamicin or amikacin or cefotaxime (2g q6h) or ceftazidime or ciprofloxacin
	Filtering bleb	Vancomycin + ceftazidime or ciprofloxacin	Vancomycin + ceftazidime	Vancomycin + /or cefotaxime, ceftazidime, ciprofloxacin
Post-traumatic		Vancomycin + gentamicin or amikacin or ceftazidime or ciprofloxacin	Vancomycin + amikacin or ceftazidime	Vancomycin + gentamicin or amikacin or ceftazidime or ciprofloxacin
Dosages given in brackets apply to all citations of each specific drug within the relevant column.				

*Dosages must be adjusted to reflect the patient's age, body weight and renal function.

that covers this pathogen and provides broad-spectrum activity against Gram-positive and Gram-negative organisms should be chosen.

Adjunctive therapy

Vitrectomy

The place of pars plana vitrectomy remains a controversial issue in the management of endophthalmitis. The theoretic rationale for such a procedure is that it offers a reduction in organism load, a reduction in traction effect on the retina with less potential for detachment, collection of adequate culture material and possibly improved distribution of intravitreal antibiotics. Evidence for its efficacy has been conflicting, often as a result of poorly controlled studies. The EVS was designed to determine

definitively the value of vitrectomy in the presence of intravitreal antibiotics. The final conclusions of this study were that visual acuity was improved significantly in patients treated with vitrectomy only if the initial vision was light perception, but not if initial vision was hand movements or better; that is, the most severe cases on presentation benefited most from vitrectomy. [24]

Corticosteroids

The use of corticosteroids to reduce the inflammatory response to infection and thus preserve ocular tissue is widely practiced with administration by several routes, including intraocular, periocular, topical and systemic, but its place in therapy remains contentious. Experimental animal studies demonstrate superior outcomes utilizing corticosteroids with antibiotics even in endophthalmitis caused by pseudomonads and fungi. In general, clinical studies do not report deterioration in outcomes if corticosteroids are used in combination with antibiotics, at least at the ocular level.[26]

Management of intraocular lens

In most cases of acute postoperative pseudophakic endophthalmitis, removal of the intraocular lens is not necessary and does not influence outcome. In fact, it may be hazardous and predispose to anterior segment hemorrhage and retinal detachment. Exceptions may occur when the pathogen is a fungus and in cases of late-onset endophthalmitis caused by *P. acnes* when conservative treatment with intravitreal vancomycin and corticosteroids is unsuccessful. In such cases, complete capsulectomy and lensectomy may be necessary to provide cure.

Outcome

Up to 50% of patients who have endophthalmitis suffer major visual loss within 24–48 hours of onset, emphasizing the essential need for early diagnosis and prompt treatment.[26] Approximately 30% of patients in recent studies of endophthalmitis achieved a final visual acuity of 20/60 or better after treatment.[27] [28] Certain factors are highly correlated with poor visual outcome; these include severity of infection, delay in time to diagnosis and institution of treatment, virulence of infecting organisms and intraocular complications such as vitreous hemorrhage and retinal detachment. Poor vision at the time of diagnosis correlates with either a virulent organism, such as *Bacillus* spp., *Streptococcus* spp. or Gram-negative bacilli or fungi, or a delay in diagnosis even with a low-virulence organism. Normally, however, *Staph. epidermidis* endophthalmitis has an excellent outcome, although even in this situation some 10% of patients develop blindness.[29] Culture-negative cases of endophthalmitis generally have a better visual outcome than do culture-positive groups, which may relate to the lower virulence of more fastidious organisms or to the veracity of diagnosis.

The outcome of post-traumatic endophthalmitis and endophthalmitis related to a conjunctival filtering bleb is poor, probably because of the intrinsic virulence of organisms implicated; however, for converse reasons, prognosis in delayed ophthalmitis, including that caused by *P. acnes*, is usually more favorable.

The primary complication of endophthalmitis is retinal detachment that may occur at any time before, during or after treatment. Prognosis in this situation is poor, although surgical repair can salvage useful vision in a substantial number of patients.[30]

Chapter 20 - Infectious Retinitis and Uveitis

Jay S Duker
Michael Barza

INTRODUCTION

Strictly speaking, uveitis is inflammation of one or more parts of the uveal tract of the eye, namely, the choroid, the iris and the ciliary body. In practice, uveitis has come to mean any inflammation of the intraocular structures, regardless of the precise anatomic sites involved. Inflammation localized to certain structures can be denoted by more specific terms. For example, inflammation of the iris (iritis) or ciliary body (cyclitis) is called anterior uveitis. Inflammation of the vitreous (vitritis), retina (retinitis) or choroid (choroiditis) is called posterior uveitis. Inflammation of the entire globe is called panuveitis. Inflammation localized to the outer coats of the eye or optic nerve without accompanying intraocular inflammation (e.g. scleritis, keratitis, optic neuritis) does not usually fall under the heading of uveitis.

The anterior segment of the eye consists of the cornea, anterior chamber, lens, iris, posterior chamber and ciliary body; the posterior segment refers to the vitreous cavity and posterior structures including the retina and optic nerve (Fig. 20.1).

The location, distribution and ophthalmoscopic appearance of inflammatory lesions is useful to the ophthalmologist in suggesting likely causes of uveitis (Table 20.1).[1] Intermediate uveitis centers about the equator of the eye between the anterior and posterior parts of the uveal tract, whereas anterior uveitis involves the anterior chamber and posterior uveitis involves the posterior segment of the eye. Chronic intermediate uveitis with certain morphologic characteristics may be termed the pars planitis syndrome.

A diagnosis of retinal vasculitis is made by finding inflammatory sheathing of the retinal vessels on ophthalmoscopic examination and leakage of dye from the involved vessels on intravenous fluorescein angiography (Fig. 20.2).[1] Retinal vasculitis is sometimes isolated, but more commonly it occurs in conjunction with posterior uveitis. It is a nonspecific finding and can occur in ischemic conditions as well as infection. Endophthalmitis, although it overlaps to some degree with uveitis and retinitis, is considered separately (see Chapter 19).

TABLE 20-1 -- Anterior, posterior and intermediate uveitis.

ANTERIOR, POSTERIOR AND INTERMEDIATE UVEITIS			
	Anterior uveitis	**Intermediate uveitis**	**Posterior uveitis**
Ophthalmoscopic signs that define the type of uveitis	Inflammatory cells in the anterior chamber with or without keratic precipitates or iris lesions	Inflammatory cells more highly concentrated in anterior vitreous than in anterior chamber	Inflammation of retina, choroid, retinal vessels, posterior vitreous humor, or a combination of these
Additional clinical signs	Ciliary flush (perilimbal injection of the sclera)	Macular edema	Retinal vasculitis
	Posterior synechiae	Inflammatory exudate on pars plana	Optic disk edema
			Macular edema
Symptoms	Pain	Floaters	'Floaters'
	Redness		Blurred vision
	Photophobia		
Definitions and common symptoms.			

There are many known causes of uveitis, including infections, autoimmune disorders, various other systemic diseases and trauma, including surgical trauma. In some instances, the ocular lesions are only one manifestation of an underlying multisystem disorder, whereas in others the eye represents the only site of overt disease. Many cases of uveitis remain of uncertain origin despite extensive investigation. In trying to determine the cause of any particular case

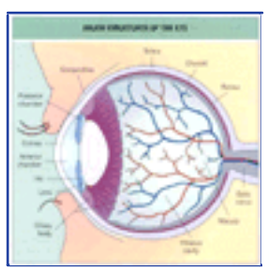

Figure 20-1 Major structures of the eye.

Figure 20-2 Retinal inflammatory vascular sheathing (vasculitis). This case occurred secondary to sarcoidosis.

of uveitis, the ophthalmologist considers a number of features, including the distribution and morphologic characteristics of the lesions, the chronicity of the disorder and the presence of underlying systemic diseases. In select cases, invasive diagnostic testing in the form of anterior chamber paracentesis, vitreous biopsy or even retinal biopsy may be necessary to rule out an infectious etiology.

Among the diagnostic tests commonly carried out to determine the cause of uveitis are:

- chest radiograph to detect sarcoidosis and tuberculosis,
- blood count,
- erythrocyte sedimentation rate,
- serologic tests for syphilis,

- HLA-B27 antigen, and
- angiotensin-converting enzyme concentration

Within the broad categories of retinitis and uveitis, there are certain distinctive syndromes, such as acute retinal necrosis (ARN), progressive outer retinal necrosis (PORN) and pars planitis, which allow the ophthalmologist to make a syndrome diagnosis on clinical grounds alone.

This chapter describes the major manifestations of uveitis and retinitis, with an emphasis on the infectious causes of these syndromes. Uveitis and retinitis in immunosuppressed patients and neonates are considered separately because the causative agents differ from those in immunocompetent and adult patients. Only the infectious aspects pertinent to the eye will be discussed. Because significant uveitis and retinitis must be managed by an experienced ophthalmologist, detailed regimens of locally applied anti-infective and anti-inflammatory agents have not been given.

EPIDEMIOLOGY

Uveitis and retinitis are uncommon in clinical practice. In Minnesota, USA, the annual incidence of new cases of uveitis has been found to be 17/100,000 population.[2] A general ophthalmologist is likely to see only a dozen patients with uveitis or retinitis each year. A specific cause can be identified in only about half of the patients with uveitis. In some instances, uveitis provides the first evidence of an underlying systemic disease. Uveitis and retinitis can occur at any age and the incidence is about equally divided between the sexes. In one study, the mean age of patients with uveitis was 45 years.[1]

Infectious uveitis or retinitis in neonates is almost always the result of congenital infection — toxoplasmosis, rubella, cytomegalovirus (CMV), herpesvirus (TORCH) syndrome (see Chapter 65). Each of the TORCH agents can involve the uvea or retina. Among immunosuppressed patients, uveitis or retinitis is found most commonly in patients who have AIDS. However, hematogenous fungal endophthalmitis occurs primarily in patients with other forms of immunosuppression.

Although uveitis does not appear to be more prevalent in any particular parts of the world, there is geographic variation in the underlying causes. For example:

- acquired ocular toxoplasmosis is quite common in Brazil, but rare in the rest of the world;
- Behçet's disease is prevalent in Turkey and the Middle East, but unusual elsewhere;
- leprosy has been eradicated in most developed countries, but can still be found in less developed regions;
- CMV retinitis associated with AIDS occurs in patients from developed countries, but is rarely seen in developing areas of the world; and
- onchocerciasis (river blindness), which primarily affects the cornea, but can produce retinitis and choroiditis, is seen only in equatorial Africa and Central America.

CLINICAL FEATURES

Common symptoms of intraocular inflammation, irrespective of the cause, are ocular pain, photophobia, 'floaters' (specks that appear to float in the visual field) and impaired vision (see Table 20.1). Both eyes may be affected simultaneously, but unilateral involvement does not rule out a systemic cause. Anyone with these symptoms should have an ophthalmologic evaluation with pharmacologic dilatation of the pupil with examination by slit lamp and indirect ophthalmoscopy. Because most of the uveal tract can be readily visualized in this fashion, the morphology of the lesions can be precisely defined. The findings allow the process to be characterized as anterior, intermediate or posterior uveitis, or panuveitis (see Table 20.1).

Additional clinical signs include conjunctival injection, anterior segment cells and 'flare' (protein floating in aqueous fluid, seen on slit lamp examination), iris nodules (granulomas), posterior synechiae, posterior segment cells, optic disk edema, retinal vasculitis, retinitis and choroiditis. A hypopyon refers to layered inflammatory cells that settle gravitationally in the inferior aspect of the anterior chamber (Fig. 20.3). In cases of severe acute uveitis, there may be so much intraocular inflammation that a cloudy media results. This may

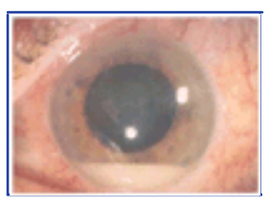

Figure 20-3 Hypopyon. The finding of a hypopyon (layered inflammatory cells in the anterior chamber of the eye) usually denotes a severe anterior uveitis.

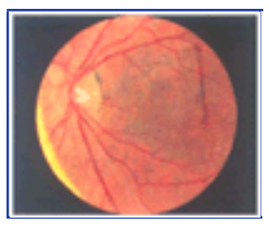

Figure 20-4 Salt-and-pepper fundus. The pigment alterations in the macula give a 'dirty' appearance to the retina. The lesion occurred following congenital rubella infection. The vertical black line across the fovea is a focusing stick.

preclude visualization of the inner aspects of the eye. Ocular ultrasonography should be performed in such cases.

Chronic uveitis can lead to:

- cataract formation,
- epiretinal membrane formation,
- iris, retinal or choroidal neovascularization, and
- retinal detachment.

TABLE 20-2 -- Uveitis in community-based and tertiary ophthalmology centers.[D]

UVEITIS IN COMMUNITY-BASED AND TERTIARY OPHTHALMOLOGY CENTERS		
	Patients in community-based ophthalmology practice	**Patients in tertiary referral center**
Mean age of patients (y)	46	45
Males (%)	49	52
Percentage with:		
Anterior uveitis	91	60
Intermediate uveitis	1	12
Posterior uveitis	5	15
Panuveitis and other	3	13
Percentage of cases of anterior uveitis that are chronic	9	63
Percentage in which specific diagnosis was made	47	58
Percentage attributable to infection	14	21

Percentage associated with systemic disease (including infections)	13	9
Most common causes of uveitis	HLA-B27-associated anterior uveitis (15%)	CMV retinitis (33%)
	CMV retinitis (7%)	HLA-B27-associated anterior uveitis (8%)
	Traumatic uveitis (5%)	Pars planitis syndrome (6%)
	VZV uveitis (4%)	HSV-associated uveitis (5%)
	Toxoplasma retinochoroiditis (4%)	*Toxoplasma* retinochoroiditis (4%)
Most common causes of posterior uveitis	CMV retinitis	CMV retinitis
	Toxoplasma retinochoroiditis	*Toxoplasma* retinochoroiditis

The characteristics of uveitis seen in a community-based ophthalmology practice and in a tertiary referral center. The figures for the proportion of cases in which a specific diagnosis was made are based on data gathered at, or requested at, the first visit; cases of CMV retinitis and 'masquerade' syndrome are omitted. The figures for the proportion of cases associated with systemic disease include cases due to varicella, candidiasis, coccidioidomycosis and syphilis.

Data from McCannel et al., 1996.[1]

A rare sequel of healed diffuse retinitis or choroiditis is known as salt-and-pepper fundus because of the stippled appearance of the retinal pigment epithelium. The lesions are nonspecific and may be seen following a variety of infectious and inherited disorders (Fig. 20.4).

The characteristic causes and clinical presentations of uveitis seen in a general community-based ophthalmologic practice and in a tertiary referral center have been found to differ (Table 20.2).[1] In the community ophthalmic practice, about 90% of uveitis was anterior and most cases of anterior uveitis were acute. By contrast, in the tertiary referral center, intermediate and posterior uveitis and panuveitis were more prevalent and much of the anterior uveitis was chronic. In both settings, a specific diagnosis could be made in only about half of patients from data gathered at the initial visit. An infectious cause was documented in 21% of the referred patients and 14% of the community-based patients. The uveitis was attributed to a systemic disease, usually rheumatologic, in a smaller number of patients. The most common causes of uveitis in both settings were:

- HLA-B27-associated anterior uveitis;
- CMV retinitis;
- herpesvirus-associated uveitis, caused either by herpes simplex virus (HSV) or varicella-zoster virus (VZV); and
- toxoplasma retinochoroiditis (see Table 20.2).

Thus, three of the four most common causes of uveitis were infectious, but infectious causes accounted for well under half of all cases of uveitis in either setting.

Anterior uveitis is much more common than posterior uveitis, and the specific cause is more likely to be identifiable. When infectious, anterior uveitis commonly arises from systemic disease that is

clinically obvious, whereas posterior uveitis may arise from an infection that has no extraocular manifestations. This is the case in uveitis caused by *Toxoplasma gondii*, *Toxocara canis* and *Histoplasma capsulatum*. The lesions of anterior uveitis not uncommonly remit without treatment, whereas those of posterior uveitis tend to persist or progress.

PATHOGENESIS AND PATHOLOGY

Most of the infectious agents discussed in this chapter gain access to the ocular structures via hematogenous spread of micro-organisms from other sites. The uveal tract is highly vascular, offering a ready target for seeding by blood-borne microbes. Some organisms (e.g. herpesviruses, *T. gondii*) seem to have a propensity for the retina itself. Furthermore, circulating inflammatory cells and mediators of inflammation have a potent impact on the uveal tract and adjacent structures. These inflammatory cells include T and B cells, macrophages and monocytes, mast cells and eosinophils. Inflammatory mediators include cytokines, complement and antibodies. In some types of infectious uveitis (e.g. tuberculous and possibly spirochetal uveitis), the inflammation may be produced by a combination of microbial invasion and immunologic mechanisms. Occasionally, uveitis occurs as a 'sympathetic' reaction to an adjacent infection (e.g. anterior uveitis in patients with HSV keratitis). It is hypothesized that other infections gain access to the eye by spreading along nerves (e.g. the ARN syndrome associated with VZV).

The eye is unique among organs in showing a neovascular response to certain stimuli, especially prolonged inflammation. New vessels may form in the cornea, iris, retina, optic nerve and choroid, presumably as a result of the production of various protein growth factors such as vascular endothelial growth factor. These newly formed, acquired vessels themselves can cause severe loss of vision. Together with specific treatment of the underlying cause, laser photocoagulation or ocular photodynamic therapy may be needed to treat ocular neovascularization.

Many of the pathogens that produce uveitis are found preferentially in an intracellular location (viruses, spirochetes, mycobacteria, fungi, parasites). Some tend to persist indefinitely and have the ability to produce episodic exacerbations. The eye may be the only site of clinically evident inflammation.

PREVENTION

Patients who have systemic infections associated with an appreciable risk of intraocular infection should be screened by an ophthalmologist for early detection and treatment. An example is the periodic

TABLE 20-3 -- Viral causes of retinitis and uveitis.

VIRAL CAUSES OF RETINITIS AND UVEITIS			
Viral infection	**Systemic infection**	**Features of retinitis or uveitis**	**Other ocular disease**
Measles	Uveitis occurs 1–2 weeks after onset of rash	Common: anterior uveitis	Common: conjunctivitis, keratitis
		Rare: chorioretinitis or neuroretinitis	Rare: optic neuritis
SSPE (see Fig. 20.5)	Uveitis occurs some years after infection	Chorioretinitis involves macula	Papillitis; motility disturbances
Herpes simplex virus	Primary infection; lids and conjunctiva	Common: anterior uveitis	Dendritic corneal ulcer common
		Rare: uveitis, retinitis, ARN	
Varicella-zoster virus	Convalescence from varicella or trigeminal zoster (often with nasociliary branch involved)	Common: mild, anterior uveitis, self-limited; rarely, chorioretinitis or ARN	Granulomatous keratic precipitates; synechiae; glaucoma, cataract
Epstein-Barr virus	Infectious mononucleosis	Rare: mild anterior uveitis or chorioretinitis	Common: follicular conjunctivitis
Influenza, adenovirus, mumps	Systemic infection usually evident	Rare: bilateral, mild, self-limited, anterior uveitis	None
		Rare: neuroretinitis or optic neuritis	
These ocular problems are seen in immunocompetent adults and children.			

examination of patients who have HIV infection and a low $CD4^+$ lymphocyte count to detect CMV retinitis. Likewise, patients who have HIV infection who develop ophthalmic zoster are at risk of developing necrotizing herpetic retinitis and are candidates for ophthalmologic screening examination. Patients who have *Candida*

fungemia merit ocular examination to detect metastatic retinitis. Neonates who have congenital HSV infection must be screened carefully for ocular lesions, which may first appear up to several months after birth.

MANAGEMENT

There are two major principles of therapy for intraocular infections. The first is to treat the infection. Drugs for the treatment of ocular diseases may be given by topical administration, periocular injection, systemic administration (orally or intravenously, or both) and intravitreal injection.

The second principle is to suppress intraocular inflammation, lest there be persisting damage to the retina and other crucial structures. This is usually accomplished by using corticosteroids, which may be given by various routes. Rarely systemic immunosuppression is employed.

Uveitis in immunocompetent adults and children

Viral causes of uveitis

Uveitis, especially anterior uveitis, may occur in the course of many viral infections, most commonly those caused by rubeola virus and the herpesvirus family (Table 20.3). The uveitis is generally self-limited and does not require treatment.

Measles often causes conjunctivitis and keratitis; the keratitis rarely leads to bacterial ulceration and perforation of the cornea. There may be anterior uveitis. Other rare complications are chorioretinitis or neuroretinitis; these may occur, together with measles encephalitis, 1–2 weeks after the onset of the rash.[3]

The ocular lesions of rubeola are generally self-limited and no specific treatment is available. Involvement of the optic disk (optic neuritis) may cause severe visual loss, but this may improve spontaneously over subsequent months. There may be residual pigmentary retinopathy with the salt-and-pepper appearance (see Fig. 20.4).

Subacute sclerosing panencephalitis (SSPE), which results from measles infection in very early life, commonly causes chorioretinitis, usually about the time that the neurologic signs of the disease become evident. The chorioretinitis is often focal, involving the macula, and there is mild vitritis (Fig. 20.5). Cortical blindness may occur. The prognosis of the ocular lesions is poor. There is no specific treatment.[4]

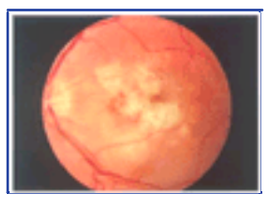

Figure 20-5 Macular retinitis. This patient has subacute sclerosing panencephalitis.

Herpes simplex virus infection of the eye in children and adults usually presents as recurrent keratitis with characteristic dendrites (see Chapter 215). There may be an associated anterior uveitis (iridocyclitis). Rarely, HSV keratitis may spread along the axons to produce retinitis and posterior uveitis. [5] Another rare manifestation of HSV ocular infection is ARN (see below). Retinitis and posterior uveitis are usually treated by antiviral agents such as aciclovir given intravenously in high dosage. Anterior uveitis alone may be treated topically except, perhaps, in immunosuppressed patients.

Varicella, especially in the convalescent stage, may cause a mild, self-limited anterior uveitis. Treatment is not usually necessary, but corticosteroid drops may be applied. A more serious lesion, keratitis, may develop in patients who have trigeminal zoster, especially during convalescence from zoster that has involved the nasociliary branch of the trigeminal nerve. The keratitis may be dendritiform or geographic. It may be accompanied by anterior uveitis with granulomatous keratic precipitates (clumps of inflammatory cells on the corneal endothelium) and posterior synechiae (adhesions between the iris and the anterior surface of the lens).[6] The uveitis of varicella infection may be treated with 1% trifluridine ophthalmic drops or oral aciclovir. Rarely, trigeminal zoster may lead to chorioretinitis and a form of necrotizing herpetic retinitis referred to as the ARN syndrome (see below). In such cases, intravenous aciclovir and corticosteroids should be administered. Cases have been reported with primary varicella infection of childhood (chickenpox). [7]

TABLE 20-4 -- Bacterial causes of retinitis and uveitis.

BACTERIAL CAUSES OF RETINITIS AND UVEITIS			
Bacterial infection	**Systemic infection**	**Features of retinitis or uveitis**	**Other ocular disease**
***Yersinia* spp.**	Infection occult, not proven	Suggested important cause of anterior uveitis in patients with HLA-B27 antigen	None
Borrelia burgdorferi	Features of extraocular	Nonspecific anterior or posterior uveitis	Conjunctivitis
	Lyme disease		
Treponema pallidum	Uveitis usually during secondary syphilis; interstitial keratitis is delayed manifestation of congenital syphilis	Common: bilateral anterior uveitis	Acute bilateral intersitial keratitis (age 5–10 years, after congenital infection)
		Rare: choroiditis (large while lesions), retinal vasculitis, papillitis	
***Bartonella* spp.** (see Fig. 20.6)	Nonspecific systemic symptoms antedate ocular symptoms	Bilateral papillitis: optic disk edema; white retinal lesions; vitritis	None
Metastatic endophthalmitis	Often extraocular source is evident	Often bilateral: focal or diffuse uveitis or retinitis	None
These ocular problems are seen in immunocompetent adults and children.			

During infectious mononucleosis caused by Epstein-Barr virus (EBV) infection, a bilateral, mild, follicular conjunctivitis may be seen. Rarely, a mild anterior uveitis can occur, as well. Recently, a choroiditis resembling that seen with histoplasmosis, but with vitritis, has been ascribed to acute or chronic EBV infection.[8] [9]

Other viral infections may produce uveitis on occasion. Influenza virus infection may cause a mild, transient, bilateral anterior uveitis during the acute infection or neuroretinitis during convalescence.[10] No treatment is needed.

One of the characteristic manifestations of adenovirus infection is epidemic keratoconjunctivitis. There may be concomitant anterior uveitis, for which either no treatment or topical corticosteroid treatment may be given.

Mumps virus infection may cause a mild, evanescent, bilateral anterior uveitis, which may appear up to 4 weeks after the onset of clinical infection. Optic neuritis, sometimes with neuroretinitis, may occur after mumps infection, but nearly always resolves spontaneously and no treatment is needed.[11]

HLA-B27-associated uveitis

An autoimmune form of recurrent, bilateral anterior uveitis is quite common in patients who harbor the HLA-B27 antigen. HLA-B27-associated uveitis is the most common type of nonidiopathic anterior uveitis. Although usually considered immune-mediated rather than infectious, it may be triggered by systemic infection with Gram-negative bacteria, *Mycoplasma pneumoniae* or *Chlamydia trachomatis*, as seen in Reiter's syndrome. Reiter's syndrome consists of the triad of conjunctivitis, urethritis and uveitis. [12] Several serologic studies from Scandinavian countries and Australia suggest that *Yersinia* infections may be important contributors.[13]

Bacterial causes of uveitis

Many bacterial species are associated with ocular infections (Table 20.4). *Borrelia burgdorferi* infection may cause a wide variety of ocular problems. Conjunctivitis and keratitis occur commonly in the early stages of infection, probably on an immunologic basis. In the later stages of Lyme disease there may be iridocyclitis, retinal vasculitis, exudative retinal detachment, vitritis and optic disk edema. Orbital pseudotumor and orbital myositis have also been described.[14] [15] [16] The treatment is with systemic antibiotics, using regimens appropriate for the stage of the disease (see Chapter 54).

Ocular lesions are common in the course of secondary syphilis (*Treponema pallidum* infection). The most common manifestation is a bilateral anterior uveitis, sometimes with iris nodules (granulomas). Less common is a choroiditis with large, white, 'geographic' lesions. There may also be retinal vasculitis, vitritis and papillitis.[17] [18] [19] Early

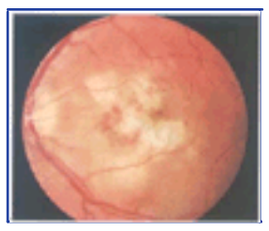

Figure 20-6 Neuroretinitis with a macular star associated with *Bartonella* infection. Note the swelling of the optic disk with hard exudate in the macula in the so-called 'stellate' pattern.

syphilis tends to be associated with a florid uveitis and Venereal Disease Research Laboratory (VDRL)-positive syphilitic meningitis, often in HIV-infected patients whereas late syphilis produces a chronic posterior uveitis with associated subclinical neurosyphilis.[20]

Syphilis should be considered in the differential diagnosis of any posterior segment inflammation or any bilateral anterior segment inflammation. The diagnosis is made serologically and treatment is according to the stage of the syphilis (see Chapter 75).

Bartonella henselae in immunocompetent patients has recently been reported as a cause of stellate neuroretinitis, also known as macular star (Fig. 20.6), and of Parinaud's oculoglandular fever with retinitis. Macular star can also seen in *Toxocara canis* infection in children and as a benign postviral illness. Cats are thought to be an important reservoir of *B. henselae*, and most infections have occurred in patients with a clearcut history of exposure to cats.[21] *Bartonella* infection should be suspected in any patient with optic disk edema and intraocular inflammation, especially if retinal lesions are seen.[22]

The infectious agent of Whipple's disease, *Tropheryma whippelii*, is associated with a multisystem disorder, which can include panuveitis, retinitis and choroiditis. The diagnosis can be made by biopsy of affected tissue (see Chapter 45). [23]

Rarely, other bacterial infections have been associated with uveitis distinct from endogenous endophthalmitis. The list includes leptospirosis,[24] brucellosis[25] and tularemia.[26]

Mycobacterium tuberculosis infection can cause anterior uveitis, posterior uveitis or isolated choroiditis. This infection should be a consideration in every case of nonspecific uveitis of unknown cause. There is nearly always active extraocular disease. The anterior uveitis may be acute or chronic, unilateral or bilateral, and there may be granulomatous keratic precipitates. A periphlebitis resembling that seen in sarcoidosis may occur, along with choroidal infiltrates; these

TABLE 20-5 -- Fungal causes of retinitis and uveitis.

FUNGAL CAUSES OF RETINITIS AND UVEITIS			
Fungal infection	**Systemic infection**	**Features of retinitis or uveitis**	**Other ocular disease**
***Candida* spp.** (see Fig. 20.7)	Risk factors for candidemia	Whitish fluffy patch of retinitis and some vitritis	Anterior segment cells with hypopyon; corneal abscess
Histoplasma capsulatum (see Fig. 20.8)	History of residence in an endemic area; no extraocular infection evident	Choroidal granulomas, scars; optic neuritis; no vitritis	No anterior segment inflammation
These ocular problems are seen in immunocompetent adults and children.			

infiltrates represent miliary tubercles. The uveitis usually improves within 2 weeks of the start of specific antituberculous treatment.

Infection with *Mycobacterium leprae* also may result in ocular inflammation. Corneal complications caused by peripheral nerve damage is the most common ocular complication, and uveitis is seen in only 2% of cases.[27]

Bacterial endophthalmitis is considered in detail in Chapter 19 . Whereas most instances of bacterial endophthalmitis are exogenous, following surgery or trauma, between 2 and 8% of cases arise from metastatic (endogenous) infection of the eye in the course of bacteremic illness.[28] The possibility of metastatic endophthalmitis should be considered in all patients with unexplained ocular inflammation, especially in those with significant underlying medical diseases. The ophthalmic findings are variable, but generally fall within the following patterns:

- one or more focal areas of inflammation within the uveal tract or retina;
- diffuse involvement of the anterior segment but sparing of the retina, choroid and vitreous;
- diffuse involvement of the retina, choroid and vitreous, but sparing of the anterior segment; and
- panophthalmitis.

The diagnosis can usually be made by blood cultures, identification of a primary source of infection, and, if necessary, aspiration and culture of the vitreous. Treatment typically does not salvage vision.

Fungal causes of uveitis

The most common fungal species that cause metastatic endophthalmitis are *Candida* spp. (Table 20.5), especially *C. albicans*. The hallmark lesion is a yellow-white, fluffy patch of retinitis with indistinct borders (Fig. 20.7), almost always associated with vitritis.

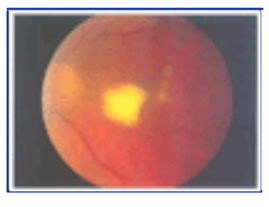

Figure 20-7 A focal area of superficial retinitis and vitritis. This occurred secondary to *Candida* albicans.

Classic 'puff balls' of the vitreous cavity may not been seen if the infection is limited to the choroid. The chorioretinal lesions may mimic those of toxoplasmosis, but inactive retinal scars are not seen in *Candida* infection. However, some cases of *Candida* endophthalmitis have an indolent course and some even improve spontaneously. The diagnosis is suspected from the appearance of the lesions in a typical clinical setting. Blood cultures may assist in the diagnosis, and vitreous

culture may prove it. Patients with *Candida* fungemia should be considered candidates for routine ophthalmoscopic screening. Treatment of *Candida* infections is discussed in Chapter 208 .

Whereas metastatic *Candida* infection usually occurs in a setting of active fungemia, *Histoplasma* ocular infection usually occurs without evident extraocular infection (see Table 20.5). The lesions arise from previous hematogenous spread to the choroid, producing a granuloma that usually becomes an inactive scar.[29] Vitritis is supposedly never seen, but disk edema with optic neuritis can occur acutely. As a late complication, choroidal neovascular membranes can emanate out of the old choroidal scars leading to retinal edema, hemorrhage and permanently decreased central vision.

A diagnosis of ocular histoplasmosis is suspected by finding the characteristic choroidal lesions (Fig. 20.8) in a patient who has resided in an area endemic for the fungal infection. Serologic or skin tests for histoplasmosis are usually positive but do not prove the diagnosis. The organisms have never been cultured from an intraocular source so the relation to *Histoplasma* infection is inferential. Pseudohistoplasmosis syndromes also exist because the characteristic chorioretinal scars are rarely seen in patients who have never resided in an endemic area and who are *Histoplasma* antibody negative. The treatment of ocular histoplasmosis depends on the stage of infection. Corticosteroids may be used to treat the acute choroidal granulomas, but have little role in the chronic, neovascular stage when there is no active inflammation. Laser photocoagulation is usually employed if there is a choroidal neovascular membrane that is not subfoveal; ocular photodynamic therapy or surgery may be carried out for subfoveal lesions because the laser would cause a permanent blind spot. There is no indication for antifungal treatment in these eyes.

Rarely, other fungi such as *Coccidioides*, *Blastomyces* and *Aspergillus* spp. and *Cryptococcus neoformans* may cause chorioretinitis by hematogenous spread. *Nocardia* spp. (Fig. 20.9) also occasionally cause chorioretinitis. Although quite rare overall, these

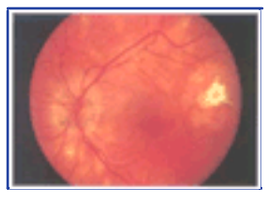

Figure 20-8 The classic ocular findings of previous histoplasmosis. Note the peripapillary atrophy and punched-out yellowish chorioretinal scars. An old choroidal neovascular membrane is present in the center of the histoplasmosis scar temporal to the macula.

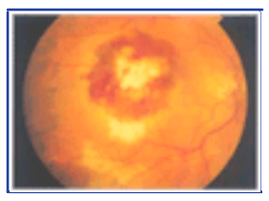

Figure 20-9 A *Nocardia* chorioretinal abscess. This abscess is in the macula of a patient on systemic immunosuppression following heart transplant.

infections develop more commonly in immunosuppressed individuals. The diagnosis should be suspected on confirmation of the associated systemic infection. Systemic antifungal treatment is required.

Parasitic causes of uveitis

Ocular infection by *Toxocara canis*, the dog roundworm, occurs in young children, especially boys, aged from 6 months to 4 years (Table 20.6). *Toxocara cati*, the cat roundworm, has been implicated, but the organisms have never been positively identified in the human eye. The typical presenting complaint is decreased vision, strabismus, or leukocoria (a whitish lesion in the pupil). *Toxocara* infection is acquired by the ingestion of soil contaminated with embryonated eggs (see Chapter 246). There may be a history of pica. The larvae are believed to reach the eye by hematogenous spread. However, most affected children do not have a history of or current evidence of visceral larva migrans. The ocular findings are generally unilateral.

There are several ophthalmoscopic presentations of ocular toxocariasis (Fig. 20.10). The features they have in common are a whitish or yellowish retinal mass, representing a granuloma surrounding the larva, and the eventual formation of traction bands between the vitreous and the granuloma, which may result in retinal folds and exudative retinal detachment. [30] There may be diffuse posterior uveitis, sometimes called nematode endophthalmitis. There is usually dense vitreous inflammation. Unlike bacterial endophthalmitis, there is little or no pain or anterior segment

TABLE 20-6 -- Parasitic causes of retinitis and uveitis.

PARASITIC CAUSES OF RETINITIS AND UVEITIS			
Parasitic infection	**Systemic infection**	**Features of retinitis or uveitis**	**Other ocular disease**
Toxocara canis (see Fig. 20.10)	Children 6 months to 4 years of age; no extraocular infection	Usually unilateral; pale granulomatous mass or focal retinitis; traction bands; vitritis	No anterior segment inflammation
Toxoplasma gondii (see Fig 20.11 , Fig 20.12)	Usually acquired *in utero* but not evident systemically	Recurrent self-limiting attacks of chorioretinitis and vitritis ('headlight in the fog')	May be keratic precipitates (granulomatous reaction) in anterior chamber
These ocular problems are seen in immunocompetent adults and children.			

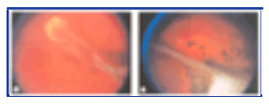

Figure 20-10 Ocular toxocariasis. (a) The posterior pole of a left eye affected by toxocariasis. There is severe macular distortion and dragging of the retina toward a granuloma in the inferotemporal retinal periphery. (b) The periphery of the inferotemporal retina in the same eye showing the granuloma.

inflammation. Other presentations include localized retinitis affecting the macula or the peripheral retina, and acute optic neuritis, in which the granuloma overlies the optic disk. A macular star (neuroretinitis), which is characteristic of toxocariasis, certain viral infections and bartonellosis, may be seen as a result of leakage from vessels in the optic disk.

The major differential diagnoses of ocular toxocariasis are noninfectious diseases such as retinoblastoma and Coats' disease, a congenital vascular disorder. Peripheral blood eosinophilia is rare in ocular toxocariasis. A serum enzyme-linked immunosorbent assay (ELISA) antibody titer to the parasite of 1 to 8 or more supports the diagnosis. A positive ELISA titer of the intraocular fluid, which may be found even if the serum titer is negative, is highly indicative of the infection. Treatment is directed toward stemming the intraocular inflammation, clearing any media opacity and preventing permanent distortion in the retinal architecture. Corticosteroids, usually applied locally in the eye, and cataract and/or vitrectomy surgery are the mainstays of treatment.

Toxoplasma gondii infection is a common cause of posterior segment infection in children and adults (see Table 20.6). In the immunocompetent, it represents the most common cause of infectious

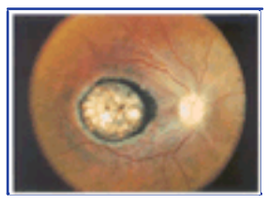

Figure 20-11 An old, inactive congenital macular toxoplasmosis scar. The patient's vision was 20/400.

posterior uveitis worldwide. In many countries, most cases of ocular toxoplasmosis are thought to represent reactivations following primary intrauterine infection (see Chapter 65). However, in some countries, such as Brazil, postnatally acquired infection is the more common antecedent of ocular toxoplasmosis. Postnatally acquired toxoplasmosis is followed by ocular toxoplasmosis in fewer than 5% of cases. The infection as it presents in immunosuppressed patients is discussed later in this

chapter.

The lesions of ocular toxoplasmosis are found preferentially in the nerve fiber layer of the retina, but can affect any layer including the choroid. [31] Healed lesions of congenital toxoplasmosis are flat, atrophic, variably pigmented chorioretinal scars that have a propensity for the macular area of the fundus (Fig. 20.11). There may be recurrent bouts of uveitis, caused by the rupture of cysts, releasing trophozoites. Most patients have their first reactivation before 30 years of age. Ophthalmoscopic examination shows vitritis and one or more white retinal lesions that are usually round or oval and up to 5mm in diameter. There may be many such lesions surrounding an old scar (Fig. 20.12). Aggregates of vitreous cells over the active lesions are the rule. The appearance of the vitreous haze and the white granuloma has been likened to a 'headlight in the fog'. There

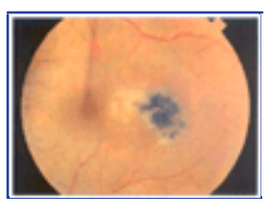

Figure 20-12 A reactivated area of retinal toxoplasmosis. The lesion is the area of whitening and is adjacent to an old scar, just temporal to the macula of the left eye.

TABLE 20-7 -- Characteristics of some infections causing posterior uveitis/retinitis without extraocular manifestations.

CHARACTERISTICS OF SOME INFECTIONS CAUSING POSTERIOR UVEITIS/RETINITIS WITHOUT EXTRAOCULAR MANIFESTATIONS				
	Usual number of lesions	**Appearance of lesions**	**Distribution of lesions**	**Accompanying vitritis**
Toxoplasma gondii (see Fig. 20.11 & Fig. 20.12)	One to a few	'Headlight in fog'	Random, but heavier in macular area	Almost always
Toxocara canis (see Fig. 20.10)	One	Granuloma	Macular, optic disk or periphery	Always
Histoplasma capsulatum (see Fig. 20.8)	Multiple	Choroidal granulomas	Various	Almost never
Treponema pallidum	Diffuse retinochoroiditis	Bilateral anterior uveitis; large white geographic choroidal lesions	Random	Always
Borrelia burgdorferi	Focal or diffuse	Anterior uveitis, retinal vasculitis, exudative retinal detachment	Random	Usually
Mycobacterium tuberculosis	One or a few	Retinitis or chorioretinitis	Random	Usually

may be retinal hemorrhages, sheathing of arterioles and venules, and papillitis. There may be a granulomatous reaction in the anterior chamber with keratic precipitates and conjunctival injection.

A diagnosis of ocular toxoplasmosis is based on the characteristic appearance of the lesions together with a positive serum antibody test for *T. gondii* (see Chapter 245). Other possible causes of localized necrotizing retinitis with vitritis, such as syphilis or tuberculosis, should be considered (Table 20.7). Further support for the diagnosis can be obtained by determining the ratio of *Toxoplasma* antibody between serum and a sample of ocular fluid.[32]

In otherwise healthy persons, flare-ups of ocular toxoplasmosis tend to be self-limited over a period of weeks to months. Not all active lesions need to be treated. The highest priority for treatment is for lesions that threaten the fovea or the optic nerve or large areas of the nerve fiber layer, as well as those that produce enough vitritis to impair vision. Once the fovea is directly involved, visual acuity is usually permanently compromised.

Treatment is the same as for other systemic forms of toxoplasmosis — pyrimethamine, sulfadiazine and clindamycin (see

TABLE 20-8 -- Infectious retinitis and uveitis in neonates.

INFECTIOUS RETINITIS AND UVEITIS IN NEONATES			
	Systemic infection	**Features of uveitis/retinitis**	**Other ocular disease**
Viral infections			
Herpes simplex virus	Disseminated infection usually evident	Anterior uveitis early; optic neuritis, retinal hemorrhages and necrosis later; sparing of choroid	Conjunctivitis, keratitis common
Varicella-zoster virus	Features of congenital varicella-zoster (rare)	Chorioretinitis	Microphthalmia; cataracts
Cytomegalovirus (CMV)	Features of congenital CMV infection	Retinitis in 20–25% of infants with symptomatic CMV infection; resembles that seen in adults with AIDS	None
Rubella	Congenital rubella syndrome	Mild, self-limiting chorioretinitis + vitritis in 25–50% with congenital rubella syndrome; unilateral or bilateral; eventual salt-and-pepper fundus	None
Bacterial infections			
Treponema pallidum	Stigmata of congenital syphilis	Salt-and-pepper fundus; occasionally optic atrophy, retinal vascular sheathing	Delayed manifestation: acute interstitial keratitis (age 5–10 years)
Fungal infections			
Candida spp. (see Fig. 20.7)	*Candida* fungemia; risk factors	Whitish fluffy patch of retinitis, some vitritis	None
Parasitic infections			
Toxoplasma gondii (see Fig. 20.11 , Fig. 20.12)	Rarely, encephalitis, hydrocephalus at birth	Rarely, chorioretinitis at birth	None

Chapter 209). Many ophthalmologists avoid pyrimethamine initially because of its marrow-suppressive effects, preferring to rely on the other two agents. Corticosteroids are often used concomitantly, but not without the anti-infective drugs. Laser photocoagulation may be used for active lesions unresponsive to medication and pars plana vitrectomy may be used to clear vitreous opacities.

Rarely, uveitis occurs in other parasitic infections such as cysticercosis, myiasis and onchocerciasis.

Uveitis in neonates

There are several causes of uveitis in neonates (Table 20.8).

Herpes simplex virus

Congenital infection by HSV is usually acquired directly from the infected birth canal, but sometimes occurs transplacentally or through the amniotic fluid. The congenital infection may mainly affect:

- the skin, eyes and oral cavity;
- the internal organs ('disseminated disease'); or
- the central nervous system.

The eyes may be involved in any of these presentations. Ocular findings may first appear from 1 week to several months after birth, and must be carefully sought by periodic ophthalmoscopic examination of infants at risk. About 80% of isolates are HSV-2 and this strain is associated with more severe ocular infections than HSV-1.

Congenital HSV infection may cause a wide variety of ocular lesions. In the anterior segment, conjunctivitis and keratitis (punctate, dendritic or geographic) are most common, and are usually seen in the acute phase of the infection. There is often an associated anterior uveitis. Peripheral anterior and posterior synechiae and secondary cataracts may be seen.

Posterior segment changes tend to occur later in the infection. [33] There may be disk edema with optic neuritis. Retinal involvement ranges from scattered hemorrhages to widespread retinal necrosis similar to that seen in the ARN syndrome. There may be retinal vasculitis and vitritis, and retinal detachments in severe cases. Residual changes include pigment migration and clumping (salt-and-pepper appearance), macular chorioretinal scars, optic atrophy and pre-retinal neovascularization.

The diagnosis and treatment of neonatal HSV infection are reviewed in Chapter 205 . Because the ocular lesions are part of a generalized infection, systemic treatment is required. In the exceptional instances in which the anterior segment of the eye is the only evident site of the suspected infection, viral cultures of the conjunctiva should be carried out and topical treatment alone may be given.

Varicella-zoster virus

Congenital infection by VZV is very rare (see Chapter 65). The ocular findings in the neonate are microphthalmia, chorioretinitis and cataract formation. If there is active chorioretinitis, an antiviral agent such as aciclovir should be given intravenously.

Cytomegalovirus

Congenital infections by CMV are usually asymptomatic (see Chapter 65). With symptomatic infections, retinitis occurs in 20–25% of cases. If retinitis is not evident at birth, it is unlikely to occur later. The retinitis resembles that seen in adult patients with HIV infection (see below).

Rebella

In the congenital rubella syndrome, ocular manifestations occur in 25–50% of affected children.[34] The classic finding is a mild, self-limited

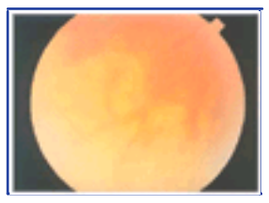

Figure 20-13 Typical appearance of the retina in the acute retinal necrosis syndrome. There is dense peripheral retinal whitening with a geographic border. Satellite lesions are common. The view is hazy owing to vitritis.

chorioretinitis that may be unilateral or bilateral. There may be vitritis. Vision is usually not impaired. A common sequel is a salt-and-pepper fundus caused by changes in the retinal pigment epithelium (see Fig. 20.4). A similar appearance is produced by congenital syphilis and influenza. Other ocular manifestations of congenital rubella include cataracts and a mild anterior uveitis that may cause posterior synechiae. There is no specific treatment.

Syphilis

The most common ocular manifestation of congenital syphilis (see Chapter 75) is salt-and-pepper fundus. The lesions are almost always bilateral, but may be sectoral or exclusively peripheral. They are the result of chorioretinitis, which may be evident at birth or appear in the first few years of life. Visual acuity is rarely affected. In more severe cases, there may be diffuse sheathing of the retinal vessels, optic atrophy and migration of the retinal pigment epithelium in a manner resembling retinitis pigmentosa.[35] Acute interstitial keratitis is a delayed manifestation of congenital syphilis. It may be accompanied by anterior uveitis and secondary glaucoma may develop. The lesions of keratitis are self-limited, but treatment of the syphilitic infection is indicated.

Other causes

Candida spp. may cause retinitis and vitritis in neonates. The infection is acquired after birth and the ocular infection is usually hematogenous. Risk factors are prematurity, low birth weight, sepsis, malnutrition and treatment with broad-spectrum antibiotics. The clinical presentation and treatment are as for adults (see Chapter 208).

Toxoplasma chorioretinitis is usually acquired in utero. Although the ocular complications usually present long after the neonatal period, they are sometimes evident at birth in the TORCH syndrome (see Chapter 65). Manifestations include encephalitis, hydrocephalus and bilateral chorioretinitis. Treatment is described in Chapter 209 .

Acute retinal necrosis syndrome

The ARN (acute necrotizing herpetic retinitis) syndrome is a recently described, rare syndrome of a vaso-obliterative retinal and choroidal vasculitis, diffuse retinal necrosis and vitritis. It is bilateral in one-third of patients, although the two eyes need not be affected simultaneously. It has been reported in children as young as 8 years of age, but it occurs most often in adults. Conclusive evidence now exists that VZV is the primary cause; HSV is a less common cause.[36] Patients infected with HIV who develop herpes zoster of the first division of the trigeminal nerve appear to have a high risk of subsequent ARN, often bilateral, over the next few weeks to months.[37]

Acute retinal necrosis causes diffuse arteritis and phlebitis with sheathing of the retinal vessels and striking white areas of retinal necrosis (Fig. 20.13). Broad areas of the peripheral retina are involved early, but the macula is usually spared initially. There is often mild inflammation of the anterior segment. As the disease progresses, there is increasing vitritis. Optic neuropathy with disk edema may appear.

Retinal detachment follows in up to 75% of patients. The detachments are notoriously difficult to repair. Previous prophylactic laser treatment of healthy retina posterior to the areas of necrosis reduces the incidence of retinal detachment.

The mainstay of treatment for ARN is aciclovir, given in high dosage intravenously (e.g. 12–15mg/kg q8h for 7–14 days). Oral aciclovir or one of its prodrugs should be continued for 2–3 months to lessen the risk of fellow eye involvement. Systemic corticosteroids are given as well, to decrease inflammation. Retinal detachments require complex vitreoretinal surgery for successful repair. It has been suggested that patients who have AIDS and who develop ophthalmic zoster are given long-term oral prophylaxis with aciclovir, but there is no proof of benefit from this approach.[37]

Uveitis and retinitis in immunosuppressed patients

Because of the AIDS pandemic, ophthalmologists are now encountering a variety of intraocular infections that were previously either unknown or extraordinarily rare.

Cytomegalovirus retinitis

The most common ocular infection in HIV-positive adult patients is CMV retinitis. In developed countries prior to 1996, CMV retinitis occured in about 35% of adult patients who had AIDS. Since highly active antiretroviral therapy (HAART) has become widely available in developed countries, the incidence of CMV retinitis has dropped dramatically. CMV retinitis rarely occurs in patients who have $CD4^+$ lymphocyte counts over 50 cells/mm^3 .[38] Pediatric patients who have AIDS have a much lower incidence of CMV retinitis than adults, presumably because most children have not been exposed to CMV. In one study of African patients who had AIDS, there were no cases of CMV retinitis.[39]

Symptoms of CMV retinitis tend to be absent or minimal at the start. 'Floaters', decreased peripheral vision or metamorphopsia are occasionally seen. Often, an active infection is noted on a routine ophthalmologic screening examination. In 40% of patients with CMV retinitis, the lesions are bilateral at presentation. Nearly 75% of patients present to the ophthalmologist with disease that is considered immediately sight-threatening due to the proximity of active lesions to the optic nerve or the macula. Pain, redness or more than a mild anterior uveitis are unusual with CMV retinitis.

The hallmark lesion of CMV retinitis is a necrotizing, full-thickness retinitis resulting in retinal cell death (Fig. 20.14). Retinal tissue adjacent to major retinal blood vessels or the optic disk is often affected initially, consistent with the theory that CMV is spread hematogenously. The areas of active retinitis have a granular appearance and are dirty-white in color. Hemorrhage is common, owing to damage to vascular endothelial cells. The appearance has been likened to a 'brush fire' and to 'ketchup and cottage cheese'. The retinitis spreads contiguously as well as by producing satellite lesions. It is common to see areas of healed retinitis alongside areas of active necrosis. Areas of burned-out necrosis show an absence of retinal tissue while the underlying retinal pigment epithelium assumes a salt-and-pepper appearance.

Loss of vision occurs because of both the death of retinal cells and retinal detachment. About 10–20% of eyes with CMV retinitis can be expected to suffer detached retina. The risk is time dependent; after 1 year the risk approaches 50%. Although vitreous surgery to

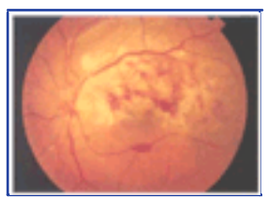

Figure 20-14 Cytomegalovirus infection with granular retinal whitening along the major blood vessels with mild hemorrhage. The view is clear because there is only mild vitritis.

repair the detached retinas is successful in more than 90% of instances, visual results are often limited by the underlying disease process.[40]

Three agents are available for systemic administration for the treatment of CMV retinitis: ganciclovir, foscarnet and cidofovir.[41] Although all three are typically effective initially, they all have potential side-effects and disadvantages that limit their long-term use. The mean time to ophthalmoscopic progression of the retinitis is only 2 months for all three medications, making long-term efficacy the major problem with intravenous therapy. An orally administered ganciclovir prodrug (valganciclovir) apprears to be equally effective as the intravenous preparation. Systemically administered agents are most useful for preventing progression of the extraocular infection that may accompany or follow CMV retinitis (see Chapter 125).

Direct intraocular treatment in the form of intravitreal injections of ganciclovir or foscarnet or intravitreal insertion of a sustained release ganciclovir implant can achieve much higher intraocular concentrations of drugs than intravenous therapy. The long-term efficacy of such local forms of therapy is superior to that of intravenous therapies. The mean time to progression of newly diagnosed CMV retinitis treated with a ganciclovir implant is 220 days (7 months), which is approximately the designed life span of the device. If the devices are replaced before the end of their estimated life span, however, at least 75% of eyes can be expected to suffer no progressions.[42] [43] High-dose (2mg per dose) weekly intravitreal injections of ganciclovir appear to have similar long-term efficacy.[44]

Implants and intravitreal injections carry the risks of invasive ocular procedures. Intravitreal injections must be given at least once a week, whereas ganciclovir implants only need to be placed at intervals of 6–8 months. If no concurrent systemic anti-CMV medication is given to patients treated with local therapy, there is a risk of systemic CMV. The incidence of systemic CMV infection in the year following initiation of exclusively local treatment for CMV retinitis is reportedly 11–30%.[43] Ongoing treatment of healed CMV retinitis or prophylaxis against end-organ infection can generally be stopped in patients who gain immune reconstitution with highly active antiretroviral therapy.[45] [46]

Other causes of uveitis and retinitis

About 75% of patients with HIV-1 infection have a non-sight-threatening retinopathy that may be caused by the HIV-1 itself.[47] The lesions are multiple, bilateral, cotton-wool spots and scattered retinal

Figure 20-15 HIV retinopathy. There are multiple superficial white patches in the retina (cotton-wool spots). These do not affect vision and typically wax and wane over time.

hemorrhages (Fig. 20.15). If there is concern that such lesions may be due to CMV, close observation over a period of days to weeks with documentation by photographs is recommended. CMV retinitis will invariably progress, whereas cotton-wool spots caused by HIV will resolve.

Opportunistic infections with *Pneumocystis carinii*, *Histoplasma capsulatum*, *Cryptococcus neoformans* and atypical mycobacteria, may produce multifocal choroiditis in patients who have AIDS. These infections are rarely sight-threatening, but they should alert the clinician to the presence of a systemic infection. Unfortunately, it is generally not possible for the ophthalmologist to distinguish between these possible opportunistic infections on the basis of the eye examination alone.[47]

Other important posterior segment infections that can occur in HIV-positive patients include toxoplasmosis, syphilis and infection with HSV and VZV. Whereas toxoplasmosis in immunocompetent patients produces a slowly progressive, focal, relapsing chorioretinitis, in immunocompromised patients it can produce a severe, diffuse retinitis.[48] Serologic testing may be helpful. Nearly one-third of patients who have AIDS and *Toxoplasma* retinitis have concurrent toxoplasmosis of the central nervous system. Ocular syphilis can also mimic CMV retinitis, but the lesions of secondary syphilis are usually a choroiditis, rather than a retinitis.[49] Syphilis is diagnosed serologically. Neuroretinitis caused by *Bartonella* infection has been reported in a patient with AIDS.[21]

Acute retinal necrosis syndrome

The ARN syndrome (see above) occurs in both healthy and immunosuppressed people, including those with AIDS. Acute retinal necrosis differs from CMV retinitis in that the lesions of ARN are typically peripheral and the course is much more rapid. In addition, significant vitreous cells are a prominent feature of ARN, but not of CMV retinitis. Patients who have HIV infection and who develop zoster of the first division of the trigeminal nerve appear to have a high risk of subsequent ARN, which is often bilateral, over the next few weeks to months.[37] Therefore, when a rash of ophthalmic zoster appears, patients who have AIDS should be followed carefully for

signs of ARN.

A specific type of rapidly progressive ARN (PORN) due to VZV infection has been described in patients who have AIDS and a low $CD4^+$ lymphocyte count.[50] Without aggressive therapy, PORN results in bilateral loss of vision within days to weeks. The recommended treatment is a combination of foscarnet, together with either ganciclovir or aciclovir, given intravenously or via intravitreal injection.

Perhaps the most common cause of noninfectious anterior uveitis in HIV-positive patients is a dose-related reaction to rifabutin. Patients receiving rifabutin for prophylaxis against *Mycobacterium avium-intracellulare* in conjunction with another agent that interferes with the metabolism of rifabutin (such as clarithromycin or ritonavir) and patients weighing less than 65kg who are receiving 600mg of rifabutin are at particular risk.[51] [52] The incidence of rifabutin-induced uveitis is 20% among AIDS patients taking the medication, but it has been reported in HIV-negative patients as well. Treatment with corticosteroids and discontinuation of the medication usually results in prompt reversal of the inflammation.[53] Systemic cidofovir has also been reported to cause uveitis in patients who have AIDS.

Chapter 21 - Practice Point

Eye problems and the patient in the intensive care unit

Harminder S Dua

Introduction

The critically ill patient in an intensive care unit (ICU) is particularly vulnerable to bacterial corneal infections, which are by far the most serious ocular surface problems encountered in these patients. Exposure keratitis and associated corneal abrasions are other, relatively minor problems, although they are significant because they are often the precursors of serious corneal infection (see Chapter 18). Despite considerable awareness of the problem and various protocols followed by ICUs all over the world, bacterial keratitis with sequelae of corneal scarring and visual impairment continues to occur in ICU patients. Critically ill patients are also susceptible to endogenous, blood-borne intraocular infections (endophthalmitis), which, although rare, can result in rapid and permanent blindness in the affected eye(s).

Ocular surface defense

The exposed position of the eyes ensures constant encounters with environmental pathogens. However, the ocular surface is equipped with a wide range of protective mechanisms. The lids provide physical and mechanical protection. The blink reflex aids flow of tears across the eye surface and helps in flushing contaminating organisms down the nasolacrimal passages into the nasopharynx, where they are effectively dealt with by the lymphoid tissue. The conjunctiva is also provided with lymphoid tissue, which can mount a competent humoral and cell-mediated immune response against invading organisms. Constant evaporation of tears keeps the ocular surface temperature down and so makes it less favorable to bacterial growth. Furthermore, tears have several important antimicrobial constituents such as immunoglobulins, lysozyme, lactoferrin, complement components, ceruloplasmins, defensins and betalysins. The integrity of the corneal surface epithelium is the single most important defense against bacterial invasion. In critically ill ICU patients, several of the above factors are breached or compromised, predisposing to infection.

Risk factors for eye infection in intensive care unit patients

Important risk factors for bacterial keratitis in the setting of an ICU are listed in Table 21.1 . Exposure, inadequate blinking and drying (leading to epithelial erosions and abrasions) are important factors that make a critically ill patient susceptible to ocular surface infection. When intermittent positive-pressure ventilation is employed, it leads to venous stasis, body fluid retention and conjunctival edema. Edematous and chemosed conjunctiva prolapses through the lids with consequent drying and bacterial contamination. Infected respiratory tract secretions are a common source of bacterial contamination of the eyes. Suction of copious tracheobronchial secretions when carried out over the patient's head, across the eyes, is known to cause bacterial dispersion and ocular contamination. *Pseudomonas aeruginosa* is the most common pathogen isolated from corneal ulcers in ICU patients. Risk factors for endophthalmitis include chronic nutritional deficiency, especially related to alcoholism, diabetes mellitus, intravenous drug abuse, AIDS and major surgical interventions, particularly on the bowels or infected tissue or organs. *Pseudomonas aeruginosa, Neisseria meningitidis, Streptococcus pneumoniae* and *Bacillus cereus* are the common and important organisms isolated from eyes with endophthalmitis.

Management

Prevention, by eliminating or addressing the risk factors, is the key to management of ocular surface infections in critically ill patients. The eyes should be frequently inspected, every 4–6 hours at least (Table 21.2). Sterile artificial tear drops should be instilled at each inspection and proper lid closure should be maintained at all times. This prevents drying of the corneal surface.

Lid closure can be achieved by placing a strip of microspore adhesive tape horizontally across the closed lid margins. Constant removal and reapplication of adhesive tape can lead to excoriation of the lid skin. The Apache eye patch (BID Instruments Ltd, Aberdeen, UK), which is shaped like a 'T' with an adhesive horizontal arm applied to the upper lid and the long arm provided with a Velcro mechanism, allows repeated opening and closure of the lids without any abrasive effect. Alternatively a temporary 'Frost suture' can be passed through the upper or lower lid. A 4.0 or 5.0 silk suture mounted on a cutting needle is passed horizontally through the skin of the lid, close to the lid margin (upper or lower). At this site, the skin is fairly firmly adherent to the underlying tissues and provides good anchorage to the suture (Fig. 21.1). The two ends are left 2–3 inches (4.5–7.5cm) long and taped to the cheek (or brow). The suture is used as a handle to open or close the lids. Eye patches or sutures can be discontinued when the blink reflex returns to normal. When the lids cannot be apposed owing to rigidity or loss of tissue, as occurs after injury or burns, or when chemosed conjunctiva protrudes through the palpebral aperture, polyacrylamide gel patches of high water content or cling wrap can be used. These provide adequate cover and protection and conserve moisture. Gel patches need to be kept constantly hydrated with sterile normal saline. Instruments used to cut gel patches or cling wrap to appropriate size must be sterile.

Suction of secretions should be carried out from the side of the head rather than over the top of the head. At all times, the eyes

TABLE 21-1 -- Risk factors for corneal and conjunctival infection in patients in intensive care units.

RISK FACTORS FOR CORNEAL AND CONJUNCTIVAL INFECTION IN PATIENTS IN ICUs
Dry eye
Inadequate tear production
Poor or absent blink reflex (e.g. because of coma or the use of paralyzing and sedating drugs)
Exposure as a result of proptosis or poor closure of lids (lagophthalmos), leading to excessive evaporation
Microtrauma
Tips of eye medication dispensers
Cotton wool or gauze wipes or patches applied over open lids
Conjunctival contamination
Nosocomial pathogens, commensals
Infected body fluids (droplets) related to suction from respiratory tract
Conjunctivitis, conjunctival edema (chemosis as a result of ventilation support), with protrusion of conjunctiva through lids
Retained contact lens
Poor host resistance
Malnutrition, chronic alcoholism, immunodeficiency, prolonged corticosteroid medication, diabetes mellitus, overwhelming systemic infection

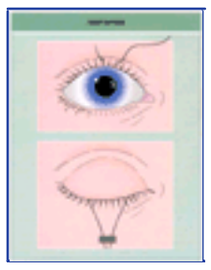

Figure 21-1 Frost suture. A 5.0 silk suture is placed at the upper lid margin through half the tissue thickness (above) and used to tape the lid shut (below).

TABLE 21-2 -- Suggested protocol for eye care in patients in intensive care units.*

SUGGESTED PROTOCOL FOR EYE CARE IN PATIENTS IN ICUs
At the outset
Assess condition of eyes (A–C)
Ensure patient is not wearing contact lenses (soft or rigid)
In road traffic accident patients, exclude conjunctival sac foreign bodies (seek ophthalmic opinion if necessary)
A Eyes are clean and moist, and lids close adequately
If blink reflex preserved:
Inspect eyes at regular intervals (4–6 hours)
Ensure that eyelids remain closed at all times
Keep eyes moist by instillation of simple eye ointment or artificial tear drops at each inspection
If blink reflex is absent:
The lids can be lightly taped shut
B There is conjunctival edema, drying of ocular surface or eyes tend to remain open
Nurse patient with head up (if possible) to encourage dispersion of conjunctival fluid
Remove any obstruction to jugular venous drainage (e.g. with endotracheal tube harness)
Instil drops or ointment as above
Close eyes fully with adhesive tape or polyacrylamide gel patches
Ensure polyacrylamide gel patches are kept hydrated with sterile normal saline
Inspect at 4–6 hours intervals for first 24 hours
If eyes remain moist and satisfactory, continue as above
If dryness increases or epithelial abrasions develop, increase frequency of simple paraffin eye ointment and consider topical antibiotic prophylaxis (gentamicin or ciprofloxacin), particularly if the patient has infection at any other site
C The eyes are/become red, inflamed and sticky
Suspect conjunctivitis or keratitis
If there is conjunctival discharge, the eyes should not be patched or taped shut
Allow free drainage of discharge, irrigate with sterile normal saline, culture swabs from conjunctival sac and commence (prophylactic) antibiotics
Because eyes are open, risk of drying becomes greater
Increased frequency of inspections and instillation of ocular lubricants
Refer to an ophthalmologist
Avoid
Touching tips of drop or ointment applicators to ocular surface
Using the same drop or ointment units for right and left eyes
Placing patch or tape over partially open eyes
Patching of eyes with discharge
Suction of secretions across the head of the patient and suction without covering the eyes
Routine eye swabs for culture in all patients in ICUs
Embarrassment of leaving contact lens in situ

** Modified from protocol used in the ICU of the University Hospital, Queen's Medical Centre, Nottingham, UK (Dr Bernard Riley, personal communication).*

should be adequately covered and shielded during suction maneuvers. In the presence of respiratory or other infections, eye swabs should be taken every 1–2 days to detect early colonization of the conjunctival sac. In the presence of a positive swab, prophylactic antibiotic drops should be commenced. Chloramphenicol or ciprofloxacin drops provide a broad range of cover. Gram staining helps to tailor the choice of antibiotic. Antibiotic ointments smeared on the surface of the lid skin will make it difficult to retain adhesive tape.

Early detection of infection is the next best step in management. Appearance of lid swelling and conjunctival swelling and redness are

important signs. Any discharge or crusting of the lid margins should be viewed with suspicion. Early signs of corneal involvement include loss of the normal shine or luster, corneal haziness and localized white infiltrates. Corneal staining with 2% fluorescein is a useful bedside test and, if positive, indicates corneal abrasion or ulcer. Instil a drop or two of 2% fluorescein, close and open the eyelid to ensure even spread, irrigate with a few drops of sterile saline 20–30 seconds later and view the cornea with a blue light (pen lights with cobalt blue filter attachments are widely available). Any area of the cornea denuded of epithelium will fluoresce green.

Treatment of established corneal infection constitutes an ocular emergency and an ophthalmologist must be involved at the outset. Corneal ulcers, particularly those caused by *Pseudomonas* spp., can progress rapidly with perforation of the cornea and loss of the eye. The usual protocol is to take corneal scrapes for Gram stain and culture (aerobes and anaerobes and fungi) and sensitivity. Eye drops of gentamicin (15mg/ml) and cefuroxime (5% or 10%) (or vancomycin 25mg/ml if the patient is hypersensitive to ß-lactams) are commenced at 1-hourly intervals, each drop alternating every half hour, round the clock, for 24–48 hours. Treatment is tapered or modified according to clinical response and sensitivity results. Ciprofloxacin 0.3% is a useful option, especially if *Pseudomonas* spp. are suspected. For all drops, an initial intensive loading regimen of 1–2 drops every 15 minutes for 4–6 hours is beneficial.

Features that should alert the physician to onset of endophthalmitis include sudden visual impairment, ocular pain and a diminished or altered fundus red reflex on ophthalmoscopy. Pus in the anterior chamber, hypopyon, can occur with both endophthalmitis and keratitis. Treatment of endophthalmitis includes intravitreal (such as amikacin 0.4mg in 0.1ml and vancomycin 1 or 2mg in 0.1ml) and intravenous injection of appropriate antibiotics and vitrectomy. An ophthalmologist should be involved

in the management at a very early stage.

Chapter 22 - Acute and Chronic Meningitis

Stephen L Leib
Martin G Täuber

INTRODUCTION

Meningitis is the most common serious manifestation of infection of the central nervous system (CNS). Inflammatory involvement of the subarachnoid space with meningeal irritation leads to the classic

TABLE 22-1 -- Microbial causes of meningitis.

MICROBIAL CAUSES OF MENINGITIS		
Acute bacterial meningitis		
Common etiologic species	*Haemophilus influenzae*	*Listeria monocytogenes*
	Neisseria meningitidis	*Streptococcus agalactiae*
	Streptococcus pneumoniae	
Other etiologic species	*Staphylococcus aureus*	*Flavobacterium* spp.

triad of headache, fever and meningism, and to a pleocytosis in the cerebrospinal fluid (CSF). Meningitis is divided clinically into acute and chronic disease; acute meningitis develops over hours or days, whereas the symptoms of chronic meningitis evolve over weeks or even months.

Acute meningitis is caused by a variety of infectious agents (Table 22.1). The most serious form of acute meningitis is caused by pyogenic bacteria, such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*. [1] [2] [3] Group B streptococci (*Streptococcus agalactiae*), Enterobacteriaceae and *Listeria monocytogenes* are the major pathogens in the neonatal period (Table 22.2).[3] [4]

TABLE 22-2 -- Bacterial causes of acute meningitis related to age and predisposing factors.

BACTERIAL CAUSES OF ACUTE MENINGITIS RELATED TO AGE AND PREDISPOSING FACTORS		
Age	**Pathogen**	**Predisposing factors**
0–4 weeks	*Streptococcus agalactiae*	Birth complications
	Escherichia coli	Birth complications
	Listeria monocylogenes	Maternal infection
	Streptococcus pneumoniae	CSF leak, asplenia
1–3 months	*Escherichia coli*	Nosocomial colonization
	Haemophilus influenzae	CSF leak, sinusitis, otitis
	Listeria monocytogenes	Immunodeficiency
	Neisseria meningitidis	Complement deficiencies, immunodeficiency
	Streptococcus agalactiae	Nosocomial colonization
	Streptococcus pneumoniae	CSF leak, immunodeficiency
3 months–18 years	*Haemophilus influenzae*	Age 3 months–6 years, CSF leak, otitis media, sinusitis
	Neisseria meningitidis	Epidemics, terminal complement deficiencies
	Streptococcus pneumoniae	CSF leak, otitis media, sinusitis, asplenia
18–50 years	*Neisseria meningitidis*	Epidemics, immunodeficiency
	Streptococcus pneumoniae	CSF leak, otitis media, sinusitis, asplenia, alcoholism
>50 years	*Listeria monocytogenes*	Immunodeficiency, diabetes mellitus
	Streptococcus pneumoniae	CSF leak, otitis media, sinusitis, asplenia, alcoholism
Not age-related	Enterobacteriaceae	Neurosurgery, nosocomial acquisition
	Staphylococcus aureus	Neurosurgery, CSF leak, endocarditis, abscesses
	Propionibacterium acnes	Neurosurgery, CSF leak, dermal sinus

Patients who have aseptic meningitis show signs of meningeal inflammation and CSF pleocytosis with predominance of lymphocytes, but no bacterial pathogen can be isolated from CSF or blood. The term 'aseptic meningitis' predates the routine use of tests to detect viruses and other difficult to culture organisms and includes cases caused by highly diverse etiologic agents. Many cases of aseptic meningitis are caused by viruses, primarily enteroviruses (Table 22.3), including Coxsackie viruses (see Chapter 23). Nonviral causes of aseptic meningitis include spirochetes, rickettsiae, *Mycobacterium tuberculosis*, *Leptospira* spp., *Brucella* spp., fungi and noninfectious etiologies (see Table 22.1).[5] While signs and symptoms overlap between bacterial and aseptic meningitis, the latter has a much more favorable prognosis, particularly when caused by viruses.

Chronic meningitis is defined by symptoms of meningeal inflammation with CSF pleocytosis that persist for more than 4 weeks.[5] The diagnosis is based on the history, clinical evidence of meningitis, CSF examination, and often on imaging studies.[6] The differential diagnosis is broad (see Table 22.1). The predominant CSF cell type can provide clues to the underlying disease (Table 22.4).

EPIDEMIOLOGY

Incidence

Acute bacterial meningitis

The incidence of acute bacterial meningitis in the USA is 5–10/100,000 persons per year, resulting in 15,000–25,000 cases annually.[1] The very old and the very young are more commonly affected. The organisms that cause bacterial meningitis vary with the age of the patient (see Table 22.2). Neonatal meningitis has been reported in 1/200–500 live births; at present more than 50% of these cases are caused *by Strep. agalactiae*.[3] [4] Until recently, young children aged 1 month to 2 years have had the highest incidence of meningitis, with *H. influenzae* type b as the predominant pathogen. The use of new conjugate *H. influenzae* type b vaccines has reduced the incidence of invasive *H. influenzae* infection, including meningitis, by more than 90% in developed countries, where the vaccine is widely used.

The incidence of bacterial meningitis shows a peak in winter and early spring and varies greatly in different areas of the world. This variability is accounted for primarily by the epidemiology of *N. meningitidis*, which can cause either sporadic cases or epidemics of meningitis. Small outbreaks typically occur in populations of young adults living in close quarters, such as dormitories of military camps or schools. Major epidemics, which dramatically increase the incidence of the disease, have occurred periodically in certain parts of the world, including sub-Saharan Africa (the so-called 'meningitis belt'), Europe (particularly Scandinavia), Asia and South America. During these epidemics, attack rates can reach several hundred per 100,000 people, with devastating consequences, particularly in areas with limited medical resources.[7]

Special clinical circumstances affect the spectrum of bacterial pathogens likely to cause meningitis in a particular patient. Age is the single most important determinant in this regard (see Table 22.2). Other important factors include surgery, trauma and focal suppurative infections of the head, various forms of immunosuppression and genetic predisposition (see Table 22.2).[8] [9]

Bacterial meningitis can occur in hospitalized patients (nosocomial meningitis). In a study of acute meningitis seen in a large city hospital, almost 40% of cases were nosocomial.[10] Most cases of nosocomial meningitis occur in patients undergoing neurosurgical procedures, including implanting of neurosurgical devices, and in patients who have focal infections of the head. The organisms responsible for nosocomial meningitis differ markedly from those causing community-acquired meningitis and include Gram-negative rods (*E. coli, Klebsiella* spp. *Pseudomonas aeruginosa, Acinetobacter* spp., *Enterobacter* spp. and others), staphylococci and streptococci other than *S. pneumoniae*.[11]

The extent to which alteration of host defenses, such as chemotherapy-induced neutropenia, increases the incidence of meningitis is not known, but it is clear that the organisms causing meningitis in these patients are markedly different from those found in community-acquired meningitis in immunocompetent patients. Bacterial pathogens causing meningitis in neutropenic patients include Gram-negative bacilli, staphylococci, non-pneumococcal streptococci (viridans and ß-hemolytic streptococci) and rare pathogens such as *Stomatococcus mucilaginosus* and *Bacillus cereus*. In patients who have T-cell deficiencies, intracellular pathogens (*Listeria* spp., *Salmonella* spp. and *Nocardia* spp.) must be considered. In addition to bacteria, fungi (*Aspergillus* spp., *Cryptococcus* spp., *Candida* spp.) and viruses (herpes simplex, cytomegalovirus, JC [JC are the initials of the patient from whom the virus was first isolated]) are well-recognized causes of meningitis in patients who have severe immunodeficiencies. Some cases of bacterial meningitis in immunocompromised patients have been rapidly fatal, but in general clinical aspects of meningitis in these patients appear to be similar to those in immunocompetent patients.[12]

Recently, several examples of genetic predisposition to infections with *N. meningitidis* have been identified.[13] Deficiencies of one of the terminal components of complement, albeit rare, are associated with recurrent neisserial infections or infections with uncommon serogroups. Other genetic traits have been associated with either increased risk for infection, risk for fatal infections or risk for septic shock as opposed to meningitis. These include variants of mannose-binding lectin, Fc?-receptor, interleukin (IL)-1 and IL-1 receptor, IL-10, tumor necrosis factor a (TNF-a) and plasminogen activator inhibitor.[14] [15] These observations point to the importance of hereditary traits of innate immunity in determining the susceptibility to and the course of invasive infections with *Neisseria* spp.

