Chapter 207 - Drugs to Treat Viral Hepatitis

David F Gardiner
Marshall J Glesby

INTERFERONS

Interferons (IFNs) are a family of naturally occurring proteins produced by eukaryotic cells that function as cytokines in an early response to viral infection. Interferons do not have direct antiviral activity, but instead induce an antiviral state in exposed cells and activate other immune functions.

Interferons are broadly characterized as type I (IFN-a and -ß), and type II (IFN-?). Interferon-a and -ß have primary antiviral activity while IFN-? has more potent immunoregulatory functions.

Interferons act through cell surface receptors to induce a complex series of intracellular events, with inhibition of viral protein production appearing to be the primary target.[1] A variety of purified and recombinant IFN-a preparations is available for clinical use. The pharmaceuticals are termed 'IFN-alfa' to distinguish them from naturally occurring 'IFN-a'.

Recently, pegylated ('peg') varieties of IFN have become available. Pegylation involves the addition of a polyethylene glycol side-chain to the protein molecule, which extends the half-life significantly. Two formulations are currently available, pegIFN alfa-2a (Pegasys) and pegIFN alfa-2b (Peg Intron). PegIFN alfa-2a has a larger branched peg molecule of about 40kDa in size attached at several sites. [2] PegIFN alfa-2b has a smaller, linear peg molecule of about 12kDa attached at several sites. Their proposed mechanism of action is similar to that of standard IFNs.

Pharmacokinetics and distribution

Standard pharmacokinetic measurements may not be relevant for IFN therapy. Plasma levels of IFN-alfa are often undetectable after subcutaneous or intralesional administration, while the plasma elimination half-life ($t_{½}$) is 2–4 hours after intravenous administration. Interferon-alfa is well absorbed (approximately 80%) following intramuscular administration and peak plasma concentrations occur after approximately 5–8 hours.[3] Interferon-alfa is filtered through the glomeruli and then undergoes rapid proteolytic degradation during tubular resorption. Negligible amounts of IFN are excreted in the urine. A small percentage of the administered dose undergoes hepatic metabolism and biliary excretion. PegIFN alfa-2b reaches maximum concentrations by 20 hours and has a half-life of 40 hours. PegIFN alfa-2a reaches maximum concentrations by 72–96 hours and has a longer $t_{½}$ of 80 hours compared to pegIFN alfa-2b.

Route of administration and dosing

Interferons are administered systemically (subcutaneously or intramuscularly) for the treatment of chronic viral hepatitis and by intralesional injection for the treatment of condylomata acuminata. Dosages vary considerably according to the specific preparation and indication (Table 207.1).

Indications

Chronic hepatitis B virus infection

Interferon is approved for the treatment of chronic hepatitis B virus (HBV) infection. A response to IFN therapy is judged by a loss of HBV DNA and hepatitis B e antigen (HBeAg) from the plasma, along with biochemical and histologic improvements. A meta-analysis of 16 randomized trials examining IFN versus control found that loss of HBeAg occurred in 33% of patients while clearance of HBV DNA occurred in 37% of patients.[4] Control patients experienced these outcomes in only 12 and 17% of cases, respectively. Clinical predictors of response to IFN in patients infected with HBV include low level of HBV DNA, elevated serum transaminases and evidence of active hepatic inflammation.[5] As seen in Figure 207.1 , IFN therapy is associated with significant adverse effects. Recent years have seen a variety of new and effective medications for the treatment of HBV infection with improved side-effect profiles compared to IFN. As a result of these therapies, discussed below, IFN is not considered first-line treatment for HBV infection by most clinicians (see also Chapter 48).

Hepatitis C virus infection

Treatment of acute hepatitis C virus (HCV) infection is still investigational; however, a recent study reported a 98% sustained virologic response rate with IFN monotherapy in this setting.[6] Treatment of chronic HCV infection is recommended in patients experiencing detectable HCV RNA levels higher than 50 IU/ml and with a liver biopsy showing portal or bridging fibrosis and moderate inflammation and necrosis.[7] A sustained virologic response (SVR) of HCV to therapy is defined as a HCV RNA assay <50 IU/ml at 24 weeks after therapy. Evaluation of data from combining results of two large prospective trials shows that IFN monotherapy results in SVR rates of less than 10% after 24 weeks of treatment and SVR rates less than 20% after 48 weeks of therapy. [8] Increasing doses of IFN provide increased responses, with concomitant increases in adverse reactions.

Hepatitis C virus has a half-life of about 3 hours and infection results in the production of about 12 billion virions daily. The dosing and pharmacokinetics of standard IFN described above result in wide variations in serum IFN levels and fluctuating antiviral activity. Pegylation of the IFN molecule maintains rapid absorption and rapid time to peak drug level, while providing a dramatically lengthened half-life. Studies show that the pegylated IFNs provide significantly improved response rates over standard IFNs. Monotherapy with pegylated IFNs yields SVR rates of 25–39% in treatment-naive patients with HCV infection.[9] These improved results over standard IFN apply to both pegIFN alfa-2a as well as pegIFN alfa-2b.[10] [11]

Dosage in special circumstances

Guidelines for adjusting systemic IFN dosage in patients who have renal insufficiency are poorly defined. Only limited data are available regarding administration to patients who have decompensated liver disease, but IFN may be poorly tolerated in this population. In pregnant monkeys, IFN has abortifacient effects and should not be used in pregnant women unless the potential benefits clearly outweigh the potential risks to the fetus.

Adverse reactions

Interferon therapy is associated with an extensive list of toxicities (see Fig. 207.1). Most patients receiving IFN doses of over one

TABLE 207-1 -- Medication dosage regimens.

MEDICATION DOSAGE REGIMENS				
Disease	**Therapy**	**Route**	**Dose**	**Duration**

Chronic hepatitis B	IFN alfa-2b	sc or im	30–35 × 10^6 IU per week administered as either	16 weeks
			5 × 10^6 IU/day or 10 × 10^6 IU three times per week	
	Lamivudine	po	100mg q24h	Optimal duration unknown
	Adefovir dipivoxil	po	10mg q24h	Optimal duration unknown
Chronic hepatitis C	IFN alfa-2a	sc or im	3 × 10^6 IU three times/week	48 weeks*
	IFN alfa-2b	sc or im	3 × 10^6 IU three times/week	48 weeks
	IFN alfacon	sc	9µg three times/week*	48 weeks
	PegIFN alfa-2a	sc	180µg/week	48 weeks
	PegIFN alfa-2b	sc	1.0µg/kg/week†	48 weeks
			or	
			1.5µg/kg/week‡	
	Ribavirin	po	800–1200mg per day††	Co-administer with IFN

** An optimal duration of IFN therapy is not universally agreed upon. Most trials describe 24–48 weeks of IFN or IFN plus ribavirin therapy. Early viral response (EVR) defined as a >2 log drop in HCV viral load after 12 weeks may be predictive of patients who will have a successful response. (http//consensus.NIH.gov/cons/116/091202116cdc_statement.htm (NIH Consensus Statement Sept, 2002)). This duration is not reflected in most package inserts. Readers should examine specific large-scale trials of each regimen for more detailed information.
* Patients who fail therapy with IFN alfacon at standard dose may receive the drug at 15µg sc three times/week for 6 months
† Monotherapy
‡ Dual therapy with ribavirin
†† Optimal dose of ribavirin varies with the co-administration of IFN products as well as patient weight. Optimal dose ranges have not been uniformly determined. Readers should enquire to specific package inserts and recent dose finding trials.

Figure 207-1 Adverse reactions to interferons.

million units experience an 'influenza-like' syndrome characterized by fever, chills, headache, myalgias and arthralgias. These symptoms appear a few hours after the IFN injection, and they usually resolve within 12 hours. The symptoms can often be prevented by premedication with antipyretics. Tolerance develops in many patients with continued therapy. The most frequent dose-limiting adverse effects are leukopenia and thrombocytopenia. Before beginning IFN therapy, a baseline complete blood count, liver function profile, urinalysis, antinuclear antibody screen and thyroid function tests should be obtained.

The adverse events seen with pegylated IFN are similar to those seen with standard IFN. The most common hematologic toxicity associated with pegylated IFNs is neutropenia with as many as 18% of patients requiring dose adjustments as a result.[12] Dose reduction is often helpful in patients experiencing significant generalized or hematologic toxicity. The pegylated IFNs are also associated with psychiatric disturbances including depression, irritability, insomnia and suicidal ideation. Caution is warranted when using IFNs and pegIFNs in patients with a history of a psychiatric disorder.

RIBAVIRIN

Ribavirin is a guanosine analog that has a broad spectrum of antiviral activity. Its mechanism of action is not clearly defined, but it is believed to act against HCV by one or more of the following mechanisms:

¦ enhancing T-cell mediated immune responses to HCV by shifting the balance towards a T-helper-1 response;

¦ inhibiting cellular inosine monophosphate dehydrogenase, thereby decreasing the intracellular guanosine triphosphate pool needed for viral RNA replication;
¦ directly inhibiting HCV polymerase; and
¦ acting as an RNA virus mutagen, thereby reducing viral fitness.[13]

Ribavirin is well absorbed after oral administration, with bioavailability ranging from 33 to 69% of the dose, and about 40% of the drug being eliminated via the kidneys. The major side-effect of ribavirin is hemolytic anemia, which may necessitate discontinuation of therapy. Ribavirin is highly teratogenic and birth control is required if the drug is used by women of child-bearing age or their partners. The benefits of ribavirin monotherapy in HCV infection disappear rapidly when the treatment is discontinued and it is therefore not recommended. As detailed below, ribavirin is used in combination with IFN or pegIFN.

Retrospective analysis of phase III studies of pegIFN plus ribavirin reveal that response is inversely correlated with the patient's body weight. In the study by Manns *et al.*,[12] patients receiving at least 10.6mg/kg of ribavirin had significantly better response rates for the same doses of IFN. This suggests that higher weight-based dosing of ribavirin may lead to improved responses. A randomized clinical trial is now underway to resolve this issue.

COMBINATION THERAPY FOR HEPATITIS C VIRUS INFECTION

Ribavirin given in combination with IFN has been shown to be more effective than the use of IFN alone for the treatment of HCV.[14] An SVR may occur in up to 40% of patients treated with combination therapy compared with approximately 20% of patients treated with IFN alone. Studies combining pegIFN alfa-2b with ribavirin had a 54% SVR compared to a 47% SVR with standard IFN alfa-2b plus ribavirin.[12] The SVR in patients infected with HCV genotype 1, which is associated with a poorer response to therapy, was also improved (42 vs 33%). Trials of pegIFN alfa-2a plus ribavirin also demonstrate excellent responses.[15] Combination therapy for HCV may also be beneficial in patients co-infected with HIV. Preliminary results of a randomized trial in HCV/HIV co-infected patients suggest that pegIFN alfa-2a plus ribavirin is superior to standard IFN alfa-2a plus ribavirin, with 24-week virologic response rates of 44 versus 15%.[16] (See Chapter 125).

THERAPIES IN DEVELOPMENT FOR HEPATITIS C

Hepatitis C virus is a single-stranded (ss) RNA virus of about 9.4kb in length. It is translated into a single polypeptide prescursor, which is cleaved into several functional gene products, including structural proteins, RNA polymerase, helicase and serine protease.[17] Several drugs are in development to target key components of the viral life cycle, including inhibitors of serine protease as well as the helicase enzyme (Fig. 207.2). Ongoing clinical trials are investigating the potential antifibrotic effects of maintenance therapy with pegIFN alfa or colchicine for virologic nonresponders to IFN-based regimens. Interferon-? is also under study as an antifibrotic agent.

NUCLEOSIDE AND NUCLEOTIDE ANALOGS

Nucleosides and nucleotides are the basic components of DNA and RNA in both prokaryotic and eukaryotic organisms. These molecules include a pentose sugar and a base moiety. A nucleotide differs from a nucleoside by the presence of one or more phosphate groups covalently bound to the molecule's sugar group. Intracellular phosphorylation is required before incorporation into the elongating nucleic acid chain. Pharmacologic analogs of these molecules have been developed for use in the treatment of several viral pathogens and

Figure 207-2 Hepatitis C virus life cycle and its inhibition.

function either as nucleic acid chain terminators or as inhibitors of polymerase enzymes. Nucleoside analogs (phosphate absent) include lamivudine, famciclovir and lobucavir, while nucleotide analogs (phosphate present) are represented by adefovir and tenofovir. These drugs inhibit a critical step of the HBV life cycle where the reverse transcriptase activity of its DNA polymerase catalyzes the conversion of RNA to DNA.[18] Resistance to nucleoside analogs can be caused by mutations in the active site of the DNA polymerase enzyme, including the highly conserved amino acid motif YMDD.[19]

Lamivudine

Lamivudine was the first nucleoside analog approved for HBV infection. It is also used for the treatment of HIV infection. Detailed pharmacokinetic and distribution data are provided in Chapter 204 . The dose used for HBV, 100mg q24h, is lower than that used for HIV. Lamivudine therapy is associated with a significant improvement in hepatic histology, normalization of hepatic enzymes and suppression of plasma HBV DNA.[20] In most patients, however, values return to baseline levels when lamivudine is discontinued. The emergence of drug-resistant HBV may limit the value of lamivudine for long-term therapy and may be associated with increases in serum liver transaminases.[21] Regimens combining lamivudine with other active compounds to enhance efficacy and limit the development of resistance are under investigation.[22]

Adefovir

Adefovir is approved for the treatment of HBV infection. Originally developed as an antiretroviral, it is associated with significant renal toxicity at the higher doses needed to inhibit HIV replication and is not approved for that indication.

Pharmacokinetics and distribution

Adefovir is administered as the prodrug adefovir dipivoxil. Unaffected by food, it achieves 60% oral bioavailability. Its half-life is about 12–30 hours and it undergoes renal excretion without significant observed metabolites. It does not substantially affect the cytochrome P450 system.

Routes of administration

Adefovir is approved for oral use only. The drug displays anti-HBV activity at doses above 5mg/day. It is approved for use at 10mg/day for HBV infection.

Indications

Chronic hepatitis B virus infection

Adefovir is highly active against HBV, producing reductions of HBV DNA of >3.5 logs. A phase III study (Adefovir Study 437) randomized patients to adefovir 10mg, 30mg or placebo; HBV viral load reduction, histologic improvement and HBeAg seroconversion rates were superior in the adefovir arms.[23] Furthermore, the drug displays in-vitro efficacy against lamivudine-resistant isolates. [24]

Adverse reactions and interactions

Adefovir appears well tolerated at the 10mg dose. Renal impairment becomes significant, however, at the 30mg dosage.[25] The most common adverse reactions are headache, gastrointestinal upset and elevated transaminases. No significant drug interactions have been documented.

Tenofovir disoprixil fumarate

Tenofovir is an orally bioavailable, nucleotide analog approved for HIV therapy. Detailed pharmacokinetic and distribution data are given in Chapter 204 . Limited data suggest that the drug has activity against lamivudine-resistant HBV isolates.[26] Tenofovir may have potential for the treatment of HBV infection in patients co-infected with HIV.[26A]

Other nucleoside analogs in development

Emtricitabine

Emtricitabine has efficacy against HIV as well as HBV. Its activity against HBV may be greater than that seen with lamivudine. In a dose-ranging study of emtricitabine at 25, 100 and 200mg daily for 48 weeks, 38, 42 and 61% of patients had reductions in HBV DNA levels to below the level of quantification by Digene Hybrid Capture II assay (<4700 copies/ml), respectively, while 32, 38 and 50% in each arm experienced loss of HbeAg.[27]

Entecavir

Entecavir is an orally bioavailable nucleoside analog with a half-life of 110 hours. A dose-ranging study of entecavir at 0.01, 0.1 and 0.5mg versus lamivudine demonstrated reductions in HBV DNA of 2.4, 4.3 and 4.7 logs at each entecavir dose, respectively, compared with a 3.4 log reduction with lamivudine.[28] Preliminary results show efficacy against the lamivudine-resistant YMDD mutant.

Famciclovir (see also Chapter 205)

Famciclovir, an orally administered prodrug of penciclovir, is approved for the treatment of herpes simplex virus and varicella-zoster virus infections. It is effective in animal models of HBV infection and has significant antiviral effects in patients with chronic HBV infection.[29] Famciclovir may not suppress virus as effectively as lamivudine, as evidenced by a lower rate of HBeAg seroconversion.[30] Furthermore, the drug does not appear to suppress lamivudine-resistant HBV mutants.

Lobucavir

Lobucavir is a cyclobutyl analog of guanine with potent in-vitro activity against HBV. In a study of 81 patients with HBV infection, treatment with lobucavir resulted in a 3.5 log decrease in HBV DNA. Levels of HBV DNA were below the level of quantitation in 68% of patients. Unfortunately, the drug appears to be associated with carcinogenic potential in long-term animal studies, and it is not clear whether further drug development will continue.

COMBINATION THERAPY FOR HEPATITIS B VIRUS INFECTION

Studies of combination therapy involving nucleoside analogs plus IFN have yielded conflicting results thus far.[31] These combinations, as well as combinations of nucleoside analogs, await future definitive evaluations before they can be recommended.

Chapter 208 - Antifungal Agents

Shmuel Shoham
Andreas H Groll
Thomas J Walsh

Invasive fungal infections have evolved into important causes of morbidity and mortality in patients with severe underlying diseases. For more than three decades, treatment has been limited to amphotericin B (AmB) deoxycholate with or without flucytosine. Therapeutic options only emerged with the clinical development of fluconazole and itraconazole in the late 1980s. The past 10 years, however, have witnessed a major expansion in our antifungal armamentarium through the introduction of less toxic formulations of amphotericin B, the development of improved antifungal triazoles and the advent of the echinocandin lipopeptides, a new class of antifungal agents that target the fungal cell wall. This chapter reviews the clinical pharmacology of approved and investigational antifungal agents for treatment of invasive fungal infections.

POLYENE ANTIBIOTICS

Amphotericin B deoxycholate

Amphotericin B is a natural polyene macrolide antibiotic and consists of seven conjugated double bounds, an internal ester, a free carboxyl group and a glycoside side chain with a primary amino group (Fig. 208.1). It is amphoteric, virtually insoluble in water, and not orally or intramuscularly absorbed. For parenteral use, AmB has been solubilized with deoxycholate as micellar suspension, and this formulation has been available for now more than 40 years.

Mechanism of action

Amphotericin B primarily acts by binding to ergosterol, the principal sterol in the cell membrane of most fungi, leading to the formation of ion channels and concentration-dependent, cell death (Fig. 208.2). These pores, composed of AmB multimers, form most readily when ergosterol is present in the cell membrane.[1] [2] With less avidity, the compound also binds to cholesterol, the main sterol of mammalian cell membranes, which is believed to account for most of its adverse effects. A second mechanism of action of AmB may involve oxidative damage of the cell through a cascade of oxidative reactions linked to its own oxidation and interactions with lipoproteins with formation of free radicals or an increase in membrane permeability. [3] [4] [5] [6]

Antifungal activity

Amphotericin B has broad-spectrum antifungal activity that includes most fungi pathogenic in humans. Primary resistance has been associated with qualitative or quantitative variations in membrane sterols,[7] but it may also be related to increased catalase activity with decreased susceptibility to oxidative damage.[8] [9] [10] Resistance remains uncommon in *Cryptococcus neoformans* and *Candida* spp. although AmB appears somewhat less active against *Candida guilliermondii, Candida parapsilosis* and *Candida tropicalis. Candida lustitaniae* isolates are often resistant to AmB, and this resistance can develop during treatment.[11] [12] *Aspergillus* spp. and other opportunistic molds, but not the dimorphic molds, tend to have more variable susceptibility to AmB. *Aspergillus terreus, Fusarium* spp., *Pseudallescheria boydii, Scedosporium prolificans*, certain other dematiaceous fungi and *Trichosporon beigelii* may be resistant to AmB at concentrations safely achievable in patients.[11] [13] [14] Acquisition of secondary resistance has been anecdotally reported but its role as a clinical problem has not been fully defined.

Pharmacodynamics

Amphotericin B displays concentration-dependent fungicidal activity against susceptible *Candida albicans, C. neoformans* and *Aspergillus fumigatus* in time-kill assays and exhibits a postantifungal effect of up to 12 hours' duration against *C. albicans* and *C. neoformans* in vitro.[15] [16] [17] Studies in laboratory animals with experimental disseminated candidiasis suggest that peak serum level to MIC ratio correlates best with antifungal efficacy in vivo.[18] These findings support the notion that large doses will be most effective and that achievement of optimal peak concentrations is important.

Pharmacokinetics

After intravenous administration, AmB dissociates from its vehicle and becomes highly protein-bound before distributing predominantly into liver, spleen, bone marrow, kidney and lung. A unique property of AmB is that protein binding in plasma is enhanced with increasing drug concentration.[19] Clearance from plasma is slow with a terminal half-life of 5 days and longer.[20] [21] Concentrations in body fluids other than plasma are generally low; however, despite mostly undetectable concentrations in the cerebrospinal fluid (CSF), AmB is effective in the treatment of fungal infections of the central nervous system. Amphotericin B is mostly excreted as unchanged drug in the urine and feces, and no metabolites have been identified.[20] Dose adjustment of AmB is not necessary in patients with unrelated renal or hepatic dysfunction. Because of its high protein binding, hemodialysis usually does not affect plasma concentrations of AmB. Infants and children appear to clear the drug from plasma more rapidly than adults, as indicated by a significant negative correlation between age and clearance.[22]

Adverse effects

Infusion-related reactions and nephrotoxicity of AmB are major problems and often limit therapy. Infusion-related reactions (fever, rigors, chills, myalgias, arthralgias, nausea, vomiting and headaches) are thought to be mediated by the release of cytokines from monocytes in response to the drug. They can be noted in up to 73% of patients during the first dose, but often improve during continued therapy.[23] Slowing the infusion rate or pre-medication with acetaminophen (10–15mg/kg), hydrocortisone (0.5–1.0mg/kg) or meperidine (0.2–0.5mg/kg) (pethidine, 25–50mg) may blunt these reactions. Continuous 24-hour infusion of AmB further reduces symptoms, but data on the antifungal efficacy of this dosing strategy is limited.[24] Cardiac arrhythmias and cardiac arrest caused by acute potassium release may occur with rapid infusion of under 60 minutes, especially if there is pre-existing hyperkalemia or renal impairment. True allergic reactions are rare.[25]

Amphotericin B-associated nephrotoxicity occurs as a result of alterations of membrane permeability in renal tubular and vascular

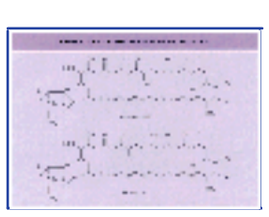

Figure 208-1 Chemical structures of amphotericin B and nystatin A1.

Figure 208-2 Biosynthetic pathway of ergosterol and points of activity by antifungal agents.

smooth muscle cells. Tubular transport defects and decreased glomerular filtration rate caused by vasoconstriction are responsible for potassium and magnesium wasting, tubular acidosis, impaired urinary concentration ability and azotemia. Decreased renal blood flow and recurrent ischemia may lead to permanent structural nephrotoxic effects.[3] Hypokalemia can be quite refractory to replacement until hypomagnesemia is corrected. Tubular acidosis and impaired urinary concentration are rarely of clinical significance. Azotemia is common; in a large prospective clinical trial, the baseline serum creatinine rose by more than 100% in over one-third of 344 unstratified patients receiving AmB for empiric therapy of fever and neutropenia.[23] Risks of developing renal toxicity are related to dose and duration of therapy, concomitant use of nephrotoxic agents such as ciclosporin and amikacin, and pre-existing renal dysfunction.[26] Renal toxicity associated with the use of AmB has the potential to lead to renal failure and dialysis. Often, however, azotemia stabilizes on therapy and is usually reversible after discontinuation of the drug. Avoiding concomitant nephrotoxic agents, appropriate hydration and normal saline loading (0.9% sodium chloride 10–15ml/kg/day) may lessen the likelihood and severity of azotemia.

Other potentially relevant adverse effects of AmB include hypotension, hypertension, flushing, vestibular disturbances and a normocytic, normochromic anemia after chronic administration.[22] Amphotericin B deoxycholate is topically irritating; therefore, a central line should be used for infusion. Local instillation, including intrathecal

administration, can cause focal areas of necrosis and should only be considered in conjunction with expert consultation.[27]

Drug interactions

In rats, AmB decreases the concentration of hepatic microsomal cytochrome P450 and inhibits propafenone metabolism.[28] Drug-drug interactions attributable to shared metabolic pathways have not been described in humans. Hypokalemia may be aggravated by corticosteroids, and hypomagnesemia may become especially profound in cancer patients with platinum-associated nephropathy. Amphotericin B therapy may enhance plasma levels and thereby toxicity of many renally cleared drugs, including aminoglycosides, vancomycin, fluorocytosine and ciclosporin. Cumulative renal toxicity has been seen when amphotericin B is given simultaneously with other nephrotoxic agents e.g., gentamicin, foscarnet or pentamidine. The simultaneous infusion of granulocytes has been associated with acute pulmonary reactions, and should therefore only be used with extreme caution. Treatment with fluconazole followed by AmB has been shown to reduce antifungal susceptibility in vitro and in vivo.[29] The sequential use of an azole followed by AmB should probably be avoided.

Indications and dosing

Despite its toxicity profile, AmB deoxycholate is still considered the drug of choice for the initial treatment of most life-threatening infections caused by susceptible organisms. Depending on both the type of infection and the host, the recommended daily dosage ranges from 0.5 to 1.5mg/kg/day administered over 2–4 hours as tolerated; the standard dosage for empiric therapy in persistently febrile neutropenic patients is 0.5–0.6mg/kg/day.[25] Continuous infusion of AmB deoxycholate may be associated with less toxicity;[24] however, this mode of administration is counterintuitive to the concentration-dependent pharmacodynamics of AmB and is therefore not recommended. Whether the enhanced plasma clearance in infants and young children has implications for dosing remains unknown. Currently, dosage recommendations for all pediatric age groups do not differ from those in adults. Treatment should be started at the full target dosage with careful bedside monitoring during the first infusion to allow for prompt intervention for infusion related reactions.

Therapeutic monitoring

Historically, it has been proposed that a plasma concentration at 1 hour after infusion of twice the MIC of the fungal isolate should be the target for treatment of yeast infections.[30] However, monitoring of AmB concentrations in plasma or CSF appears of little value, since relationships between plasma and tissue concentrations and clinical efficacy or toxicity have not been adequately characterized.[16]

Amphotericin B lipid formulations

During the past few years, three novel formulations of AmB have been approved in the USA and most of Europe:

- AmB colloidal dispersion (ABCD),
- AmB lipid complex (ABLC), and
- a small unilamellar vesicle liposomal formulation (L-AmB).

Because of their reduced nephrotoxicity in comparison to AmB deoxycholate, these compounds allow for the delivery of higher dosages of AmB. However, data from animal models also suggest that higher dosages are required for equivalent antifungal efficacy.

TABLE 208-1 -- Amphotericin B formulations and liposomal nystatin: physicochemical properties and pharmacokinetic parameters.

AMPHOTERICIN B FORMULATIONS AND LIPOSOMAL NYSTATIN: PHYSICOCHEMICAL PROPERTIES AND PHARMACOKINETIC PARAMETERS

Half-life (h)	39	28	6–18	7–10	2–6
DAMB, amphotericin B deoxycholate; ABCD, amphotericin B colloidal dispersion; ABLC, amphotericin B lipid complex; LAMB, liposomal amphotericin B; LNYS, liposomal nystatin; DMPC, dimiristoyl phosphatidylcholine; DMPG, dimiristoyl phosphatidylglycerol; HPC, hydrogenated phosphatidylcholine; CHOL, cholesterol; DSPG, disteaoryl phosphatidylglycerol; SUVs, small unilamellar vesicles (liposomes); MLVs, multilamellar vesicles (liposomes); C_{max} , peak plasma concentration; AUC_{0-8} area under the concentration vs time curve from time zero to infinity; VDss, apparent volume of distribution at steady state; Cl, plasma clearance; Half-life, apparent plasma half-life during the dosing interval of 24 hours					
Data represent mean values, stem from adult patients and were obtained after different rates of infusion. Concentrations of nystatin were measured in whole blood and are approximately half of those measured in serum					
Modified from Groll et al.[62] and Cossum et al.[45]					

Physicochemical properties and pharmacokinetics

Because of differences in the physicochemical properties of their carriers, each of the lipid formulations confers its own distinct plasma pharmacokinetics properties to AmB. All three formulations, however, preferentially distribute to organs of the mononuclear phagocytic system (MPS), sequester lipid-associated drug within deep tissues and functionally spare the kidney. L-AmB, the only truly liposomal AmB, is composed of small spherical unilamellar lipid vesicles averaging 60–70nm in size. Following infusion the liposomal preparation has a prolonged circulation time in plasma, achieves strikingly high peak plasma concentrations and AUC values, and is only slowly taken up by the MPS. However, most of the AmB in plasma remains liposome-associated, and free unbound drug concentrations are low.[19] [20]

Amphotericin B lipid complex, composed of ribbon-like lipid aggregates, is efficiently opsonized by plasma proteins and rapidly taken up by the MPS to achieve high concentrations of drug in the cellular components of blood, liver, lung and spleen. It exists as a depot in these tissues and free AmB is slowly released. Fungal and inflammatory cell lipases at the site of infection act to release the complexed AmB from the lipid carrier.[31]

Amphotericin B colloidal dispersion, a colloidal dispersion of microscopic disc-shaped particles, also preferentially collects in tissues of the MPS and free drug is slowly released over time. Drug levels in the plasma and kidney are low and terminal elimination half-life is long (Table 208.1).

Whether these distinct pharmacokinetic features translate into different pharmacodynamic properties is largely unknown. More recent experimental comparisons of all four formulations of AmB against defined invasive mycoses suggest potentially important differences in antifungal efficacy depending on agent, dose, type and site of infection.[13]

Safety and antifungal efficacy

Safety and antifungal efficacy of lipid formulations have been demonstrated in phase I and phase II studies in immunocompromised patients with a wide spectrum of

underlying disorders.[32] [33] [34]

The overall response rates in these trials ranged from 53 to 84% in patients with invasive candidiasis and from 34 to 5%, respectively, in patients with probable or documented invasive aspergillosis. Clinical and microbiologic responses were observed in patients with documented invasive fungal infections even when lipid formulations were used as salvage therapy after failure of conventional AmB deoxycholate. Patients with neutropenia responded to therapy with lipid formulations, but, as with other antifungal agents, recovery of neutrophil counts, remission from underlying malignancy and continued antifungal therapy were necessary for resolution of their fungal infections. Several randomized controlled trials have now been completed in which one of the new formulations has been compared with AmB deoxycholate. These studies have consistently shown at least equivalent therapeutic efficacy and reduced nephrotoxicity in comparison with AmB deoxycholate. A meta-analysis of 1149 neutropenic patients from three trials found that prophylactic or empiric use of L-AmB tended to be more effective than AmB deoxycholate in preventing breakthrough fungal infections and that it was associated with less nephrotoxicity, although it did not lead to improved survival.[35] Infusion-related side-effects of fever, chills and rigor appear to be less frequent with L-AmB and may even be increased with ABCD.[23] [36] [37] Several individual cases of substernal chest discomfort, respiratory distress and sharp flank pain have been noted during infusion of L-AmB,[38] and in a comparative study hypoxic episodes associated with fever and chills were more frequent in ABCD recipients than in AmB deoxycholate recipients.[39] Mild increases in serum bilirubin and alkaline phosphatase have been observed with all three formulations, Generally mild increases in serum transaminases and pancreatic enzymes with L-AmB have been observed. However, no cases of fatal liver or pancreatic diseases have been reported.

Indications and dosing

The lipid formulations are indicated for the treatment of patients with AmB-susceptible invasive mycoses that are refractory to AmB deoxycholate and for the treatment of patients who are intolerant to AmB deoxycholate; L-AmB is indicated for empiric therapy of persistently neutropenic patients. Preliminary pediatric pharmacokinetic and safety data indicate no fundamental differences in comparison with adults. The optimal dosages of each formulation for the various type and sites of invasive fungal infections remain to be defined. Based on animal data and the few randomized studies that have used AmB deoxycholate as comparator,[40] [41] we and most other experts in the field consider a dose of 5mg/kg/day of ABCD, ABLC or L-AmB to be equivalent to a dosage of 1mg/kg/day of AmB deoxycholate. Accordingly, an initial dosage of 5mg/kg/day of ABCD, ABLC or L-AmB is currently recommended for treatment of suspected or documented life-threatening infections, and a dosage of 3mg/kg/day is recommended when L-AmB is selected for empiric antifungal therapy in persistently febrile, neutropenic patients. Recent data have also suggested that lipid formulation of AmB at doses of 3mg/kg can be effective in patients with histoplasmosis and in selected patients with candidiasis. [42] [43] Because the favorable therapeutic index of the drug some clinicians have successfully used L-AmB at doses of 10mg/kg and 15mg/kg in patients with recalcitrant invasive fungal infections. The maximum tolerable dose appears to be at least 15mg/kg/day.

Use of lipid formulations of AmB has been limited by their high costs. Current in-vivo and clinical data indicate that L-AmB is the least toxic of the of these agents. However, as L-AmB also carries the highest drug acquisition cost, appreciation of its superior safety profile is often eclipsed by pharmacoeconomic concerns. Comprehensive economic analyses that include hospital and societal costs resulting from excess nephrotoxicity related to the use of conventional AmB deoxycholate appear to indicate that the high cost of lipid formulations of AmB may be supplanted by the even greater cost of AmB deoxycholate-induced nephrotoxicity.

Liposomal nystatin

Nystatin, the first antifungal polyene, is a tetraene-diene macrolide with a structure that is very similar to that of AmB. Like AmB, it binds to ergosterol in the cell membrane of fungi, creating a pore and leading to cell death. Although it is used widely as a topical agent, nystatin is ineffective when given orally and highly toxic when given parenterally (see Fig. 208.1). Although generally less potent on a molar basis, the spectrum of activity of this agent and its in-vitro pharmacodynamics are similar to those of AmB, and it might have activity against some amphotericin B-resistant isolates. [25] [44] An intravenous multilamellar liposomal formulation of nystatin has been developed that has reached clinical trials. The plasma pharmacokinetics of multilamellar liposomal nystatin are unique among the current polyenes and are characterized by comparatively high peak plasma concentrations and rapid elimination from plasma, with a half-life of 5–7 hours.[45] Animal studies have indicated that this formulation is preferentially distributed to lung, liver and spleen, and that the kidney appears to play a major role in excretion.[46] In a phase I study, multilamellar liposomal nystatin was tolerated at multiple dosages of up to 8mg/kg.[47] The compound has demonstrated clinical efficacy in the treatment of candidemia and invasive aspergillosis and as empiric antifungal therapy for neutropenic cancer patients at dosages ranging from 2mg/kg to 4mg/kg.[48] [49] [50] Submission for approval by the US Food and Drug Administration (FDA) is expected in the near future.

FLUCYTOSINE

Flucytosine (5-fluorocytosine, 5-FC) is a low-molecular-weight, water-soluble, synthetic fluorinated analog of cytosine (Fig. 208.3). It has no antifungal activity of its own. It is taken up by the fungus-specific enzyme cytosine permease and converted in the cytoplasm by cytosine deaminase to 5-fluorouracil, which causes RNA miscoding and inhibits DNA synthesis. [51] Although it was originally synthesized as a potential antitumor agent, 5-FC is relatively nontoxic to mammalian cells because of the absence or very low level of activity of cytosine deaminase. Recently, this compound has re-emerged as an antineoplastic agent for use in tumors sensitized by the addition of fungal and bacterial cytosine deaminase genes. In the USA, 5-FC is available only as oral formulation; an intravenous formulation is available in some countries.

Antifungal activity

The antifungal spectrum of 5-FC in vitro encompasses *Candida* spp., *C. neoformans, Saccharomyces cerevisiae* and selected dematiaceous moulds. Flucytosine has little to no activity against *Aspergillus*

Figure 208-3 Comparison of the chemical structures of cytosine, flucytosine and fluorouracil.

spp. and other hyaline molds.[52] [53] Synergistic or additive effects in combination with AmB have been observed against *Candida* spp. and in combination with AmB, fluconazole or the investigational agent posaconazole against *C. neoformans*. [32] [54] With the exception of *Candida krusei*, primary resistance to 5-FC occurs very rarely in *Candida* spp.[55] Resistance to 5-FC, defined as a MIC of 32µg/ml or greater, has been observed in 1.6–2.2% of *C. neoformans* isolates.[56] In contrast to primary resistance, secondary resistance, which occurs predominantly by selection of resistant clones, can evolve rapidly and appears to result from a single point mutation. In *C. neoformans* resistance to 5-FC has been observed in 30–40% of isolates from patients with meningitis who relapsed following monotherapy.[57] Resistance in susceptible fungi may involve either mutations in the enzymes necessary for cellular uptake, transport or metabolism, or competitive upregulation of pyrimidine synthesis. [51] As a consequence, 5-FC is rarely given alone but in combination with AmB or, more recently, fluconazole.

Pharmacodynamics

Flucytosine has demonstrated predominantly concentration-independent fungistatic (99% reduction in colony-forming units) activity against *Candida* spp. and *C. neoformans* in time-kill assays, and prolonged concentration- and exposure-dependent post-antifungal effects of up to 10 hours. [58] [59] Pharmacodynamic studies in mice with experimental disseminated candidiasis have revealed that both the time above the MIC and AUC:MIC ratio were important in predicting efficacy. The C_{max} :MIC ratio was the least important parameter, and maximum efficacy was observed when levels exceeded the MIC for only 20–25% of the 24-hour dosing interval.[60] Thus, lower dosages or less frequent dosing may yield identical antifungal efficacy while further reducing potential toxicities that are mostly dose-dependent.

Pharmacokinetics

Flucytosine is readily absorbed from the gastrointestinal tract, has negligible protein binding and distributes evenly into tissues and body fluids, including the CSF, peritoneal fluid, inflamed joints and the eye. At usual dosages, the drug undergoes little hepatic metabolism and is eliminated predominantly in its active form by glomerular filtration into the urine, with a half-life in plasma of 3–6 hours. Individual dosage adjustment is necessary in patients who have impaired renal function and those undergoing hemofiltration. In patients undergoing hemodialysis, a dose of 37.5mg/kg is recommended following dialysis; in peritoneal dialysis, the compound can

be administered systemically or intraperitoneally.[51] Although the data are limited, impaired liver function does not appear to alter 5-FC disposition.[61] [62] The pharmacokinetics of 5-FC in pediatric patients has not been formally characterized, so that uniform dosing recommendations cannot be made.

Adverse effects

Common adverse effects of 5-FC that occur in 5–6% of patients include gastrointestinal intolerance and reversible elevations of hepatic transaminases and alkaline phosphatase. Rarer side-effects are skin rashes, ulcerative colitis and bowel perforation, blood eosinophilia and crystalluria.[62] Hematologic adverse effects have been reported in 6% of patients receiving oral 5-FC overall; these adverse effects may include neutropenia, thrombocytopenia or pancytopenia. Among 202 AIDS patients receiving combination therapy with AmB and 5-FC for cryptococcal meningitis, the drug toxicity withdrawal rate of 3% was similar to the rate in those receiving AmB monotherapy.[63] Flucytosine-associated adverse effects are usually reversible after discontinuation of the drug or dosage reduction; however, fatal outcomes have been reported.[64] Some of the adverse effects of 5-FC may be due to the conversion of the compound to 5-fluorouracil by the gastrointestinal bacterial flora and the toxic effects of endogenous metabolites.[51] In patients treated with intravenous 5-FC, in whom the drug presumably did not undergo metabolism by the human intestinal microflora, 5-fluorouracil levels were not detected, but some toxicity was still observed.[65] Hematologic adverse effects are less frequent if plasma levels of 5-FC do not exceed 100µg/ml. [66]

Drug interactions

Orally administered, nonresorbable antibiotics and aluminum hydroxide- and magnesium hydroxide-based antacids may delay absorption of 5-FC from the gastrointestinal tract.[62] Flucytosine is not known to interfere with CYP450 enzyme system. However, any drug that can cause a reduction in the glomerular filtration rate may increase 5-FC serum levels and thereby has the potential to enhance 5-FC-associated toxicity. This includes AmB as well as number of antimicrobial agents, anticancer drugs and ciclosporin.[61] Cytosine arabinoside competitively inhibits 5-FC and the two drugs should not be given concomitantly.

Indications and dosing

Owing to the propensity for secondary resistance, 5-FC is generally not administered as a single agent. An established indication for its use in combination with AmB deoxycholate is for induction therapy of cryptococcal meningitis.[63] The combination of AmB deoxycholate with 5-FC can also be recommended for the treatment of candidal infections involving deep tissues, particularly in critically ill patients and when *Candida* spp. other than *C. albicans* are involved.[64] This includes candidal meningitis, endophthalmitis, endocarditis, vasculitis and peritonitis, as well as osteoarticular, renal and chronic disseminated candidiasis.[62] Flucytosine has been reported to delay hematopoietic recovery after cytotoxic chemotherapy and can therefore not be recommended as an addition to AmB for empiric antifungal therapy of persistently febrile neutropenic patients.[67] The combination of 5-FC with fluconazole may be used for cryptococcal meningitis, when treatment with AmB is not feasible. In addition, this combination may also be useful as second-line therapy for individual patients with invasive candidal infections involving aqueous body compartments. Currently, we recommend a starting dosage for both adults and children of 100mg/kg/day in three or four divided doses.

Therapeutic monitoring

Monitoring of plasma concentrations is essential to adjust dosage to changing renal function and to avoid toxicity. Following oral administration, near-peak levels 2 hours postdosing overlap with trough levels as patients reach steady state and are thus sufficient for therapeutic monitoring.[64] Peak plasma levels between 40µg/ml and 60µg/ml correlate with antifungal efficacy and are seldom associated with adverse hematologic effects.[64] [66] The need for monitoring plasma concentrations has limited the use of 5-FC because performance of this test is often restricted to referral laboratories.

ANTIFUNGAL TRIAZOLES

The antifungal azoles are a class of synthetic compounds that have one or more azole rings and a more or less complex side chain, which is attached to one of the nitrogen atoms. The imidazoles miconazole and ketoconazole were the first azoles developed for systemic treatment of human mycoses. Severe toxicities associated with the drug carrier (in the case of miconazole) and erratic absorption and significant interference with the human cytochrome P450 system (in the case of ketoconazole) have limited their clinical usefulness.[62] The subsequently developed triazoles fluconazole and itraconazole (Fig. 208.4), however, have become extremely useful

Figure 208-4 Chemical structures of fluconazole, itraconazole, voriconazole, posaconazole and ravuconazole.

components of the antifungal armamentarium. They possess an expanded spectrum of activity and greater target specificity and are well tolerated overall.

Mechanism of action

The antifungal azoles target ergosterol biosynthesis by inhibiting the fungal cytochrome P450-dependent enzyme lanosterol 14-a-demethylase. This inhibition interrupts the conversion of lanosterol to ergosterol, which leads to accumulation of aberrant 14-a-methylsterols and depletion of ergosterol in the fungal cell membrane (see Fig. 208.2). This alters cell membrane properties and function and, depending on the organism and the compound, may lead to cell death or inhibition of cell growth and replication. In addition, the azoles also inhibit cytochrome P450-dependent enzymes of the fungal respiration chain.[62]

Antifungal activity

Fluconazole and itraconazole are principally active against dermatophytes, *Candida* spp., *C. neoformans*, *T. beigelii* and some other uncommon yeast-like organisms, and dimorphic fungi such as *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis* and *Sporothrix schenckii*.[62] These azoles have less activity against *Candida glabrata* and almost none against *C. krusei*.[68] Useful activity against *Aspergillus* spp. and dematiaceous molds is restricted to itraconazole. Itraconazole and fluconazole are quite inactive against *Fusarium* spp. and the zygomycetes.[62] The second-generation triazoles, voriconazole and the investigational agents posaconazole and ravuconazole, are active against *C. albicans* and *C. krusei*, *Aspergillus* spp. and some *Fusarium* spp. Posaconazole is also active against the zygomycetes.[69]

Resistance

Selection and nosocomial spread of azole-resistant *Candida* spp. has become a matter of increasing concern. Resistance in *Candida* spp. is encountered most commonly in form of a primarily resistant species or through selection of resistant subclones during exposure to azoles. Several mechanisms of resistance have been identified, including but not limited to alterations at the target binding site, increased target expression and induction of cellular efflux pumps.[7] Before the advent of highly active antiretroviral therapy, azoleresistant oropharyngeal and esophageal candidiasis was a major clinical conundrum in HIV-infected patients.[70] In addition, emergence of *C. glabrata* and *C. krusei* infections in association with fluconazole prophylaxis has been observed in several bone marrow transplant centers, although frequency and attributable mortality of these breakthrough infections appears to be low overall.[71] Although cross-resistance of *Candida* spp. to antifungal azoles is common,[72] it is not obligate; patients with microbiologic and clinical fluconazole-resistant mucosal candidiasis may respond to itraconazole or newer triazoles. Acquired azole resistance has been documented in a few patients with *C. neoformans* meningitis receiving maintenance therapy. Very little is known, however, about frequency and mechanisms of secondary azole resistance in filamentous fungi.[62]

Fluconazole

Pharmacodynamics

Conventional time-kill assays performed over incubation periods of 24–48 hours in susceptible *Candida* spp. and *C. neoformans* show fungistatic activity of fluconazole with variable concentration-related growth effects.[73] [74] However, with extended incubation of up to 14 days and under nonproliferating growth conditions, fungicidal activity has been observed against *C. albicans*.[75] In serum-free growth media, fluconazole displays no measurable post-antifungal effect against *C. albicans* and *C.*

neoformans, but concentration-dependent post-antifungal effects of 1–3.6 hours were observed in the presence of fresh serum.[16] Pharmacodynamic studies in murine models of disseminated *C. albicans* infection collectively suggest that

the AUC:MIC ratio is the most predictive pharmacodynamic parameter of fluconazole. [76] Overall, the dose-independent pharmacokinetics and the available experimental and clinical data are in support of once daily dosing regimens.

Pharmacokinetics

Fluconazole is available for oral and parenteral use, and it exhibits linear plasma pharmacokinetics that are independent of route and formulation.[77] Steady state is generally reached within 4–7 days with once-daily dosing, but it can be rapidly achieved by doubling the dose on the first day. Protein binding is low, and the drug distributes evenly into virtually all tissue sites and body fluids, including the CSF, brain tissue and the eye. More than 90% of a dose is excreted via the kidney, with approximately 80% recovered as unchanged, active drug and 11% recovered as inactive metabolites. In patients with a creatinine clearance of =50ml/minute, a 50% reduction in dosage is required, and with a creatinine clearance of 21ml/minute, a 75% reduction is needed; the initial loading dose need not be adjusted. Fluconazole is dialyzable; in patients undergoing hemodialysis, 100% of the target dose is given after each dialysis session. In continuous hemofiltration, clearance of fluconazole may be faster, requiring therapy at maximum approved dosages, and in patients with peritoneal dialysis the compound can be administered either systemically or intraperitoneally. Hepatic insufficiency per se does not require dose adjustments, but careful monitoring of additional hepatic toxicity is warranted. [62] [77]

The pharmacokinetics of fluconazole in pediatric age groups reflects developmental changes characteristic for a water-soluble drug with minor metabolism and predominantly renal elimination. Except for premature neonates, in whom clearance is initially decreased, pediatric patients tend to have an increased weight-normalized clearance rate from plasma, which leads to a shorter half-life compared with adults.[78] [79] Therefore, dosages at the high end of the recommended dosage range are necessary for the treatment of invasive mycoses in children.

TABLE 208-2 -- Drug-drug interactions of fluconazole and itraconazole.

DRUG-DRUG INTERACTIONS OF FLUCONAZOLE AND ITRACONAZOLE		
Mechanism and drug involved	**Triazole involved**	**Comment**
Decreased plasma concentration of triazole		
Decreased absorption of triazole	Itra**	Take antacids and antifungal agent at least 2 hours apart
• Antacids, H_2 -antagonists		
• Omeprazole, sucralfate		
• Didanosine, grapefruit juice		
Increased metabolism of triazole	Itra**, flu	Potential for therapy failure; increased potential for hepatotoxicity
• Isoniazid, rifampin		
• Rifabutin, phenytoin		
• Phenobarbital, carbamazepine		
Increased concentration of coadministered drug through inhibition of its metabolism by triazole		
Terfenadine, astemizole, cisapride	Flu‡ , Itra‡	Concom. use prohibited

Adverse effects

In adults, fluconazole has been safely administered over prolonged periods of time at dosages of up to 1600mg/day.[80] Compiled data from adult patients who received dosages of 100–400mg/day indicate an overall incidence of significant adverse effects or laboratory abnormalities leading to the discontinuation of the drug of 2.8%. Nausea, vomiting and other gastrointestinal symptoms are seen in <5% of adult patients, skin rashes and headaches in <2% and asymptomatic hepatic transaminase elevations (which are usually reversible) in up to 7%.[81] In pediatric patients of all age groups, fluconazole is generally well tolerated at dosages of up to 12mg/kg/day, with no differences from adults in frequency and profile of adverse events.[82] Severe side-effects, including liver failure and exfoliative dermatitis, have been reported anecdotally.[62] Alopecia can be seen with higher dose fluconazole (400mg/day) given for 2 months or longer; it is reversed by discontinuing therapy or substantially reducing the daily dose.[83]

Drug interactions

Fluconazole undergoes minimal CYP-mediated metabolism, but inhibits CYP3A4 and several other CYP isoforms in vitro and interacts with enzymes involved in glucuronidation, leading to a number of significant drug-drug interactions (Table 208.2).[81] [84] On the other

hand, drugs notorious for hepatic enzyme induction may lead to decreased fluconazole levels and therapeutic failure as the ultimate consequence.[62] Altogether, the number of relevant drug-drug interactions appears to be lower than for ketoconazole and itraconazole.

Clinical indications and dosages

Fluconazole is highly effective for the treatment of superficial and invasive candidal infections, including infections in neutropenic patients.[85] However, in unstable patients and in those who have received antifungal azoles for prophylaxis, AmB remains the agent of choice for initial therapy. Further potential indications for fluconazole include consolidation therapy for chronic disseminated candidiasis, cryptococcal meningitis and infections with *T. beigelii*. Fluconazole is the drug of choice for treatment of coccidioidal meningitis and has effectiveness in nonmeningeal coccidioidal infections;[86] [87] against paracoccidioidomycosis, blastomycosis, histoplasmosis and sporotrichosis, the compound appears comparatively less active than itraconazole.[33] [88] [89] [90] In the prophylactic setting, fluconazole has proven efficacy for primary prevention of invasive candidal infections in high-risk patients with acute leukemia and in patients who have undergone bone marrow or liver transplantation, for primary prevention of cryptococcosis and histoplasmosis in HIV-infected patients with very low CD4+ cell counts, and for secondary prevention of cryptococcisis and coccidioidomycosis in HIV-infected patients. [91] [92] [93]

In adults, the recommended dosage range for treatment of invasive infections is 400–800mg; in the preventive setting 100–400mg is recommended. In pediatric patients of all age groups, the recommended dosage range of fluconazole is 6–12mg/kg/day. However, in view of the faster clearance rate, the larger volume of distribution and the safety profile of fluconazole, 12mg/kg/day may be the more appropriate dosage for treatment of serious infections in full-term neonates and in infants and children. Given the extreme variability in extravascular water content and renal function, particularly in very low birth-weight preterm infants, predictably effective and safe treatment with fluconazole may not be possible in this patient population during the first days of life.

Itraconazole

Pharmacodynamics

Itraconazole exerts species- and strain-dependent fungistatic or fungicidal pharmacodynamics in vitro. Time-kill experiments have demonstrated concentration-independent, fungistatic activity of itraconazole against *Candida* spp. and *C. neoformans*.[16] Against *Aspergillus* spp., however, itraconazole displayed time and concentration-dependent fungicidal activity with >87 to >97% killing within 24 hours of drug exposure.[94] Persistent effects have not been reported thus far, and it remains to be determined which pharmacodynamic parameter best predicts antifungal efficacy in vivo.[16]

Pharmacokinetics

Itraconazole is a high-molecular-weight, highly lipophilic bis-triazole. It is available as capsules, as oral solution in hydroxypropyl-ß-cyclodextrin (HP-ß-CD), and as a parenteral solution that also uses HP-ß-CD as solubilizer. Absorption from the capsule form is dependent on a low intragastric pH and is compromised in the fasting state, and is thus unpredictable in granulocytopenic cancer patients and in patients with hypochlorhydria. Absorption is improved when the capsules are taken with food or an acidic cola beverage. The novel oral solution of itraconazole in HP-ß-CD provides better oral bioavailability, which is further enhanced in the fasting state.[95]

Following oral administration, peak plasma concentrations occur within 1–4 hours; systemic absorption of the cyclodextrin carrier is negligible. With once-daily dosing, steady state is achieved after 7–14 days, but it can be reached more rapidly by doubling the dose over the first 2–3 days. Following administration of intravenous HP-ß-CD itraconazole, drug and carrier rapidly dissociate and follow their own disposition. Peak plasma levels of itraconazole and its carrier occur immediately after completion of the 1-hour infusion. The carrier HP-ß-CD is not significantly metabolized, and virtually 100% is eliminated from plasma within 24 hours in unchanged form via glomerular filtration. Itraconazole is highly protein-bound and is extensively distributed throughout the body. Whereas concentrations in nonproteinaceous body fluids are negligible, tissue concentrations in many organs, including the brain, exceed corresponding plasma levels by 2–10 times.[95] [96]

Itraconazole is extensively metabolized in the liver and is excreted in metabolized form into bile and urine. The major metabolite, hydroxy-itraconazole, possesses antifungal activity similar to that of itraconazole. After oral administration, the plasma concentrations of hydroxy-itraconazole at steady state are 1.5–2 times higher than those of the parent compound, whereas they are considerably lower than those of itraconazole after intravenous dosing.[62] [97] It is important to note that plasma concentrations of itraconazole measured by bioassay are different from those determined by high-performance liquid chromatography, since the latter method usually does not account for hydroxy-itraconazole. The elimination of itraconazole from plasma follows a biphasic pattern; in comparison to single dosing, the elimination half-life at steady state is about twice as long, reflecting saturable excretion mechanisms.[62]

The dosage of oral itraconazole does not need to be adjusted in patients with renal insufficiency or dialysis. However, since the elimination of HP-ß-CD parallels the glomerular filtration rate, intravenous itraconazole is contraindicated in patients with a creatinine clearance of <30ml/minute; no data are available for its use in patients undergoing dialysis. In patients with severe hepatic insufficiency, the elimination half-life of itraconazole can be prolonged, and additional hepatic toxicity or possible drug interactions should be carefully monitored.[95]

Despite considerable variability between patients, the pharmacokinetics of oral HP-ß-CD itraconazole in pediatric patients beyond the neonatal period appear not to be fundamentally different from those in adults.[98] [99] No data are currently available in this population for the capsule form and intravenous HP-ß-CD itraconazole.

Adverse effects

Itraconazole usually is well tolerated, with a similar spectrum and frequency of adverse effects to that of fluconazole. Adverse events leading to the discontinuation of itraconazole occur in approximately 4% of patients treated for systemic fungal infections at dosages of up to 400mg/day. Most observed reactions are transient, and include nausea and vomiting (in <10% of patients), hypertriglyceridemia (in 9%), hypokalemia (in 6%), elevated hepatic transaminases (in 5%), rash or pruritus (in 2%), headaches or dizziness (in <2%) and pedal edema (in 1%).[100] Gastrointestinal intolerance appears to be exceedingly frequent with oral HP-ß-CD itraconazole at dosages exceeding 400mg/day. Only a few cases of more severe hepatic injury or hepatitis have been described. Itraconazole can have negative inotropic effects; because of a possible, albeit low, risk of cardiac toxicity, itraconazole should not be administered to patients with ventricular dysfunction.[101] Oral HP-ß-CD itraconazole was safe and well tolerated in pharmacokinetic studies in pediatric patients.[102] Vomiting (12%), abnormal liver function tests (5%) and abdominal pain (3%) were the most common adverse effects in 103 neutropenic pediatric cancer patients who received the drug at a dosage of 5mg/kg/day or 2.5mg/kg twice daily for antifungal prophylaxis; 18% of patients withdrew from the study because of adverse events.[103]

Drug interactions

In comparison to fluconazole, both the propensity for and the extent of drug-drug interactions are greater with itraconazole (see Table 208.2). Itraconazole is a substrate of CYP3A4, but also interacts with the heme moiety of CYP3A, resulting in noncompetitive inhibition of oxidative metabolism of many CYP3A substrates and increased (and potentially toxic) concentrations of co-administered drugs. Increased metabolism of itraconazole resulting in decreased plasma levels can be induced by drugs known for their induction of hepatic metabolizing enzymes. Patients who receive itraconazole along with one of the drugs listed in Table 208.2 should be followed closely and plasma concentrations, ideally of both compounds, should be monitored carefully. Finally, the systemic availability of itraconazole depends in part on the activity of intestinal CYP3A4 and P-glycoprotein, which contributes to its variable bioavailability after oral administration.

Clinical indications and dosing

Itraconazole is a useful agent for dermatophytic infections, pityriasis versicolor and all forms of cutaneous and mucosal candidiasis; however, its clinical efficacy in invasive candidal infections has not been evaluated. The experience with itraconazole for induction therapy of cryptococcal meningitis is scant, but itraconazole has been used with success for consolidation and maintenance treatment of this condition in patients with HIV infection, although with less success than fluconazole (see Chapter 126). [104] Itraconazole is approved as a second-line agent for the treatment of invasive *Aspergillus* infections; few data exist on its use for first-line treatment in neutropenic patients.[105] Itraconazole may be useful in the management of infections by certain dematiaceous molds,[106] but it has no documented activity against zygomycosis and fusariosis. Itraconazole is the current treatment of choice for lymphocutaneous sporotrichosis and non-life-threatening, nonmeningeal paracoccidioidomycosis, blastomycosis and histoplasmosis. In progressive, nonmeningeal coccidioidomycosis, itraconazole appears at least as active as

fluconazole.[86] However, AmB remains the treatment of choice for most immunocompromised patients and for those with life-threatening forms of endemic mycoses.

Itraconazole has been successfully used as antifungal prophylaxis in patients undergoing stem cell transplantation or intensive chemotherapy.[103] Hydroxypropyl-ß-cyclodextrin itraconazole may reduce the incidence of proven or suspected invasive fungal infections in neutropenic patients with hematologic malignancies, but prophylactic efficacy against invasive aspergillosis has not been convincingly demonstrated thus far.[34] Itraconazole was at least as effective as conventional AmB and was superior with respect to its safety profile as empiric antifungal therapy in persistently febrile neutropenic patients,[107] which has led to the approval of this indication by the FDA.

The recommended dosage range of oral itraconazole is 100–400mg/day (capsules) and 2.5mg/kg twice daily (HP-ß-CD solution). For life-threatening infections, however, more aggressive dosing may be necessary. For such conditions, we recommend a loading dose of 600–800mg/day for 3–5 days followed by a maintenance dose of 400–600mg/day, with monitoring of serum levels. The approved dosage of intravenous HP-ß-CD itraconazole is 200mg twice daily for 2 days, followed by 200mg/day for a maximum of 12 days. Itraconazole is not approved for patients under 18 years of age; based on the available pharmacokinetic data, a starting dosage of 2.5mg/kg twice daily of oral HP-ß-CD itraconazole can be advocated. The recommended dosage range for the capsule formulation is 5–8mg/kg/day with a loading dose of 4mg/kg three times daily for the first 3 days. Data on the use of intravenous itraconazole in pediatric patients are currently lacking.

Therapeutic monitoring

While experimental studies have provided evidence of a relationship between plasma concentrations and antifungal efficacy, the main rationale for monitoring plasma levels has been the erratic oral bioavailability of itraconazole, particularly in neutropenic patients. Historically, the target plasma level for itraconazole has been estimated at 0.25µg/ml (by high-performance liquid chromatography) at trough based on the IC_{90} of a large set of clinical isolates. However, more recent clinical data from a large cohort of patients undergoing intensive chemotherapy for acute leukemia and receiving antifungal prophylaxis with itraconazole have demonstrated a significant statistical association of trough concentrations <0.5µg/ml with the occurrence of invasive fungal infections.[108] We therefore recommend rapid achievement and maintenance of trough levels of =0.5µg/ml when itraconazole is given for prevention or treatment of invasive fungal infections.

Second-generation antifungal triazoles

Further improvements in the structure-activity relationship of antifungal triazoles have led to a new group of synthetic compounds that are collectively known as second-generation triazoles. The FDA has approved voriconazole, and the investigational agents posaconazole and ravuconazole are currently in advanced stages of clinical development. While ravuconazole and voriconazole are structurally related to fluconazole, the structure of posaconazole is similar to that of itraconazole.

Pharmacology

The second-generation triazoles possess enhanced target activity and specificity. They are active against a wide spectrum of clinically important fungi, including *Candida* spp., *T. beigelii, C. neoformans, Aspergillus* spp., *Fusarium* spp. and other hyaline molds, and dematiaceous as well as dimorphic moulds; they have demonstrated efficacy in various animal models of invasive fungal infections. As with itraconazole, these novel triazoles exert fungistatic activity against susceptible yeast-like organisms and strain-dependent fungicidal activity against susceptible filamentous fungi. Fundamental differences in potency, spectrum and antifungal efficacy between posaconazole, ravuconazole and voriconazole have not surfaced, but posaconazole appears to have the best activity against the zygomycetes. Against *Candida* spp. and *C. neoformans*, voriconazole exhibits nonconcentration-dependent pharmacodynamics. Near-maximal fungistatic activity is achieved at a drug concentration of approximately three times the MIC.[109] A post-antifungal effect of up to 4 hours has been observed with *C. albicans*. [110]

Voriconazole is available as a tablet and as parenteral solution that uses sulfobutyl ether-ß-cyclodextrin as solubilizer. Taken in tablet form, voriconazole is rapidly absorbed from the gastrointestinal tract. Although bioavailability is near 100%, steady-state plasma concentrations are achieved more rapidly if an intravenous loading dose is given. Multiple enzymes of the cytochrome P450 system, including CYP2C19, which exhibit genetic polymorphism in certain racial groups, metabolize voriconazole. Drug levels in poor metabolizers, which may include up to 20% of Asian populations, can be significantly elevated. Following its metabolism in the liver, the drug is mostly excreted in urine. In addition to undergoing metabolism by the P450 system, voriconazole inhibits several CYP enzymes. Therefore, there is extensive potential for drug-drug interactions. While all three second-generation triazole agents display some nonlinearity in their disposition, undergo hepatic metabolism and have the potential for drug-drug interactions through their affinity to CYP450 isoenzymes, key pharmacokinetic parameters (oral bioavailability, extent of protein binding, plasma clearance and volume of distribution) vary. Whether these

differences are of clinical significance, however, remains to be elucidated.

Mild and reversible visual disturbances occur in approximately 30% of patients. The mechanism is unknown, but is thought to be retinal in origin. Other common adverse reactions include rashes including phototoxicity, gastrointestinal disturbances and hepatic abnormalities.

Clinical studies

In a randomized, unblinded trial of patients with invasive aspergillosis, initial therapy with voriconazole led to better responses, improved survival and less toxicity than the standard approach of initial therapy with AmB.[111] Voriconazole has been used successfully in the treatment of invasive fungal infections, including aspergillosis in children who were refractory to or intolerant of conventional antifungal therapy.[112] Voriconazole has also been shown to be effective in the treatment of oropharyngeal and esophageal candidiasis in immunocompromised patients.[113] A large randomized multicenter trial has been completed that compared voriconazole (3mg/kg intravenously twice daily or 200mg by mouth twice daily) with liposomal AmB (3mg/kg intravenously) for empiric antifungal therapy. This study showed comparable composite success rates but less proven and probable breakthrough infections, infusion-related toxicity and nephrotoxicity in the voriconazole-treated cohort. However, patients receiving voriconazole had significantly more frequent episodes of transient visual disturbances and hallucination. [114]

For treatment of invasive fungal infections in children and adults an intravenous loading dose of 6mg/kg every 12 hours on day 1 followed by 4mg/kg every 12 hours thereafter is used. Whenever feasible the drug should be given by the oral route at 200mg twice daily (in children weighing less than 40kg, the dose is 100mg twice times daily). Because sulfobutyl ether-ß-cyclodextrin clearance is related to glomerular filtration rate, oral voriconazole should be used in patients whose creatinine clearance is <50ml/min. In patients with mild to moderate hepatic cirrhosis, the standard loading dose is recommended, but the maintenance dose should be halved.

To date, preliminary data from phase II and III studies have been presented for posaconazole and voriconazole. Posaconazole (50–400mg by mouth) was well tolerated and as effective as fluconazole (100mg) in two large randomized comparative studies in HIV-infected patients with oropharyngeal candidiasis.[115] Furthermore, in a salvage study in patients with a variety of invasive fungal infections, response rates in subjects with aspergillosis, fusariosis, cryptococcosis, candidiasis and phaeohyphomycoses after 4–8 weeks of

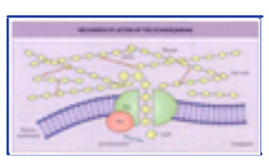

Figure 208-5 Mechanism of action of the echinocandins.

therapy with a dose of 800mg/day by mouth ranged from 44 to 80%.[116] Further clinical trials and development of an intravenous formulation are underway.

ECHINOCANDIN LIPOPEPTIDES

The echinocandins are a novel class of semisynthetic amphiphilic lipopeptides composed of a cyclic hexapeptide core linked to a variably configured lipid side chain. The echinocandins act by noncompetitive inhibition of the synthesis of 1,3-ß-glucan, a polysaccharide in the cell wall of many pathogenic fungi (Fig. 208.5). Together with chitin, the rope-like glucan fibrils are responsible for the strength and shape of the cell wall. They are important in maintaining the osmotic integrity of the fungal cell and play a key role in cell division and cell growth.[117] [118] Caspofungin has recently received approval by the FDA for treatment of refractory invasive aspergillosis and candidal esophagitis. Anidulafungin and micafungin are in advanced stages of clinical development. (Fig. 208.6).

Antifungal activity

The current echinocandins appear to possess very similar pharmacologic properties. All three compounds have potent and broad spectrum, fungicidal in-vitro activity against *Candida* spp. and potent inhibitory activity against *Aspergillus* spp.; their antifungal efficacy against these organisms in vivo has been demonstrated in various animal models. The current echinocandins have variable activity against dematiaceous and endemic mold and are inactive against most hyalohyphomycetes, zygomycetes, *C. neoformans* and *T. beigelii*.[119] Furthermore, all echinocandins have demonstrated preventive and therapeutic activity in animal models of *Pneumocystis carinii* pneumonitis. In-vitro resistance has been observed in fungal isolates overexpressing a gene encoding for a Golgi protein involved in the transport of cell wall components.[120] Primary resistance to echinocandins in otherwise susceptible fungal yeast species is rare, and resistance-induction studies have demonstrated a low potential for secondary resistance in *Candida* spp. The frequency of primary echinocandin resistance among clinical isolates of *Aspergillus* spp. and induction of secondary resistance in vitro have not been studied thus far.

Pharmacodynamics

The echinocandins demonstrate a species-dependent mode of antifungal activity. They have fungicidal activity against most *Candida* spp. but not against *Aspergillus* spp. In the latter, microscopic examination

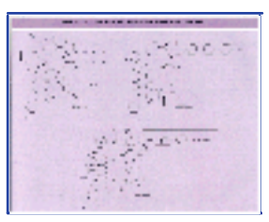

Figure 208-6 Structures of echinocandins currently in clinical practice or in clinical trials.

of exposed hyphae show a dose-dependent formation of microcolonies with progressively truncated, swollen hyphal elements that appear to be cell-wall deficient but that are able to regain their cell walls upon subculture in the absence of the drug. In a process that has been likened to pruning, caspofungin preferentially kills cells at the active centers for new cell wall synthesis within *A. fumigatus* hyphae.[121] These observations indicate differences in functional target sensitivity in both species that are not fully understood. In-vitro pharmacodynamic studies in *Candida* spp. have shown predominantly concentration-dependent fungicidal activity and rate of kill =99.9% reduction in colony-forming units) and concentration-dependent prolonged post-antifungal effects of up to 12 hours.[15] [122] In-vivo pharmacodynamic animal studies suggest similar concentration-dependent activity of the current echinocandins.

Pharmacokinetics

At present, all current echinocandins are available only for intravenous administration. They exhibit dose-proportional plasma pharmacokinetics with a ß-half-life of between 10 and 15 hours, which allows for once-daily dosing. All echinocandins are highly protein bound (>95%) and distribute into all major organ sites, including the brain; however, concentrations in uninfected CSF are low. The echinocandins are metabolized by the liver and slowly excreted into urine and feces; only small fractions are excreted into urine in unchanged form.[123] The pharmacokinetic parameters are generally lower in children than in adults. Drug levels are especially low in smaller, younger children. The ß-half-life in children is reduced by over one-third relative to adults.[124]

Adverse effects and drug interactions

At the currently investigated dosages, all echinocandins are generally well tolerated, and only a small fraction of patients enrolled in the various clinical trials (<5%) discontinued therapy because of drug-related adverse events. The most frequently reported adverse effects include increased liver transaminases, gastrointestinal upset and headaches. As with other basic polypeptides, the echinocandins have the potential to cause histamine release; however, histamine-mediated symptoms have been observed in isolated cases only. The current echinocandins appear to have no significant potential for drug interactions mediated by the CYP450 enzyme system. Caspofungin can reduce the AUC of tacrolimus by approximately 20% but has no effect on ciclosporin levels. However, ciclosporin increased the AUC of caspofungin by approximately 35%; because of transient elevations of hepatic transaminases in single-dose interaction studies, the

concomitant use of both drugs is currently not recommended. Finally, inducers of drug clearance or mixed inducer-inhibitors, namely efavirenz, nelfinavir, nevirapine, phenytoin, rifampin, dexamethasone and carbamazepine, may reduce caspofungin concentrations.

Clinical studies

The clinical efficacy of anidulafungin, caspofungin and micafungin against *Candida* spp. has been investigated in phase II or phase III studies in immunocompromised patients with esophageal candidiasis. All agents were well tolerated without serious adverse events, and all agents achieved therapeutic efficacy that was at least comparable to that of standard agents. A multicenter phase II salvage trial of caspofungin has been completed in 90 patients with definite or probable invasive aspergillosis. The majority of patients had hematologic malignancies or had undergone bone marrow transplantation, and most patients had infections that were refractory to standard therapies. As determined by an independent expert panel, a complete or partial response was observed in 45% of patients receiving at least one dose of caspofungin.[125] In a recent study of adults with invasive candidiasis (predominantly candidemia), caspofungin (70mg loading dose then 50mg/day) was compared with amphotericin B deoxycholate (0.6–1.0mg/kg/day) and found to be equivalent to but better tolerated than amphotericin B.[125A] Caspofungin is also effective and well tolerated in patients with HIV-associated esophageal candidiasis.[126] Given these results, caspofungin should be regarded as a reasonable initial treatment for candida infections. One exception may be infections due to C. parapsilosis, as the echinocandidins are less effective in vitro against this organism.

Caspofungin may be indicated in patients with probable or proven invasive aspergillosis refractory to other approved therapies and in patients who are intolerant of other therapies. The currently recommended dose regimen of caspofungin in adults consists of a single 70mg loading dose on day 1, followed by 50mg/day thereafter, administered by slow intravenous infusion of approximately 1 hour. A daily dosage regimen in the pediatric population has yet to be established. A dose of 50mg/m^2 /day is under current investigation.[124]

TERBINAFINE

Terbinafine is a highly lipophilic and keratophilic allylamine inhibitor of ergosterol biosynthesis. It is a potent noncompetitive inhibitor of fungal squalene epoxidase and prevents squalene epoxidation, an important early step in the synthesis of ergosterol. Treated fungi accumulate squalene and become deficient in ergosterol. Cell death is associated with the development of high intracellular squalene concentrations, which interfere with fungal membrane function and cell wall synthesis.[7] [127] In addition to its antifungal properties terbinafine is also anti-inflammatory and can act as a free radical scavenger.

Terbinafine is active in vitro against a wide range of pathogenic fungi, including dermatophytes, molds, dimorphic fungi, *C. neoformans* and some but not all *Candida* and *Aspergillus* spp.[128] In-vitro studies with *Aspergillus* spp. have shown terbinafine and AmB to have additive, synergistic interactions depending on the isolate. In combination with itraconazole or voriconazole, terbinafine displays potent synergistic interactions against *Aspergillus* spp. Fluconazole also increases the activity of terbinafine in an additive to synergistic fashion.[129] In vitro, combinations of terbinafine with voricoazole can overcome azole resistance in *Candida* spp. Terbinafine in combination with AmB or voriconazole is synergistic against some zygomycetes isolates. Resistance to terbinafine has been observed following a single gene mutation in *Aspergillus*.[130] In *Candida*, cross-resistance following treatment with fluconazole can occur because of upregulation of target enzymes.[131] Multidrug efflux pumps may also reduce susceptibility.[132]

Oral terbinafine is rapidly absorbed, with peak concentration occurring at 60–90 minutes postdose. It is quickly converted to multiple metabolites, which co-exist in plasma with the parent compound. Drug is delivered to peripheral tissues via sebum and by direct diffusion through the dermal layers.[133] It is detected in sebum and hair within the first week of administration and by week 3 in stratum corneum and nail samples. The terminal half-life is approximately 3 weeks and fungicidal concentrations persist in peripheral tissues for weeks to months after administration of the last dose.[134] Increasing age and concomitant hypertension are associated

with higher plasma concentrations, and smokers have lower levels than nonsmokers.[135] When given as 1% cream, terbinafine concentrations in the horny layer of skin far exceed the MICs for common dermatophytes, and effective levels of drug remains in skin well beyond discontinuation of therapy.[136]

Multiple cytochrome P450 enzymes metabolize terbinafine, and agents that affect this system alter drug concentration.[137] Terbinafine competitively inhibits CYP2D6, and elevated levels of desipramine have been observed when the drugs are co-administered. Terbinafine may reduce the level of ciclosporin A. Most of the drug and drug metabolites are eliminated in the urine. The drug is generally well tolerated, but gastrointestinal disturbances, skin rashes and headaches occur occasionally. Rare adverse reactions include hepatobiliary dysfunction, induction and exacerbation of lupus, agranulocytosis and severe skin reactions.

Oral terbinafine at doses of 250mg/day in adults and 62.5–250mg/day in children is effective and generally safe for cutaneous mycoses that warrant systemic therapy.[138] It is highly efficacious as treatment for onychomycosis. Terbinafine at daily doses of 5–15mg/kg for several months was effective in three patients with pulmonary aspergillosis who had failed standard therapy.[139] At this time, however, this agent, cannot be recommended for the treatment of systemic mycoses. Terbinafine 1% cream is effective against a variety of cutaneous mycoses. The length of treatment with either topical or oral formulation depends on the specific infection.

GRISEOFULVIN

Griseofulvin, a metabolic product of *Penicillium*, was the first oral agent available for treatment of dermatomycoses. This compound inhibits fungal cell mitosis and nucleic acid synthesis, and disrupts spindle and cytoplasmic microtubule function.[140] Griseofulvin is active against many dermatophytes, but not all. High-level resistance can develop following drug exposure, and a multiple-layered thick cell wall, which may limit griseofulvin entry, has been observed in resistant isolates.[141] [142] Griseofulvin has extremely low water solubility and moderate lipid solubility. Absorption from the gastrointestinal tract is variable and depends on the amount of dissolved drug that reaches the intestine.[143] Absorption is enhanced by a fatty meal. The bioavailability of the ultamicrosize formulation is higher than that of the microsize formulation. Once absorbed, drug is highly protein-bound. Griseofulvin is detected in the outer layer of the stratum corneum soon after it is ingested and is diffused from the extracellular fluid and sweat. Deposition of drug in growing cells may account for entry into hair and nails. [140] Concentration in plasma peaks at 3–4 hours and in skin blister fluid at 6 hours. The terminal half-life in plasma and in skin blisters is approximately 9–10 hours. During chronic administration, plasma and skin blister levels equilibrate.[144] Griseofulvin is largely metabolized in the liver and degradation metabolites are excreted in the urine. Griseofulvin is also effective in several inflammatory skin conditions, possibly

because of its anti-inflammatory properties mediated by modulation of the expression of cell adhesion molecules on leukocytes and vascular endothelial cells.[145]

Adverse effects include gastrointestinal disturbances, headaches, hepatitis and rashes. Liver and thyroid neoplasia, abnormal germ cell maturation, teratogenicity and embroyotoxicity have been observed in animal studies. The reproductive toxicity as well as the induction of chromosome aberrations in somatic cells may result from disturbance of microtubuli formation. Griseofulvin also induces accumulation of porphyrins and formation of Mallory bodies in hepatocytes. These may represent additional carcinogenic mechanisms.[146] Less common adverse events include exacerbation of lupus, porphyrias and blood dyscrasias. Drug interactions are related to induction of hepatic enzymes and include phenobarbital, oral anticoagulants and oral contraceptives.

For onychomycosis, griseofulvin has been largely supplanted by newer antifungals. Currently, its main indication is for the treatment of tinea capitis and other cutaneous mycoses. Doses of 500–1000mg/day in adults and 15–20mg/kg/day in children have been used successfully. Length of treatment depends on the site and type of infection.

AMOROLFINE

The morpholine derivative amorolfine is currently used only as a topical agent. This compound interferes with ergosterol biosynthesis and leads to the depletion of ergosterol and the subsequent accumulation of sterol precursors within the cell membrane.[147] Amorolfine also weakly inhibits the fungal enzyme squalene epoxidase. In vitro, amorolfine has a broad spectrum of activity that includes dermatophytes, dimorphic, dematiaceous and filamentous fungi, and yeasts.[148] [149] In patients, amorolfine has eradicated infections caused both by *C. albicans* and by a broad range of dermatophytes.[150] In a murine model of dermatophytosis the combinations of amorolfine with griseofulvin, terbinafine, itraconazole and fluconazole were synergistic, but 5-FC appears to be antagonistic in some fungal isolates.[151]

Amorolfine has been formulated as 0.125%, 0.25% and 0.5% creams and as a 5% lacquer. Following application, the amorolfine penetrates the nails rapidly and within 24 hours of contact it exceeds the MIC of most fungi that cause onychomycosis.[152] Following topical application, active concentration of amorolfine is retained in the skin for several days. In experimental models of systemic mycosis, amorolfine shows no significant activity, which may be due to strong protein binding or to rapid metabolism (or both).[147] The bioavailabilty of topical amorolfine is 4–10% and drug is excreted in urine and feces.[153]

Treatment-related adverse events are generally limited to burning, itching, erythema, skin dryness and scaling. Topical amorolfine has been used successfully in a variety of dermatomycoses and for the treatment of onychomycosis. Combination therapy with oral itraconazole or terbinafine may be a promising option for patients with severe disease.[154] [155]

CICLOPIROX

Ciclopirox is a poorly absorbable, synthetic hydroxypyridone antifungal agent. The mechanism of action is related to its affinity for trivalent cations. By chelating essential metal cofactors, ciclopirox inhibits fungal enzymes that are responsible for diverse metabolic processes and ultimately causes membrane and cytoplasmic disruption.[156] Ciclopirox at subinhibitory concentrations impairs candidal adherence to mucosal surfaces.[157] It has potent antifungal activity against a broad range of dermatophytic and nondermatophytic fungi. It is available in a variety of topical formulations, including as 0.77% gel and 8% nail lacquer. It readily penetrates the skin via the epidermis and the hair follicles and achieves the highest concentration in the horny layer.[158] When used as 8% nail lacquer, the drug achieves uniform distribution within the nail-plate after daily use for 1 week, and it reaches a maximum at 3–4 weeks with uniform distribution to all nail layers.[159] Within the nail the drug achieves concentrations in excess of inhibitory and fungicidal concentrations for most pathogens.[156] The bioavailability of topical ciclopirox is 2–5% and absorbed drug is mainly metabolized by glucuronidation. Excretion is predominantly renal with an elimination half-life of approximately 2 hours.[159] [160]

Treatment-related adverse events are uncommon, but local reactions such as pruritus and burning sensation can occur.

Ciclopirox has been used successfully for a variety of cutaneous mycotic infections, mucosal candidiasis and seborrheic dermatitis, and as a treatment for onychomycosis.

FUTURE DIRECTIONS

The past decade has seen a considerable expansion in antifungal drug research and the clinical development of several new compounds targeted against invasive fungal infections. Major progress has been made in defining paradigms for antifungal intervention and in designing and implementing clinical trials. The field of antifungal therapy is currently undergoing accelerated changes. Combination therapy is being explored. Several novel and promising antifungal compounds are currently in the early stages of pre-clinical investigation, and the pursuit of novel biochemical and molecular targets will result in further candidate drugs. In the light of past and present epidemiologic trends, invasive fungal infections are likely to remain a common and important complication in immunocompromised patients. An expanded drug arsenal, elucidation of resistance mechanisms, integration of pharmacokinetic and pharmacodynamic relationships, and combination therapies offer hope for further substantial progress in prevention and treatment.

Chapter 209 - Antiparasitic Agents

Samuel L Stanley Jr

INTRODUCTION

Antiparasitic agents are used to treat infestations caused by a diverse and complex group of organisms encompassing the unicellular protozoa, which have intricate life cycles often involving more than one host, as well as the helminths, which have highly developed organ systems. Many antiparasitic agents are old drugs that have never been subjected to the rigorous testing of efficacy and safety currently required by agencies in various countries, such as the US Food and Drug Administration. For most of the drugs, information regarding use in pregnancy is totally lacking.

The treatment options by organism or disease entity, along with the recommended adult and pediatric dosages, are listed in Table 209.1 . Agents that are not readily available in the USA are listed in Table 209.2 . Few of the antiparasitic agents have been extensively studied in pregnancy. Table 209.3 divides the drugs into those that are probably safe on the basis of clinical experience, those that are possibly safe on the basis of anecdotal experience or are safe during certain trimesters, and those that are known to be hazardous or for which too little information is known to make a recommendation. In general, however, the decision to use of any of these agents in a pregnant patient must be made on an individual basis, weighing the severity of the illness and the benefit of treatment to the mother against the potential toxicity to the fetus.

ANTIPROTOZOAL AGENTS

AMODIAQUINE

Amodiaquine is a 4-aminoquinoline with antimalarial activity and a mechanism of action similar to that of chloroquine. It is available only as the dihydrochloride salt for oral administration and it undergoes extensive first-pass metabolism in the liver to the active compound desethylamodiaquine, which is widely distributed throughout the body and slowly eliminated. The side-effect profile is similar to that of chloroquine but agranulocytosis and severe hepatitis have been reported with long-term use (as chemoprophylaxis). The activity of amodiaquine against some chloroquine-resistant strains of *Plasmodium falciparum* has led to a modest revival in its use.[6] [7] [8] A recent randomized clinical trial comparing amodiaquine and chloroquine showed superior efficacy for amodiaquine and a similar safety profile in an area with high levels of chloroquine-resistant *P. falciparum*.[9]

AMPHOTERICIN B

Amphotericin B, a polyene antifungal agent, is the drug of choice for primary amebic meningoencephalitis caused by *Naegleria* spp. (see Chapter 244), and it is an alternative drug for leishmaniasis (see Chapter 172).[10] [11] [12] [13] Its pharmacokinetics and side effects are detailed in Chapter 208 . Lipid-associated formulations of amphotericin B have recently been shown to be effective in the treatment of visceral leishmaniasis in India in patients who failed to respond to antimony therapy, single dose therapy with liposomal amphotericin B giving cure rates of more than 92% with minimal toxicity.[12] [13]

ANTIFOLATE AGENTS

Antifolate agents act at various steps in the folic acid cycle. For *Plasmodium* spp., *Toxoplasma* spp. and other sensitive parasites, reduced folic acid derivatives are essential for de-novo pyrimidine synthesis. Unlike mammalian cells, these parasites cannot use preformed pyrimidines. Antifolate agents are most commonly used in combination to block sequential steps in the folic acid metabolic pathway (see Chapter 197).

Pyrimethamine

Pyrimethamine is a diaminopyrimidine that inhibits plasmodial dihydrofolate reductase at a concentration that is 1000 times less than that required to inhibit the mammalian enzyme.[6] [7] [14] [15] [16] It is effective against the erythrocytic stages of all *Plasmodium* spp. that are pathogenic for humans and, in combination with sulfadiazine, clindamycin or atovaquone, it is used for the treatment of *Toxoplasma gondii*. [17] [18] Pyrimethamine also has activity against *Isospora belli*.[19] The drug is available in oral form; it is slowly but completely absorbed, is 85% protein-bound and is extensively metabolized by the liver (< 3% is excreted unchanged). The half-life is 4–6 days.

Although pyrimethamine is available as 25mg tablets, it is almost exclusively used in combination with a sulfonamide (sulfadiazine, sulfadoxine) or a sulfone (dapsone; see below). The dosage for toxoplasmosis is listed in Table 209.1 . Some clinicians give an initial pyrimethamine loading dose of 200mg. In patients who cannot tolerate sulfonamides, clindamycin (1.8–2.4g/day in divided doses) or atovaquone (1.5g q12h) may be substituted. Side effects of pyrimethamine include blood dyscrasias, rash and, very rarely, seizures or shock. At high doses, pyrimethamine causes bone marrow suppression, which can be prevented by concurrent administration of folinic acid.

Trimethoprim

Trimethoprim (TMP) is another diaminopyrimidine that inhibits microbial dihydrofolate reductase. It has activity against

- a variety of bacteria (see Chapter 197);
- *Pneumocystis carinii* (see Chapter 124); and
- the parasites *Isospora belli* and *Cyclospora cayetanensis* (see Chapter 243).[19] [20]

Trimethoprim is readily absorbed, widely distributed and 50% protein-bound. Less than 20% is hepatically metabolized to inactive metabolites and the drug is excreted both in the urine and bile. The half-life is 9–11 hours.

For parasitic infections, TMP is used in fixed combination with sulfamethoxazole (SMX; see below). Side effects include rashes, pruritus, nausea, vomiting, glossitis, elevated liver enzymes, cytopenias, megaloblastic anemia, fever, aseptic meningitis and impaired renal function.

TABLE 209-1 -- Antiparasitic agents and dosages.[†]

ANTIPARASITIC AGENTS AND DOSAGES			
Infection	**Drug**	**Adult dosage**	**Pediatric dosage**
Acanthamoeba (keratitis)			
Drug of choice	Polyhexamethylene biguanide 0.02% (topical) plus 0.1% propamidine isethionate (topical)		
Amebiasis (*Entamoeba histolytica*)			
Asymptomatic			
Drug of choice	Paromomycin	25–35mg/kg/day in three doses for 7 days	25–35mg/kg/day in three doses for 7 days
Alternatives	Diloxanide furoate	500mg q8h for 10 days	20mg/kg/day in three doses for 10 days
	Iodoquinol	650mg q8h for 20 days	30–40mg/kg/day (maximum 2g) in three doses for 20 days
Mild-to-moderate intestinal disease			
Drug of choice	Metronidazole	500–750mg q8h for 5–10 days	35–50mg/kg/day in three doses for 10 days
OR			
	Tinidazole	2g/day for 3 days	50mg/kg (maximum 2g) per day for 3 days
Severe intestinal disease and extraintestinal disease			
Drug of choice	Metronidazole	750mg q8h for 5–10 days	35–50mg/kg/day in three doses for 10 days
OR			
	Tinidazole	600mg q12h or 800mg q8h for 5 days	50mg/kg or 60mg/kg (maximum 2g) per day for 5 days

Amebic meningoencephalitis (primary)			
***Naegleria* spp.**			
Drug of choice	Amphotericin B	1mg/kg/day iv, uncertain duration	1mg/kg/day iv, uncertain duration
***Acanthamoeba* spp.**			
Drug of choice	Pentamidine, ketoconazole, flucytosine		
Balamuthia mandrillaris [*]			
Drugs of choice	Clarithromycin	500mg q8h	
	Fluconazole	400mg q24h	
	Sulfadiazine	1.5g q6h	
	Flucytosine	1.5g q6h	
Sappinia diploides [†]			
Drugs of choice	Azithromycin	250mg q24h	
	Pentamidine	300mg iv q24h	
	Itraconazole	200mg q12h	
	Flucytosine	2.75g q6h	
***Ancylostoma caninum* (eosinophilic enterocolitis)**			
Drug of choice	Mebendazole	100mg q12h for 3 days	100mg q12h for 3 days
OR			
	Pyrantel pamoate	11mg/kg (maximum 1g) for 3 days	11mg/kg (maximum 1g) for 3 days
OR			
	Albendazole	400mg, single dose	400mg, single dose
Angiostrongyliasis			
Angiostrongylus cantonensis			
Drug of choice	Mebendazole	100mg q12h for 5 days	100mg q12h for 5 days
Angiostrongylus costaricensis			
Drug of choice	Mebendazole	200–400mg q8h for 10 days	200–400mg q8h for 10 days
Alternative	Thiabendazole	75mg/kg/day in three doses for 3 days (maximum 3g/day)	75mg/kg/day in three doses for 3 days (maximum 3g/day)
Anisakiasis (*Anisakis* spp.)			
Treatment of choice		Surgical or endoscopic removal	
Ascariasis (*Ascaris lumbricoides*, roundworm)			
Drug of choice	Mebendazole	100mg q12h for 3 days or 500mg, single dose	100mg q12h for 3 days or 500mg, single dose
OR			
	Pyrantel pamoate	11mg/kg, single dose (maximum 1g)	11mg/kg, single dose (maximum 1g)
OR			
	Albendazole	400mg, single dose	400mg, single dose
Babesiosis (*Babesia* spp.)			
Drug of choice	Clindamycin	1.2g q12h iv or 600mg q8h po for 7 days	20–40mg/kg/day po in three doses for 7 days
PLUS	Quinine	650mg q8h po for 7 days	25mg/kg/day in three doses for 7 days
OR			
	Atovaquone	750mg q12h for 7–10 days	20mg/kg q12h for 7–10 days
PLUS	Azithromycin	600mg po daily for 7–10 days	12mg/kg daily for 7–10 days
Balantidiasis (*Balantidium coli*)			
Drug of choice	Tetracycline	500mg q6h for 10 days	40mg/kg/day (maximum 2g) in four doses for 10 days
Alternatives	Iodoquinol	650mg q8h for 20 days	40mg/kg/day in three doses for 20 days
	Metronidazole	750mg q8h for 5 days	35–50mg/kg/day in three doses for 5 days
Baylisascariasis (*Baylisascaris procyonis*)			
Drugs of choice	Albendazole, mebendazole, thiabendazole, levamisole or ivermectin		
Blastocystis hominis			
Drug of choice	Metronidazole	750mg q8h for 10 days	
OR			
	Iodoquinol	650mg q8h for 20 days	
Capillariasis (*Capillaria philippinensis*)			
Drug of choice	Mebendazole	200mg q12h for 20 days	200mg q12h for 20 days
Alternative	Albendazole	400mg/day for 10 days	400mg/day for 10 days
Cryptosporidiosis (*Cryptosporidium parvum*)			

No agent has yet been conclusively proved to be effective in AIDS patients. Nitazoxanide, in the doses listed below, showed efficacy in clearing infection from immunocompetent individuals.			
	Nitazoxanide	500mg q12h for 3 days	age 4–11 years: 200mg q12h for 3 days
			age 1–3 years: 100mg q12h
Cutaneous larva migrans (creeping eruption, dog and cat hookworm)			
Drug of choice	Thiabendazole	Topical administration	Topical administration
OR			
	Ivermectin	150–200µg/kg, single dose	150–200µg/kg, single dose
OR			
	Albendazole	400mg/day for 3 days	400mg/day for 3 days
Cyclosporiasis (*Cyclospora cayetanensis*)			
Drug of choice	TMP-SMX	TMP 160mg, SMX 800mg q12h for 7–10 days	TMP 5mg/kg, SMX 25mg/kg q12h for 7–10 days
Dientamoeba fragilis			
Drug of choice	Iodoquinol	650mg q8h for 20 days	40mg/kg/day (maximum 2g) in three doses for 20 days
OR			
	Paromomycin	25–30mg/kg/day in three doses for 7 days	25–30mg/kg/day in three doses for 7 days
OR			
	Tetracycline	500mg q6h for 10 days	10mg/kg q6h (maximum 2g) for 10 days
Dracunculiasis (*Dracunculus medinensis*, guinea worm)			
Drug of choice	Metronidazole	250mg q8h for 10 days	25mg/kg/day (maximum 750mg) in three doses for 10 days
Entamoeba polecki			
Drug of choice	Metronidazole	750mg q8h for 10 days	35–50mg/kg/day in three doses for 10 days
Enterobiasis (*Enterobius vermicularis*, pinworm)			
Drug of choice	Pyrantel pamoale	11mg/kg, single dose (maximum 1g); repeat in 2 weeks	11mg/kg, single dose (maximum 1g); repeat in 2 weeks
OR			
	Mebendazole	100mg, single dose; repeat in 2 weeks	100mg, single dose; repeat in 2 weeks
OR			
	Albendazole	400mg, single dose; repeat in 2 weeks	400mg, single dose; repeat in 2 weeks
Filariasis			
Wuchereria bancrofti, Brugia malayi			
Drug of choice	Diethylcarbamazine	Day 1: 50mg after food	Day 1: 1mg/kg after food
		Day 2: 50mg q8h	Day 2: 1mg/kg q8h
		Day 3: 100mg q8h	Day 3: 1–2mg/kg q8h
		Days 4–14: 6mg/kg/day in three doses	Days 4–14: 6mg/kg/day in three doses
Loa loa			
Drug of choice	Diethylcarbamazine	Day 1: 50mg after food	Day 1: 1mg/kg after food
		Day 2: 50mg q8h	Day 2: 1mg/kg q8h
		Day 3: 100mg q8h	Day 3: 1–2mg/kg q8h
		Days 4–21: 9mg/kg/day in three doses	Days 4–21: 9mg/kg/day in three doses
Mansonella ozzardi			
Drug of choice	Ivermectin	6mg, single dose	
Mansonella perstans			
Drug of choice	Mebendazole	100mg q12h for 30 days	
OR			
	Albendazole	400mg q12h for 10 days	
Mansonella streptocerca			
Drug of choice	Ivermectin	150µg/kg, single dose	
OR			
	Diethylcarbamazine	6mg/kg/day for 14 days	
Tropical pulmonary eosinophilia			
Drug of choice	Diethylcarbamazine	6mg/kg/day in three doses for 14 days	6mg/kg/day in three doses for 14 days
***Onchocerca volvulus* (river blindness)**			
Drug of choice	Ivermectin	150µg/kg, single dose, repeated every 6–12 months	150µg/kg, single dose, repeated every 6–12 months
Fluke (hermaphroditic) infection			
***Clonorchis sinensis* (Chinese liver fluke)**			
Drug of choice	Praziquantel	75mg/kg/day in three doses for 1 day	75mg/kg/day in three doses for 1 day

OR			
	Albendazole	10mg/kg for 7 days	
***Fasciola hepatica* (sheep liver fluke)**			
Drug of choice	Triclabendazole	10mg/kg, single dose	
Alternative	Bithionol	30–50mg/kg on alternate days for 10–15 doses	30–50mg/kg on alternate days for 10–15 doses
***Fasciotopsis buski, Heterophyes heterophyes, Metagonimus yokogawai* (intestinal flukes)**			
Drug of choice	Praziquantel	75mg/kg/day in three doses for 1 day	75mg/kg/day in three doses for 1 day
***Metorchis conjunctus* (North American liver fluke)**			
Drug of choice	Praziquantel	75mg/kg/day in three doses for 1 day	75mg/kg/day in three doses for 1 day
Nanophyetus salmincola			
Drug of choice	Praziquantel	60mg/kg/day in three doses for 1 day	60mg/kg/day in three doses for 1 day

Drug of choice	Praziquantel	75mg/kg/day in three doses for 1 day	75mg/kg/day in three doses for 1 day
***Paragonimus westermani* (lung fluke)**			
Drug of choice	Praziquantel	75mg/kg/day in three doses for 2 days	75mg/kg/day in three doses for 2 days
Alternative	Bithionol	30–50mg/kg on alternate for 10–15 doses	30–50mg/kg on alternate for 10–15 doses
Giardiasis (*Giardia lambia*)			
Drug of choice	Metronidazole	250mg q8h for 5 days	15mg/kg/day in three doses for 5 days
Alternative	Tinidazole	2g, single dose	50mg/kg, single dose (maximum 2g)
	Furazolidone	100mg q6h for 7–10 days	6mg/kg/day in four doses for 7–10 days
	Paromomycin	25–35mg/kg/day in three doses for 7 days	
	Quinacrine	100mg q8h for 5 days (max. 300mg/day)	2mg/kg q8h for 5 days (max. 300mg/day)
Gnathostomiasis (*Gnathostoma spinigerum*)			
Treatment of choice		Surgical removal	
OR			
	Ivermectin	200µg/kg/day for 2 days	200µg/kg/day for 2 days
OR			
	Albendazole	400mg q12h for 21 days	400mg q12h for 21 days
Hookworm infection (*Ancylostoma duodenale, Necator americanus*)			
Drug of choice	Mebendazole	100mg q12h for 2 days or 500mg, single dose	100mg q12h for 2 days or 500mg, single dose
OR			
	Pyrantel pamoate	11mg/kg (maximum 1g) for 3 days	11mg/kg (maximum 1g) for 3 days
OR			
	Albendazole	400mg, single dose	400mg, single dose
Isosporiasis (*Isospora belli*)			
Drug of choice	TMP-SMX	160mg TMP, 800mg SMX q6h for 10 days, then q12h for 3 weeks	
Leishmaniasis (*Leishmania mexicana, Leishmania tropica, Leishmania major, Leishmania braziliensis, Leishmania donovani* (kala-azar), *Leishmania infantum*)			
Drug of choice	Sodium stibogluconate	20mg Sb/kg/day iv or im for 20–28 days	20mg Sb/kg/day iv or im for 20–28 days
OR			
	Meglumine antimonate	20mg Sb/kg/day for 20–28 days	20mg Sb/kg/day for 20–28 days
Alternative	Amphotericin B	0.5–1 mg/kg by slow infusion daily or every 2 days for up to 8 weeks	0.5–1 mg/kg by slow infusion daily or every 2 days for up to 8 weeks
OR			
	Lipid-encapsulated amphotericin B	15–20mg/kg (total dose over 5 days or longer)	15–20mg/kg (total dose over 5 days or longer)
	Pentamidine isethionate	2–4mg/kg im daily or every 2 days for up to 15 doses	2–4mg/kg im daily or every 2 days for up to 15 doses
	Paromomycin	Topically q12h for 15 days	
Malaria treatment (*Plasmodium falciparum, Plasmodium ovale, Plasmodium vivax, Plasmodium malariae*)			
Chloroquine-resistant *Plasmodium falciparum* (oral regimens)			
Drug of choice	Quinine sulfate	650mg q8h for 3–7 days	25mg/kg/day in three doses for 3–7 days
PLUS			
	Doxycycline	100mg q12h for 7 days	2mg/kg/day for 7 days
OR PLUS			
	Pyrimenthamine-sulfadoxine	3 tablets, single dose on last days of quinine treatment	Aged <1 year, 1/4 tablet; aged 1–3 years, 1/2 tablet; aged 4–8 years, 1 tablet; aged 9–14 years, 2 tablets
OR PLUS			
	Clindamycin	900mg q8h for 5 days	20–40 mg/kg/day in three doses for 5 days
OR			

	Atovaquone/proguanil	Two adults tablets q12h for 3 days	11–20kg: one adult tablet/day for 3 days
			21–30kg: 2 adult tablets/day for 3 days
			31–40kg: 3 adult tablets/day for 3 days
			>40kg: adult dose
Alternatives	Mefloquine	750mg followed by 500mg 12h later	15mg/kg, single dose (if body weight <45kg), followed by 10mg/kg 12h later
	Halofantrine	500mg q6h for three doses; repeat in 1 week	8mg/kg q6h for three doses (if body weight <40kg); repeat in 1 week
	Artesunate	4mg/kg/day for 3 days	
PLUS			
	Mefloquine	1250mg, single dose	
Chloroquine-resistant *Plasmodium vivax*			
Drug of choice	Quinine sulfate	650mg q8h for 3–7 days	25mg/kg/day in three doses for 3–7 days
PLUS			
	Doxycycline	100mg q12h for 7 days	2mg/kg/day for 7 days
OR PLUS			
	Pyrimethamine-sulfadoxine	3 tablets, single dose on last day of quinine treatment	Aged <1 year, 1/4 tablet; aged 1–3 years, 1/2 tablet; aged 4–8 years, 1 tablet; aged 9–14 years, 2 tablets
OR			
	Mefloquine	1250mg, single dose	25mg/kg, single dose (if body weight <45kg)
All *Plasmodium* spp. except chloroquine-resistant *Plasmodium falciparum* and chloroquine-resistant *Plasmodium vivax* (oral regimens)			
Drug of choice	Chloroquine phosphate	1g (600mg base), then 500mg (300mg base) 6 hours later, then 500mg (300mg base) at 24 hours and 48 hours	10mg base/kg (maximum 600mg base), then 5mg base/kg 6 hours later, then 5mg base/kg at 24 hours and 48 hours
All *Plasmodium* spp. (parenteral regimens)			
Drug of choice	Quinidine gluconate	10mg/kg loading dose (maximum 600mg) in normal saline slowly over 1–2 hours, followed by continuous infusion of 0.02mg/kg/minute until oral therapy can be started	10mg/kg loading dose (maximum 600mg) in normal saline slowly over 1–2 hours, followed by continuous infusion of 0.02mg/kg/minute until oral therapy can be started
OR			
	Quinine dihydrochloride	20mg/kg loading dose iv in 5% dextrose over 4 hours, followed by 10mg/kg over 2–4 hours q8h (maximum 1800mg/day) until oral therapy can be started	20mg/kg loading dose iv in 5% dextrose over 4 hours, followed by 10mg/kg over 2–4 hours q8h (maximum 1800mg/day) until oral therapy can be started
Alternative	Artemether	3.2mg/kg im, then 1.6mg/kg q24h	3.2mg/kg im, then 1.6mg/kg q24h
Prevention of relapses (*Plasmodium vivax* and *Plasmodium ovale* only)			
Drug of choice	Primaquine phosphate	26.3mg (15mg base) per day for 14 days or 79mg (45mg base) per week for 8 weeks	0.3mg base/kg/day for 14 days
Malaria prevention			
Chloroquine-sensitive areas			
Drug of choice	Chloroquine phosphate	500mg (300mg base), once per week	5mg/kg base once per week, up to adult dose of 300mg base
Chloroquine-resistant areas			
Drug of choice	Mefloquine	250mg once per week	Weight <5kg, no data; weight 5–9kg, 1/8 tablet; weight 10–19kg, 1/4 tablet; weight 20–30kg, 1/2 tablet; weight 31–45kg, 3/4 tablet; weight >45kg, 1 tablet
OR			
	Doxycycline	100mg/day	2mg/kg/day, up to 100mg/day
OR			
	Atovaquone/proguanil	One adult tablet daily	11–20kg: 62.5mg/25mg
			21–20kg: 125mg/50mg
			31–40kg: 187.5mg/75mg
			>40kg: adult dose
Alternatives	Primaquine	0.5mg/kg base daily	0.5mg/kg base daily
	Chloroquine phosphate	500mg (300mg base) once per week	5mg/kg base once per week, up to adult dose of 300mg base
PLUS			
	Pyrimethamine-sulfadoxine for presumptive treatment	Carry a single dose (3 tablets) for self-treatment of febrile illness when medical care is not immediately available	Aged <1 year, 1/4 tablet; aged 1–3 years, 1/2 tablet; aged 4–8 years, 1 tablet; aged 9–14 years, 2 tablets
OR PLUS			
	Proguanil	200mg/day	Aged <2 years, 50mg/day; aged 2–6 years, 100mg; aged 7–10 years, 150mg; aged >10 years, 200mg
Microsporidiosis			
Ocular microsporidiosis (*Encephalitozoon hellem, Encephalitozoon cuniculi, Vittaforma corneae* (*Nosema corneum*))			
Drug of choice	Albendazole	400mg q12h	
PLUS			
	Fumagillin eyedrops		
Intestinal microsporidiosis (*Enterocylozoon bieneusi, Encephalitozoon (Septata) intestinalis*)			
Drug of choice	Albendazole	400mg q12h	

OR			
	Fumagillin	60mg/day po for 14 days	
Disseminated microsporidrosis (*Enterocytozoon hellem, Enterocytozoon cuniculi, Enterocytozoon intestinalis, Pleistophora* spp.)			
Drug of choice	Albendazole	400mg q12h	
Moniliformis moniliformis			
Drug of choice	Pyrantel pamoate	11mg/kg, single dose, repeat twice 2 weeks apart	11mg/kg, single dose, repeat twice 2 weeks apart
Oesophagostomum bifurcum			
Drug of choice	Albendazole or pyrantel pamoate		
Schislosomiasis (bilharziasis)			
Schistosoma haematobium			
Drug of choice	Praziquantel	40mg/kg/day in two doses for 1 day	40mg/kg/day in two doses for 1 day
Schistosoma japonicum			
Drug of choice	Praziquantel	60mg/kg/day in three doses for 1 day	60mg/kg/day in three doses for 1 day
Schistosoma mansoni			
Drug of choice	Praziquantel	40mg/kg/day in two doses for 1 day	40mg/kg/day in two doses for 1 day
Alternative	Oxamniquine	15mg/kg, single dose	20mg/kg/day in two doses for 1 day
Schistosoma mekongi			
Drug of choice	Praziquantel	60mg/kg/day in three doses for 1 day	60mg/kg/day in three doses for 1 day
Strongyloidiasis (*Strongyloides stercoralis,* threadworm)			
Drug of choice	Ivermectin	200µg/kg/day for 1–2 days	200µg/kg/day for 1–2 days
Alternative	Thiabendazole	50mg/kg/day in two doses (maximum 3g/day) for 2 days	50mg/kg/day in two doses (maximum 3g/day) for 2 days
Tapeworm infection (adult (intestinal stage))			
***Diphyllobothrium latum* (fish), *Taenia saginata* (beef), *Taenia solium* (pork), *Dipylidium caninum* (dog)**			
Drug of choice	Praziquantel	5–10mg/kg, single dose	5–10mg/kg, single dose
Alternative	Niclosamide	2g single dose	50mg/kg, single dose
***Hymenolepis nana* (dwarf tapeworm)**			
Drug of choice	Praziquantel	25mg/kg, single dose	25mg/kg, single dose
Tapeworm infection (larval (tissue stage))			
***Echinococcus granulosus* (hydatid cyst)**			
Drug of choice	Albendazole	400mg q12h for 28 days, repeated as necessary	15mg/kg/day for 28 days, repeated as necessary
Echinococcus multilocularis			
Treatment of choice		Surgical excision	
***Cysticercus cellulosae* (cysticercosis)**			
Drug of choice	Albendazole	400mg q12h for 8–30 days, repeated as necessary	15mg/kg/day (maximum 800mg) in two doses for 8–30 days, repeated as necessary
OR			
	Praziquantel	50mg/kg/day in three doses for 15 days	50mg/kg/day in three doses for 15 days
Alternative	Surgery		
Toxoplasmosis (*Toxoplasma gondii*)			
Drug of choice	Pyrimethamine	25–100mg/day for 3–4 weeks	2mg/kg/day for 3 days, then 1mg/kg/day (maximum 25mg/day) for 4 weeks
PLUS			
	Sulfadiazine	1–1.5g q6h for 3–4 weeks	100–200mg/kg/day for 3–4 weeks
Alternative	Spiramycin	3–4g/day	50–100mg/kg/day for 3–4 weeks
Trichinosis (*Trichinella spiralis*)			
Drug of choice	Corticosteroids for severe symptoms		
PLUS			
	Mebendazole	200–400mg q8h for 3 days, then 400–500mg q8h for 10 days	
Trichomoniasis (*Trichomonas vaginalis*)			
Drug of choice	Metronidazole	2g, single dose or 500mg q12h po for 7 days	15mg/kg/day po in three doses for 7 days
OR			
	Tinidazole	2g, single dose	50mg/kg, single dose (maximum 2g)
Trichostrongyliasis (*Trichostrongylus* spp.)			
Drug of choice	Pyrantel pamoate	11mg/kg, single dose (maximum 1g)	11mg/kg, single dose (maximum 1g)

Alternative	Mebendazole	100mg q12h for 3 days	100mg q12h for 3 days
OR			
	Albendazole	400mg, single dose	400mg, single dose
Trichuriasis (*Trichuris trichiura, whipworm*)			
Drug of choice	Mebendazole	100mg q12h for 3 days or 500mg, single dose	100mg q12h for 3 days or 500mg, single dose
Alternative	Albendazole	400mg, single dose	400mg, single dose
Trypanosomiasis			
***Trypanosoma cruzi* (American trypanosomiasis, Chagas' disease)**			
Drug of choice	Nifurtimox	8–10mg/kg/day in three or four doses for 90–120 days	Aged 1–10 years, 15–20mg/kg/day in four doses for 90 days; aged 11–16 years, 12.5–15mg/kg/day in four doses for 90 days
OR			
	Benznidazole	5–7mg/kg/day for 30–90 days	Aged =12 years, 10mg/kg/day in two doses for 30–90 days
***Trypanosoma brucei gambiense* (West African trypanosomiasis) — hemolymphatic stage**			
Drug of choice	Difluoromethylornithine (eflornithine)	400mg/kg/day iv in four divided doses for 14 days	
OR			
	Pentamidine isethionate	4mg/kg/day im for 10 days	4mg/kg/day im for 10 days
Alternative	Suramin	100–200mg (test dose) iv, then 1g iv on days 1, 3, 7, 14 and 21	20mg/kg iv on days 1, 3, 7, 14 and 21
***Trypanosoma brucei rhodesiense* (East African trypanosomiasis) — hemolymphatic stage**			
Drug of choice	Suramin	100–200mg (test dose) iv, then 1g iv on days 1, 3, 7, 14 and 21	20mg/kg iv on days 1, 3, 7, 14 and 21
Late disease with central nervous system involvement, both *T. brucei gambiense* and *T. brucei rhodesiense*			
Drug of choice	Melarsoprol	2–3.6mg/kg/day iv for 3 days; after 1 week 3.6mg/kg/day iv for 3 days; repeat again after 10–21 days	18–25mg/kg over 1 month; initial dose of 0.36mg/kg iv, increasing gradually to max. 3.6mg/kg at intervals of 1–5 days for total of 9–10 doses
OR			
	Difluoromethylornithine	400mg/kg/day iv in four divided doses for 14 days	
Visceral larva migrans (toxocariasis)			
	Albendazole	400mg q12h for 3–5 days	400mg q12h for 3–5 days
OR			
	Mebendazole	100–200mg q12h for 5 days	100–200mg q12h for 5 days
Organism or disease entity is listed alphabetically. Both adult and pediatric dosages are indicated. Sb, antimony; SMX, sulfamethoxazole; TMP, trimethoprim.

TABLE 209-2 -- Availability of antiparasitic agents.

AVAILABILITY OF ANTIPARASITIC AGENTS		
Agent	**Trade name**	**Manufacturer**
Available from the drug service provided by the US Centers for Disease Control and Prevention		
Bithionol	Bitin	Tanabe (Japan)
Dehydroemetine	Dehydroemetine	Roche
	Dametine	Merck
Melarsoprol	Arsobal	Aventis
Nifurtimox	Lampit	Bayer
Sodium stibogluconate	Pentostam	GlaxoSmithKline
Suramin	Germanin	Bayer
Available in the USA from the manufacturer		
Diethylcarbamazine	Hetrazan	Wyeth-Ayerst
Fumagillin	Fumidil B	Mid-Continent Agrimarketing
Nitazoxanide	Cryptaz	Romark Laboratories
Commercially available only outside the USA		
Amodiaquine	Camoquin	Parke-Davis
	Flavoquine	Aventis
Artemether	Artenam	Arenco (Belgium)
Artesunate	(Generic)	Guilin No 1 Factory (China)
Benznidazole	Rochagan	Roche
Diloxanide furoate	Furamide	Boots (UK)
Difluoromethylornithine	Ornidyl	Hoechst Marion Roussel
Flubendazole	Fluvermal, Flumoxane	Janssen
Halofantrine	Halfan	GlaxoSmithKline

Meglumine antimonate	Glucantime	Aventis
Metrifonate	Bilarcil	Bayer
Niclosamide	Yomesan	Bayer
Ornidazole	Tiberal	Roche
Oxamniquine	Vansil	Pfizer
Proguanil	Paludrine	Wyeth-Ayerst, Zeneca
Pyrimethamine-dapsone	Maloprim	GlaxoSmithKline
Pyrimethamine-sulfadoxine-mefloquine	Fansimef	Roche
Quinacrine (discontinued in 1992)	Atabrine	Sanofi
Quinine dihydrochloride	(Generic)	ACF Chemiefarma NV (The Netherlands)
Spiramycin	Rovamycine	Aventis
Tinidazole	Fasigyn	Pfizer
Triclabendazole	Egaten	Novartis
It is often difficult to obtain antiparasitic agents. This is not a comprehensive list; many drugs have multiple trade names and manufacturers, only some of which are included. Agents are divided into those available from the drug service provided by the Centers for Disease Control and Prevention, those available from the manufacturer in the USA and those that are commercially available only outside the USA.		

Sulfonamides

Sulfonamides, which are derivatives of sulfanilamide, interfere with microbial folic acid synthesis by competitively inhibiting the enzyme dihydropteroate synthase.[6] [7] [14] [15] This enzyme is involved in the step in folic acid synthesis that precedes the step blocked by pyrimethamine and TMP. Sulfonamides are separated into four groups:

- short- and intermediate-acting agents;
- long-acting agents;
- agents that are limited to the bowel lumen; and
- topical agents.

TABLE 209-3 -- Safety of antiparasitic agents in pregnancy.*

SAFETY OF ANTIPARASITIC AGENTS IN PREGNANCY
Category 1 drugs: probably safe
Amphotericin B
Azithromycin
Chloroquine
Clindamycin
Dapsone
Paromomycin
Praziquantel
Proguanil
Spiramycin
Category 2 drugs: possibly safe or safe during certain trimesters
Diethylcarbamazine
Ivermectin
Mebendazole
Mefloquine
Metrifonate
Metronidazole
Pyrantel pamoate
Pyrimethamine
Sulfonamides
Trimethoprim
Category 3 drugs: insufficient data or established as unsafe
Albendazole
Artemisinin and derivatives
Atovaquone
Benznidazole
Bithionol
Dehydroemetine
Diloxanide furoate
Doxycycline
Difluoromethylornithine
Emetine
Fumagillin
Furazolidone
Halofantrine
Iodoquinol
Melarsoprol
Niclosamide
Nifurtimox

Oxamniquine
Pentamidine isethionate
Piperazine
Primaquine
Quinacrine
Quinine
Quinidine
Sodium stibogluconate
Suramin
Tetracycline
Thiabendazole
There are no well-controlled studies proving the safety of any of these antiparasitic agents in pregnancy. Category 1 drugs are those for which extensive clinical experience has demonstrated safety in pregnancy. Category 2 drugs are those that have been reported as safe only anecdotally or those that have been used safely in certain trimesters only. Category 3 drugs are those that should not be used because of either inadequate information or documented fetal harm.

** Adapted from Alecrim et al.,[3] Phillips-Howard et al.,[4] and Samuel and Barry.[5]*

Only agents from the first two of these categories are used to treat parasitic diseases; these are generally combined with either pyrimethamine or TMP.

Sulfamethoxazole

Sulfamethoxazole is an intermediate-acting sulfonamide. It is rapidly absorbed, widely distributed, 50–70% protein bound, hepatically metabolized and renally excreted. The half-life is 7–12 hours. It is available in a fixed combination with TMP (see below) for numerous indications.

Sulfadiazine

Sulfadiazine, another intermediate-acting sulfonamide, is also rapidly absorbed, widely distributed (including within the cerebrospinal fluid), 45–55% protein-bound, hepatically metabolized and renally excreted. The half-life is 12 hours. It is used with pyrimethamine in the treatment of toxoplasmosis, as detailed above.

Sulfadoxine

Sulfadoxine, a long-acting sulfonamide, is rapidly absorbed but slowly eliminated and has a half-life of 7–9 days. It is available in a fixed

combination with pyrimethamine (Fansidar) for the prophylaxis and treatment of malaria (see below).

Side effects of sulfonamides

Side effects of sulfonamides are numerous. Nausea, vomiting and anorexia occur in 1–2% of patients. Hypersensitivity reactions include:

- drug eruptions (ranging from morbilliform rash to severe exfoliation);
- fever;
- serum sickness; and
- hepatocellular dysfunction and necrosis.

Acute hemolytic anemia, agranulocytosis and aplastic anemia are rare. Reversible bone marrow suppression is not uncommon in immunocompromised patients, particularly those who have AIDS. Crystalluria can occur with sulfadiazine and can be avoided by increasing fluid intake or alkalinizing the urine.

Fansidar

Fansidar tablets contain pyrimethamine 25mg and sulfadoxine 500mg. Fansidar is used in the treatment of chloroquine-resistant *P. falciparum* infections.[6] [7] [14] [15] [16] Fansidar is no longer recommended for malaria prophylaxis because of the possibility of fatal cutaneous eruptions, including erythema multiforme, toxic epidermal necrolysis and Stevens-Johnson syndrome. These reactions have been attributed to the sulfadoxine component; fatalities have occurred between 1 in 11,000 and 1 in 26,000 users, usually within 5 weeks of starting the agent. Serum sickness, bone marrow suppression, pneumonitis and hepatitis have also been documented in patients taking Fansidar for prophylaxis. There have been no fatalities described with Fansidar used for therapy. *Plasmodium falciparum* resistance to Fansidar has been described in South East Asia, eastern Africa, the Amazon basin, Bangladesh and Oceania.[16]

Fansimef

Fansimef is the combination of pyrimethamine (25mg), sulfadoxine (500mg) and mefloquine (250mg). It has been used in South East Asia and Brazil for both prophylaxis and treatment of chloroquine-resistant *P. falciparum*.

Maloprim

Maloprim tablets contain pyrimethamine 25mg and dapsone 100mg. Dapsone is a sulfone that is used in the treatment of leprosy (see Chapter 154) and *Pneumocystis carinii* pneumonia (see Chapter 124). This combination was used for malaria prophylaxis but is rarely employed today.[21] Hemolytic anemia, bone marrow suppression (including, very rarely, fatal agranulocytosis) and methemoglobinemia are occasionally seen. Dapsone is contraindicated in those who have glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Trimethoprim-sulfamethoxazole

Trimethoprim-sulfamethoxazole (TMP-SMX) is a combination used to treat bacterial infections (see Chapter 197), *P. carinii* (see Chapter 124) and the parasites *I. belli* and *C. cayetanensis*.[19] [20] This combination also has some efficacy against *P. falciparum* but resistance to the TMP component limits its use.[22] [23] It is available as single-strength tablets (80mg TMP and 400mg SMX) and as double-strength tablets (160mg TMP and 800mg SMX). An oral suspension (40mg TMP and 200mg SMX per 5ml) and an intravenous formulation (80mg TMP and 400mg SMX per 5ml vial) are available as well.

The dose for isosporiasis is 1 double-strength tablet orally q6h for 10 days, followed by 1 double-strength tablet q12h for 3 weeks. Immunocompromised patients usually require maintenance therapy of 1 double-strength tablet daily or three times weekly. For cyclosporiasis, 1 double-strength tablet q12h for 7–10 days is generally used but some clinicians extend treatment to 14 days. Immunocompromised patients sometimes require 4 tablets per day and usually need maintenance therapy as well.

Side effects of TMP-SMX include those listed for each of the two component drugs, as detailed above. Dermatologic reactions (3–4%) and gastrointestinal disturbances (3–4%) are the most common side effects in non-immunocompromised patients. For unclear reasons, patients who have AIDS have a much higher rate of

complications, ranging in different series from 45 to 90%.

Trimetrexate

Trimetrexate is a lipid-soluble dihydrofolate reductase inhibitor that was originally developed as a myelosuppressive agent but was found to have antiparasitic activity against *P. carinii* and *T. gondii*.[17] It is available for intravenous injection only. Adverse effects include rash, leukopenia, elevated liver enzymes and a reversible peripheral neuropathy. Folinic acid is administered concurrently to diminish the incidence of bone marrow suppression.

Proguanil

Proguanil is a biguanide that inhibits plasmodial dihydrofolate reductase.[6] [7] [14] [16] Although it is seldom used for therapy because of its slow action, recent studies indicate that it is effective in combination with atovaquone in uncomplicated *P. falciparum* malaria (see below, under Atovaquone).[24] Daily proguanil (200mg) in combination with weekly chloroquine is used for prophylaxis against *P. falciparum* and *Plasmodium vivax*, mainly in sub-Saharan Africa. Prophylaxis failures have been reported in Kenya.[25]

Proguanil is slowly absorbed after oral administration, is 75% protein-bound, is metabolized to the active triazine metabolite cycloguanil, and is excreted in urine (40–60%) and feces (10%). The drug is safe and well tolerated. Pancytopenia has been rarely reported. Nausea, vomiting, abdominal pain, diarrhea and hematuria are associated with the use of high doses.

ARTEMISININ AND ITS DERIVATIVES

Artemisinin, or *qinghaosu*, is a sesquiterpene lactone derived from the leaves of the sweet wormwood *Artemisia annua*.[7] [14] [16] [26] It has been used for centuries in traditional Chinese medicine and is now known to be active against intra-erythrocytic forms of *P. falciparum* and *P. vivax*, *Schistosoma mansoni*, *Schistosoma japonicum*, *Clonorchis sinensis* and *Naegleria fowleri*. It main clinical use has been in the treatment of drug-resistant *P. falciparum* infections.

Artemisinin and two of its derivatives, the water-soluble hemisuccinate artesunate and the oil-soluble methyl ether artemether, are the most rapidly acting of known antimalarials and appear to be quite safe. They are undergoing active study to define their precise role in malaria therapy and are not currently widely available. These compounds can be given by several routes:

- artemisinin is available in oral and suppository forms;
- artesunate is available in oral, intravenous and intramuscular forms; and
- artemether is available in intramuscular form.

They appear to be rapidly absorbed and eliminated, with half-lives ranging from minutes (artesunate) to hours (artemether). The two derivatives are hepatically hydrolyzed to an active metabolite, dehydroartemisinin. These compounds are believed to act by disrupting parasite protein synthesis via the production of oxygen free radicals.

Artemisinin and its derivatives are usually administered in conjunction with a longer acting antimalarial (mefloquine) to decrease the emergence of resistance and enhance efficacy. Artesunate (4mg/kg orally) is usually given q24h for 3 days and is followed by a course of mefloquine. If given as monotherapy, artesunate is

administered for 5–7 days to prevent recrudescence. Parenteral artesunate is administered at a dose of 2mg/kg initially, followed by 1mg/kg at 12–24 hours and then q24h after that. Artemether is given at a dose of 3.2mg/kg intramuscularly initially, followed by 1.6mg/kg q24h. Artemisinin suppositories, which are useful for those unable to take oral medications when there is no access to injectable formulations, can be given at 10mg/kg initially and 4 hours later, followed by 7mg/kg at 24, 36, 48 and 60 hours.

Adverse events include diarrhea, abdominal pain, transient first-degree heart block and reversible mild decreases in reticulocyte and neutrophil counts. Neurotoxicity has been described in animals but not with clinical use in humans. Resistance to artemisinin has occurred in murine malaria, and the resistant parasites also developed cross-resistance to chloroquine, quinine and mefloquine. Newer derivatives, including arteether (an ethyl ether) and the water-soluble artelinic acid, are being developed.

ATOVAQUONE AND ATOVAQUONE/PROGUANIL

Atovaquone, a synthetic hydroxynaphthoquinone derivative, has activity against *P. carinii* (see Chapter 124), *P. falciparum*, *T. gondii* and *Babesia microti*.[16] [24] [27] It interferes with pyrimidine synthesis by uncoupling mitochondrial electron transport. The drug is available only in liquid form. Because of its erratic absorption it is usually administered with a fatty meal. It is hepatically metabolized and excreted in the bile and urine. Atovaquone is an alternative oral agent for the treatment of mild to moderate *P. carinii* pneumonia in those who are intolerant of TMP-SMX, and experimental data indicate that it is synergistic with pyrimethamine or sulfadiazine for *T. gondii* infection. Atovaquone has also been used with azithromycin in the treatment of babesiosis.

The combination of atovaquone (1g q24h) and proguanil (400mg q24h) for 3 days has been used successfully to treat uncomplicated *P. falciparum* malaria in Gabon and Brazil,[24] and a combination pill containing atovaquone 250mg and proguanil 100mg has rapidly become one of the leading drugs for malaria prophylaxis in travellers.[28] A randomized controlled trial between mefloquine and atovaquone/proguanil for malaria prophylaxis in nonimmune travelers found equivalent efficacy for the two agents, with a similar number of adverse events, but fewer adverse effects of moderate or severe intensity were reported in the atovaquone/proguanil group.[29] The adult dosage for prophylaxis is 1 tablet q24h (250mg atovaquone/100mg proguanil), beginning 1–2 days prior to arrival in the malarious area and continuing for 1 week after return. Side effects include rash, nausea, vomiting, diarrhea, headache, fever, anemia, elevated liver function tests, hyponatremia and hyperglycemia.

BENZNIDAZOLE

Benznidazole is a nitroimidazole derivative that is active against *Trypanosoma cruzi* but it has not been as well studied and is relatively toxic.[6] [7] [30] It is the preferred agent for the treatment of Chagas' disease in central Brazil because of strain-susceptibility patterns. It is available in oral form and has a half-life of 12 hours. Side effects include malaise, nausea, photosensitivity rash, peripheral neuropathy, bone marrow suppression and psychiatric disturbances.

CHLOROQUINE

Chloroquine, a 4-aminoquinoline that was first synthesized in 1934 but did not become popular until the end of the Second World War, has been the agent most widely used for treating the erythrocytic stage of uncomplicated malaria caused by *P. vivax*, *Plasmodium ovale*, *Plasmodium malariae* and chloroquine-sensitive *P. falciparum*.[6] [7] [14] [16] Its precise mechanism of action has not been delineated but chloroquine and its metabolites inhibit the ability of the parasite to polymerize the heme moiety of hemoglobin, resulting in toxic levels of free heme.[31] Chloroquine was occasionally used to treat extraintestinal *Entamoeba histolytica* infection but it has been supplanted by metronidazole.

Pharmacokinetics and distribution

Absorption after oral ingestion is excellent (90%), and the volume of distribution is large owing to its extensive tissue sequestration, particularly in the liver, spleen, kidneys and erythrocytes. It is approximately 50% bound to plasma protein and is eliminated slowly. Its half-life of 4–6 days permits weekly dosing for prophylaxis. Chloroquine is metabolized by the liver to the active metabolite desethylchloroquine, but 50% is cleared by the kidneys unchanged. Thus, dosing need not be altered for abnormal renal function but caution must be exercised in patients who have hepatic, gastrointestinal, neurologic or hematologic disorders.

Route of administration and dosage

The drug is formulated as a phosphate, sulfate or hydrochloride salt and is dosed by base content. It can be administered orally or rectally or by intravenous, intramuscular or subcutaneous injection. In the USA, chloroquine is marketed as Aralen phosphate in 500mg salt tablets (equal to 300mg base). The dosage for the treatment and prophylaxis of malaria is given in Table 209.1 . If chloroquine hydrochloride is given intravenously, it must be administered by slow, constant infusion to

avoid the respiratory depression, hypotension, heart block, cardiac arrest and seizures that may occur with transient toxic levels. A dose of 300mg base q8–12h may be given by intramuscular injection.

Adverse reactions

Reversible side effects include headache, gastrointestinal disturbances, blurred vision, dizziness, fatigue and pruritus. Rarer side effects include hair depigmentation, weight loss, myalgias, leukopenia and eczematous eruptions. Very rarely, acute psychosis may occur. Permanent retinal damage has been observed with long-term (longer than 5 years) prophylactic use. The drug is contraindicated in patients who have retinal disease, psoriasis and porphyria. An oral dose of 5g is fatal without immediate mechanical ventilation, epinephrine (adrenaline) and diazepam.

Resistance of *Plasmodium falciparum* to chloroquine

Resistance of *P. falciparum* to chloroquine is ubiquitous in regions where malarial transmission occurs (Fig. 209.1) with the exception of Central America west of the Canal Zone, Mexico, Haiti, the Dominican Republic and much of the Middle East (although there are reports of resistance from Yemen, Oman and Iran). Resistance to chloroquine among *P. vivax* isolates has been reported in Brazil, Colombia, India, Myanmar, Papua New Guinea and Indonesia.[31] [33] [34] A single oral dose of mefloquine (15mg base/kg) has been used successfully in such cases.

CLINDAMYCIN

Clindamycin, a lincosamide antibiotic, is active against bacteria (see Chapter 194), *P. falciparum*, *T. gondii* and *Babesia* spp.[16] [35] [36] It is well absorbed after oral administration and is 90% protein-bound and widely distributed. It is hepatically metabolized and excreted in the urine and bile; its half-life is 2.5–3 hours.

Dosages for malaria and babesiosis are listed in Table 209.1 . For cerebral toxoplasmosis in the case of sulfonamide hypersensitivity, 1.8–2.4g divided into three daily doses is combined with a course of pyrimethamine. Clindamycin has been used in combination with

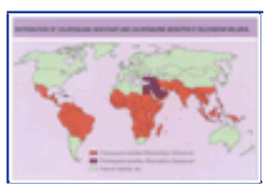

Figure 209-1 Distribution of chloroquine-resistant and chloroquine-sensitive *P. falciparum* malaria. *Adapted with permission from Lobel and Kozarsky.*[32]

quinine for short-course (3-day) treatment of travelers who have *P. falciparum* malaria, with excellent results.[37] Side effects include rash, diarrhea, nausea, vomiting, abdominal pain, pseudomembranous colitis, hepatotoxicity and cytopenias.

DIFLUOROMETHYLORNITHINE

Difluoromethylornithine is an ornithine decarboxylase inhibitor that is effective in the treatment of both early and late sleeping sickness caused by *Trypanosoma brucei gambiense*.[7] [38] [39] It has variable efficacy against *T. brucei rhodesiense* because many strains are resistant. Difluoromethylornithine inhibits ornithine decarboxylase, an enzyme involved in the first step in polyamine synthesis. It is available as the hydrochloride salt for both oral and intravenous administration. It has a half-life of approximately 3 hours, and 80% of the drug is excreted unchanged by the kidneys.

Side effects of difluoromethylornithine include anemia, thrombocytopenia, leukopenia, abdominal pain, nausea, vomiting, weight loss, arthralgias, seizures, hearing loss and alopecia. Overall, difluoromethylornithine is less toxic than other available antitrypanosomal agents but it has not seen widespread use because of its high cost.

DILOXANIDE FUROATE

Diloxanide furoate is a dichloroacetamide derivative that is a luminally active agent used to eradicate cysts of *E. histolytica* in asymptomatic carriers and in those who have mild, noninvasive disease, as well as after treatment with metronidazole in those who have invasive amebiasis.[6] [40] It is not useful in extraintestinal disease. After oral administration, diloxanide furoate is hydrolyzed by intestinal esterases, thus releasing diloxanide, the absorbable component, and the ester furoic acid, which is not well absorbed and thus attains higher intraluminal concentrations in the colon. Both compounds are amebicidal but the mechanism of action is not known. The drug has a half-life of 6 hours, is hepatically conjugated to form a glucuronide and is 60–90% excreted in the urine.

Side effects are mild; they include flatulence and, less commonly, nausea, vomiting, diarrhea, pruritus and urticaria. Because it is relatively inexpensive, diloxanide furoate is an attractive agent for use in developing countries.

EMETINE

Emetine is an alkaloid derived from ipecac, which comes from the root of *Cephaelis ipecacuanha*. This toxic tissue-active amebicide has been used since 1912, primarily for amebic colitis and amebic liver abscess. Dehydroemetine, a synthetic derivative, is less toxic but also less potent. [6] [7] [41] Both drugs have essentially been replaced by the safer nitroimidazoles (metronidazole, tinidazole, ornidazole) and are now used rarely. They are employed as supplemental therapy to metronidazole in individuals who are severely ill with amebic colitis or amebic liver abscess and are not responding well, or as primary therapy in the rare individual who cannot tolerate metronidazole. Because they are not active in the intestinal lumen, therapy with these agents must be followed by treatment with a luminally active drug. Dehydroemetine has also been used for infections caused by S. *mansoni*, *Schistosoma haematobium* and *Fasciola hepatica*. Emetine and dehydroemetine are both available only for intramuscular use. After deep intramuscular injection, they are well absorbed and excreted very slowly in the urine. They act by inhibiting protein synthesis.

The standard dose of dehydroemetine is 1–1.5mg/kg/day, up to a maximum of 90mg/day, for 5–10 days. Common adverse effects of emetine and dehydroemetine include local reactions at the injection site (e.g. pain, stiffness, urticaria and abscesses), nausea, vomiting and diarrhea. Cardiovascular toxicity includes precordial pain, hypotension, tachycardia, arrhythmias, electrocardiographic abnormalities, heart failure and, rarely, sudden death. Headache, myalgias, weakness and polyneuritis may also occur. Hospitalization with electrocardiographic monitoring is required while these drugs are being administered. They are relatively contraindicated in patients who have cardiac or renal disease.

FUMAGILLIN

Fumagillin, a water-insoluble antibiotic derived from *Aspergillus fumigatus*, was discovered in 1949 and originally used in humans as an amebicide. Fumagillin is an inhibitor of parasite RNA synthesis but may also act by inhibiting a key proteinase, type 2 methionine aminopeptidase.[42] A water-soluble preparation (Fumidil B) is used to control nosematosis, a disease of honey bees that

results from infection with microsporidian *Nosema apis*. Topical fumagillin has been used to treat microsporidial keratoconjunctivitis caused by *Encephalitozoon hellem*, *Encephalitozoon cuniculi*, *Encephalitozoon* (*Septata*) *intestinalis* and, with less success, *Vittaforma corneae* (*Nosema corneum*) in AIDS patients. [43] [44] Studies of oral fumagillin for intestinal microsporidiosis have provided promising results. [45] [46]

FURAZOLIDONE

Furazolidone is a nitrofuran derivative that is commonly used to treat giardiasis in children because of its availability in a liquid form for oral use.[6] [47] Furazolidone also has activity against *I. belli* and *Trichomonas vaginalis* as well as many enteropathogenic bacteria, and is increasingly being used for treatment of *Helicobacter pylori*

infections. The mechanism of action involves damage to DNA. It is well absorbed and is excreted mainly in the urine.

Adverse reactions include diarrhea, fever, nausea and vomiting. Urticaria, serum sickness, hypoglycemia and orthostatic hypotension occur rarely. Furazolidone has disulfiram-like properties and patients should therefore be warned to avoid alcohol. Furazolidone has monoamine oxidase inhibitor activity, but hypertensive crises have not been reported in association with this agent. Furazolidone may cause hemolysis in patients who have G6PD deficiency.

HALOFANTRINE

Halofantrine is an oral synthetic 9-phenanthrene methanol with activity against the intraerythrocytic stages of chloroquine-sensitive and chloroquine-resistant *P. falciparum* and *P. vivax*. [6] [7] [14] [48] It is more active and generally better tolerated than mefloquine but it is poorly absorbed. Ingestion with fatty meals increases absorption. Halofantrine is hepatically metabolized and excreted in feces, with a half-life of 1–2 days for the parent compound and 3–5 days for the active metabolite. Its mechanism of action is poorly understood.

There is some evidence of cross-resistance with mefloquine; therefore halofantrine may not be useful for those patients in areas with mefloquine resistance. Its side effects include prolongation of the PR and QT_c intervals on the electrocardiogram, diarrhea, abdominal pain, pruritus and rash. Because it prolongs the PR and QT_c intervals, halofantrine should not be given to anyone who has conduction defects or to anyone taking other drugs that affect the QT_c interval. Thus, a 28-day interval is recommended between the administration of halofantrine and mefloquine.

IODOQUINOL

Iodoquinol, a halogenated hydroxyquinoline, is a luminal amebicide used to eradicate cysts in patients who have asymptomatic *E. histolytica* infection.[6] [40] It is also given after metronidazole therapy to eradicate cysts in patients who have invasive disease. Iodoquinol is the drug of choice for *Dientamoeba fragilis* infection and is an alternative for *Balantidium coli*.[49] It has been used to treat *Blastocystis hominis*, but the pathogenicity of this protozoan and its need for treatment are controversial.[50] Iodoquinol also has activity against *Giardia lamblia* and *T. vaginalis* but other agents are typically employed. The mechanism of action of iodoquinol is uncertain. It is available in oral form but it is poorly absorbed and should be given with meals. Side effects include nausea, vomiting, diarrhea, abdominal pain, headache, fever, seizures and encephalopathy.

Iodochlorhydroxyquin, a related compound, is better absorbed than iodoquinol but is rarely used because of the high incidence of subacute myelo-optic neuropathy described with its use in Japan in the early 1970s. Because iodoquinol may rarely cause this syndrome when given at high dose or for prolonged periods, treatment recommendations should not be exceeded. For this reason many clinicians, including myself, prefer alternative agents such as paromomycin, metronidazole or diloxanide furoate for these indications.

MACROLIDE ANTIBIOTICS

Spiramycin

Spiramycin is used in Europe to prevent the transmission of *T. gondii* from mother to fetus.[16] The drug is concentrated in the placenta and has been shown to reduce transmission by 60%. It is given at a dose of 1g orally q8h on an empty stomach. If fetal infection has not occurred (as assessed by amniotic fluid polymerase chain reaction testing for *T. gondii*), spiramycin is continued until delivery. Because spiramycin does not cross the placenta well, it cannot be used to treat fetal toxoplasmosis; pyrimethamine and sulfadiazine are recommended in this situation. Oral spiramycin is generally well tolerated; gastrointestinal distress is the main side effect.

Azithromycin

Azithromycin (see Chapter 194), both alone and in combination with pyrimethamine, has recently been shown to be effective in cerebral toxoplasmosis in AIDS patients.[17] It is considered relatively safe in pregnancy but has not been extensively studied in preventing the vertical transmission of *T. gondii*. Azithromycin has antimalarial activity and is effective prophylaxis against *P. vivax*. However, it offers only partial protection (70–80% efficacy) against *P. falciparum* and is therefore not recommended as a first-line agent for prevention of malaria in travelers.[51] Azithromycin has also been used with both quinine and atovaquone for babesiosis. [35] High-dose azithromycin has been used in AIDS patients who have cryptosporidiosis, with variable results.[46] Another macrolide, clarithromycin, when administered for prevention of *Mycobacterium avium* complex disease in AIDS patients, appeared to prevent cryptosporidiosis as well.[52]

MEFLOQUINE

Mefloquine is an fluorinated 4-quinoline methanol derivative of quinine. It is an oral formulation that was developed as part of a search for new antimalarials.[6] [7] [14] [16] [32] [51] It is a blood schizonticide effective against all *Plasmodium* spp. that infect humans, including *P. falciparum* isolates that are resistant to chloroquine and pyrimethamine-sulfadoxine. It is ineffective against exoerythrocytic forms and gametocytes. The mechanism of action is unknown but mefloquine may interfere with the function of *Plasmodium* food vacuoles or inhibit the polymerization of heme. The drug is slowly absorbed, has a bioavailability of 85% and is almost completely protein-bound in plasma. The long elimination half-life of 2–3 weeks allows for weekly prophylaxis. Mefloquine is extensively metabolized and is excreted in bile and feces.

Common side effects at therapeutic doses include nausea, vomiting, dizziness, weakness and dysphoria.[28] [51] [53] Neuropsychiatric reactions, including acute psychosis, sleep disturbances and seizures, have been documented in approximately 0.5% of patients taking therapeutic doses and in less than 0.5% of those taking prophylactic doses. Thus, the drug is not recommended for those who have a history of seizures or psychiatric disorders. Judicious use is suggested for those whose occupations require spatial discrimination and fine motor coordination. Cardiac rhythm and conduction abnormalities and at least one instance of nonfatal cardiac arrest have occurred in patients on ß-adrenergic blockers who took mefloquine; caution should be exercised in any patient who has cardiac disease. Mefloquine should not be co-administered with quinine, quinidine or halofantrine owing to potentially fatal prolongation

of the QT_c interval. Mefloquine may also decrease the response to the live *Salmonella typhi* oral vaccine, and thus the vaccine series should be completed at least 3 days before beginning mefloquine prophylaxis.

Mefloquine resistance in *P. falciparum* isolates has been increasing along the Thailand-Myanmar and Thailand-Cambodia borders, in western Africa and in the Amazon region. In these areas, doxycycline at a dose of 100mg per day or atovaquone/proguanil may be used for prophylaxis. Treatment options include:

- quinine plus tetracycline or doxycycline for 7 days;[54]
- mefloquine plus artesunate;[55]
- mefloquine plus artemether;[56]
- doxycycline plus artesunate;[57]
- mefloquine plus doxycycline;[57] and
- quinine plus clindamycin[37] .

MELARSOPROL

Melarsoprol is a trivalent arsenical compound introduced in 1949 and used for the treatment of late-stage African trypanosomiasis caused either by *T. brucei gambiense* or *T. brucei rhodesiense*.[6] [7] [38] [39] It is also effective in treating the early or hemolymphatic stage of infection but its toxicity prohibits routine use for this stage and it should be used only in patients who have failed to respond to suramin and pentamidine.

Melarsoprol acts by interacting with protein sulfhydryl groups and subsequently inactivating enzymes, a non-specific action that is also responsible for the toxicity of the drug. Melarsoprol, formulated as a 3.6% weight per volume solution in propylene glycol, is given intravenously. A small but adequate amount of the drug penetrates the cerebrospinal fluid, where it is taken up and concentrated by susceptible trypanosomes. Resistant organisms appear to concentrate the drug poorly. Melarsoprol is rapidly excreted in the urine.

Melarsoprol is highly toxic. It is irritating to tissues and care must be taken to prevent extravasation. Fever is commonly seen. Reactive encephalopathy occurs in up to 18% of patients and may be fatal; it usually occurs during the first 3–4 days of therapy.[58] It is manifested by headache, confusion, dizziness, mental slowing and ataxia, with seizures and a progressive decline in mental status, and it is felt to be an immunologic reaction to parasite antigens released during therapy. Corticosteroids have been used to treat the encephalopathy with some success. Very rarely, a hemorrhagic encephalopathy, which is almost always fatal, may occur. Arthralgias, rash, hypertension, proteinuria and hepatic dysfunction have been seen. Abdominal pain and vomiting may be minimized by slow administration of the drug to a patient who is supine and fasting. Erythema nodosum may be precipitated in patients who have leprosy. Hemolysis may be seen in G6PD-deficient patients.

NIFURTIMOX

Nifurtimox, an oral nitrofuran, remains the drug of choice for acute Chagas' disease (American trypanosomiasis), although benznidazole is gaining favor as a first-line agent in some regions with endemic Chagas' disease (see Chapter 173).[6] [7] [30] Nifurtimox has also been used against resistant strains of *T. brucei gambiense*.[38] It acts by inhibiting nucleic acid synthesis by oxygen free radical formation. It is rapidly absorbed, has a half-life of approximately 3 hours, is extensively metabolized by the liver by a first-pass effect that results in low serum and tissue levels, and is excreted by the kidneys. There is considerable geographic variation in responsiveness to nifurtimox; better results are obtained in Argentina and Chile than in Brazil and other countries. Effectiveness in indeterminate-phase and chronic-phase infection is variable and organ damage is not reversible.

Gastrointestinal side effects including nausea, vomiting, anorexia and abdominal pain; weight loss may occur. Neurologic side effects include headache, restlessness, insomnia, disorientation, pares-thesias, polyneuritis, weakness and seizures. Rash, decreased sperm counts and neutropenia have also been described. Adherence to a full 4 months of therapy is often poor, and better agents are needed.

NITAZOXANIDE

Nitazoxanide is a nitrothiazole benzamide derivative with in-vitro activity against a wide variety of bacterial, protozoal and helminthic pathogens. In recent randomized double-blind placebo-controlled clinical trials it showed efficacy comparable to metronidazole in the treatment of giardiasis and amebiasis, and was very successful in eradicating helminths from individuals in Egypt and Mexico.[59] Healthy adults treated with nitazoxanide cleared cryptosporidia from their stool more rapidly than did placebo controls, but the efficacy of nitazoxanide in AIDS patients remains to be established.[59]

NITROIMIDAZOLE DERIVATIVES

Metronidazole

Metronidazole (see Chapter 201) has activity against many anaerobic parasites. It is the drug of choice for the treatment of:

- invasive enterocolitis and liver abscess caused by *E. histolytica* and the rarely reported *Entamoeba polecki*; [6] [7] [36] [37]
- vaginitis caused by *T. vaginalis*;[60] and
- enteritis caused by *G. lamblia*.[40] [47]

It has been used to treat *Blastocystis. hominis* in the stool (although its efficacy remains unproven) and is considered an alternative agent for *Balantidium. coli* infection. Metronidazole is also used in the treatment of infections with the guinea worm, *Dracunculus medinensis*; it decreases inflammation and facilitates worm removal but has no direct toxic effect on the worm itself.

Metronidazole acts as an electron sink under anaerobic or microaerophilic conditions, depriving the parasite of necessary reducing equivalents such as nicotinamide adenine dinucleotide phosphate, reduced form (NADPH). Reduced metronidazole (i.e. drug molecules that have gained electrons) causes a loss of the helical structure of DNA and strand breakage.

Metronidazole is available for oral and intravenous use. It is rapidly and almost completely absorbed orally, has limited protein binding and is widely distributed throughout the body. The half-life is 6–11 hours and metabolism is hepatic. Although excretion is mainly by the kidney, dosage adjustments are seldom needed in renal failure because the metabolites are less active compounds. However, the dosage should be modified in patients who have liver failure.

The most common side effects are headache, metallic taste, dry mouth and nausea. Less frequent are urticaria, pruritus, urethral burning, reversible neutropenia, and vaginal and oral candidiasis. Rarely, patients may experience central nervous system toxicity, including dizziness, vertigo, ataxia, encephalopathy and seizures, as well as peripheral neuropathy. Acute pancreatitis has been reported. Patients should be advised to avoid consuming alcohol because of the disulfiram-like effects of metronidazole, including headache, flushing, abdominal pain and vomiting. Some patients may experience a red-brown discoloration of the urine owing to the presence of metabolites of metronidazole.

Tinidazole and ornidazole

Tinidazole and ornidazole are two other nitroimidazole derivatives (see Chapter 201). Their antimicrobial spectrum is similar to that of metronidazole,[6] [7] [60] and tinidazole has been used successfully for single-dose therapy of amebic liver abscess.[61] Tinidazole has also

been used to treat metronidazole-resistant *Trichomonas* spp. These compounds are well absorbed orally and are widely distributed. Tinidazole has a half-life of 14 hours and ornidazole has a half-life of 12–13 hours; both compounds are probably hepatically metabolized and are excreted primarily in the urine. Generally, these drugs are better tolerated than metronidazole; the main side effects are headache, dizziness and anorexia.

PAROMOMYCIN

Paromomycin (also known as aminosidine) is a non-absorbable aminoglycoside antibiotic (see Chapter 196) that is concentrated in the lumen of the colon. It is active against *E. histolytica, D. fragilis* and *G. lamblia* as well as the cestodes *Taenia saginata*, *Taenia solium*, *Diphyllobothrium latum*, *Dipylidium caninum* and *Hymenolepis nana*.[6] [40] [47] Although often used for the treatment of *Cryptosporidium parvum*, it was no better then placebo in double-blind clinical trials.[62] [63] Paromomycin with methylbenzethonium chloride has been used topically in the treatment of cutaneous leishmaniasis and systemically for visceral leishmaniasis.[10] [64] Paromomycin is available as the sulfate salt for oral administration.

The dose is 25–35mg/kg/day in three divided doses for 7 days. Side effects include cramps, nausea, vomiting, diarrhea, rash, headache and vertigo. Burning may occur with topical preparations.

PENTAMIDINE ISETHIONATE

Pentamidine isethionate, an aromatic diamidine derivative, is effective in the treatment of the early or hemolymphatic stages of sleeping sickness caused by *T. brucei gambiense*, some forms of leishmaniasis and *P. carinii* pneumonia (see Chapter 124 & Chapter 245). [6] [7] [10] [38] It is less effective against *T. brucei rhodesiense*. It has also been used in the treatment of disseminated *Acanthamoeba* spp. infections and babesiosis.[65] [66] The mechanism of action of pentamidine is unclear but it may involve the binding of DNA and the interruption of DNA replication. The drug is available for parenteral and inhalational use; the latter mode is used only in the prophylaxis and treatment of *P. carinii* pneumonia because little of the inhaled drug is absorbed systemically. Parenterally administered pentamidine isethionate penetrates extensively and is excreted slowly from tissues such as liver, spleen, kidneys and adrenal glands. Very little crosses the blood-brain barrier, accounting for the lack of utility of pentamidine in late-stage trypanosomiasis.

Route of administration and dosage

There are different recommendations for dosing pentamidine isethionate. For early *T. brucei gambiense* infection, the US Centers for Disease Control and Prevention (CDC) recommends 4mg/kg per day for 10 days. The World Health Organization (WHO) recommends 3–4mg/kg daily or every other day for 7–10 doses. Because of the rapidity with which *T. brucei rhodesiense* invades the central nervous system, this drug is generally not used for this organism. Pentamidine has also been used for

prophylaxis against infection with *T. brucei gambiense* at a dose of 4mg/kg (to a maximum of 300mg) given every 3–6 months.

For leishmaniasis, the CDC recommends 2–4mg/kg/day or every other day for 12–15 doses; a second course is sometimes given after an interval of 1–2 weeks. Alternatively, the WHO recommends 4mg/kg three times a week for 5–25 weeks or longer. The dosage regimen varies slightly depending on the species of *Leishmania* and the region of the body affected.

Adverse reactions

Pentamidine isethionate may cause toxicity in 50% of patients. Precipitous hypotension with dizziness, dyspnea, tachycardia, headache, vomiting and syncope can occur with rapid intravenous infusion. Intramuscular administration may result in sterile abscesses. Hypoglycemia, which may be life-threatening, pancreatitis, hyperglycemia and diabetes mellitus probably result from a direct toxic effect of pentamidine on pancreatic ß cells. Reversible renal failure occurs in up to 25% of patients. Other side effects include fever, arrhythmias (particularly *torsades de pointes*), hypocalcemia, confusion, hallucinations, leukopenia, thrombocytopenia and elevated transaminases.

PENTAVALENT ANTIMONIAL COMPOUNDS

The pentavalent antimonial compounds are a mainstay of therapy for leishmaniasis and are less toxic than the older trivalent compounds.[6] [7] [10] [67] Sodium stibogluconate has been the most extensively studied and is the only pentavalent antimonial available in the USA. Meglumine antimoniate is used largely in French-speaking countries and parts of Latin America. These compounds appear to inhibit bioenergetic pathways such as glycolysis and fatty acid oxidation in *Leishmania* amastigotes. *Leishmania* strains resistant to pentavalent antimony compounds are becoming more common, especially in India, and this has led to treatment failures and the need for alternative agents.[68]

These compounds are available as aqueous solutions for intravenous or intramuscular use only. Each milliliter of sodium stibogluconate contains the equivalent of 100mg of pentavalent antimony, whereas each milliliter of meglumine antimonate contains 85mg. They are rapidly absorbed and are eliminated in two phases. The first has a half-life of 2 hours but the second is longer, with a half-life of between 33 hours (after intravenous administration) and 76 hours (after intramuscular administration). This slow terminal elimination may result from a conversion to trivalent antimony, which thus may be responsible for the toxicity seen with long-term therapy. Excretion is primarily renal.

Pentavalent antimonials are generally well tolerated. Malaise, nausea, vomiting, abdominal pain, headache, arthralgias, myalgias, fever, rash, elevated transaminases, nephrotoxicity and pancreatitis are seen. Dose-related electrocardiographic changes include T-wave flattening and inversion and QT_c -interval prolongation. Arrhythmias and sudden death have been described with high-dose therapy.

PRIMAQUINE

Primaquine, an 8-aminoquinoline active against hypnozoites of *P. vivax* and *P. ovale* in the liver, is the only agent with the potential for yielding complete resolution of malaria caused by these organisms.[6] [7] [14] [16] Primaquine combined with clindamycin is also effective in the treatment of *P. carinii* pneumonia (see Chapter 124). Recently, primaquine in a dose of 30mg/day showed efficacy as prophylaxis against *P. falciparum* (88% protection) and *P. vivax* (92% protection) malaria.[69] Primaquine acts by interfering with *Plasmodium* mitochondrial function, possibly through its effects on the electron transport chain and pyrimidine biosynthesis. Primaquine phosphate, which is available only in oral form, is rapidly absorbed (bioavailability 96%), widely distributed and hepatically converted to three metabolites, yielding an elimination half-life of 6–7 hours. It is unclear whether the parent compound or the metabolities possess the antimalarial activity.

Primaquine phosphate is formulated in tablets containing 26.3mg of the salt, equivalent to 15mg of the base. Dosages are given in Table 209.1 . Relapse of *P. vivax* after conventional primaquine treatment has been described in up to 30% of cases in Papua New Guinea, the Solomon Islands, Thailand and other parts of South East Asia.[70] Therefore, for cases acquired in South East Asia or Oceania, the dose should be increased to 22.5mg base per day.

The principal toxicity of primaquine is hemolysis in patients who are G6PD-deficient, and thus G6PD levels should be measured before therapy is begun. Headache, nausea, vomiting and abdominal cramps have been reported. At higher doses, mild anemia, cyanosis (due to methemoglobinemia) and leukopenia may occur. Rarely, neurotoxicity, arrhythmias, hypertension and agranulocytosis occur.

QUINACRINE

Quinacrine is an acridine dye derivative that is effective against *G. lamblia*.[6] [40] [47] and it has recently been used as combination therapy with metronidazole for individuals who failed therapy with metronidazole alone.[71] It also has activity against adult cestodes, but for this indication it has been supplanted by less toxic alternatives. In the Second World War, quinacrine was used for malaria prophylaxis and treatment. The mechanism of antiparasitic action is unclear, but the drug has been shown to intercalate with DNA and inhibit nucleic acid synthesis. Quinacrine is available in an oral formulation and is well absorbed and widely distributed. It has extensive tissue binding and has been detected in the urine 2 months after stopping therapy. Its metabolic fate is poorly understood.

The dosage in giardiasis is 100mg q8h for 5–7 days. A second treatment course may be given 2 weeks later. The drug has a bitter taste and may induce nausea and vomiting. Dizziness and headache are also common. Reversible yellow skin discoloration (with spared sclerae) is seen in 4–5% of those treated with quinacrine for giardiasis. Under Wood's light, a bright yellow-green fluorescence distinguishes this side effect from hyperbilirubinemia. Toxic psychosis may occur in 0.1–1.5% of patients. Other rare side effects include blood dyscrasias, ocular toxicity and urticaria. Patients who have psoriasis may experience exfoliative dermatitis. Quinacrine has a disulfiram-like effect, and thus patients should be advised to avoid alcohol consumption while taking it. It also interferes with the metabolism of primaquine, and toxic levels of the primaquine can result from co-administration of quinacrine with primaquine.

QUINIDINE

Quinidine is the dextrostereoisomer of quinine. It is a blood schizonticide and is the parenteral therapy of choice for chloroquine-resistant *P. falciparum* as a result of its wide availability as an antiarrhythmic. [6] [7] [14] [16] [72] It is supplied as the gluconate salt for intravenous use, with a half-life of 6–8 hours. It is 80–90% protein-bound, hepatically metabolized and renally excreted.

During treatment, continuous electrocardiographic and blood-pressure monitoring are recommended. Widening of the QRS complex and prolongation of the QT_c interval may be seen, and hypotension may ensue if the drug is infused rapidly. Other side effects are similar to those of quinine.

QUININE

Quinine is an alkaloid derived from the bark of the South American cinchona tree. It has been used as an antimalarial for over 350 years.[6] [7] [14] [16] It is effective against the asexual blood stages of all four *Plasmodium* spp. that cause malaria in humans, and it is the drug of choice for chloroquine-resistant *P. falciparum* infections. Quinine is also used with clindamycin in the treatment of *Babesia. microti* infection.[31] The basis for the antimalarial activity of quinine is unclear, but three mechanisms have been proposed:

- intercalation with parasite DNA, interrupting replication and transcription;
- interaction with erythrocyte fatty acids, promoting hemolysis and preventing schizont maturation; and
- alkalinization of parasite digestive vacuoles, interfering with hemoglobin degradation.

Pharmacokinetics and distribution

Quinine is available as the sulfate, bisulfate, hydrochloride, dihydrochloride, hydrobromide and ethylcarbonate salts for oral administration and as the dihydrochloride salt for parenteral use. It is rapidly absorbed after oral administration (bioavailability 80%), extensively protein-bound (90%), hepatically metabolized (80%) and renally excreted. The therapeutic range in plasma is 8–15mg/l, which is achieved within 1–3 hours after a single oral dose. The half-life is approximately 11 hours. In cases of severe illness, the volume of distribution decreases, clearance is reduced and the half-life is prolonged. Thus, on a given dosage schedule, plasma quinine concentrations are elevated with acute illness and decrease as the patient improves. Monitoring blood levels is recommended in those who have renal or hepatic

dysfunction; dosage reduction is needed with severe renal failure.

Route of administration and dosage

The oral dose of quinine sulfate (unlike other antimalarial agents, it is dosed by weight of salt) is 650mg salt q8h for 3–7 days. A longer course is preferred for those in areas where *P. falciparum* is less sensitive to quinine, including South East Asia and western Africa.[73]

Intravenous quinine dihydrochloride may be used for severe infections. A 20mg salt/kg loading dose in 5% dextrose is given over 4 hours, followed by 10mg salt/kg over 2–4 hours q8h (maximum 1800mg salt/day) until oral therapy can be given. The loading dose should be omitted in those who have received oral quinine, quinidine or mefloquine during the previous 24 hours. Intravenous quinidine gluconate has become the parenteral therapy of choice worldwide (see above).

Adverse reactions

The term cinchonism refers to a cluster of dose-related and reversible side effects of quinine, including tinnitus, decreased hearing, headache, nausea, vomiting, dysphoria and visual disturbances. Hypoglycemia can occur secondary to quinine stimulation of insulin release in conjunction with parasite consumption of glucose. Skin rashes (urticaria, flushing), pruritus, hepatitis, thrombocytopenia, agranulocytosis and massive hemolysis with hemoglobinuria (with resultant bilirubinuria termed blackwater fever) occur rarely. Quinine can cause respiratory depression in patients who have myasthenia gravis and hemolysis in those who have G6PD deficiency. Myocardial depression, vasodilation and shock may result from rapid intravenous infusion. Overdose can result in delirium, seizures, coma, respiratory depression, cortical blindness, shock and death. An oral quinine dose of 2–8g may be fatal for adults.

SURAMIN

Suramin is a sulfated naphthylamine introduced in 1920 and is used in the treatment of the early or hemolymphatic stage of African trypanosomiasis. [6] [7] [38] It is more effective against *T. brucei rhodesiense* than against *T. brucei gambiense*, for which pentamidine is often used for early disease. Suramin has also been used for prophylaxis in those who have intense exposure. Additionally, suramin is active against the adult forms of *Onchocerca volvulus*, but is rarely used for this infection because of its toxicity.

The mechanism of action of suramin is unclear; it is a poly-anion that inhibits many cellular enzymes. Notably, its antitrypanosomal activity correlates with inhibition of glycerol-3-phosphate oxidase and dehydrogenase, enzymes involved in energy metabolism.

Pharmacokinetics and distribution

Suramin is 99% protein-bound and persists at low levels in plasma for 3 months, which supports its use in prophylaxis. It is not metabolized and is excreted mainly by the kidneys. The large, polar, polyanionic structure affords poor cellular penetration. Very little drug penetrates into the cerebrospinal fluid, accounting for the lack of efficacy of suramin in late-stage disease.

Route of administration and dosage

Suramin is available only for intravenous use. The dosage for trypanosomiasis is given in Table 209.1 For onchocerciasis, a test dose of 100–200mg is followed by weekly infusions of 1g up to a total of 6g. Some investigators administer increasing weekly doses (200mg, then 400mg, and so on to 1g) up to a total dose of only 3–4g, with good efficacy and tolerability.

Adverse reactions

Suramin has a variety of side effects, which are generally more severe in malnourished patients. Immediate reactions include malaise, nausea, vomiting, fatigue, fever, urticaria, shock, loss of consciousness and, rarely, death. Late reactions include fever, rash, stomatitis, exfoliative dermatitis, lacrimation, photophobia, headache and hyperesthesia. Renal dysfunction (hematuria, proteinuria, casts and elevated creatinine), hepatic dysfunction (elevated transaminases and bilirubin), diarrhea, thrombocytopenia and agranulocytosis may occur. Additional side effects during treatment for onchocerciasis include pruritus, dermal edema, papular eruptions, palmoplantar paresthesias and iridocyclitis.

TETRACYCLINES

Tetracycline (see Chapter 200) is used in combination with quinine in the treatment of drug-resistant *P. falciparum* in South East Asia, where resistance to chloroquine, Fansidar and quinine is common.[6] [7] [16] [54] Doxycycline, a longer-acting derivative, is used for malaria prophylaxis in this area, and worldwide in individuals unable to tolerate mefloquine.[32] [51] [74] Tetracycline is also the drug of choice for infection with the ciliate *Balantidium. coli.*

Tetracyclines are well absorbed after oral administration and are probably active against parasite protein synthesis. Side effects include gastrointestinal distress, photosensitivity and vaginal candidiasis.

TRYPARSAMIDE

Tryparsamide, a pentavalent arsenical first described in 1919, is used primarily for the treatment of advanced *T. brucei gambiense* infections resistant to other therapy.[6] [7] It has poor efficacy against *T. brucei rhodesiense*. Side effects of tryparsamide include fever, rash, abdominal pain, vomiting, tinnitus, optic atrophy and blindness, and encephalopathy.

ANTHELMINTIC AGENTS

ALBENDAZOLE

Albendazole is a benzimidazole carbamate that has a broad spectrum of anthelmintic activity, including against *Ascaris lumbricoides*, *Enterobius vermicularis*, *Ancylostoma duodenale*, *Necator americanus*, *Strongyloides stercoralis*, *Echinococcus* spp. and *T. solium* cysticerci.[6] [7] [75] [76] [77] [78] [79] The drug has also been used to treat eosinophilic enterocolitis caused by *Ancylostoma caninum*, *Capillaria philippinensis*, cutaneous and visceral larva migrans, *C. sinensis*, *Gnathostoma spinigerum*, *Oesophagostomum bifurcum* and *Trichostrongylus* spp. It is also used in combination with diethylcarbamazine or ivermectin for mass treatment of lymphatic filariasis (*Brugia malayi* and *Wuchereria bancrofti*).[80] Additionally, it has variable efficacy in the treatment of microsporidiosis caused by *Encephalitozoon hellem*, *E. cuniculi*, *E. intestinalis*, *E. bieneusi*, and *Vittaforma corneae*.[81] Albendazole has some activity against *G. lamblia*.