Aseptic meningitis

In the USA, aseptic meningitis has an incidence similar to that of bacterial meningitis — up to 10/100,000 people per year. A recent report noted 8000–13,000 cases of aseptic meningitis over a 7-year period in the USA. [5] The true incidence rate is likely to be higher because aseptic meningitis is often not reported. The disease

preferentially affects children and young adults. Other populations at risk are those prone to acquire sexually transmitted diseases, including HIV, herpes simplex and syphilis, and those exposed to mosquitoes (which transmit arboviruses), ticks (Lyme disease, Colorado tick fever), or animals or animal products (lymphocytic choriomeningitis, *Brucella* spp.). The incidence of aseptic meningitis is often four to seven times higher in the summer to autum months than in winter. This is a direct reflection of seasonal variations in the acquisition of systemic enteroviral infections that can lead to aseptic meningitis and of arbovirus infections, whose insect vectors are most prevalent in summer and fall (see also Chapter 23).

Chronic meningitis

The epidemiology of chronic meningitis is quite varied, being determined by the specific etiologic agent (see Table 22.4).[16] Meningitis caused by *M. tuberculosis* predominantly affects young children and the elderly, with an increased incidence in developing countries and in patients who have low socioeconomic status or HIV infection.[17] [18] Some causes of chronic meningitis have defined geographic distributions, such as coccidioidomycosis, histoplasmosis, blastomycosis, paracoccidioidomycosis, Lyme disease, cysticercosis, angiostrongyloidiasis and sarcoidosis. Those exposed to animals and animal

TABLE 22-3 -- Characteristic features of aseptic meningitis by etiology.

CHARACTERISTIC FEATURES OF ASEPTIC MENINGITIS BY ETIOLOGY			
Agent	**Season**	**Clinical signs**	**Special features**
Enteroviruses	Summer–autumn	Nonspecific	Children and young adults; culture throat and stool
Coxsackie virus	Summer–autumn	Petechial rash, pleurodynia, herpangina, myopericarditis, conjunctivitis	Children and young adults; culture throat and stool
Echovirus	Summer–autumn	Dermatomyositis	Children and young adults; culture throat and stool
Arboviruses	Spring, autumn (vector dependent)	Encephalitis prominent	Serology and local epidemiology important for diagnosis
Herpes simplex virus	No seasonal pattern	May accompany primary genital herpes	CSF glucose may be low; CSF polymerase chain reaction positive
Cytomegalovirus	No seasonal pattern	Very rare complication of CMV infection	
Epstein-Barr virus	No seasonal pattern	Complication of mononucleosis	
Mumps	Spring	Orchitis, oophoritis, pancreatitis	Children and young adults; CSF glucose may be low
Lymphocytic choriomeningitis	Autumn–winter	Exposure to rodents; alopecia, orchitis, arthritis, myopericarditis	CSF glucose may be low; CSF pleocytosis may be > 1000/mm^3
HIV	No seasonal pattern	Mononucleosis-like syndrome	Check serology; if negative, recheck in 3 months
			Check p24 antigen or HIV PCR if strong suspicion
Syphilis	No seasonal pattern	During acute infection and in neurosyphillis	CSF serology
Lyme disease	Summer–autumn	History of tick bite or erythema migrans	Check blood serology
Leptospirosis	Summer–autumn	Biphasic illness after rodent or water exposure	First phase — check blood and CSF cultures; second phase — check urine cultures and serology

TABLE 22-4 -- Pathogens and clinical features of chronic meningitis.

PATHOGENS AND CLINICAL FEATURES OF CHRONIC MENINGITIS				
Pathogen		**Predominant type of CSF pleocytosis**	**Predisposition and risk factors**	**Associated clinical manifestations**
Bacteria	*Actinomyces* spp.	Neutrophils	Mouth and ear lesions	CNS lesions, endophthalmitis
	Borrelia burgdorferi (Lyme disease)	Lymphocytes	Tick bite	Cranial nerve palsy (VII nerve)
	Brucella spp.	Lymphocytes, neutrophils	Unpasteurized dairy products	Undulant fever, hepatomegaty
	Leptospira spp.	Neutrophils	Exposure to urine of infected animals	Hepatomegaly, hepatitis, thrombocytopenia
	Mycobacterium tuberculosis	Neutrophils, monocytes, lymphocytes	Immunodeficiency, high endemic prevalence	Cranial nerve palsy (VI nerve)
	Nocardia spp.	Neutrophils	Immunodeficiency	Abscesses
	Treponema pallidum	Eosinophils, lymphocytes	Sexually transmitted diseases	Cranial nerve palsy (VII and VIII nerves)
Viruses	Cytomegalovirus	Lymphocytes; neutrophils (in HIV)	Immunodeficiency	Fever, retinitis
	Echovirus	Lymphocytes	Agammaglobulinemia	Dermatomyositis
	Lymphocytic choriomeningitis virus	Lymphocytes	Exposure to rodents	Orchitis, leukocytopenia, thrombocytopenia
	Mumps virus	Neutrophils	No vaccination	Parotitis, orchitis, oophoritis
	HIV	Lymphocytes	HIV risk factors	Mononucleosis-like illness
Fungi	*Aspergillus* spp.	Lymphocytes or neutrophils	Immunodeficiency, surgery	Lung involvement
	Candida spp.	Neutrophils	Antibiotics, surgery, immunodeficiency	Disseminated disease
	Coccidioides spp.	Lymphocytes	Endemic areas	Lung involvement
	Cryptococcus spp.	Lymphocytes	Immunodeficiency	Encephalitis, headache
	Histoplasma spp.	Lymphocytes	Endemic areas, immunodeficiency	Fever, oral lesions, hepatosplenomegaly
	Pseudallescheria spp.	Neutrophils	Immunodeficiency	Skin lesions, endophthalmitis
	Sporothrix spp.	Neutrophils	Immunodeficiency	Skin lesions, endophthalmitis
Parasites	*Taenia solium*	Eosinophils	Endemic areas	Elevated intracranial pressure, calcified lesions on head imaging
	Angiostrongylus spp.	Eosinophils	Raw seafood	Fever

products are at risk of brucellosis and other zoonoses. Areas with high rates of HIV infection also have higher incidences of chronic meningitis associated with AIDS and the specific etiologies of those cases may be influenced by the geographic location (e.g. cryptococcosis, coccidioidomycosis, histoplasmosis and tuberculosis).

Agents of meningitis

Acute bacterial meningitis

Gram-positive pathogens

Streptococcus pneumoniae, an encapsulated Gram-positive diplococcus, causes a severe form of bacterial meningitis that often leaves neurologic sequelae in survivors and is fatal in up to 30% of patients. The organism can affect all age groups and causes the most severe disease in the very young and the very old. There are over 90 serotypes identified among pneumococcal isolates, but a few serotypes predominate as the causes of meningitis. Different serotypes cause invasive disease in children (14, 6, 18, 19, 23, 4, 9) and in adults (1, 3, 4, 7, 8, 9, 12, 14).[19] [20] A group B streptococcus (*Strep. agalactiae*) is a pathogen of the neonatal period and often causes a devastating sepsis and meningitis. It colonizes the birth canal of women, from where it is transmitted to the child. The colonized newborn can develop group B streptococcal disease of early onset (developing at less than 7 days of age; median 1 day) or late onset (developing later than 7 days of age). Early-onset disease presents as a sepsis-like disease with a very high mortality rate; late-onset disease presents primarily as meningitis.[21] Group B streptococci are also increasingly found as cause of meningitis in older patients, particularly those who have chronic underlying diseases.[22] *Listeria monocytogenes* is a Gram-positive rod that causes meningitis preferentially in neonates, in adults who have underlying conditions such as alcoholism and on long-term treatment with corticosteroids, and in pregnant women. There is often an encephalitic component to presentation, with early mental status alterations, neurologic deficits and seizures.[23]

Staphylococci rarely cause meningitis, except in the setting of intraventricular shunts, or as a consequence of staphylococcal bacteremia in patients who have endocarditis, intravascular devices or suppurative foci.[24] Streptococci (other than *Strep. pneumoniae*), enterococci and Gram-positive anaerobes are rare causes of bacterial meningitis.

Gram-negative pathogens

Haemophilus influenzae is a Gram-negative coccobacillus that is serotyped based on its capsule. Of the six encapsulated serotypes (a–f), type b causes almost all cases of invasive disease, including meningitis. *Haemophilus influenzae* meningitis is a disease of young children.[25]

Neisseria meningitidis, a Gram-negative diplococcus, is mainly responsible for bacterial meningitis in young adults; it causes both sporadic cases and epidemics. The organism is transmitted from person to person by droplets, a form of transmission favored by crowded conditions.[13]

Enterobacteriaceae (e.g. *Escherichia coli*, *Klebsiella* spp. and *Serratia* spp.) cause meningitis in neonates and in patients undergoing neurosurgical procedures.

Pseudomonas aeruginosa can cause meningitis in neutropenic patients and in patients after neurosurgery.[21]

Acute aseptic meningitis (see also Chapter 23)

Viruses

Viruses are the most common cause of aseptic meningitis (see Table 22.3).[5] Enteroviruses account for more than 80% of cases in which the cause is identified. Enteroviruses that cause meningitis include Coxsackie viruses A and B, echovirus and poliovirus. Enteroviruses are transmitted by the fecal-oral route and are spread through close contact in households and day care centers. Affected groups include infants, young children and those looking after them. Mumps, a paramyxovirus, is spread by respiratory droplets and is usually seen in the late winter and early spring. Neurologic complications range from encephalitis to meningitis. Young children are most commonly affected, and boys are more often affected than girls by a ratio of between 2 to 1 and 5 to 1. Mumps meningitis follows mumps parotitis, and there is often no salivary gland involvement at the time of presentation of aseptic meningitis.[5]

Lymphochoriomeningitis virus is an arenavirus spread by contact with rodent urine or feces. The disease was most prevalent in young adults and in impoverished populations, but the virus has become a rare cause of meningitis. Patients present with the typical symptoms of acute meningitis. After an initial improvement, some patients relapse into a second phase of meningitis, which is believed to be immune-mediated.[26]

Patients infected with arboviruses (St Louis encephalitis virus, Western equine encephalitis virus, California encephalitis virus and Eastern equine encephalitis virus) usually present with symptoms of encephalitis rather than meningitis. However, a minority of patients have meningitis, with a paucity of symptoms suggestive of encephalitis.

Many of the herpesviruses cause neurologic complications, including aseptic meningitis. Primary genital herpes caused by herpes simplex virus type 2 is the most common cause. Aseptic meningitis is much less likely to complicate recurrent outbreaks of herpes. Herpes aseptic meningitis is a benign and self-limited illness that must be distinguished from herpes encephalitis, which is a serious illness that often has devastating neurologic consequences and often causes death.[27]

Varicella-zoster virus, cytomegalovirus and Epstein-Barr virus can also cause aseptic meningitis. HIV-1 has been identified as a cause of aseptic meningitis. Seroconversion of HIV-1 often causes a mononucleosis-like illness with fever, malaise, rash, myalgias and arthralgias, and this is sometimes associated with aseptic meningitis (see Chapter 122).[28] Other less important viral etiologies of aseptic meningitis include adenovirus, measles and rubella.

Bacteria

Some bacterial infections can cause an aseptic meningitis syndrome. [29] Patients who have bacterial meningitis and who have been partially treated with antibiotics may have symptoms of meningitis with a CSF profile very similar to that of aseptic viral meningitis. Parameningeal bacterial foci (e.g. brain abscesses and epidural abscesses) can be associated with culture-negative meningitis, usually with a predominantly granulocytic CSF pleocytosis. Symptoms of meningitis are generally mild or absent.

Bacterial endocarditis can cause a cerebritis, which is characterized by vasculitis of the small cerebral vessels; it can also be associated with aseptic meningitis.

Spirochetes commonly cause brain infections with meningeal inflammation and a CSF profile similar to that of viral meningitis. Secondary syphilis rarely (in about 1% of all cases) causes acute, aseptic meningitis that can be associated with hydrocephalus, cranial nerve palsies and encephalitic changes.

Aseptic meningitis is also a manifestation of early Lyme disease and is frequently associated with cranial and peripheral neuropathies.[30]

Both the early and second phase of leptospirosis can cause an aseptic meningitis.[31] The CSF shows a moderate lymphocytic pleocytosis and is sterile. The meningitis resolves without specific therapy over the course of a few weeks. Rickettsiae, including *Coxiella burnetii* and *Ehrlichia* spp., can cause an aseptic meningitis with lymphocytic pleocytosis and elevated protein concentrations as part of

the meningoencephalitis that characterizes infections by these intracellular pathogens.

Amebae

Naegleria fowleri, and rarely *Acanthamoeba* spp., can cause an acute meningoencephalitis that occurs most commonly in children and young adults and resembles bacterial meningitis with signs indicating severe brain involvement. The organism is acquired by swimming in fresh water. The CSF shows a polymorphonuclear pleocytosis with increased protein and decreased glucose concentrations, many erythrocytes and a negative Gram stain. A fresh, warm sample of CSF should be examined microscopically for evidence of motile amebae. The disease is fatal in more than 95% of cases.[32]

Noninfectious causes

Neurosurgery involving the posterior fossa can result in aseptic meningitis ('posterior fossa syndrome'). Signs of meningitis appear rapidly, but patients often do not look very ill. The CSF shows a polymorphonuclear pleocytosis with elevated protein and low glucose mimicking bacterial meningitis, but cultures remain negative. The syndrome is diagnosed after excluding infectious causes (particularly bacteria) and is treated with high doses of corticosteroids for several days.

Other noninfectious diseases causing aseptic meningitis include carcinomatous meningitis, sarcoidosis, systemic lupus erythematosus and Behçet's disease. Many drugs have been linked to aseptic meningitis, most importantly trimethoprim-sulfamethoxazole (cotrimoxazole), nonsteroidal anti-inflammatory drugs and OKT3, an antibody directed against T cells.[33] Mollaret's meningitis is a recurrent lymphocytic meningitis, usually seen in young women. The cause is unknown but is thought by some to be related to herpes simplex virus.[34] The episodes are benign and self-limiting, the prognosis is good.

Chronic meningitis

Bacterial

Worldwide, tuberculous meningitis, which results from the rupture of a tubercle into the adjacent subarachnoid space, is the most important cause of chronic meningitis. The presentation is typical for chronic meningitis — slowly progressive headache and signs of meningeal irritation, followed by cranial nerve involvement, other neurologic deficits and progressive mental status changes over a period of weeks. Tuberculous meningitis may be a consequence of either primary infection or reactivation of disease. The diagnosis can be confirmed by a positive CSF culture; however, *M. tuberculosis* is recovered from the CSF in only 38–88% of cases. A moderate lymphocytic pleocytosis is most common. The glucose can be very low; the protein is often very high. Cerebrospinal fluid smears for acidfast bacilli are positive in only a minority of cases (10–20%). Skin tests for delayed hypersensitivity to tuberculin are frequently negative in tuberculous meningitis, whether resulting from primary infection or reactivated disease. [18]

Chronic meningitis is an unusual complication of brucellosis. Symptoms of the meningitis tend to progress over an extended period of months to years. The diagnosis should be entertained when there is a history of exposure to farm animals or consumption of undercooked meats or unpasteurized dairy products from endemic areas.[35]

Secondary syphilis may cause chronic meningitis. The disease is slowly progressive, and generally symptoms have been present for more than 1 month before presentation. Cranial nerve palsies are common; the facial and acoustic nerves are the most frequently affected. Diagnosis is based on a positive Venereal Disease Research Laboratory (VDRL) test in CSF.[36]

The diagnosis of meningitis associated with Lyme disease, caused by *Borrelia burgdorferi*, should be considered in patients who live or have travelled through endemic regions, particularly those with a history of a tick bite or erythema chronicum migrans. Meningitis may persist for weeks and may be associated with cranial nerve palsies and peripheral neuropathies. [30] Syphilis, other spirochetal diseases and collagen vascular diseases may result in a false-positive Lyme serology.

Fungi

Presentations of chronic meningitis caused by *Cryptococcus neoformans*, an encapsulated, ubiquitous fungus, range from a subacute meningoencephalitis to fever of unknown origin. People at highest risk are those with defects in cellular immunity such as occurs in AIDS, hematologic malignancies and prolonged use of high-dose corticosteroids, even though a significant number of patients with cryptococcal meningitis in the pre-AIDS era had no identifiable immune defect. The CSF shows a moderate lymphocytic pleocytosis, but in patients who have AIDS, inflammation may be virtually absent. Cryptococcal antigen latex agglutination is positive in more than 90% of cases, whereas microscopy of India ink preparations to visualize the yeast in CSF is less sensitive.[37]

Coccidioides immitis grows in the dry sandy soils of the southwest USA, and Central and South America. Acute infection is acquired by inhalation of the spores, and meningitis develops within a few months. There are few distinguishing features of the disease; some patients who have generalized disease have erythema nodosum; hydrocephalus is a common complication. Cerebrospinal fluid eosinophilia in patients who have lived or traveled though endemic regions should alert the clinician to the possibility of *Coccidioides* meningitis. Complement-fixing antibodies are present in the CSF in 75–95% of cases, and CSF cultures are positive in more than 50%.[38]

Histoplasma meningitis is a rare complication of histoplasmosis. The diagnosis should be considered in patients who live or have traveled through endemic regions — the Ohio River Valley of the USA, the Caribbean and South America. Cerebrospinal fluid cultures are positive in 27–65% of cases. Blood should be cultured and a buffy coat of the blood should be examined for the presence of the fungus. *Histoplasma* polysaccharide antigen is found in the urine, blood or CSF in 61% of patients and in an even higher proportion of patients who have AIDS.

Candida meningitis is rare and is most commonly a result of disseminated infection or placement of a ventricular shunt. Risk factors for candidemia are the prolonged use of antibiotics or corticosteroids, hyperalimentation, neutropenia, abdominal surgery, intravenous drug use and intravenous catheterization. Neonates are particularly prone to disseminated infection. Cerebrospinal fluid cultures are diagnostic.

Parasites

Neurocysticercosis is endemic in Mexico, South America and Asia. Infection is acquired by eating food contaminated with eggs of *Taenia solium*. Seizures are the most common manifestation. Intraventricular and basilar cysts (racemose cysticercosis) may present with signs of obstructive hydrocephalus. The CSF shows a lymphocytic pleocytosis with eosinophils. Computed tomography (CT) scans of the head show multiple calcified lesions. Serology of blood and CSF may provide support for the diagnosis.

Angiostrongylus cantonensis, the rat lung worm, is most prevalent in Asia and the Pacific Islands and is acquired by the ingestion of raw or inadequately cooked shellfish or snails. Symptoms are typical of chronic meningitis, and rash with pruritus is also common. Infection results in peripheral eosinophilia and chronic eosinophilic

---

meningitis, which resolves spontaneously within 2 months. There is no effective therapy.

Other less common causes of infectious chronic meningitis are organisms that usually cause abscesses, which may leak into the subarachnoid space to cause chronic meningitis. These conditions include blastomycosis, paracoccidioidomycosis, phaeohyphomycoses, mucormycosis, actinomycosis, nocardiosis and toxoplasmosis. Less common fungi causing this syndrome include *Sporothrix schenckii*, chromoblastomycoses and *Aspergillus* spp.

Noninfectious causes

Meningeal carcinomatosis may cause a chronic meningitis that is difficult to distinguish from infectious causes. Neurosarcoidosis is an uncommon complication of sarcoidosis. Basilar inflammation is a prominent feature, resulting in cranial nerve palsies. The CSF shows a lymphocytic pleocytosis and usually a normal glucose. Less common noninfectious causes include systematic lupus erythematosus granulomatous angiitis, Behçet's disease and Vogt-Koyanagi-Harada syndrome.

PATHOGENESIS AND PATHOLOGY

Pathogenesis

The pathogenesis of meningitis is best known from studies on bacterial meningitis, where the role of mucosal colonization, bloodstream invasion, CNS colonization and multiplication within the CSF have been elucidated in experimental systems (Fig. 22.1).

Figure 22-1 Pathogenesis of meningitis.

Nasopharyngeal colonization and invasion

Specific bacterial virulence factors for meningeal pathogens include specialized surface components (e.g. the polysaccharide capsule with specific epitopes and fimbriae or pili). These factors are crucial for adherence to the nasopharyngeal epithelium, the evasion of local host defense mechanisms and subsequent invasion of the bloodstream. Hydrogen peroxide produced by *Strep. pneumoniae* has a bactericidal effect on the microbial flora in the respiratory tract, suggesting that the ability to produce hydrogen peroxide might provide the organism with a competitive advantage for colonization. The invasion of pneumococci needs the activation of nasopharyngeal epithelial cells and the presentation of receptors suitable for pneumococci. The presence of the polymeric immunoglobulin A receptor on human mucosa, which binds to a major pneumococcal adhesin, CbpA, correlates with the ability of pneumococci to invade the mucosal barrier. Lack of specific mucosal antibodies correlates with an increased risk of invasive disease. Viral infection of the respiratory tract may also promote invasive disease. From the nasopharyngeal surface, encapsulated organisms cross the epithelial cell layer and invade the small subepithelial blood vessels.[39]

Intravascular survival

In the bloodstream, bacteria must survive host defenses, including circulating antibodies, complement-mediated bactericidal mechanisms and neutrophil phagocytosis. Encapsulation is a shared feature of the principal hematogenous meningeal pathogens (*H. influenzae, N. meningitidis, Strep. pneumoniae, E. coli* K1 and group B streptococci). The

---

capsule is instrumental in inhibiting neutrophil phagocytosis and complement-mediated bactericidal activity.

Several defense mechanisms counteract the antiphagocytic activity of the bacterial capsule. Activation of the alternative complement pathway results in cleavage of C3 with subsequent deposition of C3b on the bacterial surface, thereby facilitating opsonization, phagocytosis and intravascular clearance of the organism.

Impairment of the alternative complement pathway occurs in patients with sickle-cell disease and those who have undergone splenectomy, and these groups of patients are predisposed to the development of pneumococcal meningitis. Recently, functional deficiencies of several components involved in the activation and function of complement-mediated defenses have been identified (i.e. mannose-binding lectin, properdin, lack of terminal comple-ment components), which increase the susceptibility for invasive meningococcal infections.[13]

Meningeal invasion

Studies on the pathogenesis of experimental bacterial meningitis show that cells in the choroid plexus and cerebral capillaries possess receptors for adherence of meningeal pathogens. For *E. coli*, a complex interplay between endothelial factors and microbial genes orchestrates the crossing of the blood-brain barrier by bacteria.[40] Experimental evidence has identified the choroid plexus as a potential site for the invasion of meningeal pathogens, and this may be facilitated by its exceptionally high rate of bloodflow (200ml/g per minute) and the presence of pathogen-specific receptors.

Pneumococci are thought to enter the CNS by crossing the blood-brain barrier or the blood-CSF barrier either by local tissue damage or by transcytosis through microvascular endothelial cells.[41] Pneumolysin, a major pneumococcal virulence factor, was shown to damage endothelial cells and to be an important component for compromising the blood-brain barrier.[42]

Nonhematogenous invasion of the CSF by bacteria occurs in situations of compromised integrity of the barriers surrounding the brain (e.g. in otitis media, mastoiditis, sinusitis). Direct communication between the subarachnoid space and the skin or mucosal surfaces as a result of malformation or trauma give rise to meningeal infection with bacterial species that vary with the site of the abnormal communication. Bacteria can also reach the CSF as a complication of neurosurgery, spinal anesthesia or ventriculostomy placement.[43]

Host defense mechanisms in subarachnoid space inflammation

Pathogens reaching the CSF are likely to survive because of a paucity of resident macrophages and deficient opsonization due to low concentrations of capsule-specific immunoglobulins and complement in the CSF. Lack of opsonization greatly reduces the effectiveness of incoming granulocytes and allows largely unrestricted multiplication of the meningeal pathogens. Bacterial multiplication is associated with the release of bacterial products (fragments of cell wall, lipopolysaccharide) that:

- ¦ trigger the inflammatory response in the subarachnoid space by inducing the production and release of inflammatory cytokines (e.g. TNF-a, IL-1 and IL-6) and chemokines (e.g. IL-8, the growth-related oncogene a [GRO-a], the CC chemokine monocyte chemoattractant protein-1 [MCP-1] and others), and lipid inflammatory mediators such as platelet activation factor;
- ¦ upregulate adhesion molecules on brain vascular endothelial cells; and
- ¦ promote the recruitment of granulocytes into the CSF.

The granulocytic inflammation appears to be primarily responsible for the complex pathophysiologic CNS alterations associated with bacterial meningitis.[44] [45]

Blood-brain barrier

The blood-brain barrier separates the brain from the intravascular compartment and maintains homeostasis within the CNS. The permeability of the blood-brain barrier increases in meningitis at the level of the choroid plexus epithelium and the cerebral microvascular endothelium. Separation of intercellular tight junctions and increased pinocytosis contribute to the increased permeability. Matrix metalloproteinases (MMP), zinc-dependent enzymes produced as part of the immune response to bacteria that degrade extracellular matrix proteins, also contribute to the increased permeability of the blood-brain barrier.[46] The resulting increased extravasation of serum components, including antibiotics leads to higher concentrations in the CSF during meningitis, with an approximately fivefold increase over the uninfected state for most antibiotics.[47] [48]

Increased intracranial pressure

The major element leading to increased intracranial pressure in bacterial meningitis is the development of cerebral edema, which may be vasogenic, cytotoxic or interstitial in origin. Vasogenic cerebral edema is primarily a consequence of increased blood-brain barrier permeability.

Cytotoxic edema results from an increase in intracellular water following alterations of the cell membrane and loss of cellular homeostasis. Cytotoxic mechanisms include ischemia and the effect of excitatory amino acids. Secretion of antidiuretic hormone also contributes to cytotoxic edema by making the extracellular fluid hypotonic and increasing the permeability of the brain to water.

Interstitial edema occurs by an increase in CSF volume, either through increased CSF production via increased bloodflow in the choroid plexus, or decreased resorption secondary to increased CSF outflow resistance.[49] [50]

Cerebral vasculitis and alterations in cerebral bloodflow

Bacterial meningitis is associated with marked changes in cerebral bloodflow. In the early phase of the disease, an increase in bloodflow is observed, and this appears

to be mediated by nitric oxide and oxidative radicals. Formation of oxidative radicals in meningitis has been documented to occur together with the presence of inflammatory cells in the subarachnoid space and along penetrating cortical blood vessels, and leads to oxidative alterations of the cerebral vasculature, which may contribute to the cerebral bloodflow reduction observed in advanced meningitis. [51] [52] [53] [54]

Other factors involved in bloodflow reduction in advanced meningitis include the vasoconstrictor peptide family of endothelins, the levels of which are greatly increased in the CSF during bacterial meningitis. An antagonist of endothelin receptors normalized cerebral bloodflow and prevent cortical injury in experimental meningitis.[52] [55]

Several clinical studies have found an association between severe cerebral bloodflow reduction and adverse outcomes in children and adults with meningitis, suggesting that ischemia is an important mediator of brain damage in meningitis. Cerebral bloodflow reduction during meningitis can be global, as a result of reduced cerebral perfusion pressure (resulting from increased intracranial pressure, systemic hypotension, or both), or focal, as a result of the vascular involvement of cerebral arteries and veins by the subarachnoid space inflammation (Fig 22.2 , Fig 22.3). [51]

Neuronal injury

The exact mechanisms that lead to permanent brain injury are incompletely understood. There is converging evidence, however, that cerebral ischemic necrosis contributes to this process, particularly regarding damage to the cerebral cortex. Acute breakdown of the blood-brain barrier, intrathecal production of cytokines, and accumulation of blood-derived leukocytes in the CSF are key events leading to brain edema, cerebral vasculitis and ultimately neuronal

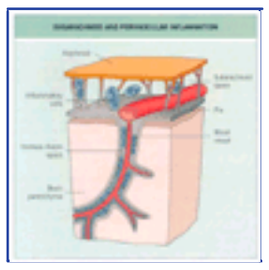

Figure 22-2 Subarachnoid and perivascular inflammation in meningitis. The inflammation in the subarachnoid space extends into the Virchow-Robin spaces along the vasculature.

injury. These events are in part mediated by MMPs (see 'Blood-brain barrier', above). CSF levels of specific MMPs (i.e. MMP-9) were significantly higher in patients who developed neurological sequelae than in those who recovered fully. The metalloproteinase TNF-a converting enzyme (TACE), a close relative of the MMPs, may contribute to the pathophysiology of bacterial meningitis by its ability to release cytokines and their receptors, thus increasing stimuli that trigger further MMP release.[46] Given as adjuvant therapy in addition to antibiotics, combined inhibition of MMP and TACE reduced the extent of cortical and hippocampal damage and protected from learning disability resulting from meningitis.[56]

While the mechanisms of necrosis in the cortex have only partially been explored, even less is known regarding the causes of neuronal injury in the dentate gyrus of the hippocampus. In patients dying from bacterial meningitis and in corresponding animal models, neuronal cell death in the hippocampal dentate gyrus fulfils criteria for apoptosis that appears to be induced by activation of the effector caspase-3 and other caspase-independent mechanisms.[57] [58] [59]

Pathology

Important pathologic findings in patients with meningitis include:

- subarachnoid space inflammation;
- inflammatory involvement of the cerebral vasculature; and
- parenchymal brain damage.

The subarachnoid space inflammation appears as a grayish yellow-to-green exudate covering the base and convexities of the brain (Fig 22.3 , Fig 22.4). The exudate consists predominantly of granulocytes in acute bacterial meningitis, and of a mixture of lymphocytes, macrophages and granulocytes in subacute and chronic forms of meningitis. On the surface of the brain, the involvement of the vasculature is often macroscopically obvious (see Fig. 22.3). Histologic examination shows infiltration of vessel walls by inflammatory cells with consecutive thrombosis of the vessel lumen (Fig. 22.5). Vascular involvement is most prominent in acute bacterial meningitis, but it is also seen in chronic, especially tuberculous meningitis.

Inflammation also involves the inner ear, to which it gains access via the cochlear aqueduct connecting the subarachnoid space with the endolymphatic space. Toxic effects of the inflammation on hair cells of the inner ear appear to be responsible for the hearing impairment associated with bacterial meningitis (Table 22.5).

TABLE 22-5 -- Common neurologic sequelae of bacterial meningitis.

COMMON NEUROLOGIC SEQUELAE OF BACTERIAL MENINGITIS	
Deficit	**Approximate frequency (%)**
Hearing loss	15–30
Parenchymal damage	5–30

Cerebral palsy	5–10
Learning disabilities	5–20
Seizure disorder	<5
Cortical blindness	<5
Cerebral hemiation	3–20
Hydrocephalus	2–3

Damage to the brain parenchyma is evidenced by the presence of brain edema (including signs of cerebral herniation), by areas of cerebral infarction resulting from ischemia and by histologic changes. Loss of neurons is associated with a marked reaction of astrocytes and microglia. Apart from the damage to the cortex, neuronal injury is evident in the dentate gyrus of the hippocampus in patients dying from meningitis, and damage to the hippocampus is further suggested by a decreased hippocampal volume in patients surviving meningitis.[60] [61] Given the function of the hippocampus, injury to this structure may represent the substrate for the learning and memory deficits in survivors of meningitis. The extent and localization of neuronal loss probably determines the type of neurologic sequelae resulting from meningitis (see Table 22.5).[40] [52]

Neurologic sequelae

Neurologic sequelae after bacterial meningitis include hearing impairment, mental retardation, focal sensorimotor deficits, epilepsy and cortical blindness. In a retrospective survey of survivors of bacterial meningitis, 31 and 24% reported attention and memory deficits, respectively, which affected their ability to work.[62] Three more recent studies have found significant functional impairment in survivors of bacterial meningitis.[63] [64] [65] Among 1584 children aged 5 years who survived bacterial meningitis during the first year of life, there was a 10-fold increase in the risk of having moderate-to-severe disabilities, including learning diffculties and behavioral problems, neuromotor disabilities, seizure disorders and hearing deficits.[63] Infection with *Strep. pneumoniae* was associated with a higher rate of disabilities than infection with *H. influenzae* or *N. meningitidis*. In a second study, many of the deficits identified at a 7-year follow-up persisted 12 years after bacterial meningitis, with 9% of the patients showing major neurologic, auditory or intellectual impairments, and 30% having less severe disabilities, compared with 11% of the controls.[64] In the third study, 16 of 22 adult patients had neurologic and psychopathologic symptoms 3 years after the acute stage of bacterial meningitis.[65] The speed of cognitive processes and psychomotor performance, concentration and memory functions were reduced in patients compared with controls. Again, sequelae were particularly pronounced in patients after meningitis caused by *Strep. pneumoniae*.

PREVENTION

The most effective prevention for bacterial meningitis is provided by vaccination. This has been most impressively documented with *H. influenzae* type b, for which the new conjugated vaccines have led to a reduction of more than 90% in the number of cases in vaccinated populations.[1] Current recommendations are to vaccinate all children against *H. influenzae* type b with one of several available vaccines, beginning at 3 months of age. Unfortunately, this is not possible in many countries for economic reasons.

A 23-valent polysaccharide vaccine and newly developed conjugate vaccines are available for vaccination against invasive pneumococcal disease, including meningitis.[66] The polysaccharide vaccine, which is cheaper and covers more serotypes than the currently available conjugate vaccines, should be offered to adults at increased risk for invasive pneumococcal infections, such as the elderly and those with underlying disease, including immunocompromising conditions, asplenia, sickle-cell disease and anatomic defects predisposing to meningitis. Some countries, including the USA, have adopted recommendations to routinely vaccinate all children under 24 months of age with the conjugate vaccine.[67] Older children at increased risk for invasive diseases should also be immunized with a conjugate pneumococcal vaccine.

In the case of meningococcal meningitis, polysaccharide vaccines are available for all major serotypes except group b, which has a poorly immunogenic capsule. For group c, new conjugate vaccines that are highly immunogenic in children under the age of 2 years have recently been licensed. Vaccination against meningococci is currently recommended for children and young adults in some countries in the setting of ongoing epidemics and for travelers to countries with high endemic infection rates. [67]

Although no vaccines to prevent transmission of group B streptococci from colonized mothers to their newborn are yet available, preventive strategies using antibiotics have been widely implemented and have substantially reduced the risk of group B streptococcal infections in neonates. Typically, intrapartum administration of penicillin is offered to women who have been shown to be colonized with group B streptococci before delivery, to women who have risk factors for neonatal infection (prematurity, prolonged rupture of the membranes, signs of infection during labor) or to both groups. A recent study suggests that screening with subsequent intrapartum treatment of colonized women may be the preferred approach.[68]

Antibiotics are widely used for the prevention of meningitis associated with neurosurgery and the placement of intraventricular shunts. In patients undergoing craniotomy, perioperative antibiotic prophylaxis appears to reduce the number of postoperative infections. Studies examining the effect of periprocedural or prophylactic antibiotics in patients receiving various types of intraventricular shunts or intracranial pressure monitors have not consistently shown a benefit. In some cases, prophylactic antibiotics have been associated with infections caused by difficult-to-treat organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and fungi. Given the increasing problems with resistant organisms and the diagnostic problems caused by prophylactic antibiotics in patients who have suspected device-associated infection, it seems preferable to refrain from routine use of long-term prophylactic antibiotics in these patients.[43]

CLINICAL FEATURES

Bacterial meningitis

Meningitis is the most likely diagnosis in patients who present with the classical triad of fever, headache and a stiff neck, which is present in at least 80% of patients. Other signs and symptoms occur less frequently (Table 22.6), and patients complaining of headache or presenting with altered mental status must be carefully examined for evidence of meningeal irritation (i.e. meningism, with Kernig's sign, Brudzinski's sign, or both).

Bacterial meningitis can be present in patients in whom the clinical diagnosis is not obvious. This is particularly true in small children and in the elderly. In children under 2 years of age, signs of meningeal inflammation are frequently absent, and the most common clinical presentations include fever and altered mental status (irritability, lethargy), which are present in over 90% of

TABLE 22-6 -- Common signs and symptoms in acute meningitis and encephalitis.

COMMON SIGNS AND SYMPTOMS IN ACUTE MENINGITIS AND ENCEPHALITIS			
Meningitis	Adult	Headache	Kernig's sign
		Fever	Brudzinski's sign
		Neck and back pain	Photophobia
		Meningism	Lethargy or coma
		Nausea and vomiting	Seizures

	Infant	Fever	Bulging fontanelles
		Irritability	Convulsions
		Lethargy	Opisthotonus
		Refusal to feed	Seizures
		Strange cry	
Encephalitis	Fever		Stupor or coma
	Vomiting		Seizures
	Psychiatric alteration		Electroencephalographic changes
	Focal neurologic deficits

patients. Similarly, in elderly patients, fever may be minimal, and mental status changes may be the most obvious symptom. In patients who have suspected meningitis, the skin should be examined carefully for the characteristic purpuric or petechial skin rash of *N. meningitidis* (Fig. 22.6). Other clues derived from the history and physical examination may help in the differential diagnosis of meningitis (Table 22.7).

Untreated bacterial meningitis is characterized by progressive loss of consciousness, which is commonly associated with other neurologic signs including seizures and focal deficits, leading to coma and death. The extent of mental status changes, with profound coma as the most extreme, provides a clinical indication of the severity of the disease. Patients presenting in coma have a very high mortality rate (up to 50%). Systemic complications of the infectious process include septic shock, disseminated intravascular coagulation (particularly with meningococcal infections) and acute respiratory distress syndrome.

Aseptic meningitis

The clinical manifestations of aseptic meningitis are often indistinguishable from those of bacterial meningitis. Acute onset of

TABLE 22-7 -- Clues from the history and physical examination in the differential diagnosis of meningitis.

CLUES FROM THE HISTORY AND PHYSICAL EXAMINATION IN THE DIFFERENTIAL DIAGNOSIS OF MENINGITIS	
Clinical feature	**Likely organism**
Purpura, petechiae	*Neisseria meningitidis*
Cellulitis of the face	*Staphylococcus aureus*, *Haemophilus influenzae*
Otitis media, sinusitis, mastoiditis	*Streptococcus pneumoniae*, *Haemophilus influenzae*
Cerebrospinal fluid fistula	*Streptococcus pneumoniae*
Parotitis	Mumps
Endocarditis (peripheral stigmata, murmur)	*Staphylococcus aureus*
Pericarditis	*Neisseria meningitidis*, *Streptococcus pneumoniae*
Pneumonia	*Streptococcus pneumoniae*, *Haemophilus influenzae*
Spondylodiscitis	*Staphylococcus aureus*, *Mycobacterium tuberculosis*
Septic arthritis	*Staphylococcus aureus*, *Streptococcus pneumoniae*
Focal signs	*Listeria monocytogenes*, brain abscess, encephalitis
Alcoholism, liver cirrhosis	*Listeria monocytogenes*, *Streptococcus pneumoniae*
Pregnancy	*Listeria monocytogenes*
Neurosurgery	Staphylococci, Enterobacteriaceae, *Pseudomonas aeruginosa*
Kidney, heart transplantation	*Listeria monocytogenes*, *Cryptococcus neoformans*
Neutropenia	Gram-negative rods, fungi
HIV infection	*Cryptococcus neoformans*, *Nocardia* spp., *Listeria monocytogenes*, *Mycobacterium tuberculosis*

fever, headache, photophobia, nausea with vomiting and meningism are most common. On the other hand, severe neurologic findings, including seizures, are very uncommon in most forms of aseptic meningitis. Overall, symptoms are generally milder than those of pyogenic meningitis. Most cases of aseptic meningitis are self-limiting and do not lead to sequelae although constitutional symptoms can persist for several weeks. Depending on the causative pathogen, signs of meningeal inflammation may be associated with other clinical findings (see Table 22.3).

Chronic meningitis

Symptoms and signs of chronic meningitis evolve over several days to weeks. Most prominently, patients complain of headaches, often associated with constitutional signs of infection (fever, anorexia). Nuchal rigidity may be subtle or absent. Many forms of chronic meningitis involve the base of the brain and lead to cranial nerve palsies, often affecting eye movements and facial musculature. As the syndrome progresses, signs of brain involvement with seizures, mental status changes, confusion or hallucinations, and focal neurologic deficits develop. Hydrocephalus and increased intracranial pressure may accompany the syndrome.

TABLE 22-8 -- Differential diagnosis of meningitis based on cerebrospinal fluid findings.

DIFFERENTIAL DIAGNOSIS OF MENINGITIS BASED ON CEREBROSPINAL FLUID FINDINGS						
Diagnosis	**Pressure (cmH_2O)**	**White blood cells ($\times 10^6$ /1)**	**Polymorphonucleocytes (%)**	**Glucose (ratio)**	**Protein (g/l)**	**Lactate (mmol/l)**
Normal	<20	1–2	<1	>0.5	<0.45	<2
Acute bacterial meningitis	>20	>1000	>50	<0.4	>1	>4
Chronic meningitis	Variable	>1000	Variable	<0.4	>0.45	>2
Aseptic (viral) meningitis	<20	<1000	<50	>0.4	Variable	<2

DIAGNOSIS

Cerebrospinal fluid examination

Examination of CSF is of paramount importance for the diagnosis of all forms of meningitis (Table 22.8). Accordingly, a lumbar puncture should be performed in patients who have suspected meningitis once a mass lesion that may lead to cerebral herniation has been ruled out on clinical grounds or by CT scan of the head. Evidence for mass lesions consists of the combination of focal neurologic signs (focal seizures, sensorimotor and visual defects) and clinical evidence of increased intracranial pressure (headache, vomiting, impaired mental status, papilledema). In patients who have suspected bacterial meningitis who show no evidence for a focal lesion or increased intracranial pressure, imaging studies before lumbar puncture are usually not necessary. While performing the lumbar puncture, CSF pressure should be recorded.

Immediate examination of the CSF provides valuable information. A Gram stain of uncentrifuged CSF (if the CSF is turbid) or centrifuged CSF (if it is not) indicates the presence of white blood cells, their approximate differential count (mononuclear versus polymorphonuclear) and whether bacteria are present.

Cultures for bacteria and fungi should always be performed, even in patients already treated with antibiotics. Tests for the detection of bacterial antigens by immunologic methods, such as latex particle agglutination, have sensitivities in the range of the Gram stain or culture and are of doubtful benefit when used routinely, but sometimes identify organisms in patients with partially treated bacterial meningitis and negative Gram stain and culture.

Cerebrospinal fluid concentrations of protein, glucose and lactate, in addition to the number and type of white blood cells are helpful in the differential diagnosis of various forms of meningitis (see Table 22.8).[69]

In addition to the routine tests carried out on all CSF samples, specific tests may be indicated under special circumstances. Viral cultures are mostly negative in CSF from patients who have aseptic meningitis and should not be performed routinely. However, nucleic acid detection by polymerase chain reaction and related tests is highly sensitive for detecting selected pathogens, particularly herpes viruses such as herpes simplex virus and cytomegalovirus. Serologic tests of CSF can establish the etiology of cases of chronic meningitis (syphilis, coccidioidomycosis). Isolation of enteroviruses from throat washes or stool should be attempted because after the first 3 days of symptoms enteroviruses are recovered only from these sites.

Systemic parameters

Signs of inflammation are most pronounced in acute bacterial meningitis, and in some cases of chronic meningitis (e.g. tuberculosis, fungal meningitis). In bacterial meningitis, the differential blood count will frequently show a leukocytosis with a left shift. The erythrocyte sedimentation rate and other acute phase reactants are typically elevated.

Blood cultures should be performed in all patients who have suspected meningitis before initiation of antibiotic therapy. They:

- yield the infecting organism in more than 60% of cases of acute bacterial meningitis;
- should be sterile in aseptic meningitis; and
- rarely reveal the organism in chronic meningitis (*Brucella* spp., *Nocardia* spp., fungi).

Patients who have acute meningitis should be examined for evidence of electrolyte imbalance. Hyponatremia is common and may indicate dehydration (in which case the urine sodium concentration is low) or the syndrome of inappropriate antidiuretic hormone (SIADH), in which case the urine sodium concentration is high, an assessment that is important for making the correct choice of fluid substitution, particularly in children who have acute meningitis.

Evidence for disseminated intravascular coagulation is most commonly seen in patients who have meningococcal meningitis. Platelet count, prothrombin time, partial thromboplastin time, fibrinogen levels and fibrin d-dimers should be measured in patients who have suspected disseminated intravascular coagulation.

Imaging studies

In patients who have bacterial meningitis, the possibility of focal infections of the head (sinusitis, otitis media) must be considered, and in selected cases, an appropriate radiologic test (e.g. a CT scan of the head) may be necessary. A CT scan of the head is also indicated in patients who have suspected intracerebral mass lesions or parameningeal foci. Chest radiographs in patients who have acute bacterial meningitis may reveal pneumonia, and in patients who have chronic meningitis, it may show evidence of pulmonary involvement by tubercle bacilli or fungi.

MANAGEMENT

Treatment of meningitis includes two main goals:

- eradication of the infecting organism; and
- management of CNS and systemic complications.

Bacterial meningitis represents a medical emergency, particularly in patients who have rapidly progressive disease and severely impaired CNS function. In these patients, we recommend initiation of empiric therapy without delay. One or two blood cultures should be obtained before administering the first antibiotic dose. We also administer adjunctive therapy with dexamethasone in these severely ill patients concomitantly with the first antibiotic dose (for more detail, see below). Once empiric therapy has been initiated, further diagnostic investigation is carried out. Further therapy depends on the CSF findings. In patients who are clinically stable and are unlikely to be adversely affected if antibiotics are not administered immediately, including those who have suspected viral or chronic meningitis, a lumbar puncture represents the first step, unless there is clinical suspicion of a mass lesion. Findings in the CSF and on CT scan, if

TABLE 22-9 -- Recommendations for empiric antibiotic therapy of bacterial meningitis.

RECOMMENDATIONS FOR EMPIRIC ANTIBIOTIC THERAPY OF BACTERIAL MENINGITIS			
Patients and special modifying circumstances	**Antibiotic**	**Dosage (intravenous)**	
		Children	**Adults**
Neonate or infant under 3 months	Ampicillin plus	50mg/kg q6h	
	cefotaxime or	50mg q6–8h	
	gentamicin	2.5mg/kg q8h	
Neonate (pre-term, low birth weight)	Vancomycin plus	10mg/kg q12h	
	ceftazidime	50mg/kg q12h	
3 months to 50 years	Ceftriaxone or	50mg/kg q12h or 100mg/kg q24h	2–4g q24h
	cefotaxime	50mg/kg q6h	2g q4–6h
Over 50 years or impaired cellular immunity	Ceftriaxone or		2–4g q24h
	cefotaxime plus		2g q4–6h
	ampicillin or		2g q4h
	penicillin G		3–4 million units q4h

Drug-resistant *Streptococcus pneumoniae*	Ceftriaxone plus	50mg/kg q12h or 100mg/kg q24h	2–4g q24h
	rifampicin	10–20mg/kg q24h	600mg q24h
	or vancomycin	10–15mg/kg q6h	0.5g q6h
Neurosurgery, CSF shunt, or head trauma	Ceftazidime	50mg/kg q8h	2g q8h
	plus nafcillin	50mg/kg q6h	2g q4h
	(or vancomycin plus	10–15mg/kg q6h	0.5g q6h
	aminoglycoside)	2.5mg/kg q8h	1.5–2mg/kg q8h

performed, will guide further diagnostic investigation and therapy in all patients.

Antibiotic chemotherapy

Empiric antibiotic therapy

Table 22.9 summarizes empiric antibiotic regimens designed to cover the likely pathogens in different patient populations with suspected bacterial meningitis. Antibiotics should be administered intravenously by bolus infusion at the highest clinically validated doses, corrected for age and renal function. High doses are needed because only a small fraction of the serum concentration (between 3 and 15% for most ß-lactam antibiotics) penetrates into the CSF and because only antibiotic concentrations that exceed the minimum bactericidal concentration (MBC) by a factor of 10–30 are rapidly bactericidal in the CSF.

Empiric therapy is primarily based on the age of the patient, with modifications if there are positive findings on CSF Gram stain or if the patient presents with special risk factors (see Table 22.2). It is safer to choose regimens with broad coverage because they can usually be modified within 24–48 hours when the antibiotic sensitivities of the infecting organism become available.

An important factor in the choice of empiric antibiotic therapy is the emergence of organisms with increasing resistance to antibiotics. Most importantly, pneumococci that are relatively resistant to penicillin — mean inhibitory concentration (MIC) 0.1–1.0µg/ml — or highly resistant to penicillin (MIC >1.0µg/ml) are increasingly important in many parts of the world. Many penicillin-resistant organisms have reduced sensitivity to cephalosporins, and failure of these drugs in the treatment of pneumococcal meningitis caused by resistant organisms has occurred. Empiric therapy with dual antibiotic coverage effective against ß-lactam-resistant pneumococci may therefore be prudent, unless a patient is highly unlikely to have pneumococcal meningitis (e.g. a Gram stain indicates other etiology) or the local incidence of highly resistant pneumococci is very low.

Patients at risk of infection with *L. monocytogenes* must be covered with ampicillin. For patients at risk of infections caused by difficult-to-treat Gram-negative bacilli with a high likelihood of resistance to many ß-lactam drugs, inclusion of an aminoglycoside in the empiric therapy regimen is recommended (see Table 22.9).[70]

In patients who have suspected shunt infections, empiric therapy should include vancomycin to cover for coagulase-negative staphylococci, the most common cause of infection in these patients. The

TABLE 22-10 -- Treatment recommendations for common treatable causes of nonpyogenic meningitis.

TREATMENT RECOMMENDATIONS FOR COMMON TREATABLE CAUSES OF NONPYOGENIC MENINGITIS			
Agent	**Therapy**	**Dose**	**Route**
Herpesviruses	Aciclovir	10mg/kg q8h	iv
Mycobacterium tuberculosis	Isoniazid	10mg/kg/day (up to 300mg/day)	po or iv
	Rifampicin	10mg/kg/day (up to 600mg/day)	po or iv
	Ethambutol	25mg/kg/day	po or iv
	Pyrazinamide	25mg/kg/day (up to 2.5g/day)	po or iv
Brucella spp. (>8 years)	Doxycycline plus gentamicin	100mg q12h	po
		1.7–2mg/kg q8h	iv
Brucella spp. (<8 years)	Trimethoprim-	5mg/kg trimethoprim q12h	po
	sulfamethoxazole	25mg/kg sulfamethoxazole q12h	po
	plus gentamicin	2mg/kg q8h	iv
Treponema pallidum	Penicillin G	2g q4h	iv
Borrelia spp.	Ceftriaxone	2–3g q24h	iv
Cryptococcus spp.	Amphotericin B	0.5–0.8mg/kg/day	iv
	plus flucytosine	37.5mg/kg q6h	po
Coccidioides spp.	Fluconazole	400–600mg/day	po
Note that the dose of flucytosine must be reduced or the drug omitted in patients who have AIDS because of the increased bone marrow toxicity (see Chapter 126).			

TABLE 22-11 -- Recommendations for antibiotic therapy for patients who have a positive cerebrospinal fluid Gram stain or culture.

RECOMMENDATIONS FOR ANTIBIOTIC THERAPY IN PATIENTS WITH A POSITIVE CSF GRAM STAIN OR CULTURE			
Bacteria		**Antibiotic**	**Alternative antibiotic (in the case of allegy)**
Gram stain	**Culture**		
Gram-positive diplococci	*Streptococcus pneumoniae*, penicillin-resistant or sensitivity unknown	Ceftriaxone plus vancomycin or rifampicin	Vancomycin plus rifampicin
	Streptococcus pneumoniae, penicillin-sensitive	Penicillin G	Ceftriaxone or meropenem or chloramphenicol
Gram-positive cocci	ß-hemolytic streptococci	Penicillin or ampicillin	Cefotaxime, chloramphenicol, or vancomycin
Gram-negative coccobacilli	*Haemophilus influenzae*	Ceftriaxone or cefotaxime	Meropenem or chloramphenicol
Gram-negative diplococci	*Neisseria meningitidis*	Penicillin G	Ceftriaxone or chloramphenicol
Gram-positive bacilli	*Listeria monocytogenes*	Ampicillin plus gentamicin	Trimethoprim-sulfamethoxazole
Gram-negative bacilli	Enterobacteriaceae	Ceftriaxone plus gentamicin	Quinolones or meropenem
Gram-negative bacilli	*Pseudomonas aeruginosa*	Ceftazidime plus tobramycin	Quinolones or meropenem

drug is given parenterally, often combined with intraventricular administration. For cure, infected ventricular shunts must be removed in most patients. If a new permanent shunt is needed, it should only be implanted after a few days of adequate antibiotic therapy, during which time the ventricles are drained externally.

In patients who have chronic meningitis, empiric antibiotic therapy should be directed at the suspected pathogen (Table 22.10). Often, a definite diagnosis is not available for several days, in which case empiric therapy may have to be initiated. It is important to cover the treatable causes of chronic meningitis, for which the outcome is poor if treatment is delayed. For example, empiric antituberculous therapy should be instituted promptly for cases of suspected tuberculous meningitis.

Definitive antibiotic therapy

Identification and sensitivity testing of the causative organism is followed by adjustment of antibiotic therapy to provide optimal but narrow coverage (Table 22.10 , Table 22.11). Information on antibiotic sensitivities is crucial in the case of the pneumococci (see above), *H. influenzae* and Gram-negative rods or staphylococci that commonly cause bacterial meningitis in neurosurgical patients. Optimal duration of treatment of bacterial meningitis has not been carefully studied, but a total of 7 days appears adequate if the disease is caused by *H. influenzae* type b or *N. meningitidis*, although treatment should be extended to 10–14 days for the other common organisms, including pneumococci, and to 21 days for neonatal meningitis. Duration of treatment of chronic meningitis depends on the pathogen and can vary from days (syphilis) to months (tuberculosis, cryptococcosis) to indefinitely (coccidioidomycosis).

Adjunctive therapy

Several recent clinical trials have indicated that adjunctive therapy with dexamethasone improves the neurologic and audiologic outcome in bacterial meningitis. This has been shown primarily in children who have *H. influenzae* meningitis; the data are more limited for children who have pneumococcal and meningococcal meningitis, and only scant for adults who have bacterial meningitis.[71] [72] [73] Experimental and clinical data suggest that the maximum benefit of dexamethasone is achieved when the drug is given either shortly before or at the same time as the first antibiotic dose. This is probably related to the fact that corticosteroids reduce the release of proinflammatory cytokines, which are stimulated by bacterial products liberated from the pathogen by the bactericidal action of antibiotics.

Based on the available data, dexamethasone is recommended for all children over 6 weeks of age who have bacterial meningitis, beginning if possible 10–15 minutes before the first antibiotic dose. The recommended dose is 0.15mg/kg intravenously q6h, for a duration of 2–4 days. A study of dexamethasone in neonates with meningitis, caused in a majority of patients by *Klebsiella pneumoniae*, has yielded negative results and dexamethasone is not recommended in this patient group.[74]

In the absence of sufficient controlled data for adult patients, a conservative approach could consist of giving dexamethasone (in the same dose as in children) to patients who have clinical evidence of severely impaired CNS physiology with altered mental status, high CSF pressure, signs of brain edema on CT scan or rapidly progressive disease. Dexamethasone in standard doses (Table 22.12) had a significant beneficial effect on the mortality rate in patients with severe pneumococcal meningitis admitted to intensive care units in a recent French study, supporting its use in high-risk populations.[75] A small controlled study in India and the preliminary results from a large, controlled European study also indicate beneficial effects of dexamethasone

TABLE 22-12 -- Measures to reduce intracranial pressure in acute meningitis.

MEASURES TO REDUCE INTRACRANIAL PRESSURE IN ACUTE MENINGITIS
Intracranial pressure monitoring
Normalization of systemic blood pressure
Dexamethasone, 0.15mg/kg q6h
Head elevation of more than 30° to the horizontal
Mannitol, 1–1.5g/kg iv over 15 min; repeat once
Intraventricular shunt with CSF drainage in cases where there is evidence of hydrocephalus

on the neurologic outcome in adults who have bacterial meningitis.[73] When instituting dexamethasone therapy, it is important to confirm the bacterial etiology of meningitis. If this cannot be achieved within 24–48 hours, it is safer to stop the anti-inflammatory drug and to reassess the appropriateness of the chosen antimicrobial therapy. At present, there is no evidence that treatment with dexamethasone for 1–2 days has any adverse effects on the outcome of viral meningitis. It is important that patients who are given dexamethasone are closely monitored for evidence of gastrointestinal blood loss.

There is no recognized benefit from either prophylactic or full anticoagulation in the management of patients who have bacterial meningitis, and the involvement of the cerebral vasculature by the inflammation is likely to increase the risk of cerebral hemorrhages in anticoagulated patients who have bacterial meningitis. In fulminant disseminated meningococcal sepsis, there may be a benefit on outcome from the administration of protein C or activated protein C.[76] However, there are no data to suggest that protein C has a beneficial effect on the outcome of meningitis caused by *N. meningitidis* or other meningeal pathogens.

Supportive care

In critically ill patients who have bacterial meningitis, intensive supportive care may be needed, indicating admission to a critical care unit. Patients who have severe meningitis are often neurologically depressed and prone to seizures; they may need intubation for airway protection or assisted ventilation.

Children may have complex requirements for fluid supplementation, with the need for a careful clinical assessment of fluid status, repletion of fluid deficits and monitoring for SIADH. If SIADH is present (indicated by falling serum sodium and reduced urine output with a urine sodium concentration of more than 50mmol/l), fluids should be reduced to two-thirds of the maintenance level until the SIADH has resolved. Resolution within 1–2 days is usual.

In addition, active attempts to reduce intracranial hypertension should be undertaken in patients who have increased intracranial pressure and severely impaired CNS function. The potential importance of aggressively controlling intracranial hypertension was documented in a recent study in patients who had severe intracranial hypertension, in whom ongoing intracranial pressure monitoring and a standardized approach to lower intracranial pressure with antihypertensive drugs, establishment of normovolemia and normal plasma colloid osmotic pressure, and sedative therapy was used ('Lund Concept').[77] Interestingly, even patients with imminent cerebral herniation survived in this small series.

Other means of lowering intracranial pressure that have been described are listed in Table 22.12 . With the exception of dexamethasone, none of these approaches has been validated in controlled studies in patients who have meningitis.[78] Hyperventilation, which is used to lower intracranial pressure in other settings, may be harmful in patients who have increased intracranial pressure due to bacterial meningitis by exacerbating focal cerebral ischemia.[75]

Monitoring during therapy

Repeat CSF examination should be carried out in patients in whom there is doubt about the success of therapy or the accuracy of the initial diagnosis, but not in patients who respond promptly to therapy. Recurrent fever after an initial response to therapy is common in patients who have meningitis, particularly in children, and is most commonly due to infected intravenous lines, secondary infectious foci (e.g. septic arthritis, purulent pericarditis, pleural or intracranial empyema) or drug fever. Sterile subdural effusions, which occur in approximately one-third of children who have meningitis, do not require drainage, unless symptoms or signs of intracranial hypertension are present. Obstructive hydrocephalus, which occurs in less than 5% of patients, usually manifests within the first few weeks of infection and should be treated with ventriculoperitoneal shunting. Neurologic sequelae, including hearing impairment, cranial nerve palsies and motor deficits, can improve for several months after the acute illness, and appropriate, individually tailored supportive therapies should be arranged for patients who are left with sequelae from the disease.

Chapter 23 - Viral Infections of the Central Nervous System

Richard J Whitley

INTRODUCTION

Central nervous system (CNS) symptoms (e.g. headache, lethargy, impaired psychomotor performance) are frequent components of viral infections; however, viral meningitis and encephalitis are unusual manifestations of human disease. Thus, while many individuals develop systemic viral illnesses, disease is usually mild and self-limiting with only a few developing symptomatic involvement of the brain.

Viruses vary widely in their potential to produce CNS infection. For some virus infections, CNS involvement is a common but a relatively benign component of the clinical syndrome (e.g. mumps). For others (e.g. Japanese encephalitis), neurologic disease is the most prominent clinical feature of illness. A third group of viruses commonly cause infection but only rarely cause encephalitis (e.g. herpes simplex virus (HSV)). Lastly, there are viruses for which human infection inevitably and exclusively results in CNS disease (e.g. rabies). In addition to acute pathology, numerous other viruses (e.g. influenza and measles) can cause syndromes of postinfectious encephalopathy.

When infection involves the CNS, there is potential for neurologic damage and, in some instances, death. Neural tissues are exquisitively sensitive to metabolic derangements and injured brain tissue recovers slowly and often incompletely. [1] Clinical presentation and patient history, while frequently suggestive of a diagnosis, remain unreliable methods for determining the specific etiology of CNS disease.[2] [3] Tumors, infections and autoimmune processes in the CNS often produce similar signs and symptoms.[3] Different diseases may share a common pathogenic mechanism and, therefore, result in a similar clinical presentation. Furthermore, understanding the pathogenic mechanism of a disease provides a rational basis for the development of antiviral medications as well as strategies for the prevention of viral CNS infections.

DEFINITIONS

Definitions of CNS viral disease are often based on both virus tropism and disease duration. Inflammation can occur at multiple sites within the brain, accounting for the myriad clinical descriptors of viral neurologic disease. Inflammation of the spinal cord, leptomeninges, dorsal nerve roots or nerves results in myelitis, meningitis, radiculitis and neuritis, respectively. Aseptic meningitis is a misnomer frequently used to refer to a benign, self-limited, viral infection that results in inflammation of the leptomeninges.[4] [5] The term hinders epidemiologic studies as the definition fails to differentiate between infectious (fungal, tuberculous, viral or other infectious etiologies) and noninfectious causes of meningitis. Encephalitis refers to inflammation of brain parenchyma and is usually accompanied by an altered level of consciousness, impaired cognition, seizures and/or focal neurologic signs. Acute encephalitis occurs over a relatively short period of time (days) while chronic encephalitis presents over weeks to months. The temporal course of slow infections of the CNS (kuru, visna, variant Creutzfeldt-Jakob disease (vCJD)) overlaps the chronic encephalitides. Slow viral infections of the CNS are distinguished by their long incubation, eventually resulting in death or extreme neurologic disability over months to years.[6]

Viral disease in the CNS can also be classified by pathogenesis. Neurologic disease is frequently categorized as either primary or postinfectious. Primary encephalitis results from direct viral entry into the CNS that produces clinically evident cortical or brainstem dysfunction.[7] Subsequent damage results from a combination of viral-induced cytopathic effects. Viral invasion, however, remains the initiating event.[7] The parenchyma exhibits neuronophagia and the presence of viral antigens or nucleic acids.[7] Postinfectious encephalitis produces signs and symptoms of encephalitis, temporally associated with a systemic viral infection, without evidence of direct viral invasion in the CNS. Pathologic specimens demonstrate demyelination and perivascular aggregation of immune cells, without evidence of virus or viral antigen, suggesting an autoimmune etiology.[7]

Meningitis and encephalitis represent separate clinical entities; however, a continuum exists between these distinct forms of disease. Nevertheless, a discussion of meningitis and encephalitis provides a useful format for this review.

VIRAL MENINGITIS

Epidemiology

Acute viral meningitis and meningoencephalitis represent the majority of viral CNS infections and frequently occur in epidemics with a seasonal distribution. [8] As illustrated in Figure 23.1 , enteroviruses cause an estimated 90% of cases (in countries that immunize against mumps), while arboviruses constitute the majority of the remaining reported cases in the USA.[4] [9] [10] Mumps is an important cause of viral CNS disease in countries that do not immunize against this agent. In a Japanese study, mumps was the second leading cause of aseptic meningitis, accounting for approximately 30% of the cases.[11] Viral meningitis is not a reportable disease to the Centers for Disease Control and Prevention (CDC); however, there are probably over 74,000 cases annually in the USA.[10] [12] Most cases occur from late spring to autumn, reflecting the increased incidence of enteroviral and arboviral infections during these seasons.[10] [13] A retrospective survey performed in the 1980s found that the annual incidence of 'aseptic meningitis' was approximately 10.9/100,000 persons or at least four times the incidence passively reported to the CDC during the same period.[8] Virus was isolated in only 11% of patients in this study, likely reflecting the technologic limits of the period, the infrequency with which viral cultures were performed and the decreased incidence of viral CNS disease resulting from widespread vaccination against mumps and polioviruses.[8] With the advent of molecular-based diagnostic techniques, namely polymerase chain reaction (PCR), identification rates now approach 50–70%.[9] [11]

Pathogenesis

The pathogenesis of viral meningitis is not completely understood. Inferences regarding the pathogenesis of viral meningitis are largely

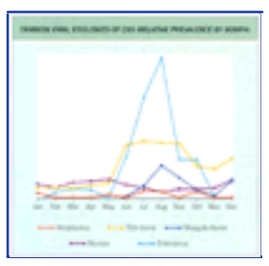

Figure 23-1 Common viral etiologies of central nervous system infection (relative prevalence by month).

derived from data on encephalitis, experimental animal models of meningitis and clinical observations.[4] Viruses use two basic pathways to gain access to the CNS, namely hematogenous and neuronal, regardless of the resulting clinical syndrome (i.e. meningitis or encephalitis). A combination of host and viral factors along with seasonal, geographic and epidemiologic probabilities influence the likelihood of CNS infection. For example, arboviral infections occur more frequently in epidemics and show a seasonal variation, reflecting the environmental prevalence of the transmitting vector.[13] Enteroviral meningitis occurs with greater frequency during the summer and early autumn months, reflecting the seasonal increase in enteroviral infections. Enteroviral infections also exemplify the difference host physiology plays in determining the extent of viral disease. In children less than 2 weeks of age, enterovirus infections can produce a life-threatening infection, including meningitis or

meningoencephalitis.[10] Ten per cent of neonates with systemic enteroviral infections die and 76% of survivors have permanent sequelae. In children over 2 weeks of age, however, enteroviral infections are rarely associated with severe disease or significant morbidity.[10]

For hematogenous spread to the CNS, as illustrated in Figure 23.2 , the virus must first either bypass or attach to and enter host epithelial cells to produce infection. Virus then spreads and initially replicates in the regional lymph nodes (e.g. measles, influenza) or, alternatively, it enters the circulatory system where it seeds other tissues (e.g. arboviruses, enteroviruses, varicella). Primary viremia allows virus to seed distant locations of the body, especially the reticuloendothelial system, and frequently marks the onset of clinical illness. In rare circumstances, such as disseminated neonatal HSV infection, virus infects the CNS during primary viremia. The liver and spleen provide ideal locations for secondary viral replication due to their highly vascular structure and reticuloendothelial network. Secondary viremia results in high titers of virus in the bloodstream, facilitating viral CNS spread. The pathophysiology of viral transport from blood to brain and viral endothelial cell tropism is poorly understood. Virus infects endothelial cells, passively channels through endothelium (pinocytosis or colloidal transport) or

Figure 23-2 Hematogenous spread of viral pathogens to the central nervous system.

bridges the endothelium within migrating leukocytes. This trans-endothelial passage occurs in vessels of the choroid plexus, meninges and/or cerebrum.

Numerous host defense barriers limit viral dissemination to the CNS. The skin and mucosal surfaces possess mechanical, chemical and cellular defenses that protect the cells from viral infection. Leukocytes and secretory factors (interleukins, interferons, antibodies) further augment these defenses and help eliminate viruses that bridge the epithelial layer. Local immune responses are crucial in limiting systemic viral infection. A prompt inflammatory response can limit viremia and subsequent symptoms of infection. In the liver and spleen, the high degree of parenchymal contact and large number of fixed mononuclear macrophage cells provide an excellent opportunity for host eradication of viremia. The blood-brain or blood-cerebrospinal fluid (CSF) barrier, a network of tight endothelial junctions sheathed by glial cells that regulate molecular access to the CNS, further limits virus access to the brain.[14]

Viral meningitis is a relatively benign, self-limited illness; thus, tissue specimens are rarely available for pathologic study.[10] The CSF, however, is frequently sampled and demonstrates a mononuclear immune cell response to most viral infections. Certain viral infections, most notably mumps and some enterovirus infections, elicit a polymorphonuclear cell infiltrate in the CSF early during disease. The initial CSF formula mimics bacterial meningitis and later shifts to a mononuclear predominance. Viral antigen presentation by mononuclear histiocytes stimulates the influx of immune cells. Recruited immune cells release soluble factors (cytokines, vasoactive amines) that mobilize other cells and change the permeability of the blood-brain barrier.[15] [16] Physical and chemical changes in this barrier allow the entry of serum proteins (i.e. immunoglobulins and interleukins), further augmenting host immune responses. The cell-mediated immune response is important for eliminating virus from the brain; however, immunoglobulin also has a role in protecting the host in some viral infections. This is best illustrated by the devastating clinical course of enteroviral meningitis in agammaglobulinemic patients as well as X-linked hyper IgM syndrome (see Chapter 98).[10] [17] Patients with impaired cell-mediated immunity have a higher incidence of CNS infections with certain viruses (e.g. varicella-zoster virus (VZV), measles, cytomegalovirus (CMV)).

Clinical manifestations

Age, immune status and viral etiology influence the clinical manifestations of viral meningitis. Patients with enteroviral meningitis often present with non-specific symptoms such as fever (100.4–104.00°F; 38–40°C) of 3–5 days duration, malaise and headache.[10] [18] Approximately 50% of patients have nausea or vomiting.[18] While nuchal rigidity and photophobia are the hallmark sign and symptom for meningitis, 33% of patients with viral meningitis have no evidence of meningismus.[18] Importantly, clinical presentation does not lead to the suggestion of etiology. Less than 10% of children younger than 2 years of age develop signs of meningeal irritation; they present with fever and irritability.[19] Children may also present with seizures secondary to fever, electrolyte disturbances or the infection itself. In the immunocompromised host, enteroviral infection is both a diagnostic quandary and a potentially life-threatening disease. Immunocompromised patients frequently do not mount brisk immune cellular responses; therefore, CSF analyses do not necessarily reflect evidence of CNS involvement.

Symptoms of meningitis (stiff neck, headache and photophobia) occur in approximately 11% of men and 36% of women with primary HSV-2 genital infection. In one study, 5% of patients with primary HSV genital infection had severe enough meningitis to require hospitalization. All hospitalized patients had evidence of a CSF lymphocytic pleocytosis. In another study, HSV-2 was cultured from the CSF of 78% of patients with meningismus during primary genital infection. These patients also exhibited a CSF leukocytosis and subsequent increases in CSF HSV antibody titers. [20] Recurrent HSV-2 meningitis (with or without genital lesions) occurs, although cases associated with primary infection are more common.[21] Herpes simplex virus meningitis may spread to the CNS neuronally along the sacral nerves. Alternatively, the virus may reach the CNS hematogenously, as virus has been cultured from the blood buffy-coat layer.[4] Varicella-zoster virus, CMV, Epstein-Barr virus (EBV) and parainfluenza virus have all been cultured or detected by PCR in the CSF of patients with meningitis.[4] [11] [22]

Laboratory findings

Initial CSF samples, while frequently suggestive of the diagnosis, are neither sensitive nor specific enough to differentiate viral from bacterial meningitis. [23] Instead, epidemiologic trends, patient history and accompanying laboratory information are important adjuncts in assessing the etiology of meningitis. The CSF in patients with viral meningitis typically exhibits pleocytosis with 10–500 leukocytes and a slightly elevated protein level (<100mg/dl). The glucose level in the CSF is typically greater than 40% of a simultaneously drawn serum sample. Tremendous variation in CSF formulas exists, with significant overlap between viral and bacterial findings.[23] In a retrospective review of over 400 patients with acute viral or bacterial meningitis performed before the *Haemophilus influenzae* B conjugate vaccine, investigators found that approximately 20% of the CSF samples that grew bacteria exhibited a CSF pleocytosis <250 WBC/mm^3 .[4] Of the patients with bacterial meningitis 15% had a CSF lymphocytosis, while 40% of the patients with viral meningitis had a predominance of polymorphonuclear cells. Some investigators recommend repeating the lumbar puncture 6–12 hours later, as the CSF profile of patients with viral meningitis will shift from a polymorphonuclear to a lymphocytic pleocytosis over this period.[24] A retrospective study found that during an enterovirus outbreak, 51% of patients demonstrated PMN predominance in their CSF profile despite symptoms of greater than 24 hours duration but the etiology of meningitis could not be confirmed in most cases. [23] Other investigators have confirmed that the change to a lymphocytic CSF profile occurs 18–36 hours into the illness. Most clinicians do not obtain CSF viral cultures.[25] [26]

Etiologic diagnosis

Historically, the techniques for identifying viral meningitis were insensitive and often impractical. While virus can be cultured from CSF during the early stages of the infection, this has little utility in the acute management of a patient who has CNS disease.[20] Depending upon the study cited and diagnostic methods used, investigators identify an agent in only 25–67% of presumed CNS infections.[3] Now, however, molecular techniques have advanced identification of agents. Recently, PCR and reverse transcription (RT)-PCR have been used to diagnose enteroviral meningitis in both normal and agammaglobulinemic patients, indicating both sensitivity and specificity. [25] Polymerase chain reaction provides a rapid and reliable test for verifying the etiology of certain types of meningitis. These techniques provide results within 24–36 hours and therefore may limit the duration of hospitalization, antibiotic use and excessive diagnostic procedures.[26] As it relates to the diagnosis of arboviral disease, the use of molecular techniques is fraught with greater variability.[10] [20] [26] Because of the diverse viral etiologies of arboviral infection, the development of specific, conserved primers that hybridize across multiple viral families (alphaviradae, flaviviradae, bunyaviradae) has been difficult. Currently, there is an emphasis on the development of improved 'universal group primers' to perform an initial group screening followed by RT-PCR using higher specificity primers as a second viral diagnostic test.[27] For other infections, molecular techniques are the standard for diagnosing viral meningitis.[9] [12]

Differential diagnosis

Unusual but treatable infections should always be considered and investigated in patients with a CSF pleocytosis and negative conventional bacterial cultures. Spirochetes (*Treponema, Borrelia, Leptospira*), mycoplasma, bartonella and mycobacteria can produce a pleocytosis with negative Gram stain and negative bacterial cultures. Fastidious bacteria (*Listeria*) may fail to grow in culture and occasionally produce a mononuclear pleocytosis similar to viral meningitis, as can occur in infants, the elderly and immunocompromised patients. Some bacteria, while not directly infecting the CNS, can release toxins that create a change in the level of consciousness, specifically *Staphylococcus aureus* and *Streptococcus pyogenes* exotoxin-mediated toxic shock syndrome. Parameningeal infections, especially from infected sinuses, produce a pleocytosis and CNS symptoms; however, these infections more frequently present as encephalitis with focal neurologic changes and altered mental status. Similarly, partially treated bacterial infections can have CSF findings resembling those of viral meningitis. Fungal and parasitic infections can produce CNS infections although they uncommonly produce only meningitis. The exceptions to this rule are Coccidioides and Cryptococcus. These pathogens

characteristically produce meningitis rather than any focal CNS disease. Cryptococcus, for example, produces subacute meningitis in both normal and immunosuppressed patients and remains the leading cause of fungal meningitis.[5] Such fungal infections as *Candida*, *Aspergillus*, histoplasmosis and blastomycosis frequently cause focal parenchymal disease of the CNS. These fungi, while often weighed in the differential diagnosis for an immunocompromised host, also cause disease in the normal host. Parasites such as *Naeglaeria fowleri* produce meningoencephalitis with purulent CSF findings. A history of recent summertime swimming in a stagnant pond raises suspicion for this infection.

Noninfectious processes that can produce true aseptic meningitis include hematologic malignancies, medications, autoimmune diseases and foreign material and proteins. Leukemia produces a CSF pleocytosis with cancerous cells and occurs most frequently with acute lymphocytic leukemia, although subarachnoid involvement can also occur in acute myelogenous leukemia.

Immunomodulatory drugs such as intravenous immunoglobulin or antilymphocytic globulin (OKT-3) can cause aseptic meningitis. Of the medications associated with meningitis, nonsteroidal anti-inflammatory agents, sulfa-containing drugs and cytosine arabinoside are the most common offenders. Drug-induced aseptic meningitis fre-quently occurs in patients who have underlying connective tissue or rheumatologic diseases.[4] [5] Epithelial or endothelial cysts can rupture and spill their contents (keratin, protein), producing a brisk inflammatory response, mimicking meningitis.