The mechanism of action is similar to that of mebendazole with blockade of parasite microtubule assembly. Albendazole is poorly soluble in water and should be taken with a fatty meal to enhance absorption. It undergoes extensive first-pass metabolism in the liver, and albendazole sulfoxide is responsible for most of the systemic anthelmintic effects. This metabolite has a half-life of 9–15 hours and is mostly excreted renally.

Single doses of albendazole are generally well tolerated; abdominal discomfort, diarrhea, or migration of *Ascaris* into the mouth and nose occur infrequently. Prolonged, high-dose treatment can be associated with reversible aminotransferase elevations, bone marrow suppression and alopecia.

BITHIONOL

Bithionol is a chlorinated bisphenol that is used for infections with *Fasciola hepatica* but may have been supplanted by triclabendazole. Bithionol is also an alternative agent against *Paragonimus* spp.[6] [7] It has activity against many other flukes but has been replaced by praziquantel. Its mechanism of action is poorly understood. Side effects include anorexia, abdominal pain, nausea, vomiting, headache, dizziness, diarrhea, urticaria and proteinuria, some of which may be allergic responses to liberated fluke antigens.

DIETHYLCARBAMAZINE

Diethylcarbamazine is a piperazine derivative used in the treatment of filariasis. It is microfilaricidal for *W. bancrofti*, *B. malayi* and *Brugia timori*. [6] [7] [76] [82] [83] It appears to be macrofilaricidal for these species as well (i.e. it kills adult worms) and is considered to be the drug of choice for these three infections. Diethylcarbamazine is a key component of mass chemotherapy approaches for the eradication of lymphatic filariasis.[80] It has been used as a sole agent for single-dose therapy, administered long-term as diethylcarbamazine-fortified dietary salt, and as a component of combination single-dose regimens with ivermectin or albendazole. Diethylcarbamazine is also the mainstay of therapy against *Loa loa* and *Mansonella streptocerca*. It has been used to treat tropical pulmonary eosinophilia, supporting the contention that the pulmonary infiltrates in this disorder are due to migrating microfilariae. It has also been used for visceral larva migrans. Diethylcarbamazine is effective in eliminating microfilariae of *O. volvulus* in the skin and eye but the resulting inflammation can cause permanent ocular damage, including uveitis, punctate keratitis and retinal pigment epithelium atrophy. Adult *Onchocerca* worms are not killed, however, and the infection may return once treatment has stopped. Ivermectin has largely replaced diethylcarbamazine for ocular onchocerciasis. Diethylcarbamazine also has activity against *A. lumbricoides*.

The mechanism of action of diethylcarbamazine involves two processes:

- first, filarial muscular activity decreases, probably secondary to hyperpolarization of membranes by the piperazine moiety of diethylcarbamazine; and
- second, diethylcarbamazine alters microfilarial surface membranes by making them more susceptible to host defenses.

Diethylcarbamazine is available as the citrate salt in 50mg tablets. It is rapidly absorbed, widely distributed in the body, hepatically metabolized and renally eliminated. It has a half-life of approximately 10 hours.

Side effects, although common, are usually mild and transient; they include headache, malaise, arthralgias, anorexia, nausea and vomiting. Toxicity can result from the destruction of organisms and release of antigens, which provokes an inflammatory response. This reaction is most severe in patients who are heavily infected with *O. volvulus*. This is termed the Mazzotti reaction and consists of severe pruritus, edema, rash, arthralgias, lymphadenopathy, fever, hypotension, increased eosinophilia, proteinuria and splenomegaly. These symptoms persist for 3–7 days. Nodular swellings along lymphatics and lymphadenitis may occur with *W. bancrofti* and *B. malayi* infections. Patients heavily infected with *L. loa* may experience encephalopathy and other neurologic complications. [84] Pretreatment with corticosteroids may lessen the severity of these inflammatory responses.

FLUBENDAZOLE

Flubendazole is a fluorine analogue of mebendazole and the two drugs have similar spectra of activity.[6] [7] Flubendazole is poorly absorbed after oral administration. It has been used against many of the common intestinal helminths and, with limited success, in the treatment of neurocysticercosis.

IVERMECTIN

Ivermectin is a derivative of avermectin B1, a type of macrocyclic lactone that was discovered in the 1970s as a product of the actinomycete *Streptomyces avermitilis*.[6] [7] [76] [77] [85] Ivermectin is used as a broad-spectrum veterinary agent for infections with helminths and arthropods. Since the 1980s, it has become the drug of choice for onchocerciasis because it kills microfilariae in the skin and the eye while provoking much less inflammation than diethylcarbamazine. The response to ivermectin is rapid and can last for 6–12 months. Adult worms appear to be unaffected by ivermectin, but the drug seems to prevent developing larvae from leaving the uterus. The drug also has activity against *W. bancrofti*, *B. malayi*, *B. timori*, *L. loa*, *Mansonella ozzardi* and *Mansonella streptocerca*, and is being used as a component of mass chemotherapy for lymphatic filiriasis.[80] Ivermectin is effective against *S. stercoralis* and is active against *E. vermicularis*, *A. lumbricoides* and *Trichuris trichiura*. Ivermectin causes tonic paralysis of the helminth musculature but the mechanism of action is poorly understood, although it is known to include ?-aminobutyric acid (GABA) blockade.

Ivermectin is available as 6mg tablets. It is highly protein-bound, has an elimination half-life of 50–60 hours, is concentrated in liver and adipose tissue and is almost entirely excreted in the feces (only 1–2% appears in the urine). Side effects include headache, fever, pruritus, lymphadenopathy, myalgias, arthralgias and, less commonly, orthostatic hypotension.

MEBENDAZOLE

Mebendazole is a benzimidazole carbamate with a broad range of anthelmintic activity.[6] [7] [75] [76] [77] It is active against the larvae and adults of *E. vermicularis*, *A. lumbricoides*, *T. trichiura*, *N. americanus* and *A. duodenale*. It is ovicidal for *Ascaris* and *Trichuris* spp. It is less effective than thiabendazole against *S. stercoralis*. Mebendazole has been used at high doses and for long periods in the treatment of *C. philippinensis*. It can also be used for infections caused by *Angiostrongylus cantonensis*, *Angiostrongylus costaricensis*, *Toxocara canis* and *Trichostrongylus* spp. The drug has activity against adult *Trichinella spiralis*, with some activity against larval forms, and it is currently recommended in the treatment of trichinosis. Mebendazole is also effective in the treatment of certain types of filariasis; it is considered the drug of choice against *Mansonella perstans* (diethylcarbamazine is ineffective), and it has been shown to have efficacy against *L. loa*, *O. volvulus* and *Dracunculus medinensis* infections. The drug has activity against *T. saginata*, *T. solium* and *Hymenolepis nana*, although praziquantel is more effective. Although mebendazole does not eradicate echinococcal infection, the drug prevents progression of existing cysts and the development of new cysts when administered in high dose for a prolonged period. Mebendazole has largely been replaced by albendazole for echinococcosis.

Mebendazole acts by binding parasite tubulin, thus blocking microtubule assembly and interfering with glucose absorption. Susceptible helminths become paralyzed and depleted of energy stores, but death and clearance of the worms from the gastrointestinal tract can take days. Mebendazole, formulated as 100mg tablets, has low

water solubility and is poorly absorbed. It is 95% protein-bound in plasma and undergoes rapid and extensive first-pass metabolism in the liver. Thus, systemic bioavailability is low, accounting not only for its poor tissue levels and relative lack of usefulness in extraintestinal infections, but also for its low rate of side effects.

Abdominal pain and diarrhea may occur after mebendazole administration. The drug also has been reported to prompt the migration of adult *Ascaris* spp. into the mouth and nose. At high doses, reversible bone marrow suppression with neutropenia, alopecia, allergic skin reactions, hepatitis, vertigo and oligospermia occur rarely.

METRIFONATE

Metrifonate is an organophosphate inhibitor of acetylcholinesterase that was originally developed as an insecticide. It has activity against *Schistosoma haematobium*.[6] [7] [86] It is well absorbed orally and metabolized quickly to dichlorvos, an active metabolite. The half-life is 1.5 hours. The dosage is 7.5–10mg/kg orally once every 2 weeks for three cycles. Side effects include nausea, vomiting, vertigo and lethargy. Patients receiving metrifonate should neither be exposed to other insecticides nor receive neuromuscular blocking agents in the 2 days before or after taking metrifonate.

NICLOSAMIDE

Niclosamide is a salicylamide derivative that is active against the cestodes *Diphyllobothrium latum*, *D. caninum*, *H. nana*, *T. saginata* and *T. solium*, as well as the trematodes *Echinostoma* spp., *Fasciolopsis buski* and *Heterophyes heterophyes*.[6] It acts by interfering with oxidative phosphorylation and production of adenosine triphosphate. Treatment failures of *Taenia* spp. with niclosamide have been reported, and praziquantel has been used successfully in these cases.[87] Niclosamide is supplied as 500mg tablets that should be chewed thoroughly because of its very poor absorption. The dosage is 2g as a single dose (or 1g and 1g, given 1 hour apart), except for *H. nana* infection, which requires 2g then 1g q24h for 6 days. Side effects include gastrointestinal distress, dizziness and rash.

OXAMNIQUINE

Oxamniquine is a tetrahydroquinoline that is effective in *S. mansoni* infections.[6] [7] [86] Its mechanism of action is unclear, but it causes adult worms to become paralyzed and dislodged from the veins they inhabit, resulting in subsequent killing by host defenses. The drug is available in 250mg capsules that are rapidly absorbed and extensively metabolized in the liver. The half-life is approximately 2 hours, and 70% of the drug is excreted by the kidneys. Side effects include drowsiness, dizziness, orange-red discoloration of the urine and, rarely, seizures. The drug should be given cautiously to patients who have a history of seizures.

PIPERAZINE

Piperazine has activity against *A. lumbricoides* and *E. vermicularis*.[6] [7] [75] In many parts of the world it has been replaced by less toxic agents such as mebendazole. However, because of its lower cost, piperazine is still frequently used. Piperazine blocks the helminth muscle response to acetylcholine by altering membrane ion permeability and causing hyperpolarization and decreased action potentials. Flaccid paralysis ensues and the worms are eliminated in the stool.

Piperazine is available as the citrate salt in 250mg tablets. There is good oral absorption and a small amount of hepatic metabolism; 60% of the drug is excreted in the urine unmodified. Different dosage schedules exist, but a single dose of 75mg/kg (maximum 4g) per day for 2 days is effective for ascariasis, and a single dose of 65mg/kg daily for 7 days is used for enterobiasis.

Side effects include gastrointestinal disturbances, headache, dizziness and urticaria. Seizures occur rarely, and piperazine is contraindicated in patients who have a history of a seizure disorder. Piperazine and pyrantel pamoate are antagonistic and should not be co-administered.

PRAZIQUANTEL

Praziquantel, a pyrazinoisoquinoline derivative developed in the early 1970s, has broad activity against trematodes and cestodes but not nematodes. [6] [7] [76] [86] All *Schistosoma* spp. that infect humans are susceptible. The drug also has activity against the trematodes *C. sinensis*, *Dicrocoelium dendriticum*, *Echinostoma* spp., *F. buski*, *H. heterophyes*, *Metagonimus yokogawai*, *Metorchis conjunctus*, *Nanophyetus salmincola*, *Opisthorchis viverrini* and *Paragonimus westermani* and other *Paragonimus* spp. *Fasciola hepatica* does not appear to be adequately treated with praziquantel; bithionol is used instead. Praziquantel is effective in treating adult cestodes, including *D. latum* and other *Diphyllobothrium* spp., *D. caninum*, *H. nana*, *Hymenolepis diminuta*, *T. saginata* and *T. solium*. It has been used successfully to treat neurocysticercosis (larval *T. solium*), but it is not useful in echinococcosis. The drug has several actions, including promoting calcium influx and parasite muscle contraction and causing vacuolization and bleb formation in the helminth tegument, thereby activating host defenses.

Praziquantel is available as 600mg tablets that are nearly insoluble in water. There is good oral absorption, 80% protein binding and rapid first-pass metabolism. The half-life is 1.5 hours. About 80% of the drug is excreted in the urine. Side effects are common but transient and include headache, dizziness, nausea, vomiting and abdominal pain. Fever and rashes are occasionally seen.

PYRANTEL PAMOATE

Pyrantel pamoate, a tetrahydropyrimidine that was originally developed as a veterinary anthelmintic, has a broad range of activity in humans.[6] [7] [75] [76] It is considered by many to be the treatment of choice for *E. vermicularis*. It also effective for *A. lumbricoides*, eosinophilic enterocolitis caused by *Ancylostoma caninum*, hookworm, the acanthocephalan *Moniliformis moniliformis* and *Trichostrongylus* spp. It does not have activity against *T. trichiura*. Oxantel pamoate, an *m*-oxyphenol derivative, can be given in a single dose for *Trichuris* sp. Pyrantel pamoate and its analogues act by causing depolarizing neuromuscular blockade and by blocking acetylcholinesterase, which result in spastic paralysis and muscle contracture, respectively, and allow expulsion of the worms.

Pyrantel pamoate is available as an oral suspension of 250mg of pyrantel base per 5ml. It is poorly absorbed. Less than 15% is excreted in the urine and most remains in the feces unmodified. Side effects include headache, dizziness, insomnia, nausea, vomiting, anorexia and abdominal pain. Pyrantel pamoate, which causes depolarization and increased spike frequency in worm muscle cells, should not be given with piperazine, which causes hyperpolarization and a reduction in spike frequency.

THIABENDAZOLE

Thiabendazole is a substituted benzimidazole compound that has better activity against *S. stercoralis* and *Strongyloides fuelleborni* than mebendazole.[6] [7] [75] [76] [77] [86] It is active against *A. costaricensis*, *C. philippinensis*, *D. medinensis*, *Trichostrongylus* spp. and *T. spiralis*. In trichinosis, however, larval stages are often resistant to thiabendazole. The drug is also used in the treatment of both cutaneous and visceral larva migrans. Thiabendazole has some activity against *A. lumbricoides*, hookworm, *E. vermicularis* and *T. trichiura* but mebendazole is less toxic and is thus preferred. The drug acts by inhibiting parasite fumarate reductase, and it may bind tubulin as well.

Thiabendazole is available in tablet and liquid form and, in contrast to other benzimidazole derivatives, is rapidly absorbed. It is extensively metabolized by the liver, has a half-life of 1 hour and is mainly excreted by the kidney.

Side effects are frequent; they include nausea, vomiting, anorexia and dizziness. Pruritus, epigastric pain, headache, drowsiness, giddiness and diarrhea are less common. Rarer still are tinnitus, hallucinations, numbness, seizures, altered olfaction, altered color perception, hypotension, bradycardia, crystalluria, leukopenia, elevated liver enzymes and intrahepatic cholestasis. Allergic manifestations, including fever, angioneurotic edema, erythema multiforme and Stevens-Johnson syndrome, have been described and may result from the release of parasite antigens during treatment. Increased theophylline levels and consequent nausea and vomiting may result from the co-administration of theophylline and thiabendazole.

TRICLABENDAZOLE

Triclabendazole, a benzimidazole derivative used as a veterinary fasciolicide, has been used safely and successfully in cases of human chronic hepatic fascioliasis.[88] [89] It is now considered the drug of choice for human hepatic fascioliasis, but in the USA it is available only by directly contacting Novartis Agribusiness (Basel, Switzerland).

Acknowledgment

This chapter is an update of the first edition version, written by Erik K Johnson and Rosemary Soave.

Chapter 210 - Immunomodulation

Jos WM van der Meer
Bart-Jan Kullberg

INTRODUCTION

Despite the availability of potent antimicrobial drugs, many infections are still difficult to treat. This is not only the case for infections for which suboptimal or no effective antimicrobial treatment is available, because of intrinsic or acquired resistance of the causative micro-organism, but also those due to failing host defense mechanisms. Based on data from experimental infections and from clinical studies, especially in the neutropenic patient, it is known that antibiotics alone are rarely capable of eradicting pathogenic micro-organisms; components of host defense, especially granulocytes, are required to effectively eliminate the infection, in conjunction with the antibiotics.

Another reason for failure of antibiotic treatment is that the response of the host to infection may be overwhelming. In that situation, proinflammatory cytokines, such as tumor necrosis factor-a (TNF-a), interleukin-1ß (IL-1ß) and IL-8, as well as secretory products of white blood cells, such as elastase, reactive oxygen metabolites and chloramines, can produce serious tissue damage.[1] [2] Not only is it the proinflammatory cytokines which can be hazardous under such circumstances; the anti-inflammatory cytokines may blunt the immune response to such an extent that a state of immunodeficiency ensues. It is, however, impossible to make a simple distinction between the good and bad effects of these cytokines. Under certain circumstances a particular cytokine effect may be beneficial, whereas under other circumstances a similar effect may harm the host.

Thus, there are good reasons to try to enhance or modulate host defenses, particularly in patients with defective host defense mechanisms or when effective drug treatment is not available. If, on the other hand, the host response is overwhelming, attempts may be made to inhibit such a response.

In a general sense, treatments fall into one of the following four categories (or combinations thereof).

- The treatment stimulates the inflammatory response (e.g. by increasing the proinflammatory cytokine status or by augmenting phagocyte or T-cell function).
- The treatment inhibits the counterregulatory, anti-inflammatory response (e.g. by inhibiting anti-inflammatory cytokines such as IL-10, IL-4 or TGF-ß).
- The treatment inhibits the inflammatory response (e.g. by decreasing the proinflammatory cytokine status or by inhibiting phagocyte or T-cell function).
- The treatment promotes the counterregulatory, anti-inflammatory response (e.g. by increasing the status of anti-inflammatory cytokines such as IL-10, IL-4 or TGF-ß).

Stimulation of the proinflammatory cytokine response and inhibition of the anti-inflammatory response are aimed at treatment of specific, difficult-to-treat infections. Inhibition of the proinflammatory response and stimulation of the anti-inflammatory response are especially applicable during overwhelming inflammation, such as the systemic inflammatory response syndrome occurring during sepsis.

These therapeutic approaches have become a great challenge in medicine. However, such interventions may have a large impact on the delicate and complicated cytokine balance and may lead to disturbances that adversely affect the status of the host.

Immunomodulatory treatment has encountered a variety of problems.

- It has turned out to be extremely difficult to determine under which clinical circumstances a certain immunomodulatory effect may be of benefit.
- Many of the immunomodulatory agents have mainly been shown to work *in vitro* or in animal experiments. Many studies have used rather artificial models and often, the infectious challenge has been administered after the immunomodulatory treatment rather than before initiation of therapy.

STIMULATION OF THE INFLAMMATORY RESPONSE

There are, in essence, two ways to augment the inflammatory response. One is to administer an exogenous ('foreign') agent that elicits an inflammatory response, the second is to administer an endogenous substance in recombinant form. So far, the former method has met with very little human application. Among a few exceptions are the addition of an adjuvant (such as alum, monophosphoryl lipid A) to a vaccine, an interferon inducer (such as ampligen[3] and the recently developed cytokine-inducing drug imiquimod, which has been applied in dermatology for topical treatment of genital warts).[4]

An interesting approach that has been tried in humans is the administration of *Mycobacterium vaccae*, a nonvirulent mycobacterial strain, to patients with tuberculosis with the aim of inducing an enhanced type 1 cytokine response (i.e. to induce cytokines like IFN-?). Despite application in a number of controlled trials, it is still controversial whether this approach is effective in tuberculosis.[5]

In experimental animals, a large variety of molecules have been used with the intention of augmenting the inflammatory response, such as bacterial endotoxin, muramylpeptides and glucans.[6] The anti-fungal drug amphotericin B does seem to have such an immunostimulatory effect [7] but it is difficult to demonstrate whether this has added value in clinical terms while treating invasive fungal infections. It is currently unclear whether the administration of nutrients, such as vitamin A and zinc, which have been shown to have a beneficial effect in the treatment of tuberculosis, should be considered as substitution therapy or immunomodulatory treatment.[8]

Colony-stimulating factors

Most clinical research has been performed with the hematopoietic growth factors granulocyte-colony stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage colony-stimulating factor (M-CSF). [9] In particular, G-CSF and GM-CSF have been studied extensively in patients with congenital or acquired neutropenia. In patients with severe congenital neutropenia, benefit of G-CSF has been shown in terms of prevention of infection and improved quality of life.[10] [11] In cancer patients, these factors have been used both to shorten the duration of chemotherapy-induced granulocytopenia[12] and as adjunctive

TABLE 210-1 -- Immunomodulators for human use.

IMMUNOMODULATORS FOR HUMAN USE
Stimulators of the inflammatory response
• Exogenous agents
? adjuvants (monophosphoryl lipid A; alum)
? interferon inducers (ampligen)
? imiquimod

? amphotericin B
? *Mycobacterium vaccae*
• Endogenous agents
? Colony-stimulating factors (G-CSF, GM-CSF, M-CSF)
? Cytokines (interferon-?, IL-1, IL-2)
? Granulocyte transfusions (G-CSF primed)
Inhibitors of the anti-inflammatory response
Inhibitors of the inflammatory response
? Antiendotoxin strategies (antibodies, polymyxin B, BPI, reconstituted HDL)
? Anticytokine strategies
- Anti-TNF strategies (infliximab, etanercept)
- Anti-IL-1 strategies (IL-1ra)
Stimulators of the anti-inflammatory response
? Anti-inflammatory cytokines (IL-10)
? Glucocorticosteroids
? Macrolides
? Inhibitors of lipid mediators (PAF antagonists, cyclo-oxygenase inhibitors, n-3 fatty acids)
? Activated protein C
? Intravenous immunoglobulin preparations

therapy in patients with neutropenia and fever.[13] However, in patients with acquired neutropenia, the benefits, i.e. prevention and treatment of infection and prolonged survival, have been less impressive than had been anticipated.[9]

Although most of these studies failed to show an effect of CSF therapy on recovery from infection or survival, the potential beneficial role of GM-CSF has been demonstrated in a prospective, randomized, placebo-controlled study of patients with acute myelogenous leukemia.[14] In that study, recombinant GM-CSF was associated with a higher rate of complete response than placebo, longer overall survival and a reduced fungal infection-related mortality rate which was only 2% for those randomized to receive rGM-CSF compared with 19% for those receiving placebo. G-CSF has very few side-effects and this may be due to concomitant anti-inflammatory effects (see below).

Since G-CSF not only augments the number of granulocytes but also activates their microbicidal action and inhibits their apoptotic response, the potential of G-CSF to enhance the host's inflammatory response to infection has been investigated in non-neutropenic conditions. Preclinical studies in animals have yielded favorable effects in bacterial and fungal infections and anecdotal clinical experiences also suggested positive effects.[15] [16] In a small, randomized study in patients with disseminated *Candida* infection, it was suggested that recombinant G-CSF may improve resolution of infection and reduce mortality.[17] Controlled studies in patients with community-acquired pneumonia have failed to demonstrate a survival benefit.[18] It is controversial whether G-CSF may improve clinical outcome in diabetic foot infection, leading to shorter duration of illness and preventing amputation.[19] [20] [21] A multicenter study in chronic recalcitrant sinusitis did not show any clinical benefit.[22] Given the waning interest of the pharmaceutical industry in G-CSF, it is unlikely that further clinical studies with G-CSF in infectious diseases will be performed. The question therefore remains under which conditions recombinant G-CSF should be considered in the treatment of infection.

In the past, several clinical trials have investigated the potential beneficial effect of white blood cell transfusions in patients with refractory neutropenia-related bacterial infections.[23] This modality was abandoned because of the low yield of these transfusions and the toxicity in recipients including fever, chills, hypotension, pulmonary infiltrates, respiratory distress and allo-immunization. Recently, the possibility was raised that administration of rG-CSF to WBC donors would increase their neutrophil to levels that would lead to a higher yield of better quality cells. Donors achieved a 4–10-fold increase of their neutrophil count and the 24-hour post transfusion counts in recipients were favorable.[24] In a recent open study, rG-CSF-elicited WBC transfusions given to cancer patients with neutropenia and documented and refractory fungal infections have been successful. [25] This small pilot study as well as several clinical observations suggest that rG-CSF-enhanced WBC transfusions may be life saving for patients with refractory neutropenia-related fungal infections and are safe to deliver. Likewise, this approach seems to be successful in patients with chronic granulomatous disease (a phagocyte disorder characterized by defective intracellular killing; see below) and refractory pyogenic infection.[26] [27]

The application of recombinant GM-CSF and M-CSF in infectious diseases has been studied less extensively and despite the expectations of many investigators, there is hardly any clinical indication for these drugs, with the possible exception of visceral leishmaniasis.[28] [29]

Interferon-?

Despite many preclinical studies demonstrating useful effects in a variety of bacterial, fungal and parasitic infections, interferon-? (IFN-?) has not gained much favor in clinical medicine. The only established indication for IFN-? is the prevention of infection in chronic granulomatous disease.

Chronic granulomatous disease (CGD) is characterized by a defect in NADPH oxidase in phagocytic cells with a consecutive impairment in synthesis of reactive oxygen species, leading to recurrent pyogenic infections with catalase-positive micro-organisms.[30] Chronic treatment with IFN-? has been shown to reduce the frequency of infections in these patients by more than 70%, without severe side effects. The mechanism of action in CGD is not clear but most likely, the effect of IFN-? is through stimulation of the nonoxidative microbicidal effects of granulocytes and mononuclear phagocytes. Promising results have also been reported in clinical studies involving mycobacterial infections.

Recombinant IFN-? decreases the bacterial load in patients with lepromatous leprosy.[31] [32] Beneficial effects have also been observed in patients with *Mycobacterium avium* complex infection.[33] [34] Recombinant IFN-? has also been investigated as adjunctive therapy in visceral leishmaniasis. Its effect in combination with pentavalent antimony has been disappointing. [35] In a recent study, recombinant IFN-? was suggested to reduce the incidence of opportunistic infections and resulted in a tendency towards increased survival in patients with advanced HIV disease.[36]

In animal experiments, the effects of IFN-? on granulocytes and mononuclear phagocytes are impressive[37] and currently, several clinical trials of IFN-? as a therapeutic agent in mycobacterial and fungal infection are ongoing. Especially now that our understanding of the mechanism of action of IFN-?, its cellular receptor and the role of related cytokines such as IL-12, IL-18 and IL-23 has expanded, the need for such studies is compelling.

Other recombinant cytokines

So far, the use of other recombinant cytokines for therapy of infection has been limited. IL-1, which is effective in enhancing survival

of mice with bacterial and fungal as well as plasmodial infection,[6] has only been used in humans as an anticancer agent.[38] [39] [40] Interestingly, IL-1 seems to be unique in that it enhances survival of lethal bacterial and fungal infections in the absence of neutrophils.[6]

IL-2 has been studied to some extent for treatment of infection. In patients with lepromatous leprosy, who exhibit impaired *Mycobacterium leprae*-specific T-cell proliferation, the administration of recombinant IL-2 may be expected to be beneficial. Indeed, in several small pilot studies, intradermal injection of IL-2 in patients with lepromatous leprosy has lead to increased infiltration of mononuclear cells and reduction of the numbers of viable acid-fast *M. leprae* in the peripheral sites.[41] [42] Interestingly, recombinant IL-12 and IL-2 strongly synergize in restoring both *M. leprae*-specific T-cell proliferation and IFN-? secretion *in vitro*.[43]

Administration of relatively high doses of recombinant IL-2 has shown an effect in HIV-infected persons by increasing their levels of circulating CD4 T cells up to normal

levels.[44] Further placebo-controlled studies have confirmed a significant rise in CD4 cell count, accompanied by a reduction in plasma HIV in recipients of IL-2 relative to control patients, associated with a nonsignificant trend toward improved clinical outcome.[45] The mechanism through which IL-2 increases $CD4^+$ T cells in HIV-infected individuals is unclear. Most $CD4^+$ T cells that expand after IL-2 administration are memory cells, although increase in naïve T cells has been also reported.[46] Of interest, IL-2 administration in combination with highly active antiretroviral therapy (HAART), but not HAART alone, seems capable of reducing the pool of resting memory CD4T cells harboring latent replication-competent HIV.[47]

Although there has been concern that the proinflammatory effects of IL-2 may be harmful in terms of transient increases in plasma viremia after each cycle of cytokine administration, the net effect of IL-2 appears to be beneficial and in several trials, no evidence of increased levels of HIV replication was found after IL-2 administration in the presence of HAART.[48] The toxicity associated with administration of relatively high doses of this cytokine to HIV-infected persons remains a major hurdle.[44] The most common toxic effect is a flu-like syndrome that manifests with fever, chills, fatigue and headache. Recent studies have suggested that low doses of intermittent sc IL-2 induced a stable increase of peripheral CD4 cells that was indistinguishable from those associated with higher, less well-tolerated doses of IL-2.[48] (see also Chapter 140).

INHIBITION OF THE ANTI-INFLAMMATORY RESPONSE

The major anti-inflammatory mediators, such as IL-4, IL-10, TGF-ß, IL-1 receptor antagonist (IL-1ra) and the soluble TNF receptors, are potential targets in immunomodulatory treatment. The net effect of inhibiting these mediators is likely to be an increased proinflammatory response, enhancing the innate host defense to infection. Although such interventions have been studied in experimental infection in animals, e.g. through targeted gene disruption, such approaches have not been undertaken in humans.

IL-10 is considered a prototypic anti-inflammatory cytokine, which inhibits the production of proinflammatory cytokines *in vitro* and *in vivo*. Elevated plasma concentrations of IL-10 have been found in patients with sepsis[49] and its inhibition leads to an increased production of TNF and an enhanced mortality. [50] In contrast, the host defense against localized infection may be enhanced by treatment with anti-IL-10 antibodies. In a murine pneumonia model, antibodies against IL-10 inhibited bacterial outgrowth in lungs and improved survival.[51] There appears to be a fine balance between beneficial and deleterious effects of IL-10, since elimination of IL-10 in a model of septic peritonitis induced by cecal ligation and puncture (CLP) was associated with an increased mortality.[52] [53] These findings are explained by the dual effects of the cytokine network, i.e. whereas in an infected organ a predominantly proinflammatory response contributes to the effective clearance of bacteria, at the systemic level such a response may be harmful to the host. Therefore, during septic peritonitis, endogenous IL-10 impairs bacterial clearance from the peritoneal cavity and facilitates dissemination of bacteria to distant organs, yet attenuates the systemic inflammatory reactions and multiple organ failure associated with this abdominal sepsis syndrome by a mechanism that in part involves inhibition of TNF production. There have been no human trials applying these strategies as yet.

INHIBITION OF THE PROINFLAMMATORY RESPONSE

In recent years, most of the preclinical and clinical studies on immunotherapy of infection have dealt with the inhibition of the proinflammatory response and enforcement of the anti-inflammatory response. These approaches include inhibiting the proinflammatory cytokine TNF-a as well as administration of anti-inflammatory cytokines, such as IL-10. This treatment is based on the notion that an exaggerated and harmful host response may occur during severe infection (Chapter 56), and inhibition of such a response may be beneficial. The therapeutic strategies may interfere at various steps in the inflammatory cascade (Fig. 210.1). First, interference with the infective agent that triggers the host response is a sensible approach. In this respect, prompt antibiotic treatment is a keystone in treatment. Although it has been demonstrated *in vitro* and in animal experiments that antibiotics, especially ß-lactam antibiotics, may liberate endotoxin (lipopolysaccharide, LPS) and hence may be harmful, [54] it has not been convincingly shown that this phenomenon contributes to morbidity in humans.[55] In fact, in fulminant meningococcal septicemia, earlier administration of antibiotics leads to an attenuated mediator response and improved outcome.[56]

Antiendotoxin strategies

Several approaches have been undertaken to block the action of endotoxin. Despite initial optimism, polyclonal as well as monoclonal antibodies against the endotoxin molecule have not met with clinical success.[57] Likewise, an engineered form of the endotoxin-binding substance BPI has not led to a breakthrough. In a randomized study in meningococcal sepsis, this molecule led to a nonsignificant trend towards lower mortality and fewer amputations of affected limbs.[58] A major problem with this study, however, was that the time needed for enrolment of patients led to important delay and to a selection of less severe patients in the trial.[59] Further studies are needed to establish whether early administration of BPI may be beneficial. This points to a key problem with all available interventions, i.e. the timing of the intervention, given the rapidity of evolvement of sepsis.

There are three additional major problems with the antiendotoxin approach. One is that it is impossible in most cases to tell, at the bedside, whether endotoxin plays a role in the clinical illness, i.e. whether the patient has a Gram-negative infection. Fulminant meningococcal sepsis, with its characteristic clinical picture, may be an exception. The second problem is that endotoxin is not the only pathogenetic factor in Gram-negative sepsis; other components of Gram-negative bacilli are also involved. The third problem is that not all endotoxins are equal; for instance, meningococcal LPS is poorly neutralized by substances that do neutralize other endotoxin species, such as polymyxin B and reconstituted high-density lipoprotein.[60]

A subsequent target for treatment may be the site where microbial components interact with host cells. Recently, a new class of recognition molecules has been identified on cells of the host, the toll-like receptors (TLR). These TLR, of which so far at least 10 have been

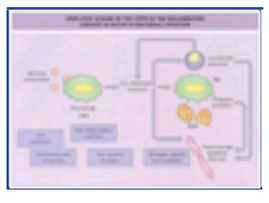

Figure 210-1 Simplified scheme of the steps in the inflammatory cascade as occur in (bacterial) infection. The block arrows indicate sites of intervention.

identified, recognize an array of components of different micro-organisms.[61] One could envisage clinical interference at this level, but tools to do so are not yet available.

Strategies to block proinflammatory cytokines

Based on pioneering work with anti-TNF antibodies in experimental animals challenged with either high-dose bacterial endotoxin or live bacteria, in which impressive reductions of mortality were demonstrated, a series of clinical trials have been performed in sepsis. The anti-TNF strategies in these studies consisted of either murine or humanized monoclonal antibodies against TNF (which only interfere with TNF-a and not with TNF-ß) or a engineered soluble TNF receptor construct (interfering with both types of TNF). None of these studies has met with consistent clinical benefit.[62] Similarly, interference with the actions of IL-1a and ß in sepsis by administration of IL-1ra has been disappointing in a large placebo-controlled trial.[63] There are various explanations for the discrepancy between the results in experimental animals and those in patients. A major explanation is that many of the animal models are not realistic in terms of challenges, timing of microbial challenge and intervention, and endpoints. A second explanation is that the magnitude and the duration of the biological effects of the cytokine intervention had not been studied adequately before the large trials were started.

A third explanation is that the entry criteria in the human studies were too imprecise; based on the idea that sepsis syndrome had a homogeneous mediator response, heterogeneous patients fullfilling the broad entry criteria for sepsis syndrome were enrolled. Another issue is the required endpoint of 28-day mortality; given the complicated course of many very sick and frail patients in the intensive care unit, it is naïve to assume that a short initial intervention will still pay off 4 weeks later. Furthermore, the concept of blocking one cytokine may be too simple, in view of the redundancy within the cytokine network. It is, however, controversial whether blocking more than one cytokine at a time is beneficial.

Finally, the idea that proinflammatory cytokines are only deleterious in sepsis is also an oversimplification. In fact, in the clinical settings in which these anticytokine strategies are effective (rheumatoid arthritis and Crohn's disease), it gradually has become apparent that these treatments enhance the risk for infection. The infections that are seen are not only those caused by facultative intracellular micro-organisms (such as mycobacteria and salmonella), but also by other pathogens. [64] [65] Given the capacity of the various proinflammatory cytokines to activate neutrophils for killing micro-organisms, it is likely that the host defense against common ('extracellular') bacteria (staphylococci, Gram-negative bacilli) is also hampered.

In terms of inhibiting the proinflammatory cytokine response, G-CSF is an interesting molecule. It does not only stimulate proliferation of neutrophils, activate them and inhibit their apoptotic response (as discussed above), but also downregulates the proinflammatory cytokine response. For instance, in human volunteers challenged with LPS, G-CSF pretreatment prevents neutrophil accumulation in the lung. [66] This dual action of G-CSF is not unique and other cytokines, such as IL-6, IL-10 and IFN-?, exhibit pro- and anti-inflammatory effects and even IL-1 has been shown to inhibit TNF production and the expression of cytokine receptors *in vivo*.[67] One way to inhibit cytokine action is to limit their production. This can be done by administration of anti-inflammatory cytokines (such as IL-10, IL-4 and TGF-ß) or by giving glucocorticosteroids. IL-10 has been evaluated as a new adjuvant therapy for several inflammatory diseases.[68] Treatment of Crohn's disease with IL-10 has been found to be associated with a bell-shaped dose-response curve.[69] However, although IL-10 is considered a potent anti-inflammatory cytokine, recent studies have suggested that it also possesses immunostimulatory effects.[70] At a low dose, IL-10 has induced clinical remissions but at higher dose, the beneficial effects are lost. It is hypothesized that these effects may be due to a proinflammatory effect of high-dose IL-10, and this potential IFN-? enhancing effect may especially warrant caution for the use of recombinant IL-10 therapy for Th1-mediated illnesses such as Crohn's disease and rheumatoid arthritis.

Glucocorticosteroids

Glucocorticosteroids have several immunomodulatory effects: not only do they inhibit the production of proinflammatory cytokines, they also inhibit the function of phagocyte and T cells. Two landmark studies demonstrated the ineffectiveness of high dosages of glucocorticosteroids in sepsis.[71] [72] There is, however, a renewed interest in the use of these drugs in sepsis, albeit in lower dosages, based on the concept that septic shock may be complicated by an

TABLE 210-2 -- Uses of systemic glucocorticosteroids in the treatment of infection.*

USES OF SYSTEMIC GLUCOCORTICOSTEROIDS IN THE TREATMENT OF INFECTION		
Infection	**Strength of recommendation#**	**Evidence‡**
Gram-negative sepsis with shock	B	I

occult adrenal insufficiency. In a randomized controlled trial in France, the efficacy of this approach has been demonstrated.[73] Glucocorticosteroids have a wider application as immunomodulators in infectious diseases. In Table 210.2 these applications are listed with the strength of the evidence for their use as put forward by the Infectious Diseases Society of America.[74]

The use of glucocorticosteroids has met with side effects that relate to their glucocorticoid, mineralocorticoid and anti-inflammatory effects. The latter are important within the context of this chapter. Their inhibition of influx and function of phagocytic cells (granulocytes and mononuclear phagocytes) enhances the susceptibility to bacterial and fungal infection, while the interference, T-cell distribution and function increase the risk for infection caused by facultative intracellular micro-organisms (such as mycobacteria, *Salmonella* spp. and cryptococci) and viruses (such as cytomegalovirus). Their effect on cytokine production probably impairs both phagocyte and T-cell defense. The degree to which these side-effects occur relates to dose and duration, as has become clear from a meta-analysis of controlled trials of glucocorticosteroid treatment[75] (Fig. 210.2).

Other non-specific inhibitors of inflammation

Macrolides are also able to inhibit the proinflammatory cytokine responses and probably have other anti-inflammatory actions. Although not studied in a randomized controlled fashion, their effect on survival in diffuse panbronchiolitis, a pulmonary disease that occurs in East Asia, points to a potent anti-inflammatory effect.[76] These findings are sustained by animal experiments with macrolides in which bronchial inflammation is modulated.[76]

Since many of the deleterious effects of proinflammatory cytokines are mediated by lipid mediators, such as platelet-activating factor (PAF) and prostaglandins, inhibitors for these secondary mediators have also been studied in sepsis. Controlled trials with PAF antagonists did not change overall mortality of septic shock.[77] [78] [79] [80] Likewise, the prostaglandin inhibitor ibuprofen did not prevent the development of shock or the acute respiratory distress syndrome and did not improve survival. [81] An explanation may be that prostaglandin inhibitors tend to increase the production of the proinflammatory cytokines.[82]

Supplementation with fish oil preparations, a source of n-3 polyunsaturated fatty acids, modulates proinflammatory cytokine production and prostaglandin synthesis. [83] Although impressive effects have been found in lethally infected experimental animals, the effects in

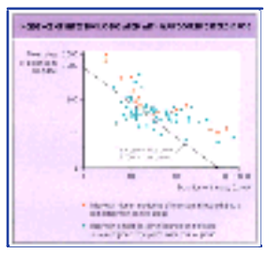

Figure 210-2 Incidence of infection associated with glucocorticosteroid use. In this meta-analysis of 71 placebo-controlled trials of prednisone, all trials in which there was a higher incidence of infection in the treated group (compared with the controls) were located above the isodose line of 700mg. This indicates that, independent of the regimen used in the trial, patients who had a cumulative dose of less than 700mg did not have an increased risk of infectious complications. *(With permission from Stuck et al.[75])*

humans with infections have not been well established.[84] The effects of these supplements seem to differ in different species (humans vs mice).

Intravenous immunoglobulins have been shown to possess anti-inflammatory properties. Although they induce proinflammatory cytokines shortly after infusion their major effect is a downregulation of the inflammatory response, e.g. through induction of IL-1ra and soluble cytokine receptors.[85] So far these complex effects of immunoglobulins have not been used therapeutically in the treatment of infection.

Activated recombinant protein C

Recently, activated protein C as a recombinant product has been investigated as a therapeutic agent in sepsis. Treatment with this product, which has antithrombotic, anti-inflammatory and profibrinolytic properties, was associated with an absolute reduction in the risk of death of 6% in patients with severe sepsis. [81] Further studies are needed to determine the exact indications for this expensive mode of treatment. In addition, the safety in septic patients with severe disseminated intravascular coagulation (such as occurs in fulminant meningococcal sepsis) has to be determined.

CONCLUSION

Despite elegant theoretical concepts and promising preclinical studies, the immunomodulatory adjunctive therapies in the field of infectious diseases have not come to fruition. Although a range of promising molecules is available, we have not yet been able to either discern the niche for them or apply them properly in terms of time and dosage. Another obstacle is that most of the immunomodulatory agents are expensive and hence not available for investigation in developing countries, where infections that are good candidates for immunomodulation (e.g. tuberculosis, leprosy, trypanosomiasis, leishmaniasis, typhoid fever) are prevalent.

Chapter 211 - Acute Gastroenteritis Viruses

Rodolfo E Bégué
Arturo S Gastañaduy

Acute gastroenteritis constitutes a major cause of morbidity and mortality worldwide (Table 211.1). Infants and young children sustain on average 3–10 episodes per year compared with less than one episode per year for those older than 5 years. In the developing world this represents more than 1000 million cases and 3–4 million deaths every year.[3] These deaths are caused mainly by dehydration, but malnutrition also plays an important role. It has been estimated that 25% of the growth difference between children in developing countries and those in the USA is related to diarrhea. In developed countries, morbidity and mortality caused by diarrheal diseases have declined as economics and sanitation have improved, but 38 million cases still occur annually in the USA, with 2–3.7 million physician visits, 220,000 hospitalizations, 325–425 deaths and at a cost of US$23 billion. [4]

APPROACH TO MANAGEMENT

The goals of management of acute gastroenteritis are prevention and treatment of the two major complications — dehydration and malnutrition (Table 211.2). Children with no or only minimal dehydration can be managed with increased fluid intake and continuation of feeding. Those who have mild or moderate dehydration should receive an oral rehydration solution (ORS). In a few cases (<5%) oral rehydration might not be appropriate and intravenous rehydration should be used instead, for example in patients with severe dehydration, intractable vomiting, high stool output or monosaccharide malabsorption. Traditional ORSs are effective in preventing and treating dehydration, but do not reduce the stool output or duration of the diarrhea. Although cereal-based ORSs do reduce the stool output and duration of the diarrhea, these advantages become clinically insignificant when glucose-based ORSs are combined with appropriate nutritional management. Supplementing ORS with probiotics (*Lactobacillus* GG), oligoelements (zinc) or others (acetorphan) might reduce duration of diarrhea by 24–48 hours; their clinical and public health impact is uncertain at this point, though. There

Diarrheal illnesses/year (millions)	1000	1500	1000	21–37
No. of diarrheal deaths/year	4.6 million	4.0 million	3.3 million	325–425

** Estimates from longitudinal, prospective, community-based studies in developing and developed countries.*

is no reason not to feed children who have gastroenteritis. Full-strength feedings initiated immediately after rehydration improve the weight gain of the children and do not contribute to the severity or duration of the diarrhea compared with diluted or delayed feeding. Despite lactose malabsorption developing frequently during diarrhea, most children can still be fed their usual lactose-containing formulas in small frequent feeds. Human milk has a high lactose content; however, it reduces stool output and hence should be maintained. Milk-cereal and cereal-legume combinations are also safe and efficacious for the nutritional management of diarrhea.

APPROACH TO PREVENTION

The agents of acute gastroenteritis are transmitted by the fecal-oral route, through either direct person-to-person contact or contaminated food or water. The former is more important for the endemic pattern of disease and the latter for outbreaks. Handwashing and hygienic measures prevent person-to-person spread. However, because these measures are difficult to enforce in small children, endemic transmission of the disease continues, even in developed countries. For outbreaks, environmental control (food, water and sanitation) is important and effective. Good handwashing (especially among food handlers), furloughing of ill personnel, thorough cooking of food and disinfection of water and surfaces should prevent or control most outbreaks. For hospitalized patients, enteric precautions (i.e. contact precautions for diapered or incontinent patients, and standard precautions otherwise) must be instituted and continued for at least 48 hours after the resolution of symptoms. Breast-feeding, through a variety of mechanisms, reduces the overall incidence of diarrhea, especially in developing countries. Unfortunately, this protective effect can be overridden by exposure to a heavy inoculum. Continuation of breast-feeding through the diarrhea episode should be encouraged. Probiotics (*Lactobacillus* GG) might confer a modest protective effect.

TABLE 211-2 -- Management guidelines for gastroenteritis.

GASTROENTERITIS: MANAGEMENT GUIDELINES				
		Degree of dehydration		
		None	Mild-moderate	Severe
Assessment	Weight loss (%)	<5	5–10	>10
	Fluid deficit (ml/kg)	<50	50–100	>100
Rehydration (usually accomplished during the first 4h of therapy)	Initial fluid	ORS	ORS	iv Ringer's or 0.9% NaCl
	Amount (ml/kg)	50	50–100	20ml/kg/h
Replacement	ORS 10ml/kg or 2–4oz for each diarrheal stool			
Maintenance	Feedings should start immediately after rehydration. Human milk, lactose-containing and lactose-free formulas; milk staple and solid foods in small frequent feeds are well tolerated by most patients, foster recovery and improve nutritional outcome			
The essential goals of therapy are prevention and treatment of the two major complications, dehydration and malnutrition. ORS, oral rehydration solution.				

TABLE 211-3 -- Acute infectious diarrhea: clinical syndromes.

ACUTE INFECTIOUS DIARRHEA: CLINICAL SYNDROMES		
	Watery	**Dysenteric**

	Enterotoxigenic	*Campylobacter spp*
	Escherichia coli	*Entamoeba histolytica*
	Vibrio cholerae	
+: mild; ++: moderate; +++: marked		
Separating the cases of diarrhea into dysenteric or watery is helpful when deciding on the need for laboratory evaluation.		

APPROACH TO DIAGNOSIS

An etiologic diagnosis is not necessary for the management of most cases of gastroenteritis. It might, however, be desirable for clinical, epidemiologic or research purposes. To identify patients that might benefit from a stool culture and antibiotic treatment, it is useful to classify the diarrhea as dysenteric or watery (Table 211.3). The distinction between these two syndromes is usually evident from the patient's history and inspection of the stool. If not, simple and inexpensive tests, such as the presence of occult blood in the stool and fecal leukocytes, should assist in the differentiation. Most diarrheal diseases that need antibiotics (e.g. shigellosis) belong to the dysenteric group, whereas viral gastroenteritis always manifests with watery diarrhea. Some bacterial pathogens can also produce watery diarrhea (e.g. enterotoxigenic *Escherichia coli* and *Salmonella* spp.), but they usually resolve spontaneously.

VIRAL AGENTS OF GASTROENTERITIS

The viruses associated with acute gastroenteritis and their morphologic and clinicoepidemiologic characteristics are shown in Table 211.4 and Table 211.5 . Rotaviruses (RVs) and enteric adenoviruses are large (70–80nm) and have distinct appearances. Astroviruses and caliciviruses (Noroviruses and Sapoviruses) are smaller (27–40nm) and possess well-defined surface structures. They used to be collectively referred to as small round structured viruses (SRSV). Somewhat smaller (20–26nm) viruses with smooth edge and no discernible surface structure were designated 'featureless viruses' or

TABLE 211-4 -- Morphologic characteristics of gastroenteritis viruses.

ds, double-stranded; ss, single-stranded.					

small round viruses (SRV). These agents resemble enterovirus or parvovirus, and some may be related to them. Rotaviruses and caliciviruses are the main agents of human viral gastroenteritis.

Dehydration or vomiting, especially if it precedes the diarrhea, suggests a viral etiology. However, there is considerable overlap in the clinical manifestations of different viruses and making an etiologic diagnosis requires complex and expensive techniques, unavailable in most clinical centers. Electron microscopy (EM) was originally used to identify all gastroenteritis viruses, and still remains the preferred screening technique, especially when investigating outbreaks. If viral particles are seen by EM, depending on their morphology, more specific tests might follow. Electron microscopy requires the presence of at least one million viral particles per ml of stool; hence, the specimen must be obtained early in the illness (first 2 days). Immunoelectron microscopy (IEM) enhances the sensitivity of EM by using virus-specific antiserum that clumps the particles and makes them easier to visualize.

Immunoassays (IAs) represent simple and rapid methods to detect viruses. Unfortunately, IAs are commercially available only for the

TABLE 211-5 -- Epidemiologic and clinical characteristics of gastroenteritis viruses.

EPIDEMIOLOGIC AND CLINICAL CHARACTERISTICS OF GASTROENTERITIS VIRUSES					
Characteristic	**Rotavirus**	**Enteric adenovirus**	**Astrovirus**	**Norovirus**	**Sapovirus**

Inpatient prevalence (%)	35–40	5–20	3–5	Rare	3–5

diagnosis of RVs and enteric adenoviruses. Recent cloning and expression of the viral genomes of most gastroenteritis viruses have made reagents more available for IAs to detect the other agents.

Viral culture is tedious but still an essential technique because it allows characterization of the viruses, study of their pathogenicity and the production of diagnostic reagents. Rotaviruses, adenoviruses and astroviruses can be cultured whereas caliciviruses cannot.

Reverse transcription polymerase chain reaction (RT-PCR) detects and amplifies genetic sequences specific to each pathogen, including unculturable ones. This technique has now been successfully applied to the detection of most gastroenteritis viruses. Other diagnostic tools are polyacrylamide gel electrophoresis (PAGE) and

restriction endonuclease digestion, which can be used to identify RVs or enteric adenoviruses, respectively, on the basis of their characteristic electrophoretic pattern. Finally, dot blot hybridization with complementary DNA (cDNA) has been used to identify adenoviruses and astroviruses. For diagnostic purposes, stool specimens can be stored at 39.2°F (4°C) for 1 week; for longer storage they should be frozen at -70°C. For serologic diagnosis, acute and convalescent specimens are required. An overview of the procedures can be found elsewhere.[5]

ROTAVIRUSES

Identified by Bishop *et al.* in 1973,[6] human RVs have emerged as the main agent of acute gastroenteritis in infants and young children worldwide.

NATURE

Rotaviruses belong to the family Reoviridae. Intact virions measure 70–75nm with a triple-shelled capsid composed of an outer layer (outer capsid), an intermediate layer (inner capsid) and an inner layer (core). Sixty spike-like structures (capsomers) radiating from the inner to the outer capsid, give the virus its characteristic EM appearance (Fig. 211.1) and its name ('rota' is Latin for 'wheel'). Single-shelled particles (55nm) and cores (37nm) can also be seen. Of the three forms, only intact virions are infectious. The core encloses the viral genome, which consists of 11 segments of double-stranded RNA (dsRNA). Each segment encodes for at least one protein: six structural proteins (VP1, VP2, VP3, VP4, VP6 and VP7)

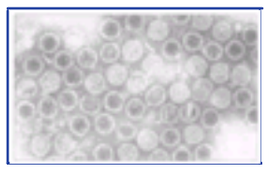

Figure 211-1 Rotavirus. Electron micrograph. *Courtesy of S Spangenberger.*

which are present in the virion; and six nonstructural proteins (NSP1 through NSP6) which are identified only in the cytoplasm of infected cells (Table 211.6). The inner core is made of VP1, VP2 and VP3, with VP2 being the major constituent. VP6 is the only component of the inner capsid. The outer capsid shell is composed of two proteins: VP7 makes about 90% of the outer capsid and is perforated by 132 channels penetrating the virion and reaching the central core; VP4 forms the capsomers, which protrude from the virus surface, pass through VP7 and interact with VP6 (Fig. 211.2).

Based on antigenic specificities, RVs are classified in groups, subgroups and serotypes. Groups and subgroups are determined by VP6. To date seven groups (A–G) and two subgroups (I and II) have been described. Groups A, B and C can infect humans and animals, whereas groups D–G have been found only in animals. Most human infections are caused by group A RVs. Subgroup II is more frequent than subgroup I; however, significant geographic variations occur. The outer capsid proteins VP4 and VP7 determine the serotypes. Those defined by VP7, a glycoprotein, are called G serotypes and those defined by VP4, a protease sensitive protein, are called P serotypes. At least 14 G serotypes (G1–G14) have been described; G1–G4 produce most human infections; however, G8, G9 and G12 infections have also been recognized.[7] [8] Thirteen VP4 serotypes (P1–P13)

TABLE 211-6 -- Rotavirus genome segments and their corresponding viral proteins.*

ROTAVIRUSES' VIRAL PROTEINS			
Genome segment	**Protein product**	**Molecular weight**	**Function/property**
1	VP1	125,000	RNA polymerase
2	VP2	94,000	RNA binding
3	VP3	88,000	Guanylyltransferase, methyltransferase
4	VP4	88,000	Hemagglutinin, neutralization antigen, infectivity
	VP5* and VP8*	529 and 247	Cleavage products of VP4
5	NSP1	53,000	RNA binding
6	VP6	41,000	Subgroup antigen, protection?
7	NSP3	34,000	Binds viral mRNA, inhibits host translation
8	NSP2	35,000	RNA binding
9	VP7	38,000	Neutralization antigen, Ca^{2+} binding protection
10	NSP4	28,000	Enterotoxin, protection?

	NSP6	12,000	Interacts with NSP5

VP, viral structural protein; NS, viral nonstructural protein.

** Modified from Estes 2001.*[15]

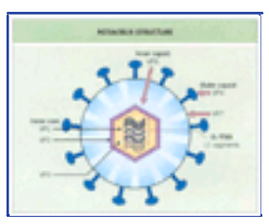

Figure 211-2 Rotavirus structure. Inner core is made of VP1, VP2 and VP3; inner capsid is made of VP6; outer capsid is made of VP7 and VP4. *Modified from Kapikian 2001.*[9]

have been identified; P1, P2, and P5 include two distinct subtypes named: P1A, P1B; P2A, P2B; P5A, P5B.

Nucleic acid hybridization and sequence analysis of the VP4 and VP7 genes permit classification of RVs according to genotypes. There is full concordance between RVs VP7 serotypes and genotypes; thus, RVs classified by either method are simply designated as G1, G2, etc. On the other hand there is poor concordance between VP4 genotypes and VP4 serotypes. For example, 21 VP4 genotypes have been described, and five of them do not have a corresponding serotype; also, the assigned numbers for serotype and genotype classification are not the same. To integrate both classifications, proper designation uses the letter P followed by an open Arabic number to indicate the serotype, and a second Arabic number in brackets to indicate the genotype.[9] For example the human RV strain Wa is designated P1A[8].

EPIDEMIOLOGY

Rotaviruses are the most commonly identified viral enteropathogens among children. In the USA RVs cause 5–10% of all diarrheal episodes and 30–50% of severe diarrhea in children under 5 years of age, resulting in 3.5 million diarrhea cases, 55,000 hospitalizations, 20–40 deaths and a cost in excess of one billion dollars.[10] Worldwide estimates are 130 million episodes, 18 million moderate or severe cases and almost one million deaths annually. The proportion of diarrhea cases caused by RVs decreases from hospital to clinic to community populations, in developed and developing countries (38–89, 10–34 and 6–12%, and 20–46, 10–30 and 10–20%,

respectively), reflecting the tendency of the virus to produce dehydration. Also, RVs account for a larger proportion of cases in developed countries than in developing ones (38–89 versus 20–46%, respectively) and in high-income groups than low-income ones (60 versus 4–30%, respectively).[7]

Rotavirus gastroenteritis is primarily a disease of infants and young children, with peak incidence rates at 6–24 months; it occurs at earlier ages in developing countries. Neonates and adults are affected infrequently unless they are exposed to infected children, in which case 11–70% can become infected. Outbreaks have been described in nursing homes for the elderly, hospital wards and military bases. Travelers' diarrhea is most commonly caused by enterotoxigenic *E. coli*, but RVs have been detected in as many as 20% of these cases. Asymptomatic shedding of RVs occurs in 10–15% of individuals.[7]

In temperate climates RVs appear in characteristic and predictable winter epidemics. In North America, the epidemic starts in Mexico and the southwestern USA in late fall, spreads in a northeast direction and ends in the northeastern USA and the Maritime provinces of Canada in the spring. The reasons for this spread pattern are not clear, but climate, virus characteristics or other factors may play a role.[11] In tropical climates RVs are endemic throughout the year, with some clustering in the cooler, drier months. Group A, serotype G1 strains are most commonly implicated in human disease (54%); other serotypes — G2 (18%), G3 (12%) and G4 (11%) are also seen. Circulating serotypes vary with geographic location and with time. Multiple serotypes can co-circulate during a specific year.[7] Group B RVs have been associated with epidemics of diarrhea among adults in China. Group C RVs have been identified in Central and South America, Europe, Australia and Asia.[7] [12]

Pathogenicity

Person-to-person transmission through the fecal-oral route is the most likely mode of spread of RVs. Fecal excretion starts immediately

before the onset of symptoms and lasts for 5–7 days. The large number of viral particles excreted in feces (approximately one trillion per ml) and the low infective dose (as few as ten RV particles in a child) favors patient-to-patient spread. Contamination of food and water has been implicated in some outbreaks, and fomites may play a role in settings such as day care centers and nurseries. Rotaviruses can survive for 60 days on environmental surfaces at different temperatures (39.2–68°F; 4–20°C) and humidities (50–90%).[13] Respiratory transmission has been suspected in two outbreaks and is supported by the way the annual RV epidemic spreads in North America. However, attempts to isolate RV from respiratory secretions have been mostly unsuccessful.

The virus preferentially infects the mature enterocytes in the villus epithelium of the small intestine. The infected cells change from columnar to cuboidal, with enlarged cisternae of the endoplasmic reticulum and fewer and shorter microvilli. The cells are eventually killed and sloughed off and, with denudation of the tip cells, the villi become shortened. Mononuclear leukocyte infiltration is minimal. These changes occur within 24 hours of infection, start proximally and progress caudally. The major mechanism of diarrhea during RV infections appears to be decreased absorption of salt and water secondary to enterocyte damage and replacement of absorptive intestinal cells by secreting cells from the crypts. Loss of disaccharidases at the damaged brush border results in carbohydrate malabsorption and osmotic diarrhea. The observation of RV diarrhea in the absence of epithelial lesions led to the discovery of a calcium-dependent signal by NSP4 that increases plasma membrane chloride permeability, leading to chloride secretion and secretory diarrhea early in the course of the illness. NSP4 is the first described viral enterotoxin. It is also postulated that RV induces intestinal fluid and electrolyte secretion by activation of the enteric nervous system. [14]

The factors that determine RV pathogenicity are not fully understood. Rotaviruses have tissue and cell-type specific tropism, suggesting the presence of receptors that mediate virus attachment or penetration. The identity of these receptors remain elusive, though. *N*-acetylneuraminic acid (sialic acid: SA) on the surface of the cells was thought to be required for virus binding; however, most RV strains are SA independent. GM1 gangliosides and cellular integrins have also been postulated as RV receptors. The VP4 spike protein mediates viral attachment to the target cells, and its cleavage into VP5* and VP8* by proteases like trypsin is essential for cell penetration. Cell penetration requires also VP7.

Two mechanisms of penetration have been proposed: direct membrane penetration and receptor-mediated endocytosis. Direct membrane penetration appears to be mediated by VP5*. Receptor-mediated endocytosis is supported by EM studies that show uptake of virus particles into coated pits, vesicles and lysosomes. Uncoating of the virus in the enterocytes is mediated by low Ca^{2+} concentrations in the cytoplasm. The next steps of RV replication have been extensively reviewed elsewhere.[15] Host factors, such as age, also influence the pathogenesis of RVs. For example symptoms are more prominent among young hosts. Although animal studies have shown that the quantity of RV-binding receptors on villus epithelial cells decreases with age, a more likely explanation for the age difference in the manifestations of the disease is the acquisition of immunity. Nutritional deficiencies, certain immunodeficiencies or co-infection with bacterial pathogens can increase the severity and duration of RV diarrhea; these situations frequently coexist in the developing world.

The mechanisms underlying immunity against RV infections and illness are not completely understood. Clinical protection may involve local (mucosal) and systemic (serum) antibodies as well as cellular immunity. Serum-neutralizing antibodies against the infecting serotype (homotypic) develop frequently and within 2 weeks of infection. Heterotypic responses (antibodies against different serotypes) also occur, but mostly among adults and vary with the infecting strain; for example G2 produces mainly homotypic antibodies, whereas G1, G3 and G4 produce homotypic and heterotypic responses. Studies have shown a correlation between the presence of homotypic neutralizing antibodies and protection. The duration of homotypic protection is probably longer than that of heterotypic; however, it is both incomplete and short-lived, as shown by the occurrence of reinfections with the same serotype. The role of serum IgM antibodies is unclear. By 3 years of age over 80% of the population has antibodies against RVs, and by 4 years of age this is practically 100%. Antibody levels are high at birth, decline by 3–6 months, rise to a peak at 2–3 years and remain elevated throughout life (probably because of repeat, mostly asymptomatic infections).[7] [12] These serum antibodies do not always prevent the infection, though. Mucosal immunity appears to be more important; it develops 4 weeks after the illness and persists for several months, eventually decreasing with advancing age.[16] Passively acquired mucosal immunity by breast-feeding or orally administered immune globulins has conferred protection to high-risk individuals. Cell-mediated immunity also seems to be important. In mice, RV-specific cytotoxic T cells appear in the intestinal mucosa soon after infection, and mice with severe combined immunodeficiency are able to clear RV infection when reconstituted with CD8T cells, despite their lack of antibodies against the virus.[17]

PREVENTION

Breast-feeding reduces the overall incidence of diarrhea, especially in developing countries. However, its role in the prevention of RV diarrhea has been questioned. Children who have RV diarrhea are as likely to have been breast-fed as those who have non-RV diarrhea. However, the severity and duration of illness might be decreased in breast-fed children.[18]

Strict adherence to enteric precautions and careful handwashing is important to reduce transmission of the virus. Fecal contamination of surfaces and objects occurs frequently in nurseries, pediatric and geriatric wards and day care centers, and, as RVs can survive in the environment for weeks, they should be thoroughly disinfected. Effective disinfectants are 6% hydrogen peroxide, 2500ppm chlorine, 80% ethanol, ethanophenolic disinfectants, ultraviolet radiation and heat; drying and phenolic disinfectants are not effective;[13] hypochlorites are inactivated by fecal organic matter. Nondisposable containers are better cleaned by washing at 176°F (80°C) for at least 1 minute.

The search for an efficacious and safe RV vaccine started 20 years ago and still continues. Multiple vaccine candidates from animal (e.g. bovine, simian) and human (e.g. nursery strains, cold adapted) strains, as well as animal-human reassortants (rhesus-human, bovine-human) have been evaluated in both developed and developing countries with variable results (Table 211.7). The first — and so far only — licensed RV vaccine was RRV-TV. This was a rhesus-human reassortant vaccine containing a mixture of strains with specificities for the four common human RV G serotypes (i.e. G1–G4). Three doses of 4×10^5 PFU of RRV-TV given orally at 2, 4 and 6 months of age showed a protective efficacy of 49% for all RV diarrhea and 80% for severe RV diarrhea, decreasing the need for physician intervention by 73% and basically eliminating all cases of RV dehydration.[19] With these results RRV-TV was licensed for use in the USA in 1998 and was incorporated in the routine immunization schedule. Unfortunately, less than 1 year later the US Centers for Disease Control and Prevention (CDC) suspended the use of this vaccine because of its association with intussusception. Intussusception is a form of intestinal obstruction that normally occurs in 1/2000 children; the risk attributable to the vaccine was estimated as one additional

TABLE 211-7 -- Candidate rotavirus vaccines tested in children.

CANDIDATE ROTAVIRUS VACCINES		
Source	**Strain**	**Specificity**

Bovine-human	WC3-QV	G1–G4 P1

case/10,000 infants vaccinated, and was most pronounced during the week following administration of the first dose of vaccine.[20] The mechanism by which RRV-TV caused intussusception is unknown at this point. New candidate reassortant vaccines using other parent strains (e.g. bovine) are currently undergoing clinical testing. In addition, nonreplicating RV vaccines have been developed using whole virions, empty capsids, vector-expressed recombinant proteins and cell culture-derived or synthetic peptides. However, the immunogenically important antigens to be included in these products have not yet been defined. Passive immunization and inhibitors of viral replication are also under study.

DIAGNOSTIC MICROBIOLOGY

Antigen detection kits based on enzyme immunoassays (EIAs) and the latex agglutination test are commercially available. They are relatively inexpensive and permit a rapid diagnosis with high sensitivity and specificity (70–100%). Newborns and breast-feeding children might have higher false-positive rates. Samples should be obtained during the symptomatic period to optimize the performance of the test. If samples are not to be processed immediately, they can be stored at 39.2°F (4°C) or frozen. Rotavirus can also be identified by its characteristic appearance on EM; this is especially useful for strains other than group A. The technique is very specific, but it is available only in centers with substantial resources.

Characteristic migration patterns of the RV genome can be detected by PAGE, with good sensitivity (>90%) and specificity (100%). Other diagnostic methods include hybridization of radiolabeled nucleic acid probes to the viral RNA and amplification by PCR. Both are more sensitive than the antigen detection techniques and at least equally specific. Rotavirus can also be cultured in some research centers.

Clinical manifestations

The clinical spectrum of RV infections ranges from asymptomatic to severe disease with dehydration and death. The incubation period is usually less than 48 hours (range 1–7 days). The clinical picture of children attending health care facilities includes:

- vomiting (60–70%), which occurs early in the illness, often as the initial symptom;
- watery diarrhea (96%) without blood or mucus, usually 3–8 stools per day, mean duration 3–4 (up to 10) days;
- fever (60–65%) usually moderate (101.3–103.1°F; 38.5–39.5°C) but can be higher if associated with significant dehydration; and
- abdominal pain.

The disease is self-limiting; the usual total duration is 6–7 days. In severe cases death may occur through dehydration and electrolyte imbalance.[4] [6] [12] Repeated or sequential infections by the same or different serotypes have been documented. Chronic infection has not been described in the normal host.[7] Neonatal RV infections are infrequent, symptomatic in less than 10–20% of cases, and usually mild; severe infections may occur among premature infants and in special care units.

MANAGEMENT

In the management of RV infections, attention should be focused on the prevention or treatment of dehydration, for which ORS should suffice in most cases. A small percentage of patients will present with severe dehydration in shock or coma, and will need intravenous rehydration. Oral immune globulin and colostrum or human milk containing RV antibodies have been used in the treatment of RV diarrhea with good results. The anti-RV titer is low in human preparations, but higher in colostrum from cows immunized against RV. This form of therapy might prove useful for immunocompromised patients and for those with chronic or severe disease. Also, formulas supplemented with *Bifidobacterium bifidum* and *Streptococcus thermophilus* reduce the incidence of diarrhea and RV shedding in infected children.[21] Interference with the overgrowth of bacteria and promotion of the intestinal immune response to RV have been suggested as the possible mechanisms.

CALICIVIRUSES (NOROVIRUS AND SAPOVIRUS)

When visualized in 1972 by Kapikian *et al.* [22] in specimens from an outbreak of diarrhea that occurred in 1968 in a public elementary school in Norwalk, Ohio, USA, caliciviruses became the first viral agents implicated in human gastroenteritis. After a slow start, recent improvements in detection systems have shown that caliciviruses are the most common agents of outbreaks of gastroenteritis.

NATURE

Caliciviruses are round, approximately 27–40nm diameter viruses, with a positive-sense ssRNA. Initially designated by the location where they were first identified (e.g. Norwalk, Sapporo, Snow Mountain, Hawaii), recent cloning of the Norwalk virus (NV) and other representative strains has allowed development of sensitive molecular diagnostics and improved our understanding of this family. Caliciviruses are members of the family Caliciviridae and, based on genomic organization, the human enteric caliciviruses are now placed into two genera:

- the Norovirus with its type species NV; and
- the Sapovirus with its type species Sapporo virus (SV).[23]

Viruses previously designated SRSVs are mostly assigned to the Noroviruses, and 'classic' human calicivirus falls into both the Noroviruses and the Sapoviruses. The NLVs are furtherly divided into two genogroups (I and II).

It is now apparent that there is great genetic diversity among caliciviruses. The Noroviruses (Fig. 211.3) are 27nm in diameter with a somewhat indistinct, rough outer edge. The Sapoviruses (Fig. 211.4) are about 35nm in diameter, and their virion surface is characterized by 32 cup-shaped (chalice-like) indentations or hollows that may give the appearance of a six-pointed star ('Star of David'). Caliciviruses are unusual among human viruses in that the virions are composed of a single major capsid protein, with a molecular weight of approximately 58–62kDa. Preliminary work suggests that the capsid protein has six distinct regions, which are the determinants of structural and antigenic domains.[5]

EPIDEMIOLOGY

During the 1970s and 1980s limited knowledge of the epidemiology of calicivirus infection emerged when EM, IEM and first generation EIAs were applied to the study of outbreaks of gastroenteritis and experimental infection of volunteers. Nowadays this knowledge is quickly expanding with the introduction of EIAs based on recombinant virus-like particles (VLPs) and the use of RT-PCR.[24] While studies in the 1980s could identify caliciviruses in only 19% of outbreaks in the USA, more recent evaluation of cases of nonbacterial gastroenteritis occurring in the 1990s have identified Noroviruses in 86 (95%) of 90 outbreaks.[25] Caliciviruses are now considered the most common cause of nonbacterial gastroenteritis outbreaks.

The epidemiology and clinical picture of Noroviruses and Sapoviruses are different. Even though there are year-to-year and geographic variations, in general Noroviruses are more frequent than Sapoviruses. Sapporo virus was identified in Sapporo, Japan, as the cause of an outbreak of gastroenteritis in a home for infants. [26] Since, Sapoviruses have been described mainly in young children (e.g. in day care centers and pediatric hospital wards) and less often they have been found in outbreaks affecting adults. The Noroviruses on the other hand infect patients of all ages. The original Norwalk epidemic affected an elementary school with 50% of teachers and students developing gastroenteritis and a secondary attack rate of 32% among household members. Application of newer molecular diagnostics have indicated that besides adults, as previously recognized, children are also frequently affected by Noroviruses. For example, Pang *et al.*[27] found that Noroviruses were implicated in 20% of cases (second only to RV) of non-outbreak, community-acquired gastroenteritis in children in Finland (Sapoviruses were found in 9% of the specimens). Noroviruses outbreaks occur all year round, but recent data suggest a winter peak.

Early outbreaks of Norovirus gastroenteritis were traced to fecally contaminated food or water. Settings where outbreaks have occurred include nursing homes (43%), restaurants (26%), schools (11%) and vacation settings (11%). A mode of transmission was sought in 51 outbreaks, and of these, food was implicated in 37%, person-to-person contact in 20%, consumption of oysters in 10% and water in 6%.[25] Classic caliciviruses (mainly Sapoviruses) were found responsible for 3% of diarrhea episodes in a day care center. Children or the elderly are usually implicated in these outbreaks, rarely adult carers. Some outbreaks have lasted for several weeks. The attack rates during the outbreaks have ranged from 50 to 70%, with frequent asymptomatic infection. Nosocomial outbreaks have been documented in an infant-mother unit and a pediatric hospital. Travelers are at risk for acquiring caliciviruses, although this topic has been rarely evaluated. During the Gulf War, gastroenteritis was the most common illness of soldiers, and 70% of these cases were attributable to Noroviruses.[28] Both Noroviruses and Sapoviruses have worldwide distribution.

PATHOGENICITY

Caliciviruses are ubiquitous and stable in the environment, providing a persistent source of infection. The NV is stable in water chlorinated to 10mg/l (most municipal water systems contain <5mg/l chlorine) and survive freezing and heating to 140°F (60°C), permitting spread in recreational and drinking water and contaminated oysters that have been steamed. The virus is ether-stable, acid-resistant and relatively heat-stable.[22] Asymptomatic shedding of Noroviruses can persist for over 1 week. Food handlers may be an important source of infection. Air-borne transmission by droplets of vomit or through the movement of contaminated laundry has also been suspected. Caliciviruses recently identified in swine and cattle were found to be genetically related to the human caliciviruses, which raises the possibility of animal-to-human transmission.[24]

Very few viruses (<100) are needed for infection; therefore transmission by droplets, person-to-person contact or environmental contamination can occur. Secondary spread to close contacts is frequent. Individuals with O blood group might be more easily infected with NV, while those with B blood group might have decreased risk. Infection is spread by the fecal-oral route either directly or indirectly. Caliciviruses demonstrate great antigenic and genetic diversity providing little cross-protection, so people can be serially infected with various strains. Volunteer studies have established that infection with caliciviruses confers excellent short-term homologous protection. However, the existence of long-term protection is still to be elucidated. Studies of the immunity to caliciviruses is evolving. Serosurveys indicate that levels of antibodies specific for the NV are low during childhood, but rise rapidly during adolescence, reaching 50% by middle age. In developing countries, antibodies are acquired at an earlier age and peak incidence of illness may also occur among younger age groups than in developed nations.[29] Norovirus antibodies peak by the third

week after infection and remain elevated until approximately the sixth week, after which they decline.

Seroprevalence studies of strains now classified as Sapoviruses indicate that antibodies are acquired during early childhood. The peak acquisition occurs between 3 months and 6 years. In London, UK a serosurvey showed that over 70% of children had evidence of infection by the age of 2 years.[30] Mothers of infected infants were rarely affected, suggesting that young adults retain immunity to classic caliciviruses, although the outbreaks among the elderly suggest that immunity may wane with age.

During gastroenteritis caused by the NV the proximal small intestine is affected preferentially, with increased epithelial cell mitoses, villus shortening, crypt hypertrophy, mucosal inflammation (mononuclear cells) and malabsorption of D-xylose, lactose and fat. Adenylate cyclase levels in jejunal mucosa are not elevated (as

occurs in cholera) and fecal leukocytes are not excreted. The gastric secretion of hydrochloric acid, pepsin and intrinsic factor are unaltered, but gastric emptying is markedly delayed, which probably explains the frequent occurrence of nausea and vomiting. These findings persist for at least 4 days after clinical symptoms clear and revert to normal within 2 weeks.

PREVENTION

Handwashing, cleaning of environmental surfaces, thorough cooking of food items, boiling or disinfection of water and furlough for 2 days after resolution of symptoms of ill food handlers should prevent most calicivirus-associated outbreaks. During outbreaks, food, water (including ice) or symptomatic food handlers should be suspected as possible sources. Vigorous handwashing with soap, decontamination of surfaces, use of barriers and disposal of linen contaminated with diarrhea or vomiting should be emphasized. When a water supply is thought to be contaminated, shock chlorine concentrations (>10mg/l for 30 minutes or longer) may be helpful.[12] Vaccines against the NV using recombinant VLPs are under development.[31]

DIAGNOSTIC MICROBIOLOGY

Electron microscopy, especially IEM, were the initial means to identify caliciviruses, and they are still useful in the investigation of outbreaks. The cloning and characterization of the genome of the NV and expression of the capsid antigen in baculovirus (a virus infecting insect cells that is easier to replicate) has provided adequate and abundant reagents suitable for EIAs.[30] Since caliciviruses demonstrate great antigenic and genetic diversity, diagnostic tests need to be able to detect the range of many different virus types. EIAs are suitable for the detection of antibody in serum and antigen in stool both with good sensitivity and specificity.[32] The antibody detecting EIAs appear to be more broadly reactive; IgM and IgA detection systems are under development. As one-half of adults in the USA have pre-existing antibodies to the virus, a single specimen is insufficient to document recent infection. But, if at least one-half of affected persons in an outbreak have a fourfold rise in their antibody titers, a calicivirus can be implicated as the causative agent.[12] More recently, nucleotide primers have been developed suitable for RT-PCR to detect caliciviruses in clinical and environmental samples. Caliciviruses still can not be grown in cell culture. Despite recent advances, further work is sorely needed because current diagnostic methods are not well suited for routine clinical use.

CLINICAL MANIFESTATIONS

Norovirus gastroenteritis usually has an abrupt onset, with explosive watery diarrhea, vomiting and abdominal cramps. In the original Norwalk outbreak diarrhea occurred in 44% of cases and vomiting in 84%. These symptoms are experienced by all age groups, but diarrhea is more prevalent among adults, whereas children experience vomiting more frequently. The incubation period is 24–48 hours, and the mean duration of illness is 12–60 hours. Between 25 and 50% of affected persons also report headache, fever, chills and myalgias. Dehydration and constitutional symptoms can be seen, particularly in the elderly.[12] Of the 93 infants affected in the Sapporo outbreak, 83% had gastrointestinal symptoms, including diarrhea (95%), vomiting (44%) and fever (18%).[26] Infection with the SV is common beginning in infancy and increasing during early childhood.[33] It mimics mild rotaviral illness. The incubation period is 1–3 days, with illness lasting an average of 4 (range 1–11) days. Diarrhea (88%) and vomiting (65%) occur frequently; fever (34%) and upper respiratory symptoms (22%) are less common. In general, Sapoviruses are less common than Noroviruses, seen at younger age and cause milder symptomatology.

MANAGEMENT

No specific therapy is available for calicivirus gastroenteritis. Attention must be paid to fluid and electrolyte balance. The main focus is on the management of dehydration, which can usually be accomplished with oral rehydration.

ENTERIC ADENOVIRUSES

Described in 1975,[34] the role of enteric adenoviruses was difficult to elucidate because of the frequent and prolonged asymptomatic fecal shedding of traditional adenoviruses after respiratory infections. Current techniques distinguish the enteric adenoviruses and have identified them as important etiologic agents of viral diarrhea in both the developed and developing world in hospitalized infants and young children.

NATURE

Human adenoviruses are nonenveloped, dsDNA viruses of the family Adenoviridae (Fig. 211.5). Their size is 70–75nm, with ten structural proteins (5–120kDa). The capsid proteins are arranged as an icosahedron with 20 triangular faces and 12 vertices. Each virion contains 240 hexons and 12 pentons; each penton consists of a base and a fiber. The genus-specific antigen is located in the hexon, but because it resides in the internal part of the capsid it does not elicit protective antibodies. Type-specific antigens are located on the hexon and the fiber; being exposed on the surface of the virion, they give rise to serum-neutralizing antibodies. The fiber is a strong hemagglutinin and elicits inhibition antibodies.[35] Hemagglutination properties allow classification of adenoviruses into six subgroups: A–F. The enteric adenoviruses belong to group F and comprise mainly serotypes 40, 41 and 31. A few other serotypes (e.g. 1, 2, 3, 5, 7 and 12) have also been implicated in gastroenteritis but because they are less frequent their role is less well defined.

EPIDEMIOLOGY

Adenoviruses are identified in 4% of outpatient acute diarrheal episodes and 2–22% of those in hospitalized children.[36] Also, 1–2% of asymptomatic controls shed the virus. Outbreaks have been documented in hospitals and day care centers. In Houston, USA, adenoviruses caused ten of 131 (8%) day care center outbreaks; during the outbreaks an average of 38% of children were infected, one-half of them asymptomatically; the outbreaks lasted 7–44 (mean 24) days,[37] and secondary spread was frequent. Enteric adenovirus infections occur more frequently among children under 2 years of age (median age 12 and 19 months for type 40 and 41, respectively) but

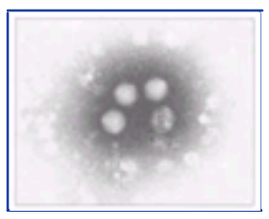

Figure 211-5 Enteric adenovirus. Electron micrograph. *Courtesy of S Spangenberger.*

older children and adults may occasionally be infected. Enteric adenoviruses types 40 and 41 circulate simultaneously and all year long with no obvious seasonality; a slight increase, especially in type 41 cases, might be seen in warmer months.

PATHOGENICITY

The mode of transmission is probably fecal-oral with spread from person to person. Food and water have not been reported as vehicles. The excretion of enteric adenoviruses in stools lasts 10–14 days, on average from 2 days before to 5 days after diarrhea stops. Asymptomatic shedding occurs frequently, but infectivity parallels symptomatic disease. Infection elicits serum-neutralizing and hemagglutination-inhibiting antibodies. Long-term immunity is thought to be acquired during childhood infection.

PREVENTION

Environmental control is important for outbreak control but has little effect on endemic transmission. Enteric adenoviruses survive temporarily in porous and nonporous environmental surfaces, but less efficiently than RVs or hepatitis A virus.[13] Infectious viruses are rapidly inactivated at 132.8°F (56°C) and by exposure to ultraviolet radiation or formalin. No vaccine is under development.

DIAGNOSTIC MICROBIOLOGY

Antigen-detection techniques using adenovirus 40 and 41 type-specific or adenovirus group monoclonal antibodies are commercially available and constitute the most convenient mode of diagnosis. They are relatively inexpensive, technically simple and quick, with a sensitivity and specificity of 98% compared with EM. Some virus variants, however, might not be detected by the assay. Its use should be restricted to diarrheal illnesses of likely viral etiology in the preschool age group or younger, because it has not been validated for other groups. A latex agglutination assay is also available with improved simplicity and speed. Electron microscopy does not discriminate between enteric and respiratory serotypes. Adenoviruses can be cultured, but the enteric serotypes are fastidious and require special cell lines, such as Graham 293 transformed lung fibroblasts or Chang conjunctival cells. The characteristic cytopathic effect generally occurs within 3–7 days but might require up to 28 days. Viral culture is not well suited for routine clinical diagnosis. PCR techniques have been developed for the identification of enteric adenoviruses in stool specimens. [38]

CLINICAL MANIFESTATIONS

Gastroenteritis caused by enteric adenoviruses is similar to that caused by RVs, but less severe and of a more prolonged course. The incubation period is 3–10 days (longer than the 1–3 days seen with other viruses) and illness typically lasts 5–12 days. Diarrhea, usually watery, is the main manifestation, occurring in 97% of patients and with a mean duration of 9 (type 40) to 12 (type 41) days. Prolonged diarrhea (>14 days) occurs in one-third of children and vomiting in 79% (lasting 1–2 days); low-grade fever and respiratory symptoms are occasionally seen. Dehydration is less frequent than with RV infection. An association with intussusception has been proposed but not proved.[39]

MANAGEMENT

No specific therapy is indicated for gastroenteritis caused by adenoviruses. Dehydration is rare and usually mild, so most episodes can be managed with oral rehydration.

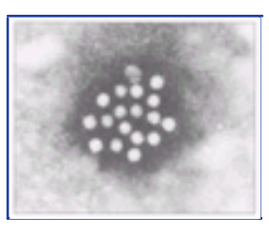

Figure 211-6 Astrovirus. Electron micrograph. *Courtesy of S Spangenberger.*

ASTROVIRUSES

Although astroviruses were well known to cause diarrhea in animals, these agents were not implicated in human gastroenteritis until 1975 when small round viruses were observed by EM in stool samples of hospitalized infants.[40] Astroviruses are now recognized as an important cause of mild gastroenteritis in young children.

NATURE

Astroviruses belong to the family Astroviridae, and are 27–32nm, nonenveloped, single-stranded (ss) RNA viruses (Fig. 211.6). They have smooth edges and characteristically a five- or six-pointed star in the center. Their surface is unbroken and rounded, unlike that of the caliciviruses, which is broken by hollows. Their three structural proteins (31–34kDa, 29–31kDa and 20–24kDa) and their distinctive morphologic and immunologic features distinguish them from caliciviruses.[5] [36] The complete sequence of a strain of human astrovirus serotype 1 has been described.

EPIDEMIOLOGY

Astrovirus infections occur mainly among children aged under 7 years, although adults can be infected and suffer mild disease. Community-based studies show a prevalence of 7–8%, and a 2% excretion rate in asymptomatic individuals. Among children hospitalized who have diarrhea, astroviruses account for 3–5% of cases. Outbreaks have been described in day care centers, hospitals, nursing homes and military facilities. Astroviruses were responsible for 7% of diarrhea outbreaks at a day care center, with about one-half of the infections being asymptomatic. The attack rate during outbreaks is about 50%, and secondary transmission to families occurs in one-third of the cases. Nosocomial outbreaks usually involve children aged under 2 years, with attack rates between 7 and 62%.[41] [42] The largest outbreak of astrovirus infection yet recorded occurred in Japan in 1991, affecting more than 4700 students and teachers in ten primary and four junior high schools; it lasted 5 days and was linked to contaminated food.[43] Sporadic and outbreak astrovirus infections are more prevalent during late fall, winter and early spring in temperate climates; in tropical climates it might be more common during the rainy season.

PATHOGENICITY

Eight human astrovirus serotypes have been identified; serotype 1 strains are the most frequent. The characteristics of immunity to astroviruses are unknown. As reported outbreaks have involved only children and the elderly, young adults may have resistance to infection. By the age of 10 years, 75% of UK children have specific antibodies, and pooled gammaglobulin preparations in the USA, prepared from adult donors, frequently contain antibodies to

astroviruses.[44] In Virginia, USA, 94 and 42% of 6–9-year-old children showed serum antibodies against astrovirus serotype 1 and 3, respectively.[45]

PREVENTION

To prevent or control outbreaks, handwashing is important, especially among food handlers and in day care centers because astroviruses may be shed asymptomatically. Adequate cooking of shellfish should prevent food-borne outbreaks; the virus is inactivated by heating to over 140°F (60°C) for at least 10 minutes. Methanol 70–90% can be used to disinfect surfaces; however, astroviruses are resistant to chloroform or alcohol.[41] No vaccine is available.

DIAGNOSTIC MICROBIOLOGY

Because astrovirus infections are usually mild and self-limiting, the diagnostic methods are not available for routine clinical diagnosis but primarily for epidemiologic studies. Electron microscopy was the only diagnostic tool until EIAs were developed using group-reactive monoclonal antibodies that detect all astroviral serotypes in stools; the sensitivity and specificity (compared with IEM) have been 91 and 96%, respectively.[42] Astroviruses can be grown in human embryonic kidney (HEK), LLC-monkey (Rhesus) kidney cells 2 (LLC-MK2) in the presence of trypsin, and other cells.[5] These systems are not well suited for routine clinical diagnosis, though. Recently, shell vial assays and latex agglutination tests have been developed, which should facilitate diagnosis. RT-PCR has been described to detect all astrovirus serotypes and seems more sensitive than EIA.[44]

CLINICAL MANIFESTATIONS

The clinical manifestations of astrovirus infection are similar to those of RV illness, but less severe. The incubation period is 3–4 days and illness lasts 1–5 days. Mild watery diarrhea is the most common symptom. Less frequent symptoms are fever (20%), vomiting (10%), dehydration (6%) and abdominal pain. Dehydration can be more prominent in children co-infected with bacterial or viral pathogens, and in immunosuppressed (including those who have HIV infection) or malnourished patients. Astroviruses have been associated with hepatitis in animals but not in humans.

MANAGEMENT

No specific therapy is indicated for gastroenteritis caused by astroviruses. Dehydration is rare and usually mild, so it can be treated with oral rehydration. In one case of protracted astrovirus diarrhea in an immunocompromised patient, the use of intravenous immune globulin was beneficial.[46]

OTHER VIRUSES

Torovirus and coronavirus are enveloped viruses, 100–150nm in diameter, with helical symmetry that belong to the family Coronaviridae. Since they do not grow reliably in cell culture, their identification is mostly limited to EM.[5] PCR techniques might hold promise.[47] Toroviruses have been associated with nosocomial out-breaks and have been implicated as the cause of acute and persistent diarrhea in children.[48] [49] Pestiviruses are ssRNA viruses classified as members of the Togaviridae family. They are well-known enteric pathogens of cattle and pigs, pleomorphic and difficult to identify by EM. In a study pestivirus antigen was detected by EIA in the stools of 23% of Arizona Indian children under 2 years of age with gastroenteritis of unknown etiology, compared with 3% of controls. Illness was relatively mild, duration was 3 days and respiratory symptoms were common.[50] Other viruses collectively referred to as small round viruses (such as the Aichi strain and others),[51] parvovirus and picobirnavirus have been identified in children who have gastroenteritis but also from controls so their role as agents of gastroenteritis is not well defined.

Chapter 212 - Measles, Mumps and Rubella Viruses

Peter Morgan-Capner

INTRODUCTION

The skin and mucous membranes are affected in the course of many infections, bacterial and viral. The viral exanthemata occur largely in childhood, but are not uncommon in adults. The rashes are maculopapular or vesicular, the latter being clinically characteristic of hand, foot and mouth disease and varicella; smallpox has been eradicated, although sporadic outbreaks of monkeypox still occur.[1]

The erythematous rashes present major problems of differential diagnosis.[2] [3] Although there are usually associated clinical features that may be characteristic, there may be considerable overlap, such as with arthralgia in rubella and parvovirus B19, and conjunctivitis in measles and rubella. As some infections such as rubella and measles become increasingly uncommon as a result of successful immunization programs, clinicians become less familiar with their presentations and may not include them in their differential diagnosis.

Other virus infections, such as Epstein-Barr virus infection, which causes infectious mononucleosis, can give generalized rashes, as can bacterial infections such as scarlet fever associated with *Streptococcus pyogenes*, disseminated meningococcal infection and toxic shock syndrome caused by toxin-producing *Staphylococcus aureus*. In some geographic areas, a number of other viruses may present problems of differential diagnosis, such as dengue[4] and other arboviruses.

A further virus infection characteristic of childhood is mumps, although infection in young adults is not uncommon. In adolescents and adults infection may be complicated by involvement of a range of other organs such as testes, ovaries and pancreas; meningitis and encephalitis can be a complication at any age. A wide range of differential diagnoses exists, depending on the symptomatology; some of these may not be infective in origin. As for rubella and measles, infection has been well controlled in some countries by widespread use of live attenuated vaccine.

MEASLES

NATURE

Measles (rubeola) has been identified for about 2000 years, although its infectious nature was not recognized until the mid 19th century when epidemics in island communities were described. It is one of the infectious diseases targeted by the World Health Organization (WHO) for eradication because an effective and safe vaccine is available, natural infection is limited to humans, there is considerable morbidity and mortality, subclinical infection is uncommon and persistent infection is rare.

Measles virus is a member of the *Morbillivirus* genus of the Paramyxoviridae and was first isolated in cell culture in 1954; the first live attenuated vaccine became available in 1963. It is pleomorphic, with a diameter of 150nm or more. Single-stranded RNA is enclosed in a capsid of helical symmetry of 18nm. This is enclosed within an envelope, the surface of which carries the hemagglutinin and fusion proteins. Replication is mainly cytoplasmic, but there is some nuclear involvement. Although there is only one major antigenic type, there has been some genetic drift in the hemagglutinin,[5] and genome analysis can distinguish geographically distinct isolates.[6] These variations are insufficient to escape protection from immunization with current vaccines.

EPIDEMIOLOGY

Measles is endemic worldwide except in those countries in which complete control has been achieved by immunization (Fig. 212.1). Infection in childhood before the impact of immunization was almost 100%, confirming measles as the most infectious of microbial agents. Epidemics occur every 2–3 years, but are less defined in the tropics.

The epidemiology of measles has been profoundly modified by immunization strategies, which have targeted developing nations as well as the industrialized world, with worldwide eradication by 2010 being the aim of the WHO Expanded Programme on Immunization.[7] It is estimated that 1 million or so children die every year from measles, particularly in the developing world. Success has been achieved in parts of the world, however, including South America, the USA and the UK.[8]

High, but not complete, rates of measles vaccination in infancy, without achieving eradication, can lead to a change in epidemiology. Those who are not immunized or are still susceptible after immunization are not exposed to the virus during early childhood, but their continued susceptibility can lead to outbreaks in older children or young adults, as has occurred in both the USA and the UK.[8] [9] These outbreaks, which occur at an age when complications are more frequent, have necessitated mass immunization campaigns and/or the introduction of a second dose of measles vaccine at an older age.

PATHOGENICITY

Infection is spread by droplet from person to person. The incubation period to onset of rash is about 14 days, with prodromal symptoms starting 1–3 days earlier. The maximum infectivity is during the prodrome, although patients are considered to be infective from 4 days before to 4 days after onset of the rash.

After infection, initial replication occurs in the respiratory epithelium with local spread by lymphatics and a primary viremia 2–3 days after infection. A secondary viremia occurs 3–4 days later and lasts for up to 7 days. The peak viremia coincides with the prodromal symptoms. The rash results from the immunologic reaction between the virus antigens and host antibody, with involvement of capillary walls. Intrauterine infection has not been convincingly reported.

PREVENTION

Live attenuated measles vaccine became available in 1963 based on the Edmonston strain, but those in current use such as Schwarz and Moraten strains are further attenuated. Measles vaccine is available in monovalent form, but also combined with mumps and rubella

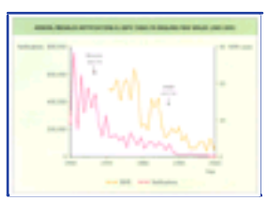

Figure 212-1 Annual measles notifications and subacute sclerosing panencephalitis (SSPE) cases in England and Wales between 1960 and 2000. The number of cases declined from the late 1960s, and there was a further decline after the introduction of MMR vaccine in 1988. *Data from the Office for National Statistics and CDSC.*

vaccine (MMR). The highest efficacy rate, over 90% protection, is achieved by giving vaccine at 12–15 months of age. Earlier administration can result in lower protection because of interference by residual maternal antibody. This is especially problematic for developing countries, where many cases of measles occur in infants under 12 months of age. Attempts to improve efficacy rates at lower ages by using high titer measles vaccines have led to an unexplained and nonspecific mortality at an older age, mainly in girls, and has led to their use being discontinued.[10] Because of a small cohort who miss first immunization, and to boost protection in those with low concentrations of antibody, many countries have introduced a second dose of vaccine at age 4–5 years.

In the patient with HIV infection who is immunocompetent, serious complications from measles vaccine are rare, although seroconversion in individuals who have HIV infection is less likely.[11] Localized pain and tenderness, mild fever (about 10%) and transient rashes (about 5%) may occur, but soon resolve. Encephalitis may occur in one in a million doses, but its causal relationship with the vaccine is uncertain. Measles vaccine is contraindicated in pregnancy because of the theoretic risk from a live vaccine, but is definitely contraindicated in those with impaired cell-mediated immunity because measles-specific complications can occur. Subacute sclerosing panencephalitis (SSPE) occurs in one dose per three million or fewer. Recently, anxieties have been expressed as to whether MMR immunization may lead to inflammatory bowel disease and autism, but the evidence is inconsistent and a direct relationship seems unlikely.[12] [13]

DIAGNOSTIC MICROBIOLOGY

Virus isolation may be attempted from throat swabs, conjunctival swabs, nasopharyngeal aspirates (NPAs) and sedimented cells from urine, but is technically demanding and unreliable. Cell lines susceptible to measles for primary isolation include primary human embryo and monkey kidney, but the cytopathic effect after inoculation is not immediately apparent because multinucleated giant cells can take up to 15 days to develop. Measles virus can also be detected by hemadsorption (monkey, human or guinea-pig red blood cells) and isolation can be confirmed by specific neutralization of the hemadsorption or by immunofluoresence.

Immunofluorescent antigen detection in NPA cells may be performed, and is particularly useful for diagnosing atypical cases or infection in the immunocompromised host. Measles genome may also be detected in cells obtained by throat swab or NPA, and this approach may also be used for determining the geographic origin of the infecting strain.[6]

Serologic diagnosis is dependent on demonstrating seroconversion, rising antibody titer, or detecting specific IgM. Hemagglutination inhibition and complement fixation testing (CFT) have been the established methods; the former detects both specific IgG and specific IgM, but these methods are now largely being replaced by immunoglobulin-specific enzyme immunoassays (EIAs). Measles hemagglutinating antigen and monkey red cells for hemagglutination inhibition have become difficult to obtain, and CFT can give elevated titers that do not indicate recent measles.

Serum should be obtained as soon as possible after onset of rash and, depending on results with this serum, further serum should be collected 10 days later. Specific IgM starts becoming undetectable about 4 weeks after onset. Diagnosis of recent measles can also be achieved by detecting specific IgG and IgM in saliva by antibody

capture techniques.[14]

Subacute sclerosing panencephalitis may be diagnosed by detection of genome or isolation of virus by co-cultivation from brain tissue. A more usual approach, however, is the detection of elevated concentrations of measles antibody in serum and concentrations indicating intrathecal synthesis in cerebrospinal fluid (CSF) by CFT; other serologic approaches may not be reliable or have not been validated for diagnosing SSPE.

For determining past measles infection, the method of choice is plaque reduction neutralization (PRN) assay, but hemagglutination inhibition and specific IgG EIA can also be used. Using PRN, a preexposure titer of >120 is associated with protection against clinically apparent measles.[15]

CLINICAL MANIFESTATIONS

Toward the end of the incubation period the prodromal symptoms of fever and malaise appear and persist for up to 4 days before the rash. Pyrexia may rise to 103–104°F (39.4–40°C) and is often

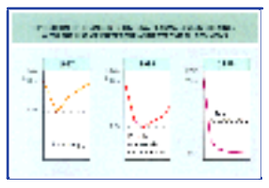

Figure 212-2 Measles. A disseminated erythematous rash can be seen over the trunk and arms.

TABLE 212-1 -- Complications of measles (% of cases).

COMPLICATIONS OF MEASLES				
Age	**USA**			**UK**
	<5 years	**5–19 years**	**>20 years**	**All ages**
Otitis media	14	2	2	5
Pneumonia	9	2	7	4
Encephalitis	0.2	0.1	0.3	0.1
Death	0.3	0.2	0.3	0.25
Hospitalization	25	8	24	1
USA data are broken down into three age groups, whereas UK data are not; however, UK data primarily reflect infection in early childhood. [16] [17]				

accompanied by conjunctivitis, cough and coryza. Koplik's spots are a pathognomonic feature of measles, and can be seen for up to 2 days before rash onset as punctate white spots on an erythematous background on the buccal mucosa.

The rash usually begins on the face and neck, and then evolves to the body and limbs (Fig. 212.2). Although lesions are usually discrete, they can coalesce, and desquamation may occur. The rash usually persists for 5–6 days. Generalized lymphadenopathy and diarrhea are common.

Complications are many, and are most common in younger and older patients (Table 212.1), and those with underlying malnutrition, as in developing countries. In industrialized countries complications are primarily respiratory or neurologic. Pneumonia, either viral or, more usually, secondary bacterial, occurs in up to 4% of patients. Neurologic complications include convulsions, in up to 1% of cases, and encephalitis, which has been reported in 1/1000 cases. Encephalitis usually starts about 1 week after onset of rash, with fever, drowsiness, convulsions, meningeal irritation, vomiting and coma: death occurs in about 15% of patients, and residual neurologic deficit occurs in a further 25%. Overall, estimates of the mortality rate for measles are 1 per 1000 patients or fewer.

Subacute sclerosing panencephalitis manifests from months to years after the initial natural measles or measles immunization; the mean interval is 7 years after natural measles and 3.3 years after immunization. The risk is less after measles immunization (1:1 million) than after natural infection (1:100,000), and is three times more common in boys than in girls. Specific risk factors for the development of SSPE have not been identified. Subacute sclerosing panencephalitis manifests as a progressive intellectual impairment, which may not be noticed for many months, although it is usually apparent in retrospect, and moves to convulsions, motor abnormalities and coma; death is inevitable after a progressive downhill course over months or years.

The immunocompromised patient with T-cell deficiencies, such as those who have leukemia or HIV, is at particular risk. A typical rash is often missing, and infection persists, manifesting as a giant cell pneumonitis or rapidly progressive encephalitis; the fatality rate is high.[18]

Figure 212-3 Cancrum oris. Necrosis of the upper lip.

Measles in pregnancy seems to carry a higher risk of complications but has not been associated with congenital abnormalities, although there is an increased risk of intrauterine death or premature delivery.[19]

Measles presents special problems in developing countries, where case fatality rates of up to 25% have been described. The high mortality rate is associated with malnutrition and, in particular, vitamin A deficiency.[20] Death usually results from bacterial superinfection, such as pneumonia, or diarrheal illness, although cancrum oris, a progressive oral necrosis, is also seen (Fig. 212.3).

Measles may be attenuated by recent normal immunoglobulin, for instance given after exposure, in younger infants with residual maternal antibody, and in those who have previously received live attenuated vaccine but in whom immunity is incomplete.

Now only of historic interest is 'atypical measles', seen in those immunized in the mid 1960s with a killed measles vaccine and subsequently exposed to natural infection. Various rash appearances were seen, including allergic-type, petechial or vesicular, and these could be accompanied by pneumonia, myalgia, edema and fever.

MANAGEMENT

Postexposure prophylaxis with human normal immunoglobulin is indicated for those who are susceptible and who would be at risk from complications, in particular immunocompromised children and pregnant women. Indeed, one of the greatest benefits to be had from minimizing or eradicating measles in industrialized countries is the impact on immunocompromised children, in whom measles is a substantial risk.

In outbreak situations and in immunocompetent persons, measles vaccine prophylaxis can be considered because there is a rapid development of protection. Administration should be within 3 days of contact.

Uncomplicated measles is managed symptomatically, with vitamin A supplementation for malnourished children. Antimicrobial therapy active against *Streptococcus pneumoniae* and *Haemophilus influenzae* is indicated for presumed bacterial superinfection. In those with major complications, such as pneumonitis in the

immunocompromised, specific antiviral treatment with ribavirin may be of benefit;[21] such treatment is of no value in SSPE, however.

RUBELLA

NATURE

Although rubella had been recognized since the 18th century as a distinct clinical illness, it was not until 1941 that Sir Norman

Gregg, an Australian ophthalmologist, made the association between rubella in early pregnancy and congenital abnormalities.[22] In 1962 the causative virus was isolated, leading to techniques for specific diagnosis and the development of attenuated live vaccines.

Rubella is a single-stranded RNA virus, with an icosahedral nucleocapsid surrounded by an envelope. Replication occurs in the cytoplasm of infected cells. It is the sole member of the genus *Rubivirus* within the family Togaviridae. There are three major virus polypeptides: C, E_1 and E_2 . Polypeptide E_1 is present in the envelope and has hemagglutinating properties. Only one antigenic strain is recognized, and natural infection of species other than humans has not been shown.

EPIDEMIOLOGY

Rubella occurs worldwide, although its contribution to congenital disease in the developing world has not been well quantified.[23]

In countries without an effective infant vaccination policy or a policy that targets females only, rubella remains endemic, with outbreaks in spring and early summer. Epidemics occur every 7–10 years. Although not as infectious as measles, before or without immunization approximately 80–85% of young adults would have had rubella.

PATHOGENICITY

Infection is transmitted by the air-borne route, with patients being potentially infective for up to 1 week before and after onset of the rash. After replication in the upper respiratory tract and local lymph nodes a viremia infects target organs such as skin, joints and placenta. The clinical features in postnatal rubella, such as the rash and arthralgia, primarily result from the immune response to the virus, with virus being found not only in the rash lesions but in surrounding normal skin.

If the patient is pregnant, placental infection can occur; transmission to the fetus is possible but not inevitable.[24] If fetal infection occurs in the first 16 weeks of gestation, persistence of the virus is likely. Virus may still be detectable in congenitally infected infants up to a few years of age, and high concentrations may be excreted in urine or from the throat during the first year of life. The fetal damage may be a consequence of numerous mechanisms, including slowing of cell division, disordered cell differentiation, intimal damage

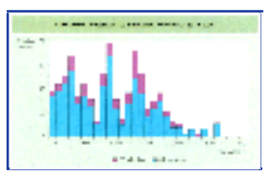

Figure 212-4 Cases of congenital rubella (CR) syndrome and infection in the UK. The number of confirmed cases was substantially reduced by the introduction of MMR vaccine in 1988. *Data from National Congenital Rubella Surveillance Programme and the PHLS Communicable Disease Surveillance Centre.*

of small blood vessels, and, at an older age, immunopathologic mechanisms.

PREVENTION

Passive prophylaxis with human normal immunoglobulin has not been proved to reduce the risk of rubella after contact or fetal infection, although it may attenuate the illness. Control of rubella has resided in using the live attenuated vaccines available since the early 1970s. The vaccine strain that has gained pre-eminence is RA27/3. It induces seroconversion in over 95% of susceptible vaccinees, and protection persists for at least 15–20 years. Vaccine virus can be isolated from the throat of vaccinees, but transmission to susceptible contacts has not been demonstrated. A mild, transient rubelliform rash illness can occur 2–3 weeks after immunization, including arthralgia, which may persist for some weeks and, rarely, some months. [25] If vaccine virus is administered to susceptible women in early pregnancy, fetal infection occurs in perhaps 1% of cases, but fetal damage has not been proved.[26] Although rubella vaccine is contraindicated in pregnancy, and conception should be avoided for 1 month after vaccine administration, if inadvertent administration in pregnancy should occur, the risk is insufficient to justify termination of pregnancy. Rubella immunization presents no significant risk to the individual who has HIV infection.

With rubella being a mild illness, control has focused on preventing infection in pregnant women. Two approaches have been used. First, as exemplified in the UK until 1988, rubella vaccine was targeted at adolescent girls and susceptible women, with rubella remaining endemic in children and men. Although cases of congenital rubella were markedly reduced, there were still 2–3% of women susceptible and at risk of rubella in pregnancy. The alternative approach, as used in the USA and in the UK from 1988, was to combine rubella vaccine with measles and mumps vaccines (MMR), and offer it to all children in the second year of life to eradicate rubella from the community. This policy was supported by identifying and immunizing susceptible women. If uptake rates of more than 90% can be obtained, control of endemic rubella is achievable (Fig. 212.4).

DIAGNOSTIC MICROBIOLOGY

With the clinical diagnosis of rubella being unreliable, laboratory confirmation is required, and is essential if a rash illness occurs in

pregnancy. In addition, in pregnancy it is imperative that contact with rash illness is investigated because subclinical rubella may occur, and this has been proved to be a risk to the fetus.[27] It is debatable whether such investigation of contacts should be pursued if there is a documented history of past detection of rubella antibody or vaccine, but vaccine is not 100% effective in inducing protection and, if there has been only one previous detection of rubella antibody, there is a remote possibility that a laboratory or labeling error could have occurred.

Rubella virus isolation has no role in diagnosing postnatal rubella because it is time-consuming, unreliable and expensive; diagnosis is serologic. The serologic response is detailed in Figure 212.5 ; tests for total rubella antibody (such as hemagglutination inhibition) have been progressively replaced with tests specific for IgG and IgM, particularly EIAs. Serum should be obtained as soon as possible after onset of illness or after contact. Detection of rubella-specific IgG, but failure to demonstrate specific IgM, indicates past primary rubella, or that the illness being investigated is not rubella, or the existence of immunity to primary rubella if it was a contact that was being investigated. If neither rubella-specific IgG nor specific IgM are detected, a later serum is needed. The incubation period after contact may be up to 21 days, and it may take up to 10 days after onset of illness for rubella antibody to be detectable. Hence in the susceptible person it will not be until about 4 weeks after contact that a subclinical illness can be excluded.

If rubella-specific IgM is detected, this is likely to indicate recent primary rubella, but care is needed in interpretation. Rubella-specific IgM reactivity persists for about 1–3 months, but may occur in a range of other infections, including those that would be differential diagnoses of rubella such as parvovirus B19 infection and Epstein-Barr virus infection (infectious mononucleosis). Rubella-specific IgM reactivity may also be nonspecific and may occur in rubella re-infection (see below). Other serologic approaches, such as determining specific IgG avidity, are of value in confirming primary rubella,[28] with specific IgG early after infection being less tightly

bound to antigen (low avidity) than the antibody found in the mature antibody response (high avidity; see Fig. 212.5).

Isolation of rubella virus in cell culture is of value in diagnosing congenital rubella because the infected infant is likely to be excreting high titers of virus in the throat and urine during the first year of life; congenitally infected infants can be highly infectious to susceptible

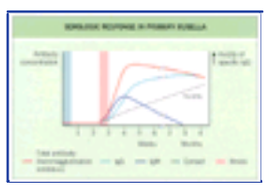

Figure 212-5 Serologic response in primary rubella. The development of specific IgG and IgM and the increasing avidity of specific IgG are illustrated.

contacts until 6 months or so of age. Rubella isolation can be performed in many cell culture lines, primary and continuous, but a cytopathic effect is only produced in a few lines, for example RK 13. Immunofluorescence is probably the best method for detecting virus growth. An alternative but less specific technique is interference, in which the cell culture is challenged with another virus such as echovirus, which will replicate with cytopathic effect in uninfected cultures but not in those in which rubella virus is growing.

The more usual approach to diagnosing congenital rubella is the detection of specific IgM; all congenitally infected infants are positive for the first 3 months of life, and most for the first 6 months.

Occasionally there may be problems with diagnosis or management of rubella in pregnancy and intrauterine diagnosis may be considered. Approaches used, but of limited availability, have included virus isolation and genome detection from amniotic fluid or trophoblast, and detection of specific IgM in fetal blood; this latter method is unreliable before 24 weeks' gestation, however, because the infected fetus may not be capable of an IgM response until that age.

In recent years assays have been developed that detect specific IgM in saliva. These assays are of limited availability, however, and although not sufficiently validated for use in pregnancy, they have been used successfully for clarifying the etiology of rashes in childhood because they are noninvasive and more acceptable for infant sampling.[14]

Irrespective of the success of population immunization and control of rubella in the community, the majority of developed countries have programs in place to identify susceptible women of childbearing age and offer immunization. Consequently, many women are screened for rubella IgG in various health care settings such as occupational health and during antenatal care. Tests for specific IgG are many and include EIAs and latex agglutination. An area of contention is the concentration of rubella-specific IgG taken to indicate protection (or, more correctly, as not necessitating immunization), with opinions varying from any confirmed antibody [possibly as low as 3–5 international units (IU)] up to 15IU; 10IU has been recommended in the USA.[29]

CLINICAL MANIFESTATIONS

In childhood, primary rubella is subclinical in perhaps 50% or more of patients, but in adolescence or older it is usually (90% or more) clinically apparent, although it may be more difficult to recognize in those with dark skin. After an incubation period of up to 21 days, usually 15–17 days, a pinkish-red maculopapular rash develops, usually starting on the face and neck but rapidly spreading over body and limbs (Fig. 212.6). Individual spots may coalesce but the rash usually clears in 3–4 days. Nonspecific symptoms, such as fever, malaise and upper respiratory tract symptoms, may precede and accompany the rash. In childhood the illness is benign and may have no systemic impact. Lymphadenopathy commonly occurs, the suboccipital nodes being frequently involved.

In adolescence and adulthood, rubella is often far more severe, not only because of complications but also because of a more severe systemic illness. Arthralgia is a frequent complication in adults, with women (30% or more) suffering more often than men. Joints frequently involved are those of the hands and wrists; resolution usually occurs in 2–4 weeks but can persist for some months or even years. Thrombocytopenia and postinfectious encephalitis are rare complications, occurring in fewer than 1/5–10,000 patients, with fatal outcome virtually unknown. Even in patients who have HIV infection and other immunocompromised patients, rubella rarely carries any additional risk, although the serologic response may be abnormal. [30]

Figure 212-6 Rubella. A pink macular rash can be seen on the forearm.

TABLE 212-2 -- Features of congenital rubella.

FEATURES OF CONGENITAL RUBELLA
Cardiovascular defects
Persistent ductus arteriosus
Pulmonary artery stenosis
Myocarditis
Ocular defects
Cataracts (unilateral or bilateral)
Pigmentary retinopathy
Micro-ophthalmus
Glaucoma
Iris hypoplasia
Auditory defects
Sensorineural deafness (unilateral or bilateral)
Central nervous system
Microcephaly
Psychomotor retardation
Meningoencephalitis
Behavioral disorders
Speech disorders
Intrauterine growth retardation
Hepatitis/hepatosplenomegaly
Thrombocytopenia, with purpura
Bone 'lesions'

Pneumonitis
Diabetes mellitus
Thyroid disorders
Progressive rubella panencephalitis
The final four features listed become apparent in infancy or later.

Primary rubella in the first 16 weeks of pregnancy presents major risks to the fetus. Consequences for the fetus and the pregnancy include abortion, miscarriage or stillbirth. If the fetus is infected and survives to term, a wide range of abnormalities may be seen (Table 212.2), some of which may be apparent at birth, but others develop later in life as a result of persistent virus infection (e.g. progressive rubella panencephalitis, late-onset deafness) or the immune response (e.g. pneumonitis). The congenital rubella triad comprises cardiac, ophthalmic and auditory lesions, but purpura, intrauterine growth and neurologic problems are also frequent.

The gestation at which the mother suffers her rubella is critical for the outcome. Onset of rubella before conception carries little, if any, risk, [31] whereas from conception to the 12th week the risk is about 90%,[32] although figures vary in different studies. Between 12 and 16 weeks' gestation the risk falls to about 20%, with sensorineural deafness being the only consequence. Beyond 16 weeks' any risk is minimal, with only rare cases of sensorineural deafness.

It has been established for many years that re-infections can occur in those with a past history of natural rubella or successful immunization. Such re-infections are rarely clinically apparent and are usually identified by a serologic response after exposure, which is usually to a close contact such as the patient's own child. Fetal infection and damage can occur after maternal re-infection, but this is rare, with the fetal risk probably being less than 5%.[33] Because of the difference in risk to the fetus, serologically distinguishing subclinical primary rubella from re-infection is critical in early pregnancy, but may be difficult in the absence of past rubella-specific IgG test results because a specific IgM response can occur in both; IgG avidity testing will usually resolve the problem because a re-infection would be characterized by high avidity.

MANAGEMENT

Rubella is a self-limiting illness that usually runs a benign course. Supportive and symptom-relieving therapy is indicated for complications such as arthralgia, and the patient can be reassured as to the unlikelihood of symptoms persisting beyond a few months.

Management of rubella in pregnancy is first dependent on achieving a correct diagnosis, given that despite some apparently characteristic symptoms and findings, such as suboccipital lymphadenopathy and arthralgia, clinical diagnosis is notoriously unreliable. A serum sample must be taken as soon as possible after contact or onset of illness, and the testing laboratory given full details of past testing and/or vaccine, and the circumstances surrounding the investigated illness/contact. On the basis of results and the clinical details, the laboratory will advise on diagnosis and any further testing required. If primary rubella or re-infection in the first 16 weeks of pregnancy is diagnosed, further management will have to take into account social, legal and religious perspectives because in many countries the risk to the fetus is sufficient to justify consideration of termination of pregnancy.

MUMPS

NATURE

Mumps was first identified as a distinct clinical illness by Hippocrates in the 5th century BC, but has only attracted attention in the past two to three centuries, particularly because of the impact of outbreaks in the armed forces. Natural infection is limited to humans and is endemic worldwide.

Mumps virus is a member of the *Paramyxovirus* genus (which also contains the respiratory paramyxoviruses) of the Paramyxoviridae family. It was first isolated in the chick embryo in 1945, with the first live attenuated vaccine being licensed in 1967. On electron microscopy it is pleomorphic (Fig. 212.7) and varies in size from 80 to 350nm, although it is usually approximately 200nm. The envelope is studded with projections containing hemagglutinin/neuraminidase or fusion proteins. Within the envelope the nucleoprotein has helical symmetry with a diameter of 15–19nm. The RNA is single stranded and of negative sense; the nucleocapsid contains an RNA-dependent RNA polymerase. This enzyme enables replication of the RNA in the cytoplasm once the cell has been penetrated. Mature virions are released from the cell by budding. There is only one serologic type although minor strain variations can be identified with monoclonal antibodies.

EPIDEMIOLOGY

Mumps is endemic worldwide, with epidemics every 2–3 years in populations not influenced by widespread use of mumps vaccine. In

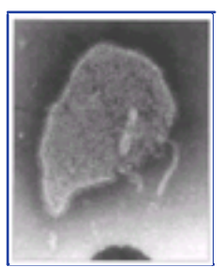

Figure 212-7 Electron micrograph of mumps virus. *Courtesy of Dr A Curry.*

the UK there was a characteristic periodicity of two epidemic years followed by one low-prevalence year (Fig. 212.8). [34] Mumps primarily occurred in 5–9 year olds. When widespread population immunization is introduced, as it was in the USA in 1977 and the UK in 1988, without eradication of the disease, susceptibility in older age groups can increase,[34] leading to a resurgence. This occurred in the USA between 1986 and 1989 in 10–19 year olds, [35] although the incidence later declined.[36] This pattern of changing epidemiology necessitated the introduction of a second dose of vaccine in the preschool or early school years.

PATHOGENICITY

Infection is acquired by droplet spread or direct contact, with initial infection most likely within the upper respiratory tract. Replication in the upper respiratory epithelium is followed by spread to local lymph nodes where further replication is followed by a primary viremia, with seeding of target organs such as parotid glands,

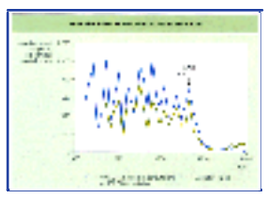

Figure 212-8 Mumps incidence reported to primary care physicians and number of laboratory diagnosed cases in England and Wales between 1962 and 2000. The number of cases declined in response to the introduction of MMR vaccine in 1988. *Data from the PHLS Communicable Disease Surveillance Centre.*

meninges and testes. A secondary viremia occurs at the onset of symptoms.

The incubation period is usually 16–18 days, with infectivity commencing 2 days or so before symptoms and persisting for 5–7 days after onset. Intrauterine infection has been reported only rarely.

PREVENTION

Two live attenuated vaccine strains have been mainly used since 1967: Jeryl Lynn and Urabe. Both are produced in chick embryo cell culture and are available in monovalent form or combined with mumps and rubella vaccine (MMR). The vaccine is usually administered as MMR at 12–15 months of age, with second doses being given later in childhood. The protective efficacy is 75–85%, with clinically apparent mumps in immunized individuals being well documented. Minor complications of mumps vaccine include mild parotitis, fever, and, very rarely, orchitis. Meningitis has been identified as a significant complication with the Urabe strain, however, and this led to its withdrawal in the UK in 1992.[34] [37]

Mumps vaccine is contraindicated in those with previous anaphylaxis to egg and in pregnancy, although adverse implications for the fetus have not been reported. It should also not be given to immunocompromised patients, with the exception of children who have HIV infection, in whom no adverse consequences have been seen.

DIAGNOSTIC MICROBIOLOGY

Virus isolation may be achieved from throat swabs, saliva, CSF and possibly urine. Mumps virus is readily isolated in monkey kidney and Hep2 cells. Although cytopathic effect may sometimes be observed (multinucleated giant cells), isolation is usually confirmed by hemadsorption with chick cells. Identification is by hemadsorption inhibition with specific neutralizing serum. Direct detection of genome can be applied to CSF, and can also be used to distinguish wild-type from vaccine virus.[37] Although feasible, rapid diagnosis by antigen detection in exfoliated upper respiratory cells by immunofluorescence is little used.

Serologic diagnosis is usually achieved by CFT or EIA; neutralization and hemagglutination inhibition testing are now little used. Complement fixation testing uses both a soluble and virion antigen.

Classically, antibody to soluble antigen appears before that to virion antigen, and virion antibody persists longer. This pattern may suggest that single serum diagnosis is feasible (elevated soluble antibody; low or elevated virion antibody), but this approach is highly unreliable because all patterns of antibody development can occur and persist.[38]

Enzyme immunoassay for specific IgG and IgM can be performed, and is relatively reliable, although care must be taken in the interpretation of IgM reactivity because of possible non-specificity. In addition, there is continuing uncertainty as to the possible significance of cross-reacting parainfluenza virus antibody. Saliva specimens can be used for specific IgM detection and are valuable for surveillance of mumps-like illness in the community.[34] For determining past, remote infection CFT has

insufficient sensitivity and EIA for specific IgG is usually used.

CLINICAL MANIFESTATIONS

Toward the end of the incubation period of 16–18 days prodromal symptoms such as pyrexia and malaise develop, to be followed in 24–48 hours by the characteristic enlarged and tender parotid glands. There is often accompanying headache and earache. Recovery is usually complete within 4–5 days. Asymptomatic mumps is common and occurs in about one-third of infections. Parotitis is present in 95% of symptomatic infections and is unilateral in about one-quarter; other salivary glands are involved in about 10% of patients. Parotitis similar to that seen with mumps may also be found in other virus infections, such as coxsackievirus B infection, and blockage of the parotid duct may on occasion give problems with diagnosis.

Complications are common;[39] the risk is the same at all ages except for orchitis and oophoritis, which are virtually limited to post puberty. Complications may manifest 1 week before, at the same time as or 2 weeks after parotid involvement; alternatively, they may manifest with no parotid involvement. The risk of orchitis in the adolescent or adult male is about 35%, with bilateral involvement in one-third of these. There may be some persisting testicular atrophy, but sterility is remarkably uncommon, despite public perceptions. Oophoritis, in contrast, is only observed in about 5% of mumps in adult women and causes lower abdominal pain; it is uncertain whether there may be long-term consequences.

Meningeal involvement, as shown by CSF changes, occurs in about 50% of patients, with signs of meningitis or meningeal irritation in about 1–10%. In about 50% of cases of mumps meningitis there is no parotitis. Characteristic findings in the CSF are a lymphocytosis, raised protein concentrations and, occasionally, a reduced glucose concentration that may lead to a misdiagnosis of early bacterial or mycobacterial meningitis. A surprising feature of the epidemiology of mumps meningitis is that it is three times more common in males than females. In countries in which mumps vaccine has not been used for community control, mumps remains a major cause of viral meningitis; enteroviruses are the other main cause and predominate where mumps has been controlled.

Mumps virus may also cause an encephalitis, presenting as impaired consciousness, fits, aphasia, etc. Two patterns of encephalitis are seen:

- direct involvement of neural tissue; and
- a postinfection encephalitis.

The incidence is about 1/6000 patients, with a mortality rate of 1.4%. Some transient impairment of hearing as a result of a labyrinthitis is not uncommon, with persisting deafness in about 1/20,000 patients. Other complications include pancreatitis, which is usually mild, arthritis, mastitis, thyroiditis and myocarditis. Investigation of renal function will often demonstrate kidney involvement, but there are no clinical consequences.

Mumps in immunocompromised patients seems to carry no undue risk, and persistent infection has not been described. Natural infection with wild-type virus usually gives lifelong protection, although re-infection may occur in 1–2% of those re-exposed.[40]

Infection in the first trimester often leads to abortion, but infection later in pregnancy carries no undue risk, and congenital infection and damage have not been convincingly shown.

MANAGEMENT

Postexposure prophylaxis with normal immunoglobulin is of no benefit, and specific mumps immunoglobulin is no longer available, although it may have reduced the risk of orchitis in adult men. Mumps vaccine administered postexposure is of no value, nor is it of any use in the acute control of outbreaks, although it may be of some use in a continuing epidemic.

Management of infection is symptomatic, with the patient being reassured that recovery occurs in a few days, even when complications are present, although the prognosis should be guarded if encephalitis arises.

Chapter 213 - Enteroviruses: Polioviruses, Coxsackie viruses, Echoviruses and Enteroviruses 68–71

Heinz Zeichhardt
Hans-Peter Grunert

NATURE

Classification and history

Human enteroviruses comprise one genus in the family Picornaviridae, which also contains the genera rhinovirus, cardiovirus, aphthovirus, hepatovirus and parechovirus.[1] The members of the enterovirus genus that infect humans include the polioviruses, the Coxsackie virus groups A and B, the echoviruses and the enteroviruses 68–71 (Table 213.1). The formerly named enterovirus type 72 has been reclassified as hepatitis A virus in its own genus hepatovirus. Echovirus types 22 and 23 have been reclassified in the new genus parechovirus. Updated information can also be found on the website of the International Committee on Taxonomy of Viruses (www.ncbi.nlm.nih.gov/ICTV/). Human enteroviruses inhabit the alimentary tract and most of them can infect the central nervous system (CNS). In addition, enteroviruses are able to induce a broad spectrum of clinical syndromes (see Table 213.3). For additional information see: Pallansch and Roos,[2] Racaniello[3] and Zeichhardt and Grunert.[4]

The crippling paralytic disease that had been recorded in ancient times was characterized as poliomyelitis with flaccid paralysis by the German orthopedist Heine and the Swedish pediatrician Medin in the 19th century, and was therefore first described as Heine-Medin disease. Evidence for a viral origin of poliomyelitis was shown in 1908 when paralytic poliomyelitis was transmitted to monkeys.[5] The animals were infected with filtered stool from a patient with paralytic disease. It took another 40 years to replace animal inoculation studies by cell culture techniques in order to propagate viruses in primate cell lines. The establishment of in-vitro cell cultures[6] was the major breakthrough for systematic diagnosis and subsequent control of poliomyelitis by vaccination.

Animal inoculation was still the basis for isolation and characterization of another enterovirus in Coxsackie, New York, in 1948. This virus was isolated in suckling mice that had been inoculated with a cell-free filtered stool from children suffering from paralysis.[7] The virus became the first member of the group A Coxsackie viruses because it could not be neutralized by antisera against any of the three poliovirus types. The first group B Coxsackie virus was isolated in 1949.[8]

Further members of the enterovirus group were isolated and characterized by using cell cultures. The first echovirus (enteric, cytopathic, human, orphan) was discovered in 1951.[9] Echoviruses were often isolated from stools of healthy children and could not, therefore, be associated with disease. This is why these enteric viruses were called 'orphan viruses'.

Structure

Enteroviruses are small, spherical and naked RNA viruses (Fig. 213.1). Of all the enteroviruses, poliovirus is the best characterized in its structural and functional features.[3] Poliovirus has a molecular weight of 8.4×10^6 Da (156S, 1.34g/ml buoyant density in cesium chloride). An icosahedral capsid of approximately 30nm in diameter surrounds one molecule of single-stranded RNA. The capsid consists of 60 protomers, each of which contains four nonglycosylated virus proteins. The capsid proteins are virus protein (VP)1 (molecular weight 33.5kDa), VP2 (30.0kDa), VP3 (26.4kDa) and VP4 (7.4kDa).[10] Virus protein 4 is myristoylated at its *N*-terminus. Structure analysis by X-ray crystallography and biochemical accessibility studies has showed that the capsid proteins VP1, VP2 and VP3 are at the capsid surface whereas VP4 is covered inside the capsid shell and has contact to the viral RNA. Virus protein 1, VP2 and VP3 together make up a pseudoequivalent packing arrangement in the capsid, which is also typical for spherical plant viruses. Human enteroviruses therefore seem to be old viruses in evolutionary terms.

Virus protein 1 and VP3 form a depression or canyon (approximately 2.5nm deep and up to 3nm wide) that is oriented around the 5-fold symmetry axis of the capsid.[11] It is proposed that the canyon is the recognition site for the virus-specific receptor; this canyon hypothesis has also been described for the related picornavirus, human rhinovirus 14.[12] The single-stranded genomic RNA has positive-stranded sense and it codes in a single open reading frame for the four capsid proteins and additionally for functional proteins with, for example, RNA polymerase and protease activities (Fig. 213.2).

Antigenicity and neutralization

Poliovirus preparations contain two distinct antigens, the D-antigen and the C-antigen. The D-antigen is characterized by infective or 'native' virus whereas C-antigen comprises noninfective virus with properties of heated antigen. The C-antigens of the three poliovirus types are immunologically cross-reactive whereas the corresponding D-antigens react in a serotype-specific manner.

Four immunodominant antigenic sites at the surface of the poliovirus capsid determine the serotype specificity.[13] Exposed regions of the capsid proteins VP1, VP2 and VP3 compose neutralization antigenic sites at which neutralizing antibodies bind. The major antigenic sites for neutralization of Coxsackie virus type B3 are composed of surface structures of the capsid protein VP2.[14]

Some enteroviruses comprise antigenic relationships as determined by neutralization tests. Partial immunologic cross-reactivity has been observed for:

- poliovirus types 1 and 2;
- Coxsackie virus types A3 and A8, A11 and A15, and A13 and A18; and
- echovirus types 1 and 8, 6 and 30, and 12 and 29.

An increased cross-reactivity can be observed for several enteroviruses in the complement fixation test. This is due to the use of soluble antigen made up of common antigenic sites of the virus proteins that are located in the interior of the virus capsids. Immunoblot techniques confirm such immunologic cross-reactivity between different enteroviruses.[15]

Differences in the composition of the capsid surface define the serotypes of enteroviruses. There are three serotypes of poliovirus (see Table 213.1). Coxsackie virus group A comprises 23 serotypes

TABLE 213-1 -- Serotypes of human enteroviruses.

SEROTYPES OF HUMAN ENTEROVIRUSES	
Viruses	**Serotypes**
Polioviruses	1, 2, 3
Coxsackie viruses	
Group A	A1–22, A24

Group B	B1–B6
Echoviruses	1–7, 9, 11–21, 24–27, 29–33
Other enteroviruses	68–71
Echovirus 8 has been deleted because it is identical to echovirus 1. The following viruses have been reclassified: Coxsackie virus A23 as echovirus 9; echovirus 10 as reovirus type 1; echoviruses 22 and 23 as parechoviruses 1 and 2; echovirus 28 as human rhinovirus 1A; echovirus 34 as Coxsackie virus A24; enterovirus 72 as hepatitis A virus in the new genus hepatovirus. Additional information can be found at the website of the International Committee on Taxonomy of Viruses (www.ncbi.nlm.nih.gov/ICTV/). Echo, enteric cytopathic human orphan.	

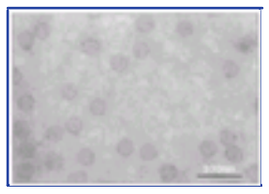

Figure 213-1 Poliovirus type 1. The particles in this electron micrograph are negatively stained with 0.5% uranyl acetate.

(A1–A22 and A24), Coxsackie virus group B has serotypes B1–B6, and the echoviruses consist of 28 serotypes (types 1–7, 9, 11–21, 24–27 and 29–33). The other human enteroviruses are the distinct serotypes 68, 69, 70 and 71.

The antigenic relationships of the enteroviruses are reflected by limited homologies among the RNA and proteins of the different viruses. Sequence identities for different enteroviruses are more than 50% over the genome as a whole. Virus strains within a species have more than 75% sequence identity over the entire genome.[1] Sequence homologies are relatively high for the functional proteins with RNA polymerase and protease activities, whereas sequence heterogeneity is observed for the sequence region coding for capsid proteins. Capsid protein homology is approximately 70% for the three poliovirus Sabin strains and approximately 50% for polioviruses and Coxsackie viruses.[3]

Reactivity to physical and chemical agents and virus stability

A prerequisite for the passage of enteroviruses through the stomach and duodenum is viral resistance to pH levels that are less than 3 as well as to several proteolytic enzymes. Because enteroviruses have no membranous envelope, they are resistant to lipid solvents (e.g. ether, chloroform and detergents). They are also resistant to several disinfectants, including 70% alcohol, 5% lysol and 1% quaternary ammonium components. Chemical inactivation can be achieved by 0.3% formic aldehyde, hydrochloric acid (0.1mol/l) and free residual chlorine (0.3–0.5 parts per million (ppm)) and other halogens (free residual bromine or iodine at a concentration of approximately 0.5ppm for 10 minutes). Because the presence of organic matter with the

Figure 213-2 Organization of the poliovirus genome. The single-stranded genomic RNA of poliovirus (2.4×10^6 Da, approximately 7500 nucleotides) has positive-stranded sense and codes in a single open reading frame for capsid and functional proteins (modified according to Racaniello[3]). The boxes represent the coding region; the lines represent the nontranslated regions (NTR) at the 5'- and 3'-termini (5'- and 3'-NTRs). A small hydrophobic protein is covalently linked to the terminal uracil of the 5'-NTR and called 'virus protein genome linked' (VPg). The 5'-NTR has a significant secondary structure and contains the initiation site for translation at nucleotide position 741 (the internal ribosome entry site). The 3'-NTR (72 nucleotides) is polyadenylated (62 nucleotides on average). The coding region of the genome is translated into a large precursor polyprotein. Region P1 codes for the capsid proteins VP0 (precursor of VP4 and VP2), VP1 and VP3. Regions P2 and P3 code for functional proteins (e.g. 2A codes for a protease, 3B codes for VPg, 3C and 3CD code for proteases, and 3D codes for the RNA polymerase). Three proteases mediate processing of the precursor proteins: protease 2A releases the P1 capsid precursor from the nascent polyprotein, and the proteases 3C and 3CD mediate most of the other cleavages before and during virus assembly. Virus assembly is completed when a single RNA molecule is surrounded by its capsid with 60 protomers, in which the precursor VP0 is then cleaved into mature VP4 and VP2. It is postulated that the viral RNA is involved in this final cleavage.

virus may result in protection against inactivation, the contact time may be prolonged. Enteroviruses can be inactivated by heat at 122°F (50°C) for 1 hour in the absence of magnesium chloride and calcium chloride and by light (in the presence of neutral red, acridine orange, proflavine and other vital dyes). Virus preparations may be stable at 39.2°F (4°C) for several days up to several weeks. At -4°F to -112°F (-20°C to -80°C), enteroviruses can be stored up to several years.

EPIDEMIOLOGY

Transmission

Humans are the only reservoir for human enteroviruses.[2] [4] Because most enteroviruses replicate in the lower or upper alimentary tract, or both, virus spread occurs by both the fecal-oral and respiratory routes. The extensive virus reproduction that occurs in the cells of the gut epithelia leads to massive virus concentrations in the feces (10^6 –10^9 infective virus particles/g feces). Viral spread in the feces can last for weeks or months. Viral spread is usually by way of fecal contamination of fingers, normal household objects (e.g. towels and toys) and food. Nosocomial transmission of enteroviruses typically takes place in newborn nurseries. Fecal-oral transmission is predominant in areas with poor sanitary conditions. Enteroviruses may be found in sewage and transmission by a fecal-water-oral route is possible. Depending on the clinical manifestations, enteroviruses can also be spread by contact infection. For example, hemorrhagic conjunctivitis caused by enterovirus 70 and a variant of Coxsackie virus A24 is effectively transmitted with conjunctival fluid. There is no evidence that enteroviruses are transmitted by sexual routes, blood transfusion or insect bites.

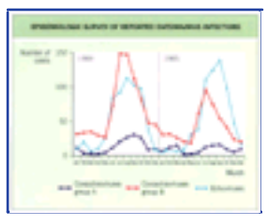

Figure 213-3 Epidemiologic survey of reported enterovirus infections. This epidemiologic survey by the German Association for Prevention of Virus Diseases (DVV) for the years 1984 and 1985 demonstrates that most infections with coxsackieviruses groups A and B and echoviruses in Germany occur during summer and autumn. *Data from Habermehl and Knocke.*

Geographic, seasonal, socio-economic, sex and age factors

Enteroviruses are distributed worldwide.[2] [4] In temperate zones, enterovirus infections typically occur during summer and autumn (Fig. 213.3);[16] in tropical and subtropical areas infections occur throughout the year. Enterovirus infections are most commonly infections of childhood and young children are the main transmitters. More than 90% of enterovirus infections cause no clinical symptoms or signs.

Poor hygiene and low socio-economic conditions increase the risk of enterovirus infections. Diseases caused by enteroviruses occur more frequently in males than females (male:female ratio of 1.5–2.5:1). The clinical signs of most enterovirus diseases are more severe in adults than in children, although newborn and young children may have severe clinical signs when infected with Coxsackie viruses and some echoviruses. For this reason, all efforts must be made to prevent nosocomial infections by these viruses in nurseries.

Epidemics of poliomyelitis frequently occurred before vaccination strategies were introduced with the inactivated Salk vaccine in 1954 and with the oral attenuated Sabin vaccine in 1962. In the prevaccine era, about 10 cases of paralysis per 100,000 population per year were recorded for the USA. The World Health Organization (WHO) still reported as many as 35,251 cases of poliomyelitis worldwide in 1988. (Statistics on global polio cases are available at www.polioeradication.org/.) There were 6349 cases reported for 1998 and only 494 cases for 2001. The WHO-led campaign aims to eradicate poliomyelitis worldwide by the first decade of the 21st century. As a result of vaccination programs, poliomyelitis has been eliminated in the Americas and in Europe. Isolated cases have been reported for The Netherlands, Canada and the USA before 1993 in enclaves of religious groups that are opposed to vaccination. Ten clinically apparent poliomyelitis cases (nine paralytic) occurred in Finland in 1984–85 owing to the occurrence of a genetically altered wild type of poliovirus type 3 against which the Finnish inactivated vaccine induced only partial

immunity. In 1996 an outbreak of paralytic poliomyelitis in Albania, Yugoslavia and Greece resulted in 167 cases of poliomyelitis with 17 deaths.

Some Coxsackie viruses and echoviruses may lead to epidemics. One of the first epidemics observed to be caused by group B Coxsackie viruses was the Bornholm disease epidemic that occurred between 1930 and 1932. The infection caused epidemic myalgia (epidemic pleurodynia) on the island of Bornholm in the Baltic Sea. In the beginning of the 1950s, echovirus 16 was responsible for the so-called Boston exanthema disease, a febrile illness with a rash predominantly occurring in Boston, Massachusetts. Echovirus 9 was responsible for a pandemic of aseptic meningitis in 1955–60. In recent years echovirus 13 outbreaks have taken place in Germany, UK and USA. Large outbreaks of acute hemorrhagic conjunctivitis have been caused by two enteroviruses: enterovirus 70 and a variant of Coxsackie virus A24. From 1969 to 1971, enterovirus 70 spread very quickly in Africa and Asia; acute hemorrhagic conjunctivitis was first recognized in Ghana and after that in other African countries, and it finally spread to Asia. In 1981, enterovirus 70 occurred in the industrialized countries of the West. In 1970–71, acute hemorrhagic conjunctivitis was caused by a variant of Coxsackie virus A24 that originated in South East Asia and was introduced to the Western hemisphere via American Samoa in 1986.

PATHOGENICITY

Virus-specific receptors

The pathogenicity mechanism of enteroviruses is largely determined by their cell tropism. This tropism depends on the specific recognition of the virus by receptors at the surface of susceptible cells (Table 213.2). Several enterovirus receptors can be grouped into receptor families. [28] [29] The receptors for the three types of poliovirus, the six types of group B Coxsackie viruses and some of the group A Coxsackie viruses are members of the immunoglobulin superfamily. The poliovirus receptor[17] [18] is a glycosylated three domain membrane protein that appears in different isoforms (molecular weight 67–80kDa). The receptor for the group B Coxsackie viruses is the coxsackievirus and adenovirus receptor (CAR), a 46kDa glycoprotein that is also used as a receptor by human adenoviruses 2 and 5.[24] Coxsackie viruses A13, A18 and A21 use intercellular adhesion molecule-1 (ICAM-1, CD54) as their receptor.[23] Intercellular adhesion molecule-1 also functions as a receptor for the major group of human rhinoviruses and recognizes as its physiologic ligand an integrin, lymphocyte function-associated molecule-1 (LFA-1), at the surface of leukocytes. The superfamily of integrins contains several enterovirus receptors. Vitronectin (a_v $ß_3$) is the receptor for Coxsackie virus A9.[22] Very late-activating antigen-2 (VLA-2) serves as receptor for echoviruses 1 and 8.[25] An additional membrane protein, decay-accelerating factor (DAF, CD55), is the receptor for echoviruses 6, 7, 12 and 21[26] as well as enterovirus 70.[27]

Further membrane proteins function as specific binding proteins for enteroviruses. They are not limiting factors for virus cell tropism, however, and they might support attachment of viruses at their host cells. Examples of these poliovirus-binding proteins are the lymphocyte-homing protein CD44[19] [20] and other glycosylated membrane proteins with low affinity for poliovirus.[21]

Viral reproduction cycle

The reproduction cycle of polioviruses is the best characterized of that of any of the enteroviruses. The early phase of the poliovirus reproduction cycle can be divided into adsorption, penetration and uncoating; the later phase can be divided into synthesis of virus-specific protein and RNA, virus assembly and virus release from the infected host cell.

Adsorption of poliovirus at the cell surface is regulated by the binding of the poliovirus receptor into the canyon at the capsid surface. The canyon hypothesis proposes that the *N*-terminal domain

TABLE 213-2 -- Enterovirus-specific receptors.

Other enteroviruses	70	Decay accelerating factor (CD55)[27]	

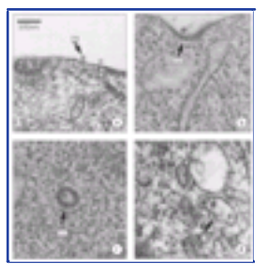

Figure 213-4 Receptor-mediated entry of poliovirus into host cells. The entry of poliovirus into HEp-2 cells is followed by transmission electron microscopy of ultrathin sections of synchronously infected cells.[31] [32] (a) Poliovirus (v) adsorbs at the cell surface immediately after infection (0 minutes after infection). (b) Beginning 1 minute after infection, poliovirus is located at areas of the cell surface that have clathrin-coated pits (cp), at which the surface membrane starts to invaginate. (c) Five minutes after infection, poliovirus is taken up by clathrin-coated vesicles (cv) into the cytoplasm. (d) Between 15 and 20 minutes after infection, poliovirus is within intracellular clathrin-free vesicles or endosomes (e), which are suggested as the sites of viral uncoating.

of the receptor interacts with the canyon, whereas other parts of the receptor are in contact with the capsid surface outside the canyon.[11] [12] [30]

Virus entry into the host cell (penetration) occurs by way of receptor-mediated endocytosis followed by a pH-dependent release of viral RNA from the virus capsid (uncoating; Fig. 213.4).[31] [32] Poliovirus is taken up via clathrin-coated pits after adsorption at the cell surface within 1–5 minutes of infection. After 15–20 minutes, poliovirus reaches acidic compartments in the cytoplasm (endosomes) via clathrin-coated vesicles. The virus capsid undergoes conformational changes during virus entry.[3] The internal capsid protein VP4 is released from the virus and the *N*-terminus of the capsid protein VP1 becomes accessible; this alteration is characterized by antigenic changes. These altered particles have a decreased sedimentation coefficient (135S) and are known as A-particles. An alternative entry mechanism has recently been proposed for poliovirus by which low pH is not required for the release of the viral genome from the capsid.[33]

After the virus has been uncoated, synthesis of viral protein and RNA is initiated by using the viral parental positive-stranded RNA as a template (Fig. 213.5). Viral protein synthesis takes place at the rough endoplasmic reticulum after release of the 'virus protein genome-linked' (VPg) from the viral genome.[13] In contrast to cellular mRNA, enteroviral mRNA has no m^7 G cap group. Initiation of viral protein synthesis takes place in the 5'-nontranslated region, which homes the internal ribosome entry site with the initiation codon AUG beginning at nucleotide position 741 (see Fig. 213.2). The polyprotein is autocatalytically processed by protease 2A via several precursor proteins into the four virus capsid proteins VP1–VP4, the virus-specific proteases 2A and 3C, and the RNA polymerases 3CD and 3D. The replication of viral RNA takes place at the smooth endoplasmic reticulum via negative-stranded RNA copies of the viral genome. During RNA synthesis, multistranded replicative

intermediates occur, from which new positive-stranded RNA is released for further translation and virus assembly.

Viral transcription is regulated by interaction of the mature RNA polymerase 3D with viral and cellular factors. Secondary structural motifs in the nontranslated regions of positive- and negative-stranded RNAs are involved in the initiation of RNA transcription. The virus morphogenesis is characterized by intermediate assembly steps of the virus capsid via precursors and a procapsid. After encapsidation of one molecule of positive-stranded RNA in the provirus, a final proteolytic cleavage of the precursor protein VP0 into VP2 and VP4 finalizes the virus maturation. It is proposed that a morphopoietic factor and smooth membranes are involved in virus maturation.

One reproduction cycle of poliovirus lasts 6–8 hours, at which time up to 10,000 virus particles have been synthesized in a single cell.[2] Light microscopy shows that infected cells are rounded and contain cytoplasmic protrusions (filopodia; Fig. 213.6a,b). [34] The nucleus is pyknotic and the chromatin is condensed. Analysis by scanning electron microscopy reveals that first changes in the cell

Figure 213-5 The reproduction cycle of poliovirus. Receptor-mediated entry of poliovirus is completed by the release of the viral RNA from the virus capsid (uncoating). The syntheses of viral protein and RNA are the next reproduction steps. The viral precursor polyprotein is autocatalytically cleaved by viral proteases, resulting in the viral RNA polymerase and, via several precursor proteins, in the virus capsid proteins (see Fig. 213.2). The viral RNA polymerase mediates viral transcription (i.e. de-novo synthesis of positive-stranded RNA via negative-stranded RNA templates). Maturation of the virus is completed by encapsidation of one molecule of positive-stranded RNA into a capsid with the complete set of proteins VP1, VP2, VP3 and VP4. RI, replicative intermediate.

surface can be observed as early as 3 hours after infection. Eight hours after infection the changes (Fig. 213.6c,d) are characterized by:[35]

- condensation of collapsed microvilli;
- formation of elongated filopodia; and
- a 'rounding up' of the cell.

The nuclear and cytoplasmic alterations are characterized by lobed nuclei with irregular distribution of condensed chromatin and vesicles arranged in clusters in the cytoplasm, as shown by transmission electron microscopy (Fig. 213.6e,f).[35] [36]

Characteristic mitotic changes and chromosomal alterations are induced by poliovirus. The mitosis is enhanced during the early stage of replication. In later stages of infection, the mitosis is arrested in the metaphase (a colchicine-like effect). Chromosomal damage is characterized by single chromatin breaks and pulverization. [37] [38] Poliovirus induces 'shut-off' of the syntheses of cellular protein, RNA and DNA within the first 2 hours of infection. The inhibition of cellular protein synthesis is caused by a proteolytic cleavage of the cellular protein p220.[39] This protein is the initiation factor eIF-4G which, as part of the cap-binding complex eIF-4F, is involved in the initiation of cellular protein synthesis mediated by capped mRNA.

PREVENTION

Vaccination

The introduction of vaccination against the three poliovirus serotypes was a prerequisite for effective prevention of poliomyelitis.[2] [4] The establishment of modern cell culture techniques [6] allowed the development of two poliovirus vaccines. Jonas Salk developed a formaldehyde-inactivated polio vaccine (IPV), which was introduced in 1954 and is administered intramuscularly. In 1962, Albert Sabin introduced an oral polio vaccine (OPV), which consists of live-attenuated viruses. Both IPV and OPV contain the three poliovirus serotypes and induce humoral immunity with circulating antibodies. In addition, OPV induces secretory IgA in the gut owing to the subclinical infection with virus multiplication that it causes in the gastrointestinal tract.

Both vaccines are administered three times several weeks apart in order to give rise to effective titers of neutralizing antibodies. Booster vaccinations are recommended every 10 years for both vaccines. In the temperate zones, it is better not to administer OPV during the summer months when there is a high frequency of other enterovirus infections. Co-infection with other enteroviruses may induce viral interference; this may also occur in the trivalent vaccine when the multiplication of one serotype of poliovirus is reduced by the other types. Such interference may be reduced by the 3-fold administration.

In very rare cases, OPV may gain neurovirulence owing to changes (often point mutations) in the genome of attenuated virus. These mutations occur not only in the genome regions that code for viral capsid proteins and the RNA polymerase but also in the 5'-nontranslated region, which is of importance for the initiation of viral protein synthesis. The Sabin type 3 polio vaccine has been observed to increase in neurovirulence because of a single base change from uracil to cytosine at position 472 in the internal ribosome entry site in the 5'-nontranslated region. [40]

The risk of developing clinical poliomyelitis, including paralysis, after live Sabin vaccination is very small; an incidence of one case of vaccine-associated paralytic poliomyelitis (VAPP) per 1.2 million doses of live vaccine administered has been reported for the USA.[2] Neurovirulent revertants occur mainly with the attenuated vaccine strains of poliovirus types 1 and 3.

All infants and young children should be vaccinated with one of the two vaccines. It is advisable that adults who have not been vaccinated as infants should be vaccinated with IPV followed by OPV. The primary IPV administration helps to prevent VAPP, which has a higher incidence in children and adults than it does in infants. Clinical personnel should be given booster vaccinations at regular intervals. In health care workers, IPV is recommended in order to prevent shedding of attenuated vaccine strains of the virus in clinical

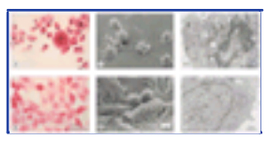

Figure 213-6 The poliovirus-induced cytopathic effect. The cytopathic effect of poliovirus type 1 in monolayers of HEp-2 cells (a, c, e) is demonstrated in comparison to noninfected control cells (b, d, f) by light microscopy, scanning electron microscopy and transmission electron microscopy. [35] (a) Light microscopy of infected cells stained with hemalum-eosin shows rounded cells with pyknotic nuclei and condensed chromatin (8 hours after infection). (b) Light microscopy of control cells. (c) Scanning electron microscopy demonstrates severe rounding of the infected cells (12 hours after infection). The infected cells are characterized by elongated filopodia and microvilli at the cell surface; these are collapsed or even lost. (d) Scanning electron microscopy of control cells. (e) Transmission electron microscopy of ultrathin sections reveals infected pyknotic cell condensation of chromatin arranged in patches in a lobed nucleus and clusters of vesicles in the cytoplasm (8 hours after infection). (f) Transmission electron microscopy of control cells.

surroundings. National health authorities in some countries where poliomyelitis has been eliminated have recently decided to administer IPV instead of OPV because, in these countries, the risk of VAPP is now greater than the risk of infection with wild-type poliovirus.

The WHO-led campaign for eradication of poliomyelitis with the expanded programs of immunization led to a 90% decrease in poliomyelitis worldwide in the years 1988–97.[41] In 2001 only 494 confirmed cases of poliomyelitis were reported. In the Americas and in Europe poliomyelitis is eliminated. Before 1993, very rare local cases of poliomyelitis in Canada and The Netherlands were introduced in ethnic groups refusing vaccination. A prerequisite for global eradication of poliomyelitis is the maintenance of the present high levels of vaccination in developed countries and the induction of immunity in the population of developing countries. For this purpose, national immunization days are performed worldwide. In 1996 on worldwide co-ordinated national immunization days, 420 million children (approximately two-thirds of the world's children under the age of 5 years) were vaccinated against poliomyelitis. The aim is the eradication of poliomyelitis in the first decade of the 21st century.[41]

Passive immunization and hygienic prevention

In contrast to infection caused by polioviruses, infections caused by Coxsackie viruses, echoviruses and enteroviruses 68–71 presently cannot be prevented by vaccination. However, interruption of the routes of virus transmission and prophylactic passive immunization are effective in the prevention of enterovirus infections. Serum that contains antibodies against polioviruses, Coxsackie viruses and echoviruses obtained from convalescing patients can be effective in preventing infections in seronegative patients when administered within 72 hours of exposure. Immunoglobulins can prevent poliovirus infections as well as Coxsackie virus and echovirus infections, which can induce 'fulminant viral sepsis', myocarditis, encephalitis and death in newborn babies when transmitted in neonatal wards.

Nosocomial transmission of enteroviruses is often caused by lack of normal hygienic conditions. Clinical personnel can prevent nosocomial transmission of enteroviruses by obeying hygiene rules and especially by changing coat and gloves between patients and hygienic hand rub and hand washing. Proper removal of feces, including diapers, is of major importance.

Patients infected with poliovirus are not considered to be highly contagious; nevertheless, they should be isolated because of the drastic clinical consequences of infection.

Antiviral chemotherapy

Effective antiviral chemotherapy against enterovirus infections does not yet exist, with the exception of the newly developed antiviral compound pleconaril. Pleconaril shows antiviral activity against different picornaviruses and seems to be a promising new drug candidate for the therapy of enteroviral meningitis. All other antiviral compounds against enteroviruses have currently been proven to show antiviral activity only in cell culture systems. Guanidine and some benzimidazoles specifically inhibit the viral RNA polymerization. Hydrophobic compounds intercalating in the viral capsid protein VP1 stabilize the virus, resulting in inhibition of viral uncoating.[3] [4] [42]

DIAGNOSTIC VIROLOGY

The laboratory diagnosis of enterovirus infections is based on virus detection, including virus isolation and identification, and serologic diagnosis. [2] [43]

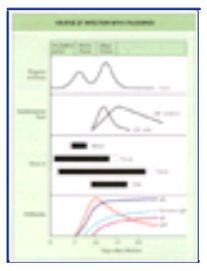

Figure 213-7 The course of infection with poliovirus.

Collection and preparation of specimens

Specimens for virus isolation and identification

Successful virus isolation from clinical specimens depends on proper collection and is related to the time since infection (Fig. 213.7) In general, virus specimens should be collected as soon as possible after onset of clinical symptoms. The specimens should preferably be transported to the laboratory under cooled conditions. If virus isolation cannot be performed immediately after receipt the specimens should be stored at -4°F (-20°C).

Owing to the pathogenesis of enteroviruses with their enteric multiplication and clinical manifestation involving the CNS, the most useful specimens for virus isolation are stools and rectal swabs, throat swabs and washings, and cerebrospinal fluid (CSF). Most enteroviruses can be isolated most effectively from the throat up to 15 days after infection or longer, and from stools and rectal swabs up to 1 month after infection or longer. When there are symptoms involving the CNS, virus isolation is usually successful from the CSF 2–3 weeks after infection. Stools are preferred for virus isolation because virus concentrations in feces are very high (up to 10^6 –10^9 virus particles/g of feces) compared with virus concentrations in other specimens.

In addition, all specimens from target organs allow virus isolation if a biopsy or autopsy specimen is taken during the clinical manifestation of disease. Viruses inducing vesicular rashes (such as Coxsackie viruses types A4, A6, A9, A10 and A16, and enterovirus type 71) can be isolated from the lesions. A Coxsackie virus A24 variant and enterovirus 70 may be responsible for hemorrhagic conjunctivitis and echovirus types 7 and 11 induce conjunctivitis; these viruses can be isolated from ocular samples, either conjunctival swabs or scrapings.

For selected diagnostic purposes, biopsy or autopsy material from the heart, muscle or brain may be successful for isolation of the virus. Autopsy specimens should be collected as soon as possible after death under sterile conditions in order to prevent virus degradation. Depending on the target organ, the order of collection should be CNS or lymph node specimens, specimens from the thorax, specimens from muscles, liver or glands, and finally specimens from peritoneum and gastrointestinal tract. For diagnosing clinical manifestation in the CNS, samples from the pons and medulla oblongata, as well as spinal cord and CSF specimens, are especially likely to yield successful isolation. A planned order of tissue collection is emphasized so that contamination from gastrointestinal contents is avoided.

Virus isolation from blood is successful only during viremia (days 6–9 after infection; see Fig. 213.7) and is therefore not generally attempted because of the short period for collection.

In rare cases, enteroviruses other than poliovirus can be isolated from urine.

Specimens for serologic diagnosis

Detection of virus-specific antibodies should be performed with at least two serum samples. The first, acute-phase serum, should be obtained as soon as possible after the onset of illness. The second, convalescent-phase serum, is usually collected 2–3 weeks later in order to monitor any increase in antibody titer. If there are CNS manifestations, antibody detection in CSF can be useful. Serum and CSF that are free of additives should be used for serologic diagnosis.

Virus isolation and identification

Virus propagation in cell cultures and animals

Virus growth in cell cultures is the preferred method for virus isolation. The human cells that are usually used for propagation of enteroviruses are primary embryonic fibroblasts of the skin and lung, permanent fibroblasts (e.g. MRC-5 cells), permanent amnion cells (e.g. FL cells), and transformed cells such as HeLa, HEp-2 and KB cells. The monkey cells that are most frequently used are primary rhesus or African green monkey kidney cells or permanent monkey kidney cells (e.g. BGM and Vero cells). These standardized cell lines for virus propagation can be obtained from national or international reference institutions (e.g. American Type Culture Collection).

Several types of group A Coxsackie viruses have exceptional growth behavior. Some of these viruses replicate only in a human rhabdomyosarcoma cell line or in newborn mice. Newborn mice are required to isolate Coxsackie virus types A1, A19 and A22.[2] Virus isolation in mice, however, is nowadays restricted to a few reference laboratories worldwide. It should be mentioned that, before the introduction of cell cultures for virus isolation, pathologic lesions in monkeys induced by polioviruses and in mice induced by Coxsackie viruses of groups A and B were the only tools for virus isolation.

Wild-type polioviruses have a tropism that is restricted to primates. Most other enteroviruses, however, also infect laboratory animals such as mice. In order to distinguish between group A and group B Coxsackie viruses before the introduction of cell culture techniques, pathologic lesions in mice were used. In newborn mice, Coxsackie group A viruses cause generalized myositis accompanied by flaccid paralysis. Group A viruses rarely induce CNS alterations. Typically, group B viruses

cause focal myositis and lesions in the brain and interscapular fat pad; myocarditis, endocarditis, hepatitis and pancreatitis may also occur.

Virus neutralization with internationally standardized antiserum pools

Proof of the presence of virus in a specimen is provided by the appearance of the typical cytopathic effect in cell culture. Virus neutralization tests using virus-specific antisera are most commonly used for identification of the virus isolates. Typing of the isolates is performed with pools of internationally standardized hyperimmune equine antisera. These sera were introduced by Lim and Benyesh-Melnick[44] and can be obtained from the WHO Collaborating Center for Virus Reference and Research in Copenhagen. The Lim-Benyesh-Melnick (LBM) sera consist of eight antiserum pools (pools A–H), which can be used for the identification of 42 enterovirus serotypes.

Isolation and identification of selected enteroviruses that cannot be propagated in cell culture are restricted to a few reference laboratories that propagate viruses in animals. For virus typing in animals, additional LBM antiserum pools with neutralizing antibodies (pools J–P) are available. Virus neutralization is characterized by absence of clinical signs in inoculated animals.

Differentiation between wild-type and Sabin vaccine-like poliovirus strains

The differentiation of wild-type strains and Sabin vaccine-like strains of polioviruses is generally performed in specialized laboratories, which use the following techniques:[45]

- determination of growth markers of polioviruses represented by the viral reproductive capacity at elevated temperatures and plaquing capacities;
- intratypic serodifferentiation of virus strains using polyclonal strain-specific antibodies;[46] [47]
- use of monoclonal antibodies against wild-type and vaccine-like viruses for virus neutralization;[47] [48] [49] and
- amplification of viral genome sequences by reverse transcriptase polymerase chain reaction (RT-PCR) followed by sequence analysis.[50] [51]

Virus detection and identification by microscopy

Specialized laboratories perform electron microscopic techniques for direct virus visualization (see Fig. 213.1). The technique of negative staining is restricted to stool specimens, because only this material contains a sufficiently high virus concentration (see above). Direct

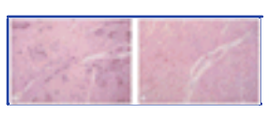

Figure 213-8 Fulminant enterovirus-induced myocarditis. In-situ hybridization of a ^{35} S-labeled enterovirus group-specific cDNA probe to the paraffinembedded autopsy heart tissue of an infant who died of acute enterovirus infection.[53] (a) Autoradiographic silver grains can be clearly localized to distinct infected myocytes, thereby providing the possibility of an unequivocal diagnosis of myocardial enterovirus infection. (b) Hybridization to myocardial cells was not observed when myocardial tissues were hybridized with the ^{35} S-labeled plasmid vector control probe, demonstrating the specificity of in-situ hybridization. Stained with hematoxylin and eosin. *Courtesy of R Kandolf, Tübingen.*

virus identification can be performed by immune electron microscopy. Virus-containing specimens are incubated with virus-specific antibodies and the resulting virus-antibody complexes can be characterized by electron microscopy.

Virus typing in specimens obtained at biopsy and autopsy can be performed by immunofluorescence techniques. Sections of target tissues are incubated with virus-specific antibodies and the resulting immune complexes are detected in a sandwich test with antibodies that are labeled with fluorescent dye and directed against the virus-specific antibody. This laborious sandwich technique is restricted to specialized laboratories.

Detection of virus genome

Techniques for the detection of enterovirus genomes have been introduced for selected diagnostic purposes. However, the traditional immunologic techniques for virus typing by neutralization cannot yet be replaced by molecular biologic techniques. The main reason for the limited use of these techniques in routine diagnostics is the relatively high sequence homology between enteroviruses, which may result in reduced specificity. Molecular biologic techniques nevertheless are very powerful tools for specialized diagnostics:[51] [52]

- the combination of PCR with restriction fragment length polymorphism analysis or sequencing allows virus typing and differentiation between wild-type and Sabin vaccine-like strains of polioviruses;
- oligonucleotide analysis ('fingerprinting') and nucleic acid sequencing is useful for detecting genome variation between different enterovirus isolates, and virus strain-specific oligonucleotide patterns in defined fingerprints detected by two-dimensional gel electrophoresis are useful for epidemiologic surveillance; and
- in-situ hybridization using labeled virus-specific gene probes is a powerful tool for enterovirus genome detection in biopsy or autopsy specimens (Fig. 213.8); the use of Coxsackie virus type B3-specific cDNA has enabled this virus to be identified as a cause of chronic dilated myocarditis,[53] which could not be proven by virus isolation in cell cultures.

The introduction of quantitative methods for nucleic acid amplification (i.e. quantitative PCR) in combination with the introduction

---

of standardized international reference material will give new possibilities for the diagnosis of enterovirus infections.

Serologic diagnosis

In order to confirm an infection with enteroviruses, a combination of serologic diagnosis with virus identification is advisable. Recent enterovirus infections can be proven by serologic means by using two kinds of documentation of a virus-specific antibody response.

Analysis of two or more sera from a patient

Ideally, the first serum of the patient should be tested at the beginning of the illness. A second serum should be collected 7–10 days later and tested in parallel with the first serum in order to detect a rise in antibody titer (see Fig. 213.7). A 4-fold or greater rise in antibody titer (i.e. at least two titer steps) proves a recent enterovirus infection.

Detection of virus-specific IgM

The detection of a single high titer of enterovirus-specific IgM proves a recent enterovirus infection. Virus-specific IgM first appears after enterovirus infection (7–10 days after infection) and persists for approximately 4 weeks in 90% of infections (see Fig. 213.7 ; also see below). Common procedures for isolating the IgM fraction of a patient serum from remaining serum proteins are either density gradient ultracentrifugation or column chromatography (i.e. conventional molecular sieve gel chromatography or high pressure liquid chromatography). The isolated IgM fraction is analyzed for virus specificity in neutralization tests.

This laborious and time-consuming isolation of IgM has the advantage that a single serum from a patient is sufficient for detecting 'fresh' virus-specific IgM. This depends on the precondition that this single serum was collected neither within the first 7 days of infection nor too late after infection, when the amount of virus-specific IgM has decreased below the level of detection.