Those common viral agents responsible for CNS infection are listed in Table 23.1 . Notably, all of these agents cause both meningitis and encephalitis with two exceptions — rabies and B virus.

Treatment and prognosis

The fundamental principle of therapy for viral meningitis lies in the identification of potentially treatable diseases. Until recently, no therapy existed for most cases of viral meningitis. Efforts instead focused on preventive strategies (largely through vaccination) as well as identification of treatable nonviral etiologies of meningitis. Antiviral therapies are emerging for the treatment of enteroviral meningitis.[28] [29] Despite recent chemotherapeutic and diagnostic advances in the approach to enteroviral infection, patients who have meningitis warrant careful assessment for treatable, nonviral etiologies of meningitis. The clinician must also anticipate and treat the complications of viral CNS disease (seizures, inappropriate ADH secretion, hydrocephalus, raised intracranial pressure). Supportive therapy includes hydration and antipyretics/analgesics.

As noted above, in the normal host, viral meningitis is a relatively benign self-limited disease. A prospective study in children less than 2 years of age, for example, found that even in the 9% of children who develop evidence of acute neurologic disease (complex seizures, increased intracerebral pressure or coma) long-term prognosis is

TABLE 23-1 -- Viral causes of meningitis or encephalitis.

VIRAL CAUSES OF MENINGITIS OR ENCEPHALITIS	
Togaviridae alphavirus	Eastern equine
	Western equine
	Venezuelan equine
Flaviviridae	West Nile
	St Louis
	Japanese B

	Cytomegalovirus
	Human herpesvirus 6
Retroviridae	HIV

excellent. During follow-up (42 months), children with acute CNS complications performed neurodevelopmental tasks and achieved developmental milestones as well as did children with an uncomplicated course.[19]

Currently, antibody preparations and an antiviral agent, pleconaril (see below), have shown activity against enterovirus infection in case reports and animal studies. Randomized, controlled trials, however, have not supported their routine use in enterovirus meningitis. In case reports, immunoglobulin preparations, given systemically or intrathecally, retarded mortality and morbidity in agammaglobulinemic patients with enteroviral meningitis. Despite the administration of immunoglobulin, patients do not eliminate virus from the CSF and in turn develop chronic enteroviral meningitis.[30] As noted previously, enteroviral infections in neonates frequently produce over-whelming viremia and CNS disease. A blind, randomized controlled trial did not demonstrate clinical benefit for enterovirus-infected neonates with severe life-threatening disease who received intravenous immunoglobulin. [31]

The antiviral agent (3-[3,5-dimethyl-4-[[3-(3-methyl-5-isoxazolyl)propyl]phenyl]-5-trifluoromethyl-1,2,4-oxadiazole), pleconaril, is a bioavailable, small-molecule inhibitor of picornavirus replication that binds the capsid and prevents uncoating of viral RNA. Because of homology among the picornaviruses, the drug has activity against enteroviruses and rhinoviruses as well. Randomized controlled, double-blind clinical trials, while demonstrating slight improvements in adults with enteroviral meningitis, do not demonstrate the substantial efficacy initially anticipated and have not been published in peer-reviewed literature. In 32 adults with aseptic meningitis, duration of headache was decreased in the pleconaril group to an average 6.5 days of headache versus 18.3 days for placebo recipients.[28] The duration of headache in the placebo group was greater than previously published. Similarly, if one uses the objective measurement of duration of analgesic use (historical average control = 5 days) versus that reported in the pleconaril study (placebo group = 11.5 days), the statistically significant 5.3 days of analgesic use by the pleconaril group is less dramatic.[28] [32] A multicenter randomized controlled trial is evaluating pleconaril in the treatment of severe neonatal infection but preliminary information is unavailable at this time.

Specific antiviral agents are available for several other viral etiologies of meningitis. Although no definitive clinical trials have been conducted, most authors recommend the use of intravenous aciclovir for HSV meningitis, as it decreases the duration of primary disease and may limit meningeal involvement.[33] There are no data on benefit of antiviral treatment or on suppressive therapy for recurrent HSV CNS disease.[21] Effective antiviral therapy exists for VZV infections of the CNS and should be instituted in these patients. [34] The issue of therapy for CMV CNS infection in the immunocompromised host is more problematic and therapy should be tailored based upon the clinical likelihood of infection.

VIRAL ENCEPHALITIS

Epidemiology

Similar to viral meningitis, passive reporting systems underestimate the incidence of viral encephalitis,[8] as reviewed. [35] An estimated 20,000 cases of encephalitis occur annually in the USA; however, the CDC received only 740 (0.3/100,000) to 1340 (0.54/100,000) annual reports of persons with encephalitis from 1990 to 1994.[7] [36] A review of the cases in Olmsted County, Minnesota, from 1950 to 1980 found the incidence of viral encephalitis to be twice that reported by the CDC.[8] A prospective multicenter study in Finland provided results similar to the Olmsted study, indicating an encephalitis incidence of 10.5/100,000.[37] Herpes simplex virus CNS infections occur without seasonal variation, affect all ages and constitute

the majority of fatal cases of endemic encephalitis in the USA.

Arboviruses, a group of over 500 arthropod-transmitted RNA viruses, are the leading cause of encephalitis worldwide and in the USA. Arboviral infections occur in epidemics and show a seasonal predilection, reflecting the prevalence of the transmitting vector.[38] Asymptomatic infections are vastly more common than symptomatic infections. Patients who have disease may develop a mild systemic febrile illness or viral meningitis.[39] Encephalitis occurs in a minority of persons with arboviral infections, but the case fatality rate varies from 5% to 70%, depending upon viral etiology and patient age. LaCrosse encephalitis is the most commonly reported arboviral disease in the USA, while St Louis encephalitis is the most frequent cause of epidemic encephalitis, although this may be replaced by West Nile encephalitis if epidemics continue.[38]

Japanese B encephalitis (JE) and rabies constitute the majority of cases of encephalitis outside North America. JE, a member of the flavivirus genus, occurs throughout Asia and causes epidemics in China despite routine immunization. In warmer locations, virus occurs endemically. As with the other arboviral infections, asymptomatic infections occur more frequently than symptomatic infections. However, the disease has a high case fatality rate and leaves half of the survivors with significant neurologic morbidity. Rabies is endemic around much of the world. Human infections in the USA decreased over the last decades to 1–3 cases per year due to the immunization of domesticated animals. In areas outside the USA, human cases of rabies number in the thousands and are caused by bites from unvaccinated domestic animals following contact with infected wild animals.

Postinfectious encephalitis, an acute demyelinating process, has also been referred to as acute disseminated encephalomyelitis (ADEM) or autoimmune encephalitis and accounts for approximately 100–200 additional cases of encephalitis annually.[36] The disease historically produced approximately one-third of the encephalitis cases in the USA and was associated with measles, mumps and other exanthematous viral infections.[40] Postinfectious encephalitis is now associated with antecedent upper respiratory virus (notably influenza virus) and varicella infections in the USA.[7] Measles continues to be the leading cause of postinfectious encephalitis worldwide and complicates 1 of every 1000 measles infections.[7]

Slow infections of the CNS or transmissible spongiform encephalopathies (TSEs) occur sporadically worldwide (Table 23.2). While not

TABLE 23-2 -- Transmissible spongiform encephalopathies.[6]

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES	
Animals (excluding experimentally transmitted diseases)	Scrapie in goats and sheep

	Fatal familial insomnia
	Sporadic fatal insomnia

caused by a classic infectious agent, brief consideration is warranted (see also Chapter 26 and Chapter 223). The prototypical TSE is Creutzfeldt-Jakob disease (CJD), occurring at high rates within families and having an estimated incidence of 0.5–1.5 cases per million population.[6] In 1986, cases of a TSE in cattle, namely bovine spongiform encephalopathy (BSE), were reported in the UK. In addition to affecting other livestock throughout Europe that were fed supplements containing meat and bone meal, cross-species transmission of BSE has been documented, leading to a ban on the use of bovine offal in fertilizers, pet food and other animal feed.[6] A decrease in the recognized cases of BSE has occurred since the institution of these restrictions. Concomitant with the increased cases of BSE in Europe, an increase in cases of an atypical CJD also occurred, suggesting animal-to-human transmission. The report of atypical CJD (unique clinical and histopathologic findings) affecting young adults (an age at which CJD rarely has been diagnosed) led to the designation of a new disease, nvCJD (see Chapter 26). According to the November 2002 fact sheet of the World Health Organization, there have been 93 confirmed cases of vCJD reported in the UK, six in France and one each in Italy, Canada, and the USA.[41]

Pathogenesis

The pathogenesis of encephalitis is similar to that of viral meningitis and requires that viruses reach the CNS by hematogenous or neuronal spread. Viruses most frequently access the CNS after a high-titer secondary viremia and cell-free or cell-associated CNS entry.[4] Other than direct entry via cerebral vessels, virus can initially infect the meninges and then enter the parenchyma across either ependymal cells or the pial linings. Viruses exhibit differences in neurotropism and neurovirulence.[42] For example, enteroviruses with similar receptors produce very different diseases. Five coxsackie B viruses (B1–B5) readily produce CNS infections while type B6 rarely produces neurologic infection.[5] Similarly, viral genes have been discovered that influence the neurovirulence of HSV-1. Mutant HSV-1 viruses in the $?_1$ 34.5 gene have a decreased ability to cause encephalitis and death following intracerebral inoculation in mice as compared with wild-type virus.

In addition to viral factors, host physiology is also important in determining the extent and location of viral CNS disease. Age, sex and genetic differences between hosts influence viral infections and clinical course.[10] Host age influences the clinical manifestations and sequelae. Variations in macrophage function between individuals

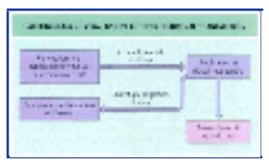

Figure 23-3 Pathogenesis of viral central nervous system infections: neuronal transmission.

can result in clinically distinct infections and disease. Moreover, macrophage-antigen response can change with age and is important in limiting spread of infection within a patient. In addition to age, physical activity may be another important host factor that determines the severity of infection. Exercise has been associated with increased risk for paralytic poliomyelitis and may result in an increased incidence of enteroviral myocarditis and aseptic meningitis.[43] [44] Increasingly host differences are recognized as equally important determinants of disease at the cellular and molecular levels.

In addition to blood-borne spread of virus to the brain, neuronal transmission plays an important role in pathogenesis; HSV and rabies are the best examples, as illustrated in Figure 23.3 . Sensory and motor neurons contain transport systems that carry virion or virion components along the axon to (retrograde) and from (anterograde) the nucleus of the sensory ganglion. Peripheral or cranial nerves provide access to the CNS and shield the virus from immune regulation.

Rabies classically infects by the myoneural route and provides a prototype for peripheral neuronal spread.[45] Rabies virus replicates locally in soft tissue following a rabid animal bite. After primary replication, the virus enters the peripheral nerve by acetylcholine receptor binding. Once in the muscle, virus buds from the plasma membrane, crosses myoneural spindles or enters across the motor endplate.[45] The virus travels by anterograde and retrograde axonal transport to infect neurons in the brainstem and limbic system and spreads from the diencephalic and hippocampal structure to the remainder of the brain, killing the animal.[45] Virus also infects the CNS through cranial nerves, as suggested from animal studies but without supporting human data.

The pathologic findings of encephalitis are unique for each virus and reflect differences in pathogenesis and virulence. In the case of typical HSV encephalitis, a hemorrhagic necrosis[7] occurs in the inferomedial temporal lobe with evidence of perivascular cuffing, lymphocytic infiltration and neuronophagia.[46] Pathologic specimens with rabies encephalitis demonstrate microglial proliferation, perivascular infiltrates and neuronal destruction. The location of the pathologic findings can be limited to the brainstem areas (dumb rabies) or the diencephalic, hippocampal and hypothalamic areas (furious rabies) based on the immune response mounted against the infection.[45]

Some viruses do not directly infect the CNS but produce immune system changes that result in parenchymal damage. Patients with postinfectious encephalitis exhibit focal neurologic deficits and altered consciousness associated temporally with a recent (1–2 week) viral infection or immunization.[40] Pathologic specimens, while showing evidence of demyelination by histologic or radiographic analysis, do not demonstrate evidence of viral infection in the CNS by culture or antigen tests. Patients with postinfectious encephalitis have subtle differences in their immune system and some authors have proposed an autoimmune reaction as the pathogenic mechanism of disease.[7]

The TSEs are noninflammatory CNS diseases involving the accumulation of an abnormal form of a normal glycoprotein, the prion protein (PrP).[47] These encephalopathies differ in their mode of transmission. While most of the TSEs are experimentally transmissible by direct inoculation in the CNS, this mode rarely occurs except for iatrogenic transmissions.[6] The scrapie agent spreads by cell-to-cell contact. There is no evidence for lateral transmission in the case of BSE or vCJD and all cases appear to have occurred following parenteral transmission or ingestion of affected materials. The transmissible agents remain infectious after treatments that would normally inactivate viruses or nucleic acids (detergent formalin, ionizing radiation, nucleases).[47]

Most of the experimental work on TSEs has involved analysis of the scrapie agent. The current working model is that post-translational alteration of the normally a-helical form of the PrP protein results in a protease-resistant ß-pleated sheet structure that accumulates in neurons, leading to progressive dysfunction, cell death and subsequent astrocytosis. In studies on the scrapie agent, gastrointestinal tract involvement with infection of abdominal lymph nodes occurs first, followed by brain involvement a year or more later.[6] Experimental subcutaneous inoculation in mice and goats also leads to local lymph node involvement followed by splenic spread and then CNS involvement. The mode of transmission to the CNS (direct versus hematogenous) and the infectivity of body fluids at different stages of infection are not known.

Clinical manifestations

While physical examination of the patient usually does not suggest an etiologic diagnosis, a few considerations are essential. For example, encephalitis caused by West Nile virus is usually accompanied by a rash and can result in severe disease. In 2001, there were 66 human cases in the USA with nine deaths reported. Fatalities have been greater among the elderly. However, in general, for patients with acute viral encephalitis, the distinction between generalized and focal neurologic findings is important. In a nonepidemic setting, the most common viral cause of focal encephalopathic findings is HSV.[3] [48] However, when signs and symptoms of patients with biopsy-proven herpes simplex encephalitis (HSE) are compared with those who did not have HSV CNS infection, there were no distinguishing clinical characteristics (see Table 23.1). Viruses that usually cause diffuse encephalitic diseases can, on occasion, localize to one area of the brain and mimic HSE,[3] as summarized in Table 23.3 .

A distinction must be made clinically between viral encephalitis and postinfectious encephalomyelitis. Postinfectious encephalomyelitis generally follows a vague viral syndrome, usually of the respiratory tract, and is most common in children. Neurologic findings vary and reflect the areas of the brain involved. Demyelination is a prominent pathologic finding. The distinction between postinfectious encephalomyelitis and acute viral encephalitis is crucial, since the management and prognosis are often quite different.

Most patients have a prodromal illness with myalgias, fever and anorexia reflecting systemic viremia. The clinical hallmark of acute viral encephalitis is a triad of fever, headache and altered level of consciousness. Other common clinical findings include disorientation, behavioral and speech disturbances, and focal or diffuse neurologic signs, such as hemiparesis or seizures. These clinical findings distinguish a patient with encephalitis from one with viral meningitis, who may have headache, nuchal rigidity and fever but not altered sensorium or focal neurologic findings. Clinical findings reflect the specific areas of CNS involvement, which are determined, in large part, by

TABLE 23-3 -- Diseases that mimic herpes simplex encephalitis.[*]

DISEASES THAT MIMIC HERPES SIMPLEX ENCEPHALITIS	
Diseases	**No. of patients**
Treatable	**46**
Infection	
Abscess or subdural empyema	
• Bacterial	5
• Listeria	1
• Fungal	2
• Mycoplasma	2
Tuberculosis	6
Cryptococcal	3
Rickettsial	2
Toxoplasmosis	1

Mucormycosis	1
Meningococcal meningitis	1
Other viruses	
• Cytomegalovirus	1
• Influenza A*	4
• Echovirus infection*	3
Tumor	5
Subdural hematoma	2
Systemic lupus erythematosus	1
Adrenal leukodystrophy	6
Nontreatable	**49**
Vascular disease	11
Toxic encephalopathy	5
Reye syndrome	1
Viral	40
Arbovirus infection	
• St Louis encephalitis	7
• Western equine encephalitis	3
• California encephalitis	4
• Eastern equine encephalitis	2
Other herpesviruses	
• Epstein-Barr virus	8
Other viruses	
• Mumps virus	3
• Adenovirus	1
• Progressive multifocal leukoencephalopathy (JC virus)	1
• Lymphocytic choriomeningitis virus	1
• Subacute sclerosing panencephalitis (measles virus)	2

* Investigation drug therapy

the tropism of different viruses for different cell types. For example, polioviruses preferentially infect motor neurons, rabies selectively infects neurons of the limbic system, while mumps can infect epithelial cells of the choroid plexus. Infection of cortical neurons results in abnormal electrical activity and can be associated with seizures or focal deficits. Demyelination may follow destruction of oligodendroglial cells, while involvement of ependymal cells can result in hydranencephaly. The predilection of HSV for temporal lobe involvement, as illustrated in Figure 23.4 , leads to clinical findings of aphasia, anosmia, temporal lobe seizures and other focal abnormalities. As noted, only two viruses, namely rabies and B virus, produce encephalitis without significant meningeal involvement; however, most patients with encephalitis have concomitant meningitis.

Laboratory findings/diagnosis

Establishing an etiologic diagnosis of encephalitis is just as difficult as for viral meningitis. As with the latter, epidemiologic features such as the season of year, prevalent diseases within the community, travel, recreational activities (e.g. caving or hiking), occupational exposures and animal contacts (e.g. insect or animal bite) may provide helpful clues to the diagnosis. Late summer and early fall are seasons when enteroviral infections are encountered in temperate climates. Similarly, during warm summer months, mosquito propagation may enhance the likelihood of transmission of arthropod-borne viruses.

A CSF pleocytosis usually occurs in encephalitis but is not necessary for the diagnosis. White blood cell counts typically number in the 10s to 100s in viral encephalitis, although higher counts occur. The CSF glucose levels are usually normal although some viral etiologies (Eastern equine encephalitis) produce findings consistent with acute bacterial meningitis. Some viruses (HSV) produce a hemorrhagic necrosis and the CSF exhibits this with moderately high protein levels and evidence of red blood cells. Supratentorial and cerebellar tumors can produce increased intracranial pressure and can mimic encephalitis. A careful fundoscopic examination should be performed to rule out any evidence of papilledema and increased intracranial pressure prior to obtaining CSF.

Unlike meningitis, encephalitis often requires additional laboratory and radiologic tests to establish the diagnosis. The clinical circumstances of the patient and the likely etiologies dictate specific laboratory and radiologic evaluations. Historically, the standard for diagnosis has been brain biopsy and viral culture. However, PCR has, for the most part, replaced this approach. For some viruses (HSV, enterovirus, VZV, JC virus), PCR detection of viral nucleic acids from the CSF has replaced culture and brain biopsy as the standard for diagnosing encephalitis.[9] [11] [25] [50] [51] [52] Radiographic studies that support the diagnosis of focal encephalitis are computerized tomography (CT) scanning and magnetic resonance imaging (MRI). The increased sensitivity of MRI to alterations in brain water content and the lack of bone artefacts make this the neuroradiologic modality of choice for CNS infections.[53] The MRI detects parenchymal changes earlier than CT scan and better defines the extent of a lesion.[53] Furthermore, MRI is more sensitive for detecting evidence of demyelinating lesions in the periventricular and deep white matter, thus allowing the differentiation of parainfectious from acute viral encephalitis.[53] Patients who have viral encephalitis frequently have diffuse or focal epileptiform discharges with background slowing.[2] These electroencephalogram (EEG) changes precede CT scan or MRI evidence of encephalitis and provide a sensitive, although non-specific, diagnostic test. Electroencephalogram changes in the temporal lobe area strongly suggest a diagnosis of HSE but absence of these changes does not rule out HSE.

Historically, patients who had viral encephalitis required a battery of different diagnostic tests. Herpes simplex encephalitis, for example, could be diagnosed acutely by brain biopsy and viral culture or retrospectively by CSF antibody and convalescent serologic tests.[46] Routine evaluation of acute and convalescence sera to demonstrate either seroconversion or sero-boosting is of no practical value in the decision to institute treatment, but remains useful for retrospective diagnosis of some infections (e.g. arboviral encephalitis). New diagnostic assays have simplified the diagnosis of viral infections of the brain. For example, an ELISA assay that detects IgM antibodies in the CSF from patients with presumed Japanese encephalitis (JE) is both sensitive and specific, as most patients have antibodies at the time of hospitalization and virtually all acquire them by the third day of illness.

A CSF PCR is used to diagnose enterovirus, HSV, VZV, human herpesvirus (HHV)-6, EBV and CMV,[54] as well as a few arboviruses (California encephalitis group, JE, West Nile virus, St Louis encephalitis (WNV), dengue fever virus 1–4 and yellow fever virus); however, the development of universal arboviral primers has been difficult.[9] [25] [27] [52] The successful detection of viral DNA in the CSF is influenced by the duration, extent and etiology of disease. Application

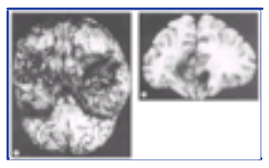

Figure 23-4 Herpes simplex encephalitis. Basilar view of herpes simplex encephalitis showing (a) hemorrhagic necrosis of temporal lobes. (b) Coronal section of brain from patient with herpes simplex encephalitis. [49]

of PCR is rapid and sensitive and provides a less invasive means to diagnose encephalitis. For example, only 4% of CSF cultures are positive in patients with sporadic HSE; however, 53 of 54 patients with biopsy-proven HSE had evidence of HSV DNA in the CSF by PCR. Cerebrospinal fluid PCR has a sensitivity in excess of 95% and a specificity approaching 100% in patients with HSE.[55] Interestingly, in the three cases where the CSF PCR was positive but the brain biopsy negative, biopsy samples were improperly prepared prior to viral culture or the biopsy site was suboptimal.[55] Efforts now focus on correlating viral nucleic acid copy number with clinical outcome.

The TSEs are currently only diagnosed by histologic examination of brain tissue, characteristic electroencephalography (EEG), MRI changes and clinical correlation. A CSF examination shows normal values or slightly elevated protein levels. The EEG in classic CJD reveals generalized slowing early in the disease, punctuated by biphasic or triphasic peaks late in the disease with the onset of myoclonus. The MRI changes late in the illness reveal global atrophy with hyperintense signal from the basal ganglia.[6] Fluid attenuation inversion recovery (FLAIR) MRI provides greater sensitivity and demonstrates signal intensity changes in the cortex that T2-weighted spin-echo MRI cannot detect. Histopathologic examination of the brain using a specific antibody to the PrP-res protein confirms the disease. In addition, evidence of gliosis, neuronal loss and spongiform changes supports the diagnosis. In cases of vCJD characteristic amyloid plaques (so-called florid plaques) microscopically define the disease. The florid plaques are not seen in other TSEs and consist of flower-like amyloid deposits surrounded by vacuolar halos. The detection of PrP-res in the tonsillar tissue by immunohistochemical staining is also strongly supportive of vCJD diagnosis.[6]

Differential diagnosis

Identifying treatable disease expeditiously is a priority in patients presenting with neurologic changes. In patients who have suspected HSE undergoing brain biopsy for confirmation of disease, alternative diagnoses are frequently found. Of 432 patients, only 45% had biopsy-confirmed HSE and 22% had another etiology established by brain biopsy. Of these, 40% had a treatable disease (9% of the biopsy group) including bacterial abscess, tuberculosis, fungal infection, tumor, subdural hematoma or autoimmune disease. The majority of the remaining 60% identifiable but nontreatable causes for encephalitis were of viral etiology. A third group of 142 patients (33%) went undiagnosed even after brain biopsy and the conventional diagnostic tests,[3] as summarized in Table 23.3 .

More specifically, mass lesions in the CNS (tumor, abscess or blood) can cause focal neurologic changes, fever and seizures, similar to encephalitis. Metabolic (hypoglycemia, uremia, inborn errors of metabolism) and toxin-mediated disorders (ingestions, tick paralysis or Reye syndrome) can cause decreased consciousness, seizures and evidence of background slowing on EEG. Limbic encephalitis can produce protracted encephalitis and is caused by paraneoplastic phenomena. Treatable infectious causes of encephalitis must be vigorously investigated. Mycoplasma produces demyelinating brainstem encephalitis in approximately 0.1% of infections.

PREVENTION

Prevention remains the mainstay of therapy. Historically, the most frequent cause of viral CNS disease, namely mumps, has largely been eliminated through vaccination. Live attenuated vaccines against measles, mumps and rubella have resulted in a dramatic decrease in the incidence of encephalitis in industrialized countries. Measles continues to be the leading cause of postinfectious encephalitis in developing countries, complicating 1 of every 1000 measles infection.[7] Vaccination has also changed the incidence of previously common viral CNS disease. In 1952, poliomyelitis affected 57,879 Americans. Widespread vaccination has eradicated

the disease currently from the Western hemisphere. Vaccines exist for some arboviral infections. Vaccination against JE virus has reduced the incidence of encephalitis in Asia; however, in China, where 70 million children are immunized for JE, 10,000 cases still occur annually.

Vaccination is not cost-effective for preventing all viral infections. For example, vector avoidance, the use of mosquito deterrents and mosquito abatement programs provide less costly strategies for preventing arboviral encephalitides in the USA.[2] [38] Pre- and immediate postexposure prophylaxis are the only ways known to prevent death in rabies-exposed individuals.[45] Case reports exist of patients surviving symptomatic rabies, but all of these patients had some prior immunity or received postexposure prophylaxis prior to developing symptoms, as discussed above. The US Food and Drug Administration has implemented guidelines eliminating whole blood or blood components prepared from individuals who later developed CJD or vCJD. Changes in agricultural practices in Europe and bans on infected cattle led to a decline in cases of vCJD. In the USA one case of vCJD has been reported and the US Department of Agriculture has programs in place to monitor for TSEs in livestock.

APPROACH TO THE PATIENT WHO HAS VIRAL CENTRAL NERVOUS SYSTEM DISEASE

The approach to a patient who has a presumed CNS viral infection must be tailored to the severity and distribution of neurologic involvement. The degree of diagnostic as well as therapeutic intervention differs based on the type of CNS disease. For example, a patient who has photophobia and nuchal rigidity but a nonfocal neurologic examination does not require invasive intracranial pressure monitoring like a patient with encephalitis and evidence of increased intracranial pressure. After establishing the degree of CNS disease by history and physical examination, and stabilizing the patient (airway, breathing, circulation), the clinician then must ascertain a diagnosis. A simplified flow diagram reviewing the way to approach the patient who has viral CNS disease is presented in Figure 23.5 . The first step of any intervention hinges on establishing the correct diagnosis. A history and physical examination are logical first steps. The thoroughness of the initial history and physical examination is tailored to the stability of the patient. A comatose individual with apneustic respirations requires immediate intervention whereas the individual with nuchal rigidity and photophobia can afford a more detailed investigation for the etiology of symptoms prior to instituting any therapy.

Treatable causes of CNS dysfunction require rapid evaluation and intervention in an effort to prevent permanent or further CNS damage. Potentially treatable disease (fungal CNS infections, partially treated bacterial meningitis, tuberculous meningitis, parameningeal infection, mycoplasma and fastidious bacterial infections) can mimic viral CNS disease and should be vigorously investigated before attributing the illness to an untreatable viral etiology. The same logic applies to treatable viral infections and noninfectious etiologies. The radiographic and laboratory studies available for establishing a diagnosis must be prioritized based on the likely etiology and the stability of the patient.

Currently, few antiviral medications are available to treat CNS infections. Antiviral therapy exists for HSV-1, HSV-2, VZV, CMV and HIV. The introduction of aciclovir and vidarabine has resulted in a sharp decline in mortality and morbidity from herpes infections. Neonatal mortality from disseminated HSV disease and HSE has declined from 70% to 40% since the development of aciclovir and vidarabine. Varicella-zoster immunoglobulin (VZIG) and aciclovir have reduced the complications from primary VZV infection and zoster in the neonate and immunocompromised patient. Although

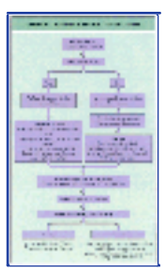

Figure 23-5 Approach to the patient who has presumed viral central nervous system disease.[56]

controlled trials have not evaluated the efficacy of aciclovir in VZV encephalitis, the medication is routinely used to treat this complication. With the increase of HIV infection, diseases previously limited to the neonatal and postnatal period now occur with increasing frequency in the adult population. Ganciclovir and foscarnet are used for the treatment of CMV encephalitis although controlled clinical trials have not confirmed the efficacy of treatment. In cases of postinfectious encephalitis, no randomized controlled trial has confirmed the benefit of immunomodulatory drugs. In practice clinicians often treat postinfectious encephalitis with different immunomodulators in an attempt to limit T-cell-mediated destruction of the CNS.[40] Importantly, no placebo-controlled studies have been performed and immunomodulatory therapy is based simply on isolated case reports. As with most case reports, clinical failures and iatrogenic morbidity from a therapeutic modality are rarely reported.

After establishing a presumptive diagnosis and instituting therapy, the clinician must also vigilantly anticipate and treat complications associated with the viral CNS disease or the therapeutic interventions. Seizures secondary to direct viral CNS damage, inflammatory vasculitis

and electrolyte changes require anticonvulsant therapy with benzodiazepines, phenytoin and barbiturates.[2] Patients with cerebral edema may require intracranial pressure monitoring and hyperventilation, osmotic therapy and CSF removal in an attempt to maintain cerebral pressures less than 15mmHg.[2] The ultimate goal of intracranial pressure monitoring is to maintain adequate cerebral perfusion. While a physician struggles to maintain an adequate intravascular blood volume, intracranial pressures can rise to dangerous levels as capillary leak complicates the patient's course. The risks of increased intracranial pressure from aggressive fluid resuscitation or the syndrome of inappropriate antidiuretic hormone release necessitate fastidious fluid management and frequent electrolyte monitoring. Cardiac arrhythmias can also develop in patients who have encephalitis secondary to electrolyte changes or brainstem damage. Cardiac and respiratory arrest can occur early in disease, and so equipment for intubation and cardioversion should be readily available for a patient who has encephalitis.

In addition to the direct damage the virus can cause in the CNS, certain viruses can also produce systemic damage and complicate the management of the CNS disease. Patients can develop overwhelming hepatitis, pneumonitis, disseminated intravascular coagulation and shock. Patients in coma from encephalitis can recover after long periods of unconsciousness. The physician should limit the amount of iatrogenic damage and vigorously support the patient during the acute phase of the illness.

CONCLUSION

Numerous factors influence the clinical manifestations of viral CNS infections. An individual's age, immune history, cultural practices and genetic make-up can influence the clinical expression of viral infection as readily as the viral serotype, receptor preference, viral load and cell tropism. Changes in behavior or cultural beliefs, increased travel and the modification of environment alter disease patterns and expose individuals to new infectious agents. Infections of the CNS, therefore, must be examined in a geographic, cultural and environmental context as well as the cellular, molecular and genetic levels.[57] [58]

Contemporary disease changes are relevant. The past 5 years have seen an outbreak of a deadly and previously unknown encephalitis virus (Nipah), dramatic extension of the range of a well-known arbovirus (WNV)[59] [60] and unexpected neurovirulence from a common pediatric pathogen (enterovirus 71).[61] [62] Each of these outbreaks suggests the high probability of future epidemics of encephalitis caused by previously unknown pathogens or novel manifestations of known agents. The Nipah virus epidemic highlights the potential for amplification of zoonotic viruses when agricultural practices force huge numbers of animals into close quarters, creating an ideal environment for exchange of pathogens. The WNV outbreak in the USA demonstrates how a pathogen can suddenly appear on the other side of the world. Although WNV is naturally spread to new regions by migratory birds, there is at least the suspicion that the New York outbreak could have originated with illegal importation of infected birds. These scenarios suggest the need for clinicians to develop a broad differential diagnosis when evaluating a new patient who presents with the acute onset of viral encephalitis. Improvements in our ability to diagnose CNS infections will produce a better understanding of the pathogenesis and true extent of CNS viral disease.

Chapter 24 - Brain Abscess and Other Focal Pyogenic Infections

Gregory C Townsend

Focal pyogenic infections of the central nervous system (CNS) include brain abscess, spinal cord abscess, subdural empyema, epidural abscess and suppurative intracranial phlebitis. The year 1993 marked the 100th anniversary of the publication of *Pyogenic Infective Diseases of the Brain and Spinal Cord* and *Atlas of Head Sections*, by Sir William Macewen, which were landmarks in the descriptions of the anatomy and natural history of focal suppurative brain processes and of their management.[1]

These conditions are characterized by the presence of one or more localized and well-defined collections of purulent material within the cranial vault or the paraspinal space. They exert their effects largely by direct involvement and destruction or encroachment of the brain or spinal cord parenchyma, by elevation of intracranial pressure or by interference with flow of blood or cerebrospinal fluid.

Infections in contiguous structures tend to lead to infections in certain areas of the cranial vault due to their anatomic relationships (Fig. 24.1). The frontal and ethmoidal paranasal sinuses underlie the anterior cranial fossa, so that infections in these sinuses often lead to infections in or near the frontal lobe. The sphenoid sinuses adjoin the sella turcica, temporal lobes and cavernous sinuses; sphenoid sinusitis may lead to infections in the frontal or temporal lobes or pituitary gland or to cavernous sinus thrombosis. Infections in the middle ear and mastoids may spread to the temporal lobe, cerebellum or brainstem. The focal nature of these infections often manifests by focal neurologic deficits, rather than by more global CNS dysfunction. This chapter focuses on the more common of these diseases (brain abscess, subdural empyema and epidural abscess), touching only briefly on the others.

BRAIN ABSCESS

Brain abscess is a focal suppurative process of the brain parenchyma. The diagnosis and management of brain abscess have undergone considerable changes during the past several years as a result of the widespread availability of noninvasive radiographic diagnostic techniques, the use of antimicrobial agents that demonstrate adequate penetration across the blood-brain barrier and into abscesses, and the refinement of minimally invasive surgical procedures.

EPIDEMIOLOGY

Brain abscess is an uncommon condition. A large series reported a cumulative lifetime incidence of approximately 1.3 per 100,000 person-years, although the overall incidence decreased from 2.7 per 100,000 person-years in 1935–44 to 0.9 per 100,000 person-years in 1965–81. The highest rates were observed in children 5–9 years old and adults over 60 (approximately 2.5 per 100,000 person-years each).[2] Recent reports have indicated that brain abscesses account for approximately 1 in 10,000 hospital admissions in the USA.[3]

The predominant age of patients with brain abscesses tends to vary somewhat with the predisposing factors; brain abscesses following otitis media are most common among young children and older adults, while those due to paranasal sinusitis are most common among older children and young adults.[3] [4] [5] [6] Although there have been conflicting reports on the possibility of a male predominance, three recent series indicated that brain abscesses are approximately 2–3 times as common among males as among females.[3] [5] [7]

The major factors that predispose to brain abscess are:

- an associated contiguous focus of infection (e.g. sinusitis, otitis media),
- trauma (e.g. penetrating head injury, post-neurosurgery),
- hematogenous spread from a distant focus (e.g. in association with lung abscess), and
- cryptogenic (no recognized focus).

Brain abscesses associated with a contiguous focus account for approximately 40–50% of the total; the percentage of cases without an identified predisposing factor has been reduced to approximately 15% with the use of newer, more sensitive imaging procedures. [7] [8] [9] In addition, brain abscesses have been reported in immunocompromised individuals or after a cerebrovascular accident.

The most common underlying conditions in patients in developed countries with brain abscess are otitis media and mastoiditis. However, it appears that the percentage of cases associated with otitis media and mastoiditis has decreased in association with early antimicrobial therapy for suspected otitis media. Recent data indicate that the risk of brain abscess in cases of otitis media is less than 0.5%.[9] [10] Brain abscess may also be associated with cyanotic heart disease and trauma at least as often as with otitis media and mastoiditis.[7] [11] Other head and neck infections associated with brain abscesses include paranasal and dental infections. In a recent report from Turkey, the most common predisposing factor in children was bacterial meningitis.[12]

As noted above, the location of focal CNS infections is often determined by proximity to a contiguous focus of infection. Thus, brain abscesses associated with otitis media and mastoiditis are most common in the temporal lobe and cerebellum (Table 24.1). Brain abscesses associated with sinus infections occur primarily in the frontal lobe or the temporal lobe. The frontal lobe is also most commonly affected following dental infections. Post-traumatic brain abscesses usually occur in the setting of a penetrating wound, but may also occur in closed head injuries. These injuries have included penetrating pencil tip and lawn dart injuries in children. Presentation of the abscess may occur months to years after the precipitating event. In one study, the median time to development of brain abscess was 113 days[13] and there have been recent reports of brain abscesses occurring at the site of war-related penetrating head injuries up to 52 years after the injuries occurred.[14]

Brain abscesses occurring in the setting of a distant primary site with hematogenous spread are often multiple; approximately 10–15% of patients with brain abscesses have multiple abscesses. They tend to occur in the distribution of the middle cerebral artery at the junction of the gray and white matter, where microcirculatory flow is poorest. Cyanotic congenital heart disease and chronic pyogenic lung diseases (e.g. lung abscess, bronchiectasis) are common predisposing factors.

Figure 24-1 Anatomic relationships between potential contiguous sources of infection and sites at which focal pyogenic central nervous system infections may occur.

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) is also associated with brain abscess; it is thought that in these cases pulmonary arteriovenous malformations allow septic microemboli to bypass the normal pulmonary filter and gain access to the cerebral circulation. Brain abscesses have been reported following dental extractions and other manipulations, dilation of esophageal strictures and endoscopic sclerosis of esophageal varices.

PATHOGENESIS AND PATHOPHYSIOLOGY

The main pathogenetic factors responsible for the development of brain abscesses are a source of virulent micro-organisms and the presence of ischemic or devitalized brain tissue. The vulnerability of compromised tissue to brain abscess is evidenced by the occurrence of brain abscesses after trauma or cerebrovascular accident, in association with cyanotic heart or lung disease and in areas of poor local perfusion such as the junction of gray and white matter.

TABLE 24-1 -- Site of brain abscess based on predisposing condition.

SITE OF BRAIN ABSCESS BASED ON PREDISPOSING CONDITION	
Predisposing condition	**Site**
Otitis media or mastoiditis	Temporal lobe
	Cerebellum
Paranasal sinusitis	Frontal lobe
	Temporal lobe
Dental infection/manipulation	Frontal lobe
Trauma/neurosurgery	Related to wound
Meningitis	Cerebellum
	Frontal lobe

Cyanotic heart disease	Middle cerebral artery distribution
Pyogenic lung disease	
Bacterial endocarditis	
Gastrointestinal source	
T-cell deficiency	
Neutropenia	

Experimental models have demonstrated differences in the abilities of various micro-organisms to induce brain abscesses. These differences may be inter- or intraspecific. For example, *Escherichia coli* has been demonstrated to be more effective in producing brain abscesses than are *Staphylococcus aureus, Streptococcus pyogenes* or *Pseudomonas* spp.; encapsulated strains of *E. coli* were more infective than nonencapsulated strains.[15] Differences in infectivity have also been demonstrated among strains of *Citrobacter diversus*.[16]

There are two main postulated mechanisms by which brain abscess may occur in association with a contiguous focus of infection: direct extension through infected bone, or hematogenous spread through emissary or diploic veins or spread through local lymphatics. Infections associated with otogenic infections may also spread through the internal auditory canal, between suture lines or through cochlear aqueducts. Brain abscesses developing after trauma or neurosurgical procedures may follow deep wound injury with direct inoculation into the brain parenchyma or may be a result of extension of a superficial infection through compromised tissue.

The areas of the brain most commonly involved by solitary brain abscess are the frontal and temporal lobes, followed by the frontoparietal region, the parietal, cerebellar and occipital lobes.[17] These areas are those most likely to be associated with a contiguous focus or hematogenous seeding. Although rare, abscesses in other areas, such as the pituitary gland, thalamus, basal ganglia and brainstem, may occur and may be associated with specific predisposing conditions. For example, abscesses of the pituitary are often associated with pre-existing pituitary adenomas and with sphenoidal sinusitis.

Experimental animal data, surgery and autopsy findings and radiographic examinations indicate that brain abscesses develop in a four-stage process:[18] an early and late cerebritis (days 1–3 and 4–9, respectively); and an early and late capsule formation (days 10–13 and day 14 and later, respectively). These represent a continuum rather than discrete steps. The evolution of this process is dependent upon the causative organism, local factors, host immunologic status and antimicrobial therapy.

The microbiology of brain abscess is dependent upon the site of the initiating infection, the patient's underlying condition and the geographic locale (Table 24.2). The organisms most commonly isolated are streptococci, the Enterobacteriaceae, anaerobes, *Staph. aureus* and fungi; approximately 30–60% are polymicrobial. Fungi

TABLE 24-2 -- Likely pathogens and suggested empiric therapy for brain abscess based on predisposing condition.

LIKELY PATHOGENS AND SUGGESTED EMPIRIC THERAPY FOR BRAIN ABSCESS		
Predisposing condition	**Likely pathogens**	**Empiric therapy**
Otitis media or mastoiditis	Streptococci (anaerobic and aerobic)	Third-generation cephalosporin + metronidazole
	Bacteroides spp.	A penicillin
	Enterobacteriaceae	
Paranasal sinusitis	Streptococci	Third-generation cephalosporin ± metronidazole
	Bacteroides spp.	
	Enterobacteriaceae	
	Staphylococcus aureus	
Dental infection or manipulation	Streptococci	Penicillin ± metronidazole
	Fusobacterium spp.	
	Bacteroides spp.	
Trauma or neurosurgery	*Staphylococcus aureus*	Antistaphylococcal penicillin + third-generation cephalosporin
	Coagulase-negative staphylococci	
	Enterobacteriaceae	
	Streptococci	Vancomycin
	Pseudomonas aeruginosa	
Cyanotic heart disease	Streptococci	Third-generation cephalosporin
	Haemophilus spp.	
Pyogenic lung disease	Streptococci	Penicillin or third-generation cephalosporin + metronidazole
	Nocardia asteroides	
	Actinomyces spp.	
	Fusobacterium spp.	
	Bacteroides spp.	
Bacterial endocarditis	Viridans streptococci	Ampicillin and gentamicin ± antistaphylococcal penicillin
	Staphylococcus aureus	
	Enterococci	
	Haemophilus spp.	
Gastrointestinal source	Enterobacteriaceae	Third-generation cephalosporin
T-cell deficiency	*Toxoplasma gondii*	Variable
	Nocardia spp.	
Neutropenia	Enterobacteriaceae	Third- or fourth-generation cephalosporin, meropenem
	Pseudomonas aeruginosa	
	Fungi, especially *Aspergillus* and *Mucor*	Amphotericin B

were the organisms most commonly isolated in a recent report from Saudi Arabia[19] and are particularly common causes of brain abscesses in immunocompromised patients; *Aspergillus* spp. are especially common in patients who have bone marrow and solid organ transplants.[20] Patients who have defects in T-cell immunity (including AIDS patients) are predisposed to infections with intracellular organisms such as *Toxoplasma gondii*, *Nocardia* spp., *Cryptococcus neoformans*, *Mycobacterium* spp. and fungi.

PREVENTION

The primary means of prevention of brain abscesses and other focal CNS infections is the appropriate use of antibiotics in patients who have predisposing infections such as otitis media and mastoiditis. Other preventive measures include surgical correction of cyanotic congenital heart disease, maintenance of dental hygiene, management of pyogenic lung infections and attention to proper sterile techniques during neurosurgical procedures. In patients who have underlying T-cell defects, measures to prevent exposure to *T. gondii* should be recommended.

CLINICAL FEATURES

The clinical manifestations of brain abscess and other focal suppurative CNS processes are due largely to the presence of a space-occupying lesion.[17] [21] [22] The most common symptom is headache, which is usually hemicranial. Other common symptoms include fever, focal neurologic findings (especially hemiparesis), nausea and vomiting, and seizures (usually generalized). Nuchal rigidity may occur if the abscess is near the meninges.

Other signs and symptoms vary depending on the stage, size and anatomic location of the abscess. Abscesses of the frontal lobe are characterized by global mental status changes, hemiparesis and expressive speech disturbances. Temporal lobe abscesses may present with headache and aphasia (if the abscess involves the dominant hemisphere). Cerebellar abscesses are associated with vomiting, ataxia, nystagmus and dysmetria. Vomiting, hemiparesis, dysphagia and facial weakness may be seen with brainstem abscesses. Rapid deterioration with nuchal rigidity suggests the possibility of rupture of an abscess into the intraventricular or subarachnoid space.

Laboratory findings may include a peripheral leukocytosis and a left shift, but approximately 40% of patients with brain abscess have normal leukocyte concentrations. The erythrocyte sedimentation rate is often elevated. An elevated C-reactive protein has been found to be both sensitive (77–90%) and specific (77–100%) when used to distinguish brain abscess from cerebral neoplasms.

The differential diagnosis of brain abscess includes subdural empyema, epidural abscess, bacterial meningitis, cerebral neoplasm, cerebrovascular accident and encephalitis.

DIAGNOSIS

Radiographic imaging with contrast-enhanced computerized tomography (CT) or magnetic resonance imaging (MRI) has contributed greatly to diagnosis and management of brain abscess. These have obviated the need for more invasive techniques such as pneumoencephalography and myelography. Plain skull radiographs are insensitive but the presence of air indicates the need for further evaluation. Technetium-99 (^{99m}Tc) brain scanning is very sensitive and is the procedure of choice where CT or MRI is unavailable; there is some evidence that ^{99m}Tc scanning may be more sensitive than CT in the early cerebritis stage. ^{99m}Tc-HMPAO labeled leukocyte single photon emission CT (SPECT) has been examined as a potential means of distinguishing brain abscess from other focal cerebral parenchymal lesions, such as neoplasms. Ultrasonography may also be used if other techniques are unavailable.

The characteristic appearance of brain abscess on CT scan varies with the stage of the disease.[23] During the cerebritis stage, cerebral edema is prominent; no abnormalities may be seen in the early cerebritis stage. As capsule formation progresses, the abscess appears as a lesion with a hypodense center composed of necrotic debris surrounded by ring enhancement, which may in turn be surrounded by hypodense cerebral edema (Fig. 24.2). Although highly sensitive, CT scanning is not specific. These findings may also be seen in patients who have cerebral neoplasms, cerebrovascular accidents or granulomas.

Magnetic resonance imaging appears to be more sensitive than CT in the early cerebritis stage of brain abscess, where it appears as

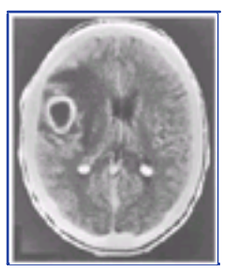

Figure 24-2 Contrast-enhanced CT scan of the head in the coronal projection of a 43-year-old man with an atrial septal defect that persisted after attempts at surgical repair. The patient presented with seizures after undergoing dental work for which he did not receive antimicrobial prophylaxis. Note the ring-enhancing lesion in the right frontoparietal region with edema and mass effect.

slightly low intensity on T1-weighted images and very low intensity on T2-weighted images and may be more sensitive in diagnosing lesions in the posterior fossa due to the absence of bone artefact[24] (Fig. 24.3). Also, MRI may allow distinction of abscess fluid from cerebrospinal fluid, which may be important if intraventricular rupture is suspected. Enhancement with gadolinium-DTPA allows evaluation of disruption of the blood-brain barrier and permits greater distinction of the radiographic appearance of the central abscess, capsule and surrounding edema. Examination by ^{1}H magnetic resonance spectroscopic imaging has been proposed as a means of distinguishing brain abscess from other focal cerebral parenchymal lesions.

It must be noted that the appearance of edema and contrast enhancement on CT and MRI may be diminished or absent in immunocompromised patients, possibly due to poor host inflammatory response.

Lumbar puncture should be avoided in patients who have known or suspected brain abscess. The yield of cerebrospinal fluid culture is low (less than 10% positive) and the risk of herniation is considerable (approximately 15–30%). In patients in whom both diagnoses are considered, blood cultures should be obtained and appropriate

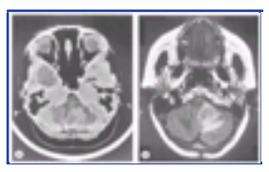

Figure 24-3 Contrast-enhanced CT and MRI scans of the head in the coronal projection of a 43-year-old woman with headaches after a recent fall on her head. (a) CT scan image reveals a cystic ring-enhancing lesion in the left cerebellum. Note the prominent bone artefact. (b) T1-weighted MRI scan image reveals an enhancing cystic lesion in the left cerebellum with significant surrounding edema. Bone artefact is absent. Both CT and MRI scans were felt to be most consistent with a primary or metastatic neoplasm, but culture of material obtained at stereotactically guided aspiration grew *Staphylococcus aureus*.

empiric therapy should be initiated, after which an imaging procedure should be performed. Lumbar puncture may be performed if there is no evidence of a mass lesion or signs of raised intracranial pressure.

MANAGEMENT

Most patients who have a brain abscess require surgical drainage. In addition to its role as a therapeutic measure, drainage also permits microbiologic evaluation of abscess material, which may be important in guiding antimicrobial therapy. It is now clear that aspiration is as effective as excision in most cases and is less invasive, and thus it has become the procedure of choice. Stereotaxic CT-guided aspiration permits accurate access even to areas that had been difficult to reach by aspiration, such as the brainstem, cerebellum and thalamus.[25] Multiple abscesses may thus be drained. Neuroendoscopic aspiration has also been used with success in a small number of patients.

Abscess material should be examined by Gram stain and by aerobic and anaerobic cultures as a minimum; in one study, the Gram stain revealed organisms in 82% of cases and the culture was positive in 88%.[26] The clinical setting may also dictate the use of special stains and cultures for fungi, mycobacteria and protozoa. In patients who have HIV infection, polymerase chain reaction (PCR) examination of cerebrospinal fluid may be useful in diagnosing tuberculous brain abscesses.

Antibiotics used in the management of brain abscess should be parenteral, have activity against the pathogens that are likely in a given clinical scenario, penetrate into abscess fluid (and into the site of any underlying infection) in adequate concentrations and be bactericidal. The combination of penicillin or a third-generation cephalosporin (cefotaxime or ceftriaxone) plus metronidazole is effective as empiric therapy in most cases (see Table 24.2). An antistaphylococcal penicillin (such as flucloxacillin, nafcillin or oxacillin) should be used if staphylococci are suspected. Vancomycin should be used instead if methicillin resistance is suspected or identified or if the patient is allergic to ß-lactam antimicrobial agents. In the case of intraventricular rupture of brain abscess, it has been recommended that optimal management include open craniotomy with debridement, intraventricular lavage and intraventricular as well as intravenous antibiotics. Changes in therapy in all cases should be guided by results of microbiologic examination and by clinical and radiographic progress.

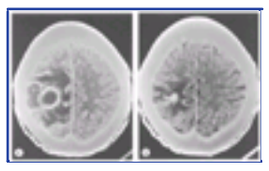

Figure 24-4 Contrast-enhanced CT scans of the head in the coronal projection of a 66-year-old woman with a group B streptococcal brain abscess demonstrating evolution of the abscess during and after surgical and antimicrobial therapy. (a) The original scan demonstrates a hypodense necrotic center surrounded by an enhancing capsule and hypodense edema. (b) Seven weeks later, after stereotactically guided aspiration and a full course of antimicrobial therapy, the central cavity can no longer be seen, although the enhancement and surrounding edema persist to a small degree.

There is a great deal of evidence that there are certain circumstances under which brain abscess may be treated without surgical drainage. Small abscesses (less than 3cm diameter) and abscesses in the cerebritis stage may respond to antimicrobial therapy alone.[8] Medical therapy alone may also be indicated if the patient is a poor surgical candidate. In these cases, prolonged courses of antibiotics (at least 8 weeks of parenteral therapy) and close monitoring with sequential CT or MRI scans are necessary; MRI may be especially useful here because of its lack of ionizing radiation.

Although the optimal duration of antimicrobial therapy for brain abscess after surgical drainage has not been established, many authorities recommend 4–6 weeks of parenteral antibiotics. Radiographic imaging procedures should be used for monitoring of therapy. Radiographic abnormalities may persist for months after successful therapy of brain abscesses (Fig. 24.4).

Adjunctive therapy with corticosteroids, mannitol and hyperventilation may be indicated where there is evidence of increased intracranial pressure. The routine use of corticosteroids in the absence of increased intracranial pressure cannot be recommended.

The prognosis for patients who have a brain abscess has improved considerably, particularly since the introduction of CT scanning. Mortality is now less than 30% in most series. Long-term sequelae may occur in about one-third of patients and include mental retardation, seizures and focal neurologic deficits. Poor prognostic factors include delayed or missed diagnosis, multiple lesions, deep-seated lesions, intraventricular rupture, severe impairment of mental or neurologic status (including coma), fungal etiology and extremes of age.[5]

SUBDURAL EMPYEMA AND INTRACRANIAL EPIDURAL ABSCESS

Subdural empyema and epidural abscess are focal collections of purulent material between the dura mater and arachnoid mater, and outside the dura mater, respectively. Subdural empyema accounts for approximately 15–20% of all focal intracranial infections.

EPIDEMIOLOGY

Subdural empyema in adults is most often a complication of acute or chronic bacterial paranasal sinusitis, otitis media or mastoiditis.[27] [28] It is the most common intracranial complication of sinusitis, accounting for approximately 60% of such cases.[29] The frontal and ethmoidal sinuses are the foci in well over half of the cases. Hematogenous spread from a distant source may also occur. In children the most common predisposing condition is bacterial meningitis. Other predisposing conditions include trauma (including neurosurgical procedures) and infection of a pre-existing subdural hematoma. As with brain abscess, there is a male predominance among patients who have subdural empyema.[30]

Intracranial epidural abscess usually follows paranasal sinusitis (particularly frontal), otitis media, mastoiditis or cranial trauma. Males are again more commonly afflicted than females.[31]

PATHOGENESIS AND PATHOPHYSIOLOGY

As with brain abscesses, extension of infection into the epidural or subdural space from a contiguous focus may occur by extension through infected bone or by hematogenous seeding through emissary veins. Intracranial epidural abscess is almost always associated with subdural empyema and with overlying osteomyelitis. In patients with subdural empyema, infection can spread rapidly through the subdural space until limited by its natural boundaries. These include the falx cerebri, tentorium cerebelli, base of the brain, foramen magnum posteriorly and the anterior spinal canal. Within the compartments defined by these boundaries, as the infection progresses it behaves as an expanding mass lesion.

As the lesion expands, intracranial pressure increases and the cerebral parenchyma is compromised. Interference with flow of blood or of cerebrospinal fluid may cause cerebral edema and hydrocephalus. Septic thrombosis of veins within the affected subdural or epidural space may lead to thrombosis of cavernous sinuses or cortical veins, leading to infarction of brain tissue.

Organisms commonly isolated from adult patients with subdural empyema and intracranial epidural abscess include anaerobes, aerobic streptococci, staphylococci, *Streptococcus pneumoniae, Haemophilus influenzae* and other Gram-negative bacilli. Polymicrobial infections are common; in one study, more than 50% of infections were polymicrobial.[30] In children, the most common causative agents are those that are responsible for the underlying meningitis. In the past, this has been *H. influenzae* in children outside the neonatal age, but as the relative frequency of *H. influenzae* meningitis declines it is likely that its role in subdural empyema will diminish as well.

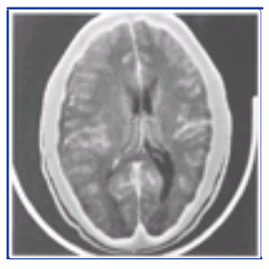

Figure 24-5 Contrast-enhanced CT scan of the head in the coronal projection of a 23-year-old man with fever and headache. There is a small isodense extra-axial fluid collection in the subdural space on the right, with significant mass effect shown by right-to-left midline shift and effacement of the right lateral ventricle. There was also opacification of the frontal and ethmoid sinuses, suggesting sinusitis as the source of this subdural empyema.

CLINICAL FEATURES

The most prominent early symptoms associated with subdural empyema and intracranial epidural abscess are fever and headache. The headache is often focal at onset but may become generalized. These are usually followed by focal neurologic defects. Abscesses near the petrous portion of the temporal bone may be associated with fifth and sixth cranial nerve palsies, causing unilateral facial pain and lateral rectus muscle weakness. Periorbital edema and subgaleal abscess (Pott's puffy tumor) may be found in up to about one-third of patients. Signs of increased intracranial pressure (such as vomiting, gait disturbances and mental status changes) and meningeal irritation may follow and may be accompanied by seizures, hemiparesis and hemisensory defects.[30]

DIAGNOSIS

Computerized tomography or MRI scanning are the procedures of choice in the diagnosis of subdural empyema and epidural abscess. Imaging reveals a hypodense lesion with displacement of the arachnoid mater in both entities, with accompanying displacement of the dura mater noted in patients who have subdural empyema. Mass effect is more common with subdural empyema than with epidural abscess (Fig. 24.5). Capsule formation with contrast enhancement may be seen in either condition, but is more common with epidural abscess (Fig. 24.6). Cranial osteomyelitis may also be noted in patients who have underlying contiguous foci of infection. Gadolinium-enhanced MRI may detect lesions not noted on CT (because the lesions may be isodense with the cerebral tissue on CT). As with brain abscess, lumbar puncture is contraindicated in patients with known or suspected subdural empyema or epidural abscess. Clinical deterioration

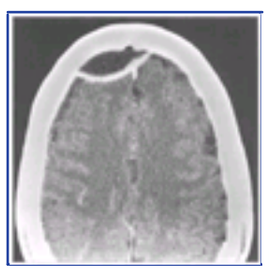

Figure 24-6 Contrast-enhanced CT scan of the head in the coronal projection of a 19-year-old man with otitis media who presented with sinus congestion 1 week earlier. Plain films of the sinuses revealed opacification of the right maxillary and ethmoidal sinuses and an intracranial air-fluid level. Note the intracranial gas in the right frontal region abutting a hypodense region in the epidural space with ring enhancement and surrounding edema, representing an intracranial epidural abscess.

was reported in 33 of 280 patients (11.3%) who underwent lumbar puncture with subdural empyema[30] and in 1 of 12 patients (8.3%) with epidural abscess.[31]

MANAGEMENT

Surgical evacuation is necessary for management of most patients who have subdural empyema and intracranial epidural abscess. This should be accomplished by craniotomy or by the use of burr holes. Although the optimal surgical procedure has not been established, in one study of 699 patients with subdural empyema, the use of limited procedures such as burr holes or craniectomies was associated with a worse prognosis than more extensive procedures such as craniotomies.[32] It may also be necessary to debride the primary source of infection. Samples should be submitted for Gram stain and aerobic and anaerobic cultures. Antimicrobial therapy alone may be used for a limited number of patients with very small fluid collections. [30] [31]

The choice of empiric antimicrobial therapy is dependent upon the age of the patient and the site of the primary infection (Table 24.3). In adults, the wide variety of

possible pathogens and the potential for polymicrobial infection dictate the use of broad-spectrum therapy. In children, therapy should be directed against the likely causes of meningitis. Parenteral antimicrobial therapy should be continued for 3–6 weeks, with close monitoring of clinical status and radiographic appearance.

SUPPURATIVE INTRACRANIAL PHLEBITIS

Suppurative intracranial phlebitis is inflammation of the blood vessels within the cranium as a result of infection.[33]

TABLE 24-3 -- Pathogens and suggested empiric antibiotic regimens for subdural empyema and intracranial epidural abscess based on underlying condition.

PATHOGENS AND SUGGESTED EMPIRIC ANTIBIOTIC REGIMENS FOR SUBDURAL EMPYEMA AND INTRACRANIAL EPIDURAL ABSCESS		
Predisposing condition	**Likely pathogens**	**Empiric therapy**
Paranasal sinusitis	Streptococci	Third-generation cephalosporin + metronidazole ± antistaphylococcal penicillin or a penicillin
	Bacteroides spp.	
	Staphylococcus aureus	
	Enterobacteriaceae	
	Haemophilus influenzae	
Otitis media or mastoiditis	Streptococci	Third-generation cephalosporin + metronidazole ± antistaphylococcal penicillin or a penicillin
	Bacteroides spp.	
	Staphylococcus aureus	
	Enterobacteriaceae	
	Pseudomonas aeruginosa	
Trauma	*Staphylococcus aureus*	Vancomycin + third-generation cephalosporin
	Coagulase-negative staphylococci	
	Enterobacteriaceae	
Dental infection	*Bacteroides* spp.	Penicillin or third-generation cephalosporin + metronidazole
	Streptococci	
	Fusobacterium spp.	
Neonate	Enterobacteriaceae	Third-generation cephalosorin + ampicillin
	Group B streptococci	
	Listeria monocytogenes	
Infant or child	*Streptococcus pneumoniae*	Third-generation cephalosporin ± Vancomycin
	Haemophilus influenzae	
	Neisseria meningitidis	

EPIDEMIOLOGY, PATHOGENESIS AND PATHOPHYSIOLOGY

These infections usually follow infections of the paranasal sinuses, middle ear, mastoids, face and oropharynx. They may also occur in association with subdural empyema, epidural abscess or bacterial meningitis. Conditions associated with increased blood viscosity or hypercoagulability increase the risk of suppurative intracranial phlebitis.

Spread generally occurs along emissary veins. The venous sinuses most commonly involved are the cavernous sinus, lateral sinus and superior sagittal sinus. If there is sufficient involvement of the vasculature, then cerebral edema and hemorrhagic infarction may result. The infarcts tend to occur in venous watershed regions. Involvement of the superior sagittal sinus or of the lateral sinuses may block reabsorption of cerebrospinal fluid and lead to hydrocephalus and increased intracranial pressure. There may also be subsequent involvement of contiguous structures leading to brain abscess, subdural empyema, epidural abscess or meningitis, or distant seeding and infection of the lungs and other organs.

The microbiology of suppurative intracranial phlebitis is similar to that of subdural empyema and intracranial epidural abscess, with *Staph. aureus*, streptococci and anaerobes being most commonly identified.

CLINICAL FEATURES

The clinical manifestations of suppurative intracranial phlebitis vary with the location of the involved venous sinuses or cortical veins.

Cavernous sinus thrombosis is associated with palsies of cranial nerves III, IV, V and VI, producing loss of corneal reflexes, ophthalmoplegia and hypesthesia over the upper part of the face. Papilledema and visual loss may result from obstruction of retinal venous return.

Lateral sinus thrombosis involves cranial nerves V and VI, resulting in altered facial sensation and lateral rectus muscle weakness. Obstruction of venous cerebrospinal fluid resorption may cause communicating hydrocephalus and increased intracranial pressure. Cranial nerves IX, X and XI may also be affected.

Involvement of the superior sagittal sinus may also diminish CSF resorption. In addition, obstruction of venous drainage from the motor cortex region of the cerebral hemispheres may lead to weakness of the legs.

Cortical vein thrombosis may be neurologically silent or produce only transient defects if collateral venous drainage can compensate for thrombosis. If collateral flow is inadequate, the lesion will manifest as progressive neurologic defects. The precise nature of the defects depends on the location of the veins involved. Unilateral or bilateral extremity weakness, hemiparesis, aphasia, seizures and mental status changes may be seen.

DIAGNOSIS

Magnetic resonance imaging is more sensitive than CT and is the diagnostic procedure of choice. The appearance on MRI is that of increased signal within the involved vessel (Fig. 24.7). Sensitivity of MRI can be enhanced by the use of magnetic resonance imaging angiography. Computerized tomography may be used when MRI is unavailable. If CT or MRI is unremarkable and suppurative intracranial phlebitis is still suspected, angiography should be performed.

MANAGEMENT

Empiric antimicrobial therapy is similar to that employed for subdural empyema and intracranial epidural abscess (see Table 24.2). It may be necessary to control

increased intracranial pressure with adjunctive measures such as corticosteroids, hyperosmolar agents

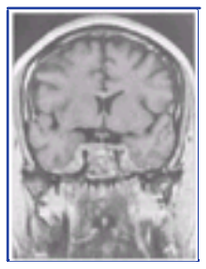

Figure 24-7 Contrast-enhanced MRI scan of the head in the sagittal projection of a 29-year-old man with sinus congestion and headache. There is non-uniform signal intensity of the cavernous venous sinuses, indicating cavernous sinus thrombosis. The sphenoid, ethmoidal and maxillary paranasal sinuses also demonstrated abnormal signal intensity.

and hyperventilation. Anticoagulant therapy has been used with some success, but carries the risk of hemorrhagic infarction. Surgery may be required for drainage of associated abscesses.

SPINAL EPIDURAL ABSCESS

Spinal epidural abscess is a focal infection of the paraspinal epidural space.

EPIDEMIOLOGY, PATHOGENESIS AND PATHOPHYSIOLOGY

Spinal epidural abscess may be secondary to a contiguous source of infection, such as vertebral osteomyelitis, penetrating trauma or decubitus ulcers, or may arise by hematogenous spread from a distant source.[27] [34] [35] [36] A history of back trauma, including spinal and paraspinal procedures, is common. Diabetes mellitus, alcoholism and injection drug use are common risk factors. In addition to pulmonary infections and infective endocarditis, as seen in patients who have brain abscess and subdural empyema, possible sources for hematogenous seeding of the spinal epidural space include cutaneous, intra-abdominal, pelvic and genitourinary infections. Spread from these sources occurs via the paravertebral venous plexus.

In most cases in adults, the thoracic spine is involved, while cervical and lumbar involvement are more common in children. There is a male predominance. [36]

The organism responsible for the majority of cases of spinal epidural abscess is *Staph. aureus*, accounting for almost three-quarters of all cases in a meta-analysis of 915 cases reported.[36] Other staphylococci, aerobic and anaerobic streptococci, *Escherichia coli* and *Pseudomonas aeruginosa* are also common. Polymicrobial infections may occur, but are uncommon.

CLINICAL FEATURES

Four clinical stages have been described for spinal epidural abscess:

- fever and focal back pain;
- nerve root compression with nerve root pain;
- spinal cord compression with accompanying deficits in motor, sensory and bowel and bladder sphincter function; and
- paralysis (respiratory compromise may also be present if the cervical cord is involved).[37]

Figure 24-8 Contrast-enhanced MRI scan of the spine in the coronal projection of a 28-year-old man with a 1-week history of headache, fever and sweats. Physical examination demonstrated meningismus but no focal neurologic deficits. Scans in the sagittal section demonstrated a substance nearly isointense with the spinal cord and running nearly the length of the cord. This scan clearly demonstrates impingement and anterior displacement of the cord by the spinal epidural abscess.

Progression tends to be rapid, with infection due to direct hematogenous spread, and may be accompanied by severe pain.

Progression to the second stage tends to occur slowly in patients who have abscesses secondary to vertebral osteomyelitis, but may accelerate after that.

Headache, meningismus and focal tenderness are common signs and symptoms. Laboratory evaluation often reveals leukocytosis and elevated erythrocyte sedimentation rate in acute cases.

DIAGNOSIS

Gadolinium-enhanced MRI has supplanted CT and myelography as the diagnostic procedure of choice for spinal epidural abscess[38] [39] (Fig. 24.8). Magnetic resonance imaging is highly sensitive (91%) and noninvasive and can identify osteomyelitis and intramedullary spinal cord lesions. If MRI is not available, then myelography should be performed.

MANAGEMENT

Surgical drainage is indicated for the management of most patients with spinal epidural abscess. This should ordinarily be achieved by laminectomy, but CT-guided aspiration may be performed in selected patients. Antimicrobial therapy alone may be considered in patients who have not progressed to the third stage of the illness (i.e. those without neurologic deficits). Such patients should be monitored closely for worsening pain, fever or appearance of neurologic deficits.

An antistaphylococcal penicillin should be instituted as empiric therapy in all patients; vancomycin may be used in patients who are allergic to penicillin. Antibiotics with antimicrobial activity against Gram-negative organisms (such as a third-generation cephalosporin) and anaerobes (such as metronidazole) should be added in patients whose underlying source might have been an intra-abdominal, pelvic or genitourinary infection. The duration of parenteral therapy should be at least 3–4 weeks; if osteomyelitis is present, then therapy should be continued for a total of 8 weeks.

SPINAL CORD ABSCESS

Intramedullary spinal cord abscess is a rare condition that can be defined as a focal suppurative processes of the spinal cord parenchyma. It usually involves the thoracic segment of the spinal cord and is generally hematogenous in origin. The lungs are usually the source of infection and there have been reports of such abscesses in injection drug users. Spinal cord abscesses may also arise secondary to congenital dermal sinuses. The organisms that have been isolated in patients with spinal cord abscesses have included *Staph. aureus*, streptococci, *Listeria monocytogenes* and *Burkholderia cepacia*.[40] The symptoms of spinal cord abscess mimic those of spinal epidural abscess. Diagnosis may be made by CT, MRI or myelography. Treatment consists of surgical debridement and prolonged antimicrobial therapy. Antibiotics should be directed against *Staph. aureus* and possibly Gram-negative bacilli.

CONCLUSION

The diagnosis of focal pyogenic infections of the CNS has been revolutionized in the past two decades with the introduction and widespread use of CT and MRI scanning. Because of its high sensitivity, ability to delineate infections in surrounding tissues and absence of ionizing radiation, MRI is generally preferable to CT for diagnosis. Management has also been altered with refinement of minimally invasive surgical techniques such as CT-guided aspiration and by studies demonstrating the efficacy of medical management alone in defined situations. It is hoped that further advances in management will lead to greater improvements in patient outcomes.

Chapter 25 - Toxin-mediated Disorders: Tetanus, Botulism and Diphtheria

Martin J Wood

The three diseases described in this chapter are caused by exotoxins that conform to the general A–B model, each being composed of an enzymatic (A) portion and a binding (B) portion. The biologic activity resides in the A portion whereas the B subunits may bind to target cells but are biologically inactive. Common to all the three toxins described, A and B are domains of a single protein that is cleaved by proteolytic activity of the bacterium.

TETANUS

Tetanus is caused by tetanospasmin, a neural toxin that interferes with inhibition of spinal cord reflexes and is produced by the obligate anaerobic bacterium *Clostridium tetani*.

EPIDEMIOLOGY

Tetanus is still common in developing tropical countries, where it is an important cause of death, particularly in neonates. The World Health Organization estimated in 1990 that there were about 715,000 deaths worldwide from neonatal tetanus. In the developed world, however, active immunization and better hygiene, wound care and management of childbirth have meant that the disease is now rare. The annual incidence of tetanus has fallen from nearly 4 to 0.2 per million population in the USA since 1947 (Fig. 25.1); mortality has dropped even more, with the death:case ratio falling from about 50% to below 30%.[1] In England and Wales there were 83 cases of tetanus (and 19 deaths) in the period from 1988 to 1997.

Neonatal tetanus usually occurs within 3–14 days of birth in infants delivered under nonsterile conditions to nonimmunized women. The umbilical cord stump is the usual portal of entry, particularly if cultural practices dictate the application of animal dung to the stump. At other ages acute wounds are the portal of entry for *C. tetani* in about 80% of cases, with the remainder associated with chronic decubitus ulcers, gangrene, abscesses or parenteral drug abuse. Tetanus is more likely to occur in the summer months when gardening and other pastimes bring people into contact with soil.

PATHOGENESIS AND PATHOLOGY

Spores of *C. tetani* contaminate a wound and germinate under anaerobic conditions. The proliferating organisms elaborate tetanospasmin (tetanus toxin), one of the most potent of the known poisons, with an estimated lethal dose of 2.5ng/kg body weight. It is produced by a plasmid-encoded gene and is synthesized as a 151kDa polypeptide. As with botulinum and diphtheria toxins, this polypeptide is then split by clostridial proteolytic cleavage into the light (L) chain (approximately 50kDa and containing the enzymatic (A) domain) and heavy (H) chain, containing the binding (B) domain (approximately 100kDa).

Most of the toxin gets into the bloodstream, but it must then gain entry into the central nervous system (CNS) via neurons to exert its toxicity. The effect of tetanus toxin is via a three-stage process: binding, internalization and induction of paralysis. The H chain interacts with the ganglioside GT_1 of neurons at neuromuscular junctions, both locally and distally (via the bloodstream), and enables the L chain to enter the cytoplasm of the neuron. The tetanospasmin is then transported intra-axonally at 75–250mm/day in a retrograde manner to the cell body in the ventral horns of the spinal cord and the motor nuclei of cranial nerves and then, via trans-synaptic spread, to other neurons within the CNS (Fig. 25.2). Within the neurons tetanospasmin acts as a zinc-dependent protease that cleaves synaptobrevin, a protein component of synaptic vesicles,[2] and prevents release of neurotransmitters at the presynaptic membrane.

The predominant adverse effect is disinhibition of spinal cord reflex arcs as a result of interference with the release of the neurotransmitters glycine and ?-aminobutyric acid (GABA) from presynaptic inhibitory Renshaw cells and 1a fibres of a motor neurons. Excitatory reflexes, freed from inhibition, thus lead to multiple, intense muscle spasms. Tetanospasmin also interferes with presynaptic acetylcholine release at the neuromuscular junction (similar to the effect of botulinum toxin; see below) and disinhibits sympathetic reflexes at the spinal level, producing autonomic dysfunction.

There are no specific gross or histologic abnormalities in tetanus. Any changes described in fatal cases reflect terminal hypoxia and autonomic dysfunction.

PREVENTION

Tetanus is a preventable disease. Generally, concentrations of antibody to tetanospasmin as low as 0.01IU/ml are regarded as protective against clinical tetanus, although cases have occurred in patients who have antibody concentrations at least 10-fold higher than this. Active immunization with tetanus toxoid is extremely effective. A primary series of three doses of tetanus toxoid given in infancy, either with diphtheria toxoid and acellular or whole cell pertussis (DTaP or DTP) or diphtheria toxoid alone (DT), with a booster at school entry, is virtually 100% effective for 5–10 years. Another dose should be given to school leavers. Five doses of vaccine are now considered to give adequate immunity and routine boosters every 10 years are not recommended. Neonatal tetanus can be prevented by ensuring that all pregnant women are immune. Owing to lack of a primary course of vaccination, many elderly individuals do not have protective levels of tetanus antibodies.[3]

The need for both active and passive immunization against tetanus, with toxoid and specific human tetanus immunoglobulin (HTIG)[4] should be reviewed after any injury that brings an individual to medical attention (Table 25.1).

Clean, minor wounds do not need any special treatment. Previously nonimmunized persons over 7 years of age should receive a three dose series of Td, the first two doses 4–8 weeks apart and the third after 6–12 months. Although protocols suggest that Td should be given if the patient has not previously completed a primary series or it is more than 10 years since the last dose of tetanus toxoid, there is little justification for any boosting if the individual has ever

received five doses of toxoid.[5] All other wounds, including frostbite, burns and others, should be considered to render the patient prone to tetanus. Foreign bodies and ischemic tissue should be removed. If the patient has not received a primary series then Td and HTIG (250 units intramuscularly), or equine tetanus antitoxin if HTIG is

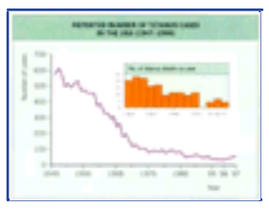

Figure 25-1 Reported number of tetanus cases in the USA (1947–97).

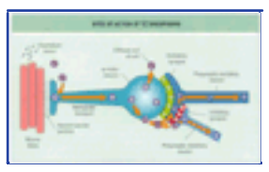

Figure 25-2 Sites of action of tetanospasmin. Tetanospasmin (TS) is produced by *Clostridium tetani* at the site of the wound and binds and internalizes at the neuromuscular junction into the a motor neuron. It then travels by retrograde axonal flow to the cell body and diffuses out into the synapses and extracellular space of the CNS. It enters other neurons and travels further into the CNS. Its major effect is to inhibit transmitter release from the glycinergic presynaptic inhibitory neuron but it can also inhibit release of transmitters at the excitatory synapses and of acetylcholine at the neuromuscular junction.