Neutralization test

The virus neutralization test is still the first-choice method for detecting virus-specific antibodies. This test has a very high sensitivity and specificity and it allows the

detection of serotype-specific antibodies, which is in contrast to most other serologic detection methods. The neutralization test is usually performed only in specialized laboratories with the following preconditions:

- an enterovirus infection is suspected because of a defined clinical or epidemiologic situation;
- an enterovirus has already been isolated from a defined patient's material; and
- group-specific antibodies have already been detected with another serologic technique (e.g. with the complement fixation test).

Cytopathic end-point tests that use enterovirus permissive cell cultures in a microtiter system are performed for the detection of the neutralization reaction. The patient's serum or its isolated IgM fraction is geometrically diluted (e.g. 1:10, 1:20 and so on up to 1:320) and each dilution is incubated with a constant infectious dose of a given enterovirus (100 tissue culture ID_{50} is the dose of virus that will induce a cytopathic effect in 50% of the cells). The absence of a cytopathic effect caused by virus neutralization is microscopically detected in comparison with non-neutralized control virus. The serum titer is calculated for the 50% cytopathic end point per inoculation volume against the challenge dose of non-neutralized virus. [43]

Complement fixation test

The complement fixation test is usually performed as a serologic screening method for the detection of enterovirus-specific antibodies. It only allows the detection of enterovirus group-specific antibodies. The use of denatured enterovirus antigen gives rise to immunologic cross-reaction between different enterovirus groups (see above).

Enzyme-linked immunosorbent assay (ELISA) and immunoblot

These serologic methods have not been implemented as routine tests as they have the same limited value as the complement fixation test due to the detection of enterovirus group-specific instead of serotype-specific antibodies.

CLINICAL MANIFESTATIONS

Asymptomatic infections

Most enterovirus infections are silent, mild or subclinical. Between 90% and 95% of poliovirus infections remain asymptomatic whereas only 0.1–1% of infections cause clinical signs involving the CNS, such as paralytic poliomyelitis. Enterovirus passage through the gut may be the reason for the high incidence of inapparent infections because the cells of the gut epithelia normally have a high rate of turnover. Therefore, the virus-induced lysis of the gut cells might be without clinical signs, even though more than 1000 infective virus particles can be reproduced in one infected cell.

Incubation times

The incubation times of all enteroviruses range from 2 to 35 days, with an average of 7–14 days. An exception has been reported for local infections of the eye by enterovirus type 70, which has a short incubation period of 12–30 hours.

Immune response

It is suggested that immunity to enterovirus infections is mediated mainly by humoral and secretory antibodies (see Fig. 213.7). The role of cellular immunity in enterovirus infections has not yet been well analyzed. Humoral neutralizing IgG, IgM and IgA with virus-type specificity prevent hematogenous spread of virus to the target organs. Virus-specific IgM appears first after infection (7–10 days after infection) and persists for at least 4 weeks in 90% of infections. Acquired humoral immunity is mediated by virus-specific IgG, which may persist for several years. After poliovirus infection, production of virus-specific antibodies in the CNS has been observed. Breakdown in the integrity of the meninges may enable serum antibodies to cross the blood-brain barrier and this may be the reason for their appearance in the CNS. Secretory IgA against poliovirus is located mainly in nasopharyngeal and gut tissues; it is induced 2–4 weeks after infection. Secretory IgA induced against each of the three poliovirus types after oral polio vaccination is the main barrier against subsequent wild-type infections because secretory IgA prevents or limits the spread of polioviruses in the alimentary tract.

Clinical syndromes

The lytic infection of host cells with severe cytopathic effects is the basis for the mechanism of pathogenicity of enterovirus infections (see above). Most enteroviruses induce cyclic infections in their host with a viremia and subsequent virus transport to the target organs (especially the spinal cord and brain, meninges, myocardium, skin and liver).[2] [4]

Polioviruses

The mode of infection of polioviruses is the best understood of all the enteroviruses. The mouth is the portal of entry. Beginning shortly after infection, poliovirus is spread via oral and fecal routes as the virus multiplies in the mucosal tissues of the pharynx, the lymphoid tissues (tonsils and Peyer's patches) and the gut. The virus infection is clinically inapparent in 90–95% cases.

TABLE 213-3 -- Clinical syndromes of enterovirus infections.[†]

CLINICAL SYNDROMES OF ENTEROVIRUS INFECTIONS		
Viruses	**Types**	**Clinical syndromes**
Polioviruses	1–3	Abortive poliomyelitis ('minor illness', undifferentiated febrile illness)
		Nonparalytic poliomyelitis (aseptic meningitis)
		Paralytic poliomyelitis ('major illness'), encephalitis (infrequently)
		Postpolio syndrome
Coxsackie viruses		

Group A	2, 3, 4, 5, 6, 8, 10	Herpangina (vesicular pharyngitis)
	10	Acute lymphatic or nodular pharyngitis
	2, 4, 7, 9, 10	Aseptic meningitis
	7, 9	Paralysis (infrequently)
	4, 14, 16	Myocarditis, pericarditis
	4, 5, 6, 9, 16	Exanthema
	4, 5, 9, 10, 16	Hand, foot and mouth disease
	9, 16	Pneumonitis in children
	21, 24	Common cold
	4, 9	Hepatitis
	18, 20, 21, 22, 24	Infantile diarrhea
	24	Acute hemorrhagic conjunctivitis
	Various types	Undifferentiated febrile illness
Group B	1, 2, 3, 4, 5	Pleurodynia
	1, 2, 3, 4, 5	Bornholm disease (epidemic pleurodynia or acute epidemic myalgia)
	1, 2, 3, 4, 5, 6	Aseptic meningitis

† *Adapted from Pallansch and Roos.*[2]
* Echoviruses 22 and 23 have been reclassified as parechoviruses 1 and 2.

Abortive poliomyelitis

Poliovirus can be spread to the draining lymph nodes, most probably with the help of M cells, which are specialized microfold cells overlying Peyer's patches. This leads to a viremia at 6–9 days after infection (see Fig. 213.7). The viremia is characterized by non-specific clinical symptoms such as fever, malaise and sore throat and sometimes headache and vomiting (Table 213.3). This abortive poliomyelitis ('minor illness') occurs in about 4–8% of poliovirus infections.

Nonparalytic poliomyelitis (aseptic meningitis)

Poliovirus can cross the blood-brain barrier by as yet unknown mechanisms to infect its target cells in the CNS. The same prodromal signs as those that occur in abortive poliomyelitis are characteristic of patients who have nonparalytic poliomyelitis, which occurs in 1–2% of poliovirus infections. Between 3 and 7 days after the 'minor illness' these patients develop an illness similar to aseptic meningitis, which is accompanied by high fever, back pain and

muscle spasm. The patients generally show rapid and complete recovery from the disease, which lasts 2–10 days.

Paralytic poliomyelitis

Between 0.1% and 1% of all people infected with poliovirus develop paralytic poliomyelitis, also called 'major illness'. In addition to the clinical signs of 'minor illness' and aseptic meningitis, the 'major illness' comprises flaccid paralysis (involvement of the whole muscle) or paresis (involvement of only some muscle groups) and, in rare cases, encephalitis. Spinal or bulbar damage, or both, is the consequence. The spinal form of poliomyelitis owing to an ascendent infection is more common than the bulbar form. Bulbar poliomyelitis is characterized by damage to the cerebral nerves and vegetative centers and it therefore has a poor prognosis. In spinal poliomyelitis, some recovery of motor function may occur after several months; any remaining paralysis, however, will be permanent.

The very specific extraintestinal tropism of poliovirus to target cells of the CNS is the basis for these severe clinical signs. Polioviruses especially infect the anterior horn cells of the spinal cord but also the dorsal root ganglia, certain brainstem centers, cerebellum, spinal sensory columns and, occasionally, the cerebral motor cortex. Histologic analysis reveals that vascular engorgement is first observed, accompanied by perivascular infiltration with lymphocytes and also polymorphonuclear neutrophils, plasma cells and microglia. Experimental infection of rhesus monkeys has shown that the anterior horn cells are severely damaged by a poliovirus-specific cytopathic effect. The cells are characterized by a diffuse decrease in the size of the Nissl bodies in the cytoplasm (chromatolysis) and nuclear alterations with breakage and condensation of chromatin.[54]

The severity of disease may be increased by certain factors, including male sex, very young and very old age, physical exertion, hypoxia, cold, chronic undernutrition, corticosteroid treatment, irradiation, tonsillectomy, pregnancy, adrenal-related endocrine changes and possibly hypercholesterolemia.[55]

Postpolio syndrome

A small number of infected people develop recrudescence of paralysis and muscle atrophy several decades after their experience with paralytic poliomyelitis. This postpolio syndrome owing to a progressive postpoliomyelitis muscle atrophy is not clearly understood. Postpoliomyelitis muscle atrophy cannot be assigned to persistent poliovirus infection,[2] although some reports have described poliovirus genome sequences in the CNS of these patients as detected by PCR. It is suggested, rather, that the muscle atrophy is a result of the additive effects of physiologic aging in these patients to the long-lasting loss of neuromuscular function resulting from the earlier infection.

Coxsackie viruses, echoviruses and enteroviruses 68–71

The nonpolio enteroviruses are characterized by less specific extraintestinal target organ tropism than the polioviruses and they can therefore induce a wider range of diseases (see Table 213.3). The primary multiplication of the nonpolio enteroviruses takes place in the pharynx and small intestine and viruses are shed in the feces for up to 1 month and in the respiratory secretions for several days. Owing to the broad target organ range, nonpolio enteroviruses can infect the meninges, CNS, myocardium and pericardium, striated muscles, respiratory tract, eye and skin. Enterovirus 69 is the only enterovirus that has not yet been clearly assigned to a disease.

Meningitis and central nervous system disease

Meningitis and mild paresis can be induced by most group A and group B Coxsackie viruses and by echoviruses. As with poliomyelitis 'minor illness', early symptoms are fever, malaise, headache, nausea and abdominal pain; these are followed by meningeal irritation with neck or back stiffness and vomiting before the onset of meningitis and mild paresis. Aseptic meningitis is very often accompanied by a rash. In contrast to the situation in poliovirus infection, the manifestation of the CNS disease is usually milder and patients nearly always recover from paresis. Severe CNS disease, which may be confused clinically with paralytic poliomyelitis, has been described for infections with Coxsackie viruses A7, A9 and B2–B5. Meningoencephalitis is seen (especially in children) in infections with several group B Coxsackie viruses. In 1955–60 a pandemic outbreak of aseptic meningitis was caused by echovirus 9. Encephalitis, ataxia and Guillain-Barré syndrome have been attributed to echovirus infections. In 1969–73 in California, enterovirus 71 was responsible for an epidemic outbreak of aseptic meningitis, meningoencephalitis and paralysis in parallel to hand, foot and mouth disease. In 1998 in Taiwan there was a further large outbreak of enterovirus 71 that affected young children and resulted in 78 deaths, mostly related to encephalitis.[56] A disease similar to poliomyelitis has been observed in some cases of acute hemorrhagic conjunctivitis caused by enterovirus 70.

Pleurodynia

Coxsackie viruses B1–B5 can cause pleurodynia (also known as epidemic myalgia or Bornholm disease), with abrupt onset of fever sometimes preceded by malaise, headache and anorexia. Characteristic clinical signs are severe chest pain, also called 'devil's grip', and abdominal pain, which may be intensified by movement or breathing. Children and adolescents are most often attacked by this disease, which can last from 2 days to 2 weeks and may be accompanied by generalized muscle hypotonia. An epidemic of this disease was first observed on the island of Bornholm (Denmark) in 1930–32. Epidemics predominantly occur during late summer and early autumn. Muscle pain in the lower extremities may be caused by echovirus infections. Patients may suffer from pleurodynia if this myalgia affects the intercostal muscles. Sporadic cases of pleurodynia may be caused by Coxsackie viruses A4, A6, A9 and A10 as well as echoviruses 1 and 6.

Herpangina

Herpangina is mainly caused by group A Coxsackie viruses such as A2–A6, A8 and A10. Infants are most often attacked by herpangina, with abrupt onset of fever, sore throat, vomiting and abdominal pain. Herpangina is characterized by discrete vesicles of different size, sometimes tiny, which most frequently occur on the tongue, anterior pillars of the fauces, the posterior pharynx, the palate, the uvula or the tonsils. Coxsackie virus A10 may also be responsible for lymphatic pharyngitis.

Hand, foot and mouth disease

Coxsackie virus A16 is associated with hand, foot and mouth disease, but Coxsackie viruses A4, A5, A9, A10, B2 and B5 may also cause it. The disease is characterized by vesicles on the hands and feet. The manifestation on the mucosa of the mouth leads to herpangina with generalized vesicular intraoral lesions, which may be ulcerative. Hand, foot and mouth disease caused by enterovirus 71 can be mixed with aseptic meningitis and encephalitis.[56]

Exanthemas

Rubelliform rash may be caused by several group A and B Coxsackie viruses, which most frequently attack young children. Several types of echoviruses are responsible for exanthemas, with a high incidence in infants. These exanthemas can be maculopapular and are sometimes morbilliform or rubelliform; they are accompanied by febrile illnesses or pharyngitis. Echovirus 19 was responsible for an

---

epidemic outbreak of a maculopapular rash in Boston, Massachusetts, in the beginning of the 1950s; since then this has been known as 'Boston exanthema disease'.

Respiratory illnesses and acute febrile illnesses

Several types of echoviruses and group A and B Coxsackie viruses are responsible for infections of the upper and lower respiratory tract that cause acute febrile illnesses of short duration without distinctive features. These illnesses predominantly occur during the summer or autumn and often resemble the common cold. In some cases, infections with Coxsackie viruses may cause pneumonia in children and adults and pneumonitis of infants. Children may suffer from pneumonia and bronchiolitis when attacked by enterovirus 68. Enterovirus 71 can lead to an influenza-like illness in children.

Conjunctivitis

Enteroviral conjunctivitis is mainly caused by Coxsackie virus A24 and enterovirus 70. A variant of Coxsackie virus A24 was responsible for an epidemic outbreak of acute hemorrhagic conjunctivitis in Singapore and Hong Kong in 1970–71. This acute hemorrhagic conjunctivitis spread throughout South East Asia and first occurred outside Asia in American Samoa in 1986 (where the incidence was 47%). Acute hemorrhagic conjunctivitis caused by enterovirus 70 first occurred in Africa, South East Asia (including Singapore), Japan and India in 1969–71, with several million cases. After sporadic outbreaks in French Polynesia in 1982, enterovirus 70 was introduced to the USA. Coxsackie virus A24 and enterovirus 70 typically cause local infections of the eye; enterovirus 70, however, can also be responsible for rare manifestations in the CNS with a poliomyelitis-like paralysis. In contrast to all other enterovirus infections, the incubation time of infections with enterovirus 70 is very short (24 hours; range 12–72 hours). Conjunctivitis without hemorrhage can be caused by echoviruses 7 and 11. An epidemic outbreak of conjunctivitis caused by echovirus 7 occurred in Sweden in 1977. It must be emphasized that enterovirus-infected conjunctival fluid can be highly infectious.

Myocarditis and pericarditis

Group B Coxsackie viruses are the main cause of myocarditis, pericarditis and dilated cardiomyopathy among the enteroviruses. In addition, cases of myocarditis and

pericarditis are also described for Coxsackie viruses A4, A14 and A16, and for echoviruses 1, 6, 9 and 19.

Coxsackie viruses and echoviruses may affect the myocardium, endocardium and pericardium. The infected myocardium is characterized by edema, diffuse focal necrosis and signs of acute inflammatory responses. The cardiac disease may be accompanied by meningism and convulsions. Myocarditis in newborns may be fatal (see Fig. 213.8); death occurs in 50% of cases. Young children and adolescents are more often attacked by pericarditis, which in general is less severe than neonatal myocarditis.

Chronic cardiovascular disease

Chronic cardiovascular disease with recurrent pericarditis can be caused by Coxsackie viruses (predominantly B2–B5). Virus-specific IgM may persist for years. Myocytes are persistently infected with Coxsackie viruses, which can be demonstrated by in-situ hybridization.[53] Viral RNA instead of mature virus persists in cardiac myocytes.[53] [57] [58] Long-lasting necrosis in the myocardium may be the consequence of this virus persistence. There are results showing that an autoimmune response is involved in Cocksackie virus-induced chronic cardiovascular disease.[59]

Gastrointestinal disease

Non-specific clinical symptoms caused by several Coxsackie viruses and echoviruses may be accompanied by diarrhea, which may be fatal in newborn babies. Generalized infections with Coxsackie viruses and echoviruses may lead to hepatitis. Pancreatitis has been associated with group B Coxsackie viruses.

Diabetes mellitus

Infections with group B Coxsackie viruses are implicated as a cause of juvenile-onset insulin-dependent diabetes mellitus. Several reports of experimental Coxsackie virus infections of animals discuss an involvement of autoimmunity in diabetes.

Neonatal disease

Nosocomial transmission of Coxsackie viruses and some echoviruses may be responsible for fatal disease in newborn babies, frequently with rapid death. Nursery outbreaks and sporadic infections, mainly with group B Coxsackie viruses and echovirus 11, cause disease within a few days of birth and may lead to an overwhelming systemic infection (viral sepsis) with acute myocarditis or pericarditis, encephalitis and hepatitis. The condition is often hemorrhagic with fatal kidney disorders. Severe diarrhea in young children may cause severe disorders of water and ion balance.

There are case reports suggesting that neonatal diseases may be acquired by intrauterine infection as a result of transplacental transmission and neonatal infection at birth by a contaminated cervix. Maternal infection in the first trimester of pregnancy with Coxsackie viruses A9, B2, B3 and B4 may be associated with fetal abnormalities of the urogenital tract, the gastrointestinal tract, the cardiovascular system and the CNS, but the risk of teratogenesis from infections with Coxsackie viruses or echoviruses cannot yet be estimated.

Chapter 214 - Hepatitis Viruses

Jane N Zuckerman
Arie J Zuckerman

INTRODUCTION

Viral hepatitis is a major public health problem throughout the world that affects several hundreds of millions of people. Viral hepatitis is a cause of considerable morbidity and mortality, both from acute infection and from chronic sequelae. In the case of infection with hepatitis B virus (HBV) and hepatitis C virus (HCV), these chronic sequelae include chronic active hepatitis, cirrhosis and primary liver cancer.

There is evidence that in addition to the five recognized pathogens, A–E, the so-called non-A–E hepatitis viruses exist. The evidence was based on the observation of short and long incubation periods in post-transfusion hepatitis and in experimental transmission studies; multiple bouts of hepatitis in the same patient; chronic hepatitis not due to HBV, HCV or hepatitis D virus (HDV); chloroform-resistant non-ABC virus; and cross-challenge experiments in susceptible primates.

The hepatitis viruses include a range of unrelated and often unusual human pathogens (Table 214.1).

HEPATITIS A VIRUS

Outbreaks of jaundice have been described frequently for many centuries and the term infectious hepatitis was coined in 1912 to describe the epidemic form of the disease. Hepatitis A virus (HAV) is spread by the fecal-oral route. It continues to be endemic throughout the world and hyperendemic in areas with poor standards of sanitation and hygiene.

NATURE

Classification

Electron microscopy examination of concentrates of filtered fecal extracts from patients in the early stages of infection reveals 27nm particles typical of the Picornaviridae (Fig. 214.1). Hepatitis A virus is a small, unenveloped, symmetric RNA virus and was classified in the genus enterovirus of the family Picornaviridae on the basis of its biophysical and biochemical characteristics. However, after the determination of the entire nucleotide sequence of the viral genome, comparison with other picornavirus sequences revealed limited homology to the enteroviruses and also to the rhinoviruses, although the structure and genome organization is typical of the Picornaviridae. Hepatitis A virus has now been placed as hepatovirus within the heparnavirus genus.

Organization of the Hepatitis A virus genome

The HAV genome comprises about 7500 nucleotides of positive-sense RNA. The RNA is polyadenylated at the 3' end and has a viral polypeptide (VPg) attached to the 5' end. A single, large open reading frame (ORF) occupies most of the genome and encodes a polyprotein with a theoretic molecular mass of M_r 252,000. An untranslated region of around 735 nucleotides precedes the ORF. Secondary structure within this region of the genome may be important for efficient translation of the RNA. There is also a short untranslated region at the 3' end of the HAV genome.

The viral polyprotein is processed to yield the structural polypeptides (located at the amino-terminal end) and the nonstructural viral polypeptides. Many of the features of replication of the picornaviruses have been deduced from studies of prototype enteroviruses and rhinoviruses, in particular poliovirus type 1.

The three-dimensional structures of a number of picornaviruses have been resolved by high-resolution crystallography; polypeptides VP1 (1D), VP2 (1B) and VP3 (1C) are exposed on the surface of the virion, whereas VP4 (1A) is located internally. After release of the structural domain from the polyprotein, the 3C protease cleaves the 1B–1C and 1C–1D junctions to yield VP0 (VP4 plus VP2), VP3 and VP1. The three polypeptides remain associated as a protomer and five protomers assemble to form a pentamer, so that the five copies of the VP1 form the apex. Finally, 12 pentamers assemble around a molecule of viral RNA to form the icosahedral capsid. As the structure locks into place, most copies of VP0 cleave (presumably autocatalytically) to yield VP2 and VP4. However, in the case of HAV it has not been possible to demonstrate VP4, which is predicted to consist of only 23 amino acids.

The functions of some of the other products of the cleavage of the polyprotein, such as 2B, 2C and 3A, are less well understood. Product 3B corresponds to the genome-linked polypeptide VPg, which in other picornaviruses is the primer for the synthesis of both genome-sense RNA and the negative-sense RNA found in replicative intermediates. Polypeptide 3AB may be the precursor of VPg. Finally, the three-dimensional product seems to be the viral replicase and contains the Gly-Asp-Asp motif common to viral RNA-dependent RNA polymerases.

EPIDEMIOLOGY

Viral hepatitis type A (infectious or epidemic hepatitis) occurs endemically in all parts of the world, with frequent reports of minor and major outbreaks. The exact incidence is difficult to estimate because of the high proportion of subclinical infections and infections without jaundice, because of differences in surveillance and because of differing patterns of disease. The degree of under-reporting is very high.

The development of specific serologic tests for hepatitis A has made possible the study of the incidence and distribution of hepatitis A in various countries. These studies have shown that infections with HAV are widespread and endemic in all parts of the world, that chronic excretion of HAV does not occur and that the infection is rarely transmitted by blood transfusion, although transmission by blood coagulation products has been reported. There is no evidence of progression to chronic liver disease.

The seroprevalence of antibodies to HAV has declined since the Second World War in many countries, and infection results most commonly from person-to-person contact, but large epidemics do occur. For example, an outbreak of hepatitis A in Shanghai in 1988 associated with the consumption of clams resulted in almost 300,000 cases.

TABLE 214-1 -- The hepatitis viruses.

THE HEPATITIS VIRUSES			
Virus	**Description**	**Viral group**	**Mode of transmission**
Hepatitis A virus	Small unenveloped symmetric RNA virus	Hepatovirus, in heparnavirus genus	Fecal-oral
Hepatitis B virus	Enveloped double-stranded DNA virus	Hepadnavirus	Blood-blood
			Sexual
Hepatitis C virus	Enveloped single-stranded RNA virus	Related to flavivirus	Blood-blood
Hepatitis D virus	Circular single-stranded RNA virus	Related to plant viral satellites and viroids	Blood-blood
Hepatitis E virus	Unenveloped single-stranded RNA	Related to calciviruses; closely resembles rubella virus and a plant virus (beet necrotic yellow vein virus)	Fecal contamination of water
			Food-borne

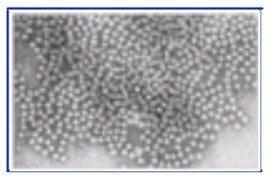

Figure 214-1 Hepatitis A virus. Note the vast number of virus particles present in a fecal extract.

PATHOGENICITY

The incubation period of hepatitis A is 3–5 weeks (Fig. 214.2), with a mean of 28 days. Subclinical and anicteric cases are common and, although the disease

generally has a low mortality rate, patients may be incapacitated for many weeks. There is no evidence of progression to chronic liver damage.

Hepatitis A virus is spread by the fecal-oral route, most commonly by person-to-person contact; infection occurs readily under conditions of poor sanitation and overcrowding. Common source outbreaks are initiated most frequently by fecal contamination of water and food, but water-borne transmission is not a major factor in maintaining this infection in industrialized communities. On the other hand, many outbreaks related to food have been reported. This can be attributed to the shedding of large quantities of virus in the feces by infected food handlers during the incubation period of the illness — the source of the outbreak can often be traced to uncooked food or food that has been handled after cooking. Although hepatitis A remains endemic and common in the developed countries, the infection occurs mainly in small clusters, often with only a few identified cases.

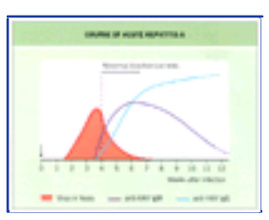

Figure 214-2 Course of acute hepatitis A.

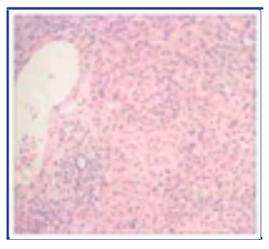

Figure 214-3 Histologic changes in the liver of a patient with acute hepatitis A.

The clinical expression of infection with HAV varies considerably, ranging from subclinical, anicteric, mild illnesses in young children to the full range of symptoms with jaundice in adolescents and adults. The ratio of anicteric to icteric illnesses varies widely, both in individual cases and during outbreaks.

Hepatitis A virus enters the body by ingestion. The virus then spreads, probably by the bloodstream, to the liver, the target organ. Large numbers of virus particles are detectable in feces during the incubation period, beginning as early as 10–14 days after exposure and continuing, in general, until peak elevation of serum amino-transferases. Virus is also detected in feces early in the acute phase of illness but relatively infrequently after the onset of clinical jaundice. Immunoglobulin G antibody to HAV persists and is also detectable late in the incubation period, coinciding approximately with the onset of biochemical evidence of liver damage.

Hepatitis A viral antigen has been localized by immunofluorescence in the cytoplasm of hepatocytes after experimental transmission to chimpanzees. The antigen has not been found in any tissue other than the liver following experimental intravenous inoculation in susceptible nonhuman primates.

Pathologic changes induced by HAV appear only in the liver (Fig. 214.3). These include marked focal activation of sinusoidal lining cells; accumulation of lymphocytes and histiocytes in the parenchyma — these cells often replace hepatocytes that have been lost by cytolytic necrosis, especially in the periportal areas; occasional

coagulative necrosis resulting in the formation of acidophilic bodies; and focal degeneration.

PREVENTION

In areas of high prevalence, most children are infected early in life, and such infections are generally asymptomatic. The later in life that infection occurs, the greater the clinical severity — fewer than 10% of cases of acute hepatitis A in children up to the age of 6 years are icteric, but this increases to 40–50% in the 6- to 14-year-age group, and to 70–80% in adults. Of 115,551 cases of hepatitis A in the USA between 1983 and 1987, only 9% of the cases, but more than 70% of the fatalities, were in those aged over 49 years. It is important, therefore, to protect those at risk because of personal contact with infected people or because of travel to a highly endemic area. Other groups at risk of hepatitis A infection include staff and residents of institutions for the mentally handicapped; day care centers for children; sexually active male homosexuals; intravenous drug abusers; sewage workers; certain groups of health care workers, such as medical students on elective studies in countries where hepatitis A is common; military personnel; and certain low socio-economic groups in defined community settings. Patients with hemophilia should be immunized.

Patients with chronic liver disease, especially if visiting an endemic area, should be immunized against HAV. In some developing countries, the incidence of clinical hepatitis A is increasing as improvements in socio-economic conditions result in infection later in life, and strategies for immunization are yet to be developed and agreed.

Passive immunization

Control of HAV infection is difficult. Because fecal shedding of the virus is at its highest during the late incubation period and the prodromal phase of the illness, strict isolation of cases is not a useful control measure. Spread of HAV is reduced by simple hygienic measures and the sanitary disposal of excreta.

Prevention or attenuation of a clinical illness can be achieved by the intramuscular administration of normal human immunoglobulin that contains at least 100IU/ml of hepatitis A antibody. The dosage should be at least 2IU of hepatitis A antibody per kilo of body weight but in pregnancy or in patients with liver disease this dosage may be doubled (Table 214.2). Immunoglobulin does not always prevent excretion of HAV. The efficacy of passive immunization is based on the presence of hepatitis A antibody in the normal human immunoglobulin, and the minimum titer of antibody required for protection is believed to be about 10IU/l.

Titers of HAV antibody vary among batches of pooled normal human immunoglobulin and the titers are decreasing in batches obtained from pooled plasma of donors in industrialized countries, resulting in clinical cases despite prophylaxis with immunoglobulin.[1] Immunoglobulin

TABLE 214-2 -- Passive immunization with normal human immunoglobulin for travelers to highly endemic areas.

PASSIVE IMMUNIZATION WITH NORMAL HUMAN IMMUNOGLOBULIN FOR TRAVELERS TO HIGHLY ENDEMIC AREAS		
Body weight	**Period of stay less than 3 months**	**Period of stay longer than 3 months**
<55lb (<25kg)	50IU anti-HAV (0.5ml)	100IU anti-HAV (1.0ml)
55–66lb (25–30kg)	100IU anti-HAV (1.0ml)	250IU anti-HAV (2.5ml)
>110lb (>50kg)	200IU anti-HAV (2.0ml)	500IU anti-HAV (5.0ml)

is used most commonly for close personal contacts of patients with hepatitis A and for those exposed to contaminated food. Immunoglobulin has also been used effectively for controlling outbreaks in institutions such as homes for the mentally handicapped and nursery schools. Prophylaxis with immunoglobulin is recommended for people without HAV antibody who are visiting highly endemic areas. After a period of 6 months the administration of immunoglobulin for travelers needs to be repeated, unless it has been demonstrated that the recipient has developed HAV antibodies. Active immunization is recommended, particularly for travelers and for controlling outbreaks, particularly if vaccine is given to all contacts immediately.

Active immunization against hepatitis A

Killed hepatitis A vaccines

The foundations for a hepatitis A vaccine were laid in 1975 by the demonstration that formalin-inactivated virus extracted from the liver of infected marmosets induced protective antibodies in susceptible marmosets on challenge with live virus.[2] Subsequently, HAV was cultivated, after serial passage in marmosets, in a cloned line of fetal rhesus monkey kidney cells, thereby opening the way to the production of hepatitis A vaccines. Later, it was demonstrated that prior adaptation in marmosets was

not a prerequisite to growth of the virus in cell cultures. Several formalin-inactivated hepatitis A vaccines are available, including combined vaccines with hepatitis B vaccine and with typhoid vaccine.

Live attenuated hepatitis A vaccines

The major advantages of live attenuated vaccines (such as the Sabin type of oral poliomyelitis vaccine) include ease of oral administration; relatively low cost, because the virus vaccine strain replicates in the gut; production of both local immunity in the gut and humoral immunity, thereby mimicking natural infection; and the longer term protection afforded.

Disadvantages include the potential of reversion toward virulence, interference with the vaccine strain by other viruses in the gut, relative instability of the vaccine, and shedding of the virus strain in the feces for prolonged periods.

The most extensively studied live attenuated hepatitis A vaccines are based on the CR 326 and HM 175 strains of the virus attenuated by prolonged passage in cell culture.

Two variants of the CR 326 strain have been investigated after passage in marmoset liver in fetal rhesus monkey kidney cells, namely MRC5 and WI-38 cells. Inoculation of susceptible marmosets demonstrated seroconversion, and protection on challenge. Biochemical evidence of liver damage did not occur in susceptible chimpanzees, although a number had histologic evidence of mild hepatitis with the F variant and the vaccine virus was shed in the feces for about 12 weeks before seroconversion. There was no evidence of reversion toward virulence. Studies in human volunteers indicated incomplete attenuation of the F variant, but better results were obtained with the F^1 variant without elevation of liver enzymes.

Studies with the HM 175 strain, which was isolated and passaged in African green monkey kidney cells, showed that this strain was not fully attenuated for marmosets, although it did not induce liver damage on challenge. Further passages and adaptation of HM 175 revealed some evidence of virus replication in the liver of chimpanzees and minimal shedding of the virus into feces. Other studies are in progress in nonhuman primates.

As with vaccine strains of polioviruses, attenuation may be associated with mutations in the 5' noncoding region of the genome, and this affects the secondary structure of the protein compounds. There is also evidence that mutations in the region of the genome encoding the nonstructural polypeptides may be important for adaptation

to cell culture and attenuation. However, markers of attenuation of HAV have not been identified, and reversion to virulence may be a problem. On the other hand, there is also concern that 'over-attenuated' viruses may not be sufficiently immunogenic.

Current candidate live attenuated hepatitis A vaccines require administration by injection. Preparations that may be suitable for oral administration are not available so far.

DIAGNOSTIC MICROBIOLOGY

Various serologic tests are available for HAV, including immune electron microscopy, complement fixation, immune adherence hemagglutination, radioimmunoassay and enzyme immunoassay. Immune adherence hemagglutination, which has been widely used, is moderately specific and sensitive. Several methods of radioimmunoassay have been described, but these have largely been replaced by sensitive enzyme immunoassay techniques.

Only one serotype of HAV has been identified in volunteers infected experimentally with the MS-1 strain of hepatitis A, in patients from different outbreaks of hepatitis in different geographic regions and in random cases of hepatitis A. Several genotypes of the virus are recognized.

Isolation of virus in tissue culture requires prolonged adaptation and it is therefore not suitable for diagnosis.

CLINICAL MANIFESTATIONS

The following description of the acute disease applies to all types of viral hepatitis. Prodromal non-specific symptoms such as fever, chills, headache, fatigue, malaise and aches and pains are followed a few days later by anorexia, nausea, vomiting and right upper quadrant abdominal pain followed by the passage of dark urine and clay-colored stools. Jaundice of the sclera and skin develops. With the appearance of jaundice, there is usually a rapid subjective improvement of symptoms. The jaundice usually deepens for a few days and persists for 1–2 weeks. The feces then darken and the jaundice diminishes over a period of about 2 weeks. Convalescence may be prolonged (see Chapter 48).

HEPATITIS E VIRUS

Retrospective testing of serum samples from patients involved in epidemics of hepatitis associated with fecal contamination of water supplies have indicated that an agent other than HAV or HBV was involved. Epidemics of enterically transmitted non-A, non-B hepatitis in the Indian subcontinent were first reported in 1980, but outbreaks involving tens of thousands of cases have also been documented in the former Soviet Union, South East Asia, northern Africa and Mexico. A huge outbreak occurred in New Delhi in 1956–7, but tests for HAV or HBV were not available then. Infection has been reported in returning travelers.

NATURE

Hepatitis E virus (HEV) is a nonenveloped single-stranded RNA virus that shares many biophysical and biochemical features with caliciviruses.

Morphologically the virus is spherical and unenveloped, measuring 32–34nm in diameter with spikes and indentations visible on the surface of the particle. Confirmation that the virus has been propagated in cell culture is awaited. The virus appears similar to the caliciviruses. However, detailed morphologic studies and the lack of similarities in genome sequence between HEV and recognized caliciviruses suggest that HEV is a single member of a novel virus genus. However, HEV resembles most closely the sequences of rubella virus and a plant virus, beet necrotic yellow vein virus. It has therefore been proposed that these three viruses should be placed in separate but related families.

Genomic organization

Hepatitis E virus was cloned in 1991 and the entire 7.5kb sequence is known. The genome is a single-stranded, positive-sense, polyadenylated RNA molecule, with three overlapping ORFs.

On the basis of the available partial sequence data, it has been suggested that HEV isolates segregate into four major groups based on full-length comparisons. However, more recent studies indicate that HEV may be distributed into at least nine different groups.

EPIDEMIOLOGY

The epidemiologic features of the infection resemble those of hepatitis A. The highest attack rates are found in young adults and high mortality rates of 20–39% have been reported in women infected during the third trimester of pregnancy.[3]

All epidemics of hepatitis E reported to date have been associated with fecal contamination of water, with the exception of a number of food-borne outbreaks in China. Sporadic hepatitis E has been associated with the consumption of uncooked shellfish and has been seen in travelers returning from endemic areas. Hepatitis E virus is an important cause of large epidemics of acute hepatitis, and these, together with a high prevalence of antibody determined by serologic tests, have occurred in the subcontinent of India, South East and central Asia, the Middle East, and northern and western Africa. There have also been outbreaks in eastern Africa and Mexico.

Unexpectedly, the highest prevalence of antibody to HEV is found in young adults and not in infants and children. In some epidemics the antibody has been found more commonly in males, although in most outbreaks the distribution between young adult males and females is equal.

Hepatitis E virus has also been isolated from patients with sporadic acute hepatitis in countries not considered to be endemic for HEV such as the USA, Italy and other European countries and in individuals who had not traveled abroad. There is now evidence that HEV may have an animal reservoir and there are HEV isolates from swine with high sequence identity to human HEV strains isolated from pigs in areas without HEV epidemics. There is recent evidence of a higher prevalence of HEV antibodies among swine farmers, particularly in those with an occupational history of cleaning barns or assisting sows at birth, and also a history of drinking raw milk.

PATHOGENICITY

Virus-like particles have been detected in the feces of infected people by immune electron microscopy using convalescent serum. However, such studies have often proved inconclusive and a large proportion of the excreted virus may be degraded during passage through the gut. Bile was shown to be a rich source. Cross reaction studies between sera and virus in feces associated with a variety of epidemics in several different countries suggest that a single serotype of virus is involved, although two distinct isolates have been recognized and designated as the Burma (B) strain and the Mexico (M) strain. Two other isolates were recently sequenced.

The average incubation period is slightly longer than for HAV, with a mean of 6 weeks.

Studies on HEV have progressed following transmission to susceptible nonhuman primates. Hepatitis E virus was first transmitted to *Cynomolgus* macaques, and a number of other species of monkeys including chimpanzees have also been infected.

PREVENTION

The provision of safe public water supplies, public sanitation and hygiene, safe disposal of feces and raw sewage, and personal hygiene are essential measures.

Passive immunization with immune globulin derived from endemic areas has not been successful. Vaccines are under development.

DIAGNOSTIC MICROBIOLOGY

Serologic tests are necessary to establish the diagnosis. The tests commercially available at present detect anti-HEV IgM in up to 90% of acute infections if serum is obtained 1–4 weeks after the onset of illness, and IgM remains detectable for about 12 weeks. Anti-HEV IgG appears early and reaches a maximum titer 4 weeks after the onset of illness, falling rapidly thereafter.

Tests for HEV RNA by the polymerase chain reaction (PCR) are available in specialized laboratories.

CLINICAL MANIFESTATIONS

Individual cases cannot be differentiated on the basis of clinical features from other cases of hepatitis. In epidemics, most clinical cases will have anorexia, jaundice and hepatomegaly. Serologic tests indicate, however, that clinically inapparent cases occur. The severity of the infection and high mortality during pregnancy have been noted above. Hepatitis E does not progress to chronicity (see Chapter 48).

HEPATITIS B VIRUS

Hepatitis B virus was originally recognized as the agent responsible for 'serum hepatitis', an important and frequent cause of acute and chronic infection of the liver.

NATURE

Hepatitis B virus is a member of the hepadnavirus group, which contains double-stranded DNA viruses that replicate by reverse transcription. Hepatitis B virus is endemic in the human population and hyperendemic in many parts of the world, The virus is transmitted essentially by blood-blood contact and by the sexual route. Mutations of the surface coat protein of the virus and of the core and other proteins have been identified in recent years.[4] [5] [6] [7] [8] [9] [10] Natural hepadnavirus infections also occur in other animals, including woodchucks, beechy ground squirrels and ducks.

Structure and organization of the virus

The hepatitis B virion is a 42nm particle comprising an electron-dense core (nucleocapsid), which is 27nm in diameter, and an outer envelope of the surface protein (hepatitis B surface antigen, HBsAg) embedded in membranous lipid derived from the host cell (Fig. 214.4). The surface antigen, originally referred to as Australia antigen, is produced in excess by the infected hepatocytes and is secreted in the form of 22nm particles and tubular structures of the same diameter.

The 22nm particles are composed of the major surface protein in both nonglycosylated (p4) and glycosylated (gp27) form in approximately equimolar amounts, together with a minority component of the so-called middle proteins (gp33 and gp36), which contain the pre-S2 domain, a glycosylated 55 amino acid amino-terminal extension. The surface of the virion has a similar composition but also contains the large surface proteins (gp39 and gp42), which include both the pre-S1 and pre-S2 regions. These large surface proteins are not found in the 22nm spherical particles (but may be present in the tubular forms in highly viremic people) and their detection in serum

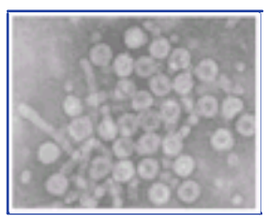

Figure 214-4 Serum from a patient with hepatitis B. The double-shelled particle is the complete virion. Tubular structures and 22nm HBsAg particles are present in small numbers.

correlates with viremia. The domain that binds to the specific HBV receptor on the hepatocyte is believed to reside within the pre-S1 region.

The nucleocapsid of the virion consists of the viral genome surrounded by the core antigen (HBcAg). The genome, which is approximately 3.2kb in length, has an unusual structure and is composed of two linear strands of DNA held in a circular configuration by base-pairing at the 5' ends.

One of the strands is incomplete and the 3' end is associated with a DNA polymerase molecule that is able to complete that strand in the presence of deoxynucleoside triphosphates.

The genomes of more than a dozen isolates of HBV have been cloned and the complete nucleotide sequences determined. Analysis of the coding potential of the genome reveals four ORFs, which are conserved between all of these isolates (Fig. 214.5).

The first ORF encodes the various forms of the surface protein and contains three in-frame methionine codons, which are used for initiation of translation. A second promoter is located upstream of the pre-S1 initiation codon. This directs the synthesis of a 2.1kb mRNA, which is coterminous with the other surface messages and is translated to yield the large (pre-S1) surface proteins.

The core ORF also has two in-phase initiation codons. The 'precore' region is highly conserved, has the properties of a signal sequence and is responsible for the secretion of hepatitis Be antigen (HBeAg).

The third ORF, which is the largest and overlaps the other three, encodes the viral polymerase. This protein appears to be another translation product of the 3.5kb RNA and is synthesized apparently after internal initiation of the ribosome. The amino-terminal domain is believed to be the protein primer for minus strand synthesis. There is then a spacer region followed by the (RNA- and DNA-dependent) DNA polymerase.

The fourth ORF was designated 'x' because the function of its small gene product was not known. However, 'x' has now been demonstrated to be a transcriptional transactivator.

Structure and organization of the virus

There are nine subtypes of HBV, with a common main antigenic determinant, *a.* The nine subtypes described, *ayw*1-*ayw*4, *ayr*, *adw*2, *adw*4, *adrq*$^-$ and *adrq*$^+$, differ in their geographic distribution. Subtyping is employed for epidemiologic studies and to trace nosocomial infection. Traditional subtyping is complemented by classification of different HBV strains into genotypes A–G.

EPIDEMIOLOGY

More than a third of the world's population has been infected with HBV, and the World Health Organization estimates that HBV results in 1,000,000–2,000,000 deaths every year.

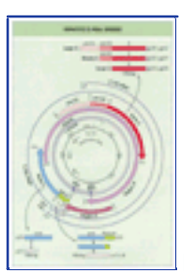

Figure 214-5 Hepatitis B viral genome.

The virus persists in approximately 5–10% of immunocompetent adults and in as many as 90% of infants infected perinatally. Persistent carriage of HBV, defined by the presence of HBsAg in the serum for more than 6 months, has been estimated to affect about 350,000,000 people worldwide.

Although various body fluids (blood, saliva, menstrual and vaginal discharges, serous exudates, seminal fluid and breast milk) have been implicated in the spread of infection, infectivity appears to be especially related to blood and to body fluids contaminated with blood. The epidemiologic propensities of this infection are therefore wide; they include infection by inadequately sterilized syringes and instruments, and transmission by unscreened blood transfusion and blood products, by close

contact and by sexual contact. Transmission of HBV from mother to child may take place — antenatal transmission is rare but perinatal transmission occurs frequently; in some parts of the world (South East Asia and Japan), perinatal transmission is very common.

PATHOGENICITY

The incubation period of hepatitis B is variable, with a range of 1–6 months.

As mentioned above, about 350 million people are carriers of HBV. The pathology is mediated by the cellular immune response of the host to the infected hepatocytes. Long-term continuing virus replication may lead to progression to chronic liver disease, cirrhosis and hepatocellular carcinoma (Fig. 214.6).

In the first phase of chronicity, virus replication continues in the liver and replicative intermediates of the viral genome may be detected in DNA extracted from liver biopsies. Markers of virus replication in serum include HBV DNA, the surface proteins (HBsAg) and a soluble antigen, HBeAg, which is secreted by infected hepatocytes. In those infected at a very young age this phase may persist for life but, more usually, virus levels decline over time. Eventually, in most infected people, there is immune clearance of infected hepatocytes associated with seroconversion from HBeAg to anti-HBe.

During the period of replication, the viral genome may integrate into the chromosomal DNA of some hepatocytes and these cells may persist and expand clonally. Rarely, seroconversion to anti-HBs follows clearance of virus replication but, more frequently, HBsAg persists during a second phase of chronicity as a result of the expression of integrated viral DNA.

Immune responses

Antibody and cell-mediated immune responses to various types of antigens are induced during the infection; however, not all of these are protective and in some instances they may cause autoimmune phenomena that contribute to disease pathogenesis. The immune response to infection with HBV is directed toward at least three antigens: HBsAg, the core antigen and the e antigen. The view that HBV exerts its damaging effect on hepatocytes by direct cytopathic changes is inconsistent with the persistence of large quantities of surface antigen in liver cells of many apparently healthy people who are carriers. Additional evidence suggests that the pathogenesis of liver damage in the course of HBV infection is related to the immune response by the host.

The surface antigen appears in the serum of most patients during the incubation period, 2–8 weeks before biochemical evidence of liver damage or onset of jaundice. The antigen persists during the acute illness and usually clears from the circulation during convalescence. Next to appear in the circulation is the virus-associated DNA polymerase activity, which correlates in time with damage to liver cells as indicated by elevated serum transaminases. The polymerase activity persists for days or weeks in acute cases and for months or years in some persistent carriers. Antibody of the IgM class to the core antigen is found in the serum 2–10 weeks after the surface antigen appears and persists during replication of the virus. Core antibody of the IgG class is detectable for many years after recovery. Finally, antibody to the surface antigen component, anti-HBs, appears.

During the incubation period and during the acute phase of the illness, surface antigen-antibody complexes may be found in the serum of some patients. Immune complexes have been found by electron microscopy in the serum of all patients with fulminant hepatitis, but are seen only infrequently in nonfulminant infection. Immune complexes are also important in the pathogenesis of other disease syndromes characterized by severe damage of blood vessels (e.g. polyarteritis nodosa, some forms of chronic glomerulonephritis and infantile papular acrodermatitis).

Immune complexes have been identified in variable proportions of patients with virtually all the recognized chronic sequelae of acute hepatitis B. Deposits of such immune complexes have also been demonstrated in the cytoplasm and plasma membrane of hepatocytes and on or in the nuclei; the reason why only a small proportion of patients with circulating complexes develop vasculitis or polyarteritis is, however, not clear. Perhaps complexes are critical pathogenic factors only if they are of a particular size and of a certain antigen-antibody ratio.

Figure 214-6 Possible consequences of hepatitis B virus infection in an adult.

Cellular immune responses are known to be particularly important in determining the clinical features and course of viral infections. The occurrence of cell-mediated immunity to HBV antigens has been demonstrated in most patients during the acute phase of hepatitis B and in a significant proportion of patients with surface-antigen-positive chronic active hepatitis, but not in asymptomatic persistent HBV carriers. These observations suggest that cell-mediated immunity may be important in terminating the infection and, in certain circumstances, in promoting liver damage and in the genesis of autoimmunity. Evidence also suggests that progressive liver damage may result from an autoimmune reaction directed against hepatocyte membrane antigens, initiated in many cases by infection with HBV.

Hepatitis B virus and hepatocellular carcinoma

When tests for HBsAg became widely available, regions of the world where the chronic carrier state is common were found to be coincident with those where there is a high prevalence of primary liver cancer (Fig. 214.7). Furthermore, in these areas, patients with this tumor are almost invariably seropositive for HBsAg. A prospective study in Taiwan revealed that 184 cases of hepatocellular carcinoma occurred in 3454 carriers of HBsAg at the start of the study, but only 10 such tumors arose in the 19,253 control males who were HBsAg-negative.[11]

Other case-control and cohort studies and laboratory investigations indicate that there is a consistent and specific causal association between HBV and hepatocellular carcinoma and that up to 80% of such cancers are attributable to this virus. Hepatitis B is thus second

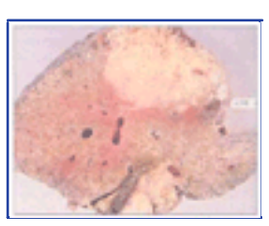

Figure 214-7 Hepatocellular carcinoma.

only to tobacco among the known human carcinogens.[12] Primary liver cancer is the seventh most common cancer in males and the ninth most common in females. Hepatocellular carcinoma is one of the three most common causes of cancer deaths in males in east and South East Asia, the Pacific Basin and sub-Saharan Africa.

Southern hybridization of tumor DNA yields evidence of chromosomal integration of viral sequences in at least 80% of hepatocellular carcinomas from HBsAg carriers. There is no similarity in the pattern of integration between different tumors, and variation is seen both in the integration sites and in the number of copies or partial copies of the viral genome. Sequence analysis of the integrants reveals that the direct repeats in the viral genome often lie close to the virus-cell junctions, suggesting that sequences around the ends of the viral genome may be involved in recombination with host DNA. Integration seems to involve microdeletion of host sequences, and rearrangements and deletions of part of the viral genome also may occur. When an intact surface gene is present, the tumor cells may produce and secrete HBsAg in the form of 22nm particles. Production of HBcAg by tumors is rare, however, and the core ORF is often incomplete, and modifications such as methylation may also modulate its expression. Cytotoxic T lymphocytes targeted against core gene products on the hepatocyte surface seem to be the major mechanism of clearance of infected cells from the liver. Thus, there may be immune selection of cells with integrated viral DNA that are incapable of expressing HBcAg.

The mechanisms of oncogenesis by HBV remain uncertain. Hepatitis B virus may act non-specifically by stimulating active regeneration and cirrhosis, which may be associated with chronicity. However, HBV-associated tumors arise occasionally in the absence of cirrhosis, and such hypotheses do not explain the frequent finding of integrated viral DNA in tumors. In rare instances, the viral genome has been found to be integrated into cellular genes such as cyclin A and a retinoic acid receptor. Translocations and other chromosomal rearrangements have also been observed. Although insertional mutagenesis of HBV remains an attractive hypothesis to explain

its oncogenicity, there is insufficient supportive evidence.

Like many other cancers, the development of hepatocellular carcinoma is likely to be a multifactorial process. The clonal expansion of cells with integrated viral DNA seems to be an early stage in this process, and such clones may accumulate in the liver throughout the period of active virus replication. In areas where the prevalence of primary liver cancer is high, virus infection usually occurs at an early

---

age and virus replication may be prolonged, although the peak incidence of tumor is many years after the initial infection.

PREVENTION

The discovery of variation in the epitopes presented on the surface of the virions and subviral particles identified several subtypes of HBV, which differ in their geographic distribution. All isolates of the virus share a common epitope — *a.* This epitope is a domain of the major surface protein, which is believed to protrude as a double loop from the surface of the particle. Two other pairs of mutually exclusive antigenic determinants — *d* or *y* and *w* or *r* — are also present on the major surface protein. These variations have been correlated with single nucleotide changes in the surface ORF, which lead to variation in single amino acids in the protein. Four principal subtypes of HBV are recognized: *adw*, *adr*, *ayw* and *ayr.* Subtype *adw* predominates in northern Europe, the Americas and Australasia, and it is also found in Africa and Asia. Subtype *ayw* is found in the Mediterranean region, eastern Europe, northern and western Africa, the Middle East and the Indian subcontinent. In the Far East, subtype *adr* predominates, but the rarer subtype *ayr* is occasionally found in Japan and Papua New Guinea.

Passive immunization

Hepatitis B immunoglobulin (HBIG) is prepared specifically from pooled plasma with high titer of hepatitis B surface antibody and may confer temporary passive immunity under certain defined conditions. The major indication for the administration of HBIG is a single acute exposure to HBV, such as occurs when blood containing surface antigen is inoculated, ingested or splashed on mucous membranes and the conjunctiva. The optimal dose has not been established but doses in the range of 250–500IU have been used effectively. It should be administered as early as possible after exposure and preferably within 48 hours. The dose is usually 3ml (200IU/ml) in adults. The first dose should not be administered after 7 days following exposure. It is generally recommended that two doses of HBIG should be given 30 days apart.

Results with the use of HBIG for prophylaxis in neonates at risk of infection with HBV are encouraging if the immunoglobulin is given as soon as possible after birth or within 12 hours of birth, and the chance of the baby developing the persistent carrier state is reduced by about 70%. More recent studies using combined passive and active immunization indicate an efficacy approaching 90%. The dose of HBIG recommended in the newborn is 1–2ml (200IU/ml).

Active immunization

The major response of recipients of hepatitis B vaccine is to the common *a* epitope with consequent protection against all subtypes of the virus. First-generation vaccines were prepared from 22nm HBsAg particles purified from plasma donations from chronic carriers. These preparations are safe and immunogenic but have been superseded in some countries by recombinant vaccines produced by the expression of HBsAg in yeast cells. The expression plasmid contains only the 3' portion of the HBV surface ORF, and only the major surface protein, without pre-S epitopes, is produced. Vaccines containing pre-S2 and pre-S1, as well as the major surface proteins expressed by recombinant DNA technology, are undergoing clinical trials.

In many areas of the world with a high prevalence of HBsAg carriage, such as China and South East Asia, the predominant route of transmission is perinatal. Although HBV does not usually cross the placenta, the infants of viremic mothers have a very high risk of infection at the time of birth.

Administration of a course of vaccine with the first dose immediately after birth is effective in preventing transmission from an HBeAg-positive mother in approximately 70% of cases and this protective efficacy rate may be increased to greater than 90% if the vaccine is accompanied by the simultaneous administration of HBIG.

Immunization against HBV is now recognized as a high priority in preventive medicine in all countries and strategies for immunization are being revised. Universal vaccination of infants and adolescents is under examination as a possible strategy to control the transmission of this infection. More than 150 countries now offer universal hepatitis B vaccine, including the USA, Canada and most western European countries.[13]

In a number of countries with a low prevalence of hepatitis B, immunization against HBV is recommended only to groups that are at an increased risk of acquiring this infection. These groups include people requiring repeated transfusions of blood or blood products, people undergoing prolonged inpatient treatment, patients who require frequent tissue penetration or need repeated circulatory access, patients with natural or acquired immune deficiency, and patients with malignant diseases. Viral hepatitis is an occupational hazard among health care personnel and the staff of institutions for the mentally retarded and some semiclosed institutions. High rates of infection with HBV occur in narcotic drug addicts and intravenous drug abusers, sexually active male homosexuals and prostitutes. People working in highly endemic areas are at an increased risk of infection and should be immunized. Young infants, children and susceptible people (including travelers) living in certain tropical and subtropical areas where socio-economic conditions are poor and the prevalence of hepatitis B is high should also be immunized. It should be noted that, in about 30% of patients with hepatitis B, the mode of infection is not known — this is a powerful argument in favor of universal immunization.

Site of injection for vaccination and antibody response

Hepatitis B vaccination should be given in the upper arm or the anterolateral aspect of the thigh and not in the buttock. There are over 100 reports of unexpectedly low antibody seroconversion rates after hepatitis B vaccination using injection into the buttock. In one center in the USA a low antibody response was noted in 54% of healthy adult health care personnel. Many studies have since shown that the antibody response rate is significantly higher in centers using deltoid injection than centers using the buttock. On the basis of antibody tests after vaccination, the Advisory Committee on Immunization Practices of the Centers of Disease Control and Prevention in the USA recommended that the arm be used as the site for hepatitis B vaccination in adults, as has the Department of Health in the UK.

These observations have important public health implications, well illustrated by the estimate that about 20% of the 60,000 people immunized against HBV in the buttock in the USA by March 1985 had failed to attain a minimum level of antibody of 10IU/l and were therefore not protected.

Hepatitis B surface antibody titers should be measured in all people who have been immunized against HBV by injection in the buttock, and when this is not possible a complete course of three injections of vaccine should be administered into the deltoid muscle or the anterolateral aspect of the thigh, the only acceptable sites for HBV immunization.[14]

Apart from the site of injection there are several other factors that are associated with a poor antibody response or no antibody response to currently licensed vaccines. Indeed, all studies of antibody response to plasma-derived HBV vaccines and HBV vaccines prepared by recombinant DNA technology have shown that 5–10% or more of healthy immunocompetent subjects do not mount an antibody response (anti-HBs) to the surface antigen component (HBsAg) present in these preparations (i.e. they are nonresponders) or that

---

they respond poorly (i.e. they are hyporesponders). The exact proportions of each group depends partly on the definition of nonresponsiveness and hyporesponsiveness; the usual definitions are a level of less than 10IU/l for nonresponders and 100IU/l for hyporesponders, measured against an international antibody standard.

Hepatitis B surface antibody escape mutants

Production of antibodies to the group antigenic determinant *a* mediates cross-protection against all subtypes, as has been demonstrated by challenge with a second subtype of the virus following recovery from an initial experimental infection. The epitope *a* is located in the region of amino acids 124–148 of the major surface protein and appears to have a double-loop conformation. A monoclonal antibody that recognizes a region within this *a* epitope is capable of neutralizing the infectivity of HBV for chimpanzees, and competitive inhibition assays using the same monoclonal antibody demonstrate that equivalent antibodies are present in the sera of subjects

immunized with either plasma-derived or recombinant HBV vaccine.

During a study of the immunogenicity and efficacy of HBV vaccines in Italy, a number of people who had apparently mounted a successful immune response and became anti-HBs-positive, later became infected with HBV. These cases were characterized by the co-existence of noncomplexed anti-HBs and HBsAg, and in 32 of 44 vaccinated subjects there were other markers of HBV infection.

Furthermore, analysis of the antigen using monoclonal antibodies suggested that the *a* epitope was either absent or masked by antibody. Subsequent sequence analysis of the virus from one of these cases revealed a mutation in the nucleotide sequence encoding the *a* epitope, the consequence of which was a substitution of arginine for glycine at amino acid position 145.[6]

There is now considerable evidence for a wide geographic distribution of the point mutation in HBV from guanosine to adenosine at position 587, resulting in an amino acid substitution at position 145 from glycine to arginine in the highly antigenic group determinant *a* of the surface antigen. This is a stable mutation that has been found in viral isolates from children and adults. It has been described in Italy, Singapore, Japan, Brunei, Taiwan, Hong Kong, India, Germany and the USA;[7] from liver transplant recipients with hepatitis B in the USA, Germany and the UK who had been treated with specific hepatitis B immunoglobulin or humanized hepatitis B monoclonal antibody; and in patients with chronic hepatitis in Japan[8] and elsewhere.

The region in which this mutation occurs is an important virus epitope to which vaccine-induced neutralizing antibody binds, as discussed above, and the mutant virus is not neutralized by antibody to this specificity. It can replicate as a competent virus, implying that the amino acid substitution does not alter the attachment of the virus to the liver cell. Variants of HBV with altered antigenicity of the envelope protein show that HBV is not as antigenically singular as previously believed and that humoral escape mutation can occur in vivo. This finding gives rise to two causes for concern: failure to detect HBsAg may lead to transmission through donated blood or organs, and HBV may infect people who are anti-HBs-positive after immunization. Variation in the second loop of the *a* determinant seems especially important.

Hepatitis B virus precore mutants

The nucleotide sequence of the genome of a strain of HBV cloned from the serum of a naturally infected chimpanzee has been reported.[9] A surprising feature was a point mutation in the penultimate codon of the precore region, which changed the tryptophan codon (TGG) to an amber termination codon (TAG). The nucleotide sequence of the HBV precore region from a number of anti-HBe-positive Greek patients was investigated by direct sequencing PCR-amplified HBV DNA from serum.[10] An identical mutation of the penultimate codon of the precore region to a termination codon was found in 7 of 8 anti-HBe-positive patients who were positive for HBV DNA in serum by hybridization. In most cases there was an additional mutation in the proceeding codon.

Similar variants were found by amplification of HBV DNA from serum from anti-HBe-positive patients in Italy and Greece. These variants are not confined to the Mediterranean region; the same nonsense mutation (without a second mutation in the adjacent codon) has been observed in patients from Japan and elsewhere, along with rarer examples of defective precore regions caused by frameshifts or loss of the initiation codon for the precore region.

Some precore variants may be more pathogenic than the wild-type virus because in many patients with severe chronic liver disease precore variants are found.

DIAGNOSTIC MICROBIOLOGY

Direct demonstration of virus in serum samples is feasible by visualizing the virus particles by electron microscopy, by detecting virus-associated DNA polymerase, by assay of viral DNA and by amplification of viral DNA by various techniques. All these direct techniques are often impractical in the general diagnostic laboratory, and specific diagnosis must therefore rely on serologic tests (Table 214.3).

Hepatitis B surface antigen first appears during the late stages of the incubation period and is easily detectable by radioimmunoassay or enzyme immunoassay. Enzyme immunoassay is specific and highly sensitive and is used widely in preference to radioisotope methods. The antigen persists during the acute phase of the disease and sharply decreases when antibody to the surface antigen becomes detectable. Antibody of the IgM class to the core antigen is found in the serum after the onset of the clinical symptoms and slowly declines after recovery. Its persistence at high titer suggests continuation of the infection. Core antibody of the IgG class persists for many years and provides evidence of past infection.

TABLE 214-3 -- Interpretation of results of serologic tests for hepatitis B virus.

INTERPRETATION OF RESULTS OF SEROLOGIC TESTS FOR HEPATITIS B						
			Anti-HBc			
HBsAg	**HBeAg**	**Anti-HBe**	**IgM**	**IgG**	**Anti-HBs**	**Interpretation**
+	+	-	-	-	-	Incubation period
+	+	-	+	+	-	Acute hepatitis B or persistent carrier state
+	+	-	-	+	-	Persistent carrier state
+	-	+	±	+	-	Persistent carrier state
-	-	+	±	+	+	Convalescence
-	-	-	-	+	+	Recovery
-	-	-	+	-	-	Infection with HBV without detectable HBsAg
-	-	-	-	+	-	Recovery with loss of detectable anti-HBs
-	-	-	-	-	+	Immunization without or recovery from infection with loss of detectable anti-HBc

CLINICAL MANIFESTATIONS

The clinical features of acute infection resemble those of the other viral hepatitides. Acute hepatitis B is frequently anicteric and asymptomatic, although a severe illness with jaundice can occur and occasionally acute liver failure may develop.

Hepatitis A and E viruses do not persist in the liver and there is no evidence of progression to chronic liver damage. Hepatitis B, with or without its satellite hepatitis D, and hepatitis C may be associated with persistent infection, a prolonged carrier state and progression to chronic liver disease, which may be severe. There is an etiologic association between hepatitis B and C viruses and hepatocellular carcinoma. GB virus C (GBV-C) tends to cause persistent infection and further studies are required (see Chapter 48).

HEPATITIS D VIRUS

This virus requires hepadnavirus helper functions for propagation in hepatocytes and is an important cause of acute and severe chronic liver damage in some regions of the world.

NATURE

Hepatitis D virus (HDV) is an unusual single-stranded circular RNA virus with a number of similarities to certain plant viral satellites and viroids.

Delta hepatitis[15] was first recognized following detection of a novel protein, d-antigen (hepatitis D antigen, HDAg), by immunofluorescent staining in the nuclei of hepatocytes from patients with chronic active hepatitis B. Hepatitis D virus is now known to require a helper function of HBV for its transmission. The virus is coated with HBsAg, which is needed for release of the HDV from the host hepatocyte and for entry in the next round of infection.

Two forms of HDV infection are known. In the first form, a susceptible person is co-infected with HBV and HDV, often leading to a more severe form of acute hepatitis caused by HBV. In the second form, a person who is chronically infected with HBV becomes superinfected with HDV. This may cause a second episode of clinical hepatitis and accelerate the course of the chronic liver disease, or cause overt disease in asymptomatic HBsAg carriers. Hepatitis D virus itself seems to be cytopathic and HDAg may be directly cytotoxic.

The HDV particle is approximately 36nm in diameter. It is composed of an RNA genome associated with HDAg, surrounded by an envelope of HBsAg. The HDV genome is a closed circular RNA molecule of 1679 nucleotides and resembles those of the satellite viroids and virusoids of plants, and similarly seems to be replicated by the host RNA polymerase II with autocatalytic cleavage and circularization of the progeny genomes by way of *trans*-esterification reactions (ribozyme activity). Consensus sequences of viroids that are believed to be involved in these processes also are conserved in HDV.[16]

EPIDEMIOLOGY

Hepatitis D is common in some areas of the world with a high prevalence of HBV infection, particularly Italy and other countries bordering the Mediterranean; eastern Europe, particularly Romania; the Middle East; the former Soviet Union; South America, particularly the Amazon basin, Venezuela, Columbia (*hepatitis de Sierra Nevada de Santa Marta*), Brazil (labrea black fever) and Peru; and parts of Africa, particularly western Africa. Antibody to HDV has been found in most countries, commonly among intravenous drug abusers, patients with hemophilia and those requiring treatment by blood and blood products. It has been estimated that 5% of HBsAg carriers worldwide (approximately 18,000,000 people) are infected with HDV. In areas of low prevalence of HBV, those at risk of hepatitis B, particularly intravenous drug abusers, are also at risk of hepatitis D.

The ratio of clinical to subclinical cases of HDV and superinfection is not known. However, the general severity of both forms of infection suggests that most cases are clinically significant. A low persistence of infection occurs in 1–3% of acute infections and in 80% or more of cases of superinfection in chronic HBV carriers. The mortality rate is high, particularly in the case of superinfection, and ranges from 2% to 20%.

PATHOGENICITY

Hepatitis B virus provides a helper function to HDV, which is a defective virus. The histopathologic pattern in the liver is suggestive of a direct cytopathic effect.

Pathologic changes are limited to the liver and histologic changes are those of acute and chronic hepatitis with no particular distinguishing features apart from severity and, in tropical areas in particular, microvesicular steatosis.

It should be noted, however, that the virus was discovered by specific nuclear fluorescence in hepatocytes of patients with chronic hepatitis B.

The modes of transmission are similar to the parenteral transmission of HBV.

PREVENTION

Prevention and control for HDV are similar to those for HBV. Immunization against HBV protects against HDV. The difficulty is protection against superinfection of the many millions of established carriers of HBV. Studies are in progress to determine whether specific immunization against HDV based on HDAg is feasible.

DIAGNOSTIC MICROBIOLOGY

Laboratory diagnosis in acute infection is based on specific serologic tests for anti-HDV IgM or HDV-RNA or HDAg in serum. Acute infection is usually self-limiting and markers of HDV infection often disappear within a few weeks.

Superinfection with HDV in chronic hepatitis B may lead to suppression of HBV markers during the acute phase. Chronic infection with HDV (and HBV) is the usual outcome in nonfulminant disease.

CLINICAL MANIFESTATIONS

The clinical features of hepatitis D are identical to those of hepatitis A (see above). For further manifestations see Chapter 48 .

HEPATITIS C VIRUS

NATURE

Hepatitis C virus (HCV) is an enveloped single-stranded RNA virus that appears to be distantly related (possibly in its evolution) to flaviviruses, although HCV is not transmitted by arthropod vectors.

Hepatitis C virus is unusual because it was identified using molecular methods rather than a conventional virologic approach. Transmission studies in chimpanzees established that the main agent of parenterally acquired non-A, non-B hepatitis was likely to be an enveloped virus some 30–60nm in diameter. Using infected chimpanzee plasma as a starting point, complementary DNA was used to create a library which was screened using serum from a patient with chronic non-A, non-B hepatitis. This approach led to the detection of

a clone that was found to bind to antibodies present in the serum of several patients infected with non-A, non-B hepatitis. Eventually, clones covering the entire viral genome were assembled and the complete nucleotide sequence determined.[17]

Properties of hepatitis C virus

The genome of HCV resembles those of the pestiviruses and flaviviruses in that it comprises around 10,000 nucleotides of positivesense RNA, lacks a 3' poly-A tract and has a similar gene organization. It has been proposed that HCV should be the prototype of a third genus in the family Flaviviridae. All these genomes contain a single large ORF, which is translated to yield a polyprotein (of around 3000 amino acids in the case of HCV) from which the viral proteins are derived by post-translational cleavage and other modifications.

The amino acid sequence of the nucleocapsid protein seems to be highly conserved among different isolates of HCV. The next domain in the polyprotein also has a signal sequence at its carboxyl-terminus and may be processed in a similar fashion. The product is a glycoprotein that is probably found in the viral envelope and is variably termed E1/S or gp35. The third domain may be cleaved by a protease within the viral polyprotein to yield what is probably a second surface glycoprotein, E2/NS1 or gp70. These glycoproteins have not been found in vivo and the molecular sizes have been estimated from sequence data and expression studies in vitro.

Other post-translational modifications, including further proteolytic cleavages, are possible. These proteins are the focus of considerable interest because of their potential use in tests for the direct detection of viral proteins and for HCV vaccines. Nucleotide sequencing studies reveal that both domains contain hypervariable regions. It is possible that this divergence has been driven by antibody selection pressure and that these regions specify important immunogenic epitopes.

The nonstructural region of the HCV genome is divided into regions NS2 to NS5 (Fig. 214.8). In the flaviviruses, NS3 has two functional domains: a protease, which is involved in cleavage of the non-structural region of the polyprotein, and a helicase, which is presumably involved in RNA replication. Motifs within this region of the HCV genome have homology to the appropriate consensus sequences, suggesting similar functions. NS5 seems to be the replicase and contains the Gly-Asp-Asp motif common to viral RNA-dependent RNA polymerases.

Hepatitis C virus consists of a family of highly related but nevertheless distinct genotypes — presently numbering six — and various subtypes with differing geographic distribution and a complex nomenclature. The C, NS3 and NS4 domains are the most highly conserved regions of the genome and therefore these proteins are the most suitable for use as capture antigens for broadly reactive tests for antibodies to HCV. The sequence differences observed between HCV groups suggest that virus-host interactions may be

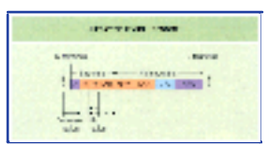

Figure 214-8 Hepatitis C viral genome.

different, which could result in differences in pathogenicity and in response to antiviral therapy.

It is important, therefore, to develop group-specific and virus-specific tests. The degree of divergence that is apparent within the viral envelope proteins implies the absence of a broad cross-neutralizing antibody response to infection by viruses of different groups.

In addition to the sequence diversity observed between HCV groups, there is considerable sequence heterogeneity among almost all HCV isolates in the amino-terminal region of E2-NS1, implying that this region may be under strong immune selection. Indeed, sequence changes within this region may occur during the evolution of disease in individual patients and may play an important role in progression to chronicity.

EPIDEMIOLOGY

Infection with HCV occurs throughout the world. Much of the seroprevalence data are based on blood donors, who represent a carefully selected population. The prevalence of antibodies to HCV in blood donors varies from 0.02% to 1.25% in different countries. Higher rates have been found in southern Italy, Spain, central Europe, Japan and parts of the Middle East, with as many as 19% in Egyptian blood donors. Until screening of blood donors was introduced, hepatitis C accounted for the vast majority of non-A, non-B post-transfusion hepatitis. However, it is clear that, although blood transfusion and the transfusion of blood products are efficient routes of transmission of HCV, these represent a small proportion of cases of acute clinical hepatitis in the USA and a number of other countries (with the exception of patients with hemophilia). Current data indicate that in some 50% of patients in industrialized countries, the source of infection cannot be identified, although 35% of patients have a history of intravenous drug use, and occupational exposure in the health care setting accounts for about 2% of cases. Household contact and sexual exposure do not appear to be major factors in the epidemiology of this common infection. Transmission of HCV from mother to infant occurs in about 10% of viremic mothers and the risk appears to be related to the level of viremia. The possibility of transmission in utero is also being investigated.

PREVENTION

Difficulties in vaccine development include the sequence diversity between viral genotypes and the substantial sequence heterogeneity among isolates in the amino-terminal region of E2-NS1. Neutralizing antibodies have not been clearly defined. The virus has not been cultivated in vitro to permit the development of inactivated or attenuated vaccines (compared with yellow fever vaccines). Much work is in progress employing recombinant DNA techniques.

DIAGNOSTIC MICROBIOLOGY

Successful cloning of portions of the viral genome have permitted the development of new diagnostic tests for infection by the virus. Because the antigen was originally detected by antibodies in the serum of an infected patient it was an obvious candidate as the basis of an enzyme-linked immunosorbent assay (ELISA) to detect anti-HCV antibodies. A larger clone, C100, was assembled from a number of overlapping clones and expressed in yeast as a fusion protein using human superoxide dismutase sequences to facilitate expression. This fusion protein formed the basis of first generation tests for HCV infection.

It is now known that antibodies to C100 are detected relatively late after acute infection. Furthermore, the first generation ELISAs were associated with a high rate of false-positive reactions when applied to low-incidence populations and there were further problems with

some retrospective studies on stored sera. Second-generation tests include antigens from the nucleocapsid and nonstructural regions of the genome. The former antigen (C22) is particularly useful and antibodies to the HCV core protein appear relatively early in the course of infection.

Positive reactions by ELISA require confirmation by supplementary testing using, for example, a recombinant immunoblot assay. Nevertheless, indeterminant results obtained by ELISA represent a significant problem that need resolution. It should also be noted that the time for seroconversion is variable, and that when it can be measured more precisely (e.g. after transfusion) it is generally 7–31 weeks.

The presence of antibodies to specific antigen components is variable and may or may not reflect viremia and, in the case of interferon treatment, a correlation between response and loss of specific antibodies to the E2 component.

Detection and monitoring of viremia are important for management and treatment. Sensitive techniques are available for the measurement of HCV RNA based on reverse-transcription (RT)-PCR amplification, nested PCR, signal amplification using branched DNA analytes and others.

The identification of specific types and subtypes is becoming increasingly important, with observations suggesting that there is an association between response to interferon and particular genotypes and that different types may differ in their pathogenicity.

CLINICAL MANIFESTATIONS

Most acute infections are asymptomatic, and about 20% of acute infections cause jaundice. Fulminant hepatitis has been described. Extrahepatic manifestations include mixed cryoglobulinemia, membranous proliferative glomerulonephritis and porphyria cutanea tarda (see Chapter 48).

Current data suggest that about 80% of infections with HCV progress to chronicity. Histologic examination of liver biopsies from asymptomatic HCV carriers (among blood donors) has revealed none with normal histology; indeed up to 70% have been found to have chronic active hepatitis, cirrhosis, or both (Fig 214.9 and Fig 214.10). Whether the virus is cytopathic or whether there is an

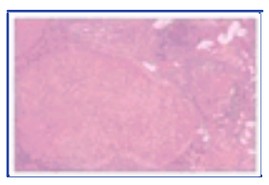

Figure 214-9 Hepatitis C virus active cirrhosis.

Figure 214-10 Acute hepatitis C.

immunopathologic element remains unclear. Infection with HCV is also associated with progression to primary liver cancer. For example, in Japan, where the incidence of hepatocellular carcinoma has been increasing despite a decrease in the prevalence of HBsAg, HCV is now believed to be a major risk factor.

OTHER HEPATITIS VIRUSES

Virus-like particles (referred to by some as candidate hepatitis F virus) have been identified by electron microscopy in the livers and grafts in a subset of British patients with sporadic fulminant hepatitis in whom liver failure recurred about 7 days after grafting.[18] However, subsequent intensive search by advanced molecular techniques have failed to identify a candidate viral agent.

About 30 years ago, a series of transmission studies of human viral hepatitis were initiated in small South American tamarins or marmosets, which were chosen because their very limited contact with humans implied that they were unlikely to have been infected with human viruses.[19]

Serum obtained on the third day of jaundice from a young surgeon (GB) induced hepatitis in each of four inoculated marmosets and was passaged serially in these animals. These important observations remained controversial until the recent application of modern molecular virologic techniques.[20] Preliminary results indicate the identification of two independent viruses, GB virus A (GBV-A) and GB virus B (GBV-B), in the infectious plasma of tamarins inoculated with GB.[21]

GB virus A does not replicate in the liver of tamarins, whereas GBV-B causes hepatitis. Cross-challenge experiments showed that infection with the original infectious tamarin inoculum conferred protection from reinfection with GBV-B but not GBV-A. A third virus, GBV-C, was subsequently isolated from a human specimen that was immunoreactive with a GBV-B protein. GB virus C RNA was found in several patients with clinical hepatitis and was shown to have substantial sequence identity to GBV-A.

A series of studies, including phylogenetic analysis of genomic sequences, showed that GBV-A, GBV-B and GBV-C are not genotypes of HCV and that GBV-A and GBV-C are closely related. GBV-A-GBV-C, GBV-B and HCV are members of distinct viral groups. The organization of the genes of the GBV-A, GBV-B and GBV-C genomes shows that they are related to other positive-strand RNA viruses with local regions of sequence identity with various flaviviruses. The three GB viruses and HCV share only limited overall amino acid sequence identity.[22]

Serologic reagents were prepared with recombinant antigens and limited testing for antibodies and by RT-PCR for specific RNA was carried out in groups of patients, blood donors and other selected people — patients with non-A,B,C,D,E hepatitis, multitransfused patients, intravenous drug abusers and other populations with a high incidence of viral hepatitis. Preliminary studies indicated the presence of antibody to each of the GB viruses in 3–14% of these people. The development and availability of specific diagnostic reagents will establish the epidemiology of these newly identified viruses, their pathogenic significance in humans, and their clinical and public health importance. It should be noted that the virus identified more recently as hepatitis G (HGV) as a new transfusion transmitted agent[23] is now believed to be identical to GBV-C. [24]

The blood-borne nature of GBV-C/HGV has been clearly demonstrated and there is evidence that the virus persists. The association of the virus with liver damage is illustrated by raised levels of alanine transaminase and detectable HGV RNA in a number of patients. However, 40–90% of viremic subjects have normal alanine transaminase levels. In a significant proportion of patients there is co-infection with HBV, HCV, or both. The primary manifestations of

GBV-C/HGV infection may be extrahepatic or hepatic and these may be the result of co-infection with the hepatitis viruses or an (as yet unidentified) hepatotropic agent. The development of sensitive and specific serologic tests for GBV-C/HGV and the application of modern virologic techniques and histologic studies where appropriate will determine the clinical significance of this newly identified virus, which at present appears to be a virus in search of a disease.[25]

A novel human virus was isolated in Japan in 1997 from the serum of a patient with post-transfusion hepatitis and was designated TT virus (TTV) after the initials of the patient (TTV is not an acronym for transfusion-transmitted virus as has been assumed and perpetuated in numerous publications). The virus has a circular single strand DNA, non-enveloped, of negative polarity and is 3965 nucleotides in length. There is 30% diversity in the coding region accounting for numerous genotypes believed to result mainly from recombination. The virus replicates in many tissues, particularly the liver, and is shed into the blood and feces. TT virus DNA is found in saliva (78%), breast milk, semen (60%), cervical swabs and other body fluids of infected persons. The virus is ubiquitous and is found in 20% to more than 90% of the general population and healthy blood donors. There is no evidence of involvement of TTV in acute or chronic liver disease. TT virus is found in farm animals, including chickens (19%), cows (25%), pigs (20%) and sheep (30%), and in other mammals including nonhuman primates.

TTV-like mini virus (TLMV) and several related viruses such as SANBAN, YONBAN and others have been described, but without any disease association in humans. These different viruses have been divided into at least 29 genotypes with sequence divergence of more than 30% from each other and placed into four phylogenetic groups. Since 1999, much attention has been devoted to the SEN virus (again the initials of a patient infected with a virus possibly related to TTV). The SEN virus (SENV) was isolated from an immunocompromised HIV patient with post-transfusion hepatitis of unknown etiology. Eight genotypes of this virus have been described (SENV-A to SENV-H), each differing by at least 25% in nucleotide sequence. SENV-C, SENV-D and SENV-H are supposedly associated with transfusion hepatitis and, although the prevalence of these viruses is common in patients with non-A-E liver disease, a causal association has not been demonstrated and these should not be considered at present as candidate hepatitis viruses.[26]

MANAGEMENT

Although a substantial number of antiviral compounds have been evaluated for the treatment of chronic hepatitis B, interferon-a has been licensed in treatment. Under optimal conditions of careful selection of patients, 30–50% respond at least transiently and about 20% clear the virus, accompanied by improvement in liver function. Combination therapy with nucleoside analogues and other drugs have shown a variable response. Lamivudine and famciclovir are valuable for treatment of hepatitis B chronic liver disease. A comparison of prednisone withdrawal followed by treatment with interferon only did not provide evidence of added benefit for the combined regimen.

Interferon-a is also the only drug approved for the treatment of chronic hepatitis C. Again, the efficacy of interferon is limited in suitable patients, and 15–20% of patients will have a sustained virologic response. Pegylated interferon appears to be more effective, and combination therapy with ribavirin is now regarded as standard of care.

For a more detailed discussion of the management of hepatitis, see Chapter 48 and Chapter 207 .

NATURE

Taxonomy

The herpesviruses comprise a large family of DNA viruses[1] with over 150 individual members. They have been found in almost all species (both vertebrate and invertebrate) in which they have been actively sought. Their widespread occurrence suggests that they first colonized animal species at an early stage of evolution[2] and this ancient colonization has led to adaptation to their natural host so that they are generally highly host specific. This adaption is further exemplified by their high rates of infection (the prevalence of positive serology in adult populations worldwide is 80–90%), the generally mild symptoms associated with primary infection and their strategy for maintaining themselves in a population with a high level of immunity to infection by establishing a latent infection.

On the basis of their biologic properties the viruses comprising the family Herpesviridae are subdivided into three subfamilies — the Alphaherpesvirinae, the Betaherpesvirinae and the Gammaherpesvirinae (Table 215.1).[1] Each of the subfamilies is further subdivided into genera:

- the Alphaherpesvirinae has two genera — Simplexvirus and Varicellovirus;
- the Betaherpesvirinae has three genera — Cytomegalovirus, Muromegalovirus and Roseolovirus; and
- the Gammaherpesvirinae has two genera — Lymphocryptovirus and Rhadinovirus.

The current classification is somewhat subjective because it is based upon biologic properties. In the future, it is likely that a more precise system based on genetic information such as the organization and sequence of reiterated sequences within the genome of the virus (Fig. 215.1), the conservation of selected genes and gene clusters, and possibly comparisons of protein sequences will provide a more objective classification system.[3]

Under the present classification scheme[1] viruses are named according to their natural host species and numbered in accordance with the order in which they were first identified. As many viruses have acquired commonly used names — for example, human herpesvirus 1 is commonly known as herpes simplex virus (HSV) type 1 — the classification is not yet rigorously applied. However, newly discovered viruses are now named in accordance with this classification scheme, for example human herpesviruses 6, 7 and 8. At present eight herpesviruses are known to have the human species as their natural host (Table 215.2). Herpes B virus, a virus belonging to the Simplex genus of the Alphaherpesvirus subfamily and also known as cercopithecine herpesvirus 1 or herpesvirus simiae, is enzootic among old world macaques and usually causes minimal or no morbidity in its natural host. However, B virus infections in humans, mostly because of accidental exposure, may cause severe and often fatal disease.

Structure

The herpesvirus virion often has a pleomorphic appearance when seen by electron microscopy. It measures 150–300nm in diameter

TABLE 215-1 -- Biologic properties of the Herpesviridae.

BIOLOGIC PROPERTIES OF HERPESVIRIDAE	
Common properties	Spheric enveloped virions, 150–200nm in diameter
	Large, linear, dsDNA genome of 125–230kbp
	Synthesis of DNA and assembly of capsid within the nucleus, acquire envelope by budding through nuclear membrane
	Specify a large array of enzymes involved in nucleic acid metabolism and synthesis
	Production of progeny virus results in destruction of the host cell
	Establish latency in their natural host
Alphaherpesvirinae	Variable host range
	Short reproductive cycle
	Rapid spread in cell culture
	Efficient destruction of infected cells
	Establish latency primarily but not exclusively in sensory ganglia
Betaherpesvirinae	Restricted host range (a nonexclusive property of this subfamily)
	Long reproductive cycle
	Infection progresses slowly in culture, frequently forming enlarged (cytomegalic) cells
	Latency in secretory glands, lymphoreticular cells, kidneys and other tissues
Gammaherpesvirinae	Experimental host range limited to family or order of natural host
	In-vitro replication in lymphoblastoid cells
	In-vivo replication and latency in either T or B cells

and is composed of an internal protein nucleocapsid enclosing the double-stranded (ds) DNA genome and an external lipid envelope. The electron microscopic appearance of a typical herpesvirus is shown in Figure 215.2 .

DNA

The genetic information of the virus is encoded by a linear molecule of dsDNA and the size of this molecule varies for different herpesviruses, from approximately 80,000 to 150,000kDa (125–245kbp). The G+C composition of individual herpesvirus DNAs varies from 31 to 75%. The size of individual herpesvirus genomes varies by approximately 10kbp and this is usually attributable to the number of terminal and/or internal reiterated sequences (see Fig. 215.1). Within the virion the DNA is a linear molecule that is tightly wound in the form of a torus. The ends of this molecule appear to attach to

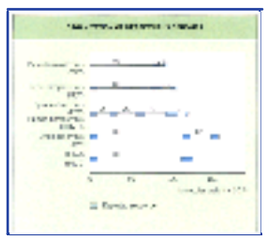

Figure 215-1 Organization of herpesvirus genomes. Inverted repeat sequences in VZV, HSV and CMV allow the genome to recombine in 2,4, and 4 isomers, respectively. Both HSV and CMV have a UL (long unique base sequence) and a US (short unique base sequence) each terminated by two sets of inverted repeated sequences. The repeated sequences allow the UL and US to invert relative to one another, so yielding four isometric forms of DNA. As there is only one set of inverted repeats in VZV, only two isomers of DNA can be produced. Both EBV and HHV-8 have only one isomeric form with several unique regions surrounded by direct repeated sequences.

the inner surface of the nucleocapsid, which prevents the DNA from circularizing until it is released during infection.

The phylogenetic relationship, based on a neighbor-joining analysis of the glycoprotein B gene, between the human herpesviruses and herpes B virus[4] is shown in Figure 215.3 .

Virion polypeptides

Herpes simplex virus type 1 virions contain about 33 virus-specific proteins, but more than double this number are found within an infected cell. The virion polypeptides (VPs) are designated by serial number. The transcription of mRNAs from the genome proceeds from both strands of the genome, in either direction, with evidence of overlapping transcription and of splicing of genes and gene products. [5] There are two sets of *cis*-acting genes embedded in the domains of viral genes. The first set enables binding of cellular transcription

TABLE 215-2 -- Human herpesviruses.

HUMAN HERPESVIRUSES			
ICTV name	**Common name**	**Subfamily**	**Genus**
Human herpesvirus-1	Herpes simplex virus (HSV)-1	Alphaherpesvirinae	Simplexvirus
Human herpesvirus-2	Herpes simplex virus-2	Alphaherpesvirinae	Simplexvirus
Human herpesvirus-3	Varicella-zoster virus (VZV)	Alphaherpesvirinae	Varicellovirus
Human herpesvirus-4	Epstein-Barr virus (EBV)	Gammaherpesvirinae	Lymphocryptovirus
Human herpesvirus-5	Human cytomegalovirus (CMV)	Betaherpesvirinae	Cytomegalovirus
Human herpesvirus-6	Human herpesvirus (HHV)-6	Betaherpesvirinae	Roseolovirus
Human herpesvirus-7	Human herpesvirus (HHV)-7	Betaherpesvirinae	-
Human herpesvirus-8	Kaposi's sarcoma-associated herpesvirus (KSHV)	Gammaherpesvirinae	Rhadinovirus
Two variants, 'a' and 'b', of human herpesvirus 4 and human herpesvirus 6 are known. ICTV, International Committee on Taxonomy of Viruses.[1]			

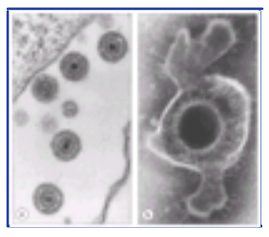

Figure 215-2 Enveloped virus particle. (a) Thin section. (b) Negative staining. These electron microscopic views (×140,000) show HSV. The DNA is surrounded by a nucleocapsid comprised of 162 individual protein subunits (150 hexavalent capsomers and 12 pentavalent capsomers) arranged in the form of an icosahedron. The nucleocapsid is in turn enclosed by the tegument and virus envelope bearing glycoprotein spikes. *Courtesy of Hans Gelderblom*.

factors and *trans*-acting factors to initiate and enhance viral gene expression. The second set enables interaction of genes with regulatory proteins (up- or downregulation). Three rounds of transcription and translation are observed, the so-called:

- ¦ a phase (resulting in the production of 'immediate-early proteins');
- ¦ ß phase (proteins responsible mainly for DNA metabolism); and
- ¦ ? phase (principally structural proteins).

Nucleocapsid

The icosahedral nucleocapsid is 100–110nm in diameter comprising 162 individual capsomers (i.e. 12 pentavalent and 150 hexavalent capsomers). Using electron cryomicroscopy and computer-aided image reconstruction the structure of herpesvirus particles has been determined at a resolution of 26 Å. In HSV individual capsomers are believed to be constructed from the four major capsid proteins VP5, VP26, VP23 and VP19.[6] [7] The interior and exterior of the capsid appear to be linked by transcapsomeric channels.

Figure 215-3 Phylogenetic relationship between the human herpesviruses and herpes B virus. The tree was created by neighbor-joining analysis of the glycoprotein B gene sequences. HVS, herpesvirus simiae (herpes B virus). *Adapted from Schultz, 2000.*[5]

Tegument

The amorphous electron-dense tegument bounded by the nucleocapsid and outer envelope of the virus contains at least eight proteins. These proteins serve important functions after the virus has penetrated the host cell (see below).

Envelope

The viral envelope is an extensively modified form of the original host cell nuclear membrane and bears a series of virus-specified glycoprotein spikes 9–15nm in length (see Fig. 215.2). The glycoprotein spikes define several of the major biologic attributes of the virus. There are major antigenic differences in glycoprotein spikes between the virus species. In HSV there are at least ten glycoproteins on the viral envelope (Table 215.3).

Physical properties

Herpesviruses are thermolabile. In cell culture media the half-life at 86°F (30°C) is between 1.5 and 14 hours. Drying in air leads to desiccation of the viral envelope and loss of infectivity. Ether in water (20%) and other lipid solvents such as 70% alcohol or chloroform rapidly inactivate herpesviruses completely.

EPIDEMIOLOGY

Transmission pathways

Herpesviruses are relatively fragile in that they require a lipid envelope to achieve attachment to and penetration of the host cell. As a consequence these viruses transmit most easily on contact with warm and moist mucosal layers. Two broad groupings of virus can be distinguished:

- those where virus is transmitted most effectively by oral secretions and nongenital contact; and
- those where the virus is transmitted most effectively by genital secretions.

These modes of transmission have a profound influence upon the epidemiology of the individual viruses.

TABLE 215-3 -- Herpes simplex virus glycoproteins.

HERPES SIMPLEX VIRUS GLYCOPROTEINS		
Glycoprotein	**Required for replication in cell culture**	**Function**
gB	+	Forms a dimer, essential for viral entry; induces neutralizing antibody
gC	-	Involved in cell attachment
gD	+	Required after attachment of virus to cell to allow virus entry into the cell
gE	-	In complex with gI; binds Fc portion of antibodies
gG	-	Involved in entry, egress and spread from cell to cell
gH	+	Forms complex with gL (see below); role in entry, egress and cell-to-cell spread
gI	-	gI and gE form a complex for transport to plasma membranes and gI and gE form an Fc receptor
gJ	-	Predicted from DNA sequence only
gK	+	Required for efficient egress (viral exocytosis)
gL	+	Forms complex with gH that is required for transport of gH and gL to the plasma membrane and for viral entry mediated by gH
gM	-	Not known
Information relates to HSV-1; not all glycoprotein species have been identified in other herpesviruses and the size, degree of glycosylation and other post-translational modifications vary for different viruses.		

Prevalence

Herpesviruses transmitted predominantly by oral secretions or nongenital contact are HSV-1, varicella-zoster virus (VZV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), human herpesvirus (HHV)-6 and HHV-7. Those transmitted predominantly by the sexual route are HSV-2 and HHV-8. The peak incidence for infection transmitted nongenitally is in early childhood (Table 215.4). The peak incidence for infections acquired by genital transmission is in adolescence and early adulthood. The rates of infection by viruses transmitted by the genital route are not usually as high as those for viruses transmitted by a nongenital route. However, for both groups there is a further distinct relation between rates of acquisition, sexual preference and the socio-economic status of the study population.

Geographic aspects

Herpesviruses are distributed worldwide and no animal reservoirs of infection are known for any of the human herpesviruses. Burkitt's lymphoma, which is associated with EBV infection, is endemic only in tropical Africa.[8] Nasopharyngeal carcinoma is also associated with EBV infection and is endemic in Japan and Southern China.[9] A sporadic, non-HIV-associated Kaposi's sarcoma is found predominantly in countries bordering the Mediterranean and in Central Africa.[10]

There is evidence that in tropical areas varicella is less prevalent in childhood than in temperate climatic areas and is more common in adults.[11] Possible explanations for this include the relative isolation of clusters of population in rural areas,[12] epidemiologic 'interference' through infections caused by other viruses, especially HSV,[13] and perhaps decreased efficiency of transmission as a result of the lability of VZV in areas where there is a high ambient temperature.[11]

TABLE 215-4 -- Features of herpesvirus infections.

FEATURES OF HERPESVIRUS INFECTIONS					
Virus	**Peak incidence of primary infection**		**Adult seroprevalence (%)**	**Principal route(s) of transmission**	**Notes**
	Childhood	**Adolescence**			
HSV-1	+++	+	75–95+	Oral secretions, close contact	Overall seroprevalence predominantly determined by socio-economic status
HSV-2	-	+++	4–95	Genital secretions, close contact	Lifetime number of sex partners is predominant influence on rates of seropositivity
VZV	+++	+	90–95	Aerosol, close contact	Epidemic spread in childhood, in tropics relatively more common in adults than children
CMV	++	++	40–95+	Oral secretions, genital secretions	Infection common in infancy, but a significant proportion of women of childbearing age are susceptible; overall seroprevalence predominantly determined by socio-economic status
EBV	++	++	70–95	Oral secretions	Second peak of incidence in early adolescence (glandular fever)
HHV-6	+++	-	>85	Oral secretions	Infection common in infancy — peak age of acquisition 2 years
HHV-7	+++	-	>85	Oral secretions	Infection common in infancy — peak age of acquisition 3 years
HHV-8	-	+++	10–25	Oral secretions, genital secretions	Homosexual men who have AIDS have highest seroprevalence
CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.					

Periodicity

The human herpesviruses are endemic in human populations as a result of their strategy of establishing latent infections. In addition, because of their modes of transmission there is no seasonal variation in the efficiency of transmission. For infections for which reactivation is infrequent (e.g. VZV infection) there may be 'outbreaks' of infection (mini-epidemics) when infection spreads rapidly through a nonimmune population. Outbreaks can also occur if large numbers of susceptible individuals are brought together (e.g. infectious mononucleosis among military recruits or college students).[14]

Determinants of infection

Early acquisition of infection is common for all herpesviruses transmitted by the nongenital route. In a classic study of HSV infection Burnet and Williams[15] showed that there was a clear relationship between the age of acquisition of the virus and socio-economic status. Populations associated with a low socio-economic environment collectively showed earlier acquisition of HSV infection than more affluent populations, although in both groups, infection rates of 90–95% were observed by early adulthood. Primary HSV-1 infection was rare in those over 30 years of age. In recent years several sero-epidemiologic studies have shown a general decrease in the overall prevalence of HSV-1 antibody in developed countries. However, even within individual countries there are variations in seroprevalence, for example the seroprevalence rates are generally higher among inner city residents than among those from rural areas. Here, the major factor determining the seroprevalence is the frequency of direct person-to-person contact rather than the socio-economic status of the individual populations.

If infection does not occur in infancy, transmission routes other than direct oral contact can constitute important risk factors. An example is found in the acquisition of CMV. Although most CMV infections occur in infancy a significant proportion (40–50% in developed countries) of women of child-bearing age are still susceptible to infection and may acquire the infection during pregnancy. Sexual transmission of infection is an important mode of acquisition of infection for these women. In addition, contact with young children of less than 24 months of age is a further important risk factor.

Viruses such as HSV-2 for which the principal mode of transmission is sexual are generally not acquired until the onset of sexual activity in adolescence and early adulthood. The major influence on acquisition of infection appears to be the number of sexual partners and sexual preference of an individual (as might be expected for a sexually transmitted virus). Seroprevalence rates of up to 95% have been reported in some female commercial sex workers. Women are generally infected at an earlier age (15–20%) than men, and rates of infection in women are higher for all age groups including those of 45 or more years of age.[16] Studies among patients attending a genitourinary medicine clinic suggest that only in homosexual men are the rates of infection with HSV-2 comparable to those found in women.

Whereas the seroprevalence of HHV-8 infection is low (<2%) in general populations, except in some parts of Italy, Greece and most of Africa, it is high in groups at high risk of infection such as homosexual men with large numbers of sex partners.[17]

PATHOGENICITY

Replication

The replicative cycle of the virus is illustrated schematically in Figure 215.4 . The initial attachment of a herpesvirus to a host cell is mediated by a glycoprotein or a complex of glycoproteins projecting from the virus envelope interacting with its specific receptor on the host cell.[4]

Initial contact of the herpesviruses with the cell is usually made by low-affinity binding to glycosaminoglycans, preferentially heparan sulphate, on the cell surface. In this way viruses are concentrated at the cell surface, facilitating subsequent binding to a specific receptor, for instance the complement receptor Cr2 (CD 21) in the case of EBV. The virus envelope and cell plasma membranes then fuse,

Figure 215-4 Herpesvirus replication. The tegument proteins effect the shut-down of host cell metabolism. On entry to the nucleus the DNA circularizes and binds a tegument protein and cellular factors to initiate transcription. Transcription and translation occur in three phases: immediate-early, early and late. Capsid proteins migrate into the nucleus and the viral DNA is encapsidated. The viral glycoproteins are extensively modified post-translationally by transit through the Golgi apparatus. The glycoproteins diffuse to the nuclear envelope. The nucleocapsids bud through the modified nuclear membrane and exit the cell via the endoplasmic reticulum or are released on cell lysis.

resulting in the introduction of tegument proteins and viral nucleocapsid into the cell cytoplasm.[18] This process probably involves several, if not all, of the virion surface glycoproteins and is accomplished rapidly.

The tegument proteins serve to both 'disable' the host cell and initiate viral replication. Soon after virus entry, host cell DNA synthesis is shut off, host cell protein synthesis declines rapidly and glycosylation of host cell proteins ceases. In this way the virus ensures that the metabolic machinery of the cell is fully available for virus replication. At the same time the virion nucleocapsid is transported via the cell cytoskeleton to a nuclear pore. At the nuclear pore the viral nucleocapsid breaks down releasing its DNA into the cell nucleus where the linear DNA molecule immediately circularizes.

Transcription of viral DNA takes place within the host cell nucleus involving three classes of mRNA, a, ß and ?, and including both host cell as well as viral proteins. In HSV, to initiate transcription, the circularized DNA must bind a host cell protein (OCT-1) to a *cis*-acting site and the tegument protein a *trans*-inducing factor (a-TIF) binds an additional factor designated C1 (and possibly others). This a-TIF-C1 complex then binds to the OCT-1-DNA complex.[6] a-TIF acts in *trans* to induce a (or 'immediate-early') genes — the first set of viral genes to be transcribed. Immediate-early or a proteins are control proteins that stimulate and regulate all the subsequent steps in the replicative cycle. All but one of the a proteins are regulatory proteins. Their production is essential to stimulate the production of ß polypeptides, which are the enzymes and other proteins involved in viral nucleic acid reproduction (e.g. DNA-dependent DNA polymerase, which reproduces the viral genome). Products of a and ß genes transactivate the translation of the ? genes, which produce the late or ? proteins, the structural proteins for the virion including the viral capsid and glycoproteins.

Productive infection is fatal for the host cell because in the process of viral DNA replication host cell chromosomes are degraded and appear as a chromatin ring around the borders of the nuclear membrane. In addition host cell metabolism is irreversible damaged.

Molecular and cellular basis of pathogenicity

The combination of virion surface glycoproteins and the distribution of cellular receptors provide a partial explanation of the cell and tissue specific tropism of members of the human herpesviruses. A common characteristic of the herpesviruses is their ability to persist in infected cells while expressing only a minimal set of genes needed for latency. After certain stimuli, or when the immune system is suppressed, the virus will be reactivated and undergo replication to produce new viral progeny. In individuals who have deficits in cell-mediated immunity (CMI), infection is more poorly controlled than in those who have intact CMI. Primary infection is in consequence more severe, and reactivation of latent infection is more likely to result in symptomatic disease.

Herpes simplex virus

In vitro, HSV can infect most types of human cells and even cells of other species, but *in vivo* it is host specific, causes lytic infection of fibroblasts and epithelial cells, and establishes latent infection in neurons. In addition, the two biotypes of HSV, HSV-1 and HSV-2, show some predilection for infecting defined anatomic sites — oropharyngeal and genital, respectively. Both viruses are capable of infecting and producing latent infection at either site, but HSV-2 reactivation 'above the waist' and HSV-1 reactivation 'below the waist' are infrequent compared with HSV-1 reactivation 'above the waist' and HSV-2 reactivation 'below the waist',[19] respectively. It is suggested that at the molecular level the site-specific reactivation phenotypes of HSV-1 and HSV-2 depend on the latency-associated transcript (LAT) regions of the viral genome.[20]

Figure 215-5 Pathogenesis of varicella-zoster virus infection.

Varicella-zoster virus

Primary VZV infection starts in the mucosa of the respiratory tract and progresses via the blood and lymphatic system to cells of the reticulo-endothelial system. A secondary viremia after 11–13 days disseminates virus to the skin where the characteristic vesicular lesions of 'chickenpox' are produced (Fig. 215.5). The virus probably establishes latent infection in the dorsal root or cranial nerves during this viremic phase. The molecular basis of latency and reactivation is poorly understood. It has been suggested that differences in the frequency and clinical expression of HSV and VZV recrudescence may be related to the type of cells that are latently infected within sensory ganglia. In one model, [21] HSV latency is restricted to neurons and virus reactivation is induced by non-specific stimuli acting upon the neuron and results in re-infection of a small area of the skin innervated by the neuron. In contrast, VZV latency is mainly established in satellite cells and reactivation requires the spread of virus to neighboring neurons within the ganglia. These neurons act as sources of virus for axonal transport and infection of a wider area of the skin. Further differences in the latency and reactivation of HSV and VZV could relate to the differing structures of the genomes of the two viruses; LATs and neurovirulence genes are encoded in the HSV genome and have no counterpart in the VZV genome.[21]

Epstein-Barr virus

During primary infection EBV establishes a productive infection in the epithelial cells of the oropharynx. Virus is shed in the saliva and gains access to B cells in lymphatic tissue and the blood.[22] A lytic infection leads to the production of EBV proteins, including the early antigens, viral capsid antigen and the glycoproteins of the membrane antigen (Fig. 215.6). Epstein-Barr virus is a B-cell mitogen, stimulating the growth and immortalization of B cells by preventing apoptosis. Epstein-Barr virus infection of B cells also

Figure 215-6 Pathogenesis of Epstein-Barr virus infections. Infection may result in lytic infection of the cell or cell immortalization, which can be distinguished by the production of virus and the expression of different viral proteins and antigens. T cells limit the outgrowth of EBV-infected cells. LMP, latent membrane protein; LP, Epstein-Barr nuclear antigen leader protein. *Adapted from Strauss et al., 1993.*[22]

alters the interaction of the virus with the immune system by enhancing the expression of cell surface proteins such as human leukocyte antigens, adhesion proteins and the CD23 blast antigen.

Cytomegalovirus

Cytomegalovirus is transmitted via infected lymphocytes and mononuclear cells throughout the body. It establishes latent infection in mononuclear leukocytes and organs such as the kidneys and heart. Virus can therefore be transmitted in cells via blood transfusions and organ transplants. Activation and replication of the virus in the ductal epithelial cells of kidney and in secretory glands result in its excretion in body fluids and secretions including semen, saliva, tears, stool, vaginal and cervical secretions, and breast milk. Reactivation of virus in the cervix can result in congenital CMV infection, although more commonly viremia during primary maternal infection is the source of fetal infection. Reactivation usually results in virus shedding without symptoms. However, as for all the human herpesvirus infections in people who have individual deficits in CMI, reactivation is often symptomatic.

Since the original sero-epidemiologic observations,[23] several studies have shown a relationship between CMV infection and atherosclerosis. [24] [25] Such a correlation has also been found for other infectious agents such as *Chlamydia pneumoniae* and *Helicobacter pylori*. The evidence includes increased CMV antibody titers as well as a higher frequency of detection of CMV antigens and sequences in the wall of atherosclerotic vessels. However, results from various studies were not unambiguous, and a causal relationship between CMV and atherosclerosis has not yet been established.

Human herpesviruses 6 and 7

Human herpesvirus-6 was originally isolated from T-cell cultures derived from the blood of patients who had AIDS,[26] and HHV-7 was isolated from the $CD4^+$ T cells of a healthy individual. Both viruses infect and kill $CD4^+$ T cells, just like HIV, yet the outcome of infection is markedly different. In contrast to HIV infection, infection by HHV-6 or -7 is rapidly controlled by the host immune response, and the virus establishes a state of latency. HHV-6 and HHV-7 are closely related to the other member of the human Betaherpesvirinae, CMV (see Fig. 215.3). HHV-6 isolates are classified into two distinct variants, HHV-6A and HHV-6B. Although closely related, consistent differences have been observed in their biologic, immunologic, epidemiologic and molecular properties. HHV-6B is the primary etiologic agent of exanthem subitum,[27] whereas no single disease has been definitively associated with HHV-6A. In the same way, HHV-7 also remains an 'orphan' virus with no firm disease association. Infection with HHV-6 and HHV-7 occurs early in life. The viruses are present in the saliva of most adults and are readily spread by oral secretions. The cellular host range of HHV-6 appears to be extensive. Virus replication in $CD4^+$ T cells is common and there is also limited replication in $CD8^+$ T cells, natural killer cells, monocytes, epithelial cells and brain cells.[28]

Human herpesvirus-7, like HHV-6, grows well in $CD4^+$ T cells, but unlike HHV-6 it uses the CD4 molecule as its receptor. Human herpesvirus-7 also downmodulates expression of CD4. The host range of HHV-7 appears to be more limited than that of HHV-6. It is less cytopathic and grows less rapidly in culture than HHV-6.[28]

Human herpesvirus-8

Using representational difference analysis[29] HHV-8 was initially identified in 90% of AIDS-related Kaposi's sarcoma (KS) lesions and in 15% of non-KS tissues from people who had HIV infection. Following these observations HHV-8 sequences were identified using polymerase chain reaction (PCR) in all forms of KS, including KS from different geographic locations in individuals who had and did not have HIV infection.[10] Human herpesvirus-8 RNA transcripts have been detected in endothelial cells lining vascular spaces, perivascular spindle cells in KS lesions and in extracts of KS tissue. Also, linear HHV-8 DNA has been noted in peripheral blood mononuclear cells from KS patients. [28] These findings suggest that certain cells in KS tumors and also mononuclear cells are able to support the replication of HHV-8.

Large numbers of HHV-8 particles can be found in phorbol ester-stimulated B lymphoma cells by electron microscopy. Nevertheless, the infectivity of the virus has proved difficult to demonstrate in the laboratory. Studies using filtered cell culture fluids from HHV-8-positive $CD19^+$ lymphocytes, KS biopsy material co-cultured with normal $CD19^+$ cells, and fluids from B-cell lymphoma lines activated with phorbol esters have shown the passage of the HHV-8 DNA sequences to fresh uninfected target cells, particularly $CD19^+$ lymphocytes.[28]

Latency

The establishment of latency is central to the success of herpesviruses in maintaining themselves in human populations. During the course of a primary infection a

latent infection is established; the exact site or site(s) varies for each subfamily of herpesvirus:

- Alphaherpesvirinae (HSV-1, HSV-2, VZV) favor neuronal sites of latency;
- Betaherpesvirinae (CMV, HHV-6, HHV-7) are selective for secretory glands, lymphoreticular cells, kidneys and other tissues; and
- Gammaherpesvirinae (EBV, HHV-8) remain latent in either T or B cells (Table 215.5).

Latency permits persistence of the virus in the presence of a fully developed immune response and allows lifelong infection of the

TABLE 215-5 -- Principal sites of latency for herpesviruses.

PRINCIPAL SITES OF LATENCY FOR HERPESVIRUSES		
Virus	**Established (most probable) site of latency**	**Other possible sites of latency**
HSV-1	Neurons (trigeminal ganglia)	Other sensory nerve ganglia, brain, eye
HSV-2	Neurons (sacral ganglia)	Other sensory ganglia
VZV	Neurons (dorsal root ganglia, thoracic nerves, trigeminal ganglia)	Brain
EBV	B cells (epithelial cells of nasopharynx and submandibular salivary glands)	-
CMV	Monocytes, lymphocytes, epithelial cells	Salivary glands, renal tubule cells
HHV-6, HHV-7	T cells	-
HHV-8	?T and B cells, mononuclear cells	-

host. Through periodic reactivation of latent virus and the production of recurrent infection, virus shedding occurs at intervals throughout life, allowing the virus to be spread to new susceptible hosts.

In order to avoid elimination by the host immune system, herpesviruses use various evasion mechanisms. Key to most mechanisms is to reduce or prevent expression of virus-specific peptide-MHC class I complexes at the cellular membrane,[30] thus preventing recognition by cytotoxic T cells that would kill the infected cell. Prevention of peptide-MHC I complexes to reach the cell surface may, for instance, be achieved through interference with the transport of these compexes to the cell surface (HSV) or by induction of degradation of MHC I molecules (CMV).

The molecular events that lead to the establishment of latency are incompletely understood. The viral genome is maintained as an episomal closed circle of DNA (analogous to a bacterial cell plasmid), but how the virus precisely switches from its replicative mode to a latency mode is unclear.

Cell transformation

Some of the human herpesviruses (HSV-1, HSV-2 and CMV) can transform cells in culture, albeit at a very low frequency, and hamster cells transformed by HSV can produce tumors when injected into hamsters. Greater oncogenic potential can be demonstrated for other herpesviruses. For example, EBV-infected human lymphocytes can be transformed into lymphoblast cell lines. All cells that carry the EBV genome express virus-specific nuclear antigens (EBNAs), regardless of whether mature virus is released. There are also clear epidemiologic links to several types of tumor. Infectious mononucleosis can progress to a fatal B-cell lymphoma in boys who are born with an X-linked immunodeficiency; EBV has also been linked to Burkitt's lymphoma and nasopharyngeal carcinoma and to the development of post-transplant lymphoproliferative disease in immunosuppressed solid-organ transplant recipients. The geographic distribution of Burkitt's lymphoma and nasopharyngeal carcinoma mentioned above suggests that factors in addition to virus infection (e.g. a genetic predisposition or an environmental cofactor) may be involved in the production of these cancers.

EBV is also known to be the etiologic agent involved in post-transplant lymphoproliferative disease (PTLD), which comprises a heterogenous group of disorders with variable clinical presentation. PTLD affects 1–5 % of transplant patients and has a very high mortality rate. EBV is also associated with a subset of cases of Hodgkin's disease as demonstrated by the presence of the viral

genome and viral-coded antigens in Reed-Sternberg cells. The exact nature of the association or its relevance to the etiology of Hodgkin's disease need further elucidation.

Human herpesvirus-8 is related to EBV, but is classified in the rhadinovirus subfamily of the Gammaherpesvirinae. The prototype of this subfamily is herpesvirus saimiri, which is not pathogenic in its natural host (the owl monkey), but can induce T-cell lymphomas in other primates. Human herpesvirus-8 contains sequences resembling cyclin D, a cell cycle inducer, cytokines and other human regulatory and DNA metabolism genes. The virus also possesses a Bcl-2-like sequence that could, by preventing apoptosis, produce transformation in a similar manner to that attributed to EBV.[31]

The ubiquitous nature of herpesvirus infections and their establishment of lifelong infections make it difficult to interpret their association with tumorigenic cells. Because of the relatively low efficiencies of transformation *in vitro* it seems likely that herpesvirus infection represents only one part of a complex sequence of events that ultimately leads to neoplasia.

PREVENTION

In a well-controlled environment, such as that of a hospital, prevention of host-to-host transmission for most human herpesviruses is achieved by simple hygiene. In the home or other social situations prevention of transmission by avoiding contact with a person who has evidence of recurrent infection is only partially effective. This is because infectious virus is often excreted before the appearance of overt symptoms of recurrent infection and 'silent' recurrent infections also occur.

Herpesviruses are readily inactivated by a variety of physical and chemical agents (see Physical properties, above) and standard methods of sterilization, including autoclaving, dry heat, ultraviolet or gamma irradiation, and ethylene oxide sterilization are adequate for decontaminating medical equipment. Most common disinfectants (5% phenol, formaldehyde, glutaraldehyde, 1:10,000 quaternary ammonium compounds and 0.3ppm hypochlorites) rapidly inactivate virus. Other virucidal compounds include detergents, chlorhexidine, Merthiolate, sodium azide, ß-propriolactone, ethylene oxide and some proteolytic enzymes. Ultraviolet and X-ray or gamma irradiation also inactivate herpesviruses.

TABLE 215-6 -- **Examples of vaccine under development for immunization to prevent herpes simplex virus-2 infection.**[*]

VACCINES UNDER DEVELOPMENT TO PREVENT HSV-2 INFECTION				
Vaccine type (name)	**Company**	**HSV subunits or mechanisms**	**Adjuvant**	**Stage of research**
Recombinant protein	Glaxo-SmithKline	gD2	MPL	Phase III
Recombinant protein	Chiron	gD2 and gB2	MF59	Phase III halted
Attenuated (DISC)	Cantab	Disabled virus (gH gene deleted)	None	Phase I
DNA (Genevax HSV)	Apollon	Encodes gD2	Bupivacaine (facilitator)	Phase I
Naked DNA	Pharmadigm	Encodes gD2, uses novel myoD promoter	1,25-D3, possibly DHEA	Preclinical
Naked DNA	Vical	Encodes gD2	None	Preclinical
Naked DNA	Merck	Encodes gD2	None	Preclinical
Recombinant protein (Heteroconjugate)	Cel-Sci	T-cell ligands linked with HSV-associated peptides	None	Preclinical

** Adapted from Hanissian, 1998.*[34]

Active immunization

Except for VZV infection (for which a live attenuated vaccine is available) there are currently no licensed vaccines available to prevent herpesvirus infections. Varicella-zoster virus infection causes particular problems in immunosuppressed children. Primary infection in immunosuppressed patients can result in a fulminant, generalized infection or severe respiratory disease. A live attenuated VZV vaccine has been licenced for use in Japan and the USA and is administered using the same schedule as the measles, mumps and rubella vaccine. Breakthrough infections can occur, but usually result in mild illness.[32] In the USA the vaccine is recommended for use for all children over 12 months of age and susceptible healthy adolescents and adults. In most other countries vaccination is only recommended for patients who are immunosuppressed or immunodeficient and who have never had chickenpox. Since its implementation in routine use in the USA, the vaccine has been found to be 97% effective in the prevention against moderately severe or severe disease.[33]

A number of vaccines to prevent HSV-2, CMV and EBV infections are under development or are undergoing clinical trials. The diversity of approaches used is illustrated by the vaccines under development for HSV-2 (Table 215.6).[34] For CMV a candidate vaccine was developed by Plotkin in the 1970s.[35] The vaccine was made from an isolate of a congenitally infected child (the Town strain) after frequent serial passaging in human embryonic fibroblasts. In early studies serconversion was seen in nearly 100% of volunteers, as well as a protective effect against a low-dose challenge with CMV. In addition, the vaccine appeared to provide partial protection as seen after natural infection. However, the vaccine failed to prevent infection of mothers in contact with CMV-excreting children, and therefore failed its primary objective: the prevention of primary infection in pregnancy. Later efforts have focused on the development of recombinant subunits and DNA vaccines; so far, however, with little success.

Attempts to develop an EBV vaccine include the use of purified gp340/220 virus envelope antigen, to which neutralizing antibodies are mainly directed.[36] Although vaccination of tamarins with this antigen preparation protected them against a virus challenge, further attempts to develop this into a vaccine for use in humans have not been successful.

TABLE 215-7 -- Currently used antiherpesvirus drugs.

CURRENTLY USED ANTIHERPESVIRUS DRUGS			
Antiviral drug	**Chemical class**	**Mechanisms of action**	**Target virus**
Aciclovir	Guanosine analog	Virus-activated DNA polymerase inhibitor	HSV-1, HSV-2, VZV
Cidofovir	Cytidylic acid analog	DNA polymerase inhibitor	CMV, HSV-1, HSV-2
Famciclovir	Guanosine analog	Virus-activated DNA polymerase inhibitor	HSV-1, HSV-2, VZV
Foscarnet	Pyrophosphate analog	DNA polymerase inhibitor	CMV, HSV-1, HSV-2
Ganciclovir	Guanosine analog	Virus-activated DNA polymerase inhibitor	CMV (HSV-1, HSV-2)
Valaciclovir	Guanosine analog	Virus-activated DNA polymerase inhibitor	HSV-1, HSV-2, VZV
CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.			

Passive Immunization

Varicella-zoster virus hyperimmune globulin (VZVIG) is an effective prophylaxis for babies born to mothers who have chickenpox 5 days before to 4 days after birth. The use of VZVIG in pregnancy, particularly during the first 20 weeks of pregnancy, is also suggested for nonimmune mothers exposed to chickenpox because pregnant women have a greater risk of developing severe pulmonary complications if they contract VZV infection. Prophylactic use of VZVIG is also appropriate to control infection in pediatric units caring for immunocompromised children (see Chapter 8).

In the future the development of human monoclonal antibody preparations may provide more reliable and consistent supplies of immunoglobulins to prevent these and other human herpesvirus infections.

Antiviral prophylaxis

A number of specific antiviral compounds are now available for the treatment of herpesvirus infection and prophylactic use of antiviral chemotherapy to control infection is now well established (Table 215.7).

TABLE 215-8 -- Laboratory diagnosis of herpesvirus infections.

LABORATORY DIAGNOSIS OF HERPESVIRUS INFECTIONS					
Virus	**Disease manifestation**	**Virus culture**	**Serology**	**Antigen detection**	**DNA amplification**
HSV-1	Skin lesions	+++	+	+	+++
	CNS infection	-	++	-	+++
HSV-2	Genital lesions	+++	+	+	+
	CNS infection	-	+	-	+++
VZV	Skin lesions	++	++	++	+++
	CNS infection	-	+	-	+++
CMV	Mononucleosis-like illness	-	+++	-	-
	Neonatal disease	+++	++	-	+++
	Systemic infection in immunocompromised	+	+	++	+++
	CNS disease	-	+	-	+++
EBV	Mononucleosis-like illness	-	+++	-	-
	Systemic infection in immunocompromised	-	+	+	+++
	CNS disease	-	+	-	+++
HHV-6	Exanthema subitum	+	+++	-	-
	CNS disease	-	++	-	+++
HHV-8	Kaposi's sarcoma	-	+	-	+++
CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.					

DIAGNOSTIC VIROLOGY

A key feature of the herpesviruses is their close adaption to their host. In general, primary infection is often asymptomatic or is accompanied by nonspecific mild signs and symptoms. Consequently most primary infections and many recurrent infections are not recognized as herpesvirus infections. Where symptoms are observed, speed in using diagnostic procedures is important because the peak of virus replication and shedding is likely to precede the appearance of symptoms. The diagnostic method chosen (Table 215.8) varies for different herpesviruses and also depends upon the type of infection (whether primary or recurrent), duration of symptoms and clinical manifestations.

Test specimens

If there are visible lesions (HSV-1, HSV-2, VZV) the base of the lesion may be sampled with a dry cotton-tipped swab, which should be placed in virus transport medium and transported to the virus laboratory as quickly as possible. If there are vesicles, vesicle fluid can be aspirated using a fine (intradermal) needle. The fluid should

---

then be transported directly to the laboratory for virus detection by electron microscopy, direct immunofluorescent antibody staining, PCR testing or culture.

Viruria and viremia are common during both primary infection and recurrent infection with CMV, EBV and HHV-6, -7 and -8. Urine collected in urine transport medium is therefore a useful specimen (only CMV). Blood collected in anticoagulant can be used to prepare buffy coat preparations that can be used for culture or direct detection techniques. In neurologic disease, cerebrospinal fluid (CSF) and a clotted peripheral blood specimen (for CSF and blood serology) are essential. Clotted blood specimens should be collected during the acute stages of illness and again after 10–14 days.

Virus culture

The fragility of the viral envelope presents a problem if virus is to be cultured. Collection of specimens into appropriate viral transport medium and rapid transportation of specimens to the diagnostic laboratory are essential for successful isolation in cell culture systems. Virus culture is only routinely attempted for HSV-1, HSV-2, VZV and CMV. For those viruses that have fastidious cell culture requirements (e.g. infection of epithelial cells and lymphocytes as for EBV and HHV-6, -7 and -8) virus propagation can be accomplished only with difficulty, and culture of these viruses is not usually attempted in routine diagnostic laboratories. Detection of virus DNA by nucleic acid amplification procedures (see below) is a more practical method for detecting these viruses.

The ability of herpesviruses to replicate in monolayer cell cultures is variable. HSV-1 and HSV-2 can be cultivated in a wide variety of cells of both human and primate origin, including primary, continuous diploid and semicontinuous heteroploid cell lines. In contrast, CMV is fastidious and in cell culture only replicates in primary or semicontinuous (fibroblast) cell cultures of human origin. VZV is intermediate in its fastidiousness. It replicates best in semicontinuous cells of human origin, but may be cultivated with less efficiency in other cells. However, with the advent of molecular diagnostic methods that are more easy to implement in daily, routine diagnostic services, many laboratories are now abandoning their herpesvirus cultures.

Shell vial culture

The efficiency of primary virus isolation and speed of diagnosis can be improved using the so-called 'shell vial' culture. In this technique specimens are inoculated onto monolayers of cells grown on cover-slips. The specimen and shell vial containing the specimen are lightly centrifuged to improve the efficiency of attachment of virus to cells. After 24 or 48 hours of culture, monolayers are fixed (e.g. using cold acetone) and stained with either:

- a virus-specific antibody tagged with fluorescein isothiocyanate and examined by ultraviolet microscopy; or
- a peroxidase-labeled antibody with subsequent dye deposition within cells to identify the agent using light microscopy.

Identification of virus in cell culture

Virus growth in culture can be identified by the appearance of a cytopathogenic effect (CPE) and virus may be further characterized using specific antiserum (i.e. virus neutralization). This labor-intensive and time-consuming technique is now rapidly being replaced by more rapid methods of identification such as shell vial culture, direct immunofluorescent staining of cultures showing CPE and molecular diagnostic methods.

Electron microscopy

The limiting factor in the sensitivity of detecting virus by electron microscopy is the requirement that the sample contains at least 10^6 particles/ml. Electron microscopy is therefore useful in the examination of vesicle fluid from children who have suspected chickenpox and occasionally in the examination of atypical lesions of HSV infection as might be found in eczema herpeticum. The vesicle fluid is mixed with 3% buffered phosphotungstic acid, placed on a formvar and carbon-coated grid, blotted dry and examined in the electron microscope for the characteristic viruses (see Fig. 215.2). Although the morphology of herpesviruses is characteristic, differentiation of HSV-1, HSV-2 and VZV requires immune electron microscopy using virus-specific monoclonal antibodies.

Antigen detection

Antigen detection has a limited but important role to play in the diagnosis of most herpesvirus infections. In general, specimens may contain too little virus to allow reliable detection of antigen. Nevertheless, in a case of vesicular eruption, vesicle fluid (air dried and fixed in cold acetone) can be stained with monoclonal antibodies tagged with fluorescein isothiocyanate to provide a rapid specific diagnosis of infection.

Antigen detection also has an important role in monitoring organ transplant recipients (e.g. bone marrow transplant recipients) for the development of CMV disease. Buffy coat blood samples are examined for CMV pp65 antigen using a monoclonal antibody tagged with fluorescein. This procedure makes it possible to detect and monitor viremia and has been extremely useful to monitor and control CMV infections in various kind of transplant patients. Examination of CSF lymphocytes can provide a diagnosis of CMV infection of the central nervous system (CNS).

A variety of rapid immunoassay tests has been developed for 'within the office' testing for HSV. However, the sensitivity and specificity of these tests are too low to allow their use in diagnosis for hospitalized patients. As with virus cultures, these approaches are now being replaced by rapid molecular diagnostic techniques.

Nucleic acid amplification

The use of molecular diagnostic methods has changed the face of diagnostic virology. With increasing automation and further technical developments the very high sensitivity and the potential for early, rapid diagnosis are now outweighing the well-known disadvantages of technical complexity and lack of robustness, risk of contamination and cost. In addition to many in-house protocols used, a number of nucleic acid amplification systems[37] [38] are now available commercially. They are all based upon either:

- target amplification, for example PCR, ligase chain reaction, nucleic acid sequence based amplification (NASBA) and transcription-mediated amplification (TMA); or
- signal amplification, for example branched DNA amplification (bDNA).

Of these, PCR is currently the most widely used amplification method. Many assay procedures based upon the PCR procedure have been described and the use of PCR for diagnosing neurologic disease caused by the human herpesviruses has become the gold standard.[39] Single (sPCR) and nested (nPCR) PCR procedures have been described, including procedures that detect RNA and those that detect DNA. Both qualitative and quantitative assay procedures are available. Detection of several herpesviruses within the same clinical sample is possible using multiplex PCR where primers are included in the reaction mixture for several different herpesvirus DNA targets. For all these procedures a thorough evaluation of test protocols and rigorous quality control are essential to produce reliable test results.

Many protocols have also been described for extracting DNA from clinical samples. The purpose of DNA extraction is to render the target DNA free from potential inhibitors of the DNA polymerase used in the amplification step, that could result in false-negative PCR test results. As yet, there is no 'universal' extraction procedure

suitable

for all procedures. To determine whether sample inhibition has occurred, PCR test reactions often include an internal control molecule. Usually this is a bacterial plasmid DNA containing regions of DNA equivalent to those in the target DNA where the primers will bind. However, between the primer-binding sequences a 'scrambled' DNA sequence is inserted so that internal control and target DNAs can be distinguished upon amplification.

Detection of amplified DNA is usually accomplished by gel electrophoresis and staining with ethidium bromide. The product can also be detected by hybridization techniques where the dsDNA product is denatured and the ssDNA is hybridized with an oligonucleotide 'probe' sequence.

Progressively this cumbersome post-amplification handling with its inherent contamination risk is being replaced by 'real-time' amplification techniques, where the generation of amplified product is measured during the amplification process itself. Furthermore, the 'real-time' methodology also makes it relatively easy to quantitate the amount of virus present in the patient's specimen. This has been a great step forward in patient management because it allows much better monitoring of the course of disease and treatment of patients by clinicians and virologists.

Nucleic acid amplification techniques are now indispensible for the diagnosis of herpesvirus infections, particularly HSV, of the CNS.[40] [41] Determination of the viral load may be helpful for prognosis.[42] In transplant patients, quantitative 'real-time' assays have become of crucial importance in monitoring the development of CMV and EBV infections and a patient's response to treatment. Further rapid implementation of 'real-time' or other nucleic acid amplification techniques for the detection and quantitation of human herpesviruses is to be expected.

Genotypic analyses (restriction fragment length polymorphism)

Restriction fragment length polymorphism (RFLP) analysis is a specialist procedure of possible value in the investigation of outbreaks of infection and epidemiologic studies. Virus isolates in cell culture or PCR products are labeled with phosphorus-32 and DNA is extracted and digested using a range of restriction enzymes. On gel electrophoresis a series of fragments are segregated. Comparison of the migration of these fragments (RFLP patterns) gives information on the genetic relatedness (or unrelatedness) between strains of virus. Restriction fragment length polymorphism analysis also provides a reference procedure that allows identification and typing of isolates in one procedure.

Virus serology

Complement fixation and indirect immunofluorescence tests are still used in many viral diagnostic laboratories. However, their use is declining in favor of more reproducible and sensitive enzyme-linked immunosorbent assay (ELISA) methodologies.[39] Neutralizing antibody tests for herpesvirus antibodies are not routinely performed in diagnostic laboratories and none of these viruses has hemagglutinating capability.

Many immunoassays are available for the detection of antibodies to HHV-1 to HHV-5 and assays for antibody to HHV-6 to HHV-8 are now becoming commercially available. The antibody-capture ELISA principle is used to detect IgM antibody, but results of IgM tests must be interpreted with care:

- as IgM antibody is the first antibody to be produced in response to infection it is by nature a broadly reactive antibody, so cross-reactivity and false positivity may occur; and
- IgM antibody is produced during both acute (primary) infection and recurrent disease, although the amount produced is generally higher during primary infection.

Quantitation of virus-specific IgG antibody in serial samples (10 or more days apart) often provides a more reliable diagnostic procedure, but it takes considerably longer (up to 2 weeks) to obtain results.

Detection of IgA antibody is not generally carried out, but may have a role in the serologic diagnosis of recurrent herpesvirus infections.[43]

CLINICAL MANIFESTATIONS

With the exception of VZV, primary herpesvirus infections in the immunocompetent host are usually asymptomatic or are associated with a minor illness only, with no specific symptoms such as fever and malaise (Table 215.9). As a consequence, primary herpesvirus infections may not be recognized. When symptoms do occur, herpesvirus infections in the immunocompetent host are normally self-limiting and require only symptomatic treatment. Antiviral therapy is available for a number of herpesviruses, but is usually only indicated for those patients who have more severe disease manifestations or when it is appropriate to minimize the likelihood of complications.

Herpesvirus infections in the immunocompromised host are frequently severe and sometimes life-threatening. Antiviral drug therapy is required for these patients to control the infection (see Table 215.7).

Herpes simplex viruses

Although HSV infections can result in a wide spectrum of disease (Fig. 215.7), mucocutaneous lesions are by far the most common manifestation of primary HSV infections.[44]

Mucocutaneous manifestations

Oropharyngeal infection

Primary oropharyngeal HSV-1 infection usually occurs in childhood and is often asymptomatic. In symptomatic infections acute gingivostomatitis is seen in 10–30% of cases.[45] Lesions on the buccal and gingival mucosa evolve from vesicles to shallow ulcerations on an erythematous base. Frequently the child is unable to eat or swallow liquids because of the significant edema, ulceration of the oropharyngeal membranes and associated pain. Primary HSV gingivostomatitis is usually accompanied by fever and submandibular lymphadenopathy. The incubation period varies from 2 to 12 days (mean 4 days). The duration of clinical illness may extend from 2 to 3 weeks, with virus excretion from the oropharynx for an average of 7–10 days. In many countries the epidemiology of this infection is changing, this change being characterized by an increasing incidence of primary HSV-1 infection later in life. Primary HSV infection in an adolescent or adult is often associated with pharyngitis and a mononucleosis-like syndrome.

The severity and duration of clinical illness in recurrent infection is considerably less than in primary HSV infection. Recurrent orolabial lesions ('cold sores') are heralded by a prodrome of pain, burning, itching or tingling for several hours before the development of the characteristic vesicles. The vesicular stage persists for less than 48 hours and progresses to the ulcerative and crusting stage within 3–4 days. Pain resolves quickly during the same period, and healing is generally complete within 8–10 days. Systemic illness is usually absent in recurrent infection. Recurrence rates are highly variable and the precipitating factors involved are not well defined, but include the type of HSV (HSV-1 is more likely to recur than HSV-2), fever, stress, exposure to ultraviolet light and impaired CMI in the host.

Genital infections

Primary genital herpes usually occurs in adolescents and young adults.[16] Approximately 20–40% of first-episode genital herpes is now due to HSV-1, but the recurrence rate of genital HSV-2 infections is ten times higher than that of genital HSV-1 infections.[46] [47]

TABLE 215-9 -- Clinical manifestations of herpesvirus infections.

CLINICAL MANIFESTATIONS OF HERPESVIRUS INFECTIONS

Agent	Primary infection	Recurrent infection	Complications
HSV-1, -2	Usually asymptomatic; orofacial/genital, mucocutaneous lesions, gingivostomatitis, paronychia	Usually asymptomatic, cold sores, genital herpes, recurrent skin lesions	Meningitis, encephalitis, hepatitis, keratitis, generalized disease (neonates), eczema herpeticum
VZV	Varicella	Herpes zoster, zoster, ophthalmicus, oticus	Pneumonitis, hepatitis, encephalitis, keratitis, postherpetic neuralgia, cerebellar ataxia
CMV	Usually asymptomatic; mononucleosis-like syndrome, fever, malaise, myalgia, lymphadenopathy	Usually asymptomatic	Pneumonia, retinitis, esophagitis, colitis, hepatitis, enteritis
	Neonates: growth and mental retardation, hepatosplenomegaly, microcephaly		
EBV	Usually asymptomatic, infectious mononucleosis	Usually asymptomatic	X-linked proliferative syndrome, persistent mononucleosis-like syndrome, Burkitt's lymphoma, nasopharyngeal carcinoma, lymphoma, encephalitis
HHV-6	Usually asymptomatic; febrile illness exanthema subitum, febrile convulsions	Usually asymptomatic	Meningoencephalitis, pneumonitis, hepatitis
HHV-7	Unknown, occasionally exanthema subitum	Unknown	Unknown
HHV-8	Unknown	Unknown	Kaposi's sarcoma, body cavity lymphoma

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

The incubation period is 3–7 days. The majority of cases (50–70%) are asymptomatic or so mild that the infection is not recognized. The severity and duration of clinical symptoms depend upon both viral and host factors and include the type of virus, past exposure to HSV-1, previous episodes of genital herpes and gender. [46] (See Chapter 76 .)

Primary genital herpes is characterized by the appearance of vesicular lesions — in males usually on the glans penis, on the penile shaft or in the perianal region, and in women involving the vulva, vagina, cervix and perineum. Extragenital lesions (on the buttocks and thighs) occur in 10–20% of patients. The lesions can be very painful and associated with inguinal adenopathy and dysuria. Urinary retention is observed in up to 20% of female patients. Systemic symptoms occur in 40–70% of patients who have primary genital herpes and include fever, malaise, headache and myalgia.

Patients usually present with bilateral pustular or ulcerative lesions on the external genitals that coalesce into larger areas of ulceration. The ulcerative lesions persist for 4–15 days and usually resolve without residual scarring after a phase of crusting and re-epithelialization.

The average duration of primary symptomatic genital herpes is 3 weeks. During this time the pain and irritation caused by the lesions gradually increase during the first week, reach their peak of intensity early in the second week and gradually resolve during the second and third week. Tender lymphadenopathy is usually seen in the second and third week of illness.

Complications of primary genital herpes include aseptic meningitis, which has been reported in up to 36% of women and 12% of men, and sacral radiculopathy, which may lead to urinary retention.[16] [46] In homosexual men primary anal HSV-2 infection is frequently associated with proctitis.

The signs and symptoms of recurrent genital herpes are usually restricted to the genital region and are relatively mild and of shorter duration than for primary disease. Prodromal symptoms are a feature of approximately 50% of episodes. They vary from mild tingling to stabs of pain in the buttocks, legs and hips. As for primary disease, recurrent lesions in women are more often painful and of longer duration than in men (60–90 vs 30–70%, and mean 5.9 vs 3.9 days, respectively).

Other mucocutaneous manifestations

Other mucocutaneous manifestations of HSV infections include classic herpetic lesions — a close crop of vesicles on other areas of the skin, notably of the head, neck and shoulders, or the eyes, where there may be vesiculation of the eyelid and associated conjunctivitis.

Herpetic whitlow is an often painful infection of the finger that can result from auto-inoculation or direct contact with an individual who has an HSV infection. It is therefore an occupational hazard of dentists, doctors and nurses.

In patients who have atopic dermatitis, superinfection with HSV may appear as eczema herpeticum. Most cases are mild with localized lesions, but severe disseminated cases (Kaposi's varicelliform eruption, resembling severe varicella) occur, resulting in a widespread vesicular eruption and are associated with a small but significant risk of fatal disseminated infection.

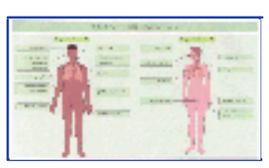

Figure 215-7 Diseases caused by herpes simplex virus-1 and herpes simplex virus-2.

Other manifestations

Herpes simplex virus encephalitis

Herpes simplex virus encephalitis is one of the most severe manifestations of HSV infection.[48] Although rare — incidence 1/250,000 to 1/500,000 population per year — it is the most commonly diagnosed cause of sporadic fatal encephalitis. Either HSV-1 or HSV-2 can cause HSV encephalitis, but approximately 95% of cases are due to HSV-1.[49] It can occur at any time of life and there is no apparent seasonal or geographic clustering of cases. Symptoms include fever, headache, behavioral abnormalities, altered consciousness and focal or generalized seizures suggestive of focal temporal lobe disease. The amount of HSV DNA in the CSF appears to be correlated with prognosis and outcome.[42] Early antiviral treatment is imperative. If untreated, the disease is frequently fatal or results in severe persisting neurologic sequelae (see also Chapter 23).

Neonatal herpes

Neonatal infection is a rare but severe manifestation of HSV infection acquired during delivery or in the immediate postpartum period.[50] It usually occurs in neonates who do not have protective maternal HSV antibody, and HSV-2 infection is usually more severe than HSV-1 infection.

Constitutional signs and symptoms include fever, irritability, seizures, failure to feed and a characteristic vesicular exanthem. Localized neonatal infections mostly involve the skin and are characterized by clusters of discrete vesicles at multiple sites. Localized infection may also occur in the mouth and oropharynx or the eye. In disseminated disease the principal tissues involved are the liver and adrenals, but other organs such as brain, lungs, esophagus, lower gastrointestinal tract, spleen and kidneys can be affected.

If untreated the mortality rate exceeds 50% and children who have disseminated infection have the worst prognosis. Even with prompt administration of specific antiviral chemotherapy survivors often experience neurologic complications. In all cases of neonatal herpes prompt initiation of antiviral chemotherapy is mandatory to prevent the development of long-term neurologic impairment.

Herpes simplex keratoconjunctivitis

Ophthalmic infections with HSV are among the most common causes of corneal blindness.[51] Dendritic ulceration of the cornea is the most characteristic manifestation. Most frequently it is unilateral. Visual acuity is decreased in the presence of ulcers and progression of the disease can result in visual loss. Despite appropriate antiviral treatment attacks can last several weeks to months.

Immunocompromised host

Patients compromised by immunosuppressive therapy (e.g. organ transplant recipients) or patients who have immunodeficiency are at risk of developing a severe primary infection and more severe and frequent recurrent disease. Disease severity is directly related to the degree of immunosuppression or immunodeficiency. Mucocutaneous infections are usually more extensive and severe and take longer to heal, even when appropriate antiviral therapy is initiated. Progression of the infection may involve the respiratory tract, esophagus or gastrointestinal tract.

Varicella-zoster virus

Varicella (chickenpox) and herpes zoster (shingles) are due to infection with the same virus, VZV. Varicella is the usual manifestation of primary infection, herpes zoster of recurrent infection.[52]

Varicella (see Chapter 8)

After an incubation period of 14–15 days (range 10–20 days) a vesicular rash accompanied by low-grade fever and pruritus emerges in successive crops over a 3- to 6-day period. The rash is characterized by maculopapular lesions that vesiculate in about 3–4 days before crusting and scab formation. Scabs may remain in situ for up to 3 weeks.[53]

Varicella is a common childhood exanthematous disease, usually affecting children in their early school years. The exanthem is centripetal rather than centrifugal with most lesions being present on the trunk and proximal extremities. Rashes beginning on the face and hands with subsequent spread to the trunk have been described. Secondary bacterial infection of the lesions as a result of scratching is the most frequent complication. Occasionally cerebellar ataxia, transverse myelitis or Reye's syndrome may complicate the infection. Primary VZV infection occurring in adolescence and adult life is often associated with more severe disease. The rash is often widespread and dense and patients are more likely to develop visceral complications such as pneumonitis, encephalitis and hepatitis.[54]

Primary VZV infection may have a more aggressive course in pregnant women.[55] This frequently includes visceral complications, notably pneumonitis. The fetus is at risk of infection and there is a low risk of severe fetal abnormalities ranging from longlasting rash, limb or dermatomal scarring, to severe neurologic damage.[56] Severe neonatal varicella may occur when maternal varicella presents within 5 days of delivery.

As for other herpesvirus infections, primary VZV infection of immunocompromised patients such as children undergoing cancer chemotherapy or corticosteroid treatment usually has a more severe protracted course with an increased rate of complications, particularly pneumonitis.

Herpes zoster (see Chapter 29)

Herpes zoster is typically a disease of the elderly. Usually there is a prodrome of pain followed within a few days by the development of a unilateral vesicular rash within the dermatome served by the sensory nerve from the affected ganglion.[57] New lesions form over 2–5 days and the rash then pustulates and scabs over 2–3 weeks.

Persisting pain, known as postherpetic neuralgia, is the most common complication of herpes zoster. It can be severe and last for several months. The rate, severity and duration of postherpetic neuralgia are directly related to age. It is uncommon in patients under 50 years of age, but occurs in over 40% of those over 60 years of age.[58]

The sites most commonly affected by herpes zoster are the dermatomes T3 through L3, often the same as those that were most affected during chickenpox. Complications including motor weakness and visceral manifestations may occur, but are unusual. However, in up to 50% of patients where herpes zoster involves the trigeminal nerve ocular manifestations such as conjunctivitis, ulcerative keratitis, uveitis and iridocyclitis occur. Ocular complications are particularly common when the zosteriform lesions extend to the tip of the nose. Herpes zoster oticus, also called the Ramsay Hunt syndrome, consists of lesions on the ear or within the auditory canal, which are sometimes barely visible, and can result in hearing loss and facial paralysis.

Herpes zoster is frequently observed in patients who are immunocompromised, including those undergoing radiotherapy, chemotherapy and other types of immunosuppressive therapy, and those who have immunodeficiency syndromes. In such patients herpes zoster presents with larger, more extensive and hemorrhagic vesicles, which are often multidermatomal. Chronic cutaneous lesions and disseminated infections have been described, particularly in patients who have HIV infection. Meningoencephalitis, pneumonitis or hepatitis can also occur in immunocompromised patients, but are rare.

Cytomegalovirus

CMV is an uncommon cause of disease in people who are immunocompetent. Primary infection may occasionally cause a glandular fever-type illness resembling EBV mononucleosis.[59] In such patients persistent fever, myalgia and asthenia accompanied by atypical lymphocytosis and elevated liver transaminases are common signs and symptoms. Occasionally hepatitis is the presenting symptom. The presence of fever and atypical lymphocytes distinguishes CMV mononucleosis with liver involvement from infections by the usual hepatitis viruses.

In contrast, in patients who have an immature (e.g. fetus or newborn) or compromised immune system both primary and recurrent infection with CMV can result in severe and sometimes fatal disease.

Congenital and perinatal infections

CMV infections are the most common cause of congenital viral infections. [60] Both primary and recurrent infection in a pregnant woman can cause congenital and perinatal disease, but the frequency of severe disease is at least 10-fold higher after primary maternal infection. Overt clinical symptoms occur in 5–10% of cases of intrauterine CMV infection and include growth retardation, hepatosplenomegaly and thrombocytopenic purpura, and less frequently jaundice, microcephaly and chorioretinitis. The prognosis is poor for these infants. Another 10–15% of cases are neonates who are asymptomatic at birth and develop late sequelae, particularly mental retardation and sensorineural hearing loss.

Perinatal infections are nearly always asymptomatic, but neonates occasionally develop CMV pneumonitis, particularly when born prematurely. Severe disseminated disease may follow transfusion of CMV-infected blood products to premature neonates who have CMV-seronegative mothers.

Immunocompromised patients

The pathogenesis and clinical spectrum of CMV disease in patients who are immunocompromised depend upon the cause and degree of immunosuppression. [61] [62] Treatment regimens must take into account the fact that the disease manifestations may have an immunopathologic or viral etiology.

Persistent intermittent fever is often the presenting symptom of CMV infection in patients who have had a transplant. The infection may progress to cause pneumonitis, gastrointestinal disease, hepatitis and retinitis. In recipients of a solid organ transplant, CMV disease most frequently occurs when the donor is CMV-seropositive and the recipient is CMV-seronegative. In bone marrow transplant patients, however, CMV disease most commonly results from reactivation of latent virus in the recipient, usually 20–90 days after the transplant. The most frequent manifestation is CMV pneumonitis. Unless treated very early, preferably before the appearance of

respiratory symptoms, pneumonitis in these patients is often fatal.

Reactivation of latent CMV is usually the cause of CMV disease in patients who have HIV infection, frequently occurring in the later stages of the HIV infection when $CD4^+$ T cell counts are less than $50/mm^3$. The most frequent manifestation is CMV retinitis presenting with blurred vision and decreased acuity (see Chapter 125). [62]

Gastrointestinal disease, hepatitis, encephalitis and pneumonia also occur in patients who have HIV infection. Gastrointestinal disease includes esophagitis, gastritis, enteritis and colitis and is usually associated with fever and weight loss. Although CMV is often detected in respiratory specimens from patients with AIDS who have pneumonitis, the pulmonary process is usually caused by other pathogens, particularly *Pneumocystis carinii*.

Epstein-Barr virus

In most individuals EBV infection does not cause overt disease. [11] Primary infections in adolescents can, however, result in infectious mononucleosis. As for CMV infection, immunocompromised hosts may develop severe manifestations during both primary and recurrent EBV infection. Such severity is exemplified by the role of EBV infection in the causation of lymphoproliferative disease.[63] [64]

Immunocompetent host

Infectious mononucleosis (glandular fever) usually presents as fever, fatigue and malaise accompanied by a sore throat, cervica1 lymphadenopathy, hepatomegaly and splenomegaly. A rash may develop, particularly in those treated with ampicillin. Disease manifestations, especially fatigue and malaise, can persist for several weeks. Relapses and a chronic course have been described but the relationship to EBV infection is uncertain.

The X-linked lymphoproliferative (or Duncan's) syndrome is a rare manifestation of primary EBV infection and occurs in (young) males who have an X-linked genetic defect in their immune response to EBV.[63] Most die from fulminant mononucleosis, fulminant hepatitis or aplastic anemia.

Patients who have Burkitt's lymphoma have large swollen lymph nodes, usually involving the jaw and orbital cavities.[8] The disease occurs mainly in young children. In contrast, nasopharyngeal carcinoma is usually seen in older male patients in South East Asia.[9]

EBV has been associated with Hodgkin's disease. EBV-specific sequences and EBV-induced antigens have been found in Reed-Sternberg cells.[64] The precise role of EBV in the etiology of Hodgkin's disease, however, remains to be established. Other EBV-associated lymphoepithelial tumors have been described in the parotid gland, thymus, stomach, lung and larynx.[64]

Immunocompromised host

Immunocompromised patients are at risk of developing lymphoproliferative disorders following EBV infection. The polyclonal B lymphocyte proliferation is often associated with fever, lymphadenopathy and hepatosplenomegaly,[64] and is frequently life-threatening in severely immunocompromised patients, such as bone marrow transplant patients.

Patients who have AIDS may develop oral hairy leukoplakia, which is characterized by white plaques on the lateral margin of the tongue.[65] EBV is associated with lymphocytic interstitial pneumonia (which is common in pediatric patients who have AIDS) and a rapidly progressing, diffuse encephalitis.

Human herpesviruses-6, -7 and -8

Human herpesviruses-6, -7 and -8 have only been recognized during the past 15 years.[28] Although their etiologic role in the development of a variety of disease manifestations is well documented, their full disease spectrum remains to be determined.

Human herpesvirus-6

HHV-6, variant B, is the cause of exanthema subitum (roseola infantum) in young children.[27] Symptomatic infection is characterized by fever, sometimes associated with a mild respiratory illness and lymphadenopathy, which is followed by the appearance of a fine maculopapular rash spreading from the trunk to the extremities. More recent studies have shown that the primary characteristic of HHV-6 infection in infants is a high fever for 3–4 days, often associated with inflammation of tympanic membranes. Only a small proportion of these (<10%) develops exanthema subitum.[66] Up to 20–25% of hospital admissions of children under 3 years of age with acute febrile illness is due to primary HHV-6 infection.[66] [67] Primary HHV-6 infection has also been demonstrated as a frequent cause of febrile seizures in infants, and accounts for up to one-third of all febrile seizures under the age of 3 years.[67] [68] Recovery is usually rapid and uneventful, although a more protracted and severe course characterized by severe meningoencephalitis, fulminant hepatitis or fatal pancytopenia has been described. In adolescents and adults primary HHV-6 infection can cause a mononucleosis-like illness.

Some recent studies have suggested a role for HHV-6 in the etiology of multiple sclerosis. This is based on the finding by PCR of HHV-6 DNA in the brain. [69] However, literature findings still remain ambiguous, and further studies are needed to define the possible role of HHV-6 in multiple sclerosis.

In severely immunocompromised patients, such as those who have AIDS or received a bone marrow transplant, reactivation of HHV-6 infection mainly has an immunosuppressive effect, subsequent to which other pathogens may cause severe disease. In bone marrow transplant patients HHV-6 reactivation is associated with bone marrow suppression, probably as the result of viral replication in particular progenitor cells.[70] HHV-6 has also been associated with interstitial pneumonia and encephalitis in these patients. Finally, mainly on the basis of *in-vitro* studies, HHV-6 has been reported as a possible cause of or cofactor for certain lymphoproliferative disorders.

Human herpesvirus-7

Although some cases of exanthema subitum appear to be due to HHV-7, a causal association between human disease and HHV-7 infection has not yet been established. HHV-7 has been associated with infant febrile illness as well as subsequent CNS complications. In renal transplant patients evidence has been obtained that HHV-7 may be a cofactor in the development of CMV disease.

Human herpesvirus-8

No association has been recognized between primary HHV-8 infection and specific clinical disease, but it is now generally accepted that HHV-8 has a causal role in KS and a rare form of abdominal B-cell lymphoma, body-cavity associated lymphoma and primary effusion lymphoma.[27] [28] The virus is also found in some cases of multicentric Castleman's disease. The possible involvement of HHV-8 in the development of other endothelial cell-derived tumors requires further investigation.

Herpes B virus

Herpes virus simiae (herpes B virus) causes a benign latent infection in macaques that is analogous to HSV infection in humans.[71] The infection is infrequently transmitted to humans. After an incubation period varying from 3 days to 3 weeks there may be localized pain, redness and vesicular skin lesions near the site of the viral inoculation, followed by localized neurologic symptoms. Encephalopathy is common and fatal in up to 70% of patients. The virus is susceptible to aciclovir and early treatment can be life-saving.[72]

MANAGEMENT

As most herpesvirus infections in the immunocompetent host are self-limiting, patients usually only require supportive care. The type of supportive treatment required varies for different disease manifestations and may consist of rest, hydration, the appropriate use of antipyretics, analgesics, and treatment to soothe skin lesions and to prevent secondary bacterial infection. Effective antiviral therapy is available for more severe cases of infection caused by HSV, VZV or CMV. It is stressed, however,

that although antiviral drugs can help to control a herpesvirus infection they cannot eliminate the infection.

Antiviral drugs

Most antiherpetic drugs are nucleoside analogs[73] that inhibit virus-specified DNA polymerases and terminate DNA chain elongation (see Table 215.7 ; see Chapter 205). The first generation of these drugs — idoxuridine, vidarabine and trifluridine — have only a limited selectivity for the viral DNA polymerase. Due to the interaction of the phosphorylated form of these drugs with cellular DNA polymerases, there are severe adverse effects.

Aciclovir is the prototype of the present generation of antiviral drugs (see Chapter 205). [74] Its high specificity and therefore safety is

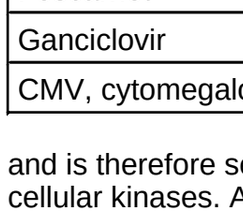

Figure 215-8 Mode of action of aciclovir. Phosphorylation is effected by virus-specified thymidine kinase. The aciclovir monophosphate is then converted to the triphosphate form by cellular kinases. Aciclovir triphosphate binds with high affinity to the virus-specified (but not host derived) DNA polymerase, leading to inactivation of the enzyme's activity. In addition, incorporation of aciclovir in the DNA blocks further chain elongation.

based on its specific interaction with viral and not cellular enzymes (Fig. 215.8). It is an acyclic analog of guanosine that is activated by viral and not the cellular thymidine kinase to serve as substrate for the viral DNA polymerase. Aciclovir is virtually inert as administered. Approximately 90–92% is excreted unchanged by renal excretion with the majority of the remainder appearing as the metabolite 9-carboxymethoxymethylguanine. The serum half-life of the drug is about 2–3 hours. Virus-infected cells appear to be slightly more permeable to aciclovir than noninfected cells, but aciclovir is only entrapped and selectively concentrated within virus-infected cells. This is achieved by phosphorylation effected by virus-specified thymidine kinase. Host cell kinases do not appear capable of effecting this primary phosphorylation to any significant degree. Aciclovir monophosphate cannot traverse cellular membranes

TABLE 215-10 -- Comparative susceptibility of herpesviruses to antiviral drugs.

COMPARATIVE SUSCEPTIBILITY OF HERPESVIRUSES TO ANTIVIRAL DRUGS					
Antiviral drug	**Viral susceptibility**				
	HSV-1	**HSV-2**	**VZV**	**CMV**	**Main target agents**
Aciclovir, valaciclovir	+++	+++	++	-	HSV-1, HSV-2, VZV
Cidofovir	+	+	++	+++	CMV, resistant HSV
Famciclovir	+++	+++	++	-	HSV-1, HSV-2, VZV
Foscarnet	++	++	+	++	CMV, resistant HSV, VZV, CMV
Ganciclovir	+	+	+	+++	CMV
CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.					

and is therefore selectively concentrated in virus-infected cells. The monophosphate is converted to the active antiviral aciclovir triphosphate through the action of cellular kinases. Aciclovir triphosphate is a potent and highly selective inhibitor of viral-specified DNA polymerase. A further but less significant antiviral action is the chain termination effected by the incorporation of aciclovir into the growing viral DNA chain (absence of 2' and 3' carbons of guanosine). Aciclovir is a safe, relatively nontoxic drug and is effective for therapeutic use as well as long-term suppressive treatment.

The recently approved drugs famciclovir and valaciclovir are similar to aciclovir in their mechanism of action, but have different pharmacologic properties. These drugs have improved oral bioavailability, thereby allowing less frequent administration than is required for aciclovir. As with aciclovir, famciclovir and valaciclovir have excellent safety records.

The alternate antiherpetic drugs, ganciclovir, foscarnet and cidofovir have similar mechanisms of action, (i.e. inhibition of the viral DNA polymerase), but generally have a higher toxicity profile, including neutropenia and thrombocytopenia for ganciclovir, and nephrotoxicity for foscarnet and cidofovir. The susceptibility of different herpesviruses to the various antiviral drugs is shown in Table 215.10 .

Antiviral resistance has been described for all of the antiherpes compounds mentioned, particularly when antivirals are administered to immunocompromised patients over extended periods of time. Studies in these patients have shown resistance to aciclovir in 5% and to ganciclovir in 7% of patients.[75] [76] Antiviral resistance is due to mutations in the viral thymidine kinase or in the DNA polymerase.[77] Resistant viruses, however, appear to be less virulent.[78] Significant circulation in the general population has not yet been found.[76] Because of their similar mechanisms of action cross-resistance frequently occurs (e.g. between aciclovir, famciclovir and valaciclovir).

Herpes simplex virus

In several placebo-controlled studies, intravenous, oral or topical administration of aciclovir, famciclovir and valaciclovir have been shown to be effective against mucocutaneous HSV infections (Table 215.11). All three drugs significantly reduce:

- duration of viral shedding;
- time to healing of lesions;
- duration of pain and itching; and
- rate of complications.

The effect is more pronounced for primary or first-episode HSV infections than for recurrent disease in the immunocompetent host. Oral or intravenous administration is generally more effective than topical treatment. Intravenous administration of aciclovir is the treatment of choice for patients who have suspected systemic or neurologic disease due to HSV (e.g. patients who have herpes encephalitis). Antiviral therapy should be initiated as soon as possible

for these patients, even before laboratory confirmation of the clinical diagnosis.

For patients who have frequent severe episodes of genital herpes, a choice can be made between patient-initiated episodic treatment or longer-term suppressive therapy. Episodic treatment must be initiated at the first sign of prodromal symptoms to be of benefit. Long-term suppressive therapy, however, is very effective and can dramatically reduce the frequency of recurrent disease and asymptomatic shedding. [79] [80] Although recurrent disease and intermittent shedding of HSV are not fully prevented,[81] suppressive therapy has been safe, effective and well tolerated in patients treated for more than 6 years. In addition, there is no evidence that it greatly enhances the emergence of antiviral resistance.[81]

Varicella-zoster virus

VZV is significantly less susceptible to aciclovir, famciclovir and valaciclovir than HSV. Therefore, higher dosage regimens are required. Intravenous therapy with aciclovir or oral administration of valaciclovir or famciclovir is indicated for children who have severe manifestations of varicella, particularly those who are immunocompromised (see Table 215.11). Therapy should also be considered for adolescent or adult patients who have varicella because of the increased risk of

complications in these patients. In immunocompetent children the antiviral effect is beneficial only when therapy is started very early after the onset of disease symptoms (<48 hours).

Intravenous aciclovir therapy has become the therapy of choice for patients who have a high risk of developing severe or progressive recurrent VZV disease (herpes zoster). These include patients treated for lymphoproliferative disorders, transplant recipients, other patients who have immunodeficiency conditions and patients who have herpes zoster ophthalmicus and herpes zoster oticus.

The poor bio-availability of aciclovir after oral administration has limited its use for immunocompetent patients who have herpes zoster. Valaciclovir and famciclovir have substantially improved bioavailability, accelerate healing and reduce pain in patients who have

TABLE 215-11 -- **Indications for antiherpesvirus drug treatment.**

INDICATIONS FOR ANTIHERPESVIRUS DRUG TREATMENT			
Antiviral drug	**Target virus**	**Infections**	**Possible side-effects**
Aciclovir, valaciclovir, famciclovir	HSV-1,2	Severe and/or frequent mucocutaneous HSV infection, including genital herpes; herpes encephalitis, herpes keratitis	Headache, nausea, diarrhea
	VZV	Severe cases of varicella, varicella in patients at risk for complications (immunocompromised, adolescents, adults)	Headache, nausea, diarrhea
		Severe cases of herpes zoster, including those at risk of developing postherpetic neuralgia, herpes zoster ophthalmicus, oticus	
Cidofovir	CMV	CMV retinitis	Severe nephrotoxicity
Foscarnet	CMV, HSV-1, HSV-2, VZV; severe disease due to aciclovir-, valaciclovir- and famciclovir-resistant HSV or VZV strains	Severe CMV disease refractory to ganciclovir treatment	Nephrotoxicity, crystalluria
Ganciclovir	CMV	Severe CMV disease in immunocompromised host (e.g. retinitis, esophagitis, colitis, pneumonia, encephalitis)	Neutropenia, thrombocytopenia
CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.			

herpes zoster,[82] [83] and are now licensed for these reasons in many countries. The effect is significant only in patients who are at risk of developing severe disease (i.e. those over 50 years of age who have considerable pain at the onset of symptoms). Furthermore, treatment has to start early (within 72 hours) to be beneficial. Treatment is always indicated for patients who have herpes zoster ophthalmicus or oticus.

Cytomegalovirus

There is no generally accepted indication for using antiviral therapy for immunocompetent patients who have CMV infection. In the immunocompromised host the first line of treatment of CMV disease is, if possible, appropriate reversal of immunosuppressive therapy. Additional, antiviral therapy is often required for these patients (see Table 215.11). For this purpose three drugs are now available — ganciclovir, foscarnet and cidofovir. Because CMV disease frequently recurs after cessation of antiviral therapy in patients who are immunodeficient, lifelong maintenance treatment is often required to prevent or delay disease progression.

Of the available drugs, intravenous ganciclovir is the treatment of choice for immunocompromised patients who have an episode of CMV disease, such as pneumonia, gastrointestinal tract disease or retinitis.[84] For maintenance therapy, particularly for patients who have AIDS and retinitis, there is an approved oral preparation of ganciclovir. Oral valganciclovir (the prodrug of ganciclovir) is recommended (see Chapter 125 and Chapter 205). [85] [86]

In general, foscarnet is less well tolerated than ganciclovir. Its nephrotoxicity is the most common dose-limiting adverse effect and foscarnet is mostly used for patients who have severe adverse effects to ganciclovir or who have ganciclovir-resistant CMV disease.[84]

Experience with cidofovir is limited. Its major benefit is its long half-life, permitting relatively infrequent dosing. The main application of cidofovir therapy has been for patients who have retinitis, using intravitreal administration every 6 weeks, or intravenous infusion once weekly for induction and every other week for maintenance therapy.

Although not very effective in the treatment of CMV infection, prophylactic use of valaciclovir in renal transplant patients has been found to have a preventive effect on the development of CMV disease.[87]

Other herpesviruses

EBV and HHV-6 have shown *in-vitro* susceptibility to various antiherpesvirus drugs such as aciclovir or ganciclovir. However, apart from aciclovir treatment of oral hairy leukoplakia in patients who have AIDS, no significant clinical benefit has so far been demonstrated. As for CMV disease, antiviral drug therapy is probably only effective when the disease is due to a viral rather than an immunopathologic process.

Recent *in-vitro* studies [69b] have shown that for HHV-6, -7 and -8 the most potent, presently available drugs with the highest antiviral selectivity index were:

- for HHV-6 — foscarnet and cidofovir;
- for HHV-7 — cidofovir and foscarnet; and
- for HHV-8 — cidofovir and ganciclovir.

However, so far no data from well-designed clinical studies have been reported to show the effectiveness of these drugs in the treatment of HHV-6, -7 or -8 infections. In addition, a number of experimental compounds, particularly S2242, an acyclic guanosine analog, were also found to have a marked antiviral effect in combination with an acceptable toxicity profile.[88]

Immunotherapy

Options for immunotherapy of herpesvirus-induced disease are limited and require further development, particularly for immunopathologically mediated herpesvirus disease (e.g. as occurs in CMV and EBV infections).