TABLE 25-1 -- Recommendations for use of tetanus prophylaxis in wound management.

RECOMMENDATIONS FOR USE OF TETANUS PROPHYLAXIS IN WOUND MANAGEMENT				
History of tetanus toxoid administration	**Clean, minor wounds**		**All other wounds**	
	Tetanus toxoid*	**Immunoglobulin**	**Tetanus toxoid***	**Immunoglobulin**
Unknown or less than three doses	Yes and proceed with basic immunization	No	Yes and proceed with basic immunization	Yes (250IU HTIG or 3000IU equine tetanus antitoxin)

Three or more doses	No, unless >10 years since last dose	No	No, unless >5 years since last dose	No

*Administered as Td (i.e. low dose of diphtheria toxoid) in adults

not available within 24 hours, should be given. Patients who have previously received five or more doses of vaccine probably need no immunization although some countries (notably the USA, many European countries and Australia) still recommend that a Td booster be given if it is more than 5 years since the last dose of tetanus toxoid.

CLINICAL FEATURES

Although tetanus can occur at any age, those over 60 are at greatest risk in the developed world since they have lowest immunization levels;[3] elderly women are at greatest risk since they are less likely to have been immunized during earlier military service.

The incubation period to the first symptom ranges from 1 day to several months but most cases start between 3 and 21 days after an acute injury. There is a correlation between the distance of the injury from the CNS and the duration of the incubation period. The time between the first symptom and the first reflex spasm is termed the 'period of onset'.

There are four clinical forms of tetanus: neonatal disease and localized, cephalic and generalized tetanus, depending on the predominant site of toxin action.

Localized tetanus consists of fixed muscle rigidity and painful spasms, sometimes lasting weeks or months, confined to an area close to the site of the injury. It is rare and generally mild but may herald generalized tetanus. Cephalic tetanus is a particular form of localized tetanus associated with wounds to the head or face or with

Figure 25-3 Facial spasm and risus sardonicus in a Filipino patient who has tetanus.

chronic otitis media, and manifested by atonic palsies involving the motor cranial nerves. The incubation period is often only 1–2 days and generalized tetanus may follow.

Generalized tetanus (which is by far the most common form) typically starts with rigidity and spasm of the masseter muscles, causing trismus or lockjaw and the characteristic risus sardonicus — a grimace through clenched teeth and closed mouth with wrinkled forehead and raised eyebrows (Fig. 25.3). Other muscles, first in the neck, then the thorax, back and extremities, become rigid and go into spasms, producing opisthotonos, abdominal rigidity and apnea. Tetanospasms are intermittent, irregular and unpredictable, although they are often triggered by external stimuli, sometimes very trivial such as a sudden noise or puff of cold air, or even the internal stimulus of a distended bladder or bowel. Each spasm is sudden, painful and generalized, resulting in opisthotonos, leg extension and arm flexion; pharyngeal spasm causes dysphagia and spasm of the glottis may cause immediate asphyxiation and death. Cognitive functions are not affected. Severe tetanus is accompanied by abnormalities of the autonomic nervous system, including hypo- or hypertension, arrhythmias and flushing.

Neonatal tetanus typically starts with poor sucking and irritability, followed by trismus and tetanospasms. It has a higher death:case ratio than tetanus at other ages.

With intensive care the death rate from tetanus (which is due to respiratory dysfunction or autonomic cardiovascular instability) may be as low as 10–20%, with higher rates in infants and in the elderly. A rating scale for the severity and prognosis of tetanus (Table 25.2) may be used. In general, the more rapid the evolution of symptoms and signs, the worse the prognosis but the belief that a short incubation period leads to a worse prognosis has been challenged.[6]

Complications related to spasms include vertebral and long bone fractures, glottic obstruction and asphyxia, and intramuscular hematomas. Rhabdomyolysis is common in generalized tetanus. Other complications are those related to general debility and prolonged intensive care.

Strychnine poisoning is the only true mimic of tetanus although there are several other diseases that may overlap to some extent. Strychnine poisoning develops more rapidly than tetanus and there is usually no muscle rigidity between spasms; serum analysis for strychnine should be performed in suspect cases. Other causes of trismus include dystonic reactions to phenothiazines, which may be ruled out by administration of benztropine 1–2mg intravenously or diphenhydramine 50mg intravenously, and dental abscesses. Tetany

TABLE 25-2 -- Rating scale for severity and prognosis of tetanus.

RATING SCALE FOR SEVERITY AND PROGNOSIS OF TETANUS		
Score 1 point for each of the following		
• Incubation period <7 days		
• Period of onset <48 hours		
• Acquired from burns, surgical wound, compound fracture, septic abortion		
• Narcotic addiction		
• Generalized tetanus		
• Pyrexia >104°F (40°C)		
• Tachycardia >120 beats/min (>150 beats/min in neonates)		
Total score provides indication of severity and prognosis		
Score	**Severity**	**Mortality**
0–1	Mild	<10%
2–3	Moderate	10–20%
4	Severe	20–40%
5–6	Very severe	>50%
NB: Cephalic tetanus is always scored as severe or very severe, and neonatal tetanus as very severe.		

from hypocalcemia or alkalosis tends to affect the extremities rather than the axial muscles and there is no trismus.

DIAGNOSIS

The diagnosis of tetanus depends upon clinical features, and epidemiologic history and laboratory tests are usually unhelpful. There is often a moderate leukocytosis but the CSF is normal, except for increased pressure. Neither electroencephalography nor electromyography is helpful. Occasionally, characteristic Gram-positive bacilli with terminal or subterminal spores may be visualized in aspirates from a wound but anaerobic cultures are rarely positive and the organism may be grown from

wounds in the absence of disease.

MANAGEMENT

A guide to the general management of the patient with tetanus has been published.[7] Human tetanus immunoglobulin 500IU as a single intramuscular injection[4] should be given at the time of diagnosis in order to prevent further circulating toxin from reaching the CNS. The use of intrathecal HTIG to neutralize toxin that has entered but is not yet fixed to nervous tissue has not been consistently beneficial and is not routinely recommended; intrathecal injections are potent stimuli for tetanospasms.

The source of toxin should be removed by wound debridement and removal of foreign bodies. Only vegetative forms of *C. tetani* will be susceptible to antibiotics. Therapy with metronidazole (15mg/kg intravenously followed by 20–30mg/kg/day intravenously for 7–14 days) should be used to eradicate *C. tetani*, even though antibiotics are not likely to penetrate into the anaerobic conditions that support growth of the organism.[8] Penicillin is theoretically less suitable (it acts as a central GABA antagonist) although it is still used in much of the world.

A benzodiazepine (midazolam administered intravenously at 5–15mg/h is suitable) should be used to produce sedation, decrease rigidity and control spasms. Airway protection during spasms is paramount. If the patient's ventilation is compromised then he or she should be sedated, intubated, provided with a soft nasal feeding tube and transferred to a quiet and darkened area. A tracheotomy may be needed. If benzodiazepines do not adequately control the spasms then the patient will need long-term neuromuscular blockade.

TABLE 25-3 -- Characteristics of groups of *C. botulinum* and the toxins that produce human disease.

CHARACTERISTICS OF GROUPS OF *C. BOTULINUM* AND THE TOXINS THAT PRODUCE HUMAN DISEASE				
Group	**Toxins produced**	**Proteolysis**	**Heat resistance of spores**	**Disease severity**
Group I	A, B, F	Yes	High	Severe
Group II	B, E, F	No	Low	Less severe

The management over the next few weeks is that of any ventilated patient plus specific therapy for autonomic nervous system complications and control of spasms.[9] Sympathetic hyperactivity is treated with combined a- and ß-blockade or morphine. Intrathecal baclofen has been shown to be effective in controlling muscle rigidity.[10] Epidural blockade with local anesthetics may be needed. Hypotension requires fluid replacement and dopamine or norepinephrine (noradrenaline) administration. Parasympathetic overactivity is rare but if bradycardia is sustained then a pacemaker may be needed.

Clinical tetanus does not induce immunity against further attacks of the disease and all patients should be fully immunized with tetanus toxoid (in the form appropriate for their age) during convalescence.

BOTULISM

Botulism is caused by neurotoxins (antigenic types A, B, E and F cause human disease) produced by groups I or II of *Clostridium botulinum*, an anaerobic, spore-forming bacillus (Table 25.3). There are three forms of the illness: food-borne botulism from ingestion of preformed toxin; wound botulism; and botulism from intestinal colonization, usually, but not universally, in infants.[11] [12]

EPIDEMIOLOGY

All three forms of botulism occur throughout the world but for food-borne botulism, the causative strains, the responsible foods and the resulting illness vary in different geographic areas.

Accurate data about the incidence of botulism are difficult to obtain but it is estimated that, in France, there were about 300 food-borne outbreaks between 1979 and 1988, and in the USA there were 474 outbreaks (a large proportion from Alaska) involving nearly 1050 persons between 1950 and 1990. Outbreaks were most frequent in the summer or autumn. In the UK the incidence is much lower than in Europe or the USA, with only nine outbreaks between 1922 and 1988. In 1989 the largest ever outbreak of food-borne botulism in the UK affected 27 people who had eaten hazelnut yoghurt. The illness was caused by type B toxin formed by bacteria growing in canned hazelnut conserve used to flavour the yoghurt and that had been inadequately heat treated.[13]

Nearly 1000 cases of infant botulism (roughly equally divided between type A and type B *C. botulinum*) were reported in the USA between 1976 and 1990. Almost half the cases were reported from California, with an incidence of 7 per 100,000 live births. Cases occur most frequently in the second month of life and 95% of cases are in infants less than 6 months old.[11]

Most cases of food-borne botulism are associated with home-preserved meats, fish and vegetables but the common vehicles are often idiosyncratic to a country or culture.[14] In the USA (apart from Alaska), Spain, Italy and China most cases follow consumption of home-preserved vegetables (home-canned asparagus, beans and peppers in the USA, home-fermented bean curd in China)

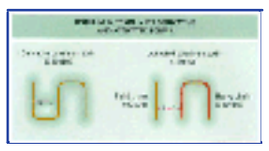

Figure 25-4 Botulinum toxin in its derivative and activated forms.

contaminated with type A *C. botulinum*. In Alaska, Japan, Canada and Scandinavia cases are usually due to type E toxin and follow eating fermented foods or preserved fish products; in central continental Europe cases typically arise from home-cured meats and are caused by nonproteolytic strains of type B *C. botulinum*. Commercially prepared foods are only rarely implicated. There is a significant association between infant botulism and ingestion of bee honey.

Occasionally, botulism can follow wound infections with *C. botulinum*. The wounds are often compound fractures or penetrating wounds; cases have also been reported in intravenous drug users[15] and complicating sinusitis in chronic cocaine sniffers.

PATHOGENESIS AND PATHOLOGY

In food-borne botulism there is ingestion of preformed toxin, but in other forms of the syndrome the toxin is produced in vivo and released when vegetative cells lyse. The toxin is not released from spores. Botulinum toxins are the most poisonous substances known to man and are synthesized as a polypeptide of molecular weight 150–165kDa, which is then broken into an H chain of about 100kDa and an L chain joined by a disulfide bond (Fig. 25.4). The mechanism of action is similar or identical to that of tetanospasmin, resulting in cleavage of synaptobrevin and inhibition of release of acetylcholine at peripheral cholinergic synapses.[2] The H chain of the toxin binds rapidly to the membrane of the presynaptic a motor neuron and then some or all of the toxin molecule translocates through the membrane. Finally, there is a slow paralytic step that may partially depend upon temperature and activity of the neuron. The process is irreversible and the synapse is permanently damaged; recovery of function depends upon the budding and growth of new presynaptic end-plates.

Infant botulism[16] results from colonization of the infant's gastrointestinal tract with as many as 10^8 proteolytic *C. botulinum* organisms per gram of feces. The mechanisms that relate to colonization and toxin absorption from the infant gut are unclear, and both the organism and toxin may sometimes continue to be excreted in the feces for several months after the illness has resolved. Wound botulism typically results from soil contamination of severe head wounds, as occurs in warfare.

Death results from respiratory paralysis and there are no specific pathologic findings on gross or histologic examination in any of the forms of botulism.

PREVENTION

The key to the prevention of botulism is adequate processing and storage of food to destroy spores and prevent their germination and

toxin production. Spores are not killed by boiling at 212°F (100°C) but are destroyed by heating at 250°F (121°C) for 2.5 minutes (the type of temperature achieved under pressure processing of low-acid foods). Once toxin is formed, it can be inactivated by boiling or heating at 176°F (80°C) for 30 minutes.

Toxin production by strains of *C. botulinum* is inhibited at a pH below 4.6, in saline and at low temperatures (below 38°F (3.3°C)); the respective values differ somewhat for different strains. Commercial canneries pay particular attention to less acid (pH >4.6) fruit and vegetables; the canning and curing of meats relies on a reduced heat treatment to kill vegetative bacteria and sodium chloride and nitrite to inhibit spore growth. Vacuum packaging of food may encourage the growth of anaerobes and there are concerns that botulinum toxin may be produced before spoilage is obvious. Toxin has been detected in mushrooms and coleslaw kept in modified atmosphere packaging. This should be preventable by piercing the packaging of fresh vegetables with air holes to allow sufficient oxygen to be present.

Honey has been associated with infant botulism and honey is not recommended as a food for infants less than 1 year old.

CLINICAL FEATURES

Food-borne botulism usually develops 12–36 hours after ingestion of the toxin, although the interval may be as short as 6 hours or as long as 10 days. Patients who have type E toxin-mediated disease tend to have shorter, and those with type B tend to have longer incubation periods. Wound botulism occurs at a mean of 7.5 days (range 4–18 days) after the injury.[17]

Typically, botulism first affects the muscles supplied by the cranial nerves with disturbances of vision and difficulties in swallowing and speech followed by descending weakness of muscles of the trunk and extremities that is bilateral but not necessarily symmetric. Cardiovascular, gastrointestinal and urinary autonomic dysfunction may follow. The presentation may be related to the type of toxin: autonomic symptoms occur earlier and are more prominent in intoxication with type B and E toxins.

Common presenting symptoms are diplopia, dysphagia, dysarthria, dry mouth and fatigue (Table 25.4). [18] Ptosis and ophthalmoplegia are common physical signs, together with facial weakness and a decreased gag reflex. The pupils are dilated or fixed in less than 50% of cases. Frequently, there is weakness of the extremities, although deep tendon reflexes are usually normal. Patients are usually afebrile and have no

TABLE 25-4 -- Frequency of symptoms in types A, B and E food-borne botulism.[18]

FREQUENCY OF SYMPTOMS IN TYPES A, B AND E FOOD-BORNE BOTULISM			
Symptoms	**Type A disease (% of cases)**	**Type B disease (%)**	**Type E disease (%)**
Dysphagia	25–96	77–100	63–90
Dry mouth	26–83	96–100	55–88
Diplopia	50–90	57–100	85
Dysarthria	25–100	69–100	50
Fatigue	8–92	69–100	Not known
Weakness of arm	16–86	64–86	Not known
Constipation	73	17–100	25–38
Weakness of leg	16–76	64–86	Not known
Dyspnea	35–91	34	88
Vomiting	70	50–100	88–100
Dizziness	8–86	30–100	63
Diarrhea	35	8–14	10
Paresthesiae	20	12–14	Not known

sensory deficits. Patients who have wound botulism have a similar presentation but acute gastrointestinal symptoms are lacking.

Constipation is the first sign of infant botulism, with neurologic signs developing either concurrently or up to several weeks later. The neurologic signs progress in a similar fashion to those in other forms of botulism but they may be overlooked by the parents, who merely note the infant is irritable, lethargic or unable to suck. There is a wide range of clinical illness associated with infant botulism; 50% of cases develop ventilatory failure. Although some studies suggested that it was responsible for 5% of cases of the sudden infant death syndrome (SIDS) in California, no evidence of botulism has been found in any SIDS cases elsewhere in the USA.

COMPLICATIONS

The severity and duration of food-borne botulism are related to the amount of toxin ingested. Respiratory failure occurs in 20–35% of patients; the mean duration of respiratory support is 7 weeks for those requiring mechanical ventilation. Recovery from botulism is usually complete but persistent dysphagia, diplopia and prolonged weakness are rare complications of severe cases.[19] [20]

There has been a steady decline in mortality associated with botulism over the past century; the rate was about 70% in the period 1910–19 and about 9% during 1980–89. The mortality is higher in type A disease than in type B.[21]

The prognosis for infants hospitalized with botulism and given meticulous supportive care is very good, with less than 1.3% case fatality and full recovery.

DIFFERENTIAL DIAGNOSIS

The diseases most often confused with botulism are Guillain-Barré syndrome (particularly the Miller-Fisher variant confined to the cranial nerves), myasthenia gravis and the Eaton-Lambert myasthenic syndrome, other forms of food poisoning and tick paralysis. Guillain-Barré syndrome frequently has sensory complaints and the Miller-Fisher syndrome includes prominent ataxia. The myasthenias lack autonomic dysfunction and are less fulminant than botulism. In tick paralysis a careful search will reveal the *Dermacentor* tick still attached.

DIAGNOSIS

Routine laboratory tests are not helpful in the diagnosis of botulism. The diagnosis is best confirmed by assay of botulism toxin in the patient's blood, gastric washings or feces by means of toxin neutralization tests in mice. Toxin may also be demonstrated in the incriminated food. This test takes anything from 6 to 96 hours to perform and the initial diagnosis must therefore be based on clinical findings.

Clostridium botulinum may be cultured or the toxin detected by an enzyme-linked immunosorbent assay in the patient's feces, particularly in infant botulism and other cases resulting from intestinal colonization.

Electrophysiologic studies show normal nerve conduction velocities but the electromyogram is often abnormal with facilitation (an incremental increase) of the M-wave amplitude when high-frequency (20–50 per second) repetitive stimuli are applied. These abnormalities may persist for several months after the onset of illness.

MANAGEMENT

Elimination of any unabsorbed toxin from the gastrointestinal tract should be encouraged in patients who have suspected botulism. Administration of an emetic or gastric lavage is recommended if ingestion of the suspect food has occurred within the preceding few

hours and (unless there is a paralytic ileus) purgation or high enemas should be administered even several days after food ingestion.

The mainstay of therapy for botulism is meticulous supportive care. Patients should be admitted to an intensive care unit and their respiratory function monitored by repeat vital capacity measurements. Intubation should be performed if vital capacity falls below 12ml/kg.

Equine antitoxin, containing antibodies to types A, B and E toxin, is available through public health services in many countries. There are few data concerning its use in humans but it is clearly effective in experimental animals. It has to be given as early as possible in the course of the illness but its use needs careful consideration in view of the risk of serious anaphylaxis or serum sickness. A test dose is administered into the skin or the conjunctiva. If there is no hypersensitivity, then one vial is given intravenously and one vial intramuscularly for an average adult; further doses may be given 2–4 hours later if the symptoms persist. In view of the good prognosis in infant botulism, the risks of equine antitoxin probably preclude its use. The potential role of human or monoclonal botulism immune globulin is still unclear in infant botulism.

Although guanidine hydrochloride (which increases release of acetylcholine from nerve terminals in response to nerve stimulation) has theoretical advantages, there was no improvement in recovery in a controlled study of patients with type A disease. Guanoxan and 3,4-diaminopyridone are investigational. Antibiotics do not help except as part of meticulous debridement of the wound in wound botulism.

The relevant public health authorities should be notified promptly of a suspected case of botulism so that the necessary investigation may be conducted.

DIPHTHERIA

EPIDEMIOLOGY

The incidence of diphtheria has fallen dramatically in the technically developed world over the past 50 years but the disease remains endemic in many parts of the Third World, including India, Nigeria, Brazil, Indonesia and the Philippines. [22] Between 1990 and 1995 there was a considerable epidemic of diphtheria in Russia and other parts of the former Soviet Union; nearly 50,000 cases occurred, including some in tourists and other visitors.[23] [24]

Spread of *Corynebacterium diphtheriae* takes place via respiratory droplets or by direct contact with infected respiratory secretions and 3–5% of healthy persons may harbor the organism in their throats. Epidemics have also resulted from contaminated milk. Skin infections are important reservoirs of infection and sources of dissemination of diphtheria in tropical countries and among alcoholic persons in urban areas of the West; person-to-person spread by exudate from infected skin lesions is relatively easy.[25] Three biotypes (mitis, gravis and intermedius), producing different quantities of toxin, can be differentiated. Occasional cases of diphtheria are caused by toxigenic strains of *Corynebacterium ulcerans*, which is usually transmitted by unpasteurized dairy products or contact with farm animals.[26]

Although immunization with toxoid does have a dramatic effect upon the incidence of diphtheria, the disease incidence started to decline well before the widespread use of immunization and other factors are also important. Toxoid after all only attenuates the effects of toxin and does not prevent colonization with the organism; carriage rates should therefore remain high and there should be frequent epidemics among the relatively large proportion of individuals with subprotective antitoxin levels. The evidence, however, points to an extremely low carrier rate and disease is very rare in most developed countries. It is still unclear why this should be so.

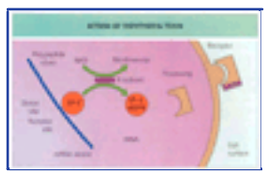

Figure 25-5 Action of diphtheria toxin. The binding subunit attaches to the cell surface and the toxin enters the cell. After endocytosis the toxin is cleaved and the active A subunit is released. This then catalyzes the cleavage of nicotinamide adenine dinucleotide (NAD) and the transfer of adenine diphosphate ribose (ADPR) to EF-2. EF-2 is essential for ribosomal reactions at the acceptor and donor sites, whereby the mRNA code is transferred via tRNA to an amino acid sequence and the building of a polypeptide chain. EF-2-ADPR is incapable of adding amino acids to a polypeptide chain and protein synthesis is stopped.

PATHOGENESIS AND PATHOLOGY

Corynebacterium diphtheriae is not very invasive and organisms remain in the superficial layers of the respiratory mucosa or skin. Its major virulence is the result of the exotoxin, which inhibits protein synthesis in mammalian cells. Exotoxin production by *C. diphtheriae* is the result of a lysogenic ß-phage that carries the *tox*+ gene into the bacterium. Toxin production in a phage-bearing strain depends upon genetic and nutritional factors, especially a deficiency of iron in the environment. The toxin is secreted as a 62kDa polypeptide comprising two segments: the B segment binds to specific receptors on the cell surface and, after endocytosis, the toxic segment A is released by proteolytic cleavage. Segment A catalyzes the cleavage of nicotinamide adenine dinucleotide leading to ribosylation and inactivation of elongation factor-2 (EF-2), which is necessary for the interaction of mRNA and tRNA. Its inactivation prevents the addition of further amino acids to the developing polypeptide chain (Fig. 25.5).[27] The toxin is very potent; a single molecule can inactivate all the EF-2 in a cell and stop protein synthesis within a few hours.

The toxin affects all cells but the major effects are local in the vicinity of bacterial growth and distant on the heart, nerves and kidneys.

Within a few days of respiratory infection the toxin produces a local necrotic coagulum of fibrin, dead epithelial cells and cellular infiltrate, which forms the adherent pseudomembrane. This gray-green or black membrane can be local or extend widely to cover the entire pharyngeal or tracheobronchial mucosa. There is a marked underlying soft tissue edema and regional lymphadenitis producing the bull neck appearance. Palatal paralysis is an early local effect of the toxin.

Myocarditis, renal tubular necrosis and demyelination and axon degeneration within cranial or peripheral nerves are prominent features of the more severe infections with *C. diphtheriae*.

PREVENTION

Diphtheria can be prevented by active immunization with formalin-detoxified diphtheria toxin (toxoid). Mass immunization with four

or five doses of diphtheria toxoid-containing vaccine is given to infants/children in most developed countries but immunity declines over time and 20–80% of adults have antibody titers below the level of 0.01IU/ml that is considered protective. Indeed, epidemic diphtheria may occur when more than 70% of a population have antitoxin titres below 0.01IU/ml. In order to maintain population immunity to diphtheria a booster dose (usually given with tetanus toxoid) is recommended every 10 years in adults. Persons over age 7 years have a higher incidence of constitutional symptoms to the concentration of diphtheria toxoid in infant vaccines and hence an adult vaccine (Td), with low dose purified diphtheria toxoid, is used. The resurgence of diphtheria in the former Soviet Union emphasizes the need to ensure that population immunity is maintained by booster immunization of adults.[23] [28] (See also Chapter 178).

CLINICAL FEATURES

Symptoms of diphtheria may be divided into two groups: those that occur locally as a result of noninvasive infection of the respiratory tract or skin, and those that occur at distant sites secondary to dissemination of diphtheria toxin.

After an incubation period of 2–4 days the onset of diphtheria is usually insidious with a mild sore throat and fever; local symptoms and signs of inflammation may then develop at various sites within the respiratory tract. Infection limited to the anterior nares is generally a mild disease, with a thin blood-stained or purulent nasal discharge and a delicate membrane on the nasal mucosa. Toxin absorption from the nasal mucosa is poor and there are usually few systemic symptoms or toxin-mediated problems. The most common site for clinical diphtheria is the posterior structures of the mouth and pharynx. The membrane develops typically on the tonsil(s) and spreads locally. The membrane is initially translucent, thin and white but rapidly becomes thicker and develops a gray-green color with patches of necrosis. It is adherent to the underlying tissues and its removal produces bleeding. The patient is feverish and there are enlarged lymph glands in the neck. In severe cases the membrane spreads rapidly over the uvula, palate, oropharynx and nasopharynx; the extent of the membrane correlates with the severity of the local and systemic symptoms. In the most severe cases there is a weak thready pulse, profound exhaustion and muscle weakness. Severe cervical lymphadenopathy and edema of the anterior cervical tissues creates the bull neck appearance and may cause respiratory embarrassment.

Spread of the membrane downward leads to laryngeal diphtheria; the voice becomes hoarse and there is a bovine cough and stridor. The patient becomes cyanosed and anxious and requires urgent intubation and removal of the membrane if death is to be prevented.

In tropical areas *C. diphtheriae* is a cause of skin infections, which may be impetiginous or appear as chronic ulcers with a grayish slough or membrane. Outbreaks of cutaneous diphtheria have been recorded among vagrants and other impoverished, homeless groups.[29] Cutaneous infection rarely causes clinical disease but is an important reservoir for the organism.

It is the later effects of diphtheria toxin on the heart and the nervous system that produce the most severe complications. Some degree of cardiac toxicity is detectable in most cases of diphtheria with a widespread membrane and about 50% of those with a moderate local exudate. Myocarditis characteristically begins during the first 1–2 weeks of the illness, often as the local respiratory disease is settling. First-degree heart block or ST-T wave changes on the electrocardiogram and raised serum aspartate aminotransferase concentrations develop early and warn of more severe forms of heart block or life-threatening arrhythmia. Myocarditis is a poor prognostic sign, increasing the mortality 3- or 4-fold. Bundle branch block or complete heart block has a mortality rate of up to 90% and the survivors are often left with conduction

defects.

Some form of neuritis occurs in between 10% and 20% of patients who have diphtheria and in up to 75% of those who have severe primary disease. Bilateral paralysis of the palate and posterior pharyngeal wall often appears in the first week of the illness and produces rhinolalia, dysphagia and nasal regurgitation of swallowed liquids. Other manifestations of neuritis are oculomotor and accommodation defects, facial paralysis and a peripheral motor neuropathy. These are usually delayed effects, developing 5 weeks or more after the onset of diphtheria. The degree of dysfunction is variable but footdrop is particularly common. Sensory neuropathies are rare complications of diphtheria. Although it may be slow, recovery of diphtheritic neuropathy is usually complete.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes infectious mononucleosis, streptococcal tonsillitis and acute epiglottitis. The tonsillar exudate of infectious mononucleosis is creamy in color, does not extend beyond the tonsil and does not produce bleeding if removed. Streptococcal pharyngotonsillitis is associated with more severe local symptoms and a higher fever and epiglottitis is more acute in onset and is not associated with a local membrane.

DIAGNOSIS

The need to initiate antitoxin therapy as soon as possible means that the diagnosis of diphtheria needs to be presumptive and made on clinical grounds. It must be suspected whenever there is a membrane in the throat or nares. Many individuals have diphtheroids in their throats and hence microscopy for *C. diphtheriae* is unreliable; confirmation of the diagnosis of diphtheria depends upon isolation of a toxin-producing strain of *C. diphtheriae*. The organism can be cultured on selective media and isolates tested for toxin production by inoculation of guinea pigs or by the Elek's plate method (immunoprecipitation of toxin in agar cultures by overlaid diphtheria antitoxin-containing filter paper strips). Polymerase chain reaction testing for the *tox* gene can be performed at the Centers for Disease Control and Prevention in the USA and at central public health laboratories in other countries.

MANAGEMENT[30]

Administration of diphtheria antitoxin (DAT) is the crucial therapeutic measure in diphtheria. It will only neutralize extracellular toxin and hence needs to be administered as early as possible, often before the disease can be microbiologically confirmed. It is an equine antiserum, however, and all patients must be tested for hypersensitivity to horse protein; this is done by instilling diluted DAT into the conjunctival sac or injecting 0.1ml of a 1:100 dilution subcutaneously, while taking appropriate precautions for anaphylaxis. Even if hypersensitivity is shown, DAT will need to be administered but only after desensitization procedures. The therapeutic dose and route of administration of DAT depend upon the extent of the disease. The recommended doses (the minimum therapeutic dose has never been determined) are as follows: for mild disease of less than 48 hours' duration, 20,000–40,000IU (or 500IU/kg body weight) given half intramuscularly and half by intravenous infusion over 30 minutes; for more severe disease or illness more than 3 days old, 80,000–120,000IU (up to 2500IU/kg) by intravenous infusion.

Erythromycin (2g/day for 6 days, then 1g/day for 8 days (50% of these dosages for children less than 6 years old)) or procaine penicillin (1.2 million IU/day for 6 days, then 600,000IU/day for 8 days (50%

of these doses for children less than 6 years old)) should be administered to eradicate *C. diphtheriae* and terminate toxin production. The patient should be kept in strict isolation during this period and until three throat swabs taken after therapy are culture negative. Patients with diphtheria due to *C. ulcerans* do not need isolation since person-to-person spread has never been documented. Supportive measures are also important. Patients should be confined to bed and their electrocardiogram monitored daily until the danger of myocarditis has passed; those who develop cardiac toxicity need full support and effective therapy for any conduction abnormalities. Corticosteroid therapy does not prevent myocarditis or neuritis in diphtheria.[31] Respiratory monitoring needs to be vigilant and early tracheotomy and intubation is sensible for those who have laryngeal diphtheria.

Because clinical infection does not always induce immunity, a course of toxoid should be commenced at the end of the first week of illness and completed during convalescence.

Those exposed to a case of diphtheria who have been fully immunized need to have throat cultures taken and to be observed for 7 days. Those with incomplete or unclear immunity should be started on erythromycin (7 days of oral therapy) or benzathine penicillin (a single intramuscular dose of 1.2 million units) and a course of toxoid. The antibiotic can be stopped if the cultures are negative; those initially carrying the organism need to have eradication confirmed 2 weeks after completing therapy.

Chapter 26 - Transmissible Spongiform Encephalopathies of Humans and Animals

Sarah J Tabrizi
John Collinge

The prion diseases or transmissible spongiform encephalopathies are a group of closely related transmissible neurodegenerative conditions of humans and animals. In recent years prion diseases have captured the public attention with the emergence of the bovine spongiform encephalopathy (BSE) epidemic in Europe and more recently with the appearance of a novel phenotype of Creutzfeldt-Jakob disease (CJD), variant CJD (vCJD) in humans, which is experimentally linked to dietary exposure to BSE.

The nature of the transmissible agent in these diseases has been the subject of intense controversy. The understandable initial assumption that the agent must be some form of virus was challenged by the failure to directly demonstrate such a virus (or an immunological response to it) and by the remarkable resistance of the transmissible agent to treatment expected to inactivate nucleic acids (such as ultraviolet radiation or treatment with nucleases). Such findings had led to suggestions as early as 1966 by Alper and others that the transmissible agent may be devoid of nucleic acid[1] [2] and led Griffith to suggest in 1967 that the transmissible agent might be a protein. [3] Progressive enrichment of brain homogenates for infectivity resulted in the isolation of a protease-resistant sialoglycoprotein, designated the prion protein (PrP), by Prusiner and co-workers in 1982.[4] This protein was the major constituent of infective fractions and was found to accumulate in affected brains and sometimes to form amyloid deposits. The term prion (from *pr*oteinaceous *in*fectious particle) was proposed by Prusiner in 1982[5] to distinguish the infectious pathogen from viruses or viroids. Prions were defined as 'small proteinaceous infectious particles that resist inactivation by procedures which modify nucleic acids'.

The unifying hallmark of the prion diseases is the aberrant metabolism of the PrP, which exists in at least two conformational states with different physicochemical properties. The normal form of the protein, referred to as PrP^{C} , is a highly conserved cell surface protein attached via a glycophosphatidyl inositol anchor (Fig. 26.1). It is expressed in a wide range of cell types and particularly in neuronal cells. PrP^{C} is a sialoglycoprotein of molecular weight 33–35kDa with a high content of a-helical secondary structure that is sensitive to protease treatment and soluble in detergents (Fig. 26.1). The diseaseassociated isoform, referred to as PrP^{Sc} , is found only in infected brains as aggregated material, is partially resistant to protease treatment and insoluble in detergents and has a high content of ß-sheet secondary structure.

Due to its physicochemical properties, the precise atomic structure of the infectious particle or prion is still undetermined but considerable evidence argues that prions are composed largely, if not entirely, of an abnormal isoform of PrP. According to the protein-only hypothesis of prion replication, PrP^{Sc} recruits PrP^{C} into the infectivity-associated isoform, an event that is central to prion propagation. Prion propagation may involve recruitment of an alternately folded form of PrP^{C} , ß-PrP, into such aggregates, the process being driven thermodynamically by intermolecular interactions[6] (Fig. 26.2).

EPIDEMIOLOGY

Animal prion diseases

Scrapie is the prototypic prion disease (Table 26.1). It has been recognized as an enzootic disease of sheep and goats for more than 250 years. Present in many countries, its prevalence in the UK has been estimated as 0.5–1% of the sheep population. The etiology of natural scrapie has been the subject of intense debate for many years, but it is now clear that it is an infectious disease,[7] for which susceptibility is genetically modulated by the host.

Following its discovery in 1985, BSE reached epidemic proportions, with over 180,000 confirmed cases in UK cattle and much smaller numbers in many other European countries. It has been estimated that up to 1 million cattle were infected with BSE in the UK.[8] Smaller epidemics have also been described in Switzerland, Ireland, Portugal and France and in September 2001 the first case was reported in Japan.[9] In May 2003, cases were reported in Western Canada. Epidemiologic studies point to contaminated offal, used in the manufacture of meat and bone meal and fed to cattle, as the source of prions responsible for BSE.[10] Because the UK has a relatively large sheep population in which scrapie is endemic, it was hypothesized that scrapie-contaminated sheep offal was the initial source of BSE. An alternative view is that BSE prions originated spontaneously in cattle and that infection was subsequently amplified by recycling of infected cattle that had subclinical disease. As sheep were also fed meat and bone meal, it is not unreasonable to expect that a BSE-like disease with characteristics different from conventional scrapie strains might also appear in the sheep population, although there is currently no confirmation that this has occurred. However, this is currently of concern in the countries where BSE is prevalent.

The host range of BSE appears to be unusually wide, affecting many other animal species (Table 26.1). Foodstuffs contaminated with BSE appear to have caused disease in several other animal species in the UK, including feline spongiform encephalopathy (FSE) in domestic cats, exotic ungulates and captive cats in zoos. In addition to these 'natural' infections, BSE has been experimentally transmitted to a wide variety of species. Outbreaks of transmissible mink encephalopathy and chronic wasting disease in captive populations of mink, mule deer and elk in certain regions of the USA have also been attributed to prion-infected foodstuffs, although the origin of infection is less certain in these diseases. Epidemiological studies suggest lateral transmission as the most plausible explanation for the spread of chronic wasting disease in captive populations of Rocky Mountain elk. Chronic wasting disease has also been diagnosed in free-ranging mule deer, Rocky Mountain elk and white-tailed deer from north-central Colorado.

Human prion diseases

The human prion diseases are unique in biology in that they manifest as sporadic, genetic and infectious diseases (Table 26.2). The majority of cases of human prion disease occur sporadically as

Figure 26-1 Structure of the human prion protein. Model of glycosylated human prion protein indicating positions of *N*-linked glycans (blue), the single disulfide bond linking helixes 2 and 3, and the glycosylphosphatidylinositol (GPI) anchor to the outer surface of the cell membrane. *Courtesy of Dr Richard Sessions and Mr Ray Young.*

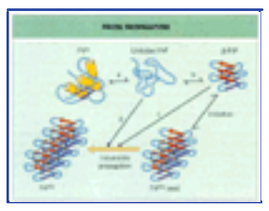

Figure 26-2 Prion propagation. Schematic representation of a possible mechanism for prion propagation. The predominantly a-helical form of the normal prion protein (PrP^{C}) proceeds via an unfolded state (a) to refold into a predominantly ß-sheet form (ß-PrP) (b). Prion replication may require a critical 'seed' size. Further recruitment of ß-PrP (c) or unfolded PrP (d) occurs as an essentially irreversible process. *Courtesy of Prof Tony Clarke and Mr Ray Young.*

TABLE 26-1 -- Animal prion diseases.

ANIMAL PRION DISEASES		
Disease	**Host**	**Etiology**
Scrapie	Sheep and goats	Thought to involve both horizontal and vertical transmission
Transmissible mink encephalopathy	Captive mink	Probably food-borne, although the origin of infectious prions is uncertain
Chronic wasting disease	Captive and free-ranging mule deer and Rocky Mountain elk	Origin unknown There is evidence for horizontal transmission
Bovine spongiform encephalopathy (BSE)	Cattle	Food-borne in the form of contaminated meat and bone meal
Feline spongiform encephalopathy	Domestic and zoo cats	Feed contaminated with bovine spongiform encephalopathy prions
Exotic ungulate encephalopathy	Captive bovidae	Feed contaminated with bovine spongiform encephalopathy prions

Creutzfeldt-Jakob disease (sporadic (s) CJD) at a rate of roughly 1 per 10[6] population across the world, with an equal incidence of disease in men and women. However, very recently, an increased incidence of sCJD has been reported in Switzerland, with a twofold increase in 2001, and figures from the first quarter of 2002 indicated that it continues to rise.[11] These cases are clinically definite sCJD and vCJD was excluded on histopathological and laboratory analysis. Several scenarios have been proposed to account for this increase in sCJD in Switzerland, including improved reporting, iatrogenic transmission and transmission of a prion zoonosis similar to that of CJD which is thought to be caused by exposure to bovine prions. The etiology of sCJD is unknown, although hypotheses include somatic mutation of the PrP gene (referred to as *PRNP*) and the spontaneous conversion of PrP^{C} into PrP^{Sc} as a rare stochastic event. There is a common coding polymorphism at codon 129 of *PRNP* encoding either methionine or valine (Fig. 26.3). Homozygosity at this position predisposes people to the development of sporadic and iatrogenic CJD.[12] [13] Additionally, a *PRNP* susceptibility haplotype has been identified indicating additional genetic susceptibility to sporadic CJD at or near the *PRNP* locus.[14]

Approximately 15% of human prion diseases are inherited with an autosomal dominant mode of inheritance. Inherited human prion diseases have been shown to segregate with more than 30 different missense and insertion mutations in the coding sequence of *PRNP* (see Fig. 26.3).[15] [16] [17] [18] Although the human prion diseases are experimentally transmissible, the acquired forms have, until recently, been confined to rare and unusual situations. For example, kuru was caused by cannibalism among the Fore linguistic group of the Okapa district of the Eastern Highlands in Papua New Guinea.[19] The disease had its origins at the beginning of the 20th century and was the leading cause of death in this population by the middle of the century, killing over 3000 people in the total population of 30,000. Mainly adult women as well as children of both sexes were affected, to give an annual disease-specific mortality of approximately 3%. It is thought that the roughly sevenfold higher incidence of disease in adult women than adult men was the result of higher exposure of women to infectious brain material. Since the cessation of cannibalistic

practices around 1956, the disease has all but died out, with

TABLE 26-2 -- Human prion diseases.

HUMAN PRION DISEASES			
Disease	**Incidence**	**Etiology**	**Age of onset or incubation period and duration of illness**
Sporadic Creutzfeldt-Jakob disease	1 case per 1 million population	Unknown but hypotheses include somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}	Age of onset is usually 45–75 years; age of peak onset is 60–65 years; 70% of cases die in under 6 months
Inherited prion diseases (GSS, FFI, CJD)	10–20% of cases of human prion disease	Autosomal dominant *PRNP* mutation	Onset tends to be earlier in familial CJD compared to sporadic CJD. Can be wide phenotypic variability between and within families
Kuru	>2500 cases among the Fore people in Papua New Guinea	Infection through ritualistic cannibalism	Incubation period 5->40yrs; duration of illness 12 months
Iatrogenic Creutzfeldt-Jakob disease	About 90 cases to date	Infection from contaminated human growth hormone, human gonadotropin, depth electrodes, corneal transplants, dura mater grafts, neurosurgical procedures	Incubation periods of cases from human growth hormone 4–30 years; duration of illness 6–18 months
Variant Creutzfeldt-Jakob disease	128 young adults in the UK and France*	Infection by bovine spongiform encephalopathy-like prions	Mean age of onset 26 years; mean duration of illness 14 months
PrP^{C} , normal form of prion protein; PrP^{Sc} , disease-associated isoform of prion protein; *PRNP*, prion protein gene.			

* to Oct 2002

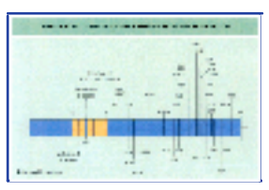

Figure 26-3 Pathogenic mutations and polymorphisms in the human prion protein. The pathogenic mutations associated with human prion disease are shown above the PrP coding sequence. These consist of 1, 2 or 4–9 octapeptide repeat insertions within the octarepeat region between codons 51 and 91, a deletion of 2 octapeptide repeats; and various point mutations causing missense amino acid substitutions. Point mutations are designated by the wild-type amino acid preceding the codon number, followed by the mutant residue, using single-letter amino acid conventions. Polymorphic variants are shown below the PrP coding sequence. Deletion of one octapeptide repeat is not associated with disease.

only a handful of cases currently occurring in older people who were presumably exposed to kuru as young children, indicating an incubation time in these cases of greater than 40 years. Other examples of acquired human prion diseases have resulted from iatrogenic transmission of CJD during corneal transplantation, contaminated electroencephalographic (EEG) electrode implantation and surgical operations using contaminated instruments or apparatus. In addition, iatrogenic CJD has occurred after implantation of dura mater grafts and treatment with growth hormone or gonadotropin derived from the pituitary glands of human cadavers.[20] [21] [22]

The appearance of CJD cases in teenagers and young adults in the UK during the mid-1990s prompted considerable concern that they might have acquired the illness as a result of exposure to BSE. By March 1996, it became clear that the unusual clinical presentation and neuropathology were remarkably consistent in these new cases.[23] Up to October 2002, 128 cases of probable and pathologically confirmed vCJD were reported in predominantly teenagers and young adults in the UK, six cases in France, one case in Hong Kong in an ex-UK resident, one case in the Republic of Ireland, two cases in the USA in ex-UK residents and one case in Italy.[24] Molecular strain typing, which focuses on the biochemical properties of PrP^{Sc} from the brains of BSE-infected cattle and patients who have CJD, has demonstrated that vCJD is different from sporadic CJD but similar to BSE.[25] [26] Moreover, the incubation times and profile of neuropathologic lesions of vCJD and BSE prions are indistinguishable in inbred lines of mice.[27] These data argue that BSE and vCJD are the same strain. All reported cases of vCJD have been homozygous for methionine at the polymorphic codon 129, a genotype

shared by ~40% of the British Caucasian population.[28] Polymorphisms in the human *PRNP* gene are not the sole genetic influence on disease susceptibility and incubation time. Studies with inbred lines of mice show that large differences occur even with the same amino acid sequence of the prion protein, suggesting that other genes may contribute to the observed variation.

Studies of quantitative trait loci (QTL) linked to prion disease incubation periods in mice have identified susceptibility loci on chromosomes 2, 4, 8, 11 and 12 and 15.[29] [30] These QTL studies provide strong evidence that genetic loci other than the coding region of *PRNP* have a major influence on scrapie incubation time in experimental prion disease. These findings suggest the need for caution in interpreting estimates of vCJD epidemic sizes utilizing existing genetic epidemiological studies which may result in overly optimistic predictions of the size of the vCJD epidemic because these models assume that only methionine-homozygous individuals are susceptible to vCJD.[31] [32] This is unlikely given the evidence from another acquired human prion disease, kuru, which occurred in all codon 129 genotypes as the epidemic evolved, with codon 129 heterozygotes having the longest mean incubation time.[33] [34] Therefore the patients identified to date with vCJD represent those individuals most genetically susceptible to the disease.

Iatrogenic secondary transmission of vCJD prions from asymptomatic carriers is of considerable concern in the UK. If secondary transmission does occur, the mean incubation time is likely to be much shorter than in primary cases because transmission does not involve a species barrier. As there is no diagnostic test for preclinical carriers of vCJD, estimates of asymptomatic carriers relies on screening of surgical lymphoreticular tissue to assess the prevalence of preclinical disease. [35] [36] Therefore a large prospective longitudinal study of surgical tonsil samples is currently being undertaken in the UK.

CLINICAL FEATURES

The human prion diseases can be divided etiologically into inherited, sporadic and acquired forms with CJD, Gertsmann-Straussler-Scheinker syndrome (GSS) and kuru now seen as clinicopathological syndromes rather than individual disease entities. The identification of one of the pathogenic *PRNP* mutations in a patient with neurodegenerative disease allows the diagnosis of an inherited prion disease and subclassification according to mutation.[37] Over 30 pathogenic mutations have been described in two groups:

- point mutations resulting in amino acid substitutions in PrP or, in one case, production of a stop codon resulting in expression of a truncated PrP;
- insertions encoding additional integral copies of an octapeptide repeat present in a tandem array of five copies in the normal protein (see Fig. 26.3).

They are all autosomal dominantly inherited conditions. Kindreds with inherited prion disease have been described with phenotypes of classic CJD and GSS and also with a range of other neurodegenerative disease phenotypes. Some families show remarkable phenotypic variability which can encompass both CJD- and GSS-like cases as well as other cases which do not conform to either CJD or GSS phenotypes.[38] Such atypical prion diseases may lack the classic histologic al features of a spongiform encephalopathy entirely although PrP immunohistochemistry is usually positive.[39] Progressive dementia, cerebellar ataxia, pyramidal signs, chorea, myoclonus, extrapyramidal features, pseudobulbar signs, seizures and amyotrophic features are seen in variable combinations. *PRNP* analysis is also used for

presymptomatic genetic testing in affected families.[40]

Classic CJD is a rapidly progressive dementia accompanied by myoclonus. Decline to akinetic mutism and death is rapid and often occurs within 3–4 months. Cerebellar ataxia, extrapyramidal and pyramidal features and cortical blindness are also frequently seen The EEG may show characteristic pseudo-periodic sharp wave activity which is helpful in diagnosis but present only in around 70% of cases. To some extent, demonstration of a typical EEG is dependent on the number of EEGs performed and serial EEG is indicated to try and demonstrate this appearance. Cerebrospinal fluid (CSF) immunoassay for the neuron-specific 14-3-3 protein may be helpful.[41] A combination of both 14-3-3 CSF analysis and EEG is recommended in the investigation of suspected classic CJD cases to increase the sensitivity of pre-mortem case definition. [41] A raised 14-3-3 protein is not, however, specific for classic CJD and is raised in viral encephalitis or recent stroke; it is a marker of neuronal injury and loss. Of more concern with respect to the differential diagnosis is that it may also be raised in rapidly progressive forms of Alzheimer's disease, which may be confused with CJD. MRI scanning may show signal changes in the basal ganglia that, although not specific, can be diagnostically helpful.[42] Atypical cases of classic CJD are well recognized, however, and can still present diagnostic difficulties.

The clinical features of kuru consist of a progressive cerebellar ataxia accompanied by dementia in the later stages and death, which usually occurs within 12 months. Iatrogenic prion disease arising from intracerebral or optic inoculation usually manifests clinically as classic CJD, whilst those arising from a peripheral route of inoculation, such as pituitary growth hormone, commonly present like kuru with a progressive ataxia. GSS commonly presents as a chronic cerebellar ataxia with pyramidal features and dementia occurs much later in the clinical course, which is longer than that seen in classic CJD. Fatal familial insomnia (FFI) is characterized by progressive untreatable insomnia, dysautonomia and dementia and selective thalamic degeneration and is most commonly associated with a missense mutation at codon 178 of *PRNP*.[43] The FFI phenotype has also been described as occurring sporadically with no causative mutation in *PRNP* identified.[44]

The early clinical presentation of vCJD resembles kuru more than classic CJD and consists of behavioral and psychiatric disturbances, peripheral sensory disturbance and cerebellar ataxia. Common early psychiatric features include dysphoria, withdrawal, anxiety, insomnia and apathy. Neurological symptoms preceded psychiatric symptoms in 15% of cases studied and were present in combination with psychiatric symptoms in 22% of cases from the onset of disease. No common early neurological features were noted, but paresthesiae and/or pain in the limbs is seen in around half of the cases. However, a significant proportion of patients exhibited neurological symptoms within 4 months of clinical onset and these included poor memory, pain, sensory symptoms, unsteadiness of gait and dysarthria. Disorientation, hallucinations, paranoid ideation, confabulation, impaired self-care and the most common neurological features (cerebellar signs, chorea, dystonia, myoclonus, upper motor neuron signs and visual symptoms) developed late in the course of the illness.[45] The duration of disease is longer in vCJD with mean patient survival times of about 13 months, compared with about 4 months for classic CJD. Moreover, whereas classic CJD is predominantly a late-onset disease with a peak onset between 60 and 65 years, the median age of onset of vCJD is 26 years.[45]

The EEG is not helpful in the diagnosis of vCJD; whilst generalized slowing is usually present, the characteristic periodic changes associated with classic CJD are not. The CSF 14-3-3 protein is not helpful and may often be negative. Magnetic resonance imaging, however, is useful in the diagnosis of vCJD; in the majority of cases high signal is noted in the posterior thalamus (pulvinar) bilaterally on dual echo (T_2 - or proton density-weighted) MRI (Fig. 26.4).[46] Other common MRI features of vCJD are medial thalamic and periaqueductal gray matter high signal and the notable absence of cerebral

Figure 26-4 Axial T_2 -weighted MRI brain demonstrating high signal bilaterally in the posterior thalamus (arrowed) — the 'pulvinar sign' in a patient with vCJD.

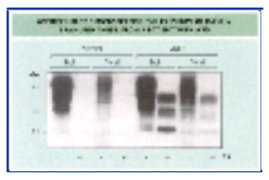

Figure 26-5 Western blot demonstrating the presence of PrP^{Sc} in brain and tonsil from a patient with vCJD. The presence of PrP^{Sc} is revealed after proteinase K (PK) treatment, which digests the normal form of PrP (PrP^{C}) but not the pathological form (PrP^{Sc}). *Courtesy of Ms Susan Joiner and Dr Andy Hill.*

atrophy.[46] All cases to date are homozygous for methionine at *PRNP* codon 129.[28] [35] vCJD can be diagnosed by detection of characteristic PrP^{Sc} immunostaining on tonsil biopsy.[35] Importantly, PrP^{Sc} is only detectable in tonsil and other lymphoreticular tissues in vCJD and not other forms of human prion disease, indicating that it has a distinctive pathogenesis.[35] [47] The PrP^{Sc} type detected on Western blot in vCJD tonsil has a characteristic pattern designated type 4t. Tonsil is the tissue of choice for diagnostic biopsy in the investigation of possible vCJD. Tonsil biopsy is well tolerated, with minor discomfort, and has, so far, shown 100% sensitivity and specificity.[35] If the tonsil biopsy is positive with the specific vCJD banding pattern (Fig. 26.5), then a more invasive brain biopsy becomes unnecessary.

PATHOGENESIS AND PATHOLOGY

Molecular strain typing

The marked clinical heterogeneity observed in sporadic CJD has yet to be explained. However, it has been clear for many years that distinct isolates, or strains, of prions can be propagated in the same host and these are biologically recognized by distinctive clinical and pathological features in experimental animals (for review see[48]). It is therefore likely that a proportion of the clinicopathological heterogeneity in CJD, and other human prion diseases, relates to the propagation of distinct human prion strains. The identification of these prion strains would allow an etiology-based classification of CJD by typing of the infectious agent itself.

The existence of prion strains has been difficult to accommodate within the protein-only model of prion propagation. As they can be serially propagated in inbred mice with the same *PRNP* genotype, they cannot be encoded by differences in PrP primary structure. Furthermore, strains can be re-isolated in mice after passage in intermediate species with different PrP primary structures.[49] Conventionally, distinct strains of conventional pathogens are explained by differences in their nucleic acid genome. However, in the absence of such a scrapie genome, alternative possibilities must be considered. A wealth of experimental evidence now suggests that PrP^{Sc} itself may encode strain-specific phenotypic properties. Different subtypes of PrP^{Sc} were associated initially with two strains of transmissible mink encephalopathy in hamsters.[50] [51] Recently, several human PrP^{Sc} types have been identified which are associated with different phenotypes of CJD.[25] [52] The different fragment sizes seen on Western blots, following treatment with proteinase K, suggest that there are several different human PrP^{Sc} conformations, referred to as 'molecular strain types'. These types can be further classified by the ratio of the three PrP bands seen after protease digestion, representing di-, mono- and unglycosylated fragments of PrP^{Sc} . Sporadic CJD is associated with PrP^{Sc} types 1–3, while type 4 human PrP^{Sc} is uniquely associated with vCJD and characterized by glycoform ratios which are distinct from those observed in sporadic CJD.[25]

Importantly, these biochemical changes in PrP^{Sc} are transmissible to PrP in a host. This has been demonstrated in studies with CJD isolates, with both PrP^{Sc} fragment sizes and the ratios of the three PrP glycoforms maintained on passage in transgenic mice expressing human PrP.[25] Furthermore, transmission of human prions and bovine prions to wild-type mice results in murine PrP^{Sc} with fragment sizes and glycoform ratios which correspond to the original inoculum.[25] Variant CJD is associated with PrP^{Sc} glycoform ratios which are distinct from those seen in sporadic CJD. Similar ratios are seen in BSE, and BSE when transmitted to several other species. [25] Recently, it has been demonstrated that BSE propagated in transgenic mice expressing the human prion protein can induce two different prion strain types — the type 4 PrP^{Sc} pattern associated with vCJD and the type 2 PrP^{Sc} pattern which is commonly associated with sporadic CJD. This finding has important potential implications as it raises the possibility that some humans infected with BSE prions may develop a clinical disease indistinguishable from sporadic CJD associated with type 2 PrP^{Sc} .[53] All these data strongly support

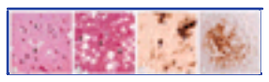

Figure 26-6 Neuropathology of prion disease — histopathological findings in vCJD. (a) Florid plaques, a characteristic feature of vCJD pathology. They consist of a round amyloid core (arrowed) surrounded by a ring of vacuoles (hematoxylin and eosin stain). (b) Spongiform degeneration in prion disease. This area shows severe vacuolization (spongiosis), there is severe neuronal loss and many strongly reactive astrocytes (arrowed) (hematoxylin and eosin stain). (c) Immunostaining of the pathological prion protein. The specimen is pretreated to denature the normal PrP and staining with a prion protein antibody reveals the presence of plaques (P) and synapses (S) staining positively for PrP^{Sc} . (d) Detection of pathological prion protein in the follicular dendritic cells in a tonsil. Accumulation of prion protein in lymphoreticular organs, such as spleen, tonsils or appendix, is a specific finding in vCJD and is not present in other forms of CJD. Therefore tonsillar biopsies can be used to specifically diagnose vCJD when clinical symptoms are only emerging. *Courtesy of Dr Sebastian Brandner.*

the 'protein-only' hypothesis of infectivity and suggest that strain variation is encoded by a combination of PrP conformation and glycosylation pattern.

Pathology

The animal and human prion diseases share a number of characteristic features, the most consistent being the neuropathological changes that accompany disease in the central nervous system. Indeed, it was the neuropathological similarities between scrapie and kuru that strongly suggested that the two diseases might be closely related and that kuru, like scrapie, might also be transmissible by inoculation. [54] Subsequently, brain extracts from patients who have kuru produced a progressive neurodegenerative condition in inoculated chimpanzees after a prolonged incubation period of 18–21 months.[55] The neuropathologic similarities between kuru and CJD prompted similar transmission experiments from CJD patients.[56]

Although the brains of patients or animals who have prion disease frequently show no recognizable abnormalities on gross examination, microscopic examination of the central nervous system typically reveals characteristic histopathologic changes, consisting of neuronal vacuolation and degeneration, which gives the cerebral gray matter a microvacuolated or 'spongiform' appearance (Fig. 26.6b), and a reactive proliferation of astroglial cells (Fig. 26.6b), which is often out of all proportion to the degree of nerve cell loss. Although spongiform degeneration is frequently detected, it is not an obligatory neuropathologic feature of prion disease; astrocytic gliosis, although not specific to the prion diseases, is more constantly seen. The lack of an inflammatory response is also an important characteristic. Although it is by no means a constant feature, some examples of prion disease are characterized by deposition of amyloid plaques composed of insoluble aggregates of PrP. Amyloid plaques are a notable feature of kuru and GSS but they are infrequently found in the brains of patients who have classic CJD.

Although there is wide variation in the neuropathologic profiles of different forms of human prion disease, the histopathologic features of vCJD are remarkably consistent and distinguish it from other human prion diseases. Large numbers of PrP-positive amyloid plaques are a consistent feature of vCJD but they differ in morphology from the plaques seen in kuru and GSS in that the surrounding tissue takes on a microvacuolated appearance, giving the plaques a florid appearance (Fig. 26.6a).[23] It is noteworthy that transmission of BSE to three macaques produced disease with neuropathologic features similar to those reported in cases of vCJD in humans.[57] vCJD is clearly very different in its pathogenesis from other human prion diseases and this is reflected in the tissue distribution of PrP^{Sc} in vCJD. AS mentioned, it is readily detectable in lymphoreticular tissue and, using highly sensitive immunoassays, PrP^{Sc} has been found in retina, optic nerve, rectum, adrenal gland and thymus in vCJD postmortem tissue (Fig. 26.7).[47]

Figure 26-7 The tissue distribution of PrP^{Sc} in vCJD compared to classic CJD. In vCJD PrP^{Sc} is found in lymphoreticular tissue as well as brain and spinal cord. Using highly sensitive immunodetection methods, PrP^{Sc} has also been found in the optic nerve, retina, adrenal gland and rectum. *Courtesy of Dr Jonathon Wadsworth and Mr Ray Young.*

Pathogenesis

Detection of PrP^{Sc} in brain material by immunohistochemical or immunoblotting techniques is considered to be diagnostic of prion disease (Fig. 26.6c). However, certain examples of natural and experimental prion disease occur without accumulation of detectable protease-resistant PrP^{Sc} ,[17] [58] [59] and the time course of neurodegeneration is not equivalent to the time course of PrP^{Sc} accumulation in mice expressing lower than normal levels of PrP^{C} .[60] Moreover, PrP^{Sc} is not toxic to cells that do not express PrP^{C} . [61] Additional evidence that PrP^{Sc} may not be the sole neurotoxic species has been demonstrated in mice inoculated with^{Sc} 237 hamster prions. These mice replicate prions to high levels in their brains but do not develop any signs of clinical disease during their normal lifespan. [62]

The essential role of host PrP^{C} for prion propagation and pathogenesis is demonstrated by the fact that mice in which the PrP gene has been disrupted (referred to as $Prnp^{0/0}$) are resistant to scrapie infection[63] [64] and that reintroduction of the murine PrP^{C} transgene restores susceptibility to infection.[65]

Gene-targeted $Prnp^{0/0}$ mice have also been studied to probe the normal function of PrP^{C} . Two independently generated lines of gene-targeted $Prnp^{0/0}$ mice developed normally and appeared to suffer no gross phenotypic abnormalities. [64] [66] The relative normality of these PrP null mice was thought to result from effective adaptive changes during development. However, data from *Prnp* conditional knockout mice suggest this is not the case;[67] these mice undergo ablation of neuronal PrP expression at 9 weeks of age. The mice remain healthy without evidence of neurodegeneration or an overt clinical phenotype, demonstrating that acute loss of neuronal PrP in adulthood is tolerated and that the pathophysiology of prion diseases is not due to loss of normal PrP function. [67] The normal function of PrP is not known but evidence from PrP knockout mice reveals defects in neurophysiological and biochemical function. Electrophysiological studies have demonstrated that fast inhibition and long-term potentiation mediated by d-aminobutyric acid receptors were impaired in hippocampal slices from $Prnp^{0/0}$ mice [68] [69] and that calcium-activated potassium currents were disrupted.[67] [70] These abnormalities of synaptic inhibition are reminiscent of the neurophysiological defects seen in patients who have CJD and in scrapie-infected mice[68] and suggest a direct role for PrP in the modulation of neuronal excitability. Normal PrP has also been shown to bind copper ions,[71] [72] with femtomolar affinity,[73] and a role for PrP in copper metabolism or transport has also been suggested.

Thus, it appears that neither accumulation of PrP^{Sc} , nor loss of normal PrP function, is the cause of the neurodegeneration in prion diseases. It is possible that a toxic intermediate species is produced in the conversion of PrP^{C} to PrP^{Sc} and that the steady-state level of such an intermediate could then determine the rate of neurodegeneration.[74]

Although the pathological consequences of prion infection occur in the central nervous system and experimental transmission of these diseases is most efficiently accomplished by intracerebral inoculation, most natural infections do not occur by these means. Indeed, administration to sites other than the central nervous system is known to be associated with much longer incubation periods, which may extend to 20 years or more. Experimental evidence suggests that this latent period is associated with clinically silent prion replication in the lymphoreticular tissue, whereas neuroinvasion takes place later.[75] The *M* cells in the intestinal epithelium mediate prion entry from the gastrointestinal lumen into the body[76] and follicular dendritic cells (FDCs) are thought to be essential for prion replication and for accumulation of disease-associated PrP^{Sc} within secondary lymphoid organs. Inhibition of the lymphotoxin (LTß) signaling pathway with a soluble receptor that depletes FDCs abolishes prion replication in spleens and prolongs the latency of scrapie after intraperitoneal challenge.[77] B cell-deficient mice are resistant to intraperitoneal inoculation with prions, [78] possibly because of impaired FDC maturation. [77] [79] Opsonization by complement system components may also be important in peripheral neuroinvasion as mice genetically engineered to lack complement factors[80] or mice deleted of the C3 complement component by the administration of cobra venom [81] are resistant to peripheral prion inoculation.

PREVENTION

Because there are currently no treatments for these invariably fatal diseases, prevention is particularly important. Perhaps the most effective example of prevention was the cessation of cannibalistic practices among the Fore people of Papua New Guinea in the 1950s, which resulted in the disappearance of kuru. The replacement of growth hormone derived from the pituitary glands of human cadavers with recombinant growth hormone was implemented to avoid the continued iatrogenic transmission of CJD to young children who have growth hormone deficiency. Similarly, because CJD has resulted from the use of prion-contaminated surgical instruments or apparatus after neurosurgical or ophthalmic procedures, it is advised that surgical instruments be incinerated in cases where CJD is confirmed so as to avoid future iatrogenic transmission of prion disease. Current policy in the UK is to quarantine surgical instruments until a suspected diagnosis is confirmed, and instruments used on a confirmed case are destroyed. Recent experimental studies have confirmed that prions adhere readily to metal following a contact time with infected brain of as little as 5 minutes.[82]

When it was realized that BSE was caused by feeding prion-contaminated foodstuffs to cattle, a number of preventive measures were introduced in the UK. In July 1988 a ban on feeding ruminant-derived protein to other ruminants was introduced to break the cycle of infection via feed. Because the available evidence indicates that vCJD has resulted from human exposure to bovine prions via the food chain, the BSE epidemic prompted concerns over the safety of prion-contaminated foodstuffs. A ban on specified bovine offals was introduced in the UK in 1989 to prevent inclusion in the human food chain of bovine tissues thought to contain the highest titer of prions; these included tissues from the lymphoreticular system and the central nervous system. The European Union imposed a worldwide ban on the export of British cattle, products derived from them (with the exception of products for technical uses) and mammalian meat and bone meal in March 1996 after the announcement that BSE and vCJD might be linked. Since then, more than 1.35 million cattle over 30 months old have been culled in the UK in a further attempt to limit human exposure to BSE. The 'over thirty month' (OTM) rule is one of the UK BSE controls used to prevent further BSE-infected cattle from entering the human food chain because cattle over 30 months are more likely to develop BSE than younger animals. Therefore, since 1996 there has been a ban on selling meat in the UK from slaughtered cattle over 30 months old. The cost of tackling BSE to the British and European taxpayer has been estimated at over £3500 million (approximately $US5600 million). These measures appear to have been effective in reducing the incidence of BSE in the UK and the number of newly identified BSE cases is in sharp decline.[9] The EU-imposed worldwide ban on British beef exports was lifted in late 1999 after the EU was satisfied that appropriate measures had been taken to counteract the likelihood of BSE-infected animals getting into the human food chain.

Although there is no current evidence that vCJD can be transmitted via blood or blood products, the long incubation period of prion diseases and the possibility of increased numbers of future cases of vCJD as a result of exposure to BSE have raised the issue of blood as a possible vehicle for iatrogenic disease. There have been no reported cases of prion transmission in cases where humans have

been transfused with blood from a patient who has gone on to develop either classic CJD or vCJD. During the past 20 years more than 20 patients have received blood components from donors who have later developed vCJD.[83] Although to date there is no evidence of disease transmission, incubation periods are likely to be prolonged and these recipients continue to be carefully monitored.

Many animal experiments have addressed the question of whether blood, buffy coat, plasma or blood extracts from diseased animals or animals incubating the disease can transmit the disease to healthy animals via the intracerebral, intravenous or intraperitoneal route and they have recently been reviewed.[83] As a protective measure against the theoretical risk of iatrogenic transmission of vCJD via blood transfusions, a number of policies have been implemented in the UK. The UK government decided in 1998 that all blood donations should be leukodepleted. Since then the majority of European countries have followed this strategy. The UK National Blood Transfusion Service now imports all plasma and plasma derivatives from BSE-free countries and blood donors are screened to exclude anyone with a blood relative with classic CJD or vCJD. Several countries have instituted policies of deferral of blood donors who have resided in the UK for a cumulative period of 6 months or more from 1980 until the end of 1996. In view of the potential exposure to the vCJD agent in other European countries in addition to the UK, the US Food and Drug Administration has a blood donation deferral policy for cumulative 10-year residence in France, Portugal and Ireland. The American Red Cross Blood Banks have adopted a deferral policy of 3 months' residence in the UK and 6 months' residence in any other European country. The efficacy of these risk reduction procedures is not known and a screening test for blood infectivity is urgently needed.

DEVELOPMENT OF THERAPIES

Prion diseases are invariably fatal and whilst curative therapies for prion infection are conceivable, such therapies, if developed, will not be available for some years.[74] Such approaches may involve targeting PrP itself.[74] However, the development of neuroprotective agents and pre- and postexposure prophylaxis is also important. In addition, early firm diagnosis will be crucial to allow such treatments to be initiated before extensive brain damage occurs.

A number of compounds have been shown to be effective at clearing PrP^{Sc} in cell culture systems.[84] These include the acridine and phenothiazine derivatives quinacrine and chlorpromazine, Congored, sulfated polyanions and anti-PrP antibodies (reviewed in[84]). A few compounds have been shown to prolong survival in animal models after intraperitoneal inoculation with prions. These include pentosan polysulfate, cyclic tetrapyrroles[85] and CpG oligodeoxynucleotides.[86] Recently vaccination with recombinant mouse prion protein, before and after intraperitoneal inoculation of prions in mice, demonstrated delayed disease onset in both groups but this was more prolonged in animals immunized before prion exposure.[87] Only amphotericin B and dapsone prolonged life when animals were prion inoculated by the more challenging intracerebral route, in which neuroinvasion is directly initiated. However, amphotericin B was not effective in prolonging survival in a CJD patient and the results with dapsone were not substantiated in another rodent model of prion disease. Currently clinical trials using quinacrine and chlorpromazine treatment in CJD and vCJD patients are under way in both the UK and USA, but results are not yet published. However, there is no evidence that these drugs are useful against prion disease *in vivo* and recently quinacrine treatment in a rodent model of CJD demonstrated no efficacy.[88]

Currently a huge international research effort is attempting to develop therapies aimed at both pre- and postexposure prophylaxis, in addition to neuroprotective agents that may slow disease progression.

Chapter 27 - Postinfectious and Vaccine-related Encephalitis

Edwin J Asturias
Rodney E Willoughby Jr

INTRODUCTION

Infections or immunizations can cause disease by aberrant host responses directed against brain, spinal cord or peripheral nerves. Pathogenesis is divided by anatomic differences in myelin into diseases of the central nervous system (CNS) and peripheral nervous system (PNS). The CNS syndromes discussed below are encephalomyelitis, transverse myelitis, cerebellar ataxia, optic neuritis, Sydenham's chorea, encephalopathy and Reye syndrome. The PNS syndromes are Guillain-Barré syndrome (GBS), brachial neuritis and cranial neuropathies.

ENCEPHALOMYELITIS, TRANSVERSE MYELITIS AND RELATED CONDITIONS

EPIDEMIOLOGY

The most important of the various postinfectious CNS syndromes are:

¦ acute disseminated encephalomyelitis (ADEM), an inflammatory demyelinating disease, probably autoimmune in nature, that characteristically follows a monophasic course.[1] Acute hemorrhagic leukoencephalitis is a hyperacute necrotizing form of ADEM;
¦ postinfectious encephalomyelitis (PIE), a subset of ADEM affecting brain and spinal cord after an infection;
¦ postvaccinal encephalitis (PVE) follows various immunizations;
¦ acute cerebellar ataxia, characterized by predominant cerebellar dysfunction;
¦ acute transverse myelitis, a distinctive syndrome affecting the spinal cord; and
¦ optic neuritis, inflammation of the ophthalmic nerve, which can occur in isolation or with multifocal CNS involvement.

Although postinfectious CNS syndromes are differentiated by their predominant anatomic involvement, they probably represent similar pathologic mechanisms; overlapping syndromes and variants may occur. Encephalitis associated with antecedent bacterial infections displays a predilection for basal ganglia, producing Sydenham's chorea or stereotypic behaviors.

The incidence of ADEM varies by country as a function of endemic diseases, intercurrent epidemics and use of international or locally developed vaccines. Seasonality, reported in some case series, might reflect underlying epidemics that trigger these rare diseases. With the introduction of vaccines against common childhood diseases, the proportion of PIE decreased from 33% to 15% of reported acute encephalitis cases in the USA and Europe.[2] The incidence of PIE in the USA is approximately 1/100,000 population. The incidence after immunization is generally much lower than after natural infection (Table 27.1). Annual incidence of acute transverse myelitis in the USA is 0.8/100,000 population.[3] The incidence of Sydenham's chorea in the USA and Europe is approximately 0.1/100,000 population. There are no population-based estimates for optic neuritis or acute cerebellar ataxia.

The association of optic neuritis with subsequent development of multiple sclerosis is well established. The autoimmune, demyelinating but multiphasic phenotype of multiple sclerosis is an invariable contrast to these monophasic postinfectious syndromes. The prevalence of multiple sclerosis is 60/100,000 population. For comparison with ADEM, adrenoleukodystrophy, a rare genetic demyelinating syndrome, occurs with a prevalence of 2/50,000 males.

PATHOGENESIS AND PATHOLOGY

The pathogenesis of postinfectious syndromes of the CNS has been best delineated following measles infection and immunization against rabies.[4] [5] The pathology of encephalomyelitis following measles infection is perivenular mononuclear inflammation, edema and demyelination, with relative sparing of axons. Lipid-laden macrophages are present in areas of demyelination. Almost identical pathology is seen in PVE and experimental models of allergic encephalomyelitis. The pathology of acute cerebellar ataxia, which is benign and self-limited, is rarely described; the pathology of optic neuritis and acute transverse myelitis is similar to that of PIE. The pattern of demyelination observed in postinfectious syndromes is distinct from the demyelination seen in progressive multifocal leukoencephalopathy due to papovavirus infection, human T-cell leukemia/lymphoma virus (HTLV)-1 infection or multiple sclerosis.[6] Repeated attempts to recover infectious agents from brain tissue (culture, viral antigen or nucleic acid) have been mostly unsuccessful. Intrathecal production of interferons or antibodies, which are indicators of CNS infection, are frequently absent.[1] [4]

Patients who have major neurologic complications after rabies vaccine or measles infection have elevated levels of antibody reactive to brain white matter or myelin basic protein (MBP), as well as increased lymphoproliferative responses to MBP.[4] [5] The animal model of experimental allergic encephalomyelitis, using repeated immunization with brain tissue, induces inflammatory demyelinating lesions in the CNS similar to those in PIE or PVE. The pathogenesis is by cell-mediated attack on CNS myelin. The incidence of PIE is low relative to the prevalence of associated infectious agents (Table 27.2). Genetic factors predisposing to autoimmunity or enhanced CNS inflammation are important in experimental allergic encephalomyelitis and may determine which individuals develop ADEM.[7]

The pathogenesis of CNS autoimmunity following bacterial infections is less clear. Mycoplasmas are associated with PIE; mycoplasmal antigens cross-react with brain tissue.[8] Limited pathologic descriptions in Sydenham's chorea indicate neuronopathy rather than demyelination. Antibodies of IgG subclass reactive against subthalamic and caudate nuclei are detected more frequently in patients who have acute rheumatic fever or Sydenham's chorea than in controls. Children who have tics or obsessive-compulsive disorder with attention deficit-hyperactivity disorder can have antibodies to caudate and putamen.[9] The role of cell-mediated immunity has not been defined.

TABLE 27-1 -- Incidence of postinfectious and postvaccinal encephalomyelitis.

INCIDENCE OF POSTINFECTIOUS AND POSTVACCINAL ENCEPHALOMYELITIS		
Disease	**Disease-associated**	**Vaccine-associated**
Smallpox	1/2000	1/20,000
Rabies	Fatal disease	Semple vaccine 1/400
		Suckling mouse vaccine 1/7500
		Duck embryo vaccine 1/50,000
		Human diploid vaccine: none
Measles	1/1000	1.2/million
Rubella	1/6000	<1/million
Mumps	1/6000	<1/million
Pertussis	1/125	1/140,000
Varicella	1/4000	<1/100,000

TABLE 27-2 -- Infections associated with postinfectious central nervous system syndromes.

INFECTIONS ASSOCIATED WITH POSTINFECTIOUS CNS SYNDROMES
Non-specific upper respiratory infections
Non-specific gastrointestinal infections
Measles
Mumps
Rubella
Varicella-zoster virus

Epstein-Barr virus
Herpes simplex virus
Influenza
Smallpox (variola)
Mycoplasma pneumoniae
Streptococcus pyogenes
Campylobacter jejuni
Vaccines
Smallpox (vaccinia)
Rabies
Measles
Oral poliovirus
Diphtheria-tetanus (DT and Td) and tetanus toxoid vaccines
Haemophilus influenzae type b
Plasma-derived hepatitis B
Inactivated *Vibrio cholerae*
Japanese B encephalitis

Common infections are frequently associated with postinfectious ADEM (see Table 27.2). Acute cerebellar ataxia is especially common after chickenpox, occurring in 35% of cases of ADEM associated with varicella-zoster virus (VZV).[10] Abnormalities of the CNS and PNS are common in children and adults who have HIV and AIDS. Involvement of the CNS in primary HIV infection includes periventricular demyelination resembling ADEM. Other retroviruses, such as HTLV-1, have also been linked to tropical spastic paraparesis and myelopathy, both chronic and progressive demyelinating neuropathies. The overall risk of tropical spastic paraparesis/myelopathy after HTLV-1 infection is 25/100,000 in endemic areas.