A few studies have shown a beneficial effect for a combination of ganciclovir and intravenous CMV immune globulin over the use of ganciclovir alone in bone marrow transplant recipients who have CMV pneumonia.[89] More recently, promising results have been obtained in the treatment of bone marrow transplant patients with PTLD by infusing donor T cells[90] and by the use of anti-CD20 monoclonal antibodies.[91]

Chapter 216 - Papillomaviruses and Polyomaviruses

Keerti V Shah

Until recently, these two virus families were grouped together as subfamilies in the papovavirus family because they shared the following characteristics: small size, nonenveloped virion, icosahedral capsid made up of 72 capsomers, double-stranded, circular, supercoiled DNA genome and nuclear site of multiplication. They were separated as different families because they are unrelated genetically and immunologically and are also biologically dissimilar. Papillomaviruses grow on surface epithelia, do not have a systemic phase of infection and are etiologically linked to cancer of the uterine cervix, other lower genital tract cancers and some oropharyngeal cancers. Polyomaviruses, on the other hand, have a viremic phase during which they infect internal organs such as the kidney and the brain and human polyomavirus JC is the etiologic agent for the degenerative central nervous system (CNS) disease progressive multifocal leukoencephalopathy (PML). Polyomaviruses are not linked to naturally occurring cancers.

PAPILLOMAVIRUSES

NATURE

Papillomaviruses are widely distributed in nature; among mammals they infect humans, cattle, dogs, rabbits, monkeys and other species. Some animal papillomaviruses affect both epithelial and fibroblastic tissues and produce fibropapillomas, but human papillomaviruses (HPVs) are strictly epitheliotropic and infect the skin or the mucous membranes.

Papillomaviruses cannot be propagated in cell culture. Therefore, rapid advances in the knowledge about papillomaviruses date from the 1970s, when molecular cloning of the viral genomes allowed comparisons between viruses from different species and from different sites of the same species. The cloned genomes provided reagents for examination of affected tissues for viral sequences.

The papillomavirus particle (Fig. 216.1) is about 55nm in diameter and has a double-stranded, covalently closed, circular genome of about 8000bp. All of the genomic information is located on one strand. The genome is divided into an early region that has eight open reading frames (ORFs E1–E8), a late region that has two ORFs (L1 and L2), and a noncoding long control region (LCR), which contains regulatory elements for viral DNA replication and transcription.

The L1 ORF codes for the major L1 capsid protein, which accounts for most of the virion mass and mediates viral attachment and immune response to infection. The prophylactic HPV vaccine strategies which are being tested are based largely on the use of the L1 protein expressed by recombinant DNA technology and self-assembled as virus-like particles (VLPS). The function of the minor L2 capsid protein is unclear. The early region genes E6 and E7 of high-risk HPVs code for the transforming proteins of the virus that mediate the oncogenic properties of the virus. The E1 gene is required for viral DNA replication and the E2 gene modulates viral transcription. The E5 gene is a membrane protein that interacts with growth factor receptors; it is the main transforming gene for bovine papillomaviruses but not for HPVs. The E4 gene, although it is located in the early region, is expressed late in the virus cycle; it disrupts cytokeratins and probably facilitates virus exit from infected cells. The functions of E3 and E8 ORFs are not known.

EPIDEMIOLOGY

More than 100 individual HPV types have been described to date. [1] They naturally fall into two groups, mucosal HPVs and cutaneous HPVs.

Mucosal human papillomaviruses

The genital tract is the reservoir for mucosal HPVs, except for two HPV types (HPV-13 and HPV-32), which infect the oral cavity. About 40 HPV types infect the genital tract. Genital HPV infections are the most prevalent sexually transmitted pathogens. As many as 30–40% of sexually active young women may have a prevalent HPV infection of the genital tract, as determined by a sensitive, amplification-based DNA detection technique. A history of multiple sexual partners, and having a male sexual partner who has many sexual partners, are the main risk factors for a woman for the acquisition of HPVs. Circumcision may decrease the risk of HPV acquisition in the male.[2] The HPV prevalence reaches its peak in young adults and declines at older ages. HPV infections are largely asymptomatic and of 1–2 years' duration. Infection probably confers partial immunity to re-infection with the same type. The course of HPV infection is altered profoundly by HIV-induced immunosuppression (see Chapter 77).

HPV-6 and HPV-11 are the etiologic agents of genital warts (condylomas), which occur in sexually active individuals, and also of recurrent respiratory papillomatosis (RRP), which may have onset in childhood or in adult life. HPV-16, -18, -31, -45 and some other types account for more than 90% of cervical cancers, as described in later sections of this chapter.

HPV-13 and HPV-32 cause focal epithelial hyperplasia in the oral cavity. This condition is found frequently in indigenous populations, but rarely in other groups. How they are transmitted from person to person is unclear.

Cutaneous human papillomaviruses

Skin warts are transmitted by direct contact with an infected tissue or indirectly by contact with virus-contaminated objects. There is some specificity between HPV type, and site and morphology of the warts; plantar warts most often yield HPV-1, common warts HPV-2 and flat warts HPV-3 and HPV-10.

Epidermodysplasia verruciformis is a rare condition in which an extensive lifelong wart virus infection of the skin is never resolved.[3] The disease may be familial. The warts may be flat or they may be in the form of reddish-brown macular plaques. In about one-third of these patients, malignant transformation occurs in the reddish-brown plaques in areas exposed to sunlight. The epidermodysplasia verruciformis lesions contain a large number of HPV types. Types most commonly associated with skin cancers in epidermodysplasia verruciformis patients are HPV-5 and HPV-8.

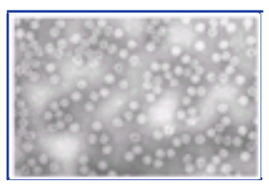

Figure 216-1 Human papillomavirus particles. The particles are nonenveloped, have icosahedral capsids and are 55nm in diameter. *Courtesy of Dr M Reissig.*

Low levels of HPV DNA sequences of a number of HPV types, including several novel types, have been recovered from nonmelanoma skin cancers. HPV sequences are also found in plucked hair roots of healthy skin. It is not clear if HPVs play a role in the development of non-melanoma skin cancers.[4]

PATHOGENICITY

Infectious agent

Papillomaviruses have a high degree of species and tissue specificity. Genital HPVs are rarely detected on skin other than that of the genital tract, but they can infect other mucosal sites in the body such as the aerodigestive tract. Cutaneous HPVs are almost never encountered in the genital tract.

Papillomaviruses cannot be grown in monolayer cell cultures to yield virus particles. Full epithelial differentiation is required for the production of infectious particles.[5] Limited numbers of papillomavirus particles are produced by infection in organotypic cultures of the epithelium or by transplantation of infected human cells to certain sites in immunodeficient mice.

Pathogenesis of cervical cancer

Nearly all cervical cancers originate in the 'transformation zone', located at the lower end of the cervix, where the stratified squamous epithelium of the vagina forms a junction with the columnar cells of the endocervix. The cells in the transformation zone of the cervix must be highly susceptible to the oncogenic effects of HPVs, because cancers arise much less frequently at other sites in the genital tract (vulva, vagina, penis) that are infected with HPVs as frequently as the cervix but do not have an area similar to the transformation zone.

Invasive cervical cancer is preceded by a progressive spectrum of cytologic abnormalities, classified as atypical squamous cells of undetermined significance

(ASCUS), low-grade squamous intraepithelial lesions (LSILs) and high-grade squamous intraepithelial lesions (HSILs). The progression from initial HPV infection to invasive cancer may take 15–20 years.

Although almost all squamous cell abnormalities of the cervix including cervical cancer are the result of HPV infections, the probability of any one HPV infection progressing to cervical cancer is quite small. Most HPV infections produce only transient cytologic abnormalities and are resolved completely without a trace. Cytologic abnormalities are seen in only about 10% of women who are positive

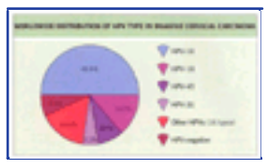

Figure 216-2 Worldwide distribution of HPV type in invasive cervical carcinoma. *The data are based on tests of over 900 cancers from different countries.*[7]

for HPV DNA in the genital tract. A large majority of LSIL regresses completely. In the USA, annually, there are tens of millions of HPV infections but only about 15,000 cases of invasive cancer. The relatively small number of cases is partly the result of treatment of LSIL and HSIL identified from Pap smear screening programs, but it is also, in a large measure, because most HPV infections do not result in significant cervical disease. In countries that have no effective Pap smear screening programs, the number of cases of cervical cancer is still a small fraction of the number of HPV infections in women.

HPVs are found in nearly all lesions spanning the entire spectrum of cytologic abnormalities from LSIL to invasive cancer. The distribution of HPV types changes markedly with increasing severity of disease.[6] Almost all genital HPV types are represented in HPV DNA-positive cytologically normal specimens and in ASCUS and LSIL cases, but only about a dozen HPV types are found in invasive cervical cancer. Of these, four HPV types, HPV-16, -18, -45 and -31, account for nearly 80% of invasive cancers (Fig. 216.2). The genital HPV types

TABLE 216-1 -- Major clinical associations of HPV infections.

MAJOR CLINICAL ASSOCIATIONS OF HPV INFECTIONS		
Disease	**HPV type**	**Transmission**
Cervical cancer		Sexual
High risk	HPV-16, -18, -45, -31	
Intermediate risk	HPV-33, -35, -39, -51, -52 -56, -59, -68, -73	
Low risk	HPV-6, -11, -26, -42, -43, -44, -53, -54, -55, -62, -66	
Cancer of vulva, vagina, anal canal, penis	HPV-16 and others	Sexual
Anogenital warts	HPV-6, -11	Sexual
Juvenile-onset RRP	HPV-6, -11	Mother-child, at birth
Adult-onset RRP	HPV-6, -11	Unclear
Cutaneous warts	HPV-1, -2, -3, -4, -10 and others	Nonsexual contact
Epidermodysplasia verruciformis	HPV-5, -8 and others	Nonsexual contact
Skin cancers	EV HPVs and novel HPVs	Unclear
Focal epithelial hyperplasia of the oral cavity	HPV-13, -32	Nonsexual contact

have therefore been categorized as high-risk, intermediate-risk or low-risk types (Table 216.1) on the basis of their prevalence in invasive cervical cancer.[7]

The oncogenic potential of HPVs is mediated by the E6 and E7 proteins of high-risk HPVs. In laboratory studies, E6 and E7 of high-risk HPVs can each transform mouse 3T3 cells and, together, can immortalize human keratinocytes. Viral constructs containing E6 and E7 genes of high-risk HPVs produce HSIL-like lesions in organotypic cervical epithelium. The E6 and E7 genes are invariably expressed in cells of HPV-associated cervical cancers. The viral genome of HPVs remains episomal in infections that are not associated with cervical cytopathology, as well as in cases of LSIL and in most instances of HSIL. However, in most invasive cancers the viral genome is integrated into the cellular DNA. Integration requires linearization of the circular viral genome, which almost always occurs by a break in the E2 region of the genome. The E6 and E7 genes not only remain intact after integration, but they are released from the inhibitory effect of the E2 protein, and are expressed at high levels in invasive

Figure 216-3 Effect of high-risk HPV E6 on the cell cycle. In normal cells (left), DNA damage results in increased p53 production, which leads to arrest of cell cycle in G1 phase, allowing the cell time to repair DNA damage. In cells infected with high-risk HPVs (right), the HPV E6 mediates degradation of p53, so there is no accumulation of p53, no cell-cycle arrest, and continued cell multiplication. This leads to genetic instability and accumulation of cellular mutations. *Courtesy of Dr TD Kessis.*

cancers. High levels of antibodies to E6 and E7 proteins are markers for invasive cancer.

The molecular mechanisms of cellular transformation by E6 and E7 genes of high-risk HPVs are well understood and are described in detail in excellent reviews.[8] [9] Briefly, the E6 protein complexes with tumor suppressor protein p53 and targets it for destruction via the ubiquitin pathway. The E7 protein complexes with tumor suppressor protein Rb, thereby releasing the transcription factor E2F from its complex with Rb. The E2F activates expression of *myc* and other genes that activate the cell cycle. In the normal cell cycle, tumor suppressor proteins p53 and Rb inhibit cellular proliferation. The functional inactivation of both of these cellular tumor suppressor proteins by the HPV oncoproteins result in continued cell proliferation without time for repair of DNA damage (Fig. 216.3). This leads to genetic instability and accumulation of additional cellular mutations and chromosomal changes. Thus, infections with high-risk HPVs prepare the ground for the cellular genetic alterations that underlie cervical cancer. For example, gain of 3q chromosome was found to be consistently associated with the early stages of invasive cervical carcinoma (Fig. 216.4).[10]

PREVENTION

HPV-related diseases for which preventive strategies are being investigated are cervical and other lower genital tract cancers, genital warts and recurrent respiratory papillomatosis.

Cervical cancer

There are high hopes that HPV-based strategies will help reduce cervical cancer burden in the world. Primary cervical cancer screening by examination of cervical scrapes for DNAs of high-risk HPVs has been shown to have a sensitivity greater than that of Pap smears for the detection of HSIL and cancer.[11] Furthermore, adequate genital

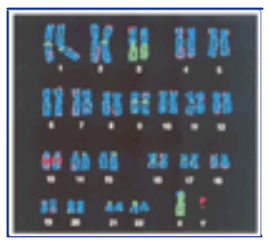

Figure 216-4 Gain of chromosome 3q in early cervical carcinoma. The figure displays a ratio image after comparative genome hybridization, in which normal reference metaphase chromosomes are hybridized with a mixture of differentially labeled tumor DNA (green label) and normal DNA (red label). The chromosomes are ordered in a karyogram-like fashion. Chromosome 3q is gained (over-representation of green label) and chromosomal band 13q21 is lost (over-representation of red label) in this carcinoma. *With permission from Heselmeyer et al.,*[10] *copyright (1996) National Academy of Sciences, USA.*

tract specimens can be self-collected by the women themselves, thus making it possible to avoid a pelvic examination. Assays for genital tract HPV DNAs are useful in the clinical management of mild cervical cytological abnormalities.[12]

Virus-like particles that self-assemble from the L1 capsid protein when it is expressed by baculovirus or yeast recombinant DNA vectors have provided the immunogen for candidate prophylactic vaccines. The VLPs are free of viral DNA and possess conformational epitopes of authentic virions. Immunization with VLPs leads to very high titers of virus neutralizing antibodies and to protection against subsequent HPV infection.[13] The vaccines are expected to provide immunity only to the VLP types included in the vaccine preparation; no cross protection against other types is anticipated. Initial vaccine constructs are for HPV-16 and -18. Several strategies are also being tried for therapeutic immunization, aimed at destroying established lesions of HSIL and invasive cancer. For this purpose, the objective is to generate cytotoxic T cells directed against cells expressing the E6 and E7 proteins of high-risk HPVs.[14] Chimeric vaccines which may have both prophylactic and therapeutic properties are also under investigation.

Genital warts

Although they are benign, genital warts (condylomas) are a significant problem in sexually active populations and especially in immunocompromised individuals. Vaccine strategies, similar to those described above for cervical cancer, but using HPV-6 and HPV-11 VLPs and E6 and E7 proteins, are envisaged for the prevention and treatment of genital warts.

Recurrent respiratory papillomatosis (RRP)

Juvenile-onset RRP results from transmission of HPV-6 and HPV-11 at birth, during fetal passage through an infected birth canal. Potential ways to reduce the incidence of this disease are treatment of condylomas during pregnancy and cesarean delivery when there is an active infection of the maternal genital tract. Vaccines based on HPV-6 and HPV-11 may have a role in the prevention and treatment of juvenile-onset RRP.

DIAGNOSTIC MICROBIOLOGY

Hybridization assays

The presence of HPV in a tissue is ascertained by nucleic acid hybridization assays. The most widely used methods, especially in epidemiologic investigations, are those based on polymerase chain reaction (PCR) amplification. [15] [16] Typically, consensus primers are employed to target conserved regions of the viral genome so that a large number of HPVs are amplified in a single amplification reaction. The PCR products are then screened for different HPVs by hybridization with type-specific oligonucleotide probes, and by a 'generic' probe (a mixture of probes of several HPVs) that would detect many HPVs. The methods have high analytic sensitivity and a high specificity. Recently, this assay has been modified so that the type specific hybridizations are performed in a single step as line blots against probes immobilized on a strip.[17] Hybrid Capture is a signal-amplification based hybridization assay approved by the FDA in the USA. In this assay, genital tract specimens are screened for HPVs in an enzyme-linked immunosorbent assay (ELISA)-type format with two pools of HPV probes, one pool consisting of high-risk HPVs and the other of low-risk HPVs.[18] This test has been found to be useful in 'triaging' women with abnormal Pap smears for colposcopy.[12]

Immunologic assays

Immunologic assays are rarely used for type-specific HPV diagnosis. In most HPV infections, viral particles and capsid proteins are present in very small amounts and so are difficult to detect with antiviral serum. Also, as cervical SILs progress toward higher grade disease and cervical cancer, synthesis of capsid proteins and infectious particles is completely shut down. Type-specific antiserum is not available for any HPV type.

Antibody response to HPVs may be measured using ELISA with virus-like particles.[19] Antibody response to HPV infections is low-titered and detectable in only about 40–50% of infected individuals. The proportion of infected individuals who are antibody positive increases with increased duration of infection and with greater viral load in the genital tract specimens.[20]

Antibodies to E6 and E7 proteins are markers of HPV-associated invasive cancer. These antibodies may be detected by peptide-based ELISA or by radioimmunoprecipitation assays with *in-vitro* synthesized full length E6 and E7 proteins. Elevated levels of E6 or E7 antibodies are found in about 40% of patients who have invasive cancer but in less than 1% of controls.

CLINICAL MANIFESTATIONS

The major clinical associations of HPVs are listed in Table 216.1 . Aspects not covered in the earlier sections of this chapter or in Chapter 77 are discussed below.

Cervical cancer

Cervical cancer is the most common female malignancy in the developing world. Approximately 500,000 cases of cervical cancer occur worldwide per year. The incidence of cervical cancer varies widely in different countries. Cervical cancer has long been known to have all the epidemiologic characteristics of a sexually transmitted disease. Recent evidence from many fields clearly points to the causative role of HPVs in cervical cancer (Table 216.2), making it the first major human cancer with a single infectious etiology.[21] The anticipated use of HPV-based vaccines holds promise for the prevention and treatment of cervical cancer. The sexual behavior of the female, the sexual behavior of her male partners and the availability of an effective Pap smear screening program explain the wide differences in cervical cancer incidence in different countries.[22] In many high-incidence areas, male sexual behavior is the key factor for the high cervical cancer rates among relatively monogamous women.

Other cancers

HPV infections are responsible for the basaloid or warty vulvar cancers that occur in younger women but are not related to the more common typical keratinizing squamous cell carcinomas that occur in older women. They are strongly associated with cancers of the anal canal, vagina and penis. In addition, HPV infections are linked to a subset of oropharyngeal cancers, especially tonsillar cancers.

Recurrent respiratory papillomatosis (laryngeal papilloma)

This results from the transmission of HPV-6 and HPV-11 infections from the genital tract to the respiratory tract. For juvenile-onset disease, a large majority of the transmissions occur at birth, during passage of the fetus through an infected birth canal. Some reports suggest occasional intrauterine transmission. About 25% of the cases occur in the first year of life and most of these in the second 6 months. There are progressively fewer cases in each year thereafter.

The most common site of the papilloma is in the larynx on the vocal cords (Fig. 216.5). The tumors are benign but may threaten life if they grow and obstruct respiration. The tumors tend to recur after surgical removal, and in the worst cases operations may be required every few weeks. Operative procedures, especially tracheotomy, may spread the tumor by inadvertently transplanting tumor cells to other sites. Rarely, the tumor may undergo malignant transformation.

TABLE 216-2 -- **Evidence linking HPVs with invasive cervical cancer.**

EVIDENCE LINKING HPVS WITH INVASIVE CERVICAL CANCER	
Epidemiology	• HPVs present in over 90% of cervical cancers both in low-and in high-incidence areas
	• HPV infections precede invasive cancer
	• HPV epidemiology and cervical cancer screening practices together account for differences in worldwide incidence of cervical cancer
Pathogenesis	• HPV genome present in every tumor cell and transcriptionally active
	• HPVs associated with the entire spectrum of cervical neoplasia, from low-grade cytologic abnormalities to invasive disease
	• HPV types most frequent in cancers are the most oncogenic in laboratory assays
	• HPV oncogenes E6 and E7 invariably expressed in cancers
	• Viral genome which is episomal in preinvasive disease, integrates into cellular DNA in invasive cancers
Molecular mechanisms	• Oncoproteins E6 and E7 of high-risk HPVs distort cell cycle and promote genetic instability by degradation of tumor suppressor protein p53 and inactivation of tumor suppressor protein Rb
	• Integration of viral genome in cellular DNA enhances E6 and E7 expression
Observations from the field, the clinic and the laboratory are mutually corroborative in building a compelling case for the HPV etiology of cervical cancer.	

 **Figure 216-5 RRP of juvenile onset.** (a) A respiratory papilloma on the vocal cord of a child. (b) Papilloma obstructing the respiratory tract. *Courtesy of Dr H Kashima.*

MANAGEMENT

The clinical conditions associated with HPV infections are very diverse. Regular Pap smear screening and follow-up of women who have Pap smear abnormalities would greatly decrease the risk of cervical cancer. The preinvasive cervical disease is readily treated with greater than 90% cure rates. Genital and skin warts may regress spontaneously or may be treated with caustic agents (podophyllin), cryotherapy, application of an immunomodulating agent (imiquimod), or by surgical removal. Intralesional or parenteral administration of interferon has been successful in the treatment of refractory genital warts (see Chapter 77).

POLYOMAVIRUSES

NATURE

Polyomaviruses are small, nonenveloped viruses with a diameter of about 42nm. The virions have icosahedral symmetry and 72 capsomers. The viral genome is a circular, covalently closed, supercoiled, double-stranded DNA of about 5000bp. Each DNA strand carries about one-half of the genetic information. The genome is divided into an early region (2.4kb), which codes for large and small T proteins, a late region (2.3kb), which codes for viral proteins VP1, VP2 and VP3, and a non-coding regulatory region (0.4kb), which contains regulatory elements for viral DNA replication and transcription.

EPIDEMIOLOGY

BK virus (BKV) and JC virus (JCV) are two polyomaviruses that infect humans.[23] Infections with both viruses occur in childhood, but infections with BKV occur at an earlier age. In the USA, serologic studies suggest that about 50% of children are infected with BKV by the age of 3 or 4 years, and 100% by 10–11 years. JCV antibody prevalence peaks at about 75–80% by adulthood. The exact mode of transmission of these infections is not known.

Between 1955 and 1961, a large number of people in the USA and elsewhere were exposed to simian virus 40 (SV40), an infection of macaque species, because the virus was an inadvertent contaminant of inactivated poliovirus vaccines that were prepared from virus pools grown in simian kidney cultures. The contaminating SV40 virus was not fully inactivated. Although there have been occasional reports of recovery of SV40 from a number of human cancers, the significance of these observations is unclear.[24]

PATHOGENICITY

The viruses probably multiply at the site of entry (which is not known) and then reach the kidney, the main target organ, by viremia. They undergo further multiplication in the kidney and produce transient viruria. After primary infection, the viruses remain latent in the kidney for an indefinite period of time. In times of immunologic impairment, the viruses may be reactivated in the kidney and virus-infected cells are excreted in the urine. The infected urinary cells have enlarged nuclei and basophilic inclusions. The reactivated viruses may reach other organs, such as the brain. Almost all the diseases associated with BKV and JCV are a result of reactivated infections. The viruses may also persist in B cells and in the brain, after primary infection.

The pathogenesis of progressive multifocal encephalopathy (PML) is discussed below.

PREVENTION

No attempts have been made to prevent primary BKV or JCV infections, which are essentially harmless in immunocompetent individuals.

DIAGNOSTIC MICROBIOLOGY

Tests for BKV and JCV are indicated when urinary cytology reveals abnormal epithelial cells. Differential diagnosis includes urinary tract infections with other viruses, for example cytomegalovirus, and tumor cells from bladder cancer. Tests for BKV and JCV are also indicated in the investigation of cystitis, hemorrhagic cystitis and hematuria.

BKV and JCV can be readily identified by PCR assays or by Southern hybridization of DNA from infected tissue. BKV can be

cultivated in several cell lines of human origin. JCV grows best in human fetal glial cell cultures, which are rich in spongioblasts. Isolation of BKV and JCV in cell cultures is rarely attempted because it is inefficient and cumbersome, and the needed cell types are not readily available.

Cells and tissues infected with BKV or JCV can be identified by immunoperoxidase and immunofluorescence tests with antiviral antiserum. Immunization of rabbits with disrupted viral capsids produces a broadly cross-reactive antiserum. The viruses in urine supernatants can be identified by ELISA. Serologic diagnosis of BKV and JCV infections can be made by hemagglutination-inhibition assays or by ELISA.

CLINICAL MANIFESTATIONS

Progressive multifocal leukoencephalopathy

PML is a fatal, subacute, demyelinating disease of the CNS that occurs as a complication of conditions that impair T-cell immunity, for example HIV infection, lymphoproliferative disorders, chronic diseases and inherited immunodeficiency diseases. In addition, prolonged immunosuppressive therapy, as required for organ transplant recipients, is a risk factor for PML. Until the advent of AIDS, PML was a rare disease with onset typically in the fifth or sixth decades of life. PML cases in patients who have AIDS now outnumber PML cases in all other illnesses combined, and the age distribution of cases has shifted to lower age groups. PML was recognized as an AIDS-defining illness in 1987 and occurs in about 0.7% of patients who have AIDS.[25] Children who have inherited immunodeficiency diseases and children who have AIDS also develop PML.

PML has an insidious onset. Early signs are impairment of speech and vision and mental deterioration. Paralysis of limbs, cortical blindness and sensory impairments are common. Typically, death occurs within 3–6 months of onset. During the course of the disease, the patient is afebrile, with normal cerebrospinal fluid (CSF) and no signs of increased intracranial pressure.

The key event in the pathogenesis of PML is the infection of oligodendrocytes with JCV, which leads to the death of the infected cells. The enlarged nuclei of the oligodendrocytes are the pathognomonic lesion in PML; they contain abundant numbers of JCV viral particles. Oligodendrocytes secrete and maintain myelin; the destruction of the infected oligodendrocytes leads to the characteristic foci of demyelination of PML (Fig. 216.6).[26] The enlarged oligodendrocytes are seen at the periphery of the demyelinating lesion (Fig. 216.7). Giant bizarre astrocytes are seen within the areas of demyelination.

The multifocal nature of the PML lesions suggests that JCV reaches the CNS by the hematogenous route, probably transported by infected B cells. Alternatively, JCV seeded in the normal brain after primary infection may be reactivated by immunosuppression to cause PML. Active PML lesions contain abundant amounts of infectious JCV, JCV proteins and JCV DNA. It is likely that a rearrangement of the regulatory region of the JCV genome facilitates the growth of the virus in the CNS.[27]

Until a few years ago, diagnosis of PML required a brain biopsy but it is now possible to diagnose the disease by noninvasive techniques

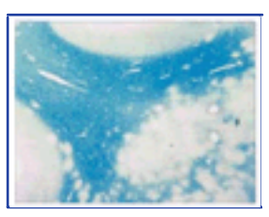

Figure 216-6 Foci of demyelination in PML. The foci in the superior frontal gyrus are the result of PML (Luxol fast blue stain). *With permission from Harrison and McArthur.*[26]

such as computed tomography or magnetic resonance imaging. The use of the PCR to detect JCV in CSF is still investigational.

BKV-related diseases

BKV infection seems to be responsible for occasional cases of cystitis in healthy children and also for hemorrhagic cystitis, which is a complication of bone marrow transplantation. Atypical primary BKV infection in an immunocompromised child may cause tubulointerstitial nephritis and irreversible renal damage.

A new syndrome, BKV nephropathy, has been recently identified in renal transplant recipients.[28] [29] It may be a complication of newly introduced immunosuppressive drugs. The disease is characterized by extensive BKV multiplication in the tubular epithelium, urinary shedding of a large number of infected epithelial cells, the presence of BKV in the serum, and a loss of allograft function. An unusual tropism of BKV for endothelial cells has been described recently in a fatal case of disseminated BKV infection. [30]

MANAGEMENT

PML is almost always fatal. Nucleic acid based analogs have not been effective in the treatment of PML. For a fuller discussion on treatment options see Chapter 125 . The course of disease may be slowed if it is possible to reduce iatrogenic immunosuppression (e.g. in organ transplant patients). Patients who have AIDS and PML have shown improvement with control of the HIV infection with multidrug therapy including protease inhibitors.

Chapter 217 - Parvoviruses

Stanley J Naides

NATURE

The family Parvoviridae consists of small, nonenveloped, single-stranded DNA viruses of animals. It is divided into the subfamilies Parvovirinae of vertebrates and Densovirinae of insects. Parvovirinae is further divided into three genuses: *Parvovirus*, *Erythrovirus* and *Dependovirus*. The genus *Parvovirus* consists of a number of nonhuman mammalian viruses including mice minute virus, Aleutian disease virus of mink, feline panleukopenia virus, Kilham rat virus and the bovine, porcine, canine, goose and feline parvoviruses, among others. The Erythroviruses consist of primate parvoviruses that require erythroid precursors for productive infection and notably in the case of B19, the human parvovirus, cause an erythematous rash. Dependoviruses consist of mammalian parvoviruses that require a helper virus for replication. The typical helper virus is adenovirus, hence the name adeno-associated virus (AAV). Human AAVs are candidate gene therapy vectors because they are nonpathogenic and have broad tissue tropism.

Densovirinae are viruses of insects and crustaceans; several have economic importance such as those affecting silk production.

Parvovirus B19 is the only known human pathogen. Cossart and colleagues discovered B19 serendipitously in 1974 during the development of diagnostic tests for hepatitis B virus. B19 was named after the viremic serum (number 19 in panel B) in which a new antigen was detected in Ouchterlony immunodiffusion plates. [1] In short order, the antigen was determined to be a previously unrecognized human parvovirus measuring approximately 23nm in diameter. It appeared icosahedral or spherical on electron microscopy and was non enveloped (Fig. 217.1). Molecular studies have since demonstrated that B19 has palindromic terminal repeats at both ends that are nearly identical. B19 uses a modified rolling hairpin model of replication, as do the other parvoviruses. Progeny virus is assembled in the nucleus and may be observed as intranuclear inclusions. Equal numbers of B19 positive and negative sense DNA strands are encapsidated. B19 utilizes a single strong upstream promoter from which are transcribed message for a 72 kilodalton (kDa) nonstructural protein (NS1), and 84 and 58 kDa capsid proteins (VP1 and VP2, respectively). Transcripts of the capsid proteins utilize alternate start sites, making VP1 identical to VP2 except for the addition of 227 N-terminal amino acids in VP1, often designated the unique VP1 region, uVP1. VP2 is the major capsid protein. VP1 is thought to occupy the five fold axis of symmetry of the icosahedron. Epitopes in uVP1 and adjacent regions are thought to contain the target structures for neutralizing antibodies. NS1 is a helicase and serves to reduce covalently linked monomeric (two gene copies) and dimeric (four genome copies) replicative forms to packageable progeny genome. NS1 is thought to cause transactivation of cellular genes including interleukin 6 and possibly tumor necrosis factor-a (TNF-a), virus-cell interactions that may be important in pathogenesis. Several smaller viral proteins detected during replication have unknown function. Although the B19 genome is generally highly conserved, a variant of unknown significance, designated V9, has been described.[2]

EPIDEMIOLOGY

B19 is found worldwide. It occurs as both sporadic cases and in recurrent epidemics. Transmission is via nasopharyngeal secretions, explaining the frequency of outbreaks in the late winter and spring. Occurrence in susceptible cohorts of school-aged children may also contribute to outbreaks during the school year. However, outbreaks have also been described in summer and fall. Populations of children acquire B19 antibodies in an age-dependent fashion, beginning with entry into schools. Epidemics tend to occur in 3–5-year cycles, the time required for the generation of a susceptible school cohort. Approximately 50% of adults are anti-B19 IgG seropositive, indicating past infection. Illness in susceptible individuals occurs after an incubation period of 7–18 days.[2] IgG antibody is considered protective. B19 is not removed from blood by current solvent detergent-based methods of blood decontamination and therefore pooled blood products may contain infectious B19.[3]

PATHOGENICITY

B19 is typically transmitted through nasopharyngeal secretions. Following an incubation period of 7 days in experimental infections, a brisk viremia of 10^{11} or more viral particles/ml blood occurs. Viral replication causes maturation arrest at the giant pronormoblast stage of erythroid development, likely through viral induction of apoptosis. Nonerythroid lineages may be affected as well, although they are less efficient in supporting B19 replication. In individuals with shortened erythrocyte survival, as in those with inherited or acquired hemolytic anemias, the period of areticulocytosis is associated with severe anemia. On approximately day 11 post infection, specific IgM antibody appears, followed shortly after by anti-B19 IgG.[4] Initially, IgG is directed against VP2 but after 1 week anti-VP1 IgG antibody appears. Failure to produce anti-VP1 IgG results in persistent or recurrent viremia and chronic or recurrent bone marrow suppression. [5]

Two clinical phases of illness are described in experimental infection, but these may overlap in natural infections. In the first phase, fever, malaise and myalgia may occur during the viremia. Areticulocytosis, leukopenia and thrombocytopenia may occur. In the second phase, the appearance of anti-B19 IgM is associated with rash (Fig. 217.2), arthralgia and frank arthritis.[4] In the pregnant susceptible woman, B19 may cross the placenta to cause erythroid maturation arrest, anemia and a high-output congestive heart failure characterized as hydrops fetalis. B19 viral myocarditis as a cause of fetal hydrops has been described.[2]

PREVENTION

Infection control measures include secretion precautions during periods of viremia; some institutions require respiratory precautions. Patients should be considered infectious from 7 days post exposure until either 18 days post exposure or 24 hours after onset of rash or

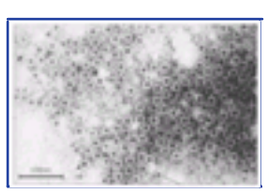

Figure 217-1 Electron micrograph of parvovirus B19 particles showing both full particles (short arrow) and empty capsids (long arrow).

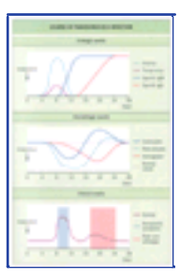

Figure 217-2 Course of parvovirus B19 infection. Volunteers were inoculated nasally with viremic serum and virologic, hematologic and clinical events observed.

Figure 217-3 Classic 'slapped cheeks' of a child with erythema infectiosum, or fifth disease, caused by parvovirus B19. A lacy macular erythematous eruption is also present on the trunk but not shown. *Courtesy of Dr K Motton.*

arthritis.[6] Immunocompromised individuals with chronic B19 infection tend to have low-titer viremia and are of low infection risk to others. The utility of excusing pregnant workers with frequent exposure to children from work responsibilities during an outbreak is controversial. While a susceptible teacher, for example in a class with five or more children with B19 rash, has a 50% risk of infection,[7] absence from the workplace does not prevent exposure at home or in the community. Secretion precautions and handwashing in the childcare setting remain prudent.

DIAGNOSTIC MICROBIOLOGY

Detection of viremia by immune electron microscopy, DNA hybridization or polymerase chain reaction-based methodologies is diagnostic of B19 infection. Detection of anti-B19 IgM in the setting of acute onset of consistent symptoms is likewise diagnostic (Fig. 217.3). As B19 is not readily grown in tissue culture, viremic serum or recombinant capsid proteins have been used as antigen. The presence of anti-B19 IgG is diagnostically useful only when acute and convalescent samples demonstrate seroconversion. Anti-B19 IgM is usually undetectable by 2 months after infection. Immunocompromised individuals such as those with HIV may have chronic or recurrent viremia followed by poor IgM or IgG responses.[2] Finding B19 DNA in tissues of immunocompetent patients is of questionable diagnostic significance because B19 DNA has been found in about 50% of healthy military recruits in Finland undergoing arthroscopy for joint injury.[8]

CLINICAL MANIFESTATIONS

B19 may cause asymptomatic infections. As many as 70% of childhood infections may be asymptomatic. Individuals with chronic hemolytic anemia, such as sickle cell disease or hereditary spherocytosis, develop transient aplastic crisis during the areticulocytosis phase of the infection. The most common presentation in children is the childhood exanthema erythema infectiosus, or fifth disease, characterized by bright red 'slapped cheek' macular or maculopapular rash. The eruption spreads from the trunk to the extremities in a centrifugal progression, often appearing blotchy or fishnet-like. Activity, heat or sun exposure exacerbates the rash. Headache, fever, cough, sore throat, anorexia, vomiting or diarrhea may occur but is usually mild. Rarely, children have joint symptoms.[2] Adults tend to have either no rash or a subtle one, but a sudden onset, symmetric rheumatoid-like polyarthritis may occur and may be accompanied by a more severe flu-like illness than seen in children. Joint symptoms usually improve within 2 weeks, but in some adults may persist for months to years and are associated with persistent or episodic morning stiffness and arthralgias.[9] In pregnant women the unborn child may develop hydrops fetalis. Immunocompromised individuals may develop chronic or recurrent episodes of anemia, leukopenia or thrombocytopenia. Rarely, isolated anemia, leukopenia or thrombocytopenia may occur in an immunocompetent patient. Hepatitis,

acute fulminant liver failure, myocarditis, vasculitis, Henoch-Schönlein purpura, vesicular skin eruptions, 'socks and gloves' acral rash, purpura with or without thrombocytopenia, benign acute lymphadenopathy, hemophagocytic syndrome, peripheral neuropathy, sensorineural hearing loss, aseptic meningitis and rarely encephalopathy have all been described in association with B19 infection. B19 is the leading cause of pure red cell aplasia in AIDS patients.[2]

MANAGEMENT

Therapy for B19 infection is supportive in most clinical presentations. In immunocompromised patients with persistent B19 infection and chronic or recurrent bone marrow suppression because of failure to make neutralizing anti-VP1 antibody, intravenous immunoglobulin may allow clearing of apparent infection and resolution of bone marrow suppression.[5] Patients with transient aplastic crisis may require transfusion support. Likewise, fetal hydrops may require intrauterine transfusion for anemia. B19 is not considered a cause of congenital anomalies.

Chapter 218 - Poxviruses

R Mark L Buller

NATURE

Virion morphology, structure and biochemistry

Poxviruses are the largest of all animal viruses and can be visualized under the light microscope, although the details of the virion structure remain obscure. Using negative-staining electron microscopy and/or cryoelectron microscopy, parapoxvirus virions appear ovoid with long and short axes of approximately 260 and 160nm, respectively, whereas all other poxviruses are 'brick'-shaped, with dimensions of 350 by 250nm on average. In clinical specimens two forms of virion have been identified: the intact 'M' (mulberry; Fig. 218.1) form is found mainly in the vesicular fluid, and the 'C' (capsule) form, which appears to be a degenerative 'M' form, is associated with dried scabs.

Electron micrographs of thin sections of poxvirus-infected tissue culture cells have revealed at least three infectious forms of the virion; intracellular mature virions, extracellular enveloped virions and occluded virus in A-type inclusion body.[1]

It has been proposed that the intracellular mature virions form from the membrane structures of the intermediate compartment, and can acquire an additional two membranes from the Golgi, one of which is lost on egress at the plasma membrane. These extracellular enveloped virions are thought to be most important in cell-to-cell spread and systemic disease. In certain poxvirus species the intracellular mature virion can also occlude in a dense protein matrix within the cytoplasm to form an acidophilic inclusion body (A-type inclusion or Downie body), which is thought to protect the virion from the environment.[2] All vertebrate poxviruses have cytoplasmic basophilic (B-type) inclusion bodies, which represent areas of the infected cells that contain large amounts of virus DNA and protein.

Depending on the poxvirus, the genome can range from 130kbp for the parapoxviruses to 300kbp for the avipoxviruses, which is sufficient to encode more than 140 proteins. A schematic intracellular replication cycle based on the poxvirus vaccinia is presented

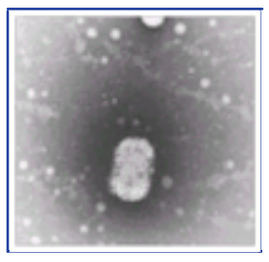

Figure 218-1 A negative-stained M form of molluscum contagiosum virus. Molluscum contagiosum virus from lesion material.

in Figure 218.2 and described in more detail by Moss.[1] The poxvirus virion is notoriously stable in the environment, and this stability is increased by its association with the A-type inclusion bodies or scab material. Thus for poxviruses, fomites must be considered in disease transmission.

Poxviruses pathogenic for humans

Ten poxviruses infect humans (Table 218.1).[2] Except for the 'extinct' variola virus and the increasingly important molluscum contagiosum virus, the poxvirus diseases are zoonoses. With rare exception these zoonotic poxviruses fail to establish a human chain of transmission. Most human poxvirus infections occur through minor abrasions in the skin. Orf, molluscum contagiosum, and monkeypox viruses cause the most frequent poxvirus infections worldwide; the incidence of molluscum contagiosum and monkeypox virus infections is on the rise, the former as an opportunistic infection in late-stage AIDS and the latter as a zoonotic infection in cental Africa. Individuals with atopic dermatitis may be predisposed to poxvirus infections such as molluscum contagiosum, orf or cowpox.

PREVENTION

Because most poxvirus infections are rare zoonoses or, as in molluscum contagiosum virus, cause only superficial, 'nuisance' skin lesions in immunocompetent individuals, there are no recommended prevention strategies other than education of patients and various types of workers as to how the diseases are spread.

MOLLUSCUM CONTAGIOSUM VIRUS

EPIDEMIOLOGY

Geographic range

Molluscum contagiosum virus has a worldwide distribution. Restriction endonuclease analysis of genomic DNA from molluscum contagiosum virus isolates has revealed the existence of at least four virus subtypes or strains, and one recent study suggests the distribution of subtypes can vary geographically.[3]

Prevalence and incidence

For nonsexually transmitted molluscum contagiosum, the disease is more prevalent in the tropics than in Europe. For example, molluscum contagiosum was diagnosed in 1.2% of outpatients in Aberdeen, UK between 1956 and 1963, the mean age of infection was between 10 and 12 years and spread within households and schools was infrequent. On the other hand, in Fiji in 1966, 4.5% of an entire village had the disease, mean age of infection was between 2 and 3 years and 25% of households harbored more than one case.[4] [5] Prevalence of infection in New Guinea was greater than 50% in many villages. In England between 1971 and 1985 there was a 400% increase in cases of genital molluscum contagiosum; the majority of patients were aged 15–24 years, with affected women

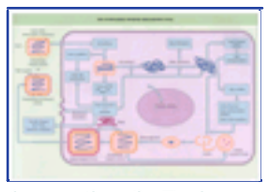

Figure 218-2 The cytoplasmic poxvirus replication cycle. Poxvirus virions containing early RNA transcription machinery attach to, and fuse with, the plasma membrane (uncoating I). Early genes are expressed that code for a variety of functions that modify the host cell for optimal virus replication, attentuate the host response to infection and mediate virus synthetic processes. After further uncoating (II), the virus genome is replicated via concatamers, late transcription factors are expressed from intermediate genes and late gene RNA is synthesized. Late genes encode the early transcription system, enzymes and structural proteins necessary for virion assembly, which commences with the formation of membrane structures in the intermediate compartment and the packaging of resolved unit length genomic DNA. The intracellular mature virion has two membranes derived from the intermediate compartment. It may remain in the cytoplasm or (in certain virus species) become occluded in an A-type inclusion body or become wrapped by a further two membranes in the Golgi and exported from the cell with the loss of one membrane (extracellular enveloped virions). The extracellular enveloped virions are thought to be most important in cell-to-cell spread and systemic disease. This replication scheme is based on the study of the prototypic poxvirus vaccinia.[1] Other poxvirus species probably vary from this model mainly in the types of growth factors and host response modifiers encoded by the virus and the amounts of extracellular enveloped virions produced. *Adapted from Moss.*[1]

being younger than affected men.[5] In the USA between 1966 and 1983 there was a ten-fold increase in cases in patients aged 25–29 years.[5] Molluscum contagiosum is a common and sometimes severely disfiguring opportunistic infection of between 5 and 18% of patients with HIV infection, especially those with severely depressed $CD4^+$ T cell numbers.[6]

Pathogenicity

Transmission

Molluscum contagiosum is observed in children and adults, with spread within this latter group governed in part by sexual practices. Nonsexual transmission is a consequence of infection by direct contact or through fomites. Case histories have suggested transmission from surgeons' fingers, swimming pools, bath towels in gymnasia, contact between wrestlers and as a result of tattooing. [4] Transmission between persons in the absence of fomites requires fairly close contact. Lesions can be commonly observed on opposing surfaces and the virus can be further spread on the person by autoinoculation.

Lesion histopathology

Molluscum contagiosum virus has one of the narrowest cell tropisms of any virus, replicating only in the human keratinocyte of the epidermis.[7] As the virus-infected cell approaches the surface of the skin, the accumulation of progeny virions in a granular matrix in the cytoplasm forces the cell organelles, including the nucleus, to the periphery of the cell. Under light microscopy these cells stain as hyaline acidophilic masses, are referred to as molluscum or Henderson-Patterson bodies and are pathognomonic for disease. The higher magnification of a molluscum body reveals it to be entirely filled with virions, partial virions and debris (Fig. 218.3).

CLINICAL MANIFESTATIONS

Signs, symptoms and severity

Molluscum contagiosum manifests as small clusters of lesions in immunocompetent individuals. The lesions are generally painless; they appear on the trunk and limbs (rarely palms and soles) in the

TABLE 218-1 -- Poxviruses pathogenic for humans.[‡]

POXVIRUSES PATHOGENIC FOR HUMANS			
Genus/Species	**Hosts**	**Geographic distribution**	**Disease**
Molluscipoxvirus	Humans[*]	Worldwide	Molluscum contagiosum, single or multiple skin nodules
Molluscum contagiosum virus			
Parapoxvirus	Sheep[*] , goats, dogs, bighorn sheep, thinhorn sheep, Rocky Mountain goat, chamois, reindeer, musk-ox, Himalayan tahr, Steenbok, alpaca	Worldwide	Orf, localized skin lesions
Orf virus (contagious pustular dermatitis virus or contagious ecthyma virus)			
Pseudocowpox virus (milkers' nodule or paravaccinia)	European cattle[*]	Worldwide	Milkers' nodules, localized skin lesions
Bovine papular stomatitis virus	European cattle[*]	Worldwide	Localized skin lesions
Orthopoxvirus	Rodents[*] , cats, cows, zoo animals	Europe, western Asia	Cowpox, localized pustular lesions
Cowpox virus			
Monkeypox virus	Squirrels[*] , monkeys	Western and central Africa	Monkeypox, rash, generalized disease

Vaccinia virus	Natural host unknown (buffalo† and cattle)	Asia, India, Brazil and laboratory	Buffalopox, localized pustular lesions
Variola virus	Eradicated from humans in 1977	Was worldwide	Smallpox, rash, generalized disease
Yatapoxvirus	Monkeys? Rodents?	Eastern and central Africa	Tanapox, localized nodular skin lesion
Tanapoxvirus			
Yaba monkey tumor poxvirus	Monkeys?	Western Africa	Localized nodular skin lesions

† During the smallpox eradication program, water buffalo in India and cattle in Brazil were infected with the local vaccine strain of vaccinia virus, which apparently persists in these animals and occasionally infects humans.
? Putative host.

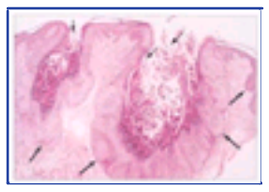

Figure 218-3 Molluscum contagiosum lesion. In this lesion a major and minor umbilicus has formed as a result of the hypertrophy of infected cells and hyperplasia of the basal cells, which caused a severe invagination of the epidermis but no loss of integrity of the basement membrane. The molluscum bodies stain as pink to purple acidophilic hyaline masses up to 37 × 27µm in size. Small arrows: molluscum bodies. Large arrows: epidermis-dermis boundary. (H & E.)

nonsexually transmitted disease. In children, the virus can also be fairly common in the skin of the eyelids, with solitary or multiple lesions, and can be complicated by chronic follicular conjunctivitis and later by a superficial punctate keratitis. [8] There may be an associated erythema 1–11 months after the appearance of the lesion, with no correlation to a history of allergy or eczema.[9] Lesions can persist for as little as 2 weeks or as long as 2 years. Re-infections can be common. As a sexually transmitted disease in teenagers and adults, the lesions are mostly on the lower abdominal wall, pubis, inner thighs and genitalia. As yet there is no solid correlation of virion DNA type with specific pathology or location of lesions (i.e. genital versus nongenital). [10]

In immunocompromised individuals (especially those with HIV infection), the infection is not self-limiting, with more frequent and larger lesions present especially on the face, neck, scalp and upper body. Multiple adjacent lesions sometimes become confluent. Molluscum contagiosum can be considered a cutaneous marker of severe immunodeficiency.

Gross lesion pathology

In immunocompetent patients, molluscum contagiosum virus lesions are epidermal, flesh-colored, raised nodules of 2–5mm in diameter. Occasionally the gross lesions may have a hypopigmented or erythematous halo. Rarely they will present as a large lesion called giant molluscum (>5mm in diameter). Both of these types of lesions usually have an umbilicated center (Fig. 218.4). Although giant molluscum lesions have been reported frequently in severely immunodeficient individuals with HIV infection, they were observed in New Guinea before the introduction of HIV, and therefore may not be a consequence of immunodeficiency.[6] [11]

Figure 218-4 Molluscum contagiosum lesions. These are the more typical, but still large, lesions of molluscum contagiosum. *Courtesy of J Burnett.*

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is usually made clinically based on the gross appearance of the lesions and their chronic nature. Confirmation is easily obtained through the detection of molluscum bodies by hematoxylin and eosin staining of a biopsy or a squash preparation of expressed material from the lesion.

Molluscum contagiosum (especially giant molluscum) can be confused with a number of other disorders such as keratoacanthoma, warty dyskeratoma, syringomas, hidrocystomas, basal cell epithelioma, trichoepithelioma, ectopic hyperplastic sebaceous glands or giant condylomata acuminata, chalazion, sebaceous cysts, verrucas, milia, lid abscess or granuloma on eyelids.[12] [13] [14] In immunodeficient patients, disseminated cutaneous cryptococcosis and cutaneous histoplasmosis can resemble typical molluscum contagiosum. [11] [12] An inflamed molluscum lesion without the association of typical lesions can be mistaken for a bacterial infection.

PARAPOXVIRUSES

The parapoxviruses orf, bovine stomatitis and pseudocowpox generally cause occupational infections of humans, with orf infections being the most common. Because of the clinical similarity of the diseases caused by these agents, they have been referred to collectively as 'farmyard-pox' diseases. No human-to-human transmission of parapoxvirus infections has been reported.

EPIDEMIOLOGY

Geographic range

Orf in sheep and goat populations has been reported in Canada, the USA, Europe, Japan, New Zealand and Africa. Pseudocowpox virus and bovine papular stomatitis virus are both maintained in European-derived dairy herds in all parts of the world.

Prevalence and incidence

In a 1-year New Zealand study 500 meat workers out of a population of 20,000 at risk were infected with orf; those involved in the initial stunning, killing and hanging of the sheep had the highest risk (4%) of infection.[15] Serologic surveys of orf-infected sheep and goat herds yielded orf antibody prevalences of up to 90%. The high seroprevalence of orf antibody in herds is likely attributable to the highly stable nature of the orf virion, which contaminates the pasture.

Pseudocowpox virus and bovine papular stomatitis are probably endemic in all European-derived dairy herds.

PATHOGENICITY

Transmission

Direct transmission of orf virus has been observed as a consequence of bottle-feeding lambs, from animal bites to the hand and contact with sheep and goat products during slaughter. Fomites such as splinters, barbed wire or farmyard surfaces, including soil, feeding troughs or barn beams, have been implicated as sources of virus.

Pseudocowpox virus from lesions on teats of cows is a major source of virus for milkers' nodule of the hand.

Bovine papular stomatitis virus infection of humans occurs generally from lesions confined to the mouth, tongue, lips or nares and occasionally from the teats of infected cattle.

Lesion histopathology

Epidermis

The most striking change in the epidermis is hyperplasia in which strands of epidermal keratinocytes penetrate the dermis.[16] Generally, a mild to moderate degree of acanthosis is detected, and parakeratosis is a common feature. Cytoplasmic vacuolation, nuclear vacuolation and deeply eosinophilic, homogeneous cytoplasmic inclusion bodies often surrounded by a pale halo are also characteristic of the infection. An intense infiltrate of lymphocytes, polymorphs or eosinophils frequently involves the epidermis.

Dermis

A dense, predominantly lymphohistiocytic inflammatory cell infiltrate is present in all cases with marked edema. The most striking feature of the dermis is the massive capillary proliferation and dilatation.

CLINICAL MANIFESTATIONS

Signs, symptoms and severity

The clinical presentation of orf is usually 3–4 weeks after infection. The disease involves the appearance of single or multiple nodules (diameters of 6–27mm),[16] which are sometimes painful, usually on the hands and, less frequently, on the head or neck. Orf infection can also be associated with a low-grade fever, swelling of the lymph nodes and/or erythema multiforme bullosum. Resolution of the disease occurs over 4–6 weeks, usually without complication; however, autoinoculations of the eye can lead to serious sequelae, and enlarged lesions can arise in humans suffering from immunosuppressive conditions, burns or atopic dermatitis.[17] Lesion healing can be complicated by bullous pemphigoid.[18] Re-infections have been documented.[15]

Pseudocowpox virus lesions usually appear on the hands and are relatively painless, but may itch. The draining lymph node may be enlarged. The nodules are gradually absorbed and disappear in 4–6 weeks.[19]

In bovine papular stomatitis, lesions occur on the hands, diminish after 14 days and are no longer evident 3–4 weeks after onset.[20]

Gross lesion pathology

The orf lesion characteristically goes through a maculopapular target stage in which a red center is surrounded by a white ring of cells which is surrounded by a red halo of inflammation (approximately 1–2 weeks after infection; Fig. 218.5); however, patients usually

Figure 218-5 A typical orf lesion at the target stage of development. *Courtesy of Andrew Mercer.*

present later when the lesion is at the granulomatous or papillomatous stages.[17]

In pseudocowpox virus infection, milkers' nodules are first observed as round cherry-red papules; these develop into purple, smooth nodules of up to 2cm in diameter and may be umbilicated. The lesions rarely ulcerate.[19]

The lesions of bovine papular stomatitis appear as circumscribed wart-like nodules that gradually enlarge until they are 3–8mm in diameter. [20]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Parapoxvirus disease diagnosis is by clinical (lesion morphology) and epidemiologic evidence (recent contact with cattle or sheep) and electron microscopy of negative-stained lesion material (presence of ovoid particles).[16]

Without knowing the animal source of the infection, orf cannot easily be differentiated from milkers' nodule on the basis of clinical finding, histology or electron microscopy (i.e. disease acquired from sheep is orf and from cattle is milkers' nodule or possibly bovine papular stomatitis).[16] Atypical giant orf lesions in patients who are immunocompromised or suffering from burns or atopic dermatitis may be confused with pyogenic granuloma.[17] [21] Orf can be misdiagnosed as pyogenic granuloma or inflammatory vascular neoplasms.

ORTHOPOXVIRUSES

Although four orthopoxviruses have been shown to cause disease in humans, only two still cause significant human infections. With the global eradication of the disease smallpox in 1977, the causative agent variola virus no longer circulates in human populations, but there is concern that it may be used as a biologic weapon by terrorist groups or rogue nations (see Chapter 6).[22]

In nature, vaccinia virus infections are limited to exposure to a vaccinia-like virus infecting milking buffalos and dairy cattle in Asia and Africa (called buffalopox) and cattle in Brazil (Cantagalo virus). Vaccinia virus (smallpox vaccine) is used also in the immunization of personnel in the laboratory, but is not recommended at this time for the general population due to the occurrence of frequent and sometimes severe complications.[22] Currently only monkeypox and cowpox viruses cause significant human infections, and the incidence of human monkeypox is increasing.

EPIDEMIOLOGY

Geographic range

Monkeypox virus is found in the tropical rain forests of countries in western and central Africa, most notably Zaire. The reservoir of monkeypox virus in nature is most likely the African arboreal squirrels (*Funisciurus* and *Heliosciurus* spp.) and perhaps monkeys.[23] Cowpox virus is endemic in Europe and some western states of the former Soviet Union. Rodents (voles, wood mice and rats) have been implicated as reservoirs of cowpox virus; cows, zoo animals and cats are incidental hosts.[24]

Prevalence and incidence

Intensive surveillance between 1981 and 1986 in Zaire by the World Health Organization confirmed 338 cases of human monkeypox, with the greatest risk of infection to inhabitants of small villages within 100m of tropical rain forests. [25] In recent years there has been an increase in the frequency of human monkeypox in central Africa perhaps due in part to the cessation of vaccination for smallpox.[26]

Although humans have been infected by cows and rodents, the domestic cat is responsible for the majority of human cowpox infections. Between 1969 and 1993 there were approximately 45 human cowpox cases in the UK, three published case histories from Germany and two each from Belgium, Sweden and France.[24]

PATHOGENICITY

Transmission

The exact mode of transmission of monkeypox virus from an animal source to humans is not known but may be via the oropharynx or nasopharynx or through abrasions of the skin or oral cavity. Person-to-person transmission (like eradicated smallpox) is believed to be by the upper respiratory tract, with virus released in oropharyngeal secretions of patients who have a rash.[25] Unlike smallpox, monkeypox person-to-person transmission is very inefficient and rarely surpasses three generations.[25]

Cowpox virus is acquired usually by direct introduction of the virus from an animal source into minor abrasions in the skin; however, 30% of infections show no known risk factor.[24]

Lesion histopathology

Orthopoxvirus lesions are characterized by epidermal hyperplasia, with infected cells becoming swollen, vacuolated and undergoing 'ballooning degeneration'. [24]

CLINICAL MANIFESTATIONS

Signs, symptoms and severity

Approximately 12 days after infection with monkeypox virus, fever and headache occur. This is followed 1–3 days later by a rash and generalized lymphadenopathy. The rash (the number of lesions is variable) appears first on the face and generally has a centrifugal distribution. The illness lasts 2–4 weeks, depending on its severity. The case fatality rate is approximately 12%.[25]

With cowpox virus infection, a lesion, usually solitary, appears on the hands or face; this can be extremely painful, and the patient can present with systemic symptoms, including pyrexia, malaise, lethargy, sore throat and local lymphadenopathy. Complete recovery

Figure 218-6 Monkeypox rash. A 7-year-old Zairian girl, 2 days after the onset of the rash. *Courtesy of M Szczeniowski.*

takes between 3 and 8 weeks. Person-to-person transmission has not been reported. Complications can include ocular or generalized infections; the latter occurs in patients who have atopic dermatitis, allergic asthma or atopic eczema and in one case was associated with death.[24]

Gross lesion pathology

The monkeypox virus skin lesions begin as macules but rapidly progress to pustules. About 8 or 9 days after the onset of rash the pustules become umbilicated and dry up; by 14–16 days after the onset of the rash a crust has formed. Most skin lesions are about 0.5cm in diameter (Fig. 218.6).[25]

The cowpox lesion appears as an inflamed macule, progresses through an increasingly hemorrhagic vesicle stage to a pustule that ulcerates and crusts over by the end of the second week to become a deep-seated, hard black eschar 1–3cm in diameter (Fig. 218.7). [24]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of monkeypox infection requires clinical (rash), epidemiologic (equatorial Africa) and laboratory (brick-shaped virion in

Figure 218-7 Primary and secondary lesions of cowpox. The primary lesion is at the early eschar stage (probably 2–3 weeks after infection), whereas the secondary lesion (below) is at the early vesicular stage. *With permission from Baxby et al.* [24]

scab material) findings. Although the rash with associated lymphadenopathy is usually pathognomonic, the sporadic nature of the disease makes it difficult to arrive at an accurate diagnosis solely on clinical grounds.[25]

Diagnosis of cowpox virus infection is rarely made on clinical findings (lesion morphology and systemic illness) and usually requires laboratory results (brick-shaped virion in scab material). Cowpox should be considered in patients who have had contact with cats and who present in July to October with a painful hemorrhagic vesicle or black eschar, with or without erythema, accompanied by lymphadenopathy and a systemic illness.[24]

Monkeypox can be confused with a number of other conditions that result in a rash:

- chickenpox, although its varicella-zoster lesions are more superficial, appear in crops and have a centripetal distribution;
- tanapox, except the tanapox lesions evolve slowly, are nodular and large, without pustulation; and
- syphilis, although the secondary rash of syphilis does not evolve past the papular stage.[25]

Generalized cowpox can be misdiagnosed as eczema herpeticum, whereas localized cowpox is most frequently misdiagnosed as:

- orf or milkers' nodules, although the parapoxvirus lesion is clinically distinct, and there are often no systemic disease symptoms;
- herpes virus reactivation, even though herpes lesions are not usually hemorrhagic or erythematous and the scab is not so deep-seated and of lighter color; and
- anthrax, although the anthrax lesion is painless and rapidly progresses to the eschar stage (5–6 days).[24]

DIAGNOSTIC MICROBIOLOGY

The appropriate biosafety level precautions must be taken for the handling, transport and processing of infected lesion material.[26]

Molluscum contagiosum virus

For a squash preparation the keratotic dome-shaped molluscum lesion is placed on a regular slide and under a coverslip or second slide. The lesion is flattened and can be examined using light microscopy either directly or after staining with Wright's or methylene blue stains. Round to ovoid molluscum bodies up to 37 × 27 µm are diagnostic of molluscum contagiosum.[4]

For histopathologic analysis, a biopsy specimen is fixed in 10% formal saline and submitted for wax embedding, sectioning at 5µm and staining with hematoxylin and eosin. Microscopic examination should provide a field of view similar to that shown in Figure 218.3 .

Parapoxvirus, orthopoxvirus and yatapoxvirus

Orthopoxvirus (brick-shaped), parapoxvirus (ovoid) and tanapox virus (enveloped brick-shaped) virions can be differentiated from one another by an experienced electron microscopist. Scab material or fluid from the vesicle should be processed by standard methods for negative-staining electron microscopy.[26]

MANAGEMENT

The management of parapoxvirus, orthopoxvirus and yatapoxvirus infections is supportive. Although at this time there are no approved systemic or topical chemotherapeutic agents commercially available for the treatment of poxvirus infections, it is anticipated that cidofovir or related compounds will be approved to treat orf virus, molluscum contagiosum virus, and orthopoxvirus infections.[27] [28] Also for complications arising from the smallpox vaccine, vaccinia immune globulin may be effective. Prevention of secondary bacterial infections through the use of antibiotic ointments is an option. In

the case of cowpox, corticosteroids are contraindicated and may exacerbate the illness. [24] Because of the chronic nature of molluscum contagiosum lesions, one can consider curettage and cryotherapy of lesions. Removal of giant molluscum lesions, but not regular lesions, usually results in scar formation. Molluscum lesions may remit when HIV infection is controlled with anti-HIV therapy.

Curettage with an analgesic

With children, pretreatment of molluscum lesions with lidocaine (lignocaine)-prilocaine for between 1 and 30 hours under plastic occlusion resulted in a decrease in the reported pain on lesion removal with a comedo extractor or curette.

Cryotherapy

Molluscum lesions are treated for 6–30 seconds with a cotton-tipped applicator dipped in liquid nitrogen; this is repeated at 3-week intervals as needed. Cryotherapy is relatively painless, cost-effective and yields good cosmetic results. For patients with HIV infection, this treatment has the added advantage of mitigating the risk of disease transmission to medical personnel.

Chapter 219 - Rabies

Mary J Warrell
David A Warrell

INTRODUCTION

Rabies is a zoonosis of dogs and other mammals that is occasionally transmitted to humans, causing fatal encephalomyelitis. Rabies virus is a member of the genus *Lyssavirus*, part of the large family of Rhabdoviruses that infect animals and plants. The bullet-shaped virions contain a nonsegmented negative strand of rabies RNA encoding five proteins. A nucleoprotein is coiled with the RNA, a phosphoprotein and an RNA-dependent RNA polymerase to form a helical ribonucleoprotein complex or nucleocapsid. This is covered by a matrix protein. An outer coat is acquired by budding through a host cell membrane, which is studded with the virus-coded glycoprotein bearing club-shaped projections. Rabies virus strains from different vector species and geographic areas can now be distinguished by nucleotide sequencing and monoclonal antibody typing.

Lyssaviruses comprise seven genotypes, of which rabies is genotype 1, and six are rabies related-viruses which may also cause fatal human encephalitis (see Rabies-related viruses, below).[1] [2]

EPIDEMIOLOGY

Animal rabies

Globally, the domestic dog is the most important vector of human rabies, responsible for about 97% of human deaths from this disease. In Asia, most of Africa, and a few urban areas of Latin America, the dog is the dominant vector. Separate reservoirs of enzootic infection also occur in several wild mammalian species (Table 219.1), with occasional overspill into other species. This sylvatic pattern of infection predominates in North America,[2] Europe, southern Africa[3] and parts of the Caribbean. Rabies is enzootic in most parts of the world

Figure 219-1 World distribution of rabies.

(Fig. 219.1). The epizootiology changes constantly, and so local advice should be sought for detailed information.

Human rabies

Estimates of human rabies mortality rates are notoriously unreliable in tropical areas, where about 99% of the deaths occur. In Asia and Africa there are an estimated 40,000–70,000 cases annually. Areas of high incidence include India, Bangladesh, Pakistan and Nepal.

In the USA, 32 cases were reported in the past 11 years, of which 19% were infected abroad, and 75% were associated with indigenous insectivorous bat rabies virus, although only two of 24 had recognized a bat bite.

PATHOGENICITY

Transmission

Human infection is usually the result of a bite by a rabid dog or other mammal. Virus in saliva can penetrate broken skin or intact mucous membranes, and so scratches or licks by a rabid animal may cause infection.

On a few occasions, human rabies has possibly resulted from inhalation of virus in caves that were densely populated by insectivorous bats in the USA, or after laboratory accidents with aerosols of virus. The saliva, respiratory secretions, and tears of rabies patients contain virus,[4] which could infect another person, but the only documented instances of human-to-human transmission have been in eight recipients of corneal grafts from donors in whom rabies had not been suspected. Several women with rabies encephalitis have delivered healthy infants. Only one case of neonatal rabies has been reported, although vertical transmission is well documented in animals.

TABLE 219-1 -- Important rabies vector species.

IMPORTANT RABIES VECTOR SPECIES		
Africa	Domestic dog	Widespread dominant vector
	Black-backed jackals (*Canis mesomelas*)	Southern Africa
	Yellow mongoose (*Cynictis penicillata*)	
	Bat-eared fox (*Otocyon megalotis*)	
Americas	Domestic dog	Mexico, Central America, South America
	Wild canids: Arctic fox (*Alopex lagopus*), red fox (*Vulpes fulva*), gray fox (*Urocyon cinereoargenteus*), Coyote (*Canis latrans*)	Alaska, Canada, New England, Arizona, Texas
	Striped skunk (*Mephitis mephitis*)	Central Canada, central USA, California
	Racoon (*Procyon lotor*)	Mid-Atlantic, northeast, and southeast USA
	Insectivorous bats	USA, South America
	Vampire bat (Desmodontidae)	Southern Texas, Mexico, Central America, South America, Trinidad and Tobago
	Mongoose (*Herpestes* spp.)	Puerto Rico, Grenada, Cuba, Dominican Republic

Asia	Domestic dog	Widespread dominant vector
	Wolf (*Lupus lupus*)	Iran, Iraq, Afghanistan
Australia	Fruit bats (Lyssavirus genotype 7)	-
Europe	Fox (*Vulpes vulpes*)	Eastern Europe, diminishing westward
	Arctic fox (*Alopex lagopus*)	Northern Russian Federation
	Racoon dog (*Nyctereutes procyonoides*)	Poland, Baltic states, Russian Federation
	Wolf	Russian Federation
	Domestic dog	Turkey, Russian Federation
	Insectivorous bats (European bat lyssaviruses genotypes 5 and 6)	Germany, Denmark, The Netherlands, Russian Federation, Poland, Spain, France, Hungary, Switzerland, UK
All vectors carry *Lyssavirus* genotype 1 except where stated.

Pathogenesis

Rabies virus will attach to a variety of cellular receptors, but in a bite wound competitive binding to acetylcholine receptors at neuromuscular junctions is probably an important route of entry into the nervous system.[5] During the incubation period, the virus travels to the central nervous system (CNS) by retrograde axonal transport at a rate of 50–100mm/day (in vitro). Infection can be halted experimentally by sectioning the nerve or by applying metabolic inhibitors (e.g. colchicine).

When the virus reaches the brain, massive replication occurs in neurons by budding from intracellular membranes, and accumulation of viral proteins results in the formation of inclusions (Negri bodies; Fig. 219.2). The virus spreads trans-synaptically and remains within neurons where it is hidden from immune surveillance. There is evidence of neuronal dysfunction — neurotransmitter activity is altered and there are electroencephalograph changes. Pathologic features of diffuse encephalomyelitis may be minimal or even absent. The virus then progresses centrifugally via peripheral nerves to many tissues, including the salivary and lacrimal glands, where replication with production of extracellular rabies virus begins (Fig. 219.3).

Immunology

Following infection, rabies virus evades the immune system[6] and no immunologic response can be detected in unvaccinated patients before signs of encephalitis develop. Neutralizing antibody usually appears 1–2 weeks after the onset of symptoms, and a little later in the cerebrospinal fluid (CSF). Rabies-specific IgM is not detectable any earlier than IgG and it is not a sensitive means of diagnosis. The presence of antibody is diagnostic in unvaccinated patients. Specific transformation of peripheral blood lymphocytes has been found in a few patients with furious rabies, but not in paralytic cases. The reverse is found experimentally in rabid mice, and the virus is immunosuppressive to unrelated virus antigens. This immunosuppressive effect is compatible with the minimal histopathologic changes in the brain. Interferon production in humans is very low, and high levels of interferon-a and interferon-ß in animal brains do not protect animals against death. Paradoxically the incubation period was shorter in patients who had had some rabies vaccine; these patients had been inadequately vaccinated. This early death phenomenon can be reproduced experimentally by injecting a little rabies antibody or immune B cells during the incubation period. Clearance of a lethal virus from the brain has been achieved in rodents by treatment with a single glycoprotein-specific neutralizing monoclonal antibody, but the mechanism of recovery is unknown.[7]

CONTROL

The design of an appropriate rabies control strategy[8] depends on surveillance to determine the principal wild or domestic reservoir

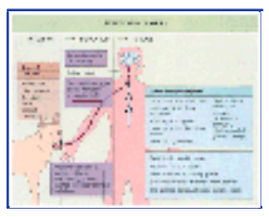

Figure 219-3 Pathogenesis of rabies.

species, which are confirmed by laboratory diagnosis. In some places where the domestic dog was the main vector, including urban areas of Latin America, mass dog vaccination campaigns have radically reduced the incidence of rabies. In contrast, attempts at control by vaccination, poisoning or shooting have been unsuccessful in parts of Africa and Asia where stray or owned, unrestricted dogs are the greatest problem. The immunization of such dogs by distributing oral vaccine in suitable baits is now possible, but is not widely used.

Control of sylvatic rabies must be tailored to particular reservoir species. In Europe the red fox *Vulpes vulpes* is the dominant vector infecting other wild and domestic species. Repeated campaigns to distribute oral live attenuated or vaccinia-recombinant vaccine expressing rabies glycoprotein in baits has almost eradicated terrestrial rabies from western Europe. In North America racoons and coyotes have been similarly immunized, and also jackals in southern Africa. Control of vampire bat rabies, which causes many deaths in cattle in Latin America, is attempted by treating cattle with small doses of anticoagulant to poison the bats. No active measures are taken to control rabies in insectivorous bats in the Americas and Europe, but instructions are issued to encourage people to avoid direct contact with these animals.

CLINICAL MANIFESTATIONS

The incubation period (bite to first symptom) ranges from 4 days to at least 19 years, but in about 75% of cases it is between 20 and 90 days. The only prodromal symptoms that are reasonably suggestive of rabies are itching, pain, or paresthesia, either at the site of the causative bite or radiating proximally from it. After 1–7 days of generally non-specific symptoms, features of either furious or paralytic (dumb) rabies develop.

The pathognomonic symptom of furious rabies is hydrophobia[9] or aerophobia. Jerky and violent contractions of the diaphragm and accessory muscles of inspiration, are associated with an inexplicable terror. This reflex can be provoked by attempts to drink liquid or by a draught of air on the skin. The hydrophobic spasm may end with the patient in opisthotonos, having generalized convulsions and in cardiac or respiratory arrest. Other features of furious rabies are periodic excitement, sometimes with hallucinations or aggression, interspersed with lucid intervals, tachycardia and other arrhythmias, hypersalivation, lacrimation, sweating, and fluctuating temperature and blood pressure. All these features are suggestive of stimulation of the autonomic nervous system as seen in severe tetanus. Conventional neurologic examination may prove surprisingly normal but meningism, cranial nerve lesions, upper motor neuron lesions, fasciculation, and involuntary movements are sometimes detected. Without intensive care, patients usually die, often during a hydrophobic spasm, in the first few days of their encephalitic symptoms.

Paralytic or dumb rabies is probably underdiagnosed but was particularly associated with an epidemic of rabies transmitted by vampire bats in Trinidad in the 1920s and 1930s. After the prodromal symptoms described above, together with fever and headache, local paresthesia and flaccid paralysis develop, usually in the bitten limb, and ascend symmetrically or asymmetrically. There is accompanying pain and fasciculation in the affected muscles and mild objective sensory disturbances. Death follows paralysis of the muscles of deglutition and respiration; there is usually no evidence of hydrophobia or aerophobia. Some patients have survived for as

long as 1 month, even without intensive care.

Patients with paralytic or dumb, or furious rabies whose lives are prolonged by intensive care may develop a variety of respiratory, cardiovascular, neurologic and gastrointestinal complications including fatal cardiac arrhythmias, pneumothorax, cerebral edema, diabetes insipidus, diffuse axonal neuropathy and hematemesis.

Differential diagnosis

Severe and unusual neurologic symptoms, whether encephalitic or paralytic, should suggest the possibility of rabies in any unimmunized person who has had contact with mammals in a rabies endemic area. Rabies patients infected by bats in the USA however, usually deny any contact with a bat.

Furious rabies can be mimicked by the pharyngeal form of cephalic tetanus ('hydrophobic tetanus'), but severe tetanus usually has a shorter incubation period than rabies. In tetanus, there is sustained muscle rigidity, often associated with trismus. Delirium tremens and the excitatory effects of some drugs and plant toxins have been confused with rabies. Paralytic rabies is indistinguishable from many other causes of an ascending paralysis, including postvaccinal encephalomyelitis complicating the use of obsolete nervous tissue rabies vaccines still used in Asia, Africa and Latin America.

Prognosis

Only five documented cases of recovery from rabies, or survival for more than eighteen months, have been reported during the virologic era.[10] No rabies virus or antigen was detected in any of them and all were diagnosed serologically. Two patients were treated after exposure with nervous tissue vaccines and recovered. [11] The other three patients, given either only pre-exposure nervous tissue vaccine or postexposure tissue culture vaccine, were left with profound neurologic deficits.

DIAGNOSIS

Rabies infection can be confirmed by isolating the virus, by identifying antigen, or, in unvaccinated patients, by detecting antibody.[12]

Viral isolation from saliva, respiratory secretions, CSF, tears, or brain biopsy[4] is the ideal method of diagnosis. Inoculation of suckling mice takes 1–3 weeks, whereas tissue culture isolation can be completed in less than 4 days. Virus identification using a panel of monoclonal antibodies or by genetic typing, will indicate the likely vector species and geographic origin of the strain. Rapid intravitam diagnosis can be made by immunofluorescent detection of rabies antigen in frozen sections of full-thickness skin biopsies from hairy areas of the nape of the neck. With controls to ensure specificity and examination of many sections, including bases of hair follicles, the sensitivity is 60–100%, the rate increasing later in the illness.[13] False-positive results have not been reported. Repeated tests should be made until the diagnosis of rabies is excluded. The corneal impression smear test is too insensitive to be useful and false-positive results have occurred. Antigen detection using polymerase chain reaction techniques has proved useful for samples of saliva and CSF.

The usual method of detecting antigen in brain samples is by the immunofluorescent antibody staining of acetone-fixed impression smears, but enzyme immunoassay can be used. Post-mortem needle necropsy of the brain can be taken without a full autopsy by inserting a Vim-Silverman needle via the medial canthus of the eye through the superior orbital fissure, or via the foramen magnum, or via the nose and ethmoid sinus into the brain.

In unvaccinated patients, diagnostic seroconversion usually occurs in the second week of illness.[14] In vaccinated patients, very high levels of antibody both in the serum and in the CSF have been used to make a diagnosis.[11]

MANAGEMENT

The life of patients with rabies encephalitis can be prolonged by intensive care. No effective antiviral or ancillary treatments have been discovered. Patients should be admitted to hospital so that their agonizing symptoms can be palliated with adequate doses of analgesic and sedative drugs. Friends, family and medical staff who have been in close contact with the patient should be given postexposure vaccination to reassure them, even though person-to-person transmission must be extremely rare.

PREVENTION

Post-exposure prophylaxis

In a rabies endemic area, the risk of infection, and hence the decision to give postexposure prophylaxis,[15] [16] depends on the species of animal, its behavior and the circumstances of contact. An unprovoked attack by a known local vector suggests a high risk of exposure to rabies, especially if the animal is unvaccinated, is unusually excitable or is partially paralyzed, or if a wild animal is unusually tame. Vaccinated animals have, however, transmitted rabies. The virus gains access through any bite, scratch, or contamination of broken skin or mucous membrane, but intact skin is an adequate barrier against infection. The risk of infection is greatest from bites on the head, neck, and hands, and multiple bites carry a higher risk than single bites. Before vaccines were available, the mortality rate from all proven rabid dog bites in India was 35–57%.[17]

Strenuous efforts should be made to have the biting animal tested for rabies. The routine immunofluorescent test for antigen may give a false-negative result in 1–2% of rabies cases, and the test is unreliable for rabies-related viruses, so the result of viral culture is important in highly suspicious cases. Specific treatment should not await laboratory results and it should always be started immediately, irrespective of the time since the bite.

Postexposure prophylaxis aims at inactivating rabies virus in a wound and stimulating the immune response to kill the virus before it enters the CNS, where it is protected from immune attack. Post-exposure therapy includes urgent would treatment, and active prophylaxis with vaccine and passive immunization with rabies immune globulin (RIG). Failures of complete optimal treatment started on the day of exposure have only been reported in two patients following bites on the head.

Treatment of mammal bites, scratches or licks

The treatment can be summarized as follows:

1. Scrub vigorously with soap or detergent and water, reaching the depth of the wound, and remove foreign material.
2. Swab with a virucidal agent: povidone iodine, tincture of iodine, or 40–70% ethanol. (The virucidal effect of quaternary ammonium compounds is neutralized by soap, and so they are not recommended.) Local or even general anesthetic may be necessary to allow effective wound cleaning and debridement, especially for children.
3. Suturing of wounds should be avoided or delayed.
4. Tetanus prophylaxis (tetanus immune globulin or toxoid booster plus metronidazole) must not be forgotten. Antibiotic prophylaxis against other potential wound pathogens is recommended.
5. If there is a risk of rabies, give specific therapy immediately.

Rabies vaccines

Vaccines of nervous tissue origin

All human rabies vaccines contain killed virus. Those cultured in sheep or goat brains (Semple vaccines) and suckling mouse brain (SMB) are still used in Asia and Africa. SMB vaccine is also used in parts of South America. These are weak antigens and neurologic reactions still occur (1 in 200 Semple vaccinees). [10] Nevertheless in the absence of a modern vaccine, a nervous tissue product should be used, at least until other treatment can be procured.

Purified tissue culture vaccines

Tissue culture-grown vaccines are used exclusively in North America, most of Europe, China, Thailand, Sri Lanka and the Philippines and increasingly in other

countries. The use of the original expensive human diploid cell vaccine (HDCV) is giving way to cheaper vaccines of equivalent efficacy and safety, including a

German purified chick embryo cell vaccine (PCECV) and a French purified vero cell vaccine (PVRV), which are now widely distributed in endemic areas.

Immunologic response to vaccination

The presence of serum neutralizing antibody is the best available indicator of protection against rabies, and it appears 7–14 days after starting a primary course of a modern rabies vaccine. A level of 0.5I U/ml is considered satisfactory, although the protective level cannot be ascertained in humans. Only the viral surface glycoprotein molecules induce neutralizing antibody. They also stimulate helper T-lymphocyte responses. The rabies nucleoprotein can also induce protection through the induction of non-neutralizing antibody, T-helper lymphocytes and interferon-?. This immunity cross-reacts broadly with other strains of rabies virus and rabies-related viruses, unlike that induced by glycoprotein.

The speed and degree of the antibody response to vaccine varies, probably under genetic influence. A relatively delayed lower level of antibody is found in about 10% of people receiving vaccine; increasing age also impairs the response.

The induction of neutralizing antibody can be accelerated by increasing the amount of antigen (within limits) or by dividing the dose between multiple sites and injecting it intradermally.

Postexposure vaccine regimens

Intramuscular vaccine regimen

The standard regimen is one dose of tissue culture vaccine (1ml or 0.5ml, depending on the product) intramuscularly into the deltoid on days 0, 3, 7, 14 and 28.

Intradermal vaccine regimens

The five-dose intramuscular regimen is unaffordable by the vast majority of patients in developing countries, but economic, safe and effective regimens are now available. The World Health Organization recommends two multiple-site intradermal regimens using specified European vaccines — PVRV, PCECV and HDCV.[15] The manufacturers' instructions must be used for all other vaccines.