PREVENTION

The incidence of PIE has decreased over the past 30 years, probably because of successful immunization against many viral diseases as well as development of more purified vaccines (see Table 27.1). Although vaccines can trigger ADEM, the probability of this event is much higher after wild-type virus infection. Although vaccinia virus vaccines are no longer in use, Semple rabies vaccines are still produced in some countries. A change to human diploid cell rabies vaccines virtually eliminates the risk of PVE. New vaccine technology, including recombinant proteins and DNA vaccines, should further reduce the incidence of PVE.

CLINICAL FEATURES

The age-specific incidences of infectious encephalitis and PIE are distinct. The incidence of encephalitis is highest in infancy (22.5/100,000), although PIE is rare in children under 2 years of age.[11] The age distribution of PIE and PVE generally coincides with the epidemiology of associated pathogens or vaccines. Most patients who have acute cerebellar ataxia are 1–6 years of age; a viral prodrome is present in 64%.[10] The incidence of acute transverse myelitis has distinct peaks in adolescence, middle age and the elderly; a viral prodrome is present in 30%.[12] The incidence of optic neuritis is highest in young to middle-aged adults; a viral prodrome is present in 50%.[13] Unlike most postinfectious CNS syndromes, the sex-specific incidence of optic neuritis is unequal, favoring females with a ratio of 2:1. Sydenham's chorea affects school-aged children; a similar age distribution is reported for the onset of childhood tics and obsessive-compulsive disorders.[9]

The onset of PIE is usually abrupt, occurring 5–14 days after infection. The illness begins with a recurrence of fever and a depressed level of consciousness. Neurologic manifestations are classically multifocal. Signs range from lethargy and irritability to convulsions (50%), involuntary movements (18%), ataxia (10%), hemiplegia (12%), visual disturbances and cranial nerve deficits. Recovery can begin within days but complete resolution occurs over weeks or months. The mortality ranges from 5% to 20%, with highly variable morbidity. A poor prognosis is associated with coma, focal neurologic deficits and extreme or persistent fever.

Postvaccinal encephalitis

This is best characterized for Semple rabies vaccines.[5] Prodromal fever, headache and myalgia develop 6–14 days after the first immunization. Within 1–4 weeks, patients develop neurologic signs of lethargy (50%), meningisms (33%), focal neurologic deficits (50%) and sphincter disturbances (33%). The duration of illness is less than 2 weeks and 80% of patients recover completely; the associated mortality is 15%.

Distinguishing between infectious encephalomyelitis and PIE can be challenging, especially when they are caused by the same infectious agent.[8] [14] The differential diagnosis of PIE and PVE includes infectious encephalitis, progressive multifocal leukoencephalitis (papovavirus), multiple sclerosis, vasculitis, cerebral emboli, cerebral vein thrombosis, chronic meningitis, sarcoidosis, intracranial hemorrhage, malignancy, mitochondrial disorders (mitochondrial encephalomyopathy-lactic acidosis-stroke-like episodes syndrome) and metabolic disorders (adrenoleukodystrophy).

The risk of PVE has recently been highlighted by the reemergence of the need to provide smallpox immunization to counteract the threat of bioterrorism. Postvaccinal encephalitis is the most serious complication of smallpox immunization, with an estimated incidence of approximately 1/100,000 and a case-fatality of 50%. [15] This problem, plus the increased risk of disseminated vaccinia in immunocompromised patients (especially those who have HIV), greatly complicate the public policy considerations of mass smallpox immunization.

Acute cerebellar ataxia

This develops suddenly with vomiting, inco-ordination, truncal ataxia and dysarthria. Refusal to walk and mutism are common presenting signs in children.[10] Cerebellitis is a frequent component of general encephalomyelitis and can be complicated by acute hydrocephalus. Acute cerebellar ataxia must be distinguished from drug ingestion, GBS, benign paroxysmal vertigo associated with migraine, peroxisomal disorders, metabolic diseases, inherited ataxias, Wernicke's encephalopathy, paraneoplastic syndromes (myoclonus-opsoclonus syndrome) and posterior fossa tumors.

Acute transverse myelitis

This is an acute syndrome mimicking transection of the spinal cord. Prodromal symptoms include fever, rash and pain in the legs, interscapular region or back. Peak neurologic dysfunction is reached within 2 hours in 15% of the patients, and within 24 hours in 50%, but progression up to 14 days has been reported. Neurologic deficit is commonly localized to the thoracic region but 20% of patients are affected in the cervical or lumbar area. Muscular weakness is accompanied by decreased or absent deep tendon reflexes. Some degree of asymmetry can be observed during early evolution of the disease; significant asymmetry suggests other diagnoses. Loss of sensation to pain and temperature below a clear demarcated level is universal; loss of perception of touch and proprioception are common. Sphincter disturbances and dysautonomia are usually described. Recovery to independent ambulation occurs in 50% of pediatric and 35% of adult cases. Improvement may continue beyond 6 months. Pulmonary emboli, urinary tract infections and decubitus ulcers are common complications.

Transverse myelitis must be differentiated from multiple sclerosis, acute epidural abscesses, hematomas or arteriovenous malformations, tumors, anterior spinal artery syndrome associated with lupus, syphilis or schistosomiasis, dissecting aneurysm and tropical paraparesis (HTLV-1), as well as infections by VZV, cytomegalovirus (CMV) and toxoplasmosis in immunocompromised hosts.

Optic neuritis

This is heralded by pain above or behind the eye aggravated by movement, loss of color discrimination and progressive central visual

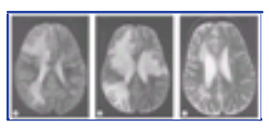

Figure 27-1 Postinfectious encephalomyelitis. (a, b) MRI of brain at presentation showing asymmetric demyelination of cortical white matter. Basal ganglia were also involved bilaterally (not shown). (b) At 7 weeks, the distribution is more symmetric. (c) Residual lesions at 4 months, with full clinical recovery.

impairment. Total blindness of the eye may follow within a few hours to days. Single eye involvement is present in 90% of adult cases; bilateral neuritis occurs in up to 40% of pediatric cases. Most patients recover within 4 weeks. The reported incidence of multiple sclerosis following optic neuritis varies widely (5–57%) but is less in children.[13]

The differential diagnosis of optic neuritis includes multiple sclerosis, hereditary retinal diseases, vasculitis (giant cell arteritis, lupus), intoxications, parasellar tumors, granulomatous meningitis, neuroborreliosis, syphilis and infection with *Bartonella henselae*.

Sydenham's chorea

Chorea is a smooth rapid movement that flows from joint to joint. Sydenham's chorea, which is associated with 15% of cases of rheumatic fever, can include dyskinesias such as tics, athetosis (worm-like movements) and ballismus (violent flinging movements). The prodrome includes emotional lability, obsessive-compulsive symptomatology and hyperactivity. The onset is insidious, with a latency of from 2 weeks to several months after streptococcal pharyngitis. Recovery varies, taking from several weeks to more than 6 months. Rheumatic carditis recurs in 20% of patients who have chorea.

The differential diagnosis of basal ganglia lesions includes metabolic disease (Wilson's disease, organic acidemias), cerebral palsy, postpump cardiac surgery, adverse drug reactions, cerebral vein thrombosis and lupus erythematosus (lupoid sclerosis).

DIAGNOSIS

It is challenging to differentiate postinfectious syndromes from infectious encephalitis (see Chapter 23). Magnetic resonance imaging (MRI) is more sensitive than computerized tomography (CT); CT scans are frequently normal;[16] MRI findings are large white matter lesions with initially asymmetric distribution and variable enhancement with contrast (Fig. 27.1). There is limited correlation between clinical signs and neuroradiologic imaging. White matter lesions may take up to 18 months to resolve, and new lesions may appear despite clinical improvement.[17]

Cerebrospinal fluid (CSF) findings are not specific. Elevated intracranial pressure is uncommon and the CSF profile is often

normal. Pleocytosis, if present, is mononuclear and rarely exceeds 200 cells/µl. With extreme inflammation (hemorrhagic leukoencephalitis), neutrophils and erythrocytes are seen. A mild elevation of CSF protein is common. The presence of MBP in the CSF is indicative of oligodendroglial damage and demyelination; the sensitivity is 60%.

Magnetic resonance imaging is recommended for acute cerebellar ataxia or optic neuritis to delineate multifocal CNS disease and to exclude vascular and space-occupying lesions. For acute transverse myelitis, exclusion of treatable causes of cord compression is essential. Computerized tomography scan or MRI of the spine has replaced myelography in the diagnostic approach; myelograms are usually normal in acute transverse myelitis. Despite clinical 'transection', MRI shows cord inflammation extending along many segments. Cerebrospinal fluid analyses are similar to those in PIE. Testing for syphilis, schistosomiasis, HIV and HTLV-1 (often coincident) is important in patients from endemic areas who have unexplained myelopathy. Polymerase chain reaction (PCR) best detects CMV, VZV and toxoplasmosis in the CSF of immunocompromised hosts.

Culture of CSF is indicated, but rarely informative in cases of ADEM. Results of genetic amplification assays such as PCR can be useful when interpreted properly. DNA or RNA derived from infectious agents can persist for weeks and should not necessarily be construed as evidence of active infection; it can identify antecedent infection.[18] [19] Genetic material can mislead when detected as false positives or 'innocent bystanders' in areas of inflammation.[20] Cerebrospinal fluid antibody titers are of limited use. An absence of CSF antibodies is consistent with PIE but CSF antibodies may be long-lived and unrelated to the acute process.[4] [21] Simultaneous seroconversions to several pathogens are common, and antibodies to *Mycoplasma pneumoniae* are cross-reactive with brain tissue.[8]

MANAGEMENT

There is no proven treatment for PIE. It is difficult to distinguish postinfectious myelitis from neurosurgical emergencies; early use of CT or MRI is indicated. Lumbar puncture should include pressure measurement. Antiviral therapy is not indicated but initial exclusion of treatable infectious encephalitis can be difficult and empiric therapy is often given. Immunoglobulin and corticosteroid therapies have no demonstrated benefit in ADEM, although corticosteroids have been used to treat swelling of the cord.[22]

Management of seizures with anticonvulsants and administration of antipyretics is recommended; autonomic instability should be treated with short-acting drugs. Protection of the airway and control of intracranial pressure are often necessary. Management of acute transverse myelitis requires meticulous care to avoid complications during prolonged recovery. Pneumonia, sepsis, renal failure and autonomic disturbances, including arrhythmias, are acute life-threatening complications. Urinary tract infection is very common; intermittent catheterization is preferable to use of an indwelling catheter to minimize this risk. Good nursing and, in some cases, anti-coagulation should minimize the risk of pulmonary embolism. Psychologic support is necessary for both the patient and his/her family. Corticosteroids are sometimes given in high doses for optic neuritis to obtain a rapid improvement but have no significant effect on long-term outcome.[23]

ENCEPHALOPATHY AND REYE SYNDROME

EPIDEMIOLOGY

The term encephalopathy is used when CNS dysfunction is not associated with histologic or indirect evidence (CSF pleocytosis, MRI findings) of inflammation. Encephalopathy following infection or immunization does not appear to be a single syndrome. The Vaccine Safety Committee of the Institute of Medicine, Washington, DC, has modified case definitions used in the National Childhood Encephalopathy Study (NCES; Table 27.3). Reye syndrome is an encephalopathy associated with liver dysfunction.

The incidence of postinfectious and postvaccinal encephalopathy varies by country, reflecting national immunization practices and sanitation. The incidence of postvaccine encephalopathy is less than 10.5/million immunizations. [24] Age-specific incidences of vaccines and postvaccinal encephalopathy overlap the ages of onset of many childhood neurologic conditions. [25] [26] The incidence of encephalopathies associated with typhoid and other enteric pathogens is highest during the summer or the rainy season. The seasonality of Reye syndrome corresponds to antecedent varicella or influenza infections. The incidence of Reye syndrome was 0.31/100,000 individuals under 18 years of age in 1980; milder forms of the encephalopathy occur in 5.6/100,000 children.[27] Reye syndrome associated with salicylate use has become less common since the educational campaigns discouraging aspirin use in children.[28]

Whole-cell pertussis (wP) is the vaccine most frequently associated with encephalopathy. Controversy over the neurologic complications of the diphtheria, tetanus and wP (DTwP) vaccine reduced the immunization rate in the UK to 31% in 1977; this in turn gave rise to the largest epidemic of pertussis observed in 20 years. The NCES, a case-control study of the association of DTwP immunization with serious neurologic diseases, was undertaken from 1976 to 1979. Estimated attributable risk for acute encephalopathy, atypical seizures, infantile spasms and Reye syndrome was 1/110,000 doses.[25] A 10-year follow-up study confirmed that all serious acute neurologic events, irrespective of association with DTwP, might be associated with important neurologic sequelae.[26] Evidence is consistent

TABLE 27-3 -- Definition of encephalopathy.*

DEFINITION OF ENCEPHALOPATHY
Acute encephalopathy
Children <24 months:
Significantly decreased level of consciousness (stupor or coma) lasting for at least 24 hours, not attributable to postical state or medication
Children = months:
Condition lasting for at least 24 hours, characterized by two of following:
Confusional state or a delirium, or a psychosis, not medication related
Significantly decreased level of consciousness (stupor or coma), independent of seizure and not attributed to medication
Seizure associated with loss of consciousness
Increased intracranial pressure is consistent with the diagnosis at any age
Excluded conditions:
Sleepiness
Persistent inconsolable crying
Bulging fontanelle
Seizures
Chronic encephalopathy
Persistence of acute findings over several months to years beyond the acute episode
Excluded conditions:
Return to normal, followed by chronic encephalopathy
Chronic encephalopathy secondary to genetic, prenatal or perinatal factors

** Modified from Vaccine Safety Committee, Institute of Medicine.[3]*

with, but does not establish, a causal relationship of DTwP vaccine with encephalopathy; there were no associations of DTwP with infantile spasms or Reye syndrome. Acellular pertussis vaccines will change the incidence of this syndrome.

PATHOGENESIS AND PATHOLOGY

The pathogenesis of postinfectious or postvaccinal encephalopathy is not known. Latency between infection or vaccination and encephalopathy is highly variable, ranging from hours up to 6 weeks. Autopsy series of postinfectious encephalitis include cases of encephalopathy; findings demonstrate cerebral edema without inflammation. Hypoxic insult, electrolyte disorders and endogenous toxins are often invoked to explain this pathology.[29] [30] Some cases of postvaccinal encephalopathy may result from unmasking or precipitation of an underlying neurologic condition by the vaccine.[24] Postinfectious encephalopathy is associated with non-specific respiratory and gastrointestinal tract infections, measles, pertussis and typhoid infections.[31] [32] Whole-cell pertussis, DT/Td/tetanus toxoid, and measles, mumps and vaccinia vaccines have been associated with encephalopathy. [24]

Liver pathology in Reye syndrome is pathognomonic. Panlobular accumulation of small lipid droplets occurs without evidence of cholestasis or inflammation. By electron microscopy, the mitochondria are large and irregular, with diminished matrix granules. There may be a proliferation of peroxisomes and smooth endoplasmic reticulum, and depletion of glycogen. The pathogenesis is not known. Underlying metabolic disorders cause some cases of Reye syndrome.[33]

PREVENTION

Repeat immunization with the specific vaccine is contraindicated in instances of postvaccinal encephalopathy not due to another identifiable cause. Avoidance of aspirin use for common fevers and for analgesia in children effectively minimizes the risk of Reye syndrome. Reye syndrome following the administration of live varicella vaccine to patients on chronic salicylate therapy has not been described. The decision of whether to give this vaccine to such patients must be individualized.

CLINICAL FEATURES

Postinfectious encephalopathy is a disease of early childhood, occurring at a mean age of 18 months. In contrast, PIE is rare in children under 2 years of age. Encephalopathy after pertussis infection occurs mostly during the first 6 months of life.[30] In contrast to postinfectious and postvaccinal encephalopathy, Reye syndrome affects school-aged children and adolescents.

Encephalopathy is indistinguishable clinically from encephalitis. [11] [29] Fever and seizures are common but the presence of focal neurologic deficits is unusual. No specific neurologic syndrome has been described after DTwP vaccination. The onset of encephalopathy after wP vaccination typically occurs in the first 3 days and is rare after 7 days, although encephalopathy after pertussis infection occurs in the second or third week. Reye syndrome is heralded by severe repetitive vomiting refractory to common interventions, followed by altered consciousness.

The differential diagnosis of encephalopathy is similar to that for PIE. In infants, shaken baby syndrome, cerebral vein thrombosis and hyperpyrexic shock with encephalopathy must be considered. In many countries, shigellosis, acute typhoid fever and malaria cause diagnostic confusion.

Encephalopathy is frequently complicated by aspiration pneumonia. Intracranial hypertension, inappropriate antidiuretic hormone secretion, electrolyte disorders and hypoxic-ischemic injury may exacerbate it and produce secondary brain damage. Cerebral edema can be severe and lead to cerebral herniation. Children suffering severe neurologic syndromes temporally associated with wP vaccine administration carry a 5-fold relative risk for chronic neurologic disease over asymptomatic vaccine recipients. [26]

DIAGNOSIS

There is no diagnostic test for postinfectious encephalopathy. The CSF is frequently under increased pressure but is otherwise normal by routine analysis. In Reye syndrome there must be evidence of liver disease consisting of elevated liver transaminases or elevated plasma ammonia. The blood glucose concentration is frequently low; bilirubin is normal.

A diagnosis of postvaccinal encephalopathy is by temporal association; proof of causation is impossible in individual cases.

MANAGEMENT

Therapy is supportive. Electrolyte or metabolic disorders and intoxications are excluded by history and laboratory analysis. Magnetic resonance imaging may reveal encephalomyelitis, cerebral edema or other pathology. Plasma and urine samples for metabolic analysis should be obtained early. Intravenous glucose is important for brain metabolism and reversal of gluconeogenesis and hyperammonemia. Complications of encephalopathy include aspiration and cerebral herniation. Intubation and mechanical ventilation are commonly indicated.

GUILLAIN-BARRÉ SYNDROME

EPIDEMIOLOGY

Guillain-Barré syndrome is an acute, ascending, symmetric paralytic disorder diagnosed by consensus clinical criteria. Acute inflammatory demyelinating polyneuropathy (AIDP) is the classic form of GBS. Variants include:

- acute motor axonal neuropathy (AMAN; Chinese paralysis syndrome);
- acute motor sensory axonal neuropathy (AMSAN);
- hyperacute GBS; and
- Miller-Fisher syndrome.

Other forms may exist.

Guillain-Barré syndrome has replaced poliomyelitis as the most common cause of acute flaccid paralysis worldwide. In the temperate Americas, Europe and Australia, GBS occurs without seasonality.[33] [34] In China, the middle latitudes of the Americas, and possibly the Indian subcontinent, the number of cases increases during summer months.[35] Geographic or familial clustering is rare with either form. Guillain-Barré syndrome and axonal variants are coincident and the incidence of GBS is estimated to be 0.4–1.5/100,000 population in temperate climates.

Guillain-Barré syndrome is associated with most antigenic triggers of PIE, including minor respiratory infections in 50% of cases. *Campylobacter jejuni* infections are associated with 26–40% of cases in industrialized nations and in up to 90% of cases in China.[35] Fewer than 5% of cases are vaccine-associated.[36] Guillain-Barré syndrome has been reported with primary HIV infection and as part of the immune reconstitution syndrome during therapy.[37]

PATHOGENESIS AND PATHOLOGY

The pathogenesis of GBS is heterogeneous.[38] [39] Peripheral nerve myelin is distinct from CNS myelin and mechanisms of demyelination

in the CNS and PNS may differ. Major proteins in peripheral myelin include P_0 , MBP and P_2 . The G_{M1} ganglioside is enriched in paranodal regions of both nerve and myelin, although the G_{Q1b} ganglioside is similarly enriched in oculomotor nerves.

Classic GBS (AIDP) is an acute monophasic demyelinating syndrome of peripheral nerves.[34] It is multifocal, with a predilection for nerve roots and internodes. Demyelination is associated with deposits of antibody and complement as well as macrophage 'stripping' of outer myelin lamellae. Inflammation at the nerve roots is believed to lead to disruption of the CNS blood-brain barrier, with leakage of serum proteins into the CSF. In AIDP, axonal loss is correlated with severe inflammation.

Experimental allergic neuritis, caused by repeated immunization with peripheral nervous tissue, is clinically, electrophysiologically and pathologically similar to GBS. Immunologic mechanisms may differ between experimental allergic neuritis and GBS. Passive transfer of lymphocytes sensitized to P_0 or P_2 myelin proteins reproduces experimental allergic neuritis; transfer of serum does not. In contrast, human T cell activation against myelin proteins is variable, although sera from GBS patients causes nerve demyelination in tissue culture. Antibodies against G_{M1} and related sialylated gangliosides are detected in up to 60% of patients with *C. jejuni*-associated GBS. Strains of *C. jejuni* contain membrane glycolipids with identical glycoconjugate structures to those of peripheral nerve gangliosides. This is antigenic identity rather than mimicry. Anti-ganglioside G_{Q1b} antibodies against the neuromuscular junction are described in 90% of cases of Miller-Fisher syndrome, a GBS variant with ophthalmoplegia.

Acute motor sensory axonal neuropathy and AMAN variants, although clinically similar to demyelinating GBS (AIDP), are characterized by axonal degeneration with or without sensory nerve involvement, respectively.[38] [39] Both syndromes are frequently associated with *C. jejuni*. Axonal degeneration correlates with macrophage infiltration of internodal and periaxonal spaces.[38] A chicken model of *C. jejuni*-associated AMAN has been reported.

Infectious and other antigenic triggers associated with GBS are common (Table 27.4). *Campylobacter* can induce several autoimmune conditions; reactive arthritis and GBS do not cosegregate. Specific matches of bacterial serotypes (Penner serotypes O:19 in Japan and O:41 in South Africa) and host genotype may be required; these may be specific for each geographic region.[40] [41]

TABLE 27-4 -- Conditions associated with Guillain-Barré syndrome.

CONDITIONS ASSOCIATED WITH GBS
Non-specific respiratory tract symptoms
Campylobacter jejuni
Mycoplasma pneumoniae
Cytomegalovirus
Epstein-Barr virus
HIV-1
Japanese encephalitis virus
Hodgkin's disease
Lymphoma
Systemic lupus erythematosus
Surgery
Parturition
Vaccines
Vaccinia
Rabies
Influenza A/New Jersey/76
Oral poliovirus in Finland

PREVENTION

Guillain-Barré syndrome associated with *C. jejuni* infections is prevented by improvements in local sanitation, water and food supplies. Control of common diseases

such as CMV, HIV, *Mycoplasma* infection and Japanese encephalitis should reduce the incidence of GBS and other postinfectious syndromes. Replacement of whole-cell or tissue-derived vaccines with purified component vaccines may also diminish the incidence of GBS.

CLINICAL FEATURES

The annual incidence of GBS in the USA increases with age, from 0.8/100,000 in individuals younger than 18 years to 3.25/100,000 in those over 60. [37] There is an overall male to female preponderance of 1.5:1 for GBS occurring in later life.[35] Acute motor axonal neuropathy in China affects children and young adults, with a mean age of 19 years.[36]

Guillain-Barré syndrome is an acute afebrile paresis that progresses over a few days to weeks. Diagnosis is by consensus criteria; there is no specific laboratory diagnosis (Table 27.5).[42] Paresthesias in toes or fingertips variably precede motor findings. Weakness is generally more profound in the legs but may predominantly affect the arms or cranial nerves in up to 10% of cases each. Weakness begins distally and progresses centrally; progression may be quite rapid. As GBS evolves, general symmetry of paresis is the rule. Dysautonomia may be prominent but bowel or bladder incontinence is rare. Pain is common, involving the large muscles of the legs and back.

Examination shows relatively symmetric motor weakness, absent or greatly diminished tendon reflexes and minimal loss of sensation despite sensory complaints. In severe cases, respiration, airway control and autonomic function are affected.

Miller-Fisher syndrome comprises ophthalmoplegia, ataxia and areflexia, with little weakness. Axonal neuropathy (AMAN or AMSAN) is clinically indistinguishable from demyelinating disease (AIDP). Curiously, axonal involvement is important for the prognosis of the adult but not the pediatric form of AMAN.[36] [43]

Phases of GBS include:

- progression (2–4 weeks);
- plateau (2–4 weeks); and
- recovery (weeks to months).

Respiratory failure develops in 20% of children and 40% of adults; pneumonia occurs in 25% of patients and urinary tract infections in 40%. Mean duration of intubation is 15–30 days with current therapy. Guillain-Barré syndrome is complicated by lability of blood pressure, cardiac arrhythmias or thrombosis in 20%, 25% and 3% of adults, respectively. Mortality with optimal supportive care and treatment is less than 5%.

A rapid onset of severe paresis, need for mechanical ventilation, increasing age, antibodies to *C. jejuni* and G_{M1} and axonal neuropathy are associated with slow or incomplete recovery.[44] Mean time to ambulation with current therapy is 40–50 days; 15% of cases do not walk at 48 weeks. Most (80%) eventually pursue normal activities but show mild residual effects under careful examination. The outcomes for children and adults are probably similar.

Guillain-Barré syndrome must be distinguished from a variety of diseases of the CNS and PNS. Chronic inflammatory demyelinating polyneuropathy, a relapsing demyelinative disease, and chronic progressive demyelinating polyneuropathy are clinically indistinguishable at onset from GBS.

DIAGNOSIS

Diagnosis requires examination of the CSF and nerve conduction studies (see Table 27.5). Cerebrospinal fluid pressure should be

TABLE 27-5 -- Criteria for diagnosis of Guillain-Barré syndrome.*

CRITERIA FOR DIAGNOSIS OF GBS	
Required	Muscle weakness
	Progressive motor weakness of more than one limb, and/or bulbar and facial paralysis (30%) and/or external ophthalmoplegia (6%)
	Areflexia
Supportive	Clinical
	Progression over 2–4 weeks
	Relative symmetry
	Mild sensory signs
	Cranial nerve involvement (without sphincter involvement; 50%)
	Recovery after interval of 2–4 weeks after nadir
	Autonomic dysfunction (20%)
	Absence of fever at onset
	Cerebrospinal fluid
	CSF protein rising after first week
	CSF leukocytosis less than 10/µl (mononuclear cells)
	Nerve conduction studies, in two or more motor nerves
	Partial conduction block or decreased M responses, or both (75%)
	Nerve conduction velocity <70% of normal, several weeks into illness (60%)
	Abnormalities in late responses (F waves, H reflexes; 46%)
	Features discordant for GBS
	Marked persistent asymmetry of weakness
	Sphincter dysautonomia at onset or persistent
	CSF leukocytosis >50/µl or neutrophils in CSF
	Sharp sensory level
	Systemic illness or constitutional symptoms
Exclusionary	-
Required criteria must be present for diagnosis. Supportive criteria strongly support the diagnosis, but may not be present initially and in all cases. Exclusionary criteria suggest an alternate diagnosis is likely.	

* *Modified from Asbury and Cornblath.* [42]

normal and contain fewer than 10 leukocytes/ml. Cerebrospinal fluid protein may be normal during the first 48 hours of illness and is not reliably elevated until the second week of illness. Nerve conduction studies must include several nerves because demyelination is patchy. Conduction studies may not become abnormal until

several weeks into the illness; up to 20% of patients never have abnormal studies. Conduction velocity is usually less than 60% of normal. F-wave responses, which measure nerve root disease, are a useful indicator of the disease.[42]

Stool cultures for *C. jejuni* are often positive in patients who have GBS, especially those who have axonal neuropathy. Diarrhea is an insensitive (70%) predictor of carriage of *C. jejuni*. Enrichment methods may improve yield from culture.[35] Serology for recent *C. jejuni* infection is of limited use. Cases may be culture-positive for *C. jejuni* but not mount an antibody response; IgM antibodies are cross-reactive with *Salmonella* and *Yersinia* spp. Approximately 50% of cases colonized with *C. jejuni* have serum antibodies against G_{M1} ganglioside. Anti-G_{M1} antibodies of IgM class are present in acute and chronic motor neuropathies, including axonal GBS; IgG class antibodies are more specific for classic GBS (AIDP).[45] Serologic evidence of infections with Epstein-Barr virus (EBV), CMV and *Mycoplasma* are reported in 15%, 8% and 5%, respectively, of GBS cases occurring in childhood and young adulthood.[46] [47] Cold agglutinins are often positive and result from EBV, CMV or *Mycoplasma* infection. Rheumatoid factor may cause false IgM seropositivity.

MANAGEMENT

The management of GBS is a challenge to the clinician because laboratory features are often absent until the second week of illness. It is essential to exclude competing diagnoses requiring emergent management, especially epidural abscess of the spine. Initial evaluation should include CT or MRI of the spine. Lumbar puncture is performed and repeated a week or two later. Nerve conduction studies are necessary for diagnosis and have prognostic significance for the course of recovery. Stool cultures with enrichment for *C. jejuni* provide corroborative data. Analysis for antiganglioside and anti-*Campylobacter* antibodies remains a research tool. Serology for syphilis and HIV are frequently ordered; some experts test for antibodies against EBV, CMV and *Mycoplasma*.

During evolution of the illness, it is imperative to monitor evolving respiratory paralysis by objective measures of vital capacity. In children unable to comply with standard testing, range of serial counting, alphabets or song in a single breath is useful at the bedside. Intensive care is indicated for rapidly declining vital capacities or those below 18ml/kg. Disease is intermittently progressive up to 4 weeks after onset.

Plasma exchange has proved to be superior to supportive treatment alone in GBS. Plasma exchange is more beneficial when started within 7 days of disease onset but is still beneficial up to 30 days after onset.[43] [44] [48] Intravenous immunoglobulin has similar ability to speed the recovery from GBS. Use of corticosteroids is not effective.[34] The natural history of GBS, with spontaneous full recovery in 80% of cases, limits statistical power for detecting differences in therapy. Therapy for Miller-Fisher syndrome has not been well studied; pediatric representation in studies is low. Complications limit therapy in 14% of plasma exchange and 3% of intravenous immunoglobulin therapies. Combination therapy with plasma exchange and intravenous immunoglobulin (IVIG) results in comparable efficacy but additive toxicities.[43] Anecdotal reports suggest better outcome after treatment with IVIG over plasma exchange in cases with both G_{M1} and *C. jejuni* antibodies. [49] Relapses occur after either therapy in 10% of cases.[34] Although therapy with IVIG can be performed at many clinics, most experts agree that GBS requires expert diagnosis and management available at tertiary referral centers. An international support group, GBS Foundation International, is accessible on the internet at http://www.webmast.com/gbs/.

BRACHIAL NEURITIS

EPIDEMIOLOGY AND PATHOGENESIS

Brachial neuritis (brachial plexus neuropathy, neuralgic amyotrophy) is a well-described but poorly understood axonopathy. Annual incidence is approximately 1.6/100,000 individuals.[3] About 15% of cases are associated with immunizations or administration of antiserum; outbreaks have been reported. Administration of tetanus toxoid carries an excess risk of 0.5–1.0/100,000 doses. Latency from immunization to disease is 6–21 days, consistent with an immunologic mechanism.[3]

CLINICAL FEATURES

Brachial neuritis begins with severe aching pain of the shoulder and upper arm. Weakness develops as pain subsides. Motor and

sensory deficits are consistent with lesions in the brachial plexus. There is no correlation of laterality of brachial neuritis and antecedent immunization; the syndrome is bilateral in up to one-third of cases. Recovery, requiring regeneration and collateral innervation of axons, begins within 1 month of onset and requires 2–3 years. Brachial neuritis can be complicated by paresis of the diaphragm.

Brachial neuritis must be distinguished from injection damage to the nerve, poliomyelitis at the site of an antecedent injection, cervical ribs, cord compression and Lyme disease. In the infant, perinatal traction injury, syphilitic pseudoparalysis and occult trauma or osteomyelitis must also be considered.

DIAGNOSIS AND MANAGEMENT

Nerve conduction studies are consistent with axonal neuropathy without a conduction block. Radiologic study of the affected arm and shoulder is often performed to exclude alternate diagnoses. Serologic testing for syphilis and Lyme disease may be indicated. There are no controlled studies on the therapy of this uncommon disorder. Psychologic support is essential during prolonged rehabilitation.

CRANIAL NEUROPATHIES

EPIDEMIOLOGY AND PATHOGENESIS

Peripheral cranial nerves can be affected singly or as a multifocal process following infections or immunizations. Facial palsy is the most common cranial neuropathy, with incidence of 35/100,000 population. Bell's palsy or isolated acute peripheral facial paralysis of unknown etiology accounts for 73% of facial palsies. Similar etiologies for GBS and Bell's palsy were suggested in one study.[37] Although a postinfectious etiology is presumed, recent molecular data implicate reactivation by herpes simplex virus (HSV)-1.[50] Bulbar nerve palsies and ophthalmoplegia occur most commonly in association with GBS (30% and 6% of GBS cases, respectively).

CLINICAL FEATURES

Mean age of onset of facial palsy is 46 years, with equal sex distribution. The onset frequently follows a respiratory tract infection. The paresis is sudden, without systemic illness. Simultaneous, bilateral disease occurs in less than 1% of cases in adults and may be associated with subclinical neuropathy of other cranial or peripheral nerves. Bilateral disease is more frequent in children. Resolution occurs within 6 weeks in 80% of cases. Bulbar nerve palsies present with a weak voice or cry, nasal intonation, nasal reflux and difficulty handling oral secretions. Ophthalmoplegia can present as torticollis or diplopia and be associated with retro-orbital pain.

In areas of endemicity, *Borrelia burgdorferi* causes 30% of facial, and most bilateral, palsies.[51] Herpes simplex virus and VZV cause facial palsy by primary infection or reactivation. Although HIV-1 is associated with facial palsy, paresis during severe immunodeficiency usually indicates another etiology. Causes of facial paresis include GBS, multiple sclerosis, skull fractures, suppurative otitis, acoustic neuroma, carcinomatous or granulomatous meningitis, sarcoidosis, leprosy, diphtheria and Kawasaki disease. [52] Causes of ophthalmoplegia include chronic meningitis, intracranial hypertension and botulism. Bulbar paresis occurs in GBS, diphtheria, botulism, poliomyelitis and paraneoplastic syndromes.

DIAGNOSIS

Polymerase chain reaction detected HSV-1 genome in 79% of endoneural fluids from a surgical series with Bell's palsy.[50] Extrapolation to PCR testing of other sterile fluids, such as CSF, is uncertain. Serologic diagnosis of Lyme borreliosis or antecedent HSV or VZV infection in facial palsy is complicated by limitations of test sensitivities and specificities.[51] Simultaneous seroconversions to several viruses are common.[52] In areas endemic for Lyme disease, physicians frequently evaluate facial palsy after empiric oral therapy against *B. burgdorferi*. Given the self-limited nature of Bell's palsy, it is poor logic to make a causal diagnosis based on the response to therapy for Lyme disease.

MANAGEMENT

Management of isolated Bell's palsy varies. Evaluation of bilateral facial palsies or other cranial neuropathies includes investigation for GBS and CNS demyelinating disease. There are few controlled therapeutic trials to address therapeutic strategies; corticosteroid therapy is no more effective than placebo. Favorable responses to aciclovir await further confirmation.

Chapter 28 - Infections in Hydrocephalus Shunts

Roger Bayston

Hydrocephalus shunts drain excess cerebrospinal fluid (CSF) from the cerebral ventricles to the peritoneal cavity (ventriculoperitoneal, VP), to the right cardiac atrium (ventriculoatrial, VA) or less commonly to other sites (Fig. 28.1). Cerebrospinal fluid is also sometimes drained from the lumbar spinal theca to the peritoneal cavity (lumboperitoneal, LP).

EPIDEMIOLOGY

The incidence of infection varies according to the age at which the shunt is inserted. Up to 25% of operations in premature infants with hydrocephalus after periventricular hemorrhage result in infection, whereas in older children the incidence is 3–8%.[1] [2] [3] There is no difference in infection rates between VA and VP routes.[4] Although the incidence of shunt infections has generally fallen, it is still unacceptably high. Some centers have reported rates of infection near to zero[5] but this is rare.

PATHOGENESIS AND PATHOLOGY

The source of the organisms is almost invariably the patient's skin, from which they gain access to the device during its insertion.[6] [7] Where there is a serious breakdown in surgical asepsis or where the operating room environment or air is grossly contaminated, these may be alternative sources. Although the bacterial population on the surface of the patient's skin can be reduced to almost zero by agents such as alcoholic chlorhexidine, recolonization by resident bacteria occurs rapidly. It is therefore usual to find coagulase-negative staphylococci in the incision during the procedure. In nonimplant surgery these are irrelevant, but where a biomaterial or device is inserted they are highly likely to adhere to and colonize the device. Coagulase-negative staphylococci, and particularly *Staphylococcus epidermidis*, predominate in shunt infections. After adhering to the shunt material, they multiply and produce copious amounts of exopolysaccharide ('slime'), enabling the formation of a biofilm. Because of nutrient depletion, growth is very slow and this accounts for the often long periods between surgery and clinical presentation of infection. *Staphylococcus aureus* causes a different clinical picture and is more frequently involved in external shunt infections (Fig. 28.2).[4] Unlike *Staph. epidermidis*, it produces a-toxin, which protects it from phagocytosis. A very active inflammatory response is also evoked, leading to erythema and suppuration.

The clinical presentation of infection in VA shunts differs from that in VP shunts (Table 28.1). In the former, bacteria enter the bloodstream directly to cause intermittent fever which, in infections caused by *Staph. epidermidis*, propionibacteria or coryneforms, may continue for months or years with little other evidence of infection. However, antibody to bacterial components is produced in large quantities and immune complex disease may ensue, with deposits of C3, C4, IgG and IgM on the synovial and glomerular basement membranes. Hypertension, renal failure (shunt nephritis) and arthropathy may result.[8] In VP and LP shunt infections, the bacteria are discharged into the peritoneal cavity, provoking the greater omentum to seal off the distal catheter. This and associated adhesions give rise to shunt obstruction and raised CSF pressure (Fig. 28.3). Occasionally, peritoneal abscesses are seen. In all types of shunts ventriculitis is seen in most cases, although the inflammatory response is usually feeble. Only a few shunt infections are due to causes other than surgery. In babies or adults whose nutritional status is poor, erosion of the skin over the shunt can take place, leading to secondary infection with *Staph. aureus* or Gram-negative bacteria. An unusual but well-documented cause of VP shunt infection is visceral perforation by the distal catheter, which results in polymicrobial infection of the cerebral ventricles.[9] However, peritonitis from this cause is rare.

No cases of hematogenous spread, including to VA shunts, have been documented. Cerebrospinal fluid shunts appear to be unusually free of risk from this source. However, VP shunts can become infected during abdominal surgery or continuous ambulatory peritoneal dialysis.

PREVENTION

Studies have shown that knowledge of the causes of shunt infections and surgical experience are very important and shunt surgery should be carried out only by experienced personnel or by fully supervised trainees. In addition, the principle that surgical infection rates can be reduced by shorter preoperative hospitalization should be applied to shunt surgery wherever possible. In view of the source of infection, most attempts at prevention have been targeted at the surgical procedure. Alcohol-based povidone-iodine and chlorhexidine should be used for skin preparation, the latter having the greater activity. Assiduous surgical technique is extremely important, but infection rates are rarely reduced below 3–5% for adults and 10% for infants. The use of prophylactic antibiotics might appear to be reasonable, but they have not been found to have a statistically significant beneficial effect in properly designed trials.[10] Those who feel obliged to use them despite this are advised to administer 10mg vancomycin hydrochloride in 1–2ml sterile water for injection intraventricularly as soon as the ventricular catheter is inserted (this should be inserted first), and 1.5g cefuroxime (25mg/kg for children) intravenously at induction of anesthesia. Intravenous antibiotics alone are not recommended.

External shunt infections (involving the tissues around the outside of the shunt) are not sufficiently common to merit the routine use of prophylaxis, but where a special problem exists a first- or second-generation cephalosporin should be administered intravenously at induction. Because of the general lack of success in further reducing the infection rate beyond acceptable minima, several innovative processes have been developed for treatment of biomaterials and devices in order to reduce bacterial adherence. To date these have not proved effective outside the laboratory and very few are suitable for central nervous system (CNS) implantation. Often, only the outside surface of the shunt is modified, so

Figure 28-1 Routes of drainage of ventriculoperitoneal and ventriculoatrial shunts. Ventriculoperitoneal shunts drain CSF from the cerebral ventricles to the peritoneal cavity via catheter tubing implanted superficially over the rib cage. The lower end of the peritoneal catheter lies free in the abdomen. Ventriculoatrial shunts drain CSF via a convenient neck vein such as the jugular and the superior vena cava to the right atrium.

Figure 28-2 External shunt infection in a premature infant with poor nutritional status. The infection can be caused by organisms introduced at surgery or they may gain access through minor skin abrasions and pressure necrosis. Differing from the more common internal shunt infections, they are usually caused by *Staphylococcus aureus* and constitute a wound infection enhanced by a foreign material.

no significant effect on the majority of shunt infections can be expected. One process (Bactiseal) consists of introducing rifampin (rifampicin) and clindamycin into the molecular matrix of the silicone in such a way that high-level protection of all surfaces can be conferred for over 2 months in long-term in-vitro tests. Antibacterial activity is undiminished in the presence of protein conditioning film, such as that found in infants with high CSF protein levels after hemorrhage or meningitis, who are at greatest risk of shunt infection.[11] The results of clinical trials are awaited.

CLINICAL FEATURES

The clinical features of VA shunt infection differ considerably from those of VP and LP shunts (see Table 28.1). Although the shunt lumen becomes colonized at implantation, in VA shunts symptoms

TABLE 28-1 -- Clinical features of ventriculoatrial and ventriculoperitoneal shunt infections of surgical origin.

CLINICAL FEATURES OF VA AND VP SHUNT INFECTIONS OF SURGICAL ORIGIN		
	VA shunts	**VP shunts**
Time from surgery to presentation	Weeks, months, several years	<9 months
Intermittent fever	75%	<50%

Anorexia, lassitude, poor sleep pattern	>80%	>50%
Shunt obstruction	<1%	>75%
Other features	Chills, rigors: 20%	Abdominal pain, bloating: >75%
	Arthralgia: 50% (late onset cases (1–15 years))	Swelling, erythema over shunt tubing: >60%
	Rash: 70% (late onset cases (1–15 years))	Headache, vomiting, etc. (i.e. recurrence of hydrocephalus): 75%
	Nephritis: 30% (late onset cases (1–15 years))	
Percentages indicate the approximate proportion of cases in which features are present. It is important to realize that each case is different and that many of these features may be absent or modified		

Figure 28-3 Cystic obstruction of a ventriculoperitoneal shunt caused by shunt infection with *Staphylococcus epidermidis.* Bacteria and bacterial products entering the peritoneal cavity via the shunt catheter evoke an inflammatory response involving the greater omentum, which seals off the catheter outlet. The resulting cyst fills with CSF, giving rise to recurrence of the hydrocephalus. Cystic obstruction can occur from noninfective causes but unlike those cases caused by infection, which present within 6–9 months of surgery, they can arise at any time.

considered serious enough to warrant specialist medical attention may not appear for months or years.[8] Many patients have intermittent low-grade fever, but some do not. Some report chills and occasionally rigors. Transient rashes are common. Sore throat and muscular and joint pains are common complaints. Anemia is almost universally found and there is increasing lassitude, anorexia, irritability and poor sleep. Dyspepsia may also be a problem. In later stages, arthralgia becomes more common. Unfortunately, these features are non-specific and are often mistaken for those of other conditions. As the disease progresses, nephritis and vasculitis may

appear. The vasculitic rash is usually confined to the lower extremities and can be frankly hemorrhagic and can ulcerate. Nephritis is indicated by hypertension, hematuria and proteinuria, edema and often loin pain. Endocarditis has been reported only rarely.

In contrast, infections in VP and LP shunts almost always present within 6 months of surgery.[12] [13] Fever is present in fewer than 50% of cases and is usually intermittent and mild. Chills and rigors are rare. There may be abdominal discomfort, bloating, pain or tenderness and occasionally persistent flatulence. In cases presenting within 1 or 2 weeks of surgery, there may be failure of the abdominal wound to heal, with CSF leak and sometimes catheter protrusion. In LP shunts there is often spinal pain. However, the most constant symptoms are those of hydrocephalus caused by obstruction at the distal end and the differential diagnosis is between infective and noninfective shunt obstruction. In the former there is often erythema and tenderness over the lower shunt track, whereas these features are absent in noninfective obstruction. In addition, distal VP shunt obstruction occurring more than 9 months after shunt surgery is very unlikely to have an infective cause.[13] [14] A very small number of cases present as acute abdomen, with fever, abdominal pain and tenderness suggesting appendicitis or peritonitis. [15] These may present at any time and may lead to unnecessary laparotomy. The tenderness is not necessarily associated with the location of the shunt tip.

Ventriculoperitoneal shunt infections can also present at any time after perforation of the bowel or vagina. The distal catheter often protrudes from the anus or vagina and CSF leaks from these sites. They usually present as meningitis rather than shunt obstruction or peritonitis, with few abdominal features. Considering the often large numbers of bacteria seen in the CSF in these cases, the patients are not usually severely ill and recovery is often uneventful after shunt removal, without need for laparotomy.

DIAGNOSIS

Blood should be drawn for culture in all cases of suspected shunt infection. However, in infected VP and LP shunts the positive culture rate is less than 5%, except where *Staph. aureus* or Gram-negative bacilli are involved. In VA infections the positivity rate is much higher and blood should be drawn for culture on several occasions. However, in longstanding infections blood cultures may remain negative, possibly because of high antibody and opsonin titres. All isolates, however doubtful, should be saved until a definitive diagnosis is made. Attempts should be made to compare consecutive isolates, by antibiograms and by proprietary kits such as API Staph, or by molecular typing techniques if available. Differentiation between contaminants and pathogens, however, remains a problem. In addition, despite claims that a positive test for adherence or 'slime' production indicates a likely pathogen rather than a contaminant,[16] [17] critical evaluation shows that these tests, as currently formulated, are of no value in the diagnostic laboratory.[18]

Aspiration of CSF from the shunt reservoir carries little risk of introducing infection. The CSF sample should be examined promptly and a portion should be centrifuged for Gram film and culture, whatever the cell count, because bacteria are not infrequently found in the absence of a significant cellular response. As with blood cultures, isolates should be kept and identified, although the isolation of an organism from a shunt aspirate, particularly if it is also seen on Gram film, is diagnostic of shunt infection. It is important to realize that no isolate should be disregarded, whatever its identity.

It should be noted that the shunt can be infected only distal to the reservoir. In such cases reservoir aspiration may yield normal CSF that is culture negative.

In the presence of symptoms and a suggestive history, negative blood and CSF cultures cannot rule out shunt infection completely and a high index of suspicion should be retained. If symptoms persist consideration should be given to removing the shunt empirically and it is then imperative that it is sent immediately to the laboratory in a sterile container for Gram stain and culture. Cultures should be incubated for at least 5 days. The Gram stain is very important; where organisms are isolated on culture without being seen on microscopy they are almost invariably contaminants, except where antimicrobials have been given immediately before shunt removal. Also, Gram-positive bacilli seen on microscopy often indicate propionibacterial infection, requiring anerobic culture for up to 2 weeks.

In view of the difficulties both of laboratory and of clinical diagnosis, serologic tests have been developed. For example, a whole-cell agglutination test using *Staph. epidermidis* has proved useful in diagnosing VA shunt infections.[8] The agglutinin titer in individuals without shunts rises with age. In patients who have VA shunt infection caused by coagulase-negative staphylococci, the titer rises before symptoms appear and, over several months, it can rise to 15–30 times the normal level for age. It can therefore be used as a screening test. When used in this way, shunt nephritis is not seen because a diagnosis is invariably made sufficiently early for it to be avoided.[8] Ventriculoperitoneal and LP shunts do not discharge directly into the bloodstream, which may explain why the agglutination test is not useful in these cases. The plasma C-reactive protein can also be helpful in distinguishing between infective and noninfective distal VP shunt obstruction.[19]

MANAGEMENT

Three factors are important in the antimicrobial chemotherapy of shunt infections. The first is the inherent multiresistance of many strains of coagulase-negative staphylococci. Almost all are resistant to penicillin and at least 50% are resistant to methicillin and therefore to cephalosporins. Resistance to aminoglycosides is also common. However, all clinical isolates of *Staph. epidermidis* are currently susceptible to vancomycin, although some strains of *Staph. haemolyticus* and a few of *Staph. epidermidis* are resistant to teicoplanin. Similarly, the incidence of resistance to rifampin and lincosamines is low in most centers.

The second factor is the lack of a vigorous inflammatory response in the CNS to most shunt infections and most systemically administered antimicrobials fail to penetrate the CSF, this being particularly true of aminoglycosides, ß-lactams, glycopeptides and streptogramins. Of the few drugs that give acceptable CSF concentrations in such circumstances, chloramphenicol is bacteriostatic and ineffective in treating shunt infections; rifampin is highly active against most organisms causing shunt infections but cannot be given alone because of rapid development of resistance; and trimethoprim is active against fewer Gram-positive bacteria than rifampin.

The third factor is the mode of growth of the organisms in the shunt lumen. Bacteria that grow as a biofilm have much lower growth rates and produce exopolymers. The concentration of antimicrobials required to kill biofilm organisms is often several logs higher than the conventional minimum inhibitory concentration. [20]

These factors explain the generally disappointing results achieved whenever attempts are made to treat shunt infections without shunt removal. The shunt should therefore be removed early and an external ventricular drain (EVD) inserted to control CSF pressure (Table 28.2). This course of action is supported by many reports,

clearly indicating that shunt retention is associated with a greater chance of relapse, a longer hospital stay and a greater risk of death.

Antimicrobials should be begun as soon as the diagnosis is confirmed. Vancomycin is recommended for coagulase-negative staphylococci, *Staph. aureus*, coryneforms and for those enterococci that are susceptible. As the drug does not give adequate CSF

TABLE 28-2 -- Treatment of shunt infections caused by *Staphylococcus epidermidis*, other coagulase negative staphylococci and other susceptible Gram-positive bacteria

TREATMENT OF SHUNT INFECTIONS CAUSED BY *STAPH. EPIDERMIDIS*, OTHER COAGULASE NEGATIVE STAPHYLOCOCCI AND OTHER SUSCEPTIBLE GRAM-POSITIVE BACTERIA
Shunt removal, insertion of external drain
Intraventricular vancomycin 20mg daily plus intravenous/oral rifampin 15mg/kg per day (pediatric) or 600mg/day (adults), both in two divided doses
After 7–10 days of treatment, reshunt if necessary. Stop both antibiotics on this day

concentrations when given intravenously,[4] it should be given intraventricularly via a reservoir or through the clamped EVD tube. A Rickham reservoir should be incorporated in the system if the chosen EVD does not have a reservoir or injection port. Alternatively, an Ommaya reservoir can be inserted contralaterally. The standard dose of intraventricular vancomycin is 20mg daily, although this should be reduced to 10mg daily for those with small ventricles. It should be noted that the dose depends on ventricular volume rather than on age or body weight. The vancomycin should be diluted in 1–2ml sterile water for injection. In addition to vancomycin, rifampin should be given intravenously in a total dose of 15mg/kg per day (two divided doses) for children or 300mg q12h for adults along with intravenous or intramuscular flucloxacillin (250–500mg q6h or 60–125mg q6h for children) or oxacillin (500mg q6h; for children >40kg body weight, use adult dose, <40kg 25–50mg/kg q4h). The drugs can be given orally in most cases after a few days. Alternatively, trimethoprim can be given intravenously, 3mg/kg q8h for children and 250mg q12h for adults. Teicoplanin offers no obvious advantage over vancomycin. Intraventricular vancomycin given in the doses recommended above leads to CSF concentrations that commonly reach 5–10 times the expected plasma concentrations, but no toxicity has been encountered. Attempts should not be made to titrate the dose to keep the CSF concentrations below the toxic plasma levels. There is no indication for the use of intravenous vancomycin in addition to that given by the intraventricular route except in the case of methicillin-resistant *Staph. aureus* shunt infections, for which vancomycin might be the only available agent. The drug may be given by the intravenous route alone if the CSF cell count and protein concentration are sufficiently raised to indicate a vigorous inflammatory response, but this is the case only with *Staph. aureus* infections.

Using this regimen, coagulase-negative staphylococci should no longer be detectable in the CSF on microscopy or culture by day 4 and any fever should have resolved. A new shunt, if needed, can be inserted by day 7–10 of the regimen, the last dose of antibiotics being given on that day. It is unwise to wait for a few days after stopping treatment, as this is the period of greatest risk for secondary infection from the EVD. Using this regimen for coagulase-negative staphylococci, *Staph. aureus*, coryneforms and propionibacteria, successful eradication and reshunting within 10 days without relapse can be expected in almost all cases.[21]

For shunt infections caused by Gram-negative bacilli, the shunt should again be removed and the treatment for Gram-negative meningitis (Chapter 22) instituted.

A notable exception to the rule of shunt removal is community-acquired bacterial meningitis in shunted persons. Such patients should be treated in the same way as those without shunts and can be expected to respond at least as well. On no account should these patients be subjected to shunt removal.[4]

Chapter 29 - Neurotropic Virus Disorders

Martin J Wood

The diseases described in this chapter are all the result of infections of or infection-mediated damage to, cells within the spinal cord, the dorsal root ganglia adjacent to the cord, or the brainstem. Rabies is a zoonosis and produces a fatal encephalomyelitis and is discussed in Chapter 219 .

POLIOMYELITIS

EPIDEMIOLOGY

The incidence of acute paralytic poliomyelitis has fallen dramatically over the past four decades as a result of mass vaccination campaigns and the global poliomyelitis eradication initiative set up by the World Health Organization (WHO) in 1988. From 1988 to 2001 reported cases of paralytic polio declined by over 99% from about 35,000 to less than 1000 (Fig. 29.1).[1] The American and Western Pacific Regions of the WHO have been declared free of indigenous wild poliovirus, but India, Pakistan and Nigeria still represent major poliovirus reservoirs. Within the European region importations of wild virus have occurred: in 1996 a large outbreak occurred in Albania, which had been free of polio since 1985, confirming the high risk of importation and transmission of polio in unvaccinated and incompletely vaccinated populations that had been seen elsewhere.[2]

In countries where poliovirus is endemic, paralytic disease is caused by serotypes 1 or, to a lesser extent, 3; wild type 2 poliovirus has not been detected worldwide since 1999. Polio cases attributed to circulating vaccine-derived polioviruses now account for many reports: in 2000–2001 such cases were reported from the Caribbean island of Hispaniola (Haiti and the Dominican Republic) and the Philippines.[1] In the USA, apart from six imported cases, all reported cases of paralytic poliomyelitis since 1979 have been vaccine-associated (Fig. 29.2).[3]

Poliovirus is usually transmitted by direct fecal-oral contact, indirect contact with saliva or feces or from contaminated water. Disease occurs all year round in the tropics, and during the summer and autumn in temperate countries. Children are more susceptible to infection, but the risk of paralytic disease is higher in adults.

PATHOGENESIS AND PATHOLOGY

After exposure poliovirus multiplies in the lymphoid tissue of the tonsils and, particularly, in the Peyer's patches of the ileum. The virus passes to the regional lymph nodes, and then a primary viremia subsequently distributes the virus to the entire reticuloendothelial system. In most instances the immune system then controls the infection and viral replication ceases at this point. In a minority of persons, however, further replication occurs in the reticuloendothelial system and there is a major disseminating viremia. It is believed that virus enters the central nervous system (CNS) as a result of this hematogenous dissemination but this may be only part of the story. The cell surface receptor for poliovirus is a member of the immunoglobulin-like superfamily of proteins.[4] Experiments in transgenic mice containing the human gene for this receptor suggest that poliovirus spreads from muscle to the anterior horn cells via neural pathways. [5] Within the CNS poliovirus primarily targets motor neurons in the brainstem and the anterior horn of the spinal cord. Neurons at these sites, and to a lesser extent, those in the mesencephalon, cerebellum and precentral gyrus of the cerebral cortex are destroyed and surrounded by an inflammatory infiltrate of polymorphonuclear leukocytes and mononuclear cells (Fig. 29.3). Gliosis develops when the inflammation has subsided.

PREVENTION

Poliovirus causes an acute nonpersistent illness; humans are the only reservoir and virus survival in the environment is finite. These facts, combined with the ability of polio immunization to interrupt virus transmission, made poliovirus a candidate for eradication by the WHO.[6]

Two types of poliovirus vaccine are available:

- the orally administered Sabin vaccine (OPV) consisting of live attenuated strains of all three serotypes of poliovirus; and
- the Salk-inactivated poliovirus (IPV) vaccine.

After one dose and three doses of OPV, 50 and >95% of recipients, respectively, develop longlasting immunity. Administration of OPV interferes with subsequent infection with wild poliovirus.

After two doses of IPV 90–100% of children develop protective antibody to all three serotypes of poliovirus. Persons vaccinated with IPV may still be infected with and excrete wild-type strains of poliovirus, although epidemiologic studies have confirmed that IPV reduces circulation of wild-type virus considerably.

The strategies for global eradication of poliomyelitis eradication include the following measures aimed at interrupting transmission of wild poliovirus in endemic countries:

- high vaccination coverage of children younger than 1 year of age with three doses of OPV;
- effective surveillance systems; and
- supplemental vaccination on national immunization days, when two doses of OPV are given to all children younger than 5 years of age, irrespective of previous immunization.

The scale of this undertaking can be judged by the fact that, in India alone, more than 125 million children were immunized on 18 January 1997.

Orally administered Sabin vaccine can be complicated by paralytic poliomyelitis; the risk is one in 2.4 million doses, although for children receiving their first dose of OPV it is one in 750,000 doses. People who are immunodeficient, particularly those with hypogammaglobulinemia are at greatest risk (a 3000–7000-fold higher risk than in immunocompetent recipients). Where routine immunization has been widespread and wild poliovirus has been almost eradicated (e.g. the USA), most cases of paralytic poliomyelitis are caused by OPV. In these circumstances IPV has been recommended. Since 2000, for example, the USA guidelines for routine vaccination of children recommend exclusive use of IPV given at 2 months, 4 months, 6–18 months and 4–6 years.[7]

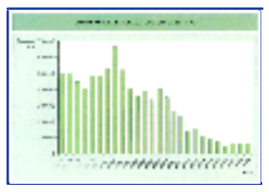

Figure 29-1 Global annual poliomyelitis cases reported to the World Health Organization 1974–99.

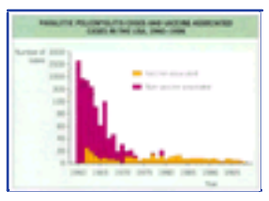

Figure 29-2 Total number of cases of paralytic poliomyelitis and vaccine-associated poliomyelitis in the USA 1960–98.

CLINICAL FEATURES

The incubation period of poliomyelitis is probably about 10–14 days but most (at least 95%) poliovirus infections are asymptomatic. Indeed, even most symptomatic cases only suffer a nonspecific febrile illness corresponding to the enteric and primary viremic phase of viral replication. This illness lasts a few days and is followed in a small percentage of cases by the major illness of aseptic meningitis and paralytic disease. The onset of this phase is abrupt, with meningitic symptoms and muscle pains, often in the neck or back, followed a few days later by the gradual onset, in less than 1% of poliovirus infections, of paralytic disease. Risk factors for paralytic

disease are a large inoculum of virus, increasing age, pregnancy, tonsillectomy, strenuous exercise and intramuscular injections during the incubation period.[8]

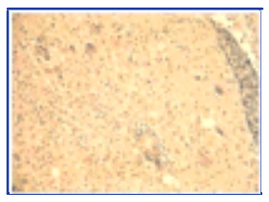

Figure 29-3 Anterior horn in poliomyelitis. Damaged and destroyed anterior horn neuron cell bodies are surrounded by an inflammatory infiltrate (hematoxylin & eosin stain).

The typical clinical features of paralytic poliomyelitis result from viral lysis of motor neurons of the anterior horn of the spinal cord and/or the brainstem. There is fever and muscle pain, and rapid progression over 2–4 days to maximal paralysis. Spinal paralysis is typically asymmetric and is more severe proximally. Bulbar paralysis may affect swallowing and respiration. Fasciculation is often evident and the deep tendon reflexes are absent or diminished. Autonomic disturbance is often evident. Although sensory symptoms are common, the presence of sensory signs should alert the clinician to an alternative diagnosis.

The mortality rate from paralytic poliomyelitis is 2–10% and is generally caused by bulbar involvement or respiratory failure. Following the acute illness there is often a degree of recovery of muscle function over the subsequent 6 months or more.

After many years of stable neurologic impairment, new neuromuscular symptoms (weakness, pain and fatigue) develop in 25–40% of patients, a disorder termed the postpolio syndrome.[9] It has been suggested that postpolio syndrome is the result of decompensation of a chronic denervation and reinnervation process, whereby surviving motor neurons no longer maintain new sprouts. It has also been suggested that reactivation of latent virus accounts for the foci of inflammation seen in some biopsies.[10] Others suggest that postpolio syndrome is caused by orthopedic factors, radiculopathies, or merely normal functional deterioration in muscles that are already weak after polio.

The most important disease likely to be confused with paralytic poliomyelitis is the Guillain-Barré syndrome (GBS). The illnesses can usually be distinguished by the symmetric paralysis and sensory signs of GBS and the elevated protein, but relatively normal cell count in the CSF of patients who have GBS.

DIAGNOSIS

In the preparalytic phase there is nothing to distinguish poliomyelitis from other causes of viral meningitis. There is an increased number of leukocytes in the CSF, but poliovirus is rarely isolated from the CSF. The diagnosis may be confirmed by serologic testing of paired acute and convalescent sera or by isolation of poliovirus from throat swabs taken during the first week of the disease, or from feces cultured up to several weeks after the onset. Polymerase chain reaction methods have been developed for detecting poliovirus, but are not yet used in routine diagnostic laboratories.

MANAGEMENT

Management of the acute phase of paralytic poliomyelitis is supportive and symptomatic. Patients need hospitalization and bed rest during the first week or so. Light splints and passive physical therapy to prevent contractures, moist hot packs for muscle pain and spasms and frequent turning to prevent bedsores are important. Nutrition and fluid balance need to be maintained, and close monitoring of respiration is vital. If the vital capacity falls below 50% of predicted values or hypoxia occurs, or there is pooling of pharyngeal secretions, assisted ventilation should be started.

When the fever subsides active physiotherapy and mobilization is started: 80% of eventual recovery is attained within 6 months, although recovery of muscle function may continue for up to 2 years.

Long-term management of the paralyzed patient is complex and outside the scope of this account. The management of postpolio syndrome includes pacing of activity and nonfatiguing exercise. No consistent benefits have been obtained with anticholinesterases[11] or corticosteroids.

HERPES ZOSTER IN THE NORMAL HOST

EPIDEMIOLOGY

Studies of the incidence of herpes zoster in the USA and UK suggest that there are about three cases per 1000 persons each year.[12] These figures suggest that in the USA there may 900,000 cases of herpes zoster and that in the UK there may be 200,000 cases of herpes zoster annually. There are few reliable data for other areas of the world. The incidence increases dramatically after middle age (Fig. 29.4). There is no sex difference, but owing to population demographics in developed countries most cases are seen in women in their sixth and seventh decades of life. Children or adolescents who acquire varicella-zoster virus (VZV) infection in utero or in the first year of life have an up to 20-fold greater risk of developing herpes zoster before 20 years of age. Almost 20% of individuals in the UK

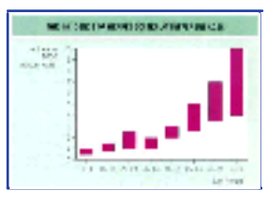

Figure 29-4 Incidence of herpes zoster at different ages.[12]

will develop herpes zoster at some stage; about 5% of immunocompetent patients can expect to suffer a second, and less than 1%, a third, episode.[12]

Typically, herpes zoster occurs unexpectedly with no seasonality. There is no evidence that it is more common during chickenpox outbreaks.

PATHOGENESIS AND PATHOLOGY

Identification of VZV nucleic acids within sensory ganglia and demonstration that VZV isolates from varicella and herpes zoster in the same patient are identical have proved that the disease is caused by reactivation of VZV from within the sensory ganglia, where it has been resident since the primary attack of chickenpox, usually many years earlier. During this latent period it is believed that host immunity to VZV is repeatedly boosted by re-exposure to VZV antigens, either from exogenous sources or from episodes of endogenous replication that did not lead to herpes zoster. The molecular mechanisms that establish and maintain VZV latency are not fully understood, but reactivation of the virus is clearly related to declining VZV-specific cell-mediated immunity (CMI). In the elderly the risk of herpes zoster is proportional to the marked decline in VZV-specific CMI associated with advancing age.[13]

After reactivation of VZV from latency, the virus replicates within the neuron and travels down the nerve to the skin that nerve innervates. As it does this the neurons are destroyed and there is a marked inflammatory neuritis with cellular infiltrate and hemorrhage. Once it reaches the skin the virus replicates within the epidermis and produces the characteristic vesicular rash. Histologically, the lesion is indistinguishable from that of varicella or herpes simplex, consisting of an intra-epidermal blister with multinucleate giant cells in its floor.

The pathogenesis of postherpetic neuralgia (PHN) is poorly understood, but the increased transmission of nociceptive impulses during the period of acute neuritis induces central sensitization and hyperexcitability of spinal neurons. This is then maintained by a changed peripheral input and by excitotoxic damage in the dorsal horn of the spinal cord.[14]

PREVENTION

The development of herpes zoster in individuals previously infected with VZV might be prevented by measures designed to boost their

declining CMI to the virus. This can be accomplished by the live attenuated VZV_{Oka} strain vaccine: when this vaccine is given to seropositive elderly adults (mean age 67 years), most have a long-lasting boost in their VZV-specific CMI to a level similar to that of normal 40-year-olds, a group with a relatively low risk of herpes zoster.[15] [16] Whether this will reduce the frequency and severity of herpes zoster in those who are vaccinated is still to be tested in a controlled trial.

CLINICAL FEATURES

Herpes zoster is almost always unilateral. The dermatome most frequently affected (10–15% of cases) is the ophthalmic division of the trigeminal nerve. Otherwise, each dermatome is affected at a similar rate. Hence, more than 50% of herpes zoster involves one or more of the thoracic dermatomes and the cervical and lumbosacral dermatomes are each affected in 10–15% of cases.

The chief clinical features of acute herpes zoster are pain and rash.[12] Systemic symptoms and signs may also occur, including headache, malaise, nausea and vomiting, fever and regional lymphadenopathy. Pain and paresthesia within the affected dermatome often precede the rash by several days: prolonged periods of prodromal pain have been reported. The pain is extremely variable in its character, periodicity and severity, and because it is similar to that occurring in a wide range of other conditions, the true nature of the cause is not usually recognized until the rash appears. The pain usually increases for a few days and then declines in severity somewhat slowly, often in parallel with skin healing.

The rash of herpes zoster (Fig. 29.5) generally appears proximally in the involved dermatome and spreads distally over the following few days. It begins as erythematous maculopapules that vesiculate within 12 hours or so. After 3–4 days, the vesicles become cloudy pustules and these then gradually dry and crust over the subsequent 7–10 days, thereafter persisting for a further 1–2 weeks. New lesions continue to appear for a mean of 2–3 days and only 10–15% of normal individuals have new lesions beyond 4 days. Virus can be cultured from the vesicles for only a few days, although in 15% of cases it is recoverable from lesions for 1 week. Occasionally, especially in the very elderly or those with poor nutrition, the rash may become necrotic, ulcerative and gangrenous. The appearance of a score or so of lesions outside the primary dermatome within a few days of rash onset is not unusual in otherwise healthy adults, but widely disseminated cutaneous disease is rare.

Figure 29-5 Typical dermatomal rash of herpes zoster.

Although most cases of herpes zoster in the immunocompetent host are self-limiting, one or more complications occur in 15–20% of patients (Table 29.1). The major complication and cause of morbidity after herpes zoster in the immunocompetent host is chronic pain or PHN. Postherpetic neuralgia is an arbitrarily defined term; some definitions include any pain after rash healing, while others limit PHN to pain persisting for 30 days or longer.[17] Pain persists for more than 4 weeks after the resolution of the rash in 10–15% of adult patients with herpes zoster; only 5–10% are still in pain after 3 months, and 2–5% after 12 months.[17] In the elderly, prolonged pain is more common. At 1, 3 and 6 months after the illness only 50–60%, 25% and 9–13%, respectively, of patients over 60 years of age are still suffering pain. The other factors that influence the likelihood of prolonged pain after herpes zoster are the severity of the acute pain, prolonged prodromal pain and psychological distress and disease conviction.

Some ocular involvement is common in patients with ophthalmic zoster. Up to 85% of patients with involvement of the nasociliary branch of the trigeminal nerve clinically suggested by Hutchinson's sign (the rash involving the lateral tip of the nose, Fig. 29.6) will develop ocular complications, but ocular involvement can occur

even if this sign is absent. Every ocular tissue can be affected by VZV.[18] Although conjunctivitis is the most frequent complication, anterior uveitis and keratitis are of greater significance. Keratitis may

TABLE 29-1 -- Complications of herpes zoster in the immunocompetent individual.

COMPLICATIONS OF HERPES ZOSTER IN THE IMMUNOCOMPETENT INDIVIDUAL	
Complication	**Examples**
Postherpetic neuralgia	
Ocular complications	Conjunctivitis
	Uveitis
	Keratitis
	Glaucoma
	Retinal necrosis
Motor weakness	Ramsay Hunt syndrome
Encephalitis, transverse myelitis, etc.	
Cerebral angiitis	

Figure 29-6 Hutchinson's sign. When the rash of herpes zoster involves the skin at the tip and side of the nose it indicates that the nasociliary branch of the trigeminal nerve is involved and there is an increased risk of uveal tract inflammation and ocular damage.

manifest as epithelial or subepithelial punctate changes, dendritic or disciform ulceration, or corneal vascularization. Eyes with stromal disease may be rendered blind.

Localized motor paralysis is observed in less than 5% of patients with herpes zoster, predominantly in cases involving the trigeminal nerve or the cervical or lumbosacral dermatomes. The true incidence of motor weakness is much greater, but there is great difficulty in assessing weakness of intercostal or abdominal musculature, the most common sites of a herpes zoster rash. Motor signs usually develop abruptly with or shortly after the rash and reach a peak within a few days; in most cases there is complete functional recovery, although this may be prolonged. A particularly common motor complication is the Ramsay Hunt syndrome (vesicles in or around the external auditory meatus and a lower motor neuron facial palsy).

Encephalitis and myelitis are uncommon complications of herpes zoster in otherwise healthy patients and are probably caused by direct extension of virus from the dorsal root ganglion to the meninges and the brain. A variety of other neurologic complications, such as aseptic meningitis, transverse myelitis, necrotizing myelopathy, cerebral angiitis and GBS have been described in association with clinical herpes zoster.

There is no evidence of any risk to fetal development if a pregnant woman has herpes zoster.[19]

DIAGNOSIS

The diagnosis of herpes zoster is essentially clinical, based on the characteristic appearance and distribution of the rash. The only condition that is likely to be confused with it with any regularity is herpes simplex virus (HSV) infection. Zosteriform rashes may be caused by HSV, but HSV usually causes a much less extensive rash than herpes zoster; the individual lesions of HSV infection are smaller and tend to recur. Patients with recurrent herpes zoster of the buttocks or thighs almost always have HSV type II infection. Confirmation of VZV infection can be obtained by polymerase chain reaction examination or culture of the vesicular fluid.

MANAGEMENT

Although steps should be instituted to ease the inflammation and irritation caused by the skin lesions, the management of herpes zoster is primarily aimed at reducing the pain and complications of the illness.[20] Adequate analgesia is very important and antiviral therapy limits the degree of neuronal damage by VZV. Placebo-controlled studies have shown that oral aciclovir (800mg five times daily for 7 days), if started within 72 hours of rash onset, reduces the severity and duration of the acute illness and also reduces the duration of the pain in the normal host with herpes zoster.[21] The newer, more bioavailable drugs, valaciclovir (1000mg q8h for 7 days) and famciclovir (250mg, the dosage licensed in much of Europe, or 500mg, the dosage licensed in the USA, q8h for 7 days) are of similar efficacy to aciclovir for rash healing, but somewhat better than aciclovir at reducing the duration of pain in individuals who have herpes zoster and who are immunocompetent.[22] As the clinical efficacy of the three drugs is very similar,[23] a choice between them may depend on fiscal constraints and personal experience. Each of the three drugs reduces the incidence of ocular complications in ophthalmic zoster. All patients with ophthalmic zoster should also be examined by an ophthalmologist.

Whichever drug is used the benefits have only been demonstrated if treatment is started within 72 hours of the appearance of the herpes zoster rash (except in ophthalmic zoster, in which the ocular complications are reduced even if aciclovir is started 7 days after the onset of the rash).

HUMAN T-CELL LEUKEMIA VIRUS I (HTLV-I)

Human T-cell leukemia virus I (HTLV-I) was the first human retrovirus to be discovered. In addition to its role in adult T-cell leukemia (ATL), it causes a progressive myelopathy termed tropical spastic paraparesis (TSP) in the West Indies and several other countries, and HTLV-I-associated myelopathy (HAM) in Japan.

EPIDEMIOLOGY

Human T-cell leukemia virus-I infection is found endemically in southwestern Japan, where 20% of the population is seropositive, and in the Caribbean basin (including northern South America and the southeastern USA) where seropositivity approaches 5%. Studies have also shown high seroprevalence rates of HTLV-I in West Africa, the islands of Melanesia in the Pacific and the Middle East. Infection is also found in immigrant populations from these areas, including West Indians in the UK.

Human T-cell leukemia virus-I can be transmitted by sexual intercourse, inoculation of infected blood or blood products and perinatal exposure. Sexual transmission is primarily via semen, from which it can be isolated. Epidemiologic data from Japan suggests a very low rate of transmission from females to males in serologically discordant couples.[24] Breast-milk is an important vehicle of transmission and seroconversion is rare in infants who are not breast-fed, even if their mother is infected. The risk of seroconversion after receiving blood infected with HTLV-I is high (up to 80% after receipt of fresh blood products).[25] In endemic populations the prevalence of infection increases with age and clusters in families. Infection is lifelong. Not unexpectedly, HTLV-I is more prevalent in intravenous drug users and homosexual males than in the general population.

PATHOGENESIS AND PATHOLOGY

Human T-cell leukemia virus-I can infect a variety of human cells but only $CD4^+$ T cells are transformed by the virus: the specific receptor has not been identified but the HTLV-I envelope glycoprotein (gp46) is the probable attachment molecule. Within the cell, reverse transcription, integration of proviral DNA, and transcription and virus replication are typical of retrovirus replication (Fig. 29.7).

There are two hypotheses for the pathogenesis of HAM/TSP.[26] In one, HTLV-I infects glial cells and the cytotoxic T-cell response against infected cells causes demyelination. In the second the HTLV-I infection induces an autoimmune process. Although indirect evidence favors the first hypothesis, direct demonstration of HTLV-I infection of CNS cells is lacking.

Gross pathology shows spinal cord atrophy but a normal brain. The histology shows a diffuse inflammatory encephalomyelitis, with predominantly midthoracic cord involvement. The inflammatory infiltrate of mononuclear cells is mostly perivascular and there is hyaloid thickening of the vascular adventitia and media.[27] Demyelination and significant axonal loss is the final result of the inflammatory process.

PREVENTION

Prevention of HTLV-I infection depends upon screening blood to minimize the risk of transfusion-related disease. This is policy in France, the UK, the USA, Canada and Japan. Health educational programs should also promote condom use and warn seropositive mothers of the risks of transmission by breast-feeding. No effective vaccine has been developed.

Figure 29-7 Life cycle of HTLV-I. HTLV-1 infection is initiated by cell-free virions or, more commonly, by cell-to-cell virus transmission. The two RNA genome copies are converted into double-stranded DNA provirus by the viral enzyme reverse transcriptase and the proviral DNA is integrated into the host chromosome. Transcription is activated by the viral Tax protein. In the early stages of infection both Tax and Rex proteins are produced. The Rex protein directs the preferential transport of unspliced or singly spliced viral messages to the cytoplasm for translation into structural proteins for virion assembly.

CLINICAL FEATURES

Only a small proportion of those infected with HTLV-I develop ATL or HAM/TSP: the lifetime risk of these diseases in HTLV-I infected Japanese is estimated to be 2–4% and 0.25%, respectively.[26] The usual age at onset of HAM/TSP is the fifth decade of life and more women than men are affected.

The myeloradiculopathy produced by HTLV-I mainly affects the pyramidal tracts and, to a lesser extent, the sensory system. Both TSP and HAM have identical features: they are clinically characterized by a chronic syndrome with a combination of upper and lower motor neuron signs. Patients often complain of difficulty walking, dragging pains and stiffness (together with numbness and paresthesia) of the legs, urinary retention and/or incontinence and impotence. About one-third of patients have weakness in the upper limbs, but the cranial nerves are only very rarely involved. Examination reveals a symmetric spastic paraparesis with mild sensory abnormalities indicative of posterior column involvement (diminished vibration and proprioception). Most patients progress gradually over months or years.

There may be confusion between HAM/TSP and multiple sclerosis. There is, however, a lack of optic neuritis or ocular movement problems in HAM/TSP while multiple sclerosis tends to run a relapsing and remitting course. The WHO has published diagnostic guidelines for HTLV-I myelopathy.[28]

DIAGNOSIS

The hallmark of HTLV-I infection is the presence of 'flower lymphocytes' (T-helper cells with multilobulated nuclei that are similar to the cells of ATL) in the blood. These cells comprise only about 1% of the circulating white cells, however, and the diagnosis of HTLV-I infection requires the demonstration of specific antibodies in the serum.

In HTLV-I CNS disease, the CSF examination may be normal or show a slightly elevated protein concentration and a mild lymphocytosis. Flower lymphocytes are found in a minority of cases. A definitive diagnosis of HAM/TSP requires detection of HTLV-I DNA in the CSF by polymerase chain reaction or evidence of intrathecal synthesis of HTLV-I antibody.

Myelography and CT scanning are usually normal apart from spinal cord atrophy. The imaging of choice is magnetic resonance imaging (MRI), which shows diffuse high-intensity signals in the thoracic cord on T_2 -weighted images. Similar lesions are sometimes seen in the periventricular white matter. Visual evoked potentials and somatosensory evoked potentials from the legs are also delayed.

MANAGEMENT

No therapy has been proven to be of benefit in TSP/HAM. Occasional patients have improved while receiving oral corticosteroids, cyclophosphamide or systemic a-interferon, and it has also been claimed that plasmapheresis leads to a temporary benefit. A potentially useful approach for ATL (which has a much poorer prognosis than neurological disease caused by HTLV-I) is a monoclonal antibody to the interleukin-2 receptor, which is upregulated by HTLV-I infection. Its potential in HAM/TSP needs to be evaluated.

At present the management of HAM/TSP is similar to that of myelopathies of any cause, with supportive therapy of spasticity and urinary sphincter disturbance.

Chapter 30 - Practice Points

30.a Neuroradiology — what and when?

Barbara McKeown
Verka Beric

The mortality from central nervous system infections has fallen since the introduction of antibiotics. The continued reduction in mortality has been attributed as much to advances in imaging, particularly computerized tomography (CT) and magnetic resonance imaging (MRI), as to improvements in chemotherapy and surgical techniques. Computerized tomography and MRI have facilitated earlier and more accurate diagnosis and can guide stereotactic biopsy and drainage. Computerized tomography remains the first choice for excluding intracranial emergencies. It is more readily available and is not subject to specific contraindications or limitations imposed by requiring compatible life support systems. However, MRI is emerging as the procedure of choice in evaluating suspected intracranial infections because of its inherent contrast resolution, multiplane capability, sensitivity in the posterior fossa, sensitivity to the presence of subacute and chronic hemorrhage and sensitivity to the detection of meningeal disease on postcontrast images. Magnetic resonance imaging is far superior to CT in detecting and evaluating lesions in the spinal cord and brain stem and it often demonstrates lesions in the brain at an earlier stage in the disease process.

Meningitis

A wide spectrum of infectious diseases can affect the cranial meninges. Imaging may be indicated in three situation: to detect increased intracranial pressure prior to lumbar puncture, to characterize the condition and to detect complications.

When meningitis is suspected, cerebrospinal fluid sampling for microbial and biochemical analysis is indicated as a matter of urgency. If the patient's conscious state is depressed or if focal neurological signs or papilledema are present, imaging should be performed before lumbar puncture. However it is critical that antimicrobial therapy be initiated rapidly — before imaging if necessary. Withdrawal of cerebrospinal fluid in the presence of raised intracranial pressure may result in coning (or cerebral herniation). This is attributed to impaction of the cerebellar tonsils with consequent compression of the medulla. In most centers CT is available more rapidly than MRI. The characteristic imaging findings include obliteration and enhancement of the basal subarachnoid cisterns, sulci or fissures. In practice, imaging studies are usually normal, especially early in the disease process. Gadolinium-enhanced T1-weighted MRI, especially in the coronal plane, and fluid-attenuated inversion recovery (FLAIR) MRI acquisitions have substantially improved the ability to detect and differentiate between the subcategories of intracranial infection. Magnetic resonance imaging also better demonstrates the extent of the infectious process.

One of the major roles of imaging in patients who have meningitis is in identifying potentially serious complications and associated phenomena, including hydrocephalus, extra-axial collections, infarcts, ventriculitis and parenchymal abscess or granuloma formation.

Brain abscess

Brain abscesses are most commonly bacterial in origin but they may be tuberculous, parasitic or fungal. They arise in the cerebral parenchyma 10–14 days after diffuse infection (cerebritis), which is usually limited to the white matter. Early cerebritis is rarely seen on CT, but MRI can demonstrate increased signal on T2-weighted images. Unfortunately, this finding is of limited clinical value as patients rarely present at this early stage. A developing abscess is well demonstrated on both CT and MRI. Necrosis develops in the region of cerebritis and becomes walled off by a fibrovascular capsule that is in turn surrounded by edema. The capsule enhances intensely with CT and MRI contrast agents and tends to be thinner on its medial side, so that it appears to 'point' toward the ventricles (Fig. 30a.1). Complications such as ependymitis and ventriculitis or daughter abscesses may occur if the abscess ruptures. If the diagnosis is in doubt, or there is a poor response to empiric treatment, CT- or MRI-guided stereotactic needle aspiration may be performed to obtain a specimen for microbial analysis. Response to treatment is best assessed by serial cross-sectional imaging, for which CT is usually adequate, and is seen as a gradual reduction in the size of the abscess and surrounding edema.

A tuberculous abscess (tuberculoma) is known to follow an episode of tuberculous meningitis; it may also arise through hematogenous spread from an extracranial source, usually of pulmonary origin. It may be solid or cavitating with a thick capsule, is often small and multiple, and is demonstrated on both contrast-enhanced CT and MRI.

Worldwide, cysticercosis (caused by *Taenia solium*) is the most common parasitic infection to affect the central nervous system. Patients may have hundreds of larvae-containing cysts scattered throughout the brain, ventricles and subarachnoid spaces. Acute illness occurs many months after initial infection when the larvae die and incite an intense local inflammatory reaction. At this stage, CT

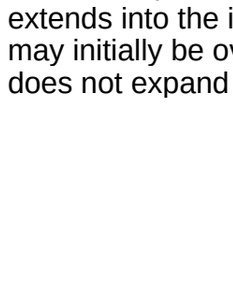

Figure 30.a-1 Cerebral abscess. Contrast-enhanced axial CT demonstrating two cerebral abscesses with surrounding edema and mass effect. Thin, smooth, enhancing capsules surround cavities of nonenhancing necrotic tissue. *Courtesy of Dr I Colquhoun.*

and MRI reveal contrast-enhancing nodular or ring lesions surrounded by extensive localized edema. The edema is most clearly seen on T2-weighted MRI. Later in the disease process, the dead larvae appear as punctate calcifications without a surrounding mass effect and are most readily visible on CT.

Hydatid disease (caused by *Echinococcus* spp.) results in a large cyst that contains fluid of the same density as cerebrospinal fluid; the cyst does not display contrast enhancement or surrounding edema. Magnetic resonance imaging confers no particular advantage over CT.

Toxoplasma gondii is a common opportunistic infection in patients who have AIDS. Multiple ring-enhancing and nodular lesions are the hallmark of toxoplasmosis but the appearances are non-specific and are similar to those of multiple brain abscesses, lymphoma or metastatic disease. Because toxoplasmosis is the most common cause of a mass lesion in the central nervous system in HIV-positive patients, empiric treatment is usually commenced if CT or MRI suggest an abnormality. Biopsy may be required for definitive diagnosis if clinical or radiologic improvements are not demonstrated.

Intracranial empyema

An intracranial empyema is an abscess that has developed in the subdural or epidural space. Subdural empyemas are more common, rapidly progressive and result in significant mortality if a delay in diagnosis occurs. Extradural empyemas cause less neurologic deficit because the dura mater minimizes the pressure exerted on the brain. Computerized tomography scans and MRI demonstrate similar features. A subdural empyema is crescent-shaped, following the contour of the skull, and often extends into the interhemispheric space, where it appears linear. This causes pressure and mass effect on the underlying cerebral hemisphere. Subdural empyemas may initially be overlooked on CT but the mass effect in the absence of a focal lesion is a clue to their presence. An extradural empyema has a lentiform shape and does not expand into the interhemispheric fissure (Fig. 30a.2). Empyemas may be readily detected on coronal MRI scans, even when small and difficult to visualize

on axial CT.

Encephalitis

Encephalitis refers to a generalized and diffuse inflammation of the brain. It is usually of viral origin. Acute infective encephalitis may be caused by the herpesviruses, rabies, arthropod-borne viruses and enterovirus (polio). Of these, herpes simplex virus type 1 is the most common. It commonly results in necrosis of the temporal lobes and

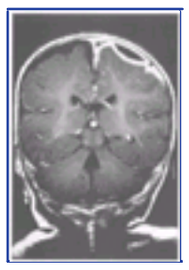

Figure 30.a-2 Extradural empyema. Contrast-enhanced T1-weighted coronal MRI demonstrating a lentiform extradural collection surrounded by enhancing dura mater. *Courtesy of Dr K Chong.*

Figure 30.a-3 Herpes simplex encephalitis. T2-weighted axial MRI demonstrating characteristic involvement of medial temporal lobes with high-signal edema. *Courtesy of Dr K Chong.*

posterior frontal gyri. Involvement is usually bilateral and a may be symmetric. Computerized tomography may demonstrate hypodense temporal lobe lesions with or without involvement of the frontal lobes. This hypodensity may be difficult to detect early on in the disease process. Parenchymal enhancement as seen by contrast-enhanced CT is infrequent. Magnetic resonance imaging can demonstrate the early edematous changes on T2-weighted images with characteristic high signal in the temporal lobes and inferior frontal lobes (Fig. 30a.3). FLAIR imaging is even more sensitive in the depiction of gray matter and white matter changes. Gyriform enhancement occurs with disease progression. Parenchymal hemorrhage is more readily detected with MRI, especially gradient echo images.

Acute disseminated encephalomyelitis (ADEM) presents with neurologic signs and symptoms 5 days to 2 weeks after a viral illness or

vaccination. Perivenous demyelination is the pathological hallmark. Magnetic resonance imaging is the imaging study of choice in detecting demyelinating plaques in the brain and spinal cord. They can be seen scattered throughout the white matter of the posterior fossa and cerebral hemispheres. Gray matter involvement is common. These hyperintense T2 lesions are more conspicuously seen with FLAIR images. Contrast enhancement is variable. Differentiation from multiple sclerosis is possible only by the clinical course of the disease.

Subacute encephalitis can be caused by various agents and includes subacute sclerosing panencephalitis caused by the measles virus, progressive rubella panencephalitis, progressive multifocal leukoencephalopathy as a result of infection by the JC virus, HIV encephalitis, cytomegalovirus and Creutzfeldt-Jakob disease. HIV encephalopathy is caused by the HIV itself. It presents as a progressive subcortical dementia and is usually a manifestation of end-stage AIDS. Magnetic resonance imaging shows global atrophy and diffuse high-signal lesions in the deep white matter on T2-weighted images. Creutzfeldt-Jakob disease also presents with dementia as the predominant feature, accompanied by sensory changes, confusion and inappropriate behavior or cerebellar ataxia. Magnetic resonance imaging shows diffuse atrophy and may be useful in identifying gray matter lesions on T2-weighted images, FLAIR images and diffusion-weighted images.

Brain stem and spinal infection

Brain stem abscess is an uncommon condition that in the past was invariably fatal. Although the abscess may be visible on CT, MRI using T1-weighted gadolinium-enhanced images is superior. A cystic mass with ring-like enhancement is seen. Management of brain stem abscess always includes antibiotic therapy. Magnetic resonance imaging-guided stereotactic aspiration may be required to obtain a sample for microbial analysis and to decompress the lesion.

Staphylococcus aureus is the most common cause of bacterial spinal infection. This may be manifested as osteomyelitis, diskitis, epidural spinal abscess, perispinal abscess or myelitis. These phenomena may occur as a solitary manifestation or in combination with one another. Magnetic resonance imaging is the imaging modality of choice. T2-weighted and precontrast and post-gadolinium-enhanced T1-weighted images are obtained in the sagittal, axial and occasionally coronal planes.

30.b When to do a lumbar puncture for evaluation of meningoencephalitis

Nasia Safdar
Dennis G Maki

Case presentation

A 25-year-old man presents to the emergency department with a 2-day history of severe headache, fever and neck stiffness. On examination he has a temperature of 101°F (38.3°C), no rash and a normal mental status and neurologic examination. He has pain on neck flexion but is able to flex his neck fully. Kernig and Brudzinski signs are absent.

Discussion

Should a lumbar puncture be performed?

The clinical history and physical examination alone are not sufficient to make the diagnosis of infective meningitis. Findings on clinical examination that have been shown to be of value in assessing the possibility of acute meningitis in adults include fever (sensitivity 85%), meningism (sensitivity 70%) and altered mental status (sensitivity 67%); however, the specificity of each of these findings is poor. In sum, short of open meningeal biopsy, the analysis of cerebrospinal fluid (CSF) is the only test to establish reliably the diagnosis of infective meningoencephalitis.

The most common indication for a lumbar puncture (LP) is as a diagnostic tool for analysis of CSF when acute infectious meningitis is suspected. It is also employed when subarachnoid hemorrhage is suspected and the results of cranial computerized tomography (CT) scan are normal, in the investigation of demyelinating diseases and Guillain-Barré syndrome, and for performing spinal anesthesia. Instillation of radiologic contrast media for myelography, delivery of antimicrobial or chemotherapeutic agents to the subarachnoid space and therapeutic removal of CSF for the treatment of pseudotumor cerebri are less frequent indications.

What are the contraindications to lumbar puncture?

Contraindications to LP are as follows:

- ¦ LP is absolutely contraindicated if there is a known or suspected space-occupying lesion with mass effect, such as an intracranial tumor, hematoma or brain abscess, or massive brain edema, each of which greatly increases the risk of catastrophic post-LP rostral-caudal herniation — if intracranial mass lesions or brain edema are suspected clinically, then LP should be deferred until a CT scan can be done;
- ¦ severe uncorrected coagulopathy (e.g. International Normalized Ratio (INR) >1.5) or thrombocytopenia (platelet count <50,000/mm^3) is also a relative contraindication to LP, which should be deferred until the coagulation deficiency has been corrected — in a retrospective review of 956 children with acute leukemia who underwent LP, no hemorrhagic complications occurred if the platelet count was higher than 50,000/mm^3 ; and
- ¦ infection at the puncture site, such as a large lumbosacral decubitus ulcer, is also a contraindication to LP because of the risk of producing iatrogenic meningitis — in this circumstance, CSF can be safely obtained by a neuroradiologist through a C1–C2 cisternal puncture.

Complications of lumbar puncture

In general, LP is a safe procedure with rare serious complications, if performed properly. Post-LP headache is the most common complication, occurring in 11–25% of patients; it typically presents within hours after the procedure and can persist for weeks. Prospective studies have shown that use of a small styleted needle (20- or 22-gauge), directing the bevel of the needle parallel rather than perpendicular to the dural fibers, and replacing the stylet in the

TABLE 30.b-1 -- Complications of lumbar puncture.

COMPLICATIONS OF LP		
Complication	**Risk factors**	**Preventive measures**
Rostral-caudal herniation	Known intracranial mass lesion or suspicion of intracranial mass lesion: coma, papilledema, focal neurologic abnormalities, immunocompromised state, >60 years of age	Perform head CT before LP to rule out intracranial mass lesion
Iatrogenic meningitis	Passage of needle through infected tract	Avoid LP if soft tissue infection in lumbar area; in this circumstance, CSF may be obtained through a C1–C2 cisternal puncture
Post-LP headache	Use of a large-gauge needle	Use small (20- or 22-gauge) needle
	Directing needle perpendicular to dural fibers	Direct needle parallel rather than perpendicular to dural fibers
	Withdrawing needle without stylet	Replace stylet in needle before withdrawing
Epidural or subdural hematoma	Uncorrected coagulopathy (INR >1.5, platelet count <50,000)	Correct coagulopathy before performing LP
Trauma to periosteum, spinal ligaments and interverterbral disks	Traumatic tap, poor technique	Careful positioning of patient, attention to landmarks before performing LP, well-trained procedurist

needle before withdrawing can lessen the risk of post-LP headache. Although widely recommended, there is no evidence to suggest that prolonged recumbency after an LP or increased intake of oral fluids decrease the risk of post-LP headache.

In the absence of soft tissue infection at the puncture site, the risk of iatrogenic meningitis during an LP is extremely low, even in severely granulocytopenic or other immunocompromised patients, and fear of iatrogenic infection should never dissuade physicians from performing an LP for suspected meningitis.

Other rare complications of LP include subdural or subarachnoid hemorrhage, epidural hematoma (which can produce paraparesis), trauma to the spinal ligaments, periosteum or intervertebral disk, entrapment of nerve roots through the dural tear and pyogenic discitis or spondylitis. Correction of pre-existing severe coagulopathy (INR >1.5, platelet count < 50,000/mm^3) is mandatory before performing an LP.

The most feared complication of LP, although rare, is acute neurologic deterioration from brain herniation, which is commonly fatal.

Table 30b.1 summarizes the complications of LP and measures to prevent them.

When should a computerized tomography scan precede a lumbar puncture?

Concern for herniation prompts many physicians to consider a head CT scan as mandatory before an LP. When CT should be performed before LP remains a

controversial and hotly debated issue.

In a prospective study in 301 patients presenting to an emergency department and suspected of bacterial meningitis, Hasbun *et al.* (2001) used the following clinical features to define a group of patients in whom CT scan was most likely to yield abnormal findings and in whom CT should be considered mandatory before performing an LP:

- aged over 60 years;
- immunocompromised state;
- history of primary neurologic disease;
- history of seizure within the past week; and
- altered mental status and focal neurologic examination.

Of 235 patients who underwent cranial CT scan before LP, 76% had normal CT scan results; 34% of the ordering emergency room physicians stated that they considered doing a CT scan before any LP as a standard of care. In a subset of 96 patients none of whom were older than 60 years of age, had altered mental status, previous history of CNS disease or focal findings on examination, 93 had a normal CT scan, yielding a negative predictive value of 97%; in contrast, all four patients with significant mass effect were identifed by one or more of these clinical markers and LP was not carried out. It is noteworthy that there was a 1 hour delay in initiation of empiric antimicrobial therapy in patients undergoing CT before LP for suspected meningitis.

Another recent prospective study in 113 adults identified three statistically significant predictors of intracranial mass lesions:

- altered mentation (positive likelihood ratio (LR) 2.2, 95% CI 1.5–32);
- focal neurologic abnormalities (LR 4.3, 95% CI 1.9–10); and
- papilledema (LR 11.1, 95% CI 1.1–115).

These studies provide support for a more selective approach to the use of CT scan before LP. The vast majority of patients with symptoms suggestive of meningitis can safely undergo LP without a preceding CT scan; a CT scan is strongly recommended before performing an LP in patients with papilledema, altered mental status, focal neurologic abnormalities, an immunocompromised state or over 60 years of age.

It must be stressed, however, that if meningitis is strongly suspected clinically but LP will be delayed because of need for CT scan, empiric anti-infective therapy (i.e antibacterial or aciclovir) should be initiated without delay, after blood and other indicated non-neurologic cultures have been obtained.

What tests should be ordered on the spinal fluid?

The CSF should be collected in four sterile tubes. A minimum of 1ml of CSF is needed for the tests needed to diagnose bacterial meningitis reliably: cytospin Gram stain and culture, cell count and differential, glucose and protein. In most cases, the laboratory would prefer at least 3–5ml; if additional studies, such as antigen tests, fungal, mycobacterial or viral cultures, polymerase chain reaction (PCR) or cytology are desired, then up to 10–15ml will be needed.

Table 30b.2 summarizes the characteristics of CSF seen in selected intracranial infections and related conditions. Normal CSF should have less than 3–5 cells/ml, all of which should be lymphocytes or mononuclear cells, a protein of 15–45mg/dl and a glucose concentration two-thirds the concomitant serum value. The typical CSF profile in acute bacterial meningitis is polymorphonuclear pleocytosis, hypoglycorrhachia and elevated protein; a Gram stain of the cytospin CSF has a sensitivity of 90% if the LP is carried out before the administration of antibiotics. Table 30b.3 summarizes the tests on CSF of greatest value to diagnose neurologic infections.

In a retrospective review of 128 children with bacterial meningitis, Kanegaye *et al.* (2001) compared 39 patients who received empiric antimicrobial therapy before LP with 55 who underwent LP before receiving antimicrobial therapy. The authors found that

TABLE 30.b-2 -- CSF characteristics in selected neurologic conditions.

CSF CHARACTERISTICS IN SELECTED NEUROLOGIC CONDITIONS				
Condition	**Opening pressure (mmH_2O)**	**Cell count**	**Protein (mg/dl)**	**Glucose**
Normal	50–150	0–5 lymphocytes	15–45	2/3 of serum glucose
Bacterial meningitis	Elevated	200–10,000 cells, 95% PMNs	Elevated, usually >100	Low (<50mg/dl; <2.8mmol/l)
Viral meningoencephalitis	Elevated	6–1000 cells, lymphocyte predominance but may show PMNs early	Elevated, usually <100	Normal
Tuberculous or fungal meningitis	Elevated	10–500, lymphocyte predominance	Greatly elevated, 100 to >3000	Low (<50mg/dl; <2.8mmol/l)
Brain abscess	Elevated	Elevated, usually <500, lymphocyte predominance, PMNs if rupture into ventricle	Elevated, usually <100	Normal
Subarachnoid hemorrhage	Normal or elevated	Mildly elevated, lymphocyte predominance, xanthochromia	Elevated	Normal or low
Guillain-Barré syndrome	Normal	Normal	Elevated	Normal
PMN, polymorphonuclear cell				

TABLE 30.b-3 -- Diagnosis of neurologic infections by analysis of CSF.

DIAGNOSIS OF NEUROLOGIC INFECTIONS BY ANALYSIS OF CSF			
Condition	**Diagnostic test**	**Sensitivity (%)**	**Specificity (%)**
Bacterial meningitis	Cytospin Gram stain	60–90	100
	Culture	90	100
	Antigen detection assays*	50–100	100
Viral meningoencephalitis	Culture	<50	100
	PCR†	94	94–100
Tuberculous meningitis	Acid-fast stain	10–22	100
	Culture	38–88	100
	PCR	27–85	95–100
Fungal meningitis	Cryptococcal antigen	85	99–100
	Coccidioides immitis antibody	55–95	100
	Histoplasma capsulatum antigen	60	Moderate-high
	H. capsulatum antibody	Moderate	Moderate
	B. dermatidis antibody	Low	Moderate

Toxoplasma encephalitis	*Toxoplama gondii* antibody	50–70	99
	PCR	11–77	100

* Available for *Hemophilus influenzae* type B, *Neisseria meningiditis, Streptococcus pneumoniae, Streptococcus agalactiae*
† Available for enterovirus, herpes simplex virus, Epstein-Barr virus, cytomegalovirus, West Nile virus and varicella-zoster virus

in the case of meningococcus, CSF sterilization occurred within 2 hours of receipt of antimicrobial therapy, whereas with pneumococcus, CSF sterilization occurred within 4 hours. While antimicrobial therapy should never be withheld if there is a delay in performing LP, every effort should be made to expeditiously obtain CSF for an early definitive diagnosis. Previous antibiotic therapy is unlikely to alter the biochemical and cellular CSF abnormalities in bacterial meningitis.

30.c Approach to the patients who has fever and headache

Iain Stephenson
Martin J Wiselka

Introduction

Fever and headache are common presenting signs with a wide differential diagnosis. The physician needs to be able to recognize the early features of bacterial meningitis and initiate appropriate treatment without delay as the consequences of a missed diagnosis or inadequate treatment can be fatal. Investigations for other causes of fever and headache can be initiated once meningitis has been excluded.

Pathogenesis

Inflammation of the meninges may result from a number of pathologic processes including infection, acute vasculitis, malignant infiltration and subarachnoid hemorrhage. Organisms enter the meninges via the nasopharyngeal mucosa or after blood-borne spread. Direct invasion can follow skull fracture or neurosurgery. Relatively poor host defenses and low complement levels in the cerebrospinal fluid (CSF) may facilitate the spread of infection.

Bacterial meningitis is associated with acute inflammation stimulated by bacterial antigens and cytokines. This results in a fibrinous neutrophilic exudate across the leptomeninges and may be associated with the systemic features of sepsis syndrome and circulatory collapse. The increased permeability of the blood-brain barrier, raised intracranial pressure and vasculitic changes around the vessels traversing the subarachnoid space may result in brain ischemia. Tuberculous and fungal infections tend to have a more insidious onset but they may begin fairly abruptly. A CSF pleocytosis with negative Gram stain and culture is termed an aseptic meningitis (Table 30c.1). Viral infections cause disease either by direct invasion of the leptomeninges and brain or indirectly by postinfective immune-mediated phenomena. Brain abscess should also be considered (see Chapter 24) and can have a variable microbial etiology. Occasionally, an abscess may rupture and involve the meninges to cause meningitis.

Microbiology

Fever and headache may be nonspecific features of many infections but they may result from infection of the meninges (meningitis) or brain tissue (encephalitis). The organisms causing bacterial meningitis vary with age and geographic region (Table 30c.2). *Neisseria meningitidis*,

TABLE 30.c-1 -- Some causes of lymphocytic cerebrospinal fluid.

SOME CAUSES OF LYMPHOCYTIC CEREBROSPINAL FLUID	
Viruses	Enteroviruses
	Mumps virus
	Herpes simplex virus
Bacteria	Partially treated bacterial meningitis
	Early bacterial meningitis
	Cerebral abscess
	Tuberculosis
	Brucellosis
	Spirochetes (treponemes, leptospira, *Borrelia* spp.)
Fungi	Cryptococcosis
	Histoplasmosis
Protozoa	Toxoplasmosis
	Amebiasis
Inflammatory conditions	Seropositive conditions (e.g. lupus)
	Seronegative conditions (e.g. Behçet's syndrome, Kawasaki disease)
Chemicals	Irritants
Carcinomatous conditions	Usually secondary deposits

Streptococcus pneumoniae and *Haemophilus influenzae* type b cause about 80% of cases of adult meningitis.

The incidence of *H. influenzae* meningitis in children has declined dramatically following the introduction of *H. influenzae* type b vaccine. Pneumococcal meningitis may follow an initial otitis media, sinus infection or pneumonia and most cases occur in infants and the middle-aged or elderly. Meningococcal meningitis is most common in infants, children and young adults. Outbreaks of infection occur in nurseries, schools, universities and residential accommodation. Cases of meningococcal infection occur more frequently during the winter months and may be associated with influenza infection. In Europe and North America meningococci belonging to groups B and C most

TABLE 30.c-2 -- Likely organisms and possible empiric treatment regimens for bacterial meningitis.

LIKELY ORGANISMS AND POSSIBLE EMPIRIC TREATMENT REGIMENS FOR BACTERIAL MENINGITIS		
Group of patients	**Likely organisms**	**Treatment**
Neonates	Group B streptococci	Ampicillin and gentamicin
	Escherichia coli	Cefotaxime
	Listeria monocytogenes	
Children	*Neisseria meningitidis*	Ceftriaxone
	Streptococcus pneumoniae	Cefotaxime (vancomycin if resistant pneumococcus)
	Haemophilus influenzae	

Adults	*Neisseria meningitidis*	Ceftriaxone (vancomycin if resistant pneumococcus)
	Streptococcus pneumoniae	
	Haemophilus influenzae	
	Listeria monocytogenes	Ampicillin
Elderly persons/underlying malignancy	*Neisseria meningitidis*	Ceftriaxone (vancomycin if resistant pneumococcus)
	Streptococcus pneumoniae	
	Haemophilus influenzae	
	Listeria monocytogenes	Ampicillin
	Gram-negative organisms	
Posttraumatic surgery	*Streptococcus pneumoniae*	Ceftriaxone
	Haemophilus influenzae	Ceftazidime
	Escherichia coli	Carbapenem
	Klebsiella pneumoniae	
	Enterobacter spp.	
	Pseudomonas spp.	
	Staphylococcus aureus	

commonly cause disease, whereas group A strains have been responsible for serious outbreaks of infection in sub-Saharan Africa. Typing of infection is relevant because the current meningococcal vaccine gives protection against groups A and C strains but has no effect on group B disease.

Rare causes of bacterial meningitis include *Listeria monocytogenes*, which is associated with pregnancy and underlying immunosuppression or malignancy. Following trauma or neurosurgery, meningitis caused by Gram-negative organisms such as *Escherichia coli, Pseudomonas* spp., *Klebsiella pneumoniae* and *Enterobacter* spp. can occur.

Viral meningitis is predominantly caused by the enteroviruses (70%), including Coxsackie viruses A and B and the echoviruses. The mumps virus causes about 10% of the diagnosed cases of viral meningitis in the UK with the remainder being caused by herpes simplex virus, varicella-zoster virus, measles virus, adenoviruses or Epstein-Barr virus. Herpes simplex encephalitis can cause necrotic edematous changes that may be asymmetric and localized in the temporal lobes.

Clinical features

The cardinal features of meningeal inflammation are:

- headache,
- neck stiffness,
- photophobia.

Meningococcal meningitis and sepsis are associated with a petechial or purpuric rash. An exanthem may be present in viral infections. The history can often localize the source of infection or may suggest a generalized febrile illness. The presence of intracranial shunts, previous head trauma, recent travel history and underlying immunosuppression will influence the range of potential pathogens. Symptoms and signs of meningitis may be nonspecific in very young or elderly patients. Wakening or early morning headache, with or without vomiting, that is worse on coughing and bending forward or that is associated with visual disturbance are symptoms of raised intracranial pressure.

On examination, vital signs must be documented and the skin should be fully exposed to look for a rash and for the presence of cervical or other lymphadenopathy. Signs of meningism should be sought, including evidence of neck stiffness, photophobia and the presence of Kernig's sign. To elicit Kernig's sign, the patient is placed supine and the lower limb is flexed at the hip and the knee is extended. Patients who have meningism resist by contracting the hamstrings. However, a prospective study of 297 adults admitted with suspected meningitis found that the diagnostic accuracy of nuchal rigidity, Kernig's and Brudzinski's signs was of limited value and not correlated with the presence of moderate meningeal inflammation, highlighting the need for clinical vigilance in presenting patients of all ages. Assessment of focal neurological signs, including cranial nerve assessment and fundoscopy for papilledema, is important. Examination of the tympanic membrane may reveal an underlying otitis media. Urinary dipstick examination should be performed. Acute meningococcal meningitis associated with a florid purpuric rash is usually unmistakable, but patients may be relatively well with equivocal signs or have a more insidious illness.

Investigations

The aim of investigation is to establish the cause of fever and headache and to identify any infecting organisms. A blood count is helpful because bacterial infections are usually accompanied by a neutrophilia. Biochemical and clotting profiles can indicate the development of systemic complications. Cultures of body fluids (blood, sputum, urine, CSF, throat swab and skin scrapings) may reveal the causative pathogen. Antigen detection kits are also available and give rapid results. Meningococcal, tuberculosis, herpes simplex and enterovirus genome detection by the polymerase chain reaction (PCR) is now available from reference laboratories. Comparison of meningococcal antibody titers in acute and convalescent serum samples can yield a retrospective diagnosis.

Chest and sinus radiographs may be helpful in revealing underlying infection. Computed tomography or MRI scans of the head can identify the presence of cerebral edema, hydrocephalus or a mass

effect and exclude alternative diagnoses of intracranial hemorrhage, subdural collection or abscess formation. Examination of the CSF remains important in many cases; routine analysis includes cell count, protein and glucose estimation, culture and Gram stain.

Acute bacterial meningitis is usually associated with polymorphonuclear leukocytosis in the CSF with raised protein and low glucose levels. Viral meningitis characteristically gives a lymphocytosis with normal protein and glucose levels. However there is a wide differential diagnosis of a lymphocytic CSF, which can be investigated by Ziehl-Neelsen and India ink staining, cytology, direct immunofluorescence and viral PCR. A low CSF glucose (<2/3 serum glucose) usually indicates a bacterial, fungal, tuberculous or carcinomatous cause.

Management

Immediate management

The possibility of meningitis should be considered in all patients who have fever and headache. Patients who appear reasonably well with no obvious source of infection need to be observed closely because the signs of meningitis may evolve very rapidly.

If bacterial meningitis is suspected, immediate hospital admission should be arranged and blood cultures and intravenous antibiotic therapy should be instituted without delay. Resuscitation may be required and all patients who have suspected or confirmed bacterial meningitis should be closely monitored, preferably in a high-dependency or intensive care unit.

There is compelling evidence that immediate empiric antibiotic therapy can improve the outcome of meningococcal sepsis and meningitis. In the UK, general practitioners are advised to give intravenous or intramuscular benzylpenicillin to any patient who has suspected bacterial meningitis. The only contraindication is a

previous anaphylactic reaction to penicillin.

Following admission and any immediate resuscitation, the major question for the clinician managing the patient is whether to do a head scan (CT or MRI) or a lumbar puncture.

Role of head scanning

Computed tomography and MRI scanning are unhelpful in uncomplicated viral meningitis, when it is safe to perform a lumbar puncture.

A prospective study of 301 adults admitted with suspected meningitis identified that immunocompromised status, age >60 years and presence of neurological abnormalities or seizure were associated with abnormal CT head scans. CT scanning in those without these features had a negative predictive value of 97% and of the misclassified patients, all underwent safe lumbar puncture, suggesting that the use of CT screening could be better targeted. The indications for performing an urgent scan before lumbar puncture include focal neurological signs, altered level of consciousness, papilledema or symptoms suggestive of raised intracranial pressure, convulsions and suspected subarachnoid hemorrhage.

Role and safety of lumbar puncture (see Practice Point 30b)

The safety of lumbar puncture in patients who have bacterial meningitis has recently been questioned because occasional patients who have unsuspected cerebral edema have developed brainstem coning and death after the procedure. This occurs most commonly in patients who have fulminant meningococcal disease and early lumbar puncture should therefore be avoided in patients who have purpuric rash. Lumbar puncture may be considered at a later stage in these patients if there has been no improvement on empiric treatment.

The value of lumbar puncture is also declining with increasing use of antibiotics before the procedure and the availability of newer diagnostic techniques. Nevertheless, the lumbar puncture remains a very important investigation in patients who have suspected viral meningitis, in whom it allows the diagnosis to be established, and in the atypical causes of meningitis. The Consensus Statement on diagnosis, investigation, treatment and prevention of acute meningitis in adults published by the British Infection Society recommends lumbar puncture in all suspected patients except where there is a clear contraindication (including signs of raised intracranial pressure, focal neurological deficit, severe shock, depressed conscious level or coagulation disorder) or a confident clinical diagnosis of meningococcemia. If the CSF is clear, further investigations should be performed to establish the cause of fever and headache. In these circumstances a chest radiograph is helpful to exclude pneumonia and urinalysis is useful to exclude a urinary tract infection, because these conditions may present with signs of meningism.

Choice of antibiotic therapy (see also Chapter 22)

Empiric therapy should cover all likely pathogens; treatment can then be modified if any organisms are identified. When considering antibiotic choice, the agent used must penetrate the CSF to achieve an adequate inhibitory concentration. Antibiotic penetration is initially good because the blood-brain barrier is impaired owing to the inflamed meninges, but as the disease resolves penetration becomes less. Ceftriaxone and cefotaxime are third-generation cephalosporins that will cover the meningococcus, the pneumococcus, *H. influenzae* and most other organisms (see Table 30c.2) and they are frequently used as empiric therapy. Cephalosporins have little activity against *Listeria* spp. and ampicillin should be added if listeriosis is suspected. Penicillin-resistant pneumococci are occurring with increasing frequency in many areas and benzylpenicillin is therefore inadequate as empiric therapy for bacterial meningitis. Vancomycin should be added in communities where there is significant resistance to penicillin among isolates of *S. pneumoniae*.

The treatment of lymphocytic meningitis is difficult because the diagnosis is often uncertain and there is a wide range of potential pathogens. It is occasionally necessary to treat patients with empiric antibiotics, antiviral therapy (aciclovir), antituberculous therapy and antifungal therapy, with the possible addition of corticosteroids. Patients who have lymphocytic meningitis can present a major diagnostic and therapeutic challenge.

Role of corticosteroids

Early dexamethasone treatment has been shown to be associated with an improved outcome in meningitis caused by *H. influenzae*, and possibly *S. pneumoniae*, but the effect of corticosteroids is less clear in other forms of bacterial meningitis. Clinicians differ widely in their practice; however, it seems sensible to give corticosteroids as early as possible to have a maximal effect.

Management of the complications of meningitis

Bacterial meningitis may be accompanied by all the features of sepsis syndrome, with multiple organ failure requiring intensive care support. It has been suggested that hemofiltration may have a therapeutic role by removing bacterial toxins and unwanted cytokines, although there are no controlled studies. A sensible approach is to consider early hemofiltration in seriously ill patients who have hypotension and oliguria. The role of extracorporeal membrane oxygenation is also uncertain, but this should be considered if the patient is failing to respond to conventional ventilation and circulatory support.

Seizures are managed with anticonvulsants or sedation and ventilation. Metastatic seeding of infection can form cerebral or epidural abscesses and progress to a subdural empyema. The blockage or interruption of CSF circulation at the foramina, aqueduct or subarachnoid granulations can produce hydrocephalus. Raised intracranial pressure can result in sinus thrombosis, cerebral edema with herniation, cranial nerve palsies or brain ischemia. Sensorineural deafness occurs in

about 10% of patients who have pneumococcal meningitis and a smaller proportion of patients who have meningococcal meningitis, and audiologic assessment is recommended for all patients who have recovered from bacterial meningitis.

Public health issues

Public health physicians should be notified immediately of any patients who have known or suspected meningitis so that appropriate action can be taken. Cases of meningitis are often associated with considerable local publicity and anxiety in the community. The role of the public health physician is to provide appropriate information and to organize antibiotic prophylaxis for close contacts of patients who have meningococcal or *Haemophilus* meningitis and more extensive prophylaxis and vaccination campaigns if these are indicated. There are published national guidelines for the management of clusters or epidemics of meningococcal disease.

30.d Empiric antimicrobial therapy for suspected infection of the central nervous system

Marc A Tack

Introduction

Bacterial infections of the central nervous system (CNS) can vary from rapidly life-threatening illnesses such as pneumococcal meningitis to more insidious infections such as neuroborelliosis and cryptococcal meningitis. The selection of an appropriate initial antimicrobial therapy is frequently empiric. The key clinical determinants of antimicrobial selection are the age of the patient, the immune status, a history of trauma or instrumentation and the clinical presentation. A detailed history including the use of immunosupressing agents such as corticosteroids is necessary to adequately assess a patient's risk of immune dysfunction as this will result in an expanded list of potential etiologic agents and thus alter the selection of empiric therapy. A previously healthy adult who has acute bacterial meningitis poses different etiologic considerations from those of a patient with asthma on long-term prednisone complaining of fever and a headache. Similarly, if the blood-brain barrier has been compromised, such as in the case of placement of a ventriculostomy or epidural pump or other surgical manipulation, empiric antimicrobial therapy must be targeted toward pathogens that gain entry by these routes.

Pathogenesis

There are several mechanisms of infection that account for most CNS infectious processes. Hematogenous spread in patients with bacteremia can lead to bacterial seeding and acute meningitis. Direct extension of local infections, such as sinusitis and otitis, have been implicated as frequent causes of brain abscesses. Surgical manipulation such as the placement of a ventriculoperitoneal shunt may allow direct seeding of the CNS. Lastly, trauma may provide a portal of entry for direct inoculation of pathogens.

Microbiology

The most frequent pathogens associated with bacterial meningitis in a previously healthy host are *Streptococcus pneumoniae* and *Neisseria meningitidis*. The emergence of strains of *Strep. pneumoniae* highly resistant to penicillin and ceftriaxone has major implications in the selection of empiric treatment of meningitis. *Haemophilus influenzae*, formerly a frequently isolated organism, is now rarely implicated owing to routine pediatric immunization. In neonates, *Streptococcus agalactiae* is frequently isolated. In elderly or immunocompromised patients, *Listeria monocytogenes* must be included in the differential diagnosis of acute bacterial meningitis (Table 30d.1).

Patients with inplanted foreign bodies or who have undergone recent neurosurgical procedures are at increased risk for infections caused by *Staph. aureus* and coagulase-negative staphylococci, although a host of other organisms including fungi have been reported. Diphtheroids and other common skin flora may cause infection in patients with recent manipulation of the CNS, including epidural injections. Aerobic Gram-negative bacilli have also been encountered in posttrauma and postoperative patients. A detailed review of bacterial meningitis is found in Chapter 22 .

Clinical features

The most common presenting clinical features of acute bacterial meningitis are fever, headache and meningismus. This triad of symptoms is seen in over 85% of cases and should be easily recognizable to the experienced clinician. Confusion and altered sensorium are also frequently noted. Physical examination frequently reveals nuchal rigidity, a positive Kernig's or Brudzinki's sign (although see comment in practice point 30c, above) and the presence of photophobia.

TABLE 30.d-1 -- Common bacterial pathogens associated with predisposing factors for meningitis.

COMMON BACTERIAL PATHOGENS ASSOCIATED WITH PREDISPOSING FACTORS FOR MENINGITIS	
Predisposing factor	**Common bacterial pathogens**
CFS shunt	Coagulase-negative staphylococci, *Staphylococcus aureus*, Gram-negative bacilli
Postneurosurgery or post-trauma	*Staphylococcus aureus*, coagulase-negative staphylococci, Gram-negative bacilli
Immuncompromise	*Streptococcus pneumoniae, Neisseria meningitidis, Listeria monocytogenes*, Gram-negative bacilli
Skull fracture	*Streptococcus pneumoniae*, group A streptococci, *Staphylococcus aureus*

Presumptive evidence of meningococcal meningitis may be apparent on physical examination. Of patients who have meningococcemia, with or without meningitis, 50% manifest a macular erythematous papular rash early in the course of the disease. This rash rapidly appears petechial and then becomes purpuric.

In neonates, the presentation of acute bacterial meningitis may be subtle. In this group, meningismus is infrequently noted and irritability and temperature instability may be the only indications of meningitis. Refusal to feed, lethargy, a high-pitched cry, vomiting, diarrhea and respiratory distress should alert the clinician to this diagnosis.

Elderly patients, especially those who have co-morbid disease, as well as immunosuppressed hosts often present with insidious manifestations. Fever is frequently absent and headache, confusion or altered level of consciousness may be the only clinical finding.

Other less common causes of meningitis may frequently present with varying clinical syndromes. Cryptococcal meningitis in a patient who has AIDS typically presents as an insidious illness; persistent fever and headache over several days or even weeks is often the only clinical complaint. Lyme meningitis, more common in highly endemic areas, often presents as a subacute basilar meningitis with cranial nerve palsies and radiculopathy as common findings. Tuberculous meningitis may also present in an insidious manner, necessitating a high index of suspicion for early recognition and successful treatment.

The clinical manifestations of a brain abscess are usually more attributable to the space-occupying effect of the lesion than to the actual infection. The classic triad (fever, headache and a focal neurologic deficit) is seen in only 50% of patients. Headache, which is usually moderate or severe, is the most common manifestation; the next most common is fever. Eventually, altered mentation, ranging from confusion to coma, ensues. Neurologic findings may be focal, but this depends on the size and location of the abscess. Seizures as well as papilledema are more common in brain abscess than in meningitis.

Infections of the CNS in patients with recent neurosurgical manipulation or with foreign inplanted devices may vary in clinical presentation depending upon the etiologic agent. A patient with a foreign body infection caused by *Staph. aureus* infection will likely appear toxic with fever and other common signs of meningeal inflammation while infection from coagulase-negative staphylococci may only cause complains of a mild headache over several days. Clinical obstruction of a previously functioning venticular drainage shunt should raise suspicion for infection and warrants evaluation of the CSF.

Investigations

Early diagnosis and rapid initiation of appropriate antimicrobial therapy are essential in patients who present with manifestations of acute CNS infection. A lumbar puncture should be performed in all patients unless there are specific contraindications to this procedure. Patients who present with papilledema or focal neurologic findings should undergo a CT scan before lumbar puncture to determine whether there is a space-occupying lesion under increased intracranial pressure; it will determine the presence of a brain abscess in most cases as well. In patients who have a shunt or reservoir, cerebrospinal fluid (CSF) samples may be obtained from

these sites.

Samples of CSF should be examined, preferrably using a cytospin technique, for the presence of bacterial and fungal pathogens using appropriate stains. Glucose and protein levels in the CSF should be obtained together with a simultaneous serum glucose level for comparison. Cultures of CSF for bacterial, fungal and mycobacterial organisms should be obtained. If cryptococcal meningitis is suspected, a cryptococcal antigen assay should be performed on CSF as well. Bacterial latex agglutination tests are frequently used but are of limited benefit in clinical practice owing to their high false-negative rate.

TABLE 30.d-2 -- Common bacterial pathogens causing meningitis according to the age of patient.

COMMON BACTERIAL PATHOGENS CAUSING MENINGITIS ACCORDING TO THE AGE OF PATIENT	
Age of patient	**Most common bacterial pathogens**
0–4 weeks	*Streptococcus agalactiae, Escherichia coli, Listeria monocytogenes, Klebsiella pneumoniae*
4 weeks to 2 years	*Streptococcus agalactiae, Streptococcus pneumoniae, Haemophilus influenzae*
2–18 years	*Haemophilus influenzae* (decreasing), *Neisseria meningitidis, Streptococcus pneumoniae*
18–60 years	*Streptococcus pneumoniae, Neisseria meningitidis*
Over 60 years	*Streptococcus pneumoniae, Listeria monocytogene*s, others

In addition to studies of the CSF, blood cultures should be sent in all cases because of the high rate of concomitant bacteremia. Other specimens, such as sputum, urine and sinus aspirates, should be obtained and evaluated when clinically appropriate.

Management

The rapid initiation of appropriate antimicrobial therapy in acute bacterial meningitis is imperative. The initiation of antibiotics should not be delayed while awaiting an imaging study before lumbar puncture. In general, the patient should receive the first dose of antibiotics within 30 minutes of arrival at the hospital if bacterial meningitis is suspected. Appropriate therapy should be based on the age, clinical presentation and predisposing factors and therapy should be modified if indicated when the etiologic agent is identified (Table 30d.2).

The empiric antibiotic of choice for acute bacterial meningitis in adults is a third-generation cephalosporin (ceftriaxone or cefotaxime) and vancomycin. In patients aged under 3 months or over 60 years, ampicillin should be included in the empiric regimen for the treatment of potential listeriosis. In the past several years the incidence of resistance of community isolates of *Strep. pneumoniae* to penicillin has risen to the point where I believe that vancomycin should be included in the initial empiric treatment. Therapy can be adjusted when antimicrobial sensitivities of the cultured isolate become available.

Patients who develop a CNS infection after trauma or postoperatively are at higher risk of Gram-negative bacillary infections. An antipseudomonal cephalosporin (ceftazidime or cefepime) in combination with vancomycin is an appropriate empiric regimen. Vancomycin is used because of the frequent ß-lactam resistance seen with coagulase-negative staphylococci, which are often identified as the pathogen in this setting. This is also the empiric regimen I suggest for

TABLE 30.d-3 -- Empiric antibiotic regimen based on clinical presentation.

EMPIRIC ANTIBIOTIC REGIMEN BASED ON CLINICAL PRESENTATION	
Acute meningitis — previously healthy adult	Third-generation cephalosporin and vancomycin
Post neurosurgery or trauma	Antipseudomonal cephalosporin and vancomycin
Brain abscess	Third-generation cephalosporin and metronidazole
Foreign body or recent manipulation	Antipseudomonal cephalosporin and vancomycin

patients who have foreign bodies in place. In patients with a reservoir, direct administration of vancomycin may be utilized (5–10mg initially, diluted in preservative-free saline) and in patients with organisms difficult to eradicate, intrathecal antimicrobial treatment should be considered.

In patients who have a brain abscess, streptococci, Gram-negative bacilli and anaerobes are frequent pathogens and empiric antimicrobial therapy must target these pathogens and penetrate purulent collections. A third-generation cephalosporin (ceftriaxone or cefotaxime) in combination with metronidazole is useful in this clinical setting. The diagnosis and treatment of brain abscess is presented in detail in Chapter 24 .

Although there are no controlled clinical trials, most clinicians treat acute bacterial meningitis for 7–14 days. The duration of therapy for brain abscesses is prolonged and determined by clinical and radiographic response. AIDS patients who are infected with cryptococcal meningitis required prolonged therapy followed by chronic suppression (see Chapter 126 and Chapter 237 for further discussion).

Chapter 31 - Pharyngitis, Laryngitis and Epiglottitis

Dennis A Clements

This chapter describes some of the most common infections of mankind, the upper respiratory infections, which include pharyngitis, laryngitis and epiglottitis. Although viruses play a significant role in the pathogenesis of many of these infections, bacteria and other organisms are responsible for many others. This chapter details the importance of these infections and provides a practical guide to diagnosis and management.

EPIDEMIOLOGY

Definition and nomenclature

Pharyngitis, commonly called 'sore throat', is an inflammatory process of the pharynx, hypopharynx, uvula and tonsils that can be caused by viral or bacterial pathogens, and occasionally both (Table 31.1). Pharyngitis can be separated into one group of illnesses with associated nasal symptoms (which are most commonly viral in origin) and another that cause only pharyngitis. It is important to distinguish between these infections because rheumatic fever and acute glomerulonephritis may complicate untreated group A ß-hemolytic streptococcal infections, but they can usually can be prevented by appropriate antibiotic treatment. Parapharyngeal abscesses and Ludwig's angina are discussed in Chapter 41 .

Laryngitis, or inflammation of the larynx (subglottic area), is almost always secondary to a viral infection. Lower voice pitch, hoarseness and aphonia frequently occur. It is important to differentiate laryngitis from other infectious forms of obstructive airway disease, such as epiglottitis, which may be life threatening. Laryngitis in small children often gives a 'croup' syndrome. Children with laryngitis are often noted to 'bark' like seals. These illnesses are generally self-limiting and require only supportive care.

Epiglottitis (bacterial cellulitis of the epiglottis), or supraglottitis, is an inflammatory process of the epiglottis and/or supraglottic structures that is almost always caused by *Haemophilus influenzae* type b (HIB). It is usually rapidly progressive, particularly in young children, and needs immediate antibiotic treatment and often intubation to avoid possible respiratory obstruction.

Incidence, prevalence and seasonality

Infections of the upper respiratory system are more common than any other acute infectious malady. The self-limiting viral infections are most frequently caused by adenoviruses, rhinoviruses, coronaviruses, enteroviruses and parainfluenza viruses (see Table 31.1). Other viral infections, such as respiratory syncytial virus (RSV) and Epstein-Barr virus (EBV), are less common but still frequently occur. Bacterial causes of upper respiratory infections are led by group A ß-hemolytic streptococci (GAS), but can also be caused by *Haemophilus influenzae, Bordetella pertussis, Chlamydia pneumoniae, Corynebacterium haemolyticum, Mycoplasma pneumoniae* and *Yersinia enterocolitica* among others.

These upper respiratory infections are often difficult to differentiate, and hence difficult to diagnose, frequently leading to futile overtreatment in many cases. Further complicating the issue is the fact that primary viral infections are often succeeded by secondary 'opportunistic' bacterial infections, making undertreatment a problem in a significant minority of infections. Additionally, individuals with allergies or structural defects are sometimes more prone to secondary bacterial infections. The clinician is therefore challenged to weigh multiple factors involved in deciding whether an infection is viral or bacterial in origin, and whether antibiotic treatment is warranted.

It is estimated that children in day care in the USA have an upper respiratory infection approximately every 3 weeks from the age of 6 months to 2 years. [1] The incidence then decreases so that by the time of school entry a child has about 3–6 episodes of upper respiratory infection per year. Most of these infections include pharyngitis and/or laryngitis. Young children often have pharyngitis on inspection but do not complain of sore throat; this symptom is more common in adolescents and adults. Often the only sign of pharyngitis in young children is refusal to eat and/or drink.

Viral upper respiratory infections frequently occur in miniepidemics (RSV, parainfluenza, influenza, varicella, measles). They are more common in the winter except for those caused by enteroviruses, which are more common in the summer. [2] Some viral infections occur year round, with no seasonal pattern (adenoviruses). Group A ß-hemolytic streptococcal infections are more common in the winter, but many other nonviral respiratory infections do not appear to be seasonally linked (*Chlamydia* and *Mycoplasma* spp.). Some bacterial infections appear to be linked to preceding viral infections and hence occur more commonly in the winter. Pharyngeal colonization may occur throughout the year. Fortunately, epiglottitis is rare now that HIB immunization is routine for infants in many countries.

Morbidity, mortality, historic change and risk factors

Influenza infections vary significantly from year to year. In the USA one subtype was predominant each year until about 1990, since which time both H3N2 and H1N1 strains have been circulating simultaneously. When there is a major shift in antigen type, significant excess morbidity occurs as the new strain infects the community. Increasing air travel has accelerated the rate at which the influenza viruses travel around the world and has perhaps been responsible for the increasing frequency with which the viruses are detected. The shifted strain outbreaks have most affected the elderly and children with congenital heart and lung disease. Minor influenza drifts have occurred also, but cause less disease. There has also been a recent decrease in the average age at which children acquire upper respiratory diseases because of the increasing use of day care for children. The long-term effect of this is unknown. In the short term it appears that it has been responsible for a significant increase in the number of ear infections in children less than 2 years old.[3]

Rheumatic fever, a complication of group A ß-hemolytic streptococcal pharyngitis, has waxed and waned in importance.[4] After a century of prominence, the disease was in considerable decline in developed countries for 40 years. Recently, clusters of rheumatic

TABLE 31-1 -- Common causes of pharyngitis, laryngitis and epiglottitis.

COMMON CAUSES OF PHARYNGITIS, LARYNGITIS AND EPIGLOTTITIS							
	Organism/entity	**Disease/syndrome**	**Pharyngitis**	**Nasopharyngitis**	**Laryngitis**	**Epiglottitis**	**Complications**
Bacteria	*Arcanobacterium haemolyticum*	Pharyngitis +/- scarlatiniform rash	++				
	Corynebacterium diphtheriae	Diphtheria with pseudomembrane	+++				
	Corynebacterium spp. (other)	Pharyngitis	++	+++			
	Haemophilus influenzae	Pharyngitis	+++				
	Legionella pneumophila	Pharyngitis	++	++		+++ (type b)	Epiglottitis, meningitis
	Neisseria gonorrhoeae	Pharyngitis	++				Pneumonia
	Neisseria meningitidis	Pharyngitis	++				Septic arthritis
	Streptococcus pyogenes (group A ß-hemolytic)	Pharyngitis (scarlet fever)	+++++				Meningitis, sepsis
	Streptococcus spp. (groups B, C and G)	Pharyngitis	+++		+		Rheumatic fever, acute glomerulonephritis
	Treponema pallidum	Secondary syphilis	+		+		
	Yersinia entercolitica	Pharyngitis and enterocolitis	++		+		

Viruses	Adenoviruses	Nasopharyngitis		+++			Pneumonia
	Coronavirus	Nasopharyngitis		++			
	Coxsackie A virus	Herpangina	++	++

	Kawasaki disease	Pharyngitis, conjunctivitis	+++				Coronary artery aneurysms
	Stevens-Johnson syndrome	Pharyngitis, stomatitis, ulcerations	+++				Shock

fever cases have occurred, for example in Salt Lake City, Utah, USA, where it is hypothesized that the re-emergence of certain M-types has been responsible.

Before HIB vaccination was instituted there were approximately 20,000 cases of HIB disease each year in the USA. Since the advent of HIB immunization the incidence of this disease has decreased by 95%.

PATHOGENESIS AND PATHOLOGY

The pathogenesis of the sore throat due to pharyngitis is poorly understood. Volunteers given rhinoviral infections produce bradykinin and lysylbradykinin, which are known inflammatory mediators that can excite nerve endings in the pharynx to cause pain.[5] There is also suggestive evidence from laboratory animals that adenovirus, RSV and other viral infections directly invade the pharyngeal cells and produce an inflammatory response. This leads to the well-described 'red, sore throat'. Additionally, adenovirus and EBV often produce lymphoid hyperplasia and tonsillar exudation. Herpes simplex virus (HSV) and coxsackievirus infections frequently lead to ulcerations of the oral mucosa. Herpes simplex virus ulcers are more common in the anterior part of the mouth and coxsackievirus ulcers occur more frequently in the posterior part of the pharynx, but this is only a guide and both viruses can cause ulcers in any part of the oropharynx. Herpes simplex often produces a significant gingivitis as well.

Streptococcal pharyngitis often inflames the posterior pharynx, with petechiae on the uvula and soft palate.[6] When one sees this clinical sign, GAS are often isolated by throat culture. A confusing factor is that up to 10% of patients who have EBV infections will

have a secondary group A ß-hemolytic streptococcal pharyngitis during their illness: *Corynebacterium diphtheriae* can also cause pharyngitis, producing a characteristic gray membrane across the structures of the posterior pharynx. This is seldom seen today except in a few geographic areas where diphtheria outbreaks have occurred recently, such as Russia. There are also noninfectious causes of pharyngitis, such as Behçet's syndrome, Kawasaki disease and Stevens-Johnson syndrome.

Laryngitis may be an isolated event, but more commonly is part of a more extensive upper respiratory infection. Young children with croup cannot inform us of the extent of their symptoms and refusal to swallow and/or eat may be their only sign of difficulty. Adults with laryngitis often had croup as children and these two entities may be one and the same illness, the only difference being that the adult subglottic airway is larger and thus adults are less likely to develop stridor. Parainfluenza viruses are the most common cause of croup,[7] but adenoviruses, influenza and RSV also cause laryngitis/croup. Normally there is a mild coryza and sore throat followed by an inflammatory process of the larynx, trachea and subglottic area. There can be significant pain during coughing. The subglottic area swells and because it is located in an area of the nondistensible cricoid cartilage, it can only swell into the airway. This gives the characteristic croupy cough and stridor in a child and laryngitis in an adult. It is of interest that croup is more pronounced after sunset and at night, when the child is lying down. During the daytime the symptoms are often markedly improved. Occasionally the distention into the airway progresses enough to cause airway compromise and intubation is necessary. Fortunately, this is a rare event.

Epiglottitis is an acute cellulitis of the epiglottis and/or surrounding tissue that has the potential to cause complete obstruction of the airway. It is almost always caused by HIB. In Melbourne, Australia, HIB was isolated from 114 (93%) out of 123 blood cultures collected from epiglottitis patients and no other pathogens were isolated.[8] The usual patient is 1–5 years old (Fig. 31.1) and onset is sudden, with sore throat and fever, with head forwardly extended, often with drooling. Respirations appear delicate, with little movement of the head. There may be a raspy sound when breathing. Fever may cause tachycardia. The mood of some affected children may seem dull or anxious. Visualization of the pharynx reveals a 'cherry red' epiglottis, but sometimes the epiglottis is less red than the surrounding periepiglottic structures or base of the tongue. Visualization of the

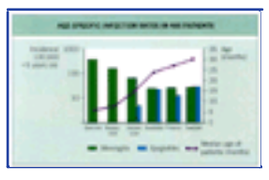

Figure 31-1 Incidence and median age of HIB disease. Disease type and geographic location per 100,000 children less than 5 years of age are shown.

epiglottis must be performed with care because respiratory arrest may occur if there is laryngeal spasm while probing the mouth.

PREVENTION

Preventing pharyngitis is desirable, but difficult to achieve. Viral pharyngitis is spread mostly by aerosolized oral secretions, hand-to-mouth contact with multiple individuals and the use of common utensils, glassware, etc. Certain viruses are known to be particularly resilient; RSV has been cultured from table tops hours after being inoculated there.[9] Measles has been known to be contracted from the air in a physician's waiting room, as long as 1 hour after the child with measles had left the

room. Other viruses may be less durable and less contagious, but close contact is obviously not necessary to transmit many of these agents. Prevention of disease depends mainly on good handwashing and preventing the spread of oral secretions. Masks and handkerchiefs inoculated with antiviral drugs have been used in experimental trials, but after several minutes of breathing, when the mask becomes wet, the benefit seems to diminish. There are vaccines available to prevent some of these diseases. Effective measles vaccines have been used for approximately 30 years, so the disease has decreased dramatically in most countries. Certain adenoviral vaccines have been used with some degree of success, mostly in military personnel. Vaccines for RSV and parainfluenza viruses are currently under development. These vaccines could have a significant effect on the population's health, particularly on that of the youngest children.

Transmission of streptococcal pharyngitis seems to require closer contact than for most viruses. Studies performed in the military during World War II showed that soldiers in barracks sleeping on either side of the index case were more likely to have disease than those further away.[10]

To date, there are no immunizations available to prevent streptococcal disease, although trials evaluating group B and group A vaccines are under way. For patients who have had prior group A disease and subsequent rheumatic fever, penicillin prophylaxis is recommended. Most patients receive intramuscular benzathine penicillin, 1.2 million units, once per month, although oral regimens are acceptable but have poorer compliance rates.

Vaccines against parainfluenza viruses would have the most impact on preventing laryngitis and croup. These are still experimental. The ability of influenza vaccine to prevent laryngitis has not been studied. To date, no other preventive measures against laryngitis are available.

In the only study to date seeking specific risk factors for epiglottitis, day care attendance was the strongest predictor for disease but the association was modified by whether the subject had had an upper respiratory illness in the previous 4 weeks.[11] There was also the suggestion that northern European ancestry was a risk factor as well. Fortunately, the incidence of epiglottitis (and meningitis) has decreased markedly since the advent of HIB vaccination. Whether the incidence of HIB disease in adults may change in the future is unknown, because long-term immunity from vaccination may prove to be either more or less effective than that due to natural infection.

CLINICAL FEATURES

Pharyngitis

Pharyngitis is a ubiquitous infection. A 'sore throat' affects most people at least once every year. Most cases of viral pharyngitis are associated with an upper respiratory infection (nasopharyngitis), as shown in Table 31.1 . Generally nasopharyngitis has a prodrome that may include malaise, diaphoresis, fever, headache and general aches and/or pains. Coryza and sore throat then begin. Many infections

will progress to produce a cough and/or laryngitis. Some viral infections produce predominantly coryza, others more pharyngitis, and others more cough or laryngitis. Coxsackieviruses often cause ulcers in the posterior pharynx along with a sore throat. Measles can cause a severe pharyngitis, but the associated symptoms of conjunctivitis, rash and Koplik's spots make the disease easily diagnosable. Parainfluenza and influenza viruses can give a particularly painful pharyngitis, with frequently associated symptoms of cough and laryngitis.

The DNA viruses (EBV (Fig. 31.2), adenovirus (Fig. 31.3), cytomegalovirus and HSV) can produce significant pharyngitis. They also tend to last longer than the other viral causes of pharyngitis. These viruses produce other upper respiratory symptoms such as non-tender cervical adenopathy (Fig. 31.4) of, in the case of HSV, tongue

Figure 31-2 Epstein-Barr virus (mononucleosis or glandular fever) pharyngitis.

Figure 31-3 Adenoviral pharyngitis.

Figure 31-4 Adenopathy associated with EBV.

and mouth ulcers (Fig. 31.5). Herpes simplex virus pharyngitis has been described as a disease in which 'the gums swell up and swallow the teeth'. Rhinoviruses and RSV infections give upper respiratory symptoms as well as pharyngitis in infants.

The syndrome of acute HIV infection ('seroconversion illness') is well described and may cause symptoms in up to 50% of patients (see Chapter 122). It is a mononucleosis-like illness with pharyngitis being a prominent feature. Patients will also have fever, lymphandenopathy, rash and myalgias. The symptoms are nonspecific.

It is important to diagnose bacterial causes of pharyngitis because, unlike viral causes, many can be treated specifically with antibiotics. Proper treatment can avoid significant morbidity and/or mortality. Pharyngitis caused by GAS is the most common infection causing significant pharyngeal edema, frequently with petechiae on the soft palate and uvula (Fig. 31.6). Tender cervical nodes are common. Small children may complain of abdominal pain, which may be due to mesenteric adenitis. Headache and raised temperature are also common. Some patients who have a streptococcal sore throat have a characteristic red 'scarlet fever' rash that begins in the groin and axillary areas and spreads over the body (Fig. 31.7). The rash is sandpaper-like and may itch. A strawberry tongue is also often present. Other patients have a characteristic rash on the face (Fig. 31.8). Without treatment the illness usually resolves over 3 or 4 days, but rheumatic fever may ensue.

The recommended treatment is penicillin, or clindamycin, erythromycin or azithromycin for those allergic to penicillin. There is concern about the recurrence rate of streptococcal pharyngitis in adequately treated patients but there is no evidence for microbiological resistance to therapy. It is more likely that the organism is reacquired or sequestered in a nonapproachable site and simply reemerges after therapy is discontinued. Some have used rifampin at

Figure 31-5 Herpes simplex virus stomatitis.

Figure 31-7 Scarlet fever. Skin rash and pharyngitis associated with GAS infection.

Figure 31-8 Facial rash associated with GAS infection.

the end of therapy in an attempt to alleviate this possibility. While all therapies have similar treatment profiles, azithromycin has a higher culture-positive recurrence rate. The risk of rheumatic fever without antibiotic treatment is complex. Rates as high as 3% were documented by Wannamaker[12] in 1952; however, more typical rates of 0.4% were found in a pediatric population in 1961.[13] Certainly M protein type, genetic susceptibility and previous infection play a part in this diversity of recurrence rates. Other ß-hemolytic streptococcal infections (groups C, G and B) can cause pharyngitis but not rheumatic fever. For these, antibiotic treatment may provide symptomatic relief. Occasionally, pharyngitis can be secondary to an abscess in the peritonsillar area. This is usually easily diagnosed by an asymmetry of the tonsillar pillars. The affected side is asymmetrically enlarged and protrudes anteriorly into the mouth.

Haemophilus influenzae (nontypable and types a–f) can cause pharyngitis and type b can also cause epiglottitis or meningitis. The appearance of pharyngitis is nondiagnostic. Many individuals are carriers but are not ill. *Corynebacterium diphtheriae* causes diphtheria, which is easily diagnosed because of the gray pseudomembrane in the posterior pharynx along with pharyngitis. The disease has recently become endemic in parts of the former Soviet Union. *Arcanobacterium* (previously *Corynebacterium*) *haemolyticum* is a common cause of pharyngitis and can also cause a scarlatiniform rash. It is the cause of many non-GAS throat infections.[14] *Neisseria gonorrhoeae* can also cause pharyngitis. The appearance of the pharyngitis is nondiagnostic, so a heightened awareness is required to make this diagnosis.[15]

Chlamydia pneumoniae and *Mycoplasma pneumoniae* can cause pharyngitis, but generally will go on to cause cough also, often with wheezing and pneumonia.[16] [17] *Candida albicans* can cause pharyngitis but normally only in the immunocompromised host. The pharyngitis is hyperemic, with white plaques on the buccal mucosa.

Aphthous stomatitis is a common cause of mouth ulcers. The etiology is unclear. Small painful ulcers appear on the buccal mucosa, but can also appear in the posterior pharynx. The ulcers are usually stress related and last approximately 1 week. Very extensive aphthous ulceration can also be seen as a complication of HIV infection. Behçet's syndrome may cause pharyngitis. Kawasaki disease, most common in children, can cause significant pharyngitis. Most children with Kawasaki disease also have fever, a strawberry tongue and, importantly, conjunctivitis. This condition is frequently confused with streptococcal disease. Stevens-Johnson syndrome can result in pharyngitis, stomatitis and perioral swelling and ulcerations.

Laryngitis

Laryngitis is inflammation of the subglottic area and is generally of viral etiology although there is evidence that some individuals with *M. pneumoniae* infection can also develop hoarseness.[18] The most common cause of laryngitis and croup in infants is parainfluenza virus. The order of frequency is type 3>type 1>type 2. Because the infant airway is relatively narrower, croup with a 'barky' cough is much more common in infants. Older children, adolescents and adults tend to have laryngitis only. The hoarseness lasts from 2 to 5 days. A sore throat is common. Other common causes of laryngitis are influenza, RSV and adenovirus infections.

The feared complications of laryngitis are respiratory arrest, particularly in children with croup, and bacterial tracheitis in anyone with croup/laryngitis, particularly those that might have had recent trauma to the subglottic area.[19] Croup is worse at night and when lying down. Cool air and an upright posture are the treatments of choice. Temperature may be slightly elevated, but fever is not a characteristic of the disease. Bacterial tracheitis, when it occurs, is usually heralded by the sudden onset of fever and dyspnea.[20] The syndrome may be clinically indistinguishable from epiglottitis, except that the epiglottis is normal. The most common causes of the infection are *Staphylococcus aureus*, GAS and HIB. Immediate antibiotic treatment is indicated. Sometimes intubation is necessary.

Epiglottitis

Patients with epiglottitis often have an underlying illness, presumed to be viral. They then have sudden onset of fever, with the neck extended forward, drooling and air hunger. Affected children are anxious and lean forward to open their airway (Fig. 31.9). The diagnosis is easily made by viewing the epiglottitis, which is swollen and red (Fig. 31.10). Intubation is often required. *Haemophilus influenzae* type b is almost always obtained by culturing swabs from the epiglottis in children. Some children have been discharged without intubation after receiving only one dose of ceftriaxone when the epiglottis did not appear reddened, but subsequent epiglottic and blood cultures have been positive for HIB. They were cured completely. The duration of hospital treatment averages 3 days. Intubation is needed for less than 24 hours in most cases.[21] In adults other pathogens may be obtained.[22] In most adults the disease is less severe and of slower onset. The airway obstruction occurs because of a progressive cellulitis of the supraglottic area. Thus at presentation,

antibiotic treatment and intubation at the first sign of increasing respiratory compromise may avert the need for tracheostomy. The use of steroids to reduce inflammation and decrease the need for tracheostomy is appealing but unproven.

DIAGNOSIS

The most common treatable cause of pharyngitis is GAS infection. This can be diagnosed with a simple latex antigen test directly from a throat swab, but this procedure is not widely used outside North America. The latex test has a high specificity and an adequate sensitivity,[23] but bacterial culture is the gold standard. Group

B, C and G streptococci can also cause significant morbidity, but only group A leads to rheumatic fever, so the reason for treatment is not only to eliminate the pharyngitis but also to prevent the subsequent rheumatic disease. Viral causes of pharyngitis do not normally require specific diagnosis, but serologic tests are available for mononucleosis (EBV) and cytomegalovirus. Adenoviruses, RSV and parainfluenza viruses can be diagnosed using rapid antigen tests, which are available but rarely used in uncomplicated community-acquired infections.

Laryngitis is not normally diagnosed by laboratory tests and radiographs are of little use except to exclude foreign body aspiration or epiglottitis.

The white blood cell count in epiglottitis is often elevated, with an increase in the percentage of neutrophils and band forms. A culture of the epiglottis is usually positive for HIB but the result may not be available until the child is ready for discharge. Blood cultures are frequently positive for HIB in children, although there are usually fewer of these organisms per milliliter than in children with meningitis. Efforts to determine whether there are organism subtype differences that predispose to meningitis versus epiglottitis have been equivocal. In adults, the disease is reported to be caused principally by HIB, but pneumococci, *H. parainfluenzae* and streptococci are also reported. At the time of admission, if time permits, a radiograph of the lateral

TABLE 31-2 -- Antibiotic dosages for the treatment of respiratory infections.

ANTIBIOTIC DOSAGES FOR THE TREATMENT OF RESPIRATORY INFECTIONS			
Antibiotic	**Dosage**	**Oral maximum dose**	**IV/IM maximum dose**
Azithromycin	10mg/kg 1st day, 5mg/kg days 2–5	500mg	NA
Cefotaxime	100–200mg/kg/day im/iv, q6-8h	NA	12g/24h
Ceftriaxone	50–75mg/kg/day im/iv, q12-24h	NA	4g/24h
Clindamycin	20–40mg/kg/day, q6-8h	1.8g/24h	4.8g/24h
Doxycycline	3–5mg/kg/day, q12h	300mg/24h†	NA
Erythromycin	20–40mg/kg/day, q6-8h	2.4g/24h*	2.4g/24h*
Penicillin	penV-potassium 25–50mg/kg/day, q6h	500mg/dose	NA
Tetracycline	25–50mg/kg/day, q6h	500mg/dose†	NA

† Preferable to use other antibiotics in children under age 8 because of tooth enamel staining
* Erythromycin base

neck show may the 'thumb sign' (Fig. 31.11), demonstrating an enlarged epiglottis. Absence of such a finding does not eliminate epiglottitis as a diagnosis, but it provides reassurance that the pharynx can be visualized without threat of airway obstruction.

Visualization of the posterior pharynx is the best way to confirm the diagnosis of epiglottitis. Because airway obstruction is the most feared complication of this disease, this examination should be done in a manner and place where immediate intubation can be performed if necessary.[21] At hospitals where the disease has been seen frequently it is common to give an inhaled anesthetic to allow a quick examination of the pharynx with an anesthesiologist, anesthetist or intensive care specialist standing by. Culture of the epiglottis should be performed by obtaining a swab during the examination.

MANAGEMENT

Antibiotic dosages are shown in Table 31.2 . For group A streptococcal pharyngitis the recommended therapy is 7–10 days of oral penicillin or amoxicillin. Erythromycin and clindamycin are acceptable alternatives. There have been studies showing that one dose of ceftriaxone intramuscularly or oral azithromycin for 5 days is equally effective at eliminating carriage of GAS, but recurrent pharyngeal

colonization occurs with all treatment regimens. Viral causes of pharyngitis can be most suitably treated with supportive measures: gargles, lozenges, etc. *Mycoplasma* and *Chlamydia* spp. infections can be treated with erythromycin or tetracycline (depending on age). Diphtheria and *Arcanobacterium* spp. infection should be treated with erythromycin or penicillin. *Legionella* spp. infections should be treated with tetracycline. *Haemophilus influenzae* type b and *Yersinia enterocolitica* should be treated with a third-generation cephalosporin.

Causes of laryngitis are generally viral, therefore having no specific treatment. For supportive care, cool air and humidity often relieve some of the symptoms. Patients with bacterial superinfection (tracheitis) should be treated for presumed staphylococcal superinfections with nafcillin (flucloxacillin) or vancomycin, depending on whether the infection was acquired while in the hospital and therefore more likely to be methicillin resistant.

Treatment of epiglottitis in children is with cefotaxime or ceftriaxone and immediate intubation if needed. Ampicillin should not be used due to the high frequency of ampicillin-resistant strains of HIB. Even if the airway is patent at the time of diagnosis, intubation is recommended because progression to airway obstruction is common until antibiotic therapy has begun. Most children can be successfully extubated after 24 hours of antibiotic therapy and some extubate themselves before that time has expired. Family members and daycare contacts should receive rifampin (rifampicin) prophylaxis (300mg q12h for 2 days) to avoid secondary infection.

Chapter 32 - Otitis, Sinusitis and Related Conditions

Stephen I Pelton

OTITIS MEDIA

EPIDEMIOLOGY

Acute otitis media (AOM) is a common and frequently recurrent illness associated with upper respiratory tract infection. It has been diagnosed more frequently over the past decade than previously. Although many risk factors, such as male sex, bottle feeding, an 'immature' immune system and familial predisposition, have been associated with an increased incidence,[1] the change in child rearing patterns resulting in early entry into the day care setting has been considered to be the critical factor in the increased incidence of AOM. [2] This hypothesis has been supported by an observed 2- to 3-fold increase in AOM among children in day care compared with home care.

A prospective study of children followed from birth up to 7 years of age has described the occurrence of AOM and its recurrent nature.[3] The peak incidence of disease was in the second 6 months of life. Almost two-thirds of children had at least one episode by the age of 1 year, and age at first episode was highly predictive for recurrent otitis media. Three or more episodes was relatively common during each of the first 4 years of life but became unusual by year 6 or 7. A more recent prospective study of a birth cohort suggests that the incidence of disease as well as the proportion of children with three or more episodes has increased in the first year of life, presumably as a result of the ongoing changes in entry into day care settings.[4]

PATHOGENESIS

Evidence suggests that host factors as well as infectious agents contribute significantly to the occurrence of AOM (Fig. 32.1). Two well-established host factors are eustachian tube dysfunction and immunologic abnormalities.[5] [6] Otitis media is nearly universal in children with cleft palate and the associated functional eustachian tube obstruction. In other children with recurrent disease, reflux of nasopharyngeal secretions (and presumably bacterial pathogens) into the middle ear has been demonstrated. Children who have immunologic deficiencies (especially hypogammaglobulinemia) suffer recurrent mucosal surface infections, including otitis media. More recently, recurrent otitis has been reported in children who have IgG subclass deficiency, IgA deficiency and HIV disease.[7] [8] Finally, passive immunization with antibacterial polysaccharide immunoglobulins has been demonstrated to reduce the incidence of type-specific pneumococcal otitis media.[9] These studies suggest that children who have humoral immune deficiencies are more susceptible to AOM. Respiratory viral pathogens also appear to be important in the pathogenesis of AOM, most often as a cofactor rather than as a direct invader. During seasonal respiratory syncytial virus outbreaks, the incidence of AOM increases significantly.[10]

PREVENTION

Strategies for the prevention of AOM and recurrent otitis media have focused on reducing disease caused by specific bacterial pathogens or on immunoprophylaxis against respiratory viral infection. Studies of pneumococcal polysaccharide vaccine in the early 1980s demonstrated that immunization with an octavalent or 14-valent pneumococcal polysaccharide resulted in a reduction in disease caused by serotypes that were associated with a good serum antibody response.[11] [12] Unfortunately, no reduction was observed in children less than 7 months of age, and in one of the studies the effect was limited to the first 6 months after immunization.

Recently, studies of passive immunoprophylaxis with bacterial polysaccharide immunoglobulin, both in experimental animals and in infants, have confirmed that high serum levels of antibodies to bacterial surface antigens are sufficient to provide protection against acute middle ear infection.[8] [13] [14] This has been demonstrated in experimental models for disease caused both by nontypable *Haemophilus influenzae* and *Streptococcus pneumoniae*, and in clinical trials for disease due to *S. pneumoniae*.

New formulations of pneumococcal polysaccharide conjugated to protein haptens (pneumococcal conjugate vaccine) have demonstrated enhanced immunogenicity in children immunized at 2, 4 and 6 months of age, protection against serotype-specific invasive disease and a modest effect on nasophayngeal carriage of *S. pneumoniae*.[15] [16] [17] Recent clinical trials have demonstrated a modest reduction (of about 6–8%) in episodes of AOM in children immunized with pneumococcal conjugate vaccine (heptavalent pneumococcal polysaccharide vaccine conjugate to CRM, or PCV7).[16] [18] Children immunized with PCV7 had a 57% reduction in episodes of AOM caused by one of the seven serogroups contained within the vaccine; however, a modest increase in disease caused by nonvaccine serogroups and nontypable *H. influenzae* diminished the overall benefit. Currently, PCV7 is licensed for prevention of otitis media and would be appropriate for high-risk children; however, its primary use is the prevention of invasive pneumococcal disease.

The concept of prevention of AOM through immunoprophylaxis against respiratory virus infection has been demonstrated using influenza vaccine.[19] [20] A reduction in cases of influenza virus A infection as well as a 36% decline in otitis media was observed in a day care center during a community outbreak of influenza. However, in studies documenting the role of viruses as a cofactor in the pathogenesis of AOM, influenza virus has been identified in about 5% of all episodes and therefore immunization against this pathogen will have, at most, a small benefit in the prevention of otitis media.[10] Respiratory syncytial virus (RSV) is the viral pathogen most frequently associated with AOM. Considerable progress has been made in the immunoprophylaxis of RSV disease, and two approaches have been shown to be effective.[21] [22] First, the use of immunoglobulin with high titers of neutralizing antibody against RSV has been shown to reduce incidence and severity of lower respiratory tract disease caused by RSV. It has also been shown to reduce the frequency of AOM from 0.78 episodes per child to 0.15 episodes. These studies did not permit discrimination between the anti-RSV effect and a nonspecific effect of passive administration of immunoglobulin with antibody directed against a spectrum of pathogens. Most recently, studies of an RSV monoclonal antibody demonstrated protection against

Figure 32-1 Pathogenesis of acute otitis media.

lower respiratory disease caused by RSV but failed to diminish episodes of AOM in recipients. This finding has been interpreted as showing that the reduction in AOM is most likely a result of the passive administration of antibodies against bacterial pathogens.

Antimicrobial prophylaxis has been used successfully in preventing recurrent episodes of AOM and sinusitis. However, its use should be limited to those at high risk.[23] [24] Selection criteria for patients most likely to benefit include multiple episodes within a recent 6-month time period or recognized immunologic defects that predispose to bacterial complications of respiratory infection and history of recurrent disease. Amoxicillin (20–40mg/kg/day) and sulfisoxazole (500mg q12h) have both been used successfully. This approach must be used cautiously as it is likely to contribute to the selection of resistant otopathogens both in the individual child and in the community.

Another approach has been the insertion of tympanostomy tubes to prevent AOM.[25] Although only a limited reduction in the number of episodes of acute otitis has been reported, time spent with middle ear effusion and the associated conductive hearing loss is significantly reduced.

DIAGNOSIS AND CLASSIFICATION

Optimal diagnostic criteria and classification for middle ear disease (Table 32.1) are critically important because children who have middle ear effusion and signs and symptoms of acute illness may be candidates for antibiotic therapy, whereas those lacking signs or symptoms are more likely to suffer from otitis media with effusion and are not likely to benefit significantly from antimicrobial therapy.

The hallmark of middle ear disease is the presence of middle ear effusion or otorrhea. Therefore, pneumatic otoscopy has become the diagnostic method of choice. The pneumatic otoscope permits visualization of the tympanic membrane as well as assessment of its mobility. The healthy tympanic membrane moves briskly inward when pressure is applied to the attached rubber bulb and it returns with the release of the bulb pressure. When middle ear effusion is present, the tympanic membrane has reduced or absent mobility on both positive

TABLE 32-1 -- Classification of otitis media.

CLASSIFICATION OF OTITIS MEDIA			
Diagnosis	**Middle ear effusion or otorrhea**	**Inflammation of tympanic membrane**	**Symptoms**
Acute otitis media	Effusion	Erythema	Fever, irritability, vomiting, earache
Otitis media with effusion	Effusion	Usually absent, may be opaque	Asymptomatic, may have difficulty sleeping
Chronic suppurative otitis media	Otorrhea	Perforated	Frequently painless, diminished hearing

and negative pressure. When AOM is present, the tympanic membrane usually has signs of inflammation (erythema, diminished translucency and loss of light reflex) and the child has localized clinical manifestations (earache) or systemic manifestations (e.g. fever, irritability, vomiting). It is critically important to distinguish AOM from otitis media with effusion because antimicrobial therapy is not considered effective against otitis media with effusion.

Acute otitis media with otorrhea must be distinguished from external otitis media. The history of relief from earache when drainage begins and the presence of a perforation of the tympanic membrane helps to distinguish these two diagnoses. The pain in external otitis usually continues to increase even after drainage begins, and the canal is frequently swollen so that its diameter is significantly reduced.

Chronic suppurative otitis media without cholesteatoma is a condition with persistent drainage and chronic perforation, with or without a myringotomy tube, lasting for longer than 6 weeks. The disease usually occurs in particular populations such as the Inuit, native Americans, Australian Aborigines, young infants and children who have immunodeficiency, or postmyringotomy and tube insertion. The pathogenesis and treatment for chronic suppurative otitis media is very different from that of AOM.

MICROBIOLOGY

The pathogens isolated in AOM as defined by aspiration and culture of middle ear fluid are most frequently *S. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis* and group A streptococci. The relative frequency of each pathogen varies throughout the world (Fig. 32.2).[26] A higher frequency of infection with group A streptococci is observed in Europe than in the USA, specifically in children older than 2 years of age. An increased proportion of cases caused by *M. catarrhalis* has recently been reported from Finland, mainly in infants less than 2 years of age. [27] *Haemophilus influenzae* has been demonstrated as an important pathogen in all age groups, including adults. [28]

Specific microbiologic diagnosis is rarely made because it requires needle apsiration through the tympanic membrane or culture of middle ear drainage from the site of perforation of the tympanic membrane or from the orifice of a ventilation tube. Therefore treatment is empiric, based on the likely microbial pathogen — clinical signs or symptoms, such as pain, fever and appearance of the tympanic membrane, do not distinguish etiology.[29] However, epidemiologic features are helpful in suggesting an enrichment for a given pathogen. Children with recurrent episodes of AOM are at increasing risk of nontypable *H. influenzae* whereas initial episodes are more likely to be due to the pneumococcus. [30]

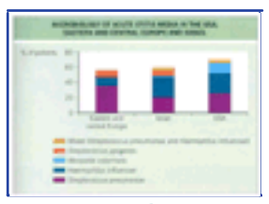

Figure 32-2 Microbiology of acute otitis media in the USA, eastern and central Europe and Israel. Culture results of middle ear aspirates from children. *Adapted from Jacobs et al.*[26]

Viruses, *Mycoplasma* spp., *Chlamydia* spp. and less common bacterial pathogens have on occasion been identified as etiologic agents in AOM. Recent studies have identified viral antigens or viruses in some children who have AOM, most frequently in combination with bacterial pathogens. Respiratory syncytial virus has been found most commonly,[31] but influenza virus, enteroviruses and rhinoviruses have also been reported. Polymerase chain reaction technologies have identified RNA from *Chlamydia pneumoniae* in middle ear fluid from children who have AOM and otitis media with effusion.[32] *Mycoplasma pneumoniae* has been cultured from one case and has been proposed as the etiology of AOM associated with bullous myringitis in patients who have concomitant pneumonia.[33]

Less common bacterial pathogens include *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Both of these are frequently found in children who have chronic suppurative otitis media but they have only occasionally have been isolated from children with intact tympanic membranes. *Mycobacterium tuberculosis* and *Pneumocystis carinii* have been isolated from the middle ear in unusual cases of otitis media.[34]

Otitis media in the first 6 weeks of life warrants special consideration. Although most children will have the usual respiratory pathogens (*S. pneumoniae*, *H. influenzae* and *M. catarrhalis*), enteric bacteria have been identified in 15% of cases and *S. aureus* in 10% of cases (Table 32.2).[35] Thus, neonates, especially those less than 2–3 weeks of age, require a different management strategy with careful evaluation, parenteral administration of broad-spectrum antimicrobial agents and close observation.

EFFECT OF ANTIMICROBIAL THERAPY ON THE OUTCOME OF ACUTE OTITIS MEDIA

The rapid increase in isolates of *S. pneumoniae* with reduced susceptibility to penicillin and a recognition of the dramatic rise in antibiotic prescriptions written each year for otitis media has resulted in a renewed evaluation of the role of antibiotics in the treatment of AOM. Studies comparing antibiotic and control-treated children who have AOM, historic reflection on the frequency of suppurative complications of AOM, and limited data from isolated areas where antibiotic therapy is often initially deferred for the diagnosis of AOM have provided evidence that antimicrobial treatment is associated with a shorter duration of local and systemic signs and symptoms such as fever, irritability and earache. [36] [37] The use of antibiotics for

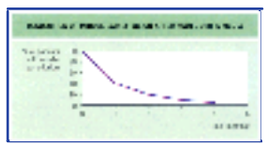

Figure 32-3 Resolution of middle ear effusion after acute otitis media. *Adapted from Klein et al.[1]*

AOM has also been associated with a reduction in acute suppurative mastoiditis over the past three decades and is further supported by recent reports of a rising incidence of mastoiditis associated with the withholding of initial antimicrobial therapy in children who have AOM.[38] Outcome measures such as resolution of signs and symptoms at 2 weeks after diagnosis, presence of middle ear fluid at 4–6 weeks and frequency of recurrent infection appear to be unrelated to initial antibiotic therapy. In most studies, middle ear effusion is found in up to 40% of children 1 month after an episode of AOM; this gradually resolves over several months in most children (Fig. 32.3).

Studies comparing antibiotic-treated children with untreated controls demonstrate that age is a critical feature in identifying the patients who are most likely to benefit from antimicrobial therapy.[39] Children under 30 months of age are at highest risk of having persistence of signs and symptoms and suppurative complications if untreated, whereas children over 30 months of age are likely to have resolution of their signs and symptoms without complications even if not treated with antibiotics. These observations have led to dichotomy in the management of children with AOM. In the USA the use of antibiotics for the treatment of AOM is standard. However, in Europe it is common to use symptomatic treatment initially (in children over 1 year of age) and to institute antibiotic therapy only when symptoms persist. It appears that this strategy reduces the need for antibiotic therapy by as much as 75%.[40] From recent studies it would appear that persistence of 'distress' (night sleep disturbance) beyond

3 days was associated with the presence of fever (over 99.5°F (37.5°C)) or vomiting or cough at diagnosis. The relative risk for persistence of symptoms following placebo was approximately 5 for children over 2 years of age with 'severe' disease, defined as temperature over 103°F (39.5°C) and substatial otalgia.[41]

Initial symptomatic intervention while reserving antimicrobial therapy for those with persistent symptoms is currently being considered by the American Academy of Pediatrics for children over the age of 2 years who have minimal signs and symptoms at presentation. The challenge will be to identify symptoms that are likely to be associated with persistent 'distress' so that parents can be included in the decision process as to the importance, within the context of the family structure, of the small differences in outcome between children treated with initial antimicrobial therapy compared with those for whom antibiotic treatment is reserved for persistence.

COMPLICATIONS

Mastoiditis is an uncommon complication of AOM that is seen predominantly in children under 2 years of age. Affected children are usually acutely ill with toxicity and localized pain and tenderness over the mastoid process. Bulging of the external ear secondary to subperiosteal abscess or inflammation or paralysis of the facial nerve are classic manifestations. Partially treated (subacute) mastoiditis may manifest itself as persistent fever, tenderness of the mastoid process and otorrhea. In contrast to uncomplicated AOM, the bacterial pathogens of mastoiditis are more virulent. Group A streptococci and *S. pneumoniae* are the two most common. *Haemophilus influenzae* type b was seen frequently before universal immunization, and it should be considered in children who have not been adequately vaccinated. *Staphylococcus aureus* and Gram-negative enteric bacteria have been identified in patients who have subacute mastoiditis.

Therapy for acute mastoiditis is parenteral antibiotics with close observation for the development of possible complications such as intracranial abscess, venous sinus thrombosis, osteomyelitis or hydrocephaly. Myringotomy is necessary if facial nerve palsy is present. Prolonged therapy for 2–4 weeks is generally required.

There is significant controversy about whether an increased risk of mastoiditis occurs in children when a strategy of delayed antibiotic therapy is used for the treatment of AOM. It is generally accepted that acute mastoiditis is most common in young children and that routine antibiotic treatment of AOM is not absolute for prevention.[42] When rates of mastoiditis in children (<14 years) are compared by country, the incidence where prescriptions for AOM exceed 96% are 50% lower than in countries where prescribing for AOM is <76%. [43]

SINUSITIS

EPIDEMIOLOGY

Sinusitis in children

The recognition and diagnosis of sinus disease in children remains difficult. The signs and symptoms frequently lack specificity and overlap with nasal allergy or airway obstruction. Physicians often have divergent views on what criteria are sufficient to warrant intervention. There is a wide variance in the monthly incidence of acute and chronic sinusitis reported by pediatric practitioners.[44] Table 32.3 summarizes the mean number of episodes and range reported by different physicians. The wide disparity and incidence probably reflects differences in diagnostic criteria rather than true differences in incidence.

CLINICAL FEATURES

The presentation of acute sinusitis changes with increasing age. In young children, persistent rhinorrhea (which is often purulent),

TABLE 32-3 -- Variability in reported incidence of sinus disease in pediatric practice.

VARIABILITY IN REPORTED INCIDENCE OF SINUS DISEASE IN PEDIATRIC PRACTICE		
	Cases per month	
Clinical diagnosis	**Mean**	**Range**
Acute sinusitis	18	1–200
Recurrent sinusitis	13	4–100
Chronic sinusitis	7.5	1–40

Figure 32-4 Acute sinusitis with facial swelling and periorbital edema.

daytime and night-time cough, foul breath and, less commonly, fever are the hallmarks of sinus disease. Less frequently, high fever, purulent rhinorrhea and facial tenderness or swelling signal the likely presence of acute sinusitis (Fig. 32.4). The overlap between uncomplicated upper respiratory tract infection and sinusitis is large. Most children who have signs and symptoms of less than 7 days duration have uncomplicated upper respiratory tract infection. Concern for sinusitis is appropriate when signs and symptoms persist beyond 7–10 days or when localized signs are present. In a prospective study of over 1000 children presenting to a pediatric office during winter months, 9.3% met the criteria of more than 9 days of symptoms for the diagnosis of sinusitis.

In older children and adults, symptoms and signs are more localized. Frontal headache, facial pain or pressure, and nasal congestion are frequent complaints. Facial tenderness or swelling over the maxillary or frontal sinus may be present. Nasal congestion or even obstruction is almost universally present except when sinus disease is of dental origin.

In chronic sinusitis, cough is especially prominent. The cough is usually present throughout the day, and it occasionally precipitates post-tussive emesis, especially soon after awakening. Chronic headache may also be part of the typical cluster of symptoms reported by patients. The pain is often dull; it often radiates to the top of the head or it may be bitemporal in nature. Nasal congestion and mucopurulent or purulent nasal discharge often complete the cluster of signs.

DIAGNOSIS

Defining the microbiology of paranasal sinus disease requires sampling of sinus secretions without contamination from normal

TABLE 32-4 -- **Bacterial species cultured from sinus aspirates performed in children.**[*]

* *Data from Wald et al.* [45]

respiratory flora. Sampling involves a transnasal approach and attempted sterilization of the area through which the trocar will be passed. Because complete sterilization is usually impossible, investigators have frequently used a colony count of $=10^4$ colony forming units/ml to define infection.

Wald *et al.* have contributed greatly to our understanding of the microbial pathogenesis.[45] *Streptococcus pneumoniae* is the most frequent pathogen isolated from children who have acute sinusitis (Table 32.4). Other pathogens are bacterial species commonly found as part of the normal respiratory flora; these include nontypable *H. influenzae*, *M. catarrhalis* and group A streptococci.

Two distinct clinical settings require special knowledge, because the bacterial pathogens are likely to differ from there in patients who have concomitant upper respiratory tract infection. The microbiology of sinusitis in the intensive care unit includes *S. aureus*, *P. aeruginosa* and other Gram-negative enteric bacteria. In addition, anaerobes and yeasts are frequently isolated in combination with aerobes. In this setting, sinusitis is recognized as a cause of cryptogenic fever or in association with fulminant sepsis. Disease in this setting requires sinus aspiration to identify the specific pathogen. Initial antimicrobial therapy should be directed against nosocomial pathogens and then modified once the specific bacterial etiology has been identified.

A foul-smelling discharge and a recent history of dental pain or a dental procedure should suggest an odontogenic etiology for sinus disease. Bacterial pathogens from the oropharynx invade devitalized tissue in the gingiva and spread to the sinus. Mixed anaerobic infection with *Bacteroides* spp. and anaerobic streptococci are

commonly identified. Antimicrobial therapy, in combination with debridement or drainage of devitalized tissue or periapical abscess, is usually necessary.

A potential role for gastroesophageal reflux has been suggested as a contributing factor in the pathogenesis of sinusitis in children. A limited study of the prevalence of gastroesophageal reflux in children with chronic sinus disease identified esophageal reflux in 19 (63%) of 30 and nasopharyngeal reflux in six (32%) of the 19 using dual pH probe studies. Seventy-nine percent demonstrated improvement in their sinus disease after treatment for gastroesophageal reflux.[46] Further prospective evaluation of a nonreferral patient cohort is necessary to define the prevalence and significance of gastroesophageal reflux in children with chronic or recurrent sinus disease.

Imaging

Sinus radiographs must be interpreted with the knowledge that at birth and through early childhood only the maxillary and ethmoid sinuses are aerated. The frontal sinuses do not appear routinely until the age of 5–7 years and may be further delayed in some children. Sinus opacification without clinical signs or symptoms of sinus disease has been seen in some young infants undergoing radiologic

Improvement	14 (40)	6 (17)
No change	11 (32)	0
Failure (worsening or persistence of symptoms)	6 (17)	14 (40)

** Data from Wald et al.[48]*

studies for alternative diagnoses such as head trauma. One study reported a 60% incidence of sinus opacification in normal children under 1 year of age.[47] These observations limit the usefulness of routine sinus radiographs in the first year of life and demand that radiographic interpretations should be performed with consideration of clinical parameters.

Opacification (especially when asymmetric), mucosal swelling or air-fluid levels are all potential abnormalities in patients who have sinus infection (Fig. 32.5).

Computerized tomography (CT) and magnetic resonance imaging provide anatomic detail of the sinuses. These techniques are especially revealing when complications or extension of disease are suspected.

COMPLICATIONS

The course of untreated sinus disease and response to therapy in nontoxic children has been evaluated in placebo-controlled trials.[48] In these trials, half of the children have persistent or worsening signs or symptoms 3 days after diagnosis, and 40% are considered 'failures to improve' 10 days after diagnosis.

The American Academy of Pediatrics has published clinical practice guidelines for the management of sinusitis. These guidelines support the use of antibiotics with a strong recommendation based on limited scientific evidence but a strong consensus of their advisory panel.[49] In comparison with children treated with antimicrobial agents such as amoxicillin or amoxicillin-clavulanate, placebo-treated children are less likely to have a rapid resolution within 3 days of their signs and symptoms and are also less likely to achieve ultimate complete cure by day 10 (Table 32.5).[48] However, if end points beyond 10 days are selected, many investigators have been

TABLE 32-6 -- Classification of orbital cellulitis.*

CLASSIFICATION OF ORBITAL CELLULITIS		
Group	**Classification**	**Descriptions**
I	Preseptal	Erythema and edema of eyelids, normal vision and full range of motion
II	Orbital cellulitis without abscess	Diffuse edema (of orbit) but no abscess
III	Orbital cellulitis with subperiosteal abscess	Abscess adjacent to lamina papyracea; clinically there is proptosis, changes in vision and possibly pain on movement of the eye
IV	Orbital cellulitis with abscess in the orbital fat	Proptosis, limited motility of globe, loss of vision
V	Cavernous sinus thrombosis	Bilateral disease

** Data from Chandler et al.[50]*

unable to demonstrate any beneficial effect of antimicrobial agents on the outcome of sinus disease.

The complications of sinus disease frequently cause substantial morbidity and may require surgical intervention. The most common complications of sinusitis arise primarily from bacterial spread to the orbit, frontal bone or central nervous system. Extension of infection is usually direct through a complex network of venous channels and not the result of hematogenous spread. Occasionally, hematogenous dissemination produces bacterial complications at distant sites.

Orbital cellulitis is the most common serious complication of sinusitis and is most frequently associated with ethmoiditis. The clinical manifestations represent a spectrum of severity and they often predict the response to antibiotic therapy or the need for surgical drainage. A widely accepted classification system is that proposed by Chandler *et al.* (Table 32.6).[50] Proptosis, motility of the globe and visual acuity are the key features that differentiate the various stages of disease. A Marcus-Gunn pupil in the swinging flashlight test (pupillary dilatation when the light is moved from the normal eye to the affected eye) is diagnostic of optic nerve compression and a hallmark of advanced disease. Even with this classification scheme, it is often very difficult to distinguish cases that require surgical intervention from those that will respond to medical management. Computerized tomography scans should be performed if the patient has ophthalmoplegia or visual loss or if the patient is not responding to treatment. Differentiating 'inflammatory phlegmon' from abscess may still be difficult (Fig. 32.6).

Medical management requires a team approach and involves the infectious disease specialist, the otolaryngologist and the ophthalmologist. Initial therapy is directed against likely pathogens. A history of trauma or facial cellulitis can be helpful in predicting whether *S. aureus* is likely, whereas previous or concomitant sinusitis suggests *S. pneumoniae*, *H. influenzae*, group A streptococci or *M. catarrhalis*. However, the severity of illness and potential for complications mandate broad-spectrum parental therapy such as ceftriaxone, cefotaxime, amoxicillin-clavulanate or clindamycin in combination with aztreonam. The need for surgical intervention varies, and the decision is based on the response to antimicrobial therapy, the visual acuity and motility, and the results of CT scanning. Drainage of the involved sinus may also be necessary for rapid healing.

Intracranial complications from sinusitis are most common in adolescents and adults.[51] Brain abscess in the frontal lobe or subdural abscess are the most common. These complications are often difficult

Figure 32-6 Computerized tomography scan of a patient who has right subperiosteal abscess (arrow) adjacent to the lamina papyracea. Note the partial opacification in the right ethmoid sinus.

to diagnose clinically and may present without signs or symptoms of increased intracranial pressure or toxicity. Fever, signs of meningeal irritation without toxicity, and focal neurologic abnormalities are the hallmarks. Less specific signs and symptoms include headache, behavioral changes and seizures. Currently, the diagnosis is best made by CT scan with contrast. Magnetic resonance imaging may be more sensitive for detection of small abscesses and cerebritis and for differentiation of an epidural abscess from a subdural abscess.

The mucosa of the frontal sinus and the marrow of the frontal bone have a common venous drainage. Thus, bacterial invasion of the marrow and subsequent osteomyelitis (Pott's puffy tumor) are recognized complications of frontal sinusitis. This entity was first described clinically by Sir Percival Pott in 1795, but it was not until 1879 that Lamel Oryne defined its pathology. Computerized tomography scanning is useful for defining the extent of frontal bone involvement and whether intracranial extension has occurred.

Allergic fungal sinusitis

Allergic fungal sinusitis has been increasingly described recently. Potentially mistaken for a paranasal sinus tumor, allergic funal sinusitis appears to be an allergic reaction to aerosolized, environmental fungi that occurs in immunologically normal hosts. The clinical presentation is often chronic nasal congestion and nasal obstruction. Facial abnormalities such as proptosis and malar flattening are frequently present. Unilateral disease is often present in children and bony erosion of the sinuses may be present. At the time of surgery, allergic mucin identified by the presence of degenerating eosinophils and the absence of histopathologic evidence of invasion is characteristic. Most disease is due to *Bipolaris spicifera*, *Aspergillus* spp., *Alternaria* spp., *Curvularia* spp. or *Exserohilum* spp. Surgical debridement is usually sufficient; however, a small benefit has been observed in patients treated with oral corticosteroids.[52] [53]

MANAGEMENT FOR ACUTE OTITIS MEDIA AND ACUTE SINUSITIS

The goal of antibiotic therapy is sterilization of the middle ear. Eradication of the bacterial pathogen in the middle ear is highly correlated with a successful clinical response.[54] Antibiotics should be chosen for their ability to achieve drug concentrations in the middle

TABLE 32-7 -- Antimicrobial agents commonly used in the therapy of acute otitis media.

ANTIMICROBIAL AGENTS COMMONLY USED IN THE THERAPY OF AOM				
Drug	**Pediatric dosage**	**Penicillin-sensitive *Streptococcus pneumoniae***	**ß-Lactamase-producing *Haemophilus influenzae***	**Advantages and concerns**
Amoxicillin	13.3mg/kg per dose q8h; maximum dose 500mg q8h	++++	-	1. Low cost, well tolerated
				2. Emerging high-level (MIC=2.0µg/ml) resistance among *Streptococcus pneumoniae* isolates
Amoxicillin-clavulanate	15mg/kg amoxicillin per dose with 2.4mg/kg clavulanic acid q8h; maximum dose 875mg q12h	++++	+++	1. Broad spectrum
				2. Frequent diarrhea
				3. Emerging high-level (MIC=2.0µg/ml) resistance among *Streptococcus pneumoniae* isolates
Cefaclor	20mg/kg per dose q12h; maximum dose 1g/day	++	+	1. Infrequent occurrence of serum sickness
				2. Limited activity against penicillin-intermediate (MIC 0.12–1.0mg/ml) and highly resistant isolates
Cefdinir	7mg/kg per dose q12h or 14mg/kg per dose q24h	+++	+++	1. Limited activity against resistant *Streptococcus pneumoniae* (MIC=2.0mg/ml)
				2. Diarrhea
Cefixime	4mg/kg per dose q12h or 8mg/kg per dose q24h; maximum dose 400mg q24h	++	++++	1. Limited activity against penicillin-intermediate (MIC 0.12–1.0mg/ml) and highly resistant isolates
				2. Potent activity against ß-lactamase-producing *Haemophilus influenzae*
				3. High cost
Cefprozil	15mg/kg per dose q12h; maximum dose 1g q24h	++++	+	1. High cost
				2. Active against penicillin-intermediate *Streptococcus pneumoniae*
				3. Less active against *Haemophilus influenzae*

Ceftibuten	9mg/kg per dose q24h; maximum dose 400mg q24h	+	+++	1. Not approved for AOM caused by *Streptococcus pneumoniae* 2. High cost
Ceftriaxone	50mg/kg/dose im	+++	++++	1. Parenteral administration 2. Multiple doses required for resistant *Streptococcus pneumoniae*
Cefuroxime axetil	15mg/kg per dose q12h; maximum dose 1g/day	++++	++	1. Significant after taste 2. Active against penicillin-intermediate *Streptococcus pneumoniae* 3. High cost
Cefpodoxime	5mg/kg per dose q12h or 10mg/kg per dose q24h; maximum dose 400mg q24h	++++	++++	1. Significant after taste 2. Active against penicillin-intermediate *Streptococcus pneumoniae* 3. High cost
Erythromycin sulfisoxazole liquid	12.5–16.6mg/kg erythromycin with 42.5–50mg/kg sulfisoxizole per dose q6h or q8h; maximum dose 2g erythromycin per day	++++	+++	1. Low cost 2. Gastric distress frequent 3. Four times daily dosing 4. Emerging macrolide resistance reported among *Streptococcus pneumoniae* with increasing use
Loracarbef	15mg/kg per dose q12h; maximum dose 800mg/day	+++	+	Limited activity against penicillin-intermediate *Streptococcus pneumonia*
Trimethoprim-sulfamethoxazole (co-trimoxazole)	4mg/kg trimethoprim with 20mg/kg sulfamethoxazole per dose q12h	++++	++++	1. In-vitro resistance among *Streptococcus pneumoniae* reported at 20–50% 2. Rare occurrences of Stevens-Johnson syndrome
Clarithromycin	7.5mg/kg per dose q12h; maximum dose 1g/day	++++	+	1. Undesireable after taste 2. Emerging resistance among *Streptococcus pneumoniae*
Azithromycin	10mg/kg per day on day 1, 5mg/kg per day on days 2–5; maximum dose 500mg on day 1	++++	+	1. Undesireable after taste 2. Emerging resistance among *Streptococcus pneumoniae*

ear that exceed the MIC for the likely pathogens. Successful sterilization of middle ear infection occurs when drug concentrations exceed the MIC for approximately 50% of the dosing interval for penicillins and cephalosporins and when the achieved area under the curve is sufficient for macrolides and azolides.[55] Presumptive therapy should be directed against nontypable strains of *H. influenzae*,

S. pneumoniae and *M. catarrhalis*. In AOM with perforation, activity against group A streptococci should be included routinely.

Table 32.7 lists the antimicrobial agents commonly used for therapy of AOM and acute sinusitis. Although studies of clinical outcome have rarely demonstrated significant differences, studies with microbiologic end points often suggest that sterilization of the middle ear may be more frequently achieved with antimicrobial agents that attain adequate levels in the serum and middle ear and are active in vitro against nontypable *H. influenzae* and *S. pneumoniae*. Amoxicillin remains the drug of first choice because of its ability to sterilize middle ear infection that is caused by most isolates of *S. pneumoniae* and nontypable *H. influenzae*, its low cost and its excellent safety record. None of the antimicrobials listed in Table 32.7 has been demonstrated, in appropriate trials, to be more effective than amoxicillin as initial therapy of AOM or acute sinusitis. Controvery persists about whether the initial dose of amoxicillin should remain at 40–45mg/kg/day administered in two or three doses or whether an increased dose of 80–90mg/kg/day administered in two doses is more appropriate. The use of a higher dose is intended to provide increased serum and middle ear concentrations more appropriate for the therapy of isolates of *S. pneumoniae* with reduced susceptibility to penicillin and other classes of antibiotics. In general few additional adverse events have been reported with the increased dosing of amoxicillin, and the higher dosing has gained popularity because of its enhanced pharmcokinetic profile.

Duration of therapy

Decreasing the duration of therapy reduces cost, may diminish the emergence of resistance among respiratory pathogens and should be associated with fewer adverse events. Several studies have demonstrated that by day 5 the middle ear can be successfully sterilized by antimicrobial agents with appropriate in-vitro activity.[56] Therefore, 'short-course' therapy is likely to be successful in resolving signs and symptoms caused by highly susceptible isolates. Unfortunately, the duration of acute therapy appears not to affect either the resolution of effusion at long-term follow-up or the risk of recurrence.

Recent studies that have compared short courses (5 days) with traditional courses have consistently demonstrated higher failure rates with the short course in children younger than 2 years of age, especially those attending group day care.[57] [58] These studies suggest that recommendations for short-course therapy should be limited to children older than 2 years of age. Further studies in children who have infection caused by multidrug-resistant *S. pneumoniae* suggest that short-course therapy is inadequate and should not be recommended in this setting.

Treatment failures

When a child's symptoms fail to respond within 3 days or the tympanic membrane remains bright red and bulging or full in appearance, the likelihood of persistent middle ear infection is high. Increasingly, a pathogen resistant to the initial antimicrobial agent prescribed is the likely problem. A broader spectrum antimicrobial agent that is active against ß-lactamase-producing nontypable *H. influenzae* and isolates of *S. pneumoniae* with reduced susceptibility to penicillin should be considered next (see Table 32.7). Studies suggest that high dose amoxicillin-clavulanate and cefuroxime are effective against the majority of these pathogens.

Emergence of penicillin-resistant isolates of *Streptococcus pneumoniae*

In South Africa, France and Spain, and now in the USA, strains of *S. pneumoniae* with MIC to penicillin of 2.0µg/ml or more have been isolated from the middle ear or sinus of children who have

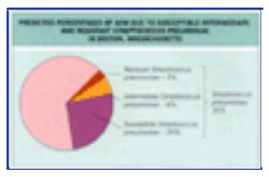

Figure 32-7 Predicted percentages of acute otitis media due to susceptible, intermediate and resistant *Streptococcus pneumoniae* in Boston, Massachusetts, USA.

AOM or sinusitis.[59] [60] These children have often already failed treatment with an antibiotic. The risk features that characterize these children include:

- recent antimicrobial treatment, most often with expanded spectrum cephalosporins or once daily macrolides;
- age under 2 years; and
- attendance at a day care center.

Clusters of cases have occurred in well defined geographic areas.[61]

Limited information is available about therapeutic regimens effective for children who have AOM caused by these isolates. Experience from Kentucky with a large cluster of cases and from Europe suggests high-dose amoxicillin (80–150mg/kg/day), amoxicillin (40mg/kg/day) plus amoxicillin-clavulanic acid (45mg/kg/day), ceftriaxone (50mg/kg/day) and clindamycin (50mg/kg/day) will successfully sterilize the middle ear and resolve symptoms.[61] More recently, studies of higher dose amoxicillin-clavulanic acid (90mg/kg/day) have demonstrated successful eradication of isolates of *S. pneumoniae* with MIC to amoxicillin as high as 4µg/ml.[62]

Disease caused by resistant isolates of *S. pneumoniae* remains infrequent among unselected cases of AOM and sinusitis. In Boston, we estimate that 3% of current unselected cases are due to resistant *S. pneumoniae* (Fig. 32.7). Initial therapy targeted at this pathogen is not recommended. However, in cases where initial and second courses of treatment fail, as well as in cases with significant toxicity, antimicrobial agents effective against resistant isolates of *S. pneumoniae* should be selected.

Penicillin allergy

For the child who has hives or anaphylaxis to penicillin, there is a limited selection of antimicrobial agents for therapy because aminopenicillins and cephalosporins have significant cross-reactivity. Macrolides such as azithromycin are effective against disease caused by susceptible isolates of *S. pneumoniae*; however, they are likely to be less effective against nontypable *H. influenzae* and multidrug-resistant isolates of *S. pneumoniae*. Trimethoprim-sulfamethoxazole (TMP-SMX; co-trimoxazole) has been effective, is low in cost and is relatively safe. However, resistance rates of 20–50% among isolates of *S. pneumoniae* have raised questions about the potential for clinical failure.

Alternatives to TMP-SMX and azithromycin include combination therapy with a macrolide and sulfisoxazole. Erythromycin sulfisoxazole has a profile of efficacy, low cost and safety, but suggested dosing is three to four times a day. Another potential selection is clindamycin in combination with sulfisoxazole.

Chapter 33 - Bronchitis, Bronchiectasis and Cystic Fibrosis

James R Yankaskas

INTRODUCTION

Genetic, environmental and infectious factors can contribute to acute and chronic inflammation of the airways of the lung. The nature, severity and duration of these insults may produce acute or chronic inflammation with associated cough, dyspnea, sputum and obstructive lung disease. Clinically, these are classified as *bronchitis* (acute or chronic) when the main symptoms are cough and sputum production or *bronchiectasis* when the airways are structurally damaged, dilated and abundant (>60ml/day) sputum is expectorated. The diagnosis and clinical management of these various airways diseases are related to the underlying pathogenic processes and to differences among patients.

This chapter describes the pathophysiology, clinical features and management of bronchitis and bronchiectasis. Guidelines for diagnosis and therapy are provided. Cystic fibrosis (CF) is a common genetic disease that leads to progressive bronchitis and bronchiectasis. The molecular, cellular and organ-level pathogenesis of CF has been elucidated and new treatments are being developed. Some of these advances are applicable to bronchiectasis caused by other diseases. It must be emphasized that clinical outcomes are highly variable and treatment decisions must be based on the presentation and responses of the individual patient.

BRONCHITIS

EPIDEMIOLOGY

Bronchitis is defined as inflammation of the bronchial mucous membranes. Acute bronchitis is manifest by the development of a cough, with or without sputum, that typically occurs during the course of an acute viral illness. Such cough commonly develops in the first week of upper respiratory tract infectious (URIs) induced by rhinoviruses in 30% of patients.[1] Acute bronchitis develops in 60% of patients during influenza A infections.[2] In the United States over 34 million annual office visits are for acute sinusitis, bronchitis or URIs. A majority of these patients are treated with antibiotics and such prescriptions comprise 31% of the total antibiotic prescriptions written.[3]

Chronic bronchitis is defined by the clinical criteria of productive cough for more than 3 months per year for at least 2 years.[4] More than 12,000,000 Americans (about 5% of the population) have chronic bronchitis. The male-to-female distribution is about 2 to 1, but the prevalence is increasing in females. Chronic bronchitis is a major category of chronic obstructive pulmonary disease (COPD) and accounts for significant morbidity and mortality, especially in individuals over age 55. COPD accounted for nearly 83,000 deaths in 1989 and was the fifth leading cause of death in the United States.[5] COPD was also a contributing factor in death due to heart disease and other illnesses.

PATHOGENESIS AND PATHOLOGY

Acute bronchitis is most commonly due to infection of the respiratory epithelium with viruses, such as rhinoviruses, adenoviruses and influenza. Acute bronchitis may also be caused by infections with *Mycoplasma pneumoniae, Chlamydia pneumoniae* or *Bordetella pertussis*. The pathogenic effects of these organisms are incompletely understood, but they infect and directly damage airway epithelia, cause release of proinflammatory cytokines, increase production of secretions and decrease mucociliary clearance. Airways damaged by such infections may be more susceptible to irritation by inhaled toxins or bacteria. The role of secondary bacterial infections in the development of symptoms is not clear.

Chronic bronchitis develops as the result of a recurring or persistent injury and the resultant inflammatory responses. Cigarette smoking is the principal etiologic factor. Air pollutants such as sulfur dioxide or occupational exposures may also contribute. The pathologic effects are an increase in the proportion of goblet cells in the surface epithelium and an increase in the size of submucosal glands (Fig. 33.1). The distribution of these pathologic changes along the airway tree depends in part on the composition of the inhaled toxins and may involve peripheral bronchioles as well as central bronchi. There is an influx of polymorphonuclear leukocytes (PMNs), surface epithelial cell hyperplasia and metaplasia, and inflammatory mucosal edema. Genetic diseases that impair airway defenses may amplify these effects. Primary ciliary dyskinesia[6] decreases mucociliary transport secondary to altered ciliary structure and function. a_1 -Antitrypsin deficiency produces an imbalance in the defenses against neutrophil elastase and leads to panacinar emphysema and bronchitis, particularly in smokers.[7]

PREVENTION

Chronic bronchitis primarily occurs in cigarette smokers. Avoidance of inhaled toxins, particularly cigarette smoke, is of paramount importance in reducing the incidence and progression of chronic bronchitis. The loss of lung function, as measured by spirometry, is more rapid in active cigarette smokers. Such individuals can gain significant benefits from stopping or significantly decreasing their cigarette consumption. Sputum production usually decreases within weeks. The accelerated decline of lung function seen in smokers slows to that of nonsmokers of the same age.[8] Thus, the importance of avoiding primary and secondhand cigarette smoke cannot be overemphasized.

CLINICAL FEATURES

Acute bronchitis typically develops during the course of an acute URI. Pharyngitis, coryza, low-grade fever and malaise precede the development of a cough with scanty sputum. Dyspnea is rare. In the absence of other lung disease, most symptoms subside over several days, although the cough may persist for weeks to several months. The quantity of sputum and frequency of cough decrease with time and no long-term sequelae occur.

The key symptoms of individuals with chronic bronchitis are chronic cough, production of sputum, wheezing and exertional

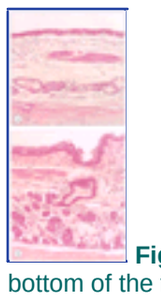

Figure 33-1 (a) Bronchial wall from normal patient. Normal pseudostratified columnar epithelium with few goblet cells overlies smooth muscle and a submucosal gland. Cartilage is at the bottom of the figure. H&E stain, 100× original magnification. (b) Bronchial wall from a patient with chronic bronchitis. Hyperplastic epithelium with mucous cell metaplasia overlies a hypertrophied submucosal gland. H&E stain, 100× original magnification.

dyspnea. These symptoms develop insidiously, often over many years. Presentation for medical care typically occurs during an acute exacerbation. Upon direct inquiry, patients often recall persistent dyspnea and sputum production following URIs for several years prior to presentation. The sputum is purulent, yellow or green, and may be blood-streaked. The daily volume ranges from scanty up to about 60ml. The cough and sputum are usually most severe soon after awakening. Exertional dyspnea and fatigue are first noticed during exacerbations and later become persistent.

Acute or subacute exacerbations are characterized by increases in cough, sputum production, dyspnea and wheezing.[9] These symptoms often follow acute URIs and tend to more frequent during winter months. The sputum often changes in color to darker yellow or green. Sputum cultures may identify one of the bacterial pathogens listed in Table 33.1 but the pathogenic role of these microbes is not certain.[10] [11] Pulmonary function decreases during such exacerbations and may lead to further complications. The progressive disease often leads to increasingly frequent exacerbations over time, further loss of lung function and worse symptoms.

Patients with severe obstructive airways disease may develop the serious complications of hypoxemic and/or hypercapnic respiratory failure. Hypoxemia develops initially during exercise or sleep and may cause morning headaches. Prolonged hypoxemia may cause cyanosis, polycythemia, pulmonary hypertension and cor pulmonale. Secondary signs of right heart failure, such as jugular venous distention, hepatomegaly and peripheral edema develop in late disease and may become chronic. The respiratory acidosis that signals hypercapnic

TABLE 33-1 -- Viral and bacterial pathogens in bronchitis.

VIRAL AND BACTERIAL PATHOGENS IN BRONCHITIS	
Common	**Uncommon**
Viruses: - rhinoviruses	*Chlamydia pneumoniae*

Moraxella catarrhalis	
Neisseria spp.	
Streptococcus pneumoniae	

respiratory failure may be of gradual onset and be compensated by a metabolic alkalosis through renal retention of bicarbonate. Individuals with scanty sputum production and greater degrees of emphysema often achieve adequate oxygenation and ventilation until late in the course of the disease. Exacerbations in the setting of severe disease often produce superimposed acute respiratory failure that is life threatening and requires intensive care.

DIAGNOSIS

The history of persistent cough and daily sputum is essential to the diagnosis of chronic bronchitis. The extent and duration of cigarette smoking quantify the major risk factor. The presence of antecedent reactive airways disease, for example, childhood asthma, may increase the risk for developing chronic bronchitis and COPD. Physical examination reveals tachypnea and late expiratory wheezes on auscultation. Patients with advanced disease develop hyperinflation of the lungs with increased anterior-posterior diameter of the thorax and a depressed diaphragm. In such patients, breath sounds and heart sounds are muted. Patients with severe disease may use accessory muscles of respiration and/or pursed-lip breathing. Medium or coarse inspiratory crackles appear in patients with bronchitis and excess airway secretions. Patients with severe disease may develop central and peripheral cyanosis or neck vein distention, hepatomegaly and peripheral edema as signs of hypoxemia and right heart failure.

Pulmonary function tests are essential to establish the diagnosis of obstructive lung disease, to measure the severity of airway obstruction and to follow the course of illness. Spirometry performed before and after inhaled ß-adrenergic agonists often reveals decreased FEV_1 and decreased FEV_1 : FVC ratio. Improved flows following inhaled ß-adrenergic agonists indicate the presence of reversible bronchoconstriction. Forced vital capacity (FVC) is also decreased in patients with very severe obstruction. In such individuals, lung volumes should be measured to distinguish restrictive and obstructive respiratory impairments and to quantify lung hyperinflation and gas trapping. The diffusing capacity for carbon monoxide (DLCO) may be reduced in patients with severe obstruction or emphysema. The chest X-ray shows increased lung volumes. In patients with emphysema the heart may appear small and the bronchovascular markings decreased. Patients with chronic bronchitis often have enlarged hearts, engorged apical vessels, bronchial cuffing and other signs of fluid overload. Arterial blood gases may reveal mild to severe hypoxemia. Patients with severe disease may develop respiratory acidosis and a compensatory metabolic alkalosis. The complete blood count may reveal polycythemia and the serum electrolytes a metabolic alkalosis. Sputum Gram stain and culture are important to assess the abundance of

PMNs and to help identify bacterial pathogens that may be associated with acute exacerbations.

MANAGEMENT

The symptoms of acute bronchitis are best managed with symptomatic treatment. Non-steroidal anti-inflammatory drugs and decongestants are useful for pharyngitis, sinusitis and coryza. Antibiotics are indicated for clinically significant bacterial bronchitis, but such a complication is difficult to distinguish from viral bronchitis. Antibiotics are prescribed for 53–66% of patients with acute sinusitis, bronchitis or URIs,[3] indicating excess usage. This practice promotes the development of antibiotic-resistant bacteria, which may lead to greater morbidity in the community. Therefore, antibiotics should be reserved for patients with acute bronchitis who have increased numbers of PMNs and numerous bacteria in Gram-stained sputum samples or who do not respond to symptomatic therapy.

The most important feature of managing chronic bronchitis is the avoidance of exposure to irritants, particularly cigarette smoke. Thus, smoking cessation is of primary importance for each individual. Support for smoking cessation can be provided by individual counseling, provision of smoking cessation literature or through smoking cessation groups. Nicotine gum or transdermal nicotine may be useful to reduce withdrawal symptoms.

No specific therapy is available to treat chronic bronchitis. Symptomatic therapy is directed at reducing mucosal edema, mucus hypersecretion, bronchial smooth muscle constriction and airway inflammation (Table 33.2). Inhaled ß-adrenergic agonists and anticholinergic drugs may be of benefit to patients with reactive airways disease, as demonstrated on pulmonary function tests.[12] Theophylline may be useful in patients with nocturnal symptoms or severe hyperinflation and respiratory muscle fatigue. In addition to relaxing bronchial smooth muscle, ß-adrenergic agonists enhance mucociliary clearance. Inhaled drugs with intermediate (4–6 hours) and long (8–12 hours) duration of action are available. These are generally preferred to systemic treatments. Metered dose inhalers (MDIs) appear to have comparable efficacy to nebulizers, but effective treatment requires co-ordination of MDI actuation and the breathing cycle. The beneficial effects can be enhanced by the use of a spacer to improve deposition of drugs in the lungs. Dry powder inhalers (DPIs) can be easier to use and move effective. Anticholinergic drugs relax bronchial smooth muscle and have an intermediate duration of

TABLE 33-2 -- Therapeutic options for acute exacerbations of chronic bronchitis.

THERAPEUTIC OPTIONS FOR ACUTE EXACERBATIONS OF CHRONIC BRONCHITIS		
Class/agent	**Examples**	**Notes**
Bronchodilators		
ß-Adrenergic agonists	Albuterol, salmeterol	Inhaled administration preferred
Anticholinergics	Ipratropium bromide	Inhaled administration mandatory
Theophylline		Second-line agent
Anti-inflammatory agents		
Corticosteroids	Prednisone, fluticasone	Administration by inhalation may reduce side-effects
Expectorants		
rhDNase	Dornase alfa	Efficacy in COPD not established
Iodinated compounds	Iodinated glycerol	Limited efficacy
Reducing agents	*N*-acetyl cysteine	Limited efficacy
Airway clearance measures		
Controlled coughing		Efficacy not established
Physical therapy		Efficacy not established
Supplemental oxygen		Corrects significant hypoxemia
Antibiotics		Indications and efficacy controversial

action (4–6 hours). Ipratropium bromide is available as an MDI. The effects of anticholinergics and ß-agonists appear to be roughly equivalent.[13] The responses of individual patients to such drugs must be assessed to determine the optimum treatment.

Systemic and inhaled corticosteroids provide a beneficial effect by reducing severity of airway inflammation. This typically results in decreased airway obstruction and decreased mucus secretion. Long-term use of systemic corticosteroids may be complicated by osteoporosis, central obesity and/or glucose intolerance. Once a beneficial steroid effect has been demonstrated with systemic therapy, these side effects can be minimized by use of moderate to high doses of inhaled steroids. Typical drugs include beclomethasone 800–1600µg per day and fluticasone 88–1760µg per day. Other forms of therapy such as cromolyn sodium, expectorants and chest physiotherapy have not been demonstrated to have significant effects in chronic bronchitis or COPD.

The role of bacterial infection in causing acute exacerbations of chronic bronchitis is controversial. It is likely that less than half the cases of acute exacerbation are due

to bacterial infection. A number of controlled studies have failed to show significant benefit of antibiotic therapy.[14] [15] Nevertheless, antibiotics have a role in patients who demonstrate a significant increase in the number of PMNs in expectorated sputum and dominant bacteria on Gram stain or in culture. Previous positive responses to antibiotic therapy may also support repeated use in individual patients. Antibiotics effective against the common bacterial species are listed in Table 33.3 . Patients with exacerbations of sufficient severity to require hospitalization should be treated with parenteral antibiotics with comparable antibacterial spectra, and the treatment modified based on sputum culture results.

Hypoxemia may be diagnosed by ambulatory, exercise or nocturnal pulse oximetry, as well as by arterial blood gases. Patients with significant hemoglobin desaturation (SaO_2 <90%) should receive supplemental oxygen. Nocturnal oxygen has been shown to improve survival[16] and continuous treatment has greater effects than nocturnal treatment alone.[17] Some patients with COPD also have obstructive sleep apnea and detailed sleep studies may be required to establish the effectiveness of oxygen and/or continuous positive airway pressure (CPAP) by nasal mask to prevent nocturnal hypoxemia.[18] Noninvasive assisted ventilation by nasal mask has been used for some patients with severe hypercapnic respiratory failure.[19] Patients with acute respiratory failure and significant respiratory

TABLE 33-3 -- Oral antibiotics for acute exacerbations of chronic bronchitis.

ORAL ANTIBIOTICS FOR ACUTE EXACERBATIONS OF CHRONIC BRONCHITIS	
Agent	**Dose**
Amoxicillin	250–500mg tid
Amoxicillin/clavulanic acid	875/125mg tid
Ampicillin	500mg qid
Azithromycin	500mg day 1, then 250mg qd
Cefaclor	500mg tid
Cephalexin	500mg qid
Ciprofloxacin	500–750mg bid
Clarithromycin	500mg bid
Doxycycline	100mg bid
Erythromycin	500mg qid
Ofloxacin	400mg bid
Tetracycline	500mg qid
Trimethoprim-sulfamethoxazole	160/800mg bid

acidosis or hypoxemia often require hospitalization, parenteral antibiotics, ICU care and mechanical ventilation.[20]

BRONCHIECTASIS

EPIDEMIOLOGY

Bronchiectasis is defined as abnormal dilatation of the bronchi. [21] [22] It typically involves medium-sized bronchi and results from destruction of the muscular and elastic components of the walls. Bronchiectasis is classified as cystic, cylindrical or varicose, based on the morphological structure of the airways. Chronic airway inflammation is the essential pathologic feature, resulting from genetic abnormalities that impair airway defense mechanisms or from chronic respiratory infections.[23] Such infections have become relatively rare in the United States; the current prevalence of bronchiectasis is less than 1 in 10,000.

PATHOGENESIS

The principal diseases that cause bronchiectasis are listed in Table 33.4 . The genetic diseases cause deficits in airway defense or immunological mechanisms that permit the development of chronic bacterial infections in the airways. Bacterial and inflammatory cell-derived proteolytic and oxidative molecules cause progressive airway wall damage that eventually produces bronchiectasis. Immune reactions to fungi can produce the central bronchiectasis that is associated with allergic bronchopulmonary aspergillosis (ABPA). Chronic infections with *Mycobacterium tuberculosis* [23] or nontuberculous mycobacteria (particularly *Mycobacterium avium* complex)[24] and *Bordetella pertussis* infections are recognized infectious causes. Bacteria that secondarily infect damaged airways following other injuries probably propagate airway damage, but the time course and relative contributions of the different organisms have not been established.

CLINICAL FEATURES

Daily cough and production of purulent sputum are the most typical symptoms of bronchiectasis. Sputum production can range from less than 10ml to greater than 150ml daily and tends to correlate with

disease extent and severity. Bronchiectasis associated with cystic fibrosis, which becomes generalized and progresses relentlessly, is described in greater detail below. Occasional individuals have no discernible sputum production ('dry bronchiectasis'). The clinical course is usually of progressive symptoms and respiratory impairment. Airway obstruction progresses and leads to increasing exertional and resting dyspnea. Acute exacerbations may be precipitated by viral or newly acquired bacterial pathogens, as with chronic bronchitis. The main clinical differentiating feature is the quantity of sputum production. In addition to progressive respiratory failure, patients with bronchiectasis are prone to hemoptysis due to hypertrophied bronchial arteries that are closely apposed to the inflamed airways.[25] Hemoptysis from this source can be massive, even fatal.

DIAGNOSIS

Diagnosis is suggested by clinical symptoms and a physical exam with hyperinflated chest and medium- to low-pitched inspiratory crackles and sometimes expiratory wheezes. Chest X-ray may demonstrate hyperinflation and bronchiectatic cysts or dilated bronchi with thickened walls forming tram track patterns radiating from the lung hila. High-resolution chest computed tomographic (CT) scans readily demonstrate mild and severe forms of bronchiectasis. CT scans have largely replaced bronchography as a diagnostic examination. Sputum culture may identify characteristic pathogens, including *H. influenzae, Strep. pneumoniae* and/or *Pseudomonas aeruginosa*. Sputum AFB smears and cultures should be performed to evaluate mycobacterial disease. Spirometry is essential to determine the severity of airway obstruction and to evaluate the course of disease.

MANAGEMENT

Specific etiologies such as tuberculosis should be identified and treated whenever possible. Standard therapy includes measures to clear excess secretions from the airways. Chest physiotherapy based on chest percussion and postural drainage is accepted as the most effective technique. Alternatives such as pneumatic vests and aerobic exercise or flow interrupter valves may be effective, but their use must be individualized. Bronchodilators have a role in patients with objective spirometric or subjective clinical responses. Acute exacerbations are managed with intensification of airway clearance measures

and the use of antibiotics directed at pathogens identified in recent sputum cultures. The use of prophylactic oral or inhaled antibiotics has been advocated to control the major symptoms of bronchiectasis and such treatment must be tailored to the individual responses. Surgical resection of localized bronchiectatic lung is occasionally indicated. [26]

CYSTIC FIBROSIS

EPIDEMIOLOGY

Cystic fibrosis is the most common lethal genetic disease in Caucasians. [27] This autosomal recessive disease is caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene located on chromosome 7. The incidence is one in every 3300 live Caucasian births, with a gene carrier rate of one in 29. Other ethnic groups have lower carrier rates, with the Hispanic birth incidence being one in 9500, the Native American one in 11,200, the African-American one in 15,300 and the Asian one in 32,100 live births.

When cystic fibrosis was first described in 1938, survival past infancy was rare. Improved treatments for pancreatic insufficiency, lung infections and other complications have increased the median survival from less than one year to more than 30 years (Fig. 33.2). Over 22,700 CF patients have been identified in the United States.[28] The median survival in 2001 was 33.4 years. Adults (=18 years old) now account for 39.5% of CF patients and survival can extend to 78 years.[28]

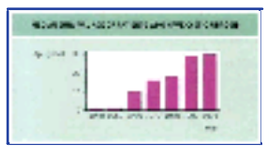

Figure 33-2 Median survival age of patients who have cystic fibrosis. The median survival age has increased dramatically. *Data from Cystic Fibrosis Foundation, Bethesda, MD.*

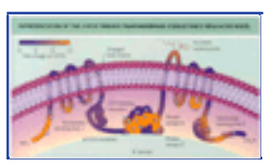

Figure 33-3 Representation of the CFTR model, based on structural, hydropathy and expression studies. The membrane-spanning domains are arranged in groups of six, each associated with a nucleotide-binding fold. These features are similar to those of the multidrug resistance 'P' glycoprotein. The 'R' domain is unique to CFTR.

PATHOGENESIS

The CFTR gene encodes a 1480 amino acid protein, with 12 membrane-spanning regions, two nucleotide-binding folds and a regulatory ('R') domain (Fig. 33.3). This protein is localized to the apical membranes of epithelia lining the organs affected by the disease, particularly the airways, pancreatic duct, sweat gland duct, intestines and reproductive tract. CFTR protein acts as a Cl^- channel[29] and as a regulator of epithelial Na^+ channels[30] and other Cl^- channels. [31] Over 700 different mutations in the CF gene have been identified, encompassing several functional abnormalities (Fig. 33.4). Class I mutations prevent protein production. Class II mutations produce proteins that fail to traffic to the apical cell membrane. The most common CF mutation, ?F508, is in this class; it accounts for 68% of US mutations. Class III mutations traffic properly but have defective regulation. Class IV mutations traffic properly but have defective Cl^- conductance. Some exon splice-site mutations have been labeled class V mutations and may permit transcription of some normal CFTR mRNA, conferring a less severe clinical

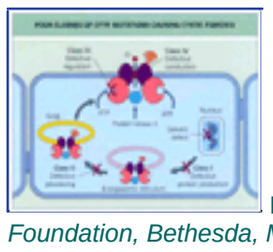

Figure 33-4 CFTR mutations are divided into classes based on the mechanisms of dysfunction. See text for detailed descriptions. *Figure provided by Cystic Fibrosis Foundation, Bethesda, MD.*

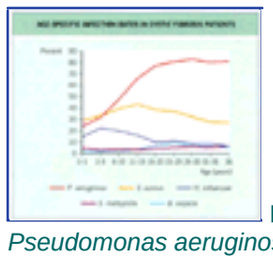

Figure 33-5 Age-specific infection rates in cystic fibrosis patients. Bacteria isolated from CF sputum samples vary with age and demonstrate the trend toward *Pseudomonas aeruginosa* as the dominant pathogen. *Figure provided by Cystic Fibrosis Foundation, Bethesda, MD.*

phenotype.[32] All classes of mutations alter Cl^- permeability and regulation of ion transport in the affected epithelial cells.

The pathogenesis of airways disease in cystic fibrosis is not completely understood. CFTR mutations produce decreased Cl^- permeability and increased net Na^+ absorption by bronchial epithelial cells. The effects on bronchiolar epithelial cells and on submucosal gland secretion are not fully understood. It has been suggested that CF mutations lead to relative dehydration, abnormal mucus sulfation or abnormal function of peptide antimicrobial molecules (defensins) in the airway surface liquid.[33] These abnormalities cause impaired

TABLE 33-5 -- Treatment approaches to CF airways disease.*

TREATMENT APPROACHES TO CYSTIC FIBROSIS AIRWAYS DISEASE			
		Approach	
Abnormality	**Solution**	**Available**	**Investigational**
Abnormal CF gene	Provide normal gene		Gene therapy

	Provide normal protein		Protein therapy
	Activate mutant form		?Phosphodiesterase inhibitors
			?Phosphatase inhibitors
			?Others
	Block Na^+ uptake		Amiloride
	Increase Cl^- efflux		UTP
	Decrease viscosity	Dormase a (rhDNase) (*in vitro*)	Gelsolin
	Augment ciliary action	Airway clearance techniques	
	Reduce bacterial count	Antibiotics	
	Decrease host reaction	Anti-inflammatory drugs (corticosteroids, ibuprofen)	Antiproteases
			Pentoxifylline
			IVIG
	Replace irreversibly damaged areas	Lung transplantation	

The pathogenesis of CF lung disease is based on a vicious cycle of airway infection, inflammation and obstruction (first column). Treatment can be directed at different pathogenic mechanisms (second column). Currently available and proposed treatment options are shown in final columns.

* *Figure provided by Cystic Fibrosis Foundation, Bethesda, MD*.

mucociliary clearance, secondary bacterial infection and airways inflammation. This chronic infection and inflammation forms a vicious cycle that produces progressive airway obstruction, bronchiectasis and eventually respiratory failure. This scheme of pathogenesis is illustrated in Table 33.5 . Some existing and potential treatments, directed at the specific pathogenic processes, are indicated.

CLINICAL FEATURES

Cystic fibrosis is classically recognized from the triad of bronchiectatic airways disease, exocrine pancreatic insufficiency and elevated sweat chloride. Most patients have onset of cough and chronic respiratory tract infections during infancy or childhood. Early respiratory tract pathogens include *Staphylococcus aureus* and *Haemophilus influenzae*. *Pseudomonas aeruginosa*, particularly mucoid variants, appears in greater prevalence with increasing age and becomes the dominant pathogen by the teenage years (Fig. 33.5). It is common to isolate several different bacteria from the sputum of adolescent and adult CF patients. Pathologically, there is inflammation and obstruction of both bronchioles (Fig. 33.6) and bronchi, with submucosal gland hypertrophy (Fig. 33.7). Bronchiectasis tends to start in the upper lobes and becomes generalized. Chest X-rays show hyperinflated lungs, cystic bronchiectasis and occasionally upper lobe atelectasis (Fig. 33.8).

The clinical course of chronic cough, mucus hypersecretion and airway obstruction is progressive and is punctuated by acute exacerbations, characterized by the features listed in Table 33.6 . When such exacerbations are effectively treated, pulmonary function may return to baseline levels. With more severe disease exacerbations become more frequent and less reversible, culminating in fatal respiratory failure (Fig. 33.9).

DIAGNOSIS

The standard diagnostic criteria for cystic fibrosis are the combination of characteristic lung disease with airway obstruction, bronchiectasis and infection with typical bacterial pathogens; exocrine

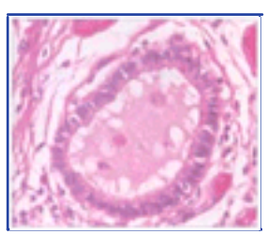

Figure 33-6 A CF bronchiole is completely occluded by mucoid secretions and surrounded by fibrotic tissue. H&E stain, original magnification 400X.

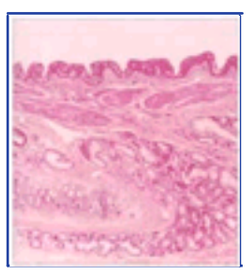

Figure 33-7 A CF submucosal gland demonstrates marked hypertrophy and dilated gland ducts with mucoid secretions. The surface epithelium has marked goblet cell metaplasia. H&E stain, original magnification 100X.

pancreatic insufficiency which occurs in more than 85% of CF patients; and elevated sweat chloride which occurs in >98% of patients. The diagnosis initially may be suggested by a family history of CF or by the presence of meconium ileus at birth, noted in 17% of cases. Of patients reported to the CF Foundation (CFF) Patient Registry, 51% presented with acute or persistent respiratory symptoms, 43% with failure to thrive or malnutrition, 35% with steatorrhea and 21% with meconium ileus or intestinal obstruction.

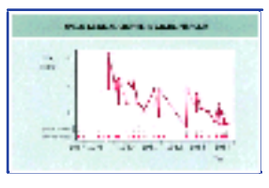

Figure 33-9 Typical clinical course in CF. Serial pulmonary function measurements (FEV_1) demonstrate a typical clinical course. Measurements are connected by solid lines

during therapy for acute exacerbations. The lower bars indicate periods of hospital treatment. Pulmonary function decreases and the exacerbations are more frequent and less responsive to treatment in advanced disease.

TABLE 33-6 -- Signs and symptoms of a CF pulmonary exacerbation.[*]

SIGNS AND SYMPTOMS OF A CF PULMONARY EXACERBATION
• Increased cough
• Increased sputum
• Increased dyspnea
• School or work absenteeism
• Reduced exercise tolerance
• Weight loss >1 kg or >5% of body weight
• Decreased FEV_1 (10% from baseline)
• New chest findings
Rales
Wheezes
• New radiographic findings

* *Figure provided by Cystic Fibrosis Foundation, Bethesda, MD.*

Developments in the understanding of the molecular and physiological pathogenesis of cystic fibrosis have led to additional diagnostic criteria. CFTR mutational analysis is offered by several companies that test for up to 70 common mutations and can detect mutations in about 95% of CF cases. Abnormal CFTR function in airway epithelia can be assessed by *in vivo* measurements of nasal electrical potential difference and its response to selected modulators of ion transport.[34] The clinical application of these tests has been summarized by a CFF-sponsored Consensus Committee.[35]

MANAGEMENT (see also Chapter 40g)

Exocrine pancreatic insufficiency and malnutrition are managed with oral pancreatic enzymes and dietary supplements. Pulmonary disease causes the major morbidity in CF and eventually death in 95% of patients. Daily clearance of airway secretions is essential (Table 33.7).[36] This can be accomplished by chest physiotherapy, which enhances sputum production and increases pulmonary function. [37] Physical exercise augments airway clearance and improves cardiovascular function. Special breathing techniques, including forced expiratory technique, autogenic drainage and active cycle of breathing,[38] have been useful in some individuals. Mechanical devices, including the flutter valve[39] and external thoracic compression devices, may improve patient independence, but their efficacy is less well established.

TABLE 33-7 -- Standard therapy for cystic fibrosis lung disease.

STANDARD THERAPY FOR CYSTIC FIBROSIS LUNG DISEASE
Airway clearance
Chest physical therapy
Physical exercise
Special breathing techniques
Mechanical devices
Antibiotics
Intravenous
Oral
Inhaled
Others
Bronchodilators
Supplemental oxygen
Anti-inflammatory agents (ibuprofen, corticosteroids)
Recombinant human deoxyribonuclease (rhDNase)

Antibiotics are used extensively. Acute exacerbations are treated with intravenous antibiotics directed at the major pulmonary pathogens, especially *Pseudomonas* species and *Staph. aureus*. Because of the high bacterial burden, two antibiotics with different mechanisms of action and with *in vitro* efficacy against each major bacterium are selected. Pharmacokinetic studies of ß-lactams, aminoglycosides and sulfa drugs demonstrate increased clearance in CF patients, necessitating the use of higher doses. Typical antibiotic choices are listed in Table 33.8 . Home intravenous antibiotic therapy has cost and convenience advantages, [40] but its clinical efficacy in this setting has not been rigorously established. The benefits of chronic oral antibiotics are controversial, but some aerosolized antibiotics have demonstrated efficacy.[41]

CF patients are particularly susceptible to the complications of massive hemoptysis and pneumothorax. Episodes of massive hemoptysis, defined as >240ml blood per 24 hours, are managed with antibiotics, transient cough suppression and reduction in chest physiotherapy, and bronchial artery embolization.[42] Such therapy is usually effective and does not compromise candidacy for eventual lung transplantation. Large pneumothoraces are managed by chest tube drainage. Recurrent pneumothoraces may require repeated chest tubes or abrasion pleurectomy. [43] Hypoxemia is best treated with supplemental oxygen plus standard pulmonary therapy. Ventilatory assistance can be effectively provided by mask ventilation.[44] [45]

Lung transplantation has become an effective form of therapy. [46] From the first heart-lung transplant for CF in 1983 to 2001, more than 1270 heart-lung or sequential double lung transplants (the preferred operation in the United States) for CF have been performed worldwide. Transplant evaluation is indicated when natural survival is expected to be slightly longer than the waiting time for donor organ availability, currently about 2 years. The highly variable progression of CF disease makes prediction difficult, but an FEV_1 less than 30% predicted or increasing functional impairment with frequent hospitalizations are accepted referral criteria. The 1- and 5-year survivals after lung transplantation for CF are 70% and 48%, respectively. These are comparable to the survival of patients who received lung transplants for other diseases. Deaths in the first year are primarily due to operative complications and infections. After

TABLE 33-8 -- Inhaled and parenteral antibiotics commonly used for cystic fibrosis.

INHALED AND PARENTERAL ANTIBIOTICS COMMONLY USED FOR CYSTIC FIBROSIS
Parenteral (normally two effective agents against each bacterial isolate)

Class/drug	Pertinent efficacy
Aminoglycosides*	
Gentamicin	*Staph. aureus, H. influenzae, Pseudomonas*
Tobramycin	*Staph. aureus, H. influenzae, Pseudomonas*
ß-lactams*	
Ceftazidime	*Pseudomonas*
Piperacillin	*H. influenzae, Pseudomonas*
Ticarcillin/clavulanate	*Staph. aureus, H. influenzae, Pseudomonas*
Monobactam	
Aztreonam	*Pseudomonas*
Carbapenem	
Imipenem-cilastatin	*Staph. aureus, H. influenzae, Pseudomonas*
Fluoroquinolones	
Ciprofloxacin	*Staph. aureus, H. influenzae, Pseudomonas*
Sulfa drugs*	
Trimethoprim/sulfamethoxazole	*Staph. aureus, B. cepacia*
Glycopeptides	
Vancomycin	Oxacillin-resistant *Staph. aureus*
Aerosolized	
Drug	**Common doses**
Tobramycin	80–300mg bid to tid
Colistamethate sodium	75–150mg bid to tid

* Higher doses required because of increased clearance in CF

1 year most deaths are caused by obliterative bronchiolitis, the pathologic marker of chronic rejection. The scanty number of donor organs limits the availability of lung transplantation and many patients wait more than 2 years after being accepted as a transplant candidate. Living donor transplantation (sequential transplantation of a lower lung lobe from each of two donors) has become an effective alternative in some centers.[47]

CONCLUSION

Inflammatory airways diseases are highly prevalent, causing significant morbidity and mortality. Different pathogenic factors cause distinct patterns of disease, including bronchitis and bronchiectasis. The ability to stop the progression of these diseases is often limited by chronic inflammation and by structural alterations in the airways. Nevertheless, antibiotics, anti-inflammatory drugs and other forms of therapy can modulate acute exacerbations and, potentially, the progression of these diseases. Elucidation of the pathogenic mechanisms, as is being done in cystic fibrosis, may uncover new and more effective means of treatment. The diagnostic tests, continued monitoring and choice of therapeutic options must be tailored to the individual clinical presentation and responses of each patient.

Chapter 34 - Community-acquired Pneumonia

David R Baldwin
John T Macfarlane

INTRODUCTION

Pneumonia can be discussed in a number of different ways. We have chosen the scheme illustrated in Table 34.1 . This chapter concentrates largely on community-acquired pneumonia (CAP) and Chapter 35 on hospital-acquired pneumonia, including ventilator-associated pneumonia. Other subjects are covered elsewhere.

EPIDEMIOLOGY

Definition and classification

Pneumonia acquired outside hospital is termed CAP. It may be a primary disease occurring at random in healthy individuals or may be secondary to a predisposing factor such as chronic lung disease or diabetes mellitus. It is important to understand that community-acquired lower respiratory tract infection (LRTI) is not synonymous with CAP and only 5–10% of patients who have LRTI actually have pneumonia characterized by radiologic evidence of lung parenchymal disease, which may include lobar or segmental opacification, patchy nonsegmental shadowing or diffuse disease. Table 34.1 shows a clinically relevant classification of CAP; categories are based on severity and the presence of pre-existing disease. Management of patients in the different categories differs in terms of general supportive measures and specific antimicrobial therapy.

Incidence

Several large studies have measured the incidence of CAP and have reported rates that vary by more than 10-fold.[1] A large community study in Seattle, Washington, USA in the 1960s and 1970s showed an overall prevalence of 12 per 1000 population for all ages, which was

TABLE 34-1 -- Classification of pneumonia.

CLASSIFICATION OF PNEUMONIA
Community-acquired pneumonia (CAP)
Nonsevere CAP: no unusual risk factors present
Nonsevere CAP: risk factors present (related to host or environment)
Severe CAP
Hospital-acquired pneumonia (HAP)*
Nonsevere HAP: no unusual risk factors
Nonsevere HAP: risk factors present
Severe HAP: early onset
Severe HAP: late onset
Pneumonia in immunocompromised host
Pneumonia peculiar to certain geographic areas
This classification is designed to provide a practical approach to likely pathogens and their appropriate management.

* Includes ventilator-associated pneumonia (VAP)

similar to the rate in Finland in 1993 (11.6 per 1000).[2] In England in 1985, a lower rate of 1–3 per 1000 was found for adults, and in Spain in 1992 a similar rate of 2.6 per 1000 was found.[3] [4] This difference may in part be explained by differences in the criteria used to define pneumonia. However, when the same criteria are used, it can be shown that a variety of factors influence incidence: age, race, social deprivation indices,[5] recent admission for pneumonia and host defense factors.[6] In the North American study, prevalence was higher in 0 to 4-year-olds (12–18 per 1000) and in the Finnish study it was higher in 2 to 5-year-olds (36 per 1000) and in those aged over 70 years (34 per 1000). A more recent study from the Mayo Clinic has also shown a rate of pneumonia of 30 per 1000 for patients aged over 65 years. [7]

The attack rate is also influenced by the seasonal pattern of pathogens either causing or predisposing to pneumonia (such as viruses).[8] The seasonal pattern of common pathogens is shown in Figure 34.1 . Most respiratory pathogens are more common in the winter months but, notably, legionellosis is more common in the summer and *Mycoplasma* infection occurs in worldwide epidemics every 3–4 years, when it is responsible for approximately 20% of cases of pneumonia. At other times *Legionella* cases are sporadic and account for fewer than 10% of pneumonia cases. Bacterial pneumonia, including that caused by *Streptococcus pneumoniae, Haemophilus influenzae* and *Staphylococcus aureus*, are seen at times of peak activity of the influenza virus. Virus infections predispose bacteria normally contained in the nasopharynx to colonize the lower airway. Furthermore, viral infections may encourage more severe infection by impairing host defense mechanisms (see Pathogenesis and pathology). *Streptococcus pneumoniae*, *H. influenzae, S. aureus* and

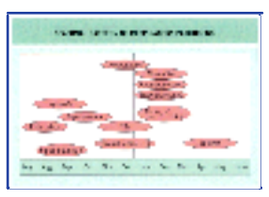

Figure 34-1 Seasonal pattern of respiratory pathogens in the northern hemisphere. Most respiratory pathogens are commoner in the winter months with the notable exceptions of *Legionella* spp. and *Coxiella burnetii* (Q fever). *With permission from Macfarlane J. Community-acquired pneumonia. Br J Dis Chest 1987;81:116–27.*

Moraxella catarrhalis are carried in the nasopharynx to varying degrees (50%, 50%, 30% and 5–50%, respectively). During epidemics of mycoplasmosis, pharyngeal carriage rates of 13.5% have been reported.[9] *Haemophilus influenzae* and *M. catarrhalis* can also colonize the lower respiratory tract in patients who have chronic obstructive pulmonary disease (COPD). This may reflect their ability to persist in a lower respiratory tract compromised by impaired defenses by producing only a low-grade inflammatory response and thereby not inducing a vigorous immune response.

When *Legionella*, psittacosis and Q fever infections occur in clusters, an environmental source should be sought. *Legionella* infections occur worldwide and are usually sporadic. Their occurrence in the summer months may partly be explained by foreign travel and exposure to risk factors such as water systems in public buildings and hotels. Debilitated or immunocompromised patients are particularly vulnerable. *Legionella* organisms are found in native waters, including rivers, lakes, thermal springs and under ice, in industrial coolant water and in water circulating in large buildings and domestic systems. *Legionella* spp. have been cultured from many hot water systems in homes, hotels and hospitals. The organisms are killed by drying but may survive for more than a year in domestic tap water. There is no human or animal reservoir, although algae and amebae may act as environmental hosts. Legionellosis epidemics have occurred in hotels and hospitals; indeed, the disease was first recognized in 1976 when an outbreak of severe pneumonia occurred among members of the Pennsylvanian branch of the American Legion who had stayed at a particular hotel. For an outbreak to occur, it is necessary to have a reservoir, such as an infected water system; bacterial amplification facilitated by stagnation, dirt or sludge; and a water temperature between 68° and 113°F (20–45°C). The bacteria then have to be disseminated via showers, fans, air conditioning, respiratory therapy equipment and, possibly, spray taps. Finally, the strain of *Legionella* must be pathogenic to humans and be inhaled in sufficient quantity to cause infection.[10]

Morbidity and mortality

Pneumonia is the sixth leading cause of death in the USA and the commonest fatal infectious disease. Mortality depends on the setting, being less than 1% in patients managed in the community and higher in those admitted to hospital. Rates reported in the UK and Europe vary from 5% to 14%. In-hospital mortality figures from the USA are higher, probably because more patients who have CAP are provided with ambulatory care and consequently only those who have more severe pneumonia or co-morbidity are admitted to hospital. If admission to intensive care is required, mortality rates may range from 22% to over 50%.[11] [12] Mortality, as well as attack rate, is influenced by co-morbidity. The majority of adult patients who die from CAP have one or more co-morbidities such as COPD, ischemic heart disease, diabetes mellitus, malignancy and neurologic disease. These are more often present in the elderly, which partly explains the rising mortality with age.

Economic implication

In the USA it has been estimated that CAP costs $8.4 billion. Half of the costs are for the 1.1 million patients treated in hospital and half for the 4.4 million outpatients.

PATHOGENESIS AND PATHOLOGY

The mode of acquisition varies by pathogen. Most bacterial infections result from aspiration of endogenous organisms resident in the nasopharyngeal secretions, although inhalation of infected droplets may occur from other patients (viral infections), from animals (psittacosis) or from environmental sources (legionellosis).

Host-pathogen interactions

The distal lung contains few commensal micro-organisms despite large numbers present in inspired air and upper airway secretions. A multifaceted defense system maintains this relatively sterile environment, which is overcome or subverted in pneumonia. Table 34.2 and Table 34.3 summarize these host defenses and the tactics used by pathogens to overcome them. The majority of bacteria entering the lungs are rapidly removed by local mechanisms such as the mucociliary escalator and cough reflex in combination with local secretory IgA and phagocytosis by macrophages. With more invasive infections, there is a progressive host response with recruitment of circulatory inflammatory cells, augmented by a specific immune response. In normal lungs, over 85% of the cells recovered from the lower airways by bronchoalveolar lavage are alveolar macrophages, but with infection this changes dramatically as outside cells are recruited. Greatly increased numbers of neutrophils are seen in conventional bacterial pneumonias such as those produced by the pneumococcus. In *Legionella* and viral infections, a lymphocyte infiltrate often predominates. Other inflammatory cells are found in lesser numbers, for example natural killer cells.[13] [14]

TABLE 34-2 -- Host defense mechanisms.

HOST DEFENSE MECHANISMS		
Host defense mechanisms		**Mechanism of lung defense**
Physical defenses	Nose	Filtering of larger particulate matter
	Cough	
	Mucociliary escalator	Bulk clearance of microbes in secretions
Non-specific cellular and humoral factors	Immunoglobulins (principally IgA)	Binding of microbes to facilitate removal by the mucociliary escalator or ingestion and destruction by alveolar macrophages or removal via pulmonary lymphatics
	Complement	
	Antiproteases	
	Opsonins	
	Lactoferrin	Depletion of essential nutrients for some bacteria
	Alveolar macrophage	Endocytosis of bacteria and release of toxic oxygen and nitrogen radicals and lysosomal enzymes
		Direct and antibody dependent cytotoxicity, secretion of IFN-?, TNF and transferrin
	Neutrophil	Endocytosis and generation of oxygen and nitrogen radicals, lactoferrin and lysozyme
Specific immune response	Specific antibody production	Enhanced production of a variety of cytokines, including IFN-?, IL-2, IL-12, TNF-ß, IgA, IgG, IgM, perforins and granzymes
	Macrophage-T-lymphocyte interaction	
	Recruitment of neutrophils, lymphocytes and natural killer cells	
TNF, tumor necrosis factor.		
The lung has several levels of defense, from mechanical barriers to a specific immune response. These processes have overlapping cellular and humoral effects.		

TABLE 34-3 -- Microbial strategies against host defense.

MICROBIAL STRATEGIES AGAINST HOST DEFENSE		
Microbial strategy	**Organism**	**Mediators/mechanisms**
Inhibition of ciliary function	*Pseudomonas aeruginosa*	Phenazine pigments
	Streptococcus pneumoniae	Pneumolysin
	Haemophilus influenzae	Unidentified low molecular weight compound
Damage to cilia	*P. aeruginosa*	Pyocyanin (a phenazine pigment)
	S. pneumoniae	Pneumolysin
	H. influenzae	Lipopolysaccharide (endotoxin)
Adherence to components of mucus	*H. influenzae, P. aeruginosa*	Pili, fibrils
Penetration of mucus and adherence	Influenza viruses	Viral neuraminidases

Inhibition of inflammatory cells	*H. influenzae*	Culture filtrates inhibit neutrophil migration
	Respiratory viruses	May induce host damage to phagocytes through cellular expression of foreign antigen effects on mobility, ingestion and microbial killing
Avoid detection	*Legionella*, fungi, mycobacteria	Survive intracellularly
	Respiratory viruses	
A knowledge of the mechanisms of microbial counter-defense can be useful in the clinical setting. For example, it is important to use antibacterial agents that are active in the intracellular environment when treating *Legionella* and mycobacterial infections.		

Inflammatory cell recruitment

Recruitment of cells from the lung interstitium and blood to the site of infection occurs through non-specific and specific immune reactions. Non-specific reactions include the local production of a variety of chemotactic and proinflammatory cytokines by resident lung macrophages and epithelial cells. In addition, a specific immune response is generated. Macrophages and dendritic cells process antigens to smaller molecules that are displayed on the cell surface as part of the major histocompatibility complex (MHC) locus. Antigen presentation requires direct $CD4^+$ T-cell-macrophage/ dendritic cell contact via intercellular adhesion molecules. The T-cell receptor binds to MHC class II molecules on the antigen presenting cell and at the same time binds the intercellular adhesion molecule (ICAM)-1 to its ligand lymphocyte function associated antigen-1. The latter provides additional co-stimulation of lymphocytes. Antigen presentation may occur in the lung interstitium, the bronchus-associated lymphoid tissue and the intrapulmonary lymph nodes. As a result a variety of cytokines are produced; interleukin (IL)-1 is secreted by antigen presenting cells, and this in turn induces IL-2 production by memory T cells. IL-2 is a potent inducer of T-cell activation and proliferation.[15]

Cell-mediated antimicrobial activity

T-cell activation and cytokine production stimulate other cells to increase antimicrobial function. For example, interferon (IFN)-? increases macrophage antimicrobial function by enhancing MHC expression and augmenting oxygen-dependent and -independent microbial killing. This mechanism acts on intracellular pathogens and inhibits growth of respiratory pathogens such as *Legionella* spp., mycobacteria, pathogenic fungi, *Pneumocystis carinii* and *Chlamydia* spp. There are many other host defense cytokines (see Table 34.2) that may interact and have common activities. They may act to stimulate or suppress host defense reactions. When viruses reach the lower airways they interact with macrophages that normally resist invasion and replication through the production of interferons. Macrophages can also reduce virus replication in neighboring cells. If a specific antibody to the virus is present, this can neutralize virus via induction of natural killer cells, T cells, IFN-? secretion and lysis by complement.

Counter-defense mechanisms employed by pathogens

Pathogenic organisms have a variety of virulence factors that may contribute to the inhibition of normal defense mechanisms. For example, many bacteria inhibit ciliary function, thus decreasing the efficacy of clearance from the lung (Table 34.3). Others may exist in the mucous layer without stimulating a significant host response, thus subverting detection and, when clearance is impaired as in COPD, may colonize the airway. Other bacteria, such as *Legionella* and *Mycobacterium* spp., may avoid host defenses by surviving and replicating intracellularly; the former exist inside membrane-bound vacuoles, which resist lysosomal fusion and acidification. Respiratory viruses can interfere with the mucociliary escalator and also produce factors such as neuraminidases, which facilitate penetration of mucus and attachment to the epithelial cells. This predisposes to bacterial colonization and secondary infection. Viruses affect phagocytic mobility, ingestion and microbial killing. Specific antibodies directed against defense cells expressing viral antigens may further impair their function.[16]

Gross pathology and histology

The interactions between host and pathogen result in the histopathologic features of pneumonia. Initially there is alveolar congestion and an exudate rich in fibrin and red blood cells. Macroscopically the consolidated lung appears rather like liver, hence the term 'red hepatization'. Later in the course of the illness the lung becomes more gray (gray hepatization) as a result of infiltration with neutrophils and other inflammatory cells. The consolidated lobe sometimes shows multiple abscess formation (Fig. 34.2) or, occasionally, frank necrosis.

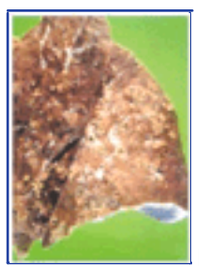

Figure 34-2 Multiple discrete areas of consolidation with abscess formation is a classic feature of *Staphylococcus aureus* pneumonia. *With permission from Macfarlane JT, Finch RG, Colton RE. A colour atlas of respiratory infections. London: Chapman & Hall; 1993.*

These features are more often present in *S. aureus*, *Klebsiella pneumoniae* and anaerobic infections.

Etiology

A key factor guiding therapy for CAP is knowledge of the spectrum of potential pathogens. Major factors that influence this spectrum are age (infection in children differs from that in adults and the elderly); severity (as defined by clinical criteria); and the presence of comorbidity, commonly chronic cardiorespiratory disease, diabetes mellitus, neurologic deficit or immunodeficiency as a result of drugs or disease. Geographic variation is also important; for example, tuberculosis is a relatively common cause of CAP in Hong Kong[17] and Q fever in Nova Scotia, Canada and northern Spain. The causative pathogens and their approximate relative frequencies are summarized in Table 34.4 .[18] [19] [20] [21]

In adults, 60–80% of CAP cases are caused by bacteria, 10–20% are 'atypical' and 10–15% are viral. *Streptococcus pneumoniae* is the commonest pathogen and is responsible for 30–50% of cases. In most series, no pathogen is identified in 30% of cases. The majority of these are also thought to be pneumococcal infections in which identification has not been made because of prior antibiotic therapy or lack of sputum for microbiologic investigations during the initial phase of the illness. The frequency of viral and atypical pneumonias may also be underestimated because the acute and convalescent serum samples required for diagnosis are often not obtained. During epidemics, *Mycoplasma pneumoniae* is the next most common pathogen, accounting for up to 23% of cases. Nontypeable (unencapsulated) *H. influenzae* is the next most common pathogen. It may

TABLE 34-4 -- Usual causes of CAP.

USUAL CAUSES OF CAP		
Age group	**Pathogens**	**Percentage of total**

Adults and the elderly	Core pathogens	*Streptococcus pneumoniae*	30–42
		Respiratory viruses	8–13
		Mycoplasma pneumoniae (during epidemics)	5–25
	Additional risk factors present	*Haemophilus influenzae*	5–10
		Staphylococcus aureus	0.8–4.0
		Moraxella catarrhalis	?
		Legionella pneumophila	0.5
		Influenza virus	5
Severe (adults and elderly)	Core pathogens	*S. pneumoniae*	22
		L. pneumophila	5–18
		S. aureus	7–8
	Unusual	*M. pneumoniae*	2
		H. influenzae	3–5
		Influenza A & B	2.3–5.4
		Enteric Gram-negative bacilli	1.6 (UK); 8.6 (Europe)
		Chlamydia psittaci	0.9–2.2
		Klebsiella pneumoniae	
		Varicella-zoster virus	
Children — less than 2 years	Core pathogens	Respiratory syncytial virus	25
		Other viruses	13
		Mixed viral and bacterial	25
		S. pneumoniae	8
		H. influenzae type b	2
Children — 2–15 years	Core pathogens	*S. pneumoniae*	25
		M. pneumoniae	10
		Mixed infections	15
		S. aureus	5
		H. influenzae type b	2
The most common pathogens in each category are shown with estimates of the overall percentage contributions. Core pathogens are those most commonly encountered and may be modified in severe adult CAP and by the presence of risk factors such as pre-existing lung disease and debility (see also Fig. 34.7).			

cause pneumonia in previously healthy individuals but is more common in patients who have pre-existing lung disease. In some series, in which subgroups of patients who have COPD have been studied, *H. influenzae* was more common.[22] *Chlamydia pneumoniae* is usually an uncommon pathogen except during epidemics, which may occur both in the community and in closed settings. It has also been described as a cause of severe pneumonia. Its usual role in pneumonia is less clear because other bacterial pathogens often coexist and patients may recover without antibiotics to which *C. pneumoniae* is sensitive. Laboratory diagnosis is usually in retrospect, employing paired serology.

Influenza virus is the most common cause of viral pneumonia and frequently precedes secondary bacterial pneumonia. Psittacosis, Q fever and *Legionella* spp. each account for 2% of cases. *Legionella* infection is more often found in hospital-based surveys of CAP and exhibits a geographic variation such that studies in Spain have shown up to 14% of cases caused by *Legionella* spp., slightly less than that for the pneumococcus (15%). Community-acquired pneumonia caused by *S. aureus* is uncommon but important because of its severity even in previously healthy individuals. A similar pattern of causative organisms is found in studies from Europe, Australia and New Zealand, but studies in North America more frequently report enteric Gram-negative bacilli (EGNB), aspiration and staphylococcal infections. This may be explained by the higher proportion of debilitated patients and drug and alcohol misusers in the study population. Two large studies from the USA and Canada found the pneumococcus to be a less frequent cause of CAP, but this may reflect different criteria for diagnosis of pneumonia. [23] [24]

In children, the spectrum of pathogens and disease is different (Table 34.4). The major LRTIs are bronchiolitis in infants under 6 months of age, pneumonia in the first 2 years of life and laryngotracheobronchitis in the second and third years of life. Respiratory syncytial virus (RSV) is the main cause of bronchiolitis, although adenovirus, parainfluenza virus type 3, rhinovirus and influenza A have been implicated. There are two important subtypes of RSV, types A and B. Epidemics occur yearly and coincide with the coldest winter month. RSV type A is the most common and tends to be the most severe. Pneumonia in children under the age of 2 years is usually caused by RSV, parainfluenza, influenza or adenovirus but less commonly by enterovirus, rhinovirus, measles virus, varicella-zoster virus and *Coxiella burnetii*. RSV is the most important cause in infants. Neonatal pneumonia usually follows premature rupture of the membranes, allowing the fetus to swallow amniotic fluid contaminated with vaginal organisms. Perinatal pneumonia is usually hospital-acquired secondary to invasive procedures and therefore is usually caused by EGNB and *S. aureus*.

In a study of 121 children hospitalized for LRTI in Helsinki, a cause was found in 69%: bacterial infection in 25%, viral in 25% and multiple organisms in 20%. *Mycoplasma pneumoniae* was more common with increasing age, as were bacterial infections. In Finland, 195 children hospitalized with pneumonia were surveyed over 12 months.[25] A viral infection alone was indicated in 19%, a bacterial infection alone in 15% and a mixed viral and bacterial infection in 16% of patients; 46% of the 69 patients who had viral infection and 52% of the 62 patients who had bacterial infection had a mixed viral and bacterial etiology. Respiratory syncytial virus was identified in 52 patients and *S. pneumoniae* in 21%. The next most common agents were nontypeable *H. influenzae* (9%), adenoviruses (5%) and *Chlamydia* spp. (4%). In Uruguay etiology was determined in 47.7% of 541 cases; 38.6% were viruses and 12.6% bacteria. Viral and mixed etiologies were more frequent in children under 12 months of age. Bacteria predominated in infants aged between 6 and 23 months. Among the viruses, RSV predominated (66%). The bacterial pneumonias accounted for 12.2% of the recognized etiologies. The most important bacterial agents were *S. pneumoniae* (64%) and *H. influenzae* (19%). [26]

In some geographic areas fungi such as *Histoplasma capsulatum* and *Blastomyces dermatidis* may also present as pneumonia (see Chapter 39 and Chapter 238 for further details).

PREVENTION

Methods for the prevention of CAP include vaccination, prophylactic antibiotic therapy, elimination of environmental sources and maintenance of good hygiene. In practice the only vaccines used to prevent CAP are pneumococcal, influenza, measles and *H. influenzae* b vaccines. Measles vaccine helps to prevent pneumonia, which may follow this disease, especially in malnourished children. Similarly, influenza may predispose to secondary bacterial pneumonia in addition to causing primary CAP. Influenza viruses A and B (especially A) regularly alter their surface hemagglutinin and neuraminidase antigens. It is essential, therefore, that influenza vaccine contains the components of the prevalent strains, which are defined each year by the World Health Organization. Influenza vaccine is recommended for all ages and especially the elderly who have the following conditions: chronic respiratory disease, including asthma; chronic heart disease; chronic renal failure; diabetes mellitus and other endocrine disorders; and immunosuppression as a result of disease or treatment. Residents of nursing or residential homes for the elderly or other long-term care institutions should also be vaccinated. Currently, influenza vaccines give 70–80% protection against vaccine strains, although this is less in the elderly.[27] Influenza vaccine is contraindicated in patients who have a history of allergy to hen's eggs.

A 23-valent capsular polysaccharide vaccine provides immunity against the most common serotypes causing pneumococcal pneumonia. It covers nearly 90% of those serotypes that cause severe disease in the UK. Overall efficacy in preventing bacteremic pneumococcal pneumonia is 60–70%, although the vaccine is not effective in

children under 2 years of age or in the immunocompromised. It has been relatively ineffective in patients who have multiple myeloma, Hodgkin's and non-Hodgkin's lymphoma (especially during treatment) and in chronic alcoholism. It does not prevent otitis media in children or reduce the frequency of exacerbations of chronic bronchitis. A large retrospective study of 47 365 adults over 65 years showed a reduction in bacteremic pneumococcal pneumonia (hazard ration 0.56: 95% confidence interval 0.33 to 0.93) with a slightly increased risk of hospitalisation for pneumonia and no effect on outpatient pneumonia.[27A] This confirms efficacy in preventing bacteremia but suggests alternative strategies are required to prevent the more common form of pneumonia. In the UK, immunization is recommended to all those over the age of 2 years who are at special risk of pneumococcal infection or in whom infection might be unusually severe. This includes patients who have homozygous sickle-cell disease, asplenia or severe dysfunction of the spleen, chronic renal disease or nephrotic syndrome, immunodeficiency or immunosuppression as a result of disease or treatment (including HIV disease), chronic heart, lung or liver disease (including cirrhosis) and diabetes mellitus.[27] However, there is little evidence for efficacy in these groups. The vaccine should not be given during an acute infection or during pregnancy, and revaccination is contraindicated within 3 years. In the USA a 7-valent polysaccharide pneumococcal conjugate vaccine has been available since 2000 and it is recommended for use in all children under 2 years of age and for high risk groups aged 2–4 years. Controlled trials have shown this to be highly effective in preventing invasive disease when given as a four dose regimen.[27B] The rate of pneumonia in children under two years of age was 69% lower in 2001 than in 2000 based on a population study of 16 million.[27C] The same study also showed a reduction of 18% in persons aged 65 years or more, suggesting that the vaccine may result in reductions in pneumonia in adults.

Varicella-zoster immunoglobulin therapy is indicated to prevent infections in exposed, susceptible individuals, who may develop severe fulminating pneumonia. Such patients include the immunocompromised, neonates and pregnant women, and those who possess no antibodies to varicella-zoster virus and have had significant exposure to chickenpox or herpes zoster.[27] Oral aciclovir or famciclovir may also be used to prevent varicella-zoster infection in this population.

Prophylactic antibacterial drugs have only limited use in the prevention of CAP. Long-term oral penicillin is recommended in patients under 16 years of age at particular risk of pneumococcal infection, for example after splenectomy.

Prevention may also require identification and elimination of an environmental source of infection. If two or more cases of *Legionella* pneumonia, psittacosis or Q fever occur, a search for a potential reservoir of infection should be made. The relevant public health officials should be informed. For legionellosis, contaminated water systems should be cleaned and sterilized by hyperchlorination and heat. *Legionella* colonization can be prevented by the use of correctly designed water systems, including sealed tanks, and regular heat or hyperchlorination treatment.

CLINICAL FEATURES

General symptoms and signs

Symptoms may be constitutional and non-specific, such as malaise, anorexia, headache, myalgia, arthralgia, sweating and rigors. Specific

symptoms to pneumonia or a specific pathogen also occur. In viral and *Mycoplasma* infections, constitutional symptoms may be preceded by upper respiratory tract symptoms of sore throat, sneezing, nasal discharge and blockage. High pyrexia and rigors are common in the young who have pneumococcal and *Legionella* infections. In contrast, the elderly or seriously ill may have minimal or no fever. Cough is the most common respiratory symptom and is present in over 80% of cases, followed by dyspnea in 60–70%, pleural pain in 60%, new sputum production in over 50% and hemoptysis in 15%.[11] [28] Sputum is initially mucoid or absent, particularly with atypical and *Legionella* infections. Purulent sputum develops later, although in patients who have pre-existing chronic bronchitis or bronchiectasis it is present at the outset.

Nonrespiratory symptoms may be more prominent and mask the diagnosis. Marked confusion may occur with any pneumonia, especially in the elderly, who may have no physical signs other than an elevated respiratory rate and localizing chest signs. Confusion is also more common in *Legionella* and psittacosis pneumonias. A prominent headache in association with confusion or impaired consciousness raises the possibility of *Legionella* infection or co-existent meningitis, especially in pneumococcal pneumonia. Lower lobe pneumonia may present with abdominal pain mimicking acute abdominal or urinary tract pathology.

The duration of history is variable. Usually, symptoms have been present for several days before hospital admission; however, it is

TABLE 34-5 -- Pathogens and their usual pattern of clinical presentation.

PATHOGENS AND THEIR USUAL PATTERN OF CLINICAL PRESENTATION	
Clinical presentation	**Organism**
Abrupt onset of severe pneumonia, with fever, rigors and signs of lobar consolidation	*Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, *Legionella* spp., *Streptococcus pyogenes*, *Klebsiella pneumoniae*, *Neisseria meningitidis*, *Yersinia pestis* (plague), *Burkholderia pseudomallei* (rare)
Indolent or low-grade infection associated with pre-existing lung disease	*H. influenzae, S. pneumoniae, Moraxella catarrhalis, Chlamydia pneumoniae, Pasteurella multocida, Pseudomonas aeruginosa, S. aureus*
Prodromal flu-like or predominantly upper respiratory tract symptoms, followed by pneumonia	*Mycoplasma* spp., *Chlamydia* spp., *Legionella* spp., *Coxiella burnetii*, respiratory viruses
Extrapulmonary manifestations	*Mycoplasma* spp. (variety see Table 34.7), *Coxiella* spp. (variety see Table 34.7), Herpesviruses (skin and mucocutaneous), *Y. pestis* (lymphadenopathy), leptospirosis (renal and hepatic), *Legionella* spp.
Tuberculosis-like illness	*K. pneumoniae* (chronic form), *B. pseudomallei* (melioidosis), *Mycobacteria* spp., e.g. *kansasii*, *Cryptococcus neoformans*
Locally invasive disease with abscess and sinus formation	*Actinomycetes* spp., *Nocardia* (immunocompromised host), *Pseudomonas mallei* (glanders), *Eikenella corrodens*
Diarrhea	*Legionella* spp., *S. pneumoniae*, *C. burnetii*, tularemia (*Francisella tularensis*)
Organisms that may cause pneumonia as a rare complication of main infection	*Salmonella typhi or paratyphi* (enteric fever), *Brucella abortus* (brucellosis), *Bacillus anthracis* (anthrax), *Listeria monocytogenes*
Although it is usually not possible to say which pathogen is responsible for CAP on clinical criteria alone, it is helpful to have some understanding of the usual pattern of illness for common pathogens.	

important to realize that patients who have pneumococcal or staphylococcal infection may become critically ill within hours, whereas in *Mycoplasma* infection symptoms can be present for 2–3 weeks.

Classic signs of lobar consolidation are infrequent and it is more common to hear localized crackles. If pneumonia is complicated by parapneumonic pleural effusion or empyema, lower zone dullness to percussion and reduced breath sounds may be present. Abdominal

TABLE 34-6 -- Classic features of more common pathogens and clinical pointers to diagnosis.

CLASSIC FEATURES OF MORE COMMON PATHOGENS AND CLINICAL POINTERS TO DIAGNOSIS	
Organism	**Classic features**
Streptococcus pneumoniae	Abrupt onset over hours with rigors, fever, malaise, tachycardia and tachypnea. Dry cough initially, then productive of 'rusty' sputum. Less acute presentation (possibly modified by antibiotics). Worsening of cardiac or respiratory failure, confusion or general physical deterioration in elderly or debilitated. Herpes labialis.
Staphylococcus aureus	Rapid onset of fever, confusion and respiratory distress, often after influenza. May be secondary to infected intravenous cannulae or right-sided endocarditis. Multiple pulmonary abscesses, empyema. Look for a potential source.
Haemophilus influenzae	Two forms: typable strains cause acute severe infection with lobar consolidation in children; vaccination has dramatically reduced this. Nontypeable strains cause patchy bronchopneumonia with persistent purulent sputum and malaise. Subacute bronchopneumonia in patients with pre-existing lung disease.

Legionella spp.	Two forms: Pontiac fever — acute self-limiting flu-like illness. Pneumonia — abrupt onset with high fever, rigors, malaise and myalgia. Slight cough, in half, severe headache, confusion and delirium, diarrhea and abdominal pain. Neurologic (cerebellar) signs. Renal failure. Elevated creatine kinase.
Klebsiella spp.	Acute severe pneumonia with thick, tenacious bloodstained sputum, commonly affects the right upper lobe. Dense consolidation on chest radiograph with 'bulging fissures'.
Mycoplasma spp.	Upper respiratory tract symptoms such as sore throat and coryza followed after 4–7 days by fever, dry cough and dyspnea. In some cases erythema nodosum, erythema multiforme, Stevens-Johnson syndrome, myringitis, splenomegaly, generalized lymphadenopathy and salivary gland enlargement.
Chlamydia spp.	Psittacosis — mild flu-like illness to fulminating pneumonias with multiple organ failure. Macular rash (Horden's spots) rarely in psittacosis. Diarrhea occurs in 25%. *Chlamydia pneumoniae* commonly causes sore throat, prominent cough, prolonged bronchitis in young adults and mild pneumonia.
Coxiella spp.	Q fever manifests with a flu-like illness and pneumonia of varying severity. Multisystem involvement — arthritis, thromboplebitis, arteritis, pericarditis, myocarditis and chronic endocarditis, particularly of the aortic valve.
Influenza	Flu symptoms — fever, rigors, myalgias may be followed by severe pneumonia or by secondary bacterial pneumonia. Epidemics (occasionally pandemics) in winter months.
Viruses*	Coryzal infection, cough and rarely pneumonia.
Herpesvirus	Both varicella-zoster and herpes simplex may cause severe pneumonia, which follows 2–3 days after clinical evidence of infection (cutaneous lesions). Rash of chickenpox in varicella. Cold sore or primary oral lesions in herpes simplex.
Although classic clinical features are described in most texts, in practice there may be considerable overlap.	

* Parainfluenza, RSV, adenovirus, coronavirus, Coxsackie virus

tenderness is not unusual, especially in lower lobe pneumonia or if there is associated hepatitis. There are no specific symptoms and signs that permit a confident clinical diagnosis of a particular etiology, although some pathogens are more often associated with a particular pattern.[29] Commonly recognized patterns of pneumonic illness are described in Table 34.5 and the pathogens that may be responsible are listed. Occasionally, a specific clinical feature or characteristic pattern may suggest a specific pathogen. For example, herpes labialis is more common in pneumococcal pneumonia, and erythema nodosum and erythema multiforme in *Mycoplasma* infection. The rash of chickenpox is always present with varicella pneumonia. *Mycoplasma* pneumonia and Q fever have a variety of extrapulmonary

TABLE 34-7 -- History and examination findings that suggest a specific diagnosis.

HISTORY AND EXAMINATION FINDINGS THAT SUGGEST A SPECIFIC DIAGNOSIS	
History	**Pathogen**
Alcoholism	*Klebsiella pneumoniae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, anaerobes
Chronic obstructive pulmonary disease	*S. pneumoniae, Haemophilus influenzae Moraxella catarrhalis*
Animal exposure	
Birds	*Chlamydia psittaci* (psittacosis)
Rats, squirrels, rabbits	*Yersinia pestis* (plague), tularemia
Rats, mice	*Leptospira* spp.
Horses	*Burkholderia mallei* (glanders)
Cats	*Coxiella burnetii* (Q fever), *Pasteurella multocida*
Cattle, sheep, goats	*C. burnetii*
Corticosteroid therapy	*S. aureus*, *Mycobacterium tuberculosis*, *Pneumocystis carinii*, *Legionella* spp.
AIDS/immunocompromised/iv drug abuse	*Mycobacterium* spp., *P. carinii*, fungal diseases, cytomegalovirus
Travel	
Thailand, South East Asia	*Burkholderia pseudomallei* (melioidosis)
Asia, Africa, Central and, South America	*Paragonimus westermani* (paragonimiasis)
Exposure to contaminated water systems	*Legionella pneumophila*
Examination	**Pathogen**
Skin	
Erythema multiforme	*Mycoplasma pneumoniae*
Maculopapular rash	Measles
Erythema nodosum	*Chlamydia pneumoniae*
Erythema gangrenosum	*M. tuberculosis, Pseudomonas aeruginosa, Serratia marcescens*
Mouth	
Dental caries	Anaerobic pneumonia
Herpes simplex	*S. pneumoniae*
Ears	
Bullous myringitis	*M. pneumoniae*
Neurology	
Poor gag reflex; altered conscious level; recent seizure	Aspiration
Cerebellar ataxia	*M. pneumoniae, L. pneumophila*
Encephalitis	*M. pneumoniae, C. burnetii*
Specific clinical features may occasionally point to a specific pathogen and may influence management.	

manifestations that, if present, may point to the diagnosis. Classic and some specific features of the more common pathogens are shown in Table 34.6 . Table 34.7 gives a more comprehensive list of clues in the history and examination that may suggest a specific pathogen.

Differential diagnosis of pneumonia

Pneumonia is most commonly confused with pulmonary infarction and pulmonary edema, and indeed may co-exist with either of these conditions. Careful attention to the exact sequence of the events in the history, for example establishing whether there was a prodrome of symptoms suggesting upper respiratory infection, may help point to pneumonia. Even with expert interpretation of examination findings and basic investigations the diagnosis may still be obscure and further investigations may be indicated. In practice, treatment is often given for more than one condition while further investigations are awaited. Pulmonary embolism may need to be excluded by ventilation perfusion scanning or pulmonary angiography. Less common differential diagnosis includes primary or metastatic lung cancer, pulmonary eosinophilia

and acute allergic or cryptogenic alveolitis. Hepatic or subphrenic abscess, pancreatitis or perforated peptic ulcer may mimic basal pneumonia.

DIAGNOSIS

The purpose of investigations in CAP are:

- to confirm the diagnosis of pneumonia;
- to determine etiology;
- to assess severity;
- to determine the impact of the illness on any underlying conditions, such as COPD or cardiac failure; and
- to provide data for epidemiologic purposes.

They can be broadly divided into general investigations, which help with the first three, and those that are mainly aimed at determining etiology.

Chest radiography, biochemistry and hematology

In relatively well patients who have suspected mild pneumonia seen in the community, investigations, including chest radiography, are not required but hypoxia should be excluded by means of pulse oximetry.

A chest radiograph is required for diagnosis of CAP and usually shows lobar or segmental opacification in bacterial pneumonias and in the majority of atypical infections. Less commonly, patchy peribronchial shadowing or more diffuse nodular or ground-glass opacification is seen, particularly in viral and atypical infections. The lower lobes are most commonly affected in all types of pneumonia, and small pleural effusions can be detected in about one-quarter of cases, especially if a lateral decubitus film is taken. Multilobar pneumonia is a feature of severe disease, and spread to other lobes despite appropriate antibiotics is seen in *Legionella* and *M. pneumoniae* infections. Hilar lymphadenopathy is unusual except in *Mycoplasma* pneumonia, particularly in children. Cavitation is uncommon but is a classic feature of *Staphylococcus aureus* and *Streptococcus pneumoniae* serotype 3 infections.

Clearance of radiographic changes usually occurs after about 8 weeks but varies from 2 weeks to many months depending on the age of the patient, the severity of pneumonia, the presence of preexisting lung disease and the pathogen. The rates of resolution of radiographic pulmonary shadows in different pneumonias are shown in Figure 34.3 . [30] Bacteremic pneumococcal pneumonia and *Legionella* infections are particularly slow to clear. After resolution of the illness it is important to arrange a further chest radiograph, as unsuspected malignant disease is surprisingly common. One study revealed the presence of unsuspected malignant disease in 7% of

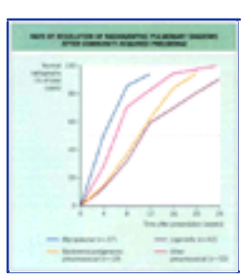

Figure 34-3 Rate of resolution of radiographic pulmonary shadows after CAP. Pneumonia can take 4–8 weeks to clear radiographically even in less severe cases such as *Mycoplasma* pneumonia. More severe pneumonias such as *Legionella* and bacteremic pneumococcal pneumonia take longer to resolve, sometimes up to 6 months. *Data from Macfarlane et al.*[30]

pneumonia cases (17% if limited to smokers) in patients over the age of 60 years. [3]

A full blood count, renal, electrolyte and liver biochemical profiles, a blood glucose and an erythrocyte sedimentation rate or C-reactive protein are useful general investigations. In most cases of pneumonia caused by *S. pneumoniae* or *H. influenzae*, the white blood cell count is above 15×10^9 /l; it is usually marginally raised in *Legionella* infections ($11–15 \times 10^9$ /l). Mildly raised hepatic enzymes and bilirubin are not uncommon in bacterial pneumonias, particularly if there is bacteremia. Raised blood urea, hyponatremia, hypokalemia, hypoalbuminemia, hyperglycemia, proteinuria and hematuria can be present in all severe pneumonias but none indicates etiology. Hyponatremia is seen in 50% of patients who have *Legionella* pneumonia.

Microbiologic investigations

For identification of the pathogen, sputum and pleural fluid (if an effusion is present) should be Gram stained and cultured. Sputum Gram staining can provide a specific and rapid diagnosis in about one-fifth of cases of pneumococcal and staphylococcal pneumonia, when large numbers of a predominant organism are usually seen. Sputum culture is less specific because it is often contaminated with upper respiratory tract organisms, and it is not produced in one-quarter to one-third of patients in the early stages of pneumonia. In addition, even a single dose of antibiotic can prevent a positive culture of *S. pneumoniae* and *H. influenzae*, and this occurs in over one-half of patients admitted to hospital in the UK. Even in the presence of untreated bacteremic pneumococcal pneumonia, sputum culture is negative in over one-half of patients. Blood cultures are positive in less than one-quarter of patients who have bacterial pneumonia who present to hospital, but when they are positive they are usually specific.

TABLE 34-8 -- Investigations aimed at determining etiology of community-acquired pneumonia.

INVESTIGATIONS AIMED AT DETERMINING ETIOLOGY OF CAP		
Investigation		**Comments**
General microbiology	Sputum Gram stain	Rapid and widely available
		Low sensitivity (10%)
		High specificity if positive (70–80%)
	Sputum culture	Prior antibiotics and contamination with oropharyngeal bacteria is a problem
	Blood culture	Positive in 20–25% of bacterial pneumonias and relates to etiology and prognosis
	Pleural fluid stain and culture	Essential to exclude empyema
	Nasopharygeal swabs	Useful in children, used to diagnose viral infections
Serologic tests	Acute and convalescent sera	Retrospective diagnosis of viral, atypical and *Legionella* infections
	Cold agglutinins	Positive in about 50% of cases of *Mycoplasma* infection
	Antigen detection	Pneumococcal-sputum positive in 80%, urine in 36–45%, serum in 9–23% of *Legionella* spp., encapsulated forms of *Haemophilus influenzae, Mycoplasma* spp., *Chlamydia* spp. and specifically *Chlamydia pneumoniae* and *Legionella pneumophila* serogroup 1
Invasive tests	Transtracheal aspiration, bronchoalveolar lavage, protected specimen bronchial brush (PSB), percutaneous needle biopsy, lung biopsy	Consider in patients who are immunocompromised, who fail to respond. Bronchoalveolar lavage and PSB are most often used
Immediate diagnosis is only possible in about 15% of cases of CAP. Even in research studies in which extensive investigations have been performed, no causative organism is identified in 30% of cases.		

Antigen detection, serology and other investigations

Antigen detection is useful for diagnosis of CAP caused by *S. pneumoniae*, encapsulated forms of *H. influenzae*, *Mycoplasma* and *Chlamydia* spp. (including specific identification of *C. pneumoniae*), and *Legionella pneumophila* serogroup 1. Detection of pneumococcal polysaccharide capsular antigen is particularly helpful as it may be detected in 80% of sputum samples, 36–45% of urine and 9–23% of serum. [31] [32] *Mycoplasma* antigen detection is a new test that improves the rate of diagnosis; *Legionella* antigen is present in urine in the first week of the illness before serum antibodies are detectable and is increasingly being found useful in early diagnosis. The most useful diagnostic tests are shown in Table 34.8 . Antigen detection adds to the cost of managing pneumonia and for the majority of patients does not influence outcome. It is therefore appropriate to reserve these tests for the more severely ill patient.

Serologic methods are used to diagnose viral, atypical and *Legionella* infections. A fourfold or greater increase in specific antibody titer in blood taken early in the course of the illness and after 10–14 days is evidence of recent infection, and high unchanging titers are suggestive. The main limitation of serology is that the diagnosis is obtained too late to influence initial management. This forces the adoption of an empiric approach to the choice of antibiotic. Specific

IgM antibody detection can be used to obtain a more rapid diagnosis in *Mycoplasma* and *Legionella* infections, although their sensitivity and specificity varies. Direct fluorescent antibody tests are available for staining respiratory secretions to detect *Legionella* spp. and some viruses, although these are not universally available. Cold agglutinins are present in about 50% of *Mycoplasma* infections but are a non-specific finding.

Viral isolation, culture and identification is a lengthy process and is of little practical value in most cases. However, in difficult cases when no diagnosis has been reached and there is no resolution it may provide a diagnosis, particularly in the immunocompromised host. Amplification of DNA from a variety of pathogens using the polymerase chain reaction has been attempted but these techniques remain under investigation.

In patients in whom the diagnosis is obscure, who fail to respond to empiric treatment or who are particularly ill or immunocompromised, invasive techniques may be indicated to sample lower respiratory secretions or lung tissue. These include fiberoptic bronchoscopy with lavage, quantitative culture and protected bronchial brush (see Invasive techniques, Chapter 35), percutaneous needle aspiration and lung biopsy (transbronchial or open). Whenever invasive techniques are used and when an unusual diagnostic test is indicated, it is most important for clinicians and microbiologists to liaise. This allows a decision about the most appropriate tests and the correct samples and ensures the laboratory is ready to process the samples.

MANAGEMENT

The management of CAP depends on the severity of the illness, the presence of underlying disease and the age of the patient. At best, immediate diagnostic tests may identify the pathogen in fewer than 30% of cases and therefore an empiric antibiotic regimen is necessary. The

TABLE 34-9 -- Features distinguishing severe pneumonia.

FEATURES DISTINGUISHING SEVERE PNEUMONIA		
Features associated with poor outcome	**Factors associated with increased mortality (from a large meta-analysis[11])**	**OR/CI (95%)**
Clinical	**Clinical**	
Age >60 years	Male sex	1.3 (1.2–1.4)
Pre-existing medical illness	Hypothermia	5.0 (2.4–10.4)
Confusion	Systolic hypotension	4.8 (2.8–8.3)
New atrial fibrillation	Tachypnea	2.9 (1.7–4.9)
Respiratory rate >30/min*	Diabetes mellitus	1.3 (1.1–1.5)
Diastolic blood pressure =60mmHg*	Neoplastic disease	2.8 (2.4–3.1)
Cyanosis	Neurologic disease	4.6 (2.3–8.9)
Investigations	**Investigations**	
White blood cells <4 × 10^9 /l or >30 × 10^9 /l	Bacteremia	2.8 (2.3–3.6)
Blood urea >7mmol/l*	Leukopenia	2.5 (1.6–3.7)
Hypoxia (Pao_2 < 8kPa)	Multilobar radiographic shadows	3.1 (1.9–5.1)
Multilobar or spreading radiographic shadows		
Severity of pneumonia has been determined by identifying those factors that are associated with increased risk of death. Some (*) are consistently identified in different studies and are used as a basis for guiding management.		

* Two or more of these three features increase risk of death by nine- to 21-fold.[29]

spectrum of organisms in the elderly and younger adult is similar, but it differs in children. In severe pneumonia, *Legionella* infection is more frequently found and hence different empiric antibiotics are required. Similarly, *H. influenzae* is more often found in patients who have pre-existing lung disease.

Assessment of severity

Studies of CAP have identified several prognostic factors on the basis of clinical and investigative features (Table 34.9).[29] [33] The American Thoracic Society guidelines[12] classify severe pneumonia on the basis of two or more minor criteria:

- low blood pressure (systolic =90mmHg, diastolic =60mmHg);
- severe respiratory failure (Pa_{O_2}/Fi_{O_2} ratio below 250; and
- bilateral or multilobe radiographic shadowing.

The British Thoracic Society Guidelines[34] suggest the CURB score for severity assessment: one point for each of confusion (new mental confusion with an Abbreviated Mental Test score of <9), urea (>7mmol/l), respiratory rate (=30 breaths per min) and blood pressure (systolic <90mmHg and/or diastolic =60mmHg).

Figure 34-4 Algorithm for the management of CAP. *Adapted from the Nottingham City Hospital CAP Guidelines, 1996.*

A modification of this score (CURB 65) has been shown by an international validation study to provide a useful way to stratify patients into different management

groups.[34A]

General management

All patients who have CAP, whether managed at home or in hospital, should rest in bed, have adequate oral fluids and should not smoke. Simple analgesics or nonsteroidal anti-inflammatory drugs can be given for pleural pain and fever. Chest physiotherapy is only useful if patients have a pre-existing lung disease, such as chronic bronchitis or bronchiectasis, that may lead to sputum retention. Patients who have moderate or severe CAP should be admitted to hospital and receive oxygen supplementation by face mask. Patients who have severe pneumonia should be monitored in a high-dependency unit and if necessary transferred to intensive care. The danger period is in the first 3–4 days after admission. In severe CAP the onset of progressive cardiorespiratory failure can be very rapid and assisted ventilation with inotropic support can preserve life while a response to antibiotics is awaited. Generally, previously fit adults will require ventilation if they are unable to maintain a Pao_2 of 8kPa with maximum supplemental oxygen. Assisted ventilation may be required for many days or weeks before successful weaning. In one study of severe CAP some patients weaned after 4 weeks of ventilation have survived.[35] Early attention to nutritional requirements is important in severe pneumonia. An algorithm for the management of CAP in adults is shown in Figure 34.4 .

TABLE 34-10 -- Empiric antibiotic therapy for CAP.

EMPIRIC ANTIBIOTIC THERAPY FOR CAP						
Choice	**Guidelines**	**Outpatients**		**Hospitalised**		
				Non-intensive care		**Intensive care**
		No modifying factors	**Modifying factors**	**No modifying factors**	**Modifying factors**	
First Choice	American	AZ or CLR	ß-lactam (CPD, CFX, high-dose AMX) + macrolide or DOX	iv AZ alone or (if allergic) DOX + ß-lactam	iv ß-lactam (CAX, CRX, AMP/sulbactam) + macrolide or DOX	iv ß-lactam (CAX, CRX) + either iv macrolide (AZ) or iv fluoroquinolone
	Canadian	Macrolide	Macrolide (AZ or CLR) or APF	APF	APF	APF + CAX, CRX or ß-lactam/ß-lactamase
	British	AMX	AMX	AMX (oral) or AMP (iv) or BPN iv + E or CLR	AMX (oral) or AMP (iv) or BPN iv + E or CLR	CAC or CFX or CAX or CRX + E or CLR ± rifampicin
	French	AMX	CAC			Macrolide + 3rd generation cephalosporin
	Spanish	PEN/AMP	CAC			Macrolide + 3rd generation cephalosporin
Second Choice	American	DOX	APF	PAF	APF (iv)	
	Canadian	DOX	CAC + macrolide or 2nd generation cephalosporin	2nd , 3rd or 4th generation cephalosporin + macrolide		iv macrolide + CAX, CRX or ß-lactam/ß-lactamase
	British	E or CLR	E or CLR	LEV (or any APF when more available)	LEV (or any APF when more available)	APF + BPN
	French	Macrolide	CAC			Macrolide + CAC
	Spanish	Macrolide	CAC			Quinolone + 3rd generation cephalosporin
AMP, ampicillin; AMX, amoxicillin; APF, antipneumococcal fluoroquinolone; AZ, azithromycin; BPN, benzyl penicillin; CAC, amoxicillin/clavulanate (co-amoxiclav); CAX, cefotaxime; CFX, cefuroxime; CLR, clarithromycin; CPD, cefpodoxime; CRX, ceftriaxone; DOX, doxycycline; E, erythromycin; LEV, levofloxacin; PEN, penicillin.						
A summary of recommendations from five countries is shown. Not all countries give specific recommendations for all categories of pneumonia						

Antibiotic therapy

Appropriate empiric antibiotic therapy choices are based on guidelines from five different countries (Table 34.10).[12] [34] [36] [37] The choices vary according to severity of illness, history of pre-existing chest disease and presence of penicillin hypersensitivity. In practice, most patients who have mild or moderate pneumonia can be managed with oral antibiotics, although there are large differences between oral and intravenous blood and tissue concentrations for some agents. Penicillins and quinolones are well absorbed and generally have an oral bioavailability of over 60% of serum. The newer third-generation cephalosporins have approximately 30% oral bioavailability, which may fall if the patient is not eating. Newer macrolides also have approximately 30% oral bioavailability but the most commonly used, erythromycin, has only 5–11%, depending on the preparation; thus, a 500mg dose will at best be equivalent to only 50mg given intravenously.

Antibiotics vary in their gastrointestinal side effects. The penicillins, quinolones and tetracyclines are relatively well tolerated, cephalosporins (especially oral third-generation) and new macrolides less so, and erythromycin causes enough side effects to warrant discontinuation of treatment in 10–30% of patients (depending on the preparation).[38] [39] Recently, newer fluoroquinolones with improved antipneumococcal activity have been included in guidelines and are being used widely. If they are used as first-line therapy, benzyl penicillin is added in severe infections. This has in part been prompted by the rising incidence of *Clostridium difficile* infection resulting in colitis, thought to be a consequence of use of broad-spectrum cephalosporins.

Adult nonsevere community-acquired pneumonia

In this category, *S. pneumoniae* is the most common organism, although other organisms such as *M. pneumoniae*, *C. pneumoniae* and *H. influenzae* may be a reason for a poor response. The latter is more likely if there is pre-existing lung disease. An aminopenicillin such as oral amoxicillin or intravenous ampicillin is an appropriate choice. In patients allergic to penicillin, a macrolide such as erythromycin can be substituted. If there is no improvement after 48 hours, the diagnosis should be reviewed and therapy adjusted if the pathogen has been identified. If pre-existing chest disease is present amoxicillin-clavulanate, a quinolone (levofloxacin or moxifloxacin) or a parenteral cephalosporin such as cefuroxime can be substituted to cover ß-lactamase-producing *H. influenzae* or *M. catarrhalis*. If there is no underlying pulmonary disease then a macrolide may be substituted to cover *M. pneumoniae* infections. Erythromycin is a less satisfactory choice for elderly patients because of the infrequency of atypical pathogens in this group and its poor activity against *H. influenzae*. Some recently updated guidelines specifically recommend newer macrolides and fluoroquinolones with antipneumococcal activity.[12] [36]

Adult severe community-acquired pneumonia

In severe infection, *Legionella* spp. becomes more important and therefore a macrolide and a ß-lactamase-stable ß-lactam (such as cefuroxime or amoxicillin-clavulanate) is recommended initially. This will cover all likely pathogens, including the commoner (pneumococcal, staphylococcal and *Legionella*) infections. A fluoroquinolone with antipneumococcal activity can be substituted for the macrolide. It is important to start antibiotic therapy as soon as possible and to use the intravenous route, although once there is clear clinical improvement this can be changed to the oral route. If there is no response to treatment, specialist advice should be sought. The diagnosis should be reviewed with all available clinical and laboratory data and consideration given to invasive diagnostic techniques. If *Legionella* infection is thought to be a possible cause, rifampin (rifampicin) or ciprofloxacin may be added to the macrolide. Some studies have suggested that clarithromycin may be more effective than erythromycin. Consideration should also be given to the possibility of secondary hospital-acquired pneumonia and appropriate antibiotics administered.

The duration of antibiotic therapy is debatable and is best dictated by clinical improvement associated with some knowledge of the half-life of the drug in plasma and tissues. In uncomplicated mild or moderate pneumonia a 5- to 7-day course is usually adequate. Patients started on intravenous therapy may be transferred to oral

therapy 24 hours after there has been a clear improvement with resolution of fever, and they should receive antibiotics for 5–10 days thereafter. Prolonged therapy may be required if lung cavitation occurs.

COMPLICATIONS

Most patients recover from CAP without complications. In about one-quarter of patients a small proteinaceous sympathetic effusion develops and resolves spontaneously. Such effusions may cause persistent fever after resolution of pneumonia even if all organisms have been eliminated. They should always be sampled to exclude empyema, which, if present, will require drainage (Fig. 34.5). Pulmonary abscess and pneumothorax are important complications that are discussed in Chapter 36 .

Figure 34-5 Chest radiograph showing a right sided lobar pneumonia with right empyema in a 25-year-old man who was training for the British rowing team. Prompt treatment with intercostal drainage ensured that he recovered without loss of lung function.

Chapter 35 - Hospital-acquired Pneumonia

John T Macfarlane
David R Baldwin

EPIDEMIOLOGY

Definition

Hospital-acquired pneumonia (HAP) is traditionally defined as pneumonia that occurs more than 48 hours after hospital admission, excluding any infection incubating at the time of admission.[1] It has been suggested that this definition is no longer adequate because cases can occur within 48 hours of hospitalization, particularly as a consequence of emergency intubation, or cardiopulmonary resuscitation.[2] Ventilator-associated pneumonia (VAP) can be regarded as a particular subgroup of HAP for which the incidence, etiology, investigation and outcome are somewhat different. It should be remembered that patients recently discharged from hospital who develop pneumonia may have an illness with features more in keeping with hospital-acquired rather than community-acquired infection.

Incidence and size of the problem

Pneumonia is the second most common infection acquired in hospital after urinary tract infection and is associated with the highest mortality rate. Hospital-acquired pneumonia is estimated to occur in 300,000 hospitalized patients each year in the USA. It adds 5–9 days to the hospital stay of survivors[3] [4] and billions of dollars to health care costs. In the UK, around 9% of patients have a hospital-acquired infection at any one time, increasing health costs by £1 billion a year.[5] The incidence varies with type of hospital and ward and age of the patient. The incidence is lowest in district hospitals and on general medical and pediatric wards, and higher in teaching hospitals (presumably because of the increased complexity of medical cases)[3] [4] and in patients over 65 years of age. The highest incidence is found in the intensive care unit (ICU). The attack rate of pneumonia for patients receiving assisted ventilation rises progressively with duration of stay in the ICU;[6] [7] prevalences of up to 50% have been reported after 7 days of mechanical ventilation.[7] [8]

Mortality rate

Reported crude mortality rates for HAP range up to 70%.[9] [10] This is misleading because pneumonia may not be the true cause of death in patients who have multiple pathology. Pneumonia has been estimated to be the 'attributable cause' of death in one-third to one-half of patients who develop HAP, particularly in ventilated patients.[1] [3] [8]

PATHOGENESIS AND ETIOLOGIC AGENTS

Pathogenesis

Factors associated with the pathogenesis of HAP are summarized in Figure 35.1 .[11] Hospital-acquired pneumonia is usually caused by the aspiration or translocation of bacteria that colonize the upper respiratory tract, into the lungs. Aspiration of upper respiratory tract secretions is usually the result of impaired mechanical host defense; subsequent colonization of the lower airway is facilitated by debility, defective host defense and changes in bacterial mucosal adherence factors. Direct translocation of upper respiratory bacteria, and bacteria carried by health care workers into the lower respiratory tract by the act of intubation is also a risk factor, especially during emergency intubation. Less commonly, other mechanisms may be involved, including hematogenous spread of infection to the lungs from a distant focus and inhalation of pathogens aerosolized either from contaminated respiratory equipment (e.g. ventilator or nebulizer equipment) or from the hospital environment (e.g. showers and water systems colonized with *Legionella* bacteria).

Microaspiration of pharyngeal secretions is usually clinically silent and occurs even in healthy subjects during sleep, but becomes very frequent in patients who have reduced consciousness.[3] Aspiration is almost inevitable in intubated patients because the normal laryngeal barrier between the oropharynx and the lower respiratory tract is compromised. Secretions pool above the cuff of the endotracheal tube from where they leak into the lower airway. In the healthy individual, aspirated secretions can be dealt with effectively by lung defenses, including mucociliary clearance and alveolar macrophages. When host defenses are impaired, bacteria are able to proliferate and cause pneumonia.

The oropharynx of debilitated patients becomes colonized rapidly by enteric Gram-negative bacteria (EGNB). These bacteria are not normally present in the upper respiratory tract and the frequency of colonization increases with increasing severity of the underlying illness, use of antibiotics and duration of hospital stay. Up to three-quarters of critically ill patients become colonized within a few days of hospital admission.[3] [4] Oropharyngeal colonization is often a harbinger of subsequent pneumonia.[12] [13] The temporal sequence of bacterial colonization in patients receiving mechanical ventilation is reported as oropharynx (36 hours), stomach (36–60 hours), lower respiratory tract (60–84 hours) and interior of the endotracheal tube (60–96 hours).[14]

Colonization of the lower respiratory tract is facilitated by changes in respiratory epithelial cells that favor bacterial adherence. Alteration of cell surface carbohydrates, loss of surface fibronectin and alteration of epithelial cell bacterial receptors all contribute to enhanced colonization by pathogenic bacteria. [3] [12] [13]

Causative organisms

The pathogens associated with HAP have been studied extensively. However, variations in the patient populations studied, the methods used to obtain and analyze specimens and the definitions used for HAP have, until recently, made it difficult to obtain a sensible overview of the problem. Fortunately, guidelines from the American Thoracic Society (ATS),[1] the Canadian Consensus Conference[15] and other countries, [16] and information from other reviews[2] [10] [17] are now in existence; these propose a classification of the pathogens causing HAP that is both sensible and practical. The approach relies on assessing three factors, including disease severity, the presence of comorbid disease and other risk factors for specific pathogens, and the time of onset of the pneumonia, in considering likely pathogens and therefore guiding initial antibiotic selection.

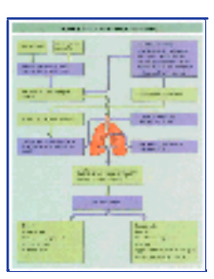

Figure 35-1 Factors involved in the pathogenesis of hospital-acquired pneumonia. *Reproduced from Macfarlane JT. Pneumonia. Medicine International 1986; 3 by kind permission of the Medicine Publishing Company.*

The Canadian Consensus document was the first to bring some order into the management of HAP, by accepting the problems inherent in the diagnosis of HAP and the difficulties in identifying an etiology. The committee argued that any initial therapy would be empiric and would need to take account of factors that would most likely

relate to outcome, specifically risk factors for specific pathogens and also severity of infection. In the ATS guidelines, the time of onset of pneumonia was introduced as the third variable.[16]

The spectrum of potential pathogens associated with HAP differs from that of community-acquired pneumonia. The bacterial pathogens most frequently associated with HAP are EGNB and *Staphylococcus aureus*. Mixed infections are not unusual, particularly in VAP. The role of viruses has not been widely studied, but is likely to be important, especially at times of community outbreaks of viral infection, when staff and visitors may transmit viral infection to hospitalized patients.

The potential pathogens can be categorized into three groups depending on the severity of the pneumonia, the presence of additional risk factors (e.g. comorbidity, previous antibiotic therapy and aspiration), and the duration of hospitalization. A group of 'core' pathogens must be considered in all cases of HAP. These include *Haemophilus influenzae* and Gram-positive organisms such as *Streptococcus pneumoniae* and methicillin-sensitive *S. aureus* and 'sensitive' EGNB (e.g. *Enterobacter* spp., *Escherichia coli*, *Klebsiella* spp., *Proteus* spp. and *Serratia marcescens*). Other pathogens, in addition to the 'core' pathogens, must be considered in certain circumstances. These include resistant Gram-negative organisms such as *Pseudomonas aeruginosa*, *Enterobacter* spp., *Klebsiella pneumoniae* and *Acinetobacter* spp., and methicillin-resistant *S. aureus* (MRSA) in cases of 'late-onset' severe pneumonia. Some pathogens will be more likely in the presence of additional risk factors such as aspiration (anaerobic organisms) or known exposure to a hospital source of *Legionella* infection (*Legionella* spp.).

For all grades of severity of HAP the duration of hospital stay before the development of infection has the same broad influence. If HAP occurs within 5 days of hospitalization, normal community respiratory commensals including *S. pneumoniae*, *H. influenzae* and *S. aureus* are the most frequently isolated pathogens. [1] [18] [19] Enteric Gram-negative bacteria become more common with increasing duration of hospital stay, presumably because the 'community'

Figure 35-2 Algorithm for classifying patients who have hospital-acquired pneumonia to provide a basis for empiric antibiotic management. *Adapted from Figure 1 in the American Thoracic Society consensus statement.*[1]

pathogens initially colonizing the oropharynx are replaced by 'hospital' pathogens. Resistant organisms such as *Pseudomonas* spp. are more likely after exposure to multiple antibiotics, or if the patient is nursed in an area of high risk of harboring such organisms, such as the ICU. An algorithm for classifying patients who have HAP is shown in Figure 35.2 . The three groups are considered below.

Patients who have mild-to-moderate HAP, no unusual risk factors and onset any time, or patients who have severe HAP with early onset

In this situation the 'core' pathogens are most likely and the antibiotic choice should reflect this possibility (Table 35.1).

Patients who have mild-to-moderate HAP, additional risk factors and onset at any time

In addition to the 'core' pathogens shown in Table 35.1 , other bacteria must be considered, depending on which risk factor is present

TABLE 35-1 -- A guide to likely 'core' pathogens and empiric antibiotic choice for patients who have non-severe HAP without any unusual risk factors, occurring at any time or early-onset severe HAP.*

A GUIDE TO LIKELY 'CORE' PATHOGENS AND EMPIRIC ANTIBIOTIC CHOICE FOR PATIENTS WHO HAVE NON-SEVERE HAP WITHOUT ANY UNUSUAL RISK FACTORS, OCCURRING AT ANY TIME OR EARLY-ONSET SEVERE HAP	
'Core' organisms	**'Core' antibiotics**
Escherichia coli	2nd or 3rd generation cephalosporins
Klebsiella spp.	or
Proteus spp.	
Serratia marcescens	ß-lactam/ß-lactamase inhibitor combination
Enterobacter spp.	
Haemophilus influenzae	Fluoroquinolone with enhanced
Streptococcus pneumoniae	pneumococcal activity (also if penicillin allergic)
Staphylococcus aureus (methicillin-sensitive)	
Specific antibiotics are mentioned in the text.	

** Adapted from Table 1 in the American Thoracic Society consensus statement.* [1]

TABLE 35-2 -- A guide to likely additional pathogens and antibiotic therapy required for patients who have mild-to-moderate HAP and additional risk factors present.*

A GUIDE TO LIKELY ADDITIONAL PATHOGENS AND ANTIBIOTIC THERAPY REQUIRED FOR PATIENTS WHO HAVE MILD-TO-MODERATE HAP AND ADDITIONAL RISK FACTORS PRESENT		
Core organisms plus:	**Core antibiotics plus:**	
Organism	**Risk factor**	**Antibiotics**
Anaerobes	Recent thoracoabdominal surgery	Clindamycin or ß-lactam ß-lactamase inhibitor combination
	Impaired swallowing	
	Witnessed aspiration	
	Dental sepsis	
Staphylococcus aureus	Coma	Consider adding vancomycin if MRSA possible
	Head trauma	
	Neurosurgery	
	Diabetes mellitus	
	Renal failure	
Legionella spp.	High-dose corticosteroids	MACROLIDE
	Organism endemic in hospital	+/- rifampicin
		+/- fluoroquinolone

Pseudomonas aeruginosa	Prior antibiotics	Treat as severe HAP (see Table 35.4)
	High-dose corticosteroids	
	Protonged ICU stay	
	Structured lung disease such as bronchiectasis	
Specific antibiotics are mentioned in the text.		

** Adapted from Table 2 in the American Thoracic Society consensus statement.*[1]

(Table 35.2). Aspiration of anaerobic organisms is more likely in certain patients, for example those with swallowing problems, poor dental hygiene or impaired consciousness. Using invasive techniques and specific anaerobic cultures,[20] such organisms can be identified in up to one-third of all patients who have HAP, but the true significance of these findings is debated in the absence of clear risk factors for anaerobic infection.[1] *Legionella* infection is well recognized as a sporadic and occasionally an endemic pathogen in the hospital environment. *Staph. aureus* infection is particularly associated with early infection in comatose patients, after multiple trauma or neurosurgical operations. The cause for this is not clear, but may relate to transfer of *S. aureus* from health care workers involved with resuscitation. However, MRSA is unlikely in this situation unless the patient has received multiple antibiotics before hospitalization.

Severe HAP

The definition of severe HAP is less developed than that for community-acquired pneumonia. Pointers to the presence of severe pneumonia are given in Table 35.3 .

When severe HAP occurs within 5 days of admission, the patient is likely to be infected by the core organisms, in particular *H. influenzae* and Gram-positive pathogens (see Table 35.1). With increasing duration of hospital stay, factors such as critical illness, mechanical ventilation, respiratory tract instrumentation, exposure to antibiotics, corticosteroids and other drugs and the ubiquitous presence of pathogenic organisms within the hospital, especially in the ICU, become increasingly important. In such circumstances resistant organisms such as *P. aeruginosa*, *Acinetobacter* spp. and MRSA must also be covered by initial therapy (Table 35.4). Infection with these organisms themselves denotes severe pneumonia because the mortality rate attributable to these organisms is greater than with other types of infection.

TABLE 35-3 -- Definition of severe HAP accepted by the American Thoracic Society.[A]

DEFINITION OF SEVERE HAP ACCEPTED BY THE AMERICAN THORACIC SOCIETY	
Chest radiographs	Multilobar, cavitating or rapidly progressing lung shadowing
	Admission required to ICU
Respiratory failure	Need for mechanical ventilation or
	Need for >35% oxygen to maintain arterial oxygen saturation >90%
Evidence of severe sepsis	Shock (systolic BP <90mmHg or diastolic BP <60mmHg)
	Need for vasopressors for >4 hours
	Urine output <80ml in 4 hours
	Renal dialysis required

Adapted from Table 4 in the American Thoracic Society consensus statement.[1]

TABLE 35-4 -- A guide to likely pathogens and appropriate empiric antibiotic therapy for patients with late-onset severe HAP, which develops after 5 days in hospital.[*]

A GUIDE TO LIKELY PATHOGENS AND APPROPRIATE EMPIRIC ANTIBIOTIC THERAPY FOR PATIENTS WITH LATE-ONSET SEVERE HAP, WHICH DEVELOPS AFTER 5 DAYS IN HOSPITAL	
Core organisms plus:	**Antibiotics**
Pseudomonas aeruginosa	Combination of:
	• Aminoglycoside or ciprofloxacin plus one of:
Acinetobacter spp.	• Antipseudomonal ß-lactamase stable ß-lactam antibiotic
	• Carbapenems
MRSA in some hospitals	• +/- Vancomycin
Those with early-onset severe HAP without unusual risk factors present are managed as shown in Table 35.1 .	

** Adapted from Table 3 in the American Thoracic Society consensus statement.* [1]

PREVENTION

With the enormous impact that HAP has on the workings and economy of hospitals, it is perhaps surprising that few evidence-based guidelines on prevention have been available until recently.[1] [3] [21] [22] A recent review has presented the evidence base for prevention of HAP[22] and highlighted the key areas to be addressed, as summarized below in descending order of importance:

- preventing colonization by hygiene, especially handwashing between patients;
- early enteral nutrition to enhance host responses;
- subglottic drainage of endotracheal tubes;
- selective digestive decontamination, especially in trauma patients;
- semirecumbent position and use of kinetic beds, to reduce aspiration of gastroesophageal contents;
- strict attention to best ventilator equipment techniques; and
- maintenance of low gastric pH, but a balance of reducing risk of infection and increased risk of gastrointestinal bleeding.

The principles of prevention relate to three factors including:

- reducing any predisposing factors for acquiring pneumonia,
- preventing colonization, and
- enhancing host defenses.

Reducing any predisposing factors for acquiring pneumonia includes cessation of smoking, weight reduction in the obese and improving control of coexisting disease

such as chronic obstructive pulmonary disease, diabetes mellitus or cardiac failure before elective surgery. Increasing the level of fitness for an operation is also likely to be of benefit, as are short preoperative hospital stays and operation times. Early nutrition is important in enhancing host defenses.

Prevention of colonization is currently the most practical approach to the general prevention of HAP.[22] The bacteria involved in nosocomial infection are frequently transmitted from patient to patient on the hands of health care workers and it is well established that use of handwashing, particularly with alcohol hand-rubs between patient contacts reduces cross-infection. Each staff member can contribute by adherence to a strict handwashing regimen. Unfortunately, compliance with handwashing strategies is a problem especially with medical staff.[23] Patient contact with staff harboring a viral respiratory infection should be avoided and influenza vaccination of staff during periods of high influenza activity should be ensured. Strict airway management during and after surgery is essential, and nasogastric and endotracheal tubes should be removed as early as possible. Noninvasive ventilation techniques carry less risk of VAP. Re-intubation increases the risk of infection, as does the use of nasal intubation, compared with the oral route. Aspiration of secretions that pool above the inflated endotracheal tube may be helpful in preventing lower respiratory colonization during prolonged mechanical ventilation.[22] Evaluation of swallowing should be a routine procedure for patients who have impaired consciousness or neuromuscular swallowing problems, with oral intake restricted as necessary. Avoidance of excess sedation may reduce the chance of silent aspiration.

It is now recognized that colonization of the gastroesophageal tract usually precedes subsequent contamination of the respiratory tree and gastric acidity plays an important part in preventing such colonization. Routine therapy with H_2 antagonists and proton pump inhibitors to reduce gastric acidity and 'prevent' stress gastric ulceration is no longer recommended, and meta-analyses support sucralfate therapy as being a safer alternative as far as reducing the incidence of HAP. Unfortunately the latter is a less effective antiulcer prophylaxis and H_2 antagonists and proton pump inhibitors should still be considered where the risk of ulceration is increased.[22] A recent meta-analysis concluded that selective decontamination of the gastrointestinal tract could reduce respiratory tract infections and overall mortality rate in some groups of critically ill patients, particularly after trauma.[24] However, there is risk of bacterial resistance and enthusiasm for selective decontamination of the gastrointestinal tract with topical and parenteral antibiotics has waxed and waned and has not become routine management in most ICUs.

One of the most important factors for prevention is probably the circumspect use of antibiotics and adoption of a strict and sensible hospital antibiotic policy, together with regular surveillance for HAP outbreaks and the antibiotic-resistant patterns of likely pathogens.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

The diagnosis of pneumonia may be obvious in the hospitalized patient who develops the classic symptoms of fever, malaise, cough, purulent sputum, localizing chest signs and consolidation on the chest radiograph. All too often, however, the situation is less straight-forward, with the list of differential diagnoses lengthening in proportion to the complexity of the underlying problem, for example:

- pulmonary infarction,
- adult respiratory distress syndrome,
- pulmonary edema,
- pulmonary hemorrhage,
- pulmonary vasculitis,
- underlying disease (e.g. malignancy),

- iatrogenic lung shadowing (e.g. drug toxicity or radiation pneumonitis), and
- pre-existing lung disease (e.g. fibrosing alveolitis).

Hospital-acquired pneumonia should be considered in the context of an illness developing after hospital admission and characterized by fever, leukocytosis, purulent sputum or tracheobronchial secretions and new or persisting infiltrates on the chest radiograph. However, the accuracy of a clinical diagnosis is poor compared with a microbiologic or pathologic diagnosis. In one study in an ICU less than one-half of the patients who have a fever and probable pneumonia diagnosed on clinical grounds had the diagnosis confirmed microbiologically.[25]

The difficulties in making an accurate diagnosis from simple clinical features has led to more complicated diagnostic criteria being developed, particularly for VAP. For example, a 'clinical pulmonary infection score' has been suggested to take account of temperature, white blood cell count, presence of purulent secretions, oxygenation requirements and chest radiograph infiltrates, combined with a clinical course consistent with a diagnosis of pneumonia, the lack of any alternative source of sepsis or histologic confirmation of pneumonia.[6] [26]

An alternative approach is to consider ventilated patients 'at risk' of pneumonia if they develop new lung infiltrates and have purulent tracheal aspirates. Daily sampling of tracheal secretions can give early warning of impending VAP because VAP is uncommon in the absence of positive tracheal cultures. A diagnosis of 'definite' VAP then requires microbiologic confirmation from quantitative culture from protected specimen bronchial brush (PSB) samples or the presence of intracellular bacteria in cells from a bronchoalveolar lavage (BAL) cytospin.[8]

DIAGNOSIS

General investigations (hematology, immunology and radiology)

Patients who have suspected HAP should have a full blood count; neutrophilia may point to infection as might a raised serum C-reactive protein. Biochemical tests are often indicated to assess the impact of the pneumonia on the underlying condition and to assess renal and hepatic function. Oxygenation should be assessed by pulse oximetry or arterial blood gas estimation. The chest radiograph will show new or worsening lung shadowing, although it is not usually diagnostic of infection. Cavitation is suggestive of infection, particularly by EGNB, anaerobes or fungi, but can be seen with pulmonary infarction.

General microbiologic investigations

Blood cultures should always be obtained. A positive culture identifies the pathogen and is equated with a worse prognosis. However, only about 8–20% of blood cultures from patients who have HAP are positive, indicating a low sensitivity.[27] The sources of the bacteremia, other than the lung, should always be considered. Up to 50% of patients with positive blood cultures may have an additional source of infection to HAP.[27] Pleural fluid should always be sampled to identify an impending empyema (Fig. 35.3). Serologic tests for viral and atypical pathogens are rarely of value, unless nosocomial *Legionella* pneumonia is a possibility or specific IgM tests are available. *Legionella* urinary antigen detection is a rapid, sensitive and specific test for nosocomial infection by *Legionella pneumophila* serogroup 1.

Special investigations and techniques to obtain lower respiratory tract samples

Ideally, there would be a widely available and accepted technique to obtain and culture uncontaminated secretions from the site of a lung

Figure 35-3 Pleural fluid, if present, should always be sampled in a patient who has pneumonia to assess etiology. In this case, purulent fluid was detected suggestive of an empyema. *Reproduced from Macfarlane JT, Finch RG, Cotton RE. A Colour Atlas of Respiratory Infections. London: Chapman & Hall; 1993.*

infection that was simple, safe and inexpensive to perform, the results of which would differentiate infection from colonization and were shown to aid management and improve outcome. Although the past 15 years has seen a rapid expansion in the use of different techniques for sampling in HAP, none fulfills the above criteria and controversy still exists among experts regarding the role of invasive and noninvasive investigations of HAP and VAP.[2] [27]

The techniques can be broadly divided into noninvasive and invasive groups (Table 35.5). A major limitation of studies that have attempted to validate these

techniques is the lack of a clear 'gold standard' for the diagnosis of pneumonia. In some studies, investigations have been performed just before death and the diagnosis of infection made after death. This is probably a better gold standard than lung biopsy, but does not reflect normal clinical practice, in which the diagnosis is attempted at an earlier stage of the illness. It is with these limitations in mind that the following techniques are described.

Noninvasive techniques

Expectorated sputum

The problems of sputum collection are well known and include contamination of the specimen by upper respiratory tract flora, making it unrepresentative of lower respiratory tract secretions. This is a particular problem in the nosocomial setting, when EGNB commonly colonize the upper respiratory tract and pathogens can be isolated with equal frequency in patients who have and do not have pneumonia.[4] The incidence of false-positive results for Gram-positive pathogens is relatively low but may rise to 50% for EGNB.[28] Only one-third to one-half of sputum cultures provide reliable information compared with blood cultures, transtracheal aspirates and PSB samples.[20] [28] [29] [30] Contamination of sputum by oral secretions should be suspected if the sputum Gram stain contains less than 25 polymorphonuclear neutrophils and over 10 squamous cell epithelial cells per low-power field. The presence of elastin fibers in potassium hydroxide preparations of sputum equates well with the presence of pneumonia, although the test is not widely available.[26]

Endotracheal aspirates

Aspiration via the endotracheal tube is the simplest method of obtaining secretions in patients on mechanical ventilation. Experience has indicated a high sensitivity but a very low specificity,

TABLE 35-5 -- Assessment of the advantages and disadvantages of the different techniques used to obtain respiratory secretions from patients who have suspected HAP.

ASSESSMENT OF THE ADVANTAGES AND DISADVANTAGES OF THE DIFFERENT TECHNIQUES USED TO OBTAIN RESPIRATORY SECRETIONS FROM PATIENTS WHO HAVE SUSPECTED HAP						
		Special equipment required (bedside + lab)	**Skill required**	**Risk of technique**	**Sensitivity**	**Specificity**
Noninvasive techniques						
	Expectorated sputum	0	0/+	0	+	+
	Endotracheal aspirate	+	+	0/+	++	+