An eight-site regimen[18] consists of eight doses of 0.1ml intradermally on day 0 (using a whole vial) on the arms, thighs, and suprascapular and lower abdominal areas; four doses on day 7 on the arms and thighs; and one dose on days 28 and 90 also over the deltoid. Human diploid cell vaccine or PCECV can be used, when the intramuscular dose is 1ml. This has a wide margin of safety because the minimum stipulated antibody response has been achieved by only four of the initial eight intradermal doses. Only four visits are needed. Patients who are anxious about the risk of rabies do not object to the method.

A two-site regimen[15] consists of two intradermal doses (0.1 or 0.2ml depending on whether the intramuscular vaccine dose is 0.5 or 1.0ml) on days 0, 3 and 7; and one intradermal dose on days 28 and 90. The injection is over the deltoid. This has proved effective in thousands of patients who also received RIG treatment in Thailand.

The eight-site regimen induces higher levels of antibody than the two-site regimen from the earliest appearance of antibody onwards.[19] Both require a similar amount of vaccine, less than two intramuscular doses, a saving of 60%. When one ampoule is shared between several patients, a new syringe and needle must be used for each.

Postexposure treatment of previously vaccinated patients

Treatment is always urgent, but, provided that the patient has previously had a complete pre-exposure or postexposure course of tissue culture vaccine or if a neutralizing antibody level has been over 0.5I U/ml at some time, only two doses of intramuscular vaccine are needed on days 0 and 3. Rabies immune globulin treatment is unnecessary.

Side-effects of tissue culture vaccines

The incidence of minor symptoms is very variable.[10] Local pain or erythema occurs in about 15% of people vaccinated, and irritation is more common following intradermal injections. Generalized nonspecific symptoms are reported by about 7% of patients, and transient maculopapular and urticarial rashes are occasionally seen. In the USA, 6% of late pre-exposure booster injections of HDCV have been accompanied by mild immune complex-like disease between three to 13 days later. All of these patients responded to symptomatic treatment. Neurologic symptoms, either Guillain-Barré-like or local limb weakness, are extremely rare, and the incidence following treatment is no greater than those following other routine vaccines. No complications have been observed in pregnancy.

Passive immunization with rabies immune globulin

Every primary postexposure vaccine course should be accompanied by RIG to cover the first 7–10 days before vaccine-induced immunity appears, [15] and it may enhance the T-cell immune response. Rabies immune globulin treatment is especially important after bites on the head, neck or hands, or multiple bites. A single dose of 20 IU/kg of human RIG or 40 IU/kg of equine RIG is given at the same time as the first dose of vaccine. As much as possible is infiltrated into and around the wound, but care is needed when injecting into fingers or other tight tissue compartments. Any remaining vaccine is injected intramuscularly away from the vaccine site. If the volume of RIG is insufficient for infiltration, it can be diluted in saline two- or threefold in order to infiltrate all wounds. Skin testing with RIG does not predict most hypersensitivity reactions, and epinephrine (adrenaline) should always be ready in case of anaphylaxis. Serum sickness occurs in 1–6% of equine RIG recipients, but has not been seen after human RIG therapy.

Pre-exposure vaccination

Pre-exposure vaccination is recommended for anyone at risk of exposure to rabies virus, including veterinary surgeons, animal handlers, zoologists, laboratory staff working with rabies, wildlife officers and people living in or traveling to rabies-endemic areas where dogs are the dominant vector species. A total of three doses of cell culture vaccine are needed on days 0 and 7 and on day 28 (or day 21). The dose can be intramuscular or intradermal. Malarial prophylaxis with choloroquine inhibits the antibody response to vaccine given intradermally, so anyone on antimalarial therapy must have intramuscular injections. A booster dose after about 1 year prolongs the antibody response, which usually lasts 5–10 years. As a prompt secondary immune response to booster doses has proved reliable, repeated booster doses are not recommended in the USA except for those at very high risk, such as laboratory staff.[16] Serologic testing is necessary only if immunosuppression is suspected or to determine the need for booster injections in those at high risk.

RABIES-RELATED VIRUSES

The *Lyssavirus* genus comprises seven genotypes: genotype 1 is classical rabies virus; genotypes 2–7 are rabies related-viruses.[1] [2] Genotype 2, Lagos bat virus, unlike the others, has not been found in humans.

Africa

Genotype 3, Mokola virus, has been identified occasionally in shrews, cats, dogs and rodents in sub-Saharan Africa.[1] [3] [17] Isolation has been reported in two Nigerian children — from the brain of one with fatal encephalitis, without hydrophobia; and from the CSF of another with transient meningitis, but neutralizing antibody was not found in convalescent serum. Genotype 4, Duvenhage virus, is

found rarely in bats in southern Africa, and has caused a rabies-like encephalitis in one patient. The true prevalence of these African infections is uncertain because the diagnosis of rabies encephalitis is normally made on clinical evidence, and the usual diagnostic rabies immunofluorescent test may give a faint result or a negative one with rabies-related viruses.

Europe

Genotype 5, European bat *Lyssavirus* type 1, is found in a variety of insectivorous bats across Europe (see Table 219.1).[1] [2] Genotype 6, European bat *Lyssavirus* type 2, has rarely been isolated from *Myotis* spp. of bats in The Netherlands, Switzerland and the UK. There are four reports of fatal rabies-like encephalitis following bat bites in Europe, and European bat lyssaviruses were confirmed in three of these cases. The most recent was a European bat *Lyssavirus* type 2 infection in Scotland in 2002.

Australia

Genotype 7, Australian bat *Lyssavirus*, was identified in 1996 in flying foxes (*Pteropus*) and other bats, and has caused two fatal human infections indistinguishable from rabies encephalitis.[20] A serologic survey also indicates endemic infection in the Philippines.

Chapter 220 - Respiratory Viruses

Alberto M La Rosa
Estella Whimbey

INTRODUCTION

Respiratory viral infections are among the most common diseases of humans. In the course of a lifetime, every individual will experience several episodes of respiratory viral infections. These illnesses are caused by a heterogeneous group of viruses commonly known as human respiratory viruses (HRVs) which includes adenovirus, coronavirus, reovirus, rhinovirus, respiratory syncytial virus, parainfluenza virus and influenza virus. Other viruses, such as some of the enteroviruses and some of the herpesviruses, can also cause respiratory disease but they are discussed elsewhere in this book.

Respiratory viral infections are largely benign and self-limited. Their impact is largely measured in terms of diminished sense of well-being, exacerbations of underlying chronic cardiopulmonary diseases, loss of productivity, time lost from work or school, increased visits to health care providers and unnecessary prescription of antibiotics with the entailing drug toxicities, emergence of antibiotic resistance and increase in health care cost. Among some subsets of the population such as those at the extremes of age, those with chronic cardiopulmonary diseases or those with primary or secondary immunodeficiencies, these illnesses are not infrequently associated with serious, potentially fatal complications. In recent years, significant progress has been made in our understanding of pathogenesis, natural history, epidemiology, molecular diagnosis, prevention and treatment of these organisms.

The more characteristic illnesses associated with the different respiratory viruses and the populations at higher risk are presented in Table 220.1 . The most common methods for the laboratory diagnosis of viral respiratory infections are summarized in Table 220.2 and Figure 220.1 Figure 220.2 Figure 220.3 Figure 220.4 Figure 220.5

ADENOVIRUS

Nature

Adenoviruses were first isolated in the 1950s from human adenoids and later from respiratory secretions of military recruits with acute febrile respiratory illnesses. Human adenoviruses belong to the family Adenoviridae. More than 50 serotypes have been described and classified into six subgroups (A–F). Approximately one-half of these serotypes are known human pathogens. Virions are nonenveloped icosahedral particles measuring 80–100nm in diameter and containing a linear double-stranded DNA genome. The capsid consists of 252 capsomers, of which 240 are hexons and 12 are pentons (vertices). A fiber with a knob at the end projects from every penton. Virions attach to human cells via interaction of the fibers with a receptor on the cell surface and enter the cell via endocytosis. Virus uncoating occurs in the cytoplasm and the virus core is imported into the nucleus. The transcription and translation of viral DNA depend in part on host cell machinery.

Epidemiology

Although epidemiologic characteristics of the adenoviruses vary by type, the route of transmission is either via respiratory tract, fecal-oral or water-borne. Infections are most common during early childhood, but continue to occur throughout life. Nearly 100% of adults have serum antibodies against multiple serotypes. Adenoviruses have been found to account for 3–5% of acute respiratory infections in children and up to 2% in adults. Close contact in crowded institutions increases the risk for adenovirus infections and outbreaks have been described in day care centers, hospitals, shipyards and military quarters. Adenovirus infections can occur throughout the year but outbreaks of adenovirus-associated respiratory disease have been more common in the late winter, spring and early summer.

Pathogenesis

Adenoviruses causing respiratory disease can be spread via contact transmission (direct or indirect) and via droplet transmission. Direct contact transmission involves a direct body surface to body surface contact and physical transfer of micro-organisms between a susceptible host and an infected person. Indirect contact transmission involves contact of a susceptible host with a contaminated intermediate object. Adenoviruses can also be transmitted when droplets containing micro-organisms generated from the infected person are propelled a short distance (less than 3 feet) through the air and deposited on the host's conjunctivae, nasal mucosa or mouth. Droplets are particles of respiratory secretions larger than 5µm in diameter that are produced during coughing, sneezing or talking and during the performance of certain procedures such as suctioning and bronchoscopy.

The replicative cycle in the host cells may be lytic or may result in the establishment of a latent infection, primarily in lymphoid tissue. The symptoms of adenovirus disease are due to the lysis of infected epithelial cells and the resulting inflammatory response. The initial immune response is probably the recognition of infected cells by natural killer cells and monocytes, which evokes a cytokine response, followed by induction of cytotoxic T cells, as well as B cells which in turn results in the production of type-specific antibodies. Prolonged shedding of adenoviruses in stools has been recognized even in immunocompetent individuals. Some adenovirus serotypes (especially 12, 18 and 31) have been shown to induce oncogenic transformation in cultured rodent cells. In recent years, intensive research has focused on the use of adenoviruses as gene vectors.[1]

Prevention

An effective oral enteric-coated vaccine has been used to prevent adenovirus serotypes 4 and 7 infections in military recruits. This vaccine is not indicated for the general population. Contact and droplet precautions are indicated for controlling nosocomial transmission of adenovirus infection. Contact precautions include the placing of patients in private rooms, cohorting, use of gowns and globes, hand washing and the use of dedicated noncritical patient care equipment when possible. Droplet precautions include the placing of patients in private rooms, cohorting, the use of masks by the personnel caring for the patient within a distance of 3 feet and

TABLE 220-1 -- Human respiratory viruses: characteristic illnesses and populations at higher risk.

HUMAN RESPIRATORY VIRUSES: CHARACTERISTIC ILLNESSES AND POPULATIONS AT HIGHER RISK		
Virus	**Associated illnesses (most common virus subtype)**	**Patient population at higher risk**

Adenovirus	URI [1–3, 5–7]	Infants, young children
	Pharyngoconjunctival fever [3, 7, 14]	School-aged children
	URI, pneumonia [3, 4, 7, 14, 21]	Military recruits
	Pertussis-like syndrome [5]	Infants, young children
	Pneumonia [1, 2, 3, 4, 7]	Infants, young children, immunocompromised
	Hemorrhagic cystitis [11, 21]	Children, immunocompromised
	Keratoconjunctivitis [8, 11, 19, 35, 37]	All ages
	Gastroenteritis [40, 41]	Children, immunocompromised
	Hepatitis [1, 2, 5, 7, 31]	Immunocompromised
	Meningoencephalitis [7, 12, 32]	Children, immunocompromised
	Disseminated disease [1–5, 7, 11, 21, 31, 32, 34, 35, 39]	Immunocompromised
	Reye's syndrome [3, 7]	Children
Coronavirus	Common cold	All ages
	Otitis	Children
	Pneumonia	Military recruits, elderly, immunocompromised
	Exacerbation of asthma-COPD	Persons with asthma-COPD
Reovirus	Common cold (?)	All ages
	Enteritis (?)	Children
Rhinovirus	Common cold	All ages
	URI	All ages
	Exacerbation of asthma-COPD	Persons with asthma-COPD
	SARS (severe acute respiratory syndrome)	
RSV	URI	All ages
	Pneumonia	Infants, young children, elderly, immunocompromised
	Bronchiolitis	Infants, young children
	Otitis	Children
	Sudden infant death syndrome (?)	Young infants
Parainfluenza	URI	All ages
	Croup	Children
	Otitis media	Children
	Pneumonia	Children, immunocompromised
Influenza	'Flu'	All ages
	URI	All ages
	Pneumonia	Young children, elderly, persons with chronic cardiopulmonary illness, pregnant women, immunocompromised
	Croup	Children
	Otitis media	Children
	Myocarditis	Children
	Toxic shock syndrome	Children
	Reye's syndrome	Children
URI: upper respiratory tract infection		

the use of a mask on the patient while being transported out of the room. Maintaining adequate levels of chlorination is necessary for preventing swimming pool-associated outbreaks of adenovirus conjunctivitis.

Diagnostic microbiology

Virus isolation, antigen detection, polymerase chain reaction assay and serology can be used to identify adenovirus infections. Adenovirus serotyping is usually accomplished by hemagglutination inhibition and/or neutralization with type-specific antisera. The isolation of adenoviruses from body secretions is not sufficient to establish a diagnosis of adenovirus disease as prolonged asymptomatic shedding of adenoviruses can occur. Examination of biopsy or autopsy materials should be pursued whenever feasible in order to identify characteristic cytopathic changes and establish a diagnosis of adenovirus disease, particularly in the setting of immunosuppression where infection with multiple organisms is frequent.

Clinical manifestations

Although adenoviruses mainly cause respiratory illness, they may also cause various other illnesses such as gastroenteritis, keratoconjunctivitis, cystitis, meningoencephalitis and hepatitis, depending on the serotype. Respiratory illnesses associated with adenovirus infections include undifferentiated upper respiratory illness, pharyngoconjunctival fever, pertussis-like syndrome and pneumonia. Adenovirus serotypes 1, 2, 3 and 5 are the most frequent among children. Adenovirus types 4 and 7 and, less often, 3, 14 and 21 are associated with outbreaks of acute respiratory disease in military recruits. Enteric adenoviruses 40 and 41 cause gastroenteritis, usually in children. Epidemic keratoconjunctivitis is associated with

TABLE 220-2 -- Human respiratory viruses.

HUMAN RESPIRATORY VIRUSES				
Virus	**Culture cell lines**	**Characteristic findings**	**Direct assay**	**Serology**

Adenovirus	Primary human embryonic kidney (HEK) and the human lung carcinoma (A549) cell lines are sensitive for a broad range of adenoviruses. Some adenoviruses may require up to 28 days to grow. The continuous epithelial lines, such as Hep-2, HeLa and KB, are sensitive but more difficult to maintain for a long period of time as required by some serotypes	Enlarged, refractile, rounded cells forming grape-like clusters (Fig. 220.1), with some isolates forming a lattice-type arrangement of rounded cells	IF, EIA, and LA	Genus-specific EIA and CF Type-specific HI and NT
Coronavirus	Culture not performed in most laboratories. Primary isolation of human respiratory coronaviruses often requires human fetal tracheal or intestinal organ cultures	Cytocidal coronavirus infections may form multinucleated syncytia, lysis or both	EIA used in research settings	CF, HI, EIA used in research settings
Reovirus	Rarely isolated in the routine diagnostic setting. PRMK, LLC-MK2, HNK, HeLa, MDBK and H292 cell lines may support the growth of this virus	CPE is slow to develop. CPE may be non-specific with increased granularity, and progressive degeneration. HI or IFA can be used for typing	IF used in research settings	CF, NI, NT, EIA used in research settings
Rhinovirus	Human embryonic kidney and human fibroblast cell lines have been used most extensively: WI-38, HFF and MRC-5. HeLa is also sensitive	CPE is usually detected in the first week. CPE consists of rounded, highly refractile cells in loose clusters (Fig. 220.2). CPE permits a presumptive diagnosis of picornavirus infection. Demonstration of lability at pH 3 is used for differentiation from enteroviruses	EIA used in research settings	NT, CF, EIA used in research settings
RSV	Hep-2 is the preferred cell line. Alternatives include HeLa, A549, MRC-5, RhMK and Vero. Calcium and glutamine in the culture medium are important for optimal replication and cytopathic effect	CPE requires 3–7 days or more. Syncytia develops along with non-specific granular degeneration (Fig. 220.3). Confirmation by means of IF (Fig. 220.3) or EIA	IF (Fig. 220.3), EIA, IP	CF, IF, EIA, NT
Parainfluenza	Primary rhesus monkey kidney (PRMK) or MDCK are the preferred cell lines. LLC-MK2, a rhesus kidney heteroploid cell line, and NCI-H292, a human lung carcinoma line, are also sensitive	CPE is variable and non-specific. HPIV-2 and HPIV-3 may induce syncytia formation. Growth may be detected by means of Had (Fig. 220.4), with confirmation and typing by IF (Fig. 220.5), EIA, HAdI or HI	IF, EIA	HI, CF, EIA, NT
Influenza	PRMK and Madin-Darby canine kidney (MDCK) cells are preferred	CPE may be absent or minimal, with non-specific degeneration and granularity. Growth may be detected by means of HAd assay (Fig. 220.4), with confirmation and typing by IF (Fig. 220.5) or EIA	IF, EIA	Type-specific CF, EIA Subtype-specific HI, EIA
IF, immunofluorescence; EIA, enzyme immunoassay; LA, latex agglutination; HAdI, hemadsorption assay; HAd, hemadsorption inhibition; HI, hemagglutination inhibition; NT, neutralization test; IP, immunoperoxidase staining; CF, complement fixation; CPE, cytopathic effect				
Most common methods for laboratory diagnosis: culture, direct assay and serology.				

adenovirus types 8, 19 and 37. Hemorrhagic cystitis is more frequent with types 11 and 21. In children, the occurrence of cerebral edema, fatty liver and liver failure characteristic of Reye's syndrome has been reported in association with adenovirus types 3 and 7. With the exception of pharyngoconjunctival fever, the respiratory symptoms are not specific. The incubation period for the endemic serotypes ranges from 5 to 10 days and the symptoms last approximately 1 week. Chronic lung damage in the form of bronchiolitis obliterans has been reported after infections with serotypes 1, 3, 4, 7 and 21.

Severe and potentially fatal disease has been observed in neonates and individuals with primary or secondary immunodeficiencies.[2] However, cases of severe adenovirus disease have also been reported in apparently normal hosts. Immunocompromised patients, particularly hematopoietic stem cell transplant (HSCT) and solid organ transplant recipients, are susceptible to severe and potentially fatal adenovirus disease,[3] [4] [5] such as protracted hemorrhagic cystitis, encephalitis, nephritis leading to renal failure, hepatitis leading to liver failure, enteritis causing gastrointestinal bleeding, pneumonia leading to respiratory failure or a combination of those illnesses (disseminated disease).

Management

Most infections are mild and require no therapy or only symptomatic treatment. Ribavirin has *in vitro* activity against several adenovirus serotypes but the clinical experience in immunocompromised individuals has produced conflicting results.[5] [6] [7] [8] [9] [10] Aerosolized ribavirin is cumbersome to administer, while intravenous administration may be complicated by the development of hemolytic anemia. Cidofovir is a nucleotide analog with a broad antiviral effect *in vitro*, including against adenoviruses. The drug is administered intravenously every 2 weeks, after two initial weekly doses. Data on the efficacy of cidofovir against adenoviruses are limited to case reports and uncontrolled series.[10] [11] [12] The most significant side-effects of cidofovir include proximal renal tubular acidosis with azotemia, as well as uveitis with hypotony. Concomitant administration of probenecid and normal saline can reduce the risk of renal toxicity.

CORONAVIRUS

Nature

Human coronavirus (HCoV) was first isolated in 1965 from a patient with symptoms of the common cold. Virions are pleomorphic and measure 80–200nm in diameter. The outer envelope bears distinctive 'club-shaped' peplomers that correspond to the S (long spike) glycoprotein. The resulting 'crown-like' appearance under electron microscopy gives the family its name. The S glycoprotein is involved in receptor binding and cell fusion and is a major target for neutralizing antibodies. Other structural proteins include the M (matrix) protein, the E (envelope) protein and the N (nucleocapsid) phosphoprotein. In some types, there is also a glycoprotein HE (hemagglutinin-esterase, short spike). Entry occurs via endocytosis and membrane fusion. Replication of the linear single-stranded positive-sense RNA genome takes place in the cytoplasm. HCoV-229E and HCoV-OC43 serve as the prototype human coronaviruses.

Epidemiology

HCoVs are ubiquitous. Serologic studies have suggested that these viruses are a major cause of respiratory disease and account for 10–30% of all common colds. Serologic studies have also suggested that one-half of the infections with coronaviruses are asymptomatic. The peak activity occurs between late fall and early winter. Outbreaks of HCoV-229E in a community occur at 2–4-year intervals and outbreaks of HCoV-OC43 occur in alternate years when the incidence of HCoV-229E infection is low.[13]

Pathogenesis

Intranasal inoculation of volunteers with these viruses results in common colds. Disruption of the ciliated epithelium and ciliary dyskinesia was observed in histological

examinations.[14] Aminopeptidase N (APN), the receptor for HCoV-229E, is expressed on the apical surfaces of respiratory and intestinal epithelium, myelocytic cells, kidney tubular epithelium and synaptic junctions.

Figure 220-4 Identification of hemadsorbing viruses. (a) Uninoculated primary rhesus monkey kidney (PRMK) cell line. (b) Non-specific rounding or clumping of PRMK cells. (c) Positive hemadsorption of guinea-pig red blood cells.

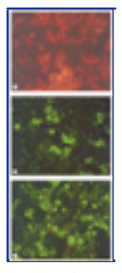

Figure 220-5 Differentiation of hemadsorbing viruses by means of IFA. (a) Negative control. (b) Influenza B positive. (c) Parainfluenza-3 positive, showing a comparatively more finely granular staining.

HCoV-OC43 binds to cells by means of the HE glycoprotein or the viral S glycoprotein, which can recognize 9-*O*-acetylated sialic acid on the cell surface.

Prevention

No specific antiviral drugs or vaccines are currently available. Infection control measures aimed at reducing exposure to respiratory secretions of infected patients should reduce the transmission of these viruses.

Diagnostic microbiology

Although animal coronaviruses can be readily isolated from infected tissues and serially propagated in continuous cell lines, isolation of human coronaviruses from infected individuals is not possible with generally available culture systems. Primary isolation of HCoVs generally requires culture in human fetal tracheal or intestinal organs. The genomes of HCoV-229E and HCoV-OC43 have been sequenced and RT-PCR can be used in the research setting.[15] Most of the population studies of HCoVs have used serologic methods, including complement fixation, hemagglutination inhibition (OC43 only) and recently EIA.

Clinical manifestations

HCoVs are second only to rhinoviruses as a cause of the common cold and the symptoms are indistinguishable. In a study of adult volunteers the mean incubation period was 3.3 days, with a range of 2–4 days. The symptoms lasted for a mean of 7 days, with a range of 3–18 days.[16] HCoVs have also been associated with otitis media, exacerbation of asthma and chronic pulmonary disease and have occasionally been associated with pneumonia, particularly in immunosuppressed patients.[17] [18] Early in 2003 an outbreak of severe pneumonia that originated in China, SARS (severe acute respiratory syndrome) was associated with atypical strains of coronavirus. The case fatality rate was approximately 4%.[110] [111] [112] Coronavirus particles have also been seen (via electron microscopy) in the stools of children and adults with diarrhea and gastroenteritis. The possible role of HCoVs in the genesis of multiple sclerosis (MS) is supported by the observation of coronavirus-like particles in brain tissue of patients with MS and by RT-PCR studies that have identified gene sequences of HCoV-229E and HCoV-OC43 in human brain tissue and cerebrospinal fluid with a higher frequency in MS patients than controls. However, the importance of human coronaviruses as a cause of diseases outside the respiratory tract remains to be determined.

Management

Treatment remains supportive. Potential targets for antiviral therapy are being identified, but no candidate drugs have been tested in clinical trials.

REOVIRUS

Nature

Isolation of the first reovirus was made in 1951, but it was in 1959 that Sabin coined the term reovirus to emphasize the fact that these viruses were isolated from the respiratory and enteric tracts and that they were not associated with any known human disease (Respiratory Enteric Orphan viruses). Reoviruses are nonenveloped viruses of about 65–75nm in diameter. They are composed of two concentric icosahedrically symmetric protein capsids, containing 10 discrete segments of genomic dsRNA. After attachment to cellular receptors, endocytosis of viral particles takes place. Replication occurs in the cytoplasm and results in cell death and lysis. Three distinct serotypes are identified by means of neutralization and hemagglutination inhibition tests (T1L, T2L and T3L).

Epidemiology

A study in which ELISA was used as the diagnostic method showed that the prevalence of antibodies against reovirus increased steadily throughout life from about 35% among 6-month to 1-year-old children to 60% among 11–19-year-olds and to more than 85% among those older than 60 years of age.[19] Infection can be achieved by intranasal inoculation as demonstrated in experiments with volunteers. Reoviruses have been recovered from water supplies and sewage effluents, presumably reflecting contamination of water with human and animal excreta. This could conceivably represent another source of virus for human infection.

Pathogenesis

It has been difficult to provide convincing evidence linking reovirus to specific human diseases. Cellular infection occurs by means of receptor-mediated endocytosis. Replication occurs in the cytoplasm. *In vitro* infection results in cell lysis. Interestingly, it has been observed that some reoviruses selectively replicate in and destroy cancer cells with an activated Ras signaling pathway, raising a possible role in the treatment of human neoplasms such as ovarian and colon cancer.[20]

Prevention

No specific strategies for prevention of transmission of reoviruses have been studied in clinical trials. Observance of appropriate handling of respiratory secretions from infected patients and avoidance of potentially contaminated water supplies could conceivably reduce the transmission of these viruses.

Diagnostic microbiology

The routine search for reovirus in clinical specimens in not recommended. In the research setting, a variety of techniques are available. In addition to identification of characteristic cytopathic effect (CPE) in cell line cultures, the presence of viral antigen can be confirmed using either immunofluorescence or immunocytochemistry. Immunocytochemical techniques can also be employed for the detection of reovirus antigens in tissue specimens. ELISA techniques have been widely used for detection of reovirus antibodies in serum. A variety of molecular techniques, including PCR, can be used for the detection of reovirus in tissues or body fluid samples.

Clinical manifestations

In a study of adult volunteers, intranasal inoculation of reovirus was followed by an increase in serotype-specific antibodies, recovery of the virus from anal swabs and development of respiratory illness in a third of the individuals infected with T1L.[21] The illness began 24–48 hours after the challenge and symptoms lasted for 4–7 days. The predominant symptoms included headache, pharyngitis, sneezing, rhinorrhea, cough and malaise. Because those findings have not been reproduced consistently, there is currently no definite etiological association of reovirus infection with human disease.

Management

Although ribavirin and other compounds exhibit *in vitro* activity against reoviruses, clinical trials seem unlikely to be performed for an organism that remains an 'orphan'.

RHINOVIRUS

Nature

Rhinovirus (RV) was first isolated in the 1950s from nasopharyngeal secretions of patients with the common cold. RV belongs to the Picornaviridae family, which includes the genera Enterovirus (poliovirus, coxsackieviruses groups A and B, echovirus and numbered enteroviruses) and Hepatovirus (hepatitis A virus). Rhinoviruses are small (30nm), nonenveloped particles that contain a linear single-stranded positive-sense RNA genome. The icosahedral capsid is composed of 60 subunits arranged as 12 pentameres. Each subunit is composed of one of each four structural proteins (VP1 to VP4). VP1–3 have exterior projections that are targets for neutralizing antibodies. More than 100 serotypes have been identified. The leukocyte binding protein ICAM-1 is the receptor for the majority of rhinovirus serotypes. The receptor-binding site resides in a depression of the capsid surface that is not accessible to antibodies. After endocytosis, an acid-dependent conformational change of the capsid allows the release of the RNA into the host cell cytoplasm, where viral replication and assembly take place. A polyprotein precursor is processed mainly by two viral proteases designated 2A and 3C. The 2A protease makes the first cleavage between the structural and nonstructural proteins, while the 3C protease catalyzes most of the remaining internal cleavages.

Epidemiology

Rhinoviruses are ubiquitous and infections occur in all age groups. They cause about half of all common colds and are also linked to a variety of complications such as otitis media, sinusitis, bronchitis and exacerbations of asthma and chronic obstructive pulmonary disease. RV infections result in frequent health care contacts, hospitalizations and excess of antibiotic use. These infections occur throughout the year with peaks in the fall and spring and with multiple serotypes circulating simultaneously in a given geographic location. Preschool children commonly introduce the virus to the rest of the family, with a secondary attack rate of about 50%, after an interval of 2–5 days. Extensive studies in susceptible individuals have shown that 95% of challenged subjects become infected and about 75% of them become ill. The major factor determining the risk of illness is the prechallenge level of neutralizing antibodies.

Pathogenesis

In spite of the extensive literature on the transmission of rhinovirus, controversy still exists about the predominant mode of transmission. Most data support the notion that contact transmission, primarily as hand shaking followed by inoculation of the nasal mucosa and lacrimal canals, is the most efficient mode of transmission. RV could survive from a few hours to as long as 4 days on nonporous surfaces and for at least 2 hours on human skin. Although droplet or airborne transmission of rhinovirus infection is possible, prolonged and close exposure is apparently required. There is no good clinical evidence to support the common notion that exposure to cold weather, getting wet or becoming chilled play a role in the genesis of RV illness.

Rhinoviruses attach to respiratory epithelium and spread locally. Most serotypes use ICAM-1 as a receptor for attachment and for subsequent viral uncoating during cell invasion. Some serotypes can upregulate the ICAM-1 expression on human epithelial cells, resulting in an increased susceptibility to infection. Infection is followed by activation of several inflammatory mechanisms including the release of cytokines (particularly IL-8), bradykinins, prostaglandins and histamine, as well as stimulation of parasympathetic reflexes.

The resulting process includes vasodilation of nasal blood vessels, transudation of plasma, glandular secretion and stimulation of nerve fibers, triggering sneeze and cough reflexes. Nasal mucociliary transport is reduced markedly during the illness and may be impaired for weeks. Immunity to individual rhinoviruses is type specific and not long lasting. Protection correlates more with the level of locally synthesized IgA antibodies, which decline within months of infection, rather than with IgG in serum, which may persist for a few years.

Prevention

Hand washing after shaking hands with someone who has a cold or after touching environmental objects potentially contaminated with relatively fresh secretions is strongly recommended. Alcohol-based, waterless antiseptics are also effective for this purpose. Symptomatic patients should be advised to hand wash frequently and to use disposable tissues. The CDC recommends contact precautions for the prevention of nosocomial RV infections. Some institutions also observe droplet isolation precautions.

The diversity of serotypes and the specificity of the immune response have precluded the development of an effective vaccine. A number of drugs have been studied for the prophylaxis of RV infection, including interferon a, pirodavir and recombinant soluble ICAM-1 molecule. However, the practical utility of these prophylaxis modalities remains to be demonstrated.

Diagnostic microbiology

Traditionally, RV infections have been detected by virus isolation in cell culture followed by acid lability testing. Virus isolation requires typically 2–14 days. Presumptive identification of a cell culture isolate as rhinovirus is based on a combination of enterovirus-like cytopathic effect and clinical information.

Further differentiation from enteroviruses is based on the diminished replication of rhinoviruses at 98.6°F compared to that at 91.4°F and at pH 3.0 compared with pH 7.0. ELISA has been developed for the detection of rhinovirus antigens. The use of serological assays is limited by the diversity of serotypes and the lack of a group-specific antigen. Recently developed RT-PCR assays are more rapid and sensitive than isolation techniques for detection of RV RNA in clinical specimens.

Clinical manifestations

Symptoms of the common cold include profuse watery rhinorrhea, nasal congestion, sneezing and quite often headache, sore throat and or cough. The symptoms begin within 8–10 hours of infection and peak around 1–3 days. There is little or no fever. By days 3–5 of the illness, nasal discharge may become mucopurulent from polymorphonuclear leukocytes that have migrated to the infection site in response to cytokines such as IL-8. Resolution of symptoms generally occurs within a week. Complications of RV infection include sinusitis, otitis media and exacerbation of asthma-COPD. Secondary bacterial infections may occur. Recent studies using CT of the sinuses have shown that RV infections can cause the accumulation of secretions in the sinuses, possibly from the passage of nasal secretions into the sinuses during nose blowing.[22] [23] Mounting evidence suggests an association between RV infections and lower respiratory tract illness, especially in immunocompromised individuals.[24] [25] [26] [27] [28] [29]

Management

Symptomatic treatment with decongestants, antihistamines and antitussives is currently the mainstay of therapy. The efficacy of zinc lozenges is controversial and their practical utility is limited because of their metallic taste. A variety of candidate drugs have been studied.[30]

Interferon-a has been found to be effective for the prevention of rhinovirus-associated colds but ineffective for the treatment of established colds. When administered through nasal spray, 80% of secondary RV cold were prevented but some patients developed blood-tinged nasal discharge and concerns about cost-effectiveness have been raised. Pirodavir (R77975) is a capsid-binding antipicornaviral agent with *in vitro* activity against most RV serotypes. Frequent intranasal sprays of pirodavir have been found to be effective in preventing experimentally induced RV illness[31] but ineffective in providing significant clinical benefit in naturally occurring rhinovirus colds. [32] Major recent therapeutic advances include the development of protease 3C inhibitors, recombinant soluble intercellular adhesion molecule (sICAM-1) and capsid-function inhibitors (pleconaril), all of which exhibit potent antirhinoviral activity *in vitro* and varying activity in clinical trials. AG7088, an irreversible inhibitor of rhinovirus 3C protease with *in vitro* activity against a broad range of RV serotypes,[33] is undergoing clinical trials. Recombinant soluble ICAM-1 molecule (Tremacamra) has been found to be effective in reducing the symptoms of experimental common colds in randomized controlled trials. This reduction in symptoms has been apparent regardless of whether the drug was given before or after the challenge with the virus.[34]

Pleconaril binds to a hydrophobic pocket in the viral capsid, inducing conformational changes that lead to altered receptor binding and viral uncoating. Pleconaril is orally bio-available and achieves serum concentrations in excess of those required to inhibit 90% of clinical rhino- and enteroviral isolates *in vitro*. In a placebo-controlled study of rhinovirus infections, pleconaril-treated patients had a 1.5-day reduction in time to resolution of symptoms, significant reduction in symptom severity within 12–24 hours after initiation of therapy and a significant reduction in median viral titers in nasal mucus.[35] The US FDA Advisory Committee has not yet recommended the approval of pleconaril for treatment of the common cold. Additional studies on safety, development of resistance and drug interactions are ongoing.

RESPIRATORY SYNCYTIAL VIRUS

Nature

Respiratory syncytial virus (RSV) belongs to the Paramyxoviridae family of viruses, which also includes parainfluenza viruses, mumps virus and measles virus. RSV was first isolated in the mid-1950s from a symptomatic laboratory chimpanzee during an outbreak of illness resembling the common cold. This virus derives its name from the characteristic formation of multinucleated giant cells in tissue culture.

RSV has a linear single-stranded, negative-sense genomic RNA. Virions are pleomorphic, with both spherical and filamentous forms seen under the electron microscope, and with an average diameter between 120 and 300nm. The envelope consists of a lipid bilayer derived from the host plasma membrane and contains three virally encoded transmembrane surface glycoproteins: the attachment protein G, the fusion protein F and the small hydrophobic SH protein. The F protein can mediate fusion with neighboring cells to form syncytia. The G glycoprotein plays a major role in the process of attachment. Two major types of RSV — A and B — are distinguished serologically based on the antigenic characteristics of the surface glycoprotein G. Other viral proteins include the matrix proteins (M and M2), the major nucleocapsid (N) protein, a phosphoprotein (P) and the major polymerase (L).

Epidemiology

RSV is the most common cause of bronchiolitis and pneumonia among infants and young children worldwide. Virtually all children are infected by the time they reach 3 years of age. Natural immunity is transient and reinfection is common. Crowding in households and day care centers increases the attack rate of RSV. In the USA, it has been estimated that 100,000 hospitalizations and 4500 deaths are related to RSV infection annually. The associated health care expenses are in excess of 300 million dollars per year. In older children and immunocompetent adults, RSV infections are seldom severe and are usually manifested as upper respiratory infection (URI) or tracheobronchitis. Individuals at high risk for severe RSV infection include premature infants (particularly those born at less than 34 weeks of gestation), young infants (particularly those with chronic lung disease, formerly designated bronchopulmonary dysplasia), elderly individuals and immunocompromised subjects.

RSV activity follows a seasonal pattern in temperate zones of the world. In urban centers, annual outbreaks occur during the fall, winter and early spring. In the northern hemisphere most outbreaks peak in February or March. In tropical or subtropical areas, epidemics peak during the rainy season.

Pathogenesis

Humans are the major reservoir. RSV is present in large numbers in the respiratory secretions of symptomatic infected persons and viral titers remain high for about 1 week after the onset of symptoms, followed by a gradual decline that may last for up to 3–4 weeks. The portal of entry is usually the conjunctiva or the nasal mucosa. Although transmission can occur via large droplets, contact transmission predominates.[36] Virus can be cultured for >5 hours on impervious surfaces such as bed rails. Thus, caregivers can contaminate their hands during routine care and transmit the virus by contact to other patients. Neutralizing antibodies to the surface glycoproteins F and G correlate with resistance to reinfection, but protection is far from complete and is of short duration.[37]

Pathologic examination of patients with bronchiolitis has revealed necrosis of ciliated bronchiolar epithelial cells, mononuclear infiltrate and edema of the peribronchial space. Bronchiolar obstruction results from the increased mucous production by goblet cells and the above-mentioned pathologic changes. Partial obstruction results in air trapping, and total obstruction results in atelectasis.

Pathologic examination of patients with pneumonia has revealed marked interstitial inflammation and edema of the lung parenchyma, along with the findings of bronchiolitis. Chronic alterations of pulmonary function tests have been described after RSV infection, but a cause-effect relationship remains to be confirmed.[38]

Prevention

In the household setting, the transmission of RSV may be decreased by means of frequent hand washing and refraining from sharing items such as cups, glasses and utensils with persons who have RSV illness. The CDC recommends contact precautions for the prevention of nosocomial RSV infections. Some institutions also observe droplet isolation precautions. Studies have shown that the implementation of multifaceted infection control strategies results in a reduction of the incidence of nosocomial RSV infection.[39]

Passive immunoprophylaxis is indicated for high-risk children. The available evidence supports the use of RSV-IVIG or palivizumab for the prophylaxis of RSV infections among infants with chronic lung disease (formerly designated bronchopulmonary dysplasia) and premature infants. Passive immunoprophylaxis is not recommended for children with cyanotic congenital heart disease.[40]

RSV intravenous immunoglobulin (RSV-IVIG, RespiGam®) is a human polyclonal immunoglobulin with high RSV microneutralization titers. In placebo-controlled studies, monthly intravenous doses of 750mg/kg during the RSV season significantly reduced the incidence of RSV hospitalizations and the severity of illness among premature infants and infants with bronchopulmonary dysplasia.[41] [42] Palivizumab is a humanized monoclonal antibody that specifically inhibits an epitope at the A antigenic site of the F protein of RSV subtypes A and B. It is dosed monthly at 15mg/kg intramuscularly during RSV season. In a large multicenter placebo-controlled trial involving high-risk infants, palivizumab prophylaxis resulted in a 55% reduction in hospitalization rates and number of hospital days ascribed to RSV infection.[43] Both agents have been well tolerated, with a few adverse effects; however, their high cost necessitates strict guidelines for their use. Cost-saving benefit has not been observed uniformly,[44] [45] [46] [47] [48] perhaps as a result of major differences in the prevalence of RSV lower respiratory tract infections in different countries and regions, suggesting the need for locally adapted recommendations. Palivizumab is easier to administer and does not interfere with the MMR vaccine or varicella vaccine. RSV-IVIG, however, provides additional protection against other respiratory viral illnesses and may be preferred for children receiving replacement IVIG because of

underlying immune deficiency.[43]

The role of passive immunoprophylaxis for the prevention of RSV infections in high-risk adults remains to be defined. Development of an RSV vaccine is ongoing but none is yet available.

Diagnostic microbiology

The gold standard diagnostic method is isolation of the virus from respiratory secretions. Appropriate samples for diagnosis include nasopharyngeal aspirate, wash or swab, tracheal aspirates, bronchioalveolar lavage and biopsy material. Given the lability of the virus, the samples should be kept cold and should be inoculated as quickly as possible. Cell line cultures show characteristics of RSV cytopathic effect after 3–7 days of incubation.

RSV was the first respiratory virus to be readily identified by means of rapid diagnostic tests based on antigen detection. Current methods for rapid detection of RSV antigen include enzyme immunoassay, immunoperoxidase staining, direct and indirect immunofluorescence tests and PCR. Serologic diagnosis requires a convalescent-phase RSV lgG antibody titer at least four times higher than the acute-phase titer.

Clinical manifestations

The incubation period ranges from 2 to 8 days. Illness begins most frequently with rhinorrhea, sneezing and cough. When fever is present it is generally low grade. Most children experience recovery from illness after 8–15 days. During their first RSV infection, 25–40% of infected infants and young children have signs or symptoms of bronchiolitis or pneumonia and 0.5–2% require hospitalization. In contrast, hospitalization will be required in up to 25% of high-risk children such as those with history of prematurity or chronic lung disease. RSV bronchiolitis or pneumonia should be suspected when an infant or young child presents with progressive cough, wheezing and dyspnea during a RSV season. Radiographic findings in patients with bronchiolitis include hyperlucency, diaphragmatic flattening and outward bowing on the intercostal spaces. Findings compatible with pneumonia include interstitial infiltrates and, less frequently, consolidation, particularly in the right upper and middle lobes.

In neonates, the clinical presentation may be atypical with lethargy, irritability or poor oral intake. RSV has been detected in lung tissue of infants with sudden death syndrome, but a cause-effect relationship has not been confirmed. Prolonged pulmonary function deficit and airway hyperreactivity have been reported following RSV infection but it remains unclear whether these abnormalities were present before the infection. Otitis media has also been associated with RSV infection.

Among immunocompetent adults, RSV infection usually manifests with rhinorrhea, pharyngitis, cough, bronchitis, headache, fatigue and fever. In older persons, particularly the institutionalized elderly and those with chronic cardiopulmonary illnesses, severe pneumonia may occur, leading to respiratory failure. Among immunocompromised individuals, RSV has been the most frequently isolated viral respiratory pathogen in surveillance studies performed at large cancer centers.[49] In this setting RSV infection typically begins as a URI and may evolve into lower respiratory tract disease in up to 50% of cases. A particularly high rate of progression to pneumonia (70–80%) has been reported among adult HSCT recipients developing RSV infection within the period prior to engraftment. In such setting the RSV pneumonia resulted in 60–80% mortality, regardless of the inclusion of antiviral drugs in the treatment strategy.

Management

For patients with mild disease, no specific treatment is necessary other than the treatment of symptoms. Children with severe disease may require hospitalization for supplemental oxygen therapy, hydration, nutrition and, sometimes, mechanical ventilation. Improvements in supportive care have made a significant impact on the mortality from RSV bronchiolitis and pneumonia. The use of bronchodilators is likely beneficial for patients with significant bronchospasm. Corticosteroids are commonly used as anti-inflammatory therapy, although there is lack of data demonstrating the benefits of such intervention. Aerosolized ribavirin (Virasole®) was approved in 1986 for the treatment of infants and children with severe RSV disease. The treatment is cumbersome to deliver and its impact on mortality remains controversial.[50] [51]

A combination of passive immunoprophylaxis and ribavirin has been reported to be well tolerated and to improve the outcome of severe RSV infection among bone marrow transplant recipients.[52] [53] In one open trial the mortality was only 22% among nine adults with pneumonia in whom therapy was initiated prior to the onset of profound respiratory failure.[53] Pre-emptive treatment strategies are being investigated primarily in immunocompromised individuals. Delay of immunosuppressive chemotherapy should be considered when severely immunosuppressed individuals, such as HSCT recipients, develop acute RSV infection.

PARAINFLUENZA VIRUS

Nature

Human parainfluenza viruses (HPIVs) were first described in the 1950s, originally as croup-associated viruses. The term parainfluenza was coined because of the associated influenza-like symptoms and the hemagglutinin and neuraminidase activities exhibited by HPIVs. However, HPIVs belong to the Paramyxoviridae family.

The virions are pleomorphic and range in average diameter from 150 to 200nm. They are enveloped particles with a linear single-stranded negative-sense RNA genome. The HPIVs encode two surface glycoproteins: an attachment protein called HN (hemagglutinin-neuraminidase), that binds to sialic acid-containing receptors on host cell surfaces, and a fusion protein F that is involved in the fusion of the viral membrane with the cellular plasma membrane. The HN protein is a multifunctional molecule with binding activity (binding to sialic acid containing surface glycoproteins and glycolipids), neuraminidase activity and fusion promotion activity. The attachment activity can be measured by hemagglutination assay. The neuraminidase activity prevents aggregation of virus particles by removing sialic acid from the virion glycoproteins and facilitates infection in the respiratory tract by digesting the mucin coating of epithelial cells.

These viruses also encode three nucleocapsid associated proteins, NP, P and L, and the nonglycosilated internal protein M. The four HPIVs are segregated in two genera, the Respirovirus (HPIV-1 and HPIV-3) and the Rubulavirus (HPIV-2 and HPIV-4), based on antigenic and structural characteristics, including additional accessory proteins (V,D,W,I,X,C and SH).

Epidemiology

HPIVs are distributed worldwide. Each of the four HPIVs can cause a full spectrum of acute respiratory tract illnesses. HPIV-1 and HPIV-2 are the most common pathogens associated with croup or laryngotracheobronchitis.[54] HPIVs 1, 2 and 3 are also important causes of bronchiolitis and pneumonia among infants and young children.[54] [55] Less is known about HPIV-4. Most children have serologic evidence of infection by 5 years of age. Reinfection is common and occurs throughout life. Most HPIV infections are detected during seasonal epidemics. In a study on an outpatient pediatric population,[56] HPIV-1 occurred in the fall of odd-numbered years, HPIV-2 was less predictable and HPIV-3 appeared yearly with peak activity in spring or summer. In a study of data from the US National Hospital Discharge Survey obtained from 1979 through 1997,[55] 3-month periods of widespread activity for each of the HPIVs were identified: HPIV-1 from September through November of odd-numbered years; HPIV-2 from October through December each year, and HPIV-3 from April through June during 1995 and 1997 and from May through July during 1994 and 1996. The estimated number of hospitalizations associated with HPIV-1–3 infections was 7600 to 48,000 among children aged <1 year and 8100 to 42,600 among children aged 1–4 years. The estimated rates of HPIV-associated hospitalizations ranged from 1.9 to 12 per 1000 children <1 year old and from 0.5 to 2.0 per 1000 children aged 1–4 years.

Pathogenesis

Although droplet transmission can occur, contact is though to be the primary mode of transmission of HPIV infection. This can be direct person to person or indirect through intermediate objects. Inoculation is into the mouth, nasopharynx or oral mucosa. The characteristic tendency to cause laryngotracheobronchitis and croup is not completely understood. Some of the HPIVs can induce syncytia formation but the role of this phenomenon is not well understood. Immune response is complex and includes the production of serum-neutralizing antibodies directed towards epitopes of the HN and F proteins. An important role in the protection against HPIVs infections is played by the mucosal immune response, primarily through the production of IgA antibodies. In animal model studies, it has been demonstrated that the role of $CD8^+$ T cells is critical for virus clearance.

Prevention

General principles for the prevention of respiratory viral infections apply to the prevention of HPIV infections. The CDC recommends contact precautions for the

prevention of nosocomial HPIV infections. Some institutions also observe droplet isolation precautions. No specific vaccine is yet available and no drugs have been tested for prophylactic use.

Diagnostic microbiology

Definite diagnosis relies on the isolation of the virus from respiratory secretions. Other diagnostic methods include detection of viral antigens or nucleic acid, and serologic analysis. Primary isolation and identification, by means of hemadsorption assay, can be followed by typing of the virus by means of immunofluorescence or hemadsorption inhibition. PCR assays can be more sensitive than isolation and antigen detection methods.[57]

Clinical manifestations

Infection in children is associated with an acute febrile illness in up to 80% of cases. Initial symptoms include coryza, sore throat, hoarseness and dry cough. In cases of croup, a brassy or barking cough may progress to stridor and some may progress to airway obstruction. The anteroposterior radiograph of the neck shows glottic and subglottic narrowing ('steeple sign') which differentiate this disease from epiglottitis. In cases of bronchiolitis and pneumonia, progressive cough is accompanied by wheezing, tachypnea and hypoxemia. Chest X-ray examination may reveal air trapping and interstitial infiltrates. Otitis media with presence of HPIVs in the middle ear fluids is common.

In older children and adults, HPIV infections tend to be milder and present as URI. However, HPIV-1 and 3 have been diagnosed by means of serologic assay in a significant number of adults admitted with acute respiratory illness. [58] A few cases of HPIV meningitis have been described. [59] Immunocompromised pediatric and adult individuals such as hematopoietic stem cell,[60] [61] [62] [63] [64] [65] lung[66] and renal[67] transplant

recipients may develop severe HPIV infections with a high rate of progression to pneumonia. The use of corticosteroids was linked with a higher risk of HPIV-3 pneumonia among recipients of hematopoietic stem cell transplantation.[62]

Management

Symptomatic treatment of croup usually includes humidification of air by ultrasonic nebulizer and inhalations of racemic epinephrine. Epinephrine provides rapid but transient relief of the airway obstruction. The anti-inflammatory effect of systemic corticosteroids is advocated to prevent or shorten the period of intubation in severe croup. Patients with bronchiolitis are also treated with bronchodilators. Ribavirin has exhibited *in vitro* activity against HPIVs[68] but data from controlled clinical trials are lacking.

INFLUENZA VIRUS

Nature

The existence of acute, usually self-limited, febrile respiratory illness that occurs in outbreaks of variable severity almost every winter has been known for centuries.[69] [70] [71] The term 'influenza' was derived from Italian in the mid-1300s to indicate that the disease resulted from astrological influences. The etiology of the disease and the explanation for its peculiar behavior remained elusive. It was not until the late 1920s that the etiology of influenza was better understood. Shope[72] showed that swine influenza could be transmitted with filtered mucus, suggesting that the causative agent was a virus. In the 1930s, Smith *et al* isolated the influenza virus from humans with respiratory illness.[73]

Influenza virions are enveloped particles of spherical or elongated shape, measuring 80–120nm in diameter and containing a linear segmented, single-stranded, negative-sense RNA. They belong to the Orthomyxoviridae family of RNA viruses. There are three major antigenic types — A, B and C — that also differ in genetic organization, structure, clinico-epidemiologic characteristics and host range (Table 220.3).

Influenza A virus serves as the prototype strain. The virion has two surface glycoproteins (hemagglutinin and neuraminidase) and a major nucleocapsid glycoprotein (NP) that associates with three other proteins (PA, PB1 and PB2) to form the transcription complex, two matrix proteins (M1 and M2) and two nonstructural proteins (NS1 and NS2). Influenza A virus adsorption to host cells involves the binding of hemagglutinin to sialic acid-containing cell surface glycoproteins or glycolipids. This is followed by virion entry into the

TABLE 220-3 -- Comparison of influenza virus types.

COMPARISON OF INFLUENZA VIRUS TYPES			
Antigenic type	**A**	**B**	**C**
RNA segments	8	8	7
Surface glycoproteins	Hemagglutinin (1 to 15)	Hemagglutinin	HEF: hemagglutinin esterase fusion protein
	Neuraminidase (1 to 9)	Neuraminidase	
Genetic variability	Drifts and shifts	Drifts	Drifts
Human disease	Epidemic, pandemic, sporadic	Epidemic, sporadic	Sporadic
Known hosts	Humans, swine, horses, poultry, sea mammals several avian species	Humans	Humans, swine
Target for current antivirals	M2 protein (amantadine, rimantadine)	Neuraminidase (zanamivir, oseltamivir)	Not available
	Neuraminidase (zanamivir, oseltamivir)		

cell via receptor-mediated endocytosis. The M2 protein ion channel activity leads to the acidification of the vesicle and fusion of the virus membrane to the vesicle membrane, resulting in the release of the viral nucleocapsid into the cytoplasm. Influenza RNA replication and translation depend on viral proteins and cell machinery functions. Budding from the plasma membrane completes assembly. The emerging virions are coated with sialic acid that is then cleaved by the neuraminidase, allowing the virus to be free and able to infect other cells.

Influenza A viruses are divided into subtypes. The current nomenclature system[74] includes the host of origin, geographic location of first isolation, strain number and year of isolation. The antigenic description of the hemagglutinin (HA) and neuraminidase (NA) is given within parentheses (e.g. A/Swine/Iowa/15/30 (H1N1)). By convention, the host of origin of human strains is omitted (e.g. A/Puerto Rico/8/34 (H1N1)). There are 15 HA and nine NA subtypes; the subtypes differ by 30% or more in amino acid sequence homology.

Epidemiology

There is no evidence of persistent or latent infection with human influenza viruses. The virus is maintained in humans by person-to-person spread during acute infection. Influenza virus is also known to infect a variety of birds and mammals (including swine, horses, seals, whales, mink and primates). The current information supports the concept that mammalian influenza viruses are derived from avian influenza reservoirs.[75] [76] [77] Some avian species, such as ducks, are asymptomatic carriers perhaps as a result of virus adaptation over many centuries.

The influenza viruses are unique among the respiratory tract viruses in that they undergo significant antigenic variation. Antigenic drift involves minor antigenic changes in the HA and NA that occur by accumulation of point mutations, resulting in amino acid substitutions in antigenic sites. These changes render the new strain different enough to avoid the immunity induced by previous strains. Influenza epidemics have been recognized as a major cause of morbidity and increased mortality, especially in the very young, the very old, people with chronic cardiopulmonary conditions, pregnant women and immunocompromised individuals. In the USA, epidemics of influenza typically occur during the winter months and are responsible for an average of approximately 16,000 to 220,000 hospitalizations and 20,000 to 40,000 deaths per epidemic.[78] In the tropics, influenza can occur throughout the year and in the temperate regions of the southern hemisphere the majority of influenza activity occurs

during the months of April to September.

During influenza A pandemics, the impact of influenza becomes global and results in significant morbidity and mortality for a broader range of hosts, including young healthy people.[70] The greatest influenza pandemic, so-called Spanish influenza, spread around the globe in 1918–19 after the First World War and resulted in the deaths of approximately 20–40 million persons, more than the war itself. The emergence of pandemic influenza A can be explained by antigenic shifts resulting from genetic reassortment within cells dually infected by human and animal influenza viruses.[79] The exchange of RNA segments between the two viruses occurs in a manner analogous to the exchange of parental chromosomes during meiosis. Interestingly, all major antigenic shifts have originated in China and have been confined to the H1, H2 and H3 subtypes. Avian influenza can be transmitted to humans with swine acting as an intermediary host in which reassortment takes place. However, a direct transmission of a pathogenic avian influenza to humans was observed in Hong Kong in 1997, when 18 people were infected with an avian H5N1 influenza virus and six died of its complications. [80] In addition, it has been observed that the Russian influenza (H1N1), that appeared in northern China in 1977, was identical to the virus that caused a human influenza epidemic in 1950, suggesting that certain influenza strains may remain confined in a natural reservoir for many years and reemerge when the herd immunity has waned.

Pathogenesis

Droplet transmission is considered the primary mode of transmission of influenza. However, scarce data also support the notion that airborne transmission can occur, spread from person to person by direct inhalation of droplet nuclei or small-particle aerosols measuring less than 5µm in diameter. After evaporation, micro-organisms remain suspended in the air for long periods of time and can be dispersed by air currents. Susceptible hosts may inhale the particles within the same room or over a longer distance from the source patient. The extent to which transmission might also occur by contact with virus-contaminated hands or fomites is less well understood.

Acute diffuse mucosal inflammation and edema of the upper airway and bronchi are observed in uncomplicated influenza. The columnar ciliated cells become vacuolated and edematous. This is followed by desquamation of the ciliated and mucus-producing epithelial cells. In cases of influenza viral pneumonia, there is an interstitial pneumonitis with a predominantly mononuclear leukocyte infiltration. The alveolar walls become denuded of epithelium; hyaline membranes form, and the intra-alveolar space becomes filled with exudate and hemorrhage.[81] At a cellular level, influenza virus disrupts protein synthesis and also induces apoptosis.

The immune response against influenza is complex and involves multiple arms of the immune system. Neutralizing antibodies in respiratory secretions are primarily of the IgA isotype[82] and constitute the first line of defense. However, the major role is played by the humoral response via neutralizing antibodies. The level of serum antibody to the HA and NA correlates with resistance to illness and with restriction of the influenza virus replication in the respiratory tract of humans.[83] [84] Interleukin-6 (IL-6), interferon-a and other proinflammatory cytokines are produced in response to influenza infection, with the peak of their production coinciding with the peak of systemic symptoms.[85] The cellular immunity also plays an important role in the immune response to influenza virus. Cytotoxic T cells participate by interacting with B cells and also by destroying cells infected with influenza.[86]

Prevention

Influenza vaccination is the primary method for preventing influenza. To be effective, the vaccine components need to match the circulating strains of the target season. Intensive surveillance of new influenza strains is maintained around the globe in order to make an informed selection of strains for the next yearly influenza vaccine and to detect early on strains that could potentially cause a new influenza pandemic. The primary target groups for annual vaccination are:

- people aged =65 years;
- residents of nursing homes and other chronic care facilities;
- people who have chronic disorders of the pulmonary or cardiovascular systems;
- those who have required regular medical follow-up or hospitalization during the preceding year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies or immunosuppression (including immunosuppression caused by medications or by human immunodeficiency virus);
- children and teenagers (aged 6 months to 18 years) who are receiving long-term aspirin therapy and therefore might be at risk for developing Reye's syndrome after influenza infection;
- and women who will be in the second or third trimester of pregnancy during the influenza season.

Vaccination of health care workers and others in close contact with persons at high risk, including household members, is recommended. When feasible, vaccination is also recommended for people aged 50–64 years, because this group has an increased prevalence of high-risk conditions, and for otherwise healthy children aged 6–23 months, because they are at increased risk for influenza-related hospitalization.[78] Depending on vaccine availability, vaccination should also be provided to any person who wishes to reduce the likelihood of becoming ill with influenza.

Vaccination results in reductions of influenza-related respiratory illness and number of physician visits among all groups of age, hospitalization and death among persons at high risk, otitis media among children and work absenteeism among adults. In the United States, the inactivated (i.e. killed virus) vaccine is recommended.[87] The vaccine contains three strains (i.e. two type A and one type B), representing the influenza viruses more likely to circulate in the upcoming winter. The vaccine is made from highly purified, inactivated virions. Subvirion and purified surface antigen preparations are also available. The effectiveness of influenza vaccine depends primarily on the age and immunocompetence of the vaccine recipient and the degree of similarity between the viruses in the vaccine and those in circulation. Local reactions to the vaccine are generally mild. Fever, malaise, myalgia and other systemic symptoms can also occur. The 1976 swine influenza vaccine was associated with an increased frequency of Guillain-Barré syndrome (<10 cases/1,000,000 persons vaccinated).

Live attenuated influenza vaccines can be administered directly to the respiratory tract, avoiding the need for injections and providing a means of inducing the production of IgA by the respiratory mucosa. Strains prepared by reassortment from cold-adapted mutants of both influenza A and B viruses have been widely shown to be well tolerated in both adults and children and to be highly efficacious. [88] [89]

Antiviral chemoprophylaxis is approximately 70–90% effective in preventing illness in healthy adults. Amantadine, rimantadine and oseltamivir are approved for chemoprophylaxis of influenza A virus infections; only oseltamivir is approved for chemoprophylaxis of influenza B virus infections (Table 220.4). Chemoprophylaxis can be considered for persons at high risk who are expected to have an inadequate antibody response to influenza vaccine, and for those with a history of anaphylactic reactions to egg protein. The efficacy of chemoprophylaxis for the prevention of influenza has not been established in immunocompromised patients.

Strategies for prevention of nosocomial transmission of influenza include vaccination programs, the use of chemoprophylaxis and compliance with droplet isolation precautions. Although influenza

TABLE 220-4 -- Comparison of antiviral drugs for prophylaxis and treatment of influenza.

COMPARISON OF ANTIVIRAL DRUGS FOR PROPHYLAXIS AND TREATMENT OF INFLUENZA					
Drug	**Trade name**	**Influenza type**	**Dosing for prophylaxis**	**Dosing for treatment**	**Main side-effects**
Amantadine	Symmetrel®	A	Age 1–9 years: 5mg/k/d po div bid	Age 1–9 years: 5mg/k/d po div bid	Central nervous system
			Age 9 and up: 100mg po bid	Age 9 and up: 100mg po bid	
Rimantadine	Flumadine®	A	Age 1–10 years: 5mg/k/d po qd	Adults: 100mg po bid	Central nervous system
			Age 10 and up: 100mg po bid		
Zanamivir	Relenza®	A and B	N/a	Age > 7 years: 10mg inhaled bid	Bronchial
Oseltamivir	Tamiflu®	A and B	Age =13 years: 75mg po qd	Age 1–12 years: dose per weight*	Gastrointestinal
				Age 13 and up: 75mg po bid	

* For children who weigh "15kg the dose is 30mg bid; for those who weigh 15–23kg, 45mg bid; for those who weigh 23–40kg, 60mg bid; and for those who weigh >40kg, 75mg bid.

can be transmitted via the air-borne route, the use of negative air pressure rooms has not been assessed.

Diagnostic microbiology

Diagnostic tests available for influenza include viral culture, serology, rapid antigen testing and immunofluorescence. Viral culture remains essential for determining the influenza subtypes and strains causing illness and for surveillance of new strains that may need to be included in the influenza vaccine. Because influenza may not produce cytopathic effects in cell culture, the hemadsorption test is used to screen for evidence of viral replication. The early diagnosis of influenza can reduce the inappropriate use of antibiotics and allow the early administration of antiviral therapy. Commercially available rapid influenza diagnostic tests differ in their ability to detect and distinguish between influenza A and B virus infections, methodologies, processing time and cost. The sensitivities of the rapid tests are lower than viral culture of respiratory specimens and a negative result might not exclude influenza virus infection. Rapid influenza tests provide results within 24 hours, while viral culture takes 3–10 days. Appropriate samples for influenza testing include nasopharyngeal or throat swabs, nasal wash or nasal aspirates, depending on which type of test is used. Samples should be collected within the first 4 days of illness. Acute and convalescent serum samples can also be tested for influenza antibodies to diagnose recent infection.

Clinical manifestations

The incubation period is 1–4 days, with an average of 2 days. The typical uncomplicated influenza A syndrome has an abrupt onset with headache, high-grade fever, chills, dry cough, myalgias, malaise and anorexia. In more severe cases, prostration is observed. Respiratory symptoms such as rhinorrhea, nasal congestion and sore throat are present but are overshadowed by the systemic symptoms during the first 3 days of illness. The cough frequently changes from a dry, hacking nature to one that is productive of small amounts of sputum that are usually mucoid but can be purulent. After the fever and upper respiratory tract symptoms resolve, cough and weakness can persist for 1–2 additional weeks. Influenza B virus can cause the same spectrum of disease as that seen after influenza A virus infection, and severe illness can occur. Influenza C virus causes sporadic, usually afebrile upper respiratory tract illness and is rarely associated with severe lower respiratory tract disease.

Influenza attack rates are higher in children compared to adults. High-grade fever, cervical lymphadenopathy, nausea and vomiting are frequent manifestations of influenza in children. Croup is a less frequent manifestation of influenza, limited to children.

Pneumonia complicates influenza predominantly in the elderly, patients with chronic cardiopulmonary disease, pregnant women and immunocompromised individuals. The etiology may be viral, bacterial or mixed viral-bacterial.[90] In primary viral pneumonia, typical influenza is followed by a rapid progression of fever, cough, dyspnea and cyanosis. Physical examination and chest X-ray disclose diffuse bilateral infiltrates consistent with adult respiratory distress syndrome. A combined viral-bacterial pneumonia is more common than primary viral pneumonia. The bacteria most commonly involved are *Streptococcus pneumoniae* and *Staphylococcus aureus*. A third type of complication is a bacterial pneumonia developing after a clinical improvement from influenza. In this case, physical and chest X-ray examinations are more likely to show localized signs of consolidation. Influenza can also exacerbate chronic underlying medical conditions such as asthma, chronic obstructive pulmonary disease and congestive heart failure.

A variety of nonrespiratory complications have been described. Myositis has been reported more frequently in children with influenza B but adults may also be affected and may develop rhabdomyolysis with acute renal failure.[91] Myocarditis and rarely pericarditis[92] [93] have been described in patients with influenza A and B. Reye's syndrome has been reported most frequently after influenza B[94] and has also been described after infections with other viruses such as varicellazoster. The syndrome is characterized by a rapidly progressive non-inflammatory encephalopathy and fatty infiltration of the viscera, especially the liver, resulting in severe hepatic dysfunction. The administration of therapeutic doses of salicylates appears to increase the risk for the development of Reye's syndrome. A wide spectrum of CNS involvement has been observed during influenza A and B virus infection, ranging from irritability and confusion to severe encephalopathy.[95] Toxic shock syndrome has been observed in association with influenza virus infection and is believed to be the consequence of the bacterial exotoxin (TSST-1) secreted by colonizing *Staph. aureus* strains.[96] Febrile convulsions leading to hospitalization occur in children with and without underlying CNS abnormalities.

Influenza viruses can cause severe disease in immunocompromised individuals.[97] [98] [99] [100] [101] [102] [103] Severe lymphopenia, elderly age, receipt of an allogeneic hematopoietic stem cell transplant and concurrent opportunistic infections were identified as independent risk factors for a complicated course in a study of adults with leukemia and adult recipients of hematopoietic stem cell transplant. In that study, significant morbidity and mortality were observed with both influenza A and B viruses. Prolonged shedding of influenza virus and rapid emergence of resistance to amantadine and rimantadine has been observed in immunocompromised persons.[104]

Management

Four antiviral medications — amantadine, rimantadine, oseltamivir and zanamivir — are approved for treatment of influenza A virus infections. Oseltamivir and zanamivir are also approved for treatment

of influenza B virus infections. When administered within 48 hours of symptom onset, antiviral treatment of influenza can reduce the duration of illness by approximately 1 day in healthy adults.

Amantadine and rimantadine inhibit the M2 protein of influenza A virus. Their side-effects include CNS symptoms such as nervousness, anxiety, difficulty concentrating and lightheadedness. Central nervous system side-effects are more frequent with amantadine than with rimantadine.[105] Gastrointestinal side-effects include nausea and loss of appetite. Amantadine and rimantadine are the least expensive antivirals against influenza and have been in use for several years.

Zanamivir and oseltamivir are analogs of sialic acid that were designed to inhibit the neuraminidase of both influenza A and B viruses.[106] Zanamivir is inhaled and may induce bronchospasm in those with underlying lung disease such as asthma and chronic obstructive pulmonary disease. Other less frequent side-effects include diarrhea, nausea, headache and dizziness. Oseltamivir may induce gastrointestinal side-effects, including nausea and vomiting, especially if the drug is not taken with food (see Table 220.4).

Data are limited concerning the effectiveness of amantadine, rimantadine, zanamivir and oseltamivir for the treatment of influenza among persons at high risk for serious complications of influenza. A retrospective analysis of a surveillance study in immunocompromised individuals showed a decreased rate of progression to pneumonia in patients with influenza A treated with amantadine or rimantadine.[107]

HUMAN METAPNEUMOVIRUS

In June 2001, it was reported that a new respiratory virus had been isolated from nasopharyngeal aspirates of 28 young children in The Netherlands. Based on virological data, sequence homology and gene constellation, the virus was classified as a member of the Metapneumovirus genus of the Paramyxoviridae family and was named human metapneumovirus (HMPV). The clinical syndrome was similar to that caused by RSV. Serological studies showed that by the age of 5 years, virtually all children in The Netherlands have been exposed to HMPV and that the virus had been circulating in humans for at least 50 years.[108] Investigators from other countries, including Australia, Canada, the UK and Finland, have reported further evidence that HMPV is an important human respiratory pathogen. The associated clinical presentation includes flu-like illness, bronchospasm and pneumonia. The severity varies from self-limiting mild respiratory illness to respiratory failure requiring mechanical ventilation. Severe lower respiratory tract infections have been observed in very young children, the elderly and immunocompromised patients. [109] The virus shows cytopathic effect in LLC-MK2 (tertiary monkey kidney) cells and molecular methods for rapid detection and identification are being developed.

CONCLUSION

A better understanding of the profound impact that HRVs have on human morbidity and mortality has resulted in more resources being devoted to their study. More efficient diagnostic tools, new antiviral agents, the use of passive immunoprophylaxis, improvements in vaccination programs and in strategies to control the nosocomial transmission of these infections are among the most significant accomplishments.

Chapter 221 - Retroviruses and Retroviral Infections

Charles AB Boucher

INTRODUCTION

The Retroviridae constitute a large family of viruses that infect both humans and animals. Retroviruses predominantly infect vertebrates, although infections of insects and molluscs have also been described. Retroviral infections may cause a wide spectrum of diseases ranging from malignancies to immune deficiencies and neurologic disorders. However, most retroviral infections occur without any detectable deleterious effect to the host. In spite of the diversity of associated pathology and the broad range of hosts, all retroviruses are united by a common mode of replication and a similar virion structure and genome organization.

This chapter discusses some general features of the retroviruses, such as virion structure, genome organization and taxonomy of retroviruses. Although there have been concerns about the potential clinical significance of porcine retroviruses in the context of xenotransplantation[95] , the main focus of attention is on human retroviruses. During the past decades, the AIDS pandemic has resulted in an upsurge of scientific interest in retroviral infections and related pathology in humans. Several human retroviruses have been identified, of which only HIV and the human T-lymphocyte leukemia viruses (HTLVs) are known to cause clinical manifestations. These two human retroviruses have been well characterized and are discussed in more detail.

NATURE

The electron microscopic view of retroviral particles shows spheric particles approximately 100nm in diameter with an electron-dense core (Fig. 221.1). Retroviruses are enveloped viruses. The envelope consists of a phospholipid double layer derived from the plasma membrane of the host cell. Viral encoded transmembrane glycoproteins are inserted into the envelope, enabling the virus to attach to the host cell (Fig. 221.2). The envelope surrounds the nucleocapsid core, which contains the viral genome: two identical RNA molecules, having the same polarity as mRNA, with which an RNA-dependent DNA polymerase enzyme, reverse transcriptase (RT), is closely associated. Also present in the core is the integrase enzyme.

The genome of retroviruses is approximately 10,000 base pairs (bp) in length. Each end of the genome consists of repeating nucleotide sequences of 4–6bp, called the long terminal repeats (LTRs). The LTRs flank the three genomic regions that encode for sets of structural genes:

- the group antigen (*gag*) region, which codes for the core antigens;
- the polymerase (*pol*) region, which codes for the enzymes protease, RT and integrase; and
- the envelope (*env*) region, which codes for glycoproteins of the envelope.

The structural genes always appear in the same order: *gag-pol-env* (Fig. 221.3).[1] There are several retroviruses that contain additional genes that encode for viral proteins involved in the regulation of several processes in the replication cycle of the virus, such as the rate of transcription, the splicing of mRNA, the transport of mRNA from the nucleus to the cytoplasm and the release of progeny virus. Retroviruses that contain additional genes are called complex retroviruses; examples of these are the HIVs and the HTLVs. The genomes of so-called simple retroviruses only contain a *gag*, *pol* and *env* gene.

The first step in the replication cycle of retroviruses is attachment of the virus to a host cell through interaction of the envelope glycoprotein with a receptor molecule on the host cell surface (Fig. 221.4). This interaction between virus and host cell largely determines the host range of the virus (i.e. which species or cell type the virus will infect). After attachment, fusion of the envelope membrane with the host cell membrane takes place and the nucleocapsid core is released into the cell. However, some retroviruses enter the cell by receptor-mediated endocytosis followed by fusion of the viral envelope with the endosomal membrane.[2]

Following the entry of the nucleocapsid core into the cytoplasm of the host cell, the viral RNA is transcribed into double stranded DNA (dsDNA). This process is catalyzed by the viral enzyme RT. The viral dsDNA, in association with RT and the viral enzyme integrase, is transferred to the nucleus. Subsequently the dsDNA is integrated into the chromosomal DNA of the cell by the action of the enzyme integrase. The integrated viral DNA copy is called provirus.

Using the proviral DNA as template, cellular DNA-dependent RNA polymerases synthesize viral mRNA. Some viral mRNA molecules are spliced and transported to the cytoplasm, where translation yields full-length viral precursor polyproteins. These polyproteins, combined with two copies of unspliced genomic viral RNA, are assembled into immature virus particles. By budding through the plasma membrane the immature particles acquire a bilipid layer envelope. Maturation into infectious and replication-competent virions is accomplished after release of the immature particles from the host cell; this process requires processing of the polyproteins by the viral-encoded protease. Then, a new cycle of replication may start.

As described above, during the replication cycle of retroviruses the viral DNA is integrated in the chromosomal DNA of the host cell. The result of this integration is that the retroviral DNA is now inherited into the progeny of the infected cell. When retroviruses infect germline cells (sperm or egg cells) and the viral DNA is integrated into the chromosomal DNA of these cells, the retrovirus is passed from parent to offspring of the infected host. In this case, the virus is named an endogenous retrovirus. We all carry the remnants of retroviral DNA in our chromosomes as a result of common ancestors who were infected with endogenous retroviruses.

Retroviruses that are not integrated in germline cells of their host are called exogenous retroviruses. The transmission route of exogenous retroviruses is both horizontally and vertically via blood and saliva and by sexual intercourse.

HUMAN ENDOGENOUS RETROVIRUSES

Approximately 1% of the human genome consists of sequences of human endogenous retroviruses (HERVs).[3] Full-length HERVs contain sequences that are homologous to the *gag*, *pol* and *env* genes

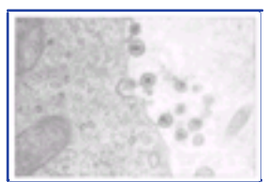

Figure 221-1 Typical electron microscopic view of retroviruses (HIV) showing an electron-dense core. *Courtesy of Dr Piet Joling.*

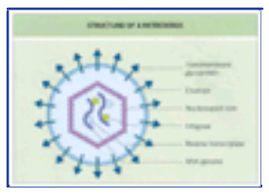

Figure 221-2 Structure of a retrovirus.

Figure 221-3 Genomic organization of three complex retroviruses. The diagram shows HIV-1, HIV-2 and HTLV. The components of the long terminal repeats are shaded. The open reading frames that encode viral proteins are depicted by unshaded boxes. *Adapted from Galasso et al.*[1]

of infectious exogenous retroviruses. The biologic properties and functions of endogenous retroviruses are still under investigation.

In general, HERVs are highly defective proviruses.[3] [4] Expression of HERV mRNA and HERV proteins has been demonstrated in several normal and pathologic tissues, and HERV retroviral particles have been detected by electron microscopy in these tissues.

Nine different HERV families have been described, some of which have as many as 50 copies in the human genome.[3] A description of the specific characteristics of the different HERV families does not fit into the scope of this chapter.

Because it was demonstrated that HERV mRNA and proteins can be expressed, it has been postulated that HERVs might be etiologically involved in human disease. In the literature, numerous pathologic conditions have been related to HERVs, such as inflammatory and degenerative diseases of the nervous system and several autoimmune diseases (systemic lupus erythematosus, rheumatoid arthritis, Sjögren's syndrome and the mixed connective tissue disease). Evidence has been found for HERV antigen expression in some of these conditions. However, no definitive proof for the putative involvement of HERVs in any of these pathologic conditions has been published. The possible role of HERVs in human disease has been reviewed,[4] but more research is required to elucidate the general role of HERVs and their specific role in human disease.

Figure 221-4 Replication cycle of retroviruses.

HUMAN FOAMY VIRUS

In 1971, a human foamy virus (HFV) was the first human exogenous retrovirus to be successfully isolated from human tissue.[5] Human foamy virus is a member of the family of Spuma retroviruses. A clear relationship between HFV and human disease has never been established, although in several publications HFV has been associated with possible involvement in the pathogenesis of disease of the thyroid gland.

Human foamy virus can be isolated from patients who have subacute thyroiditis, also known as granulomatous thyroiditis or de Quervain's thyroiditis. [6] Furthermore, evidence for an association between Graves' disease and HFV infections has been found. The presence of HFV provirus in the peripheral blood mononuclear cells (PBMCs) of 19 out of 29 patients (66%) with Graves' disease has been demonstrated using polymerase chain reaction (PCR)-based techniques.[7] In the same study the PBMCs of 23 control patients were negative for HFV provirus. In another study, it was demonstrated that antibodies directed against the *gag* antigen of HFV reacted with the thyroid glands of all seven patients who had Graves' disease. [8]

In contrast, in two other studies, no HFV provirus was found in the PBMCs of 81 patients who had Graves' disease. In conclusion, more research is needed to establish the putative relation between diseases of the thyroid gland and human Spuma virus infections.

Human foamy virus infections have also been associated with numerous other pathologic conditions, such as the chronic fatigue syndrome, hemodialysis encephalopathy, [9] multiple sclerosis, Guillain-Barré syndrome, amyotrophic lateral sclerosis[10] and Kawasaki's disease. However, again no definitive evidence has been found to support involvement of HFV in any of these diseases.

Several epidemiologic studies using an enzyme-linked immunosorbent assay (ELISA) technique to investigate the distribution of antibodies to the human Spuma virus suggest a high prevalence of the virus in patients from the African continent and low prevalence in Europe. However, in one study HFV provirus could not be detected in the PBMCs of the patients who were serum positive in the ELISA.[11] Therefore, these epidemiologic data need confirmation in additional studies.

In conclusion, more research is needed to resolve the controversy on the epidemiology and virulence of human Spuma viruses.

HUMAN T-LYMPHOCYTE LEUKEMIA VIRUSES

NATURE

Human T-lymphocyte leukemia virus-1 and HTLV-2 are complex retroviruses. In addition to a *gag*, *pol* and *env* gene, they contain four open reading frames in the pX region; these open reading frames have regulatory and accessory functions. [12] Two of these proteins, *rex* and *tax* (see Fig. 221.3), play an important role in regulation of viral replication. The *rex* protein is involved in the stabilization of viral mRNA and the transport of viral mRNA from nucleus to cytoplasm. The *rex* protein also regulates the splicing and processing of viral mRNA. The *tax* protein is a transactivator protein and is also essential for viral replication. By acting on the LTR located 5' to the viral *gag* gene, *tax* induces the transcription of viral mRNA. Apart from regulating viral replication, the *tax* protein is also believed to play a role in oncogenesis through transactivation of cellular proto-oncogenes (see below).

EPIDEMIOLOGY

Seroepidemiologic studies have shown that the highest incidence of anti-HTLV-1 antibodies is found in south-western Japan, ranging from 5 to 35% in endemic areas. Other areas with high incidence are the Caribbean islands, some regions of South and Central America, the south-west Pacific and Papua New Guinea. [2] [11] The general incidence in the USA and Europe is low (0.05%), although an increasing incidence has been reported among homosexuals and intravenous drug users.

The epidemiology of HTLV-2 has been less well studied. It is difficult to distinguish serologically between HTLV-1 and HTLV-2 because of antigenic cross-reactivity. Therefore, HTLV-2 incidence has been studied with the help of a technique based on a PCR using primers specific for the HTLV-2 proviral genome. A high incidence of HTLV-2 has been found among native Americans in Panama and New Mexico and among intravenous drug users in the USA and Italy.[13] [14] [15] [16]

PATHOGENESIS

It is believed that HTLV-1 is transmitted by infected lymphocytes and not as free virus in cell-free body fluids. Three transmission routes for HTLV-1 have been described.

- first, transmission of HTLV-infected lymphocytes from mother to child is a major route; it can occur via the placenta, during birth, or after birth through the mother's milk;
- second, evidence has also been found for transmission from male to female during sexual intercourse — no evidence has been found for sexual transmission of HTLV-1 in the other direction, from female to male; and
- finally, blood transfusions are an efficient transmission route of HTLV-1. [2] [11]

Human T-lymphocyte leukemia virus-1 is a lymphotropic virus that preferentially infects $CD4^+$ T cells. Usually, the leukemic cells in adult T-lymphocyte leukemia (ATL) have the following phenotype: $CD2^+$, $CD3^+$, $CD5^+$, $CD7^-$, $CD4^+$ and $CD8^-$; they also express the activation surface markers CD38 (the interleukin (IL)-2 receptor), CD30 and major histocompatibility complex class II.[17] [18] The cellular receptor mediating the HTLV-1 infection of lymphocytes has not been identified.

The molecular mechanisms by which HTLV-1 is able to induce cell transformation have not been unraveled. Human T-lymphocyte leukemia virus does not contain a typical oncogene. Several other hypothetic mechanisms of HTLV-induced oncogenesis have been formulated.

It has been hypothesized that in HTLV-1-infected T cells the *tax* protein may transactivate cellular growth factor genes such as the IL-2 gene or the IL-2 receptor gene, thus promoting unbridled division of T cells. Human T-lymphocyte leukemia virus-1-infected, immortalized cells have been demonstrated to express high levels of the IL-2 receptor. Normally, in an uninfected person, most of the T cells are in a quiescent state, with low levels of IL-2 production and IL-2 receptor expression, and they only become activated in cases of clone-specific stimulation caused by the presence of an antigen.

Another mechanism of cell transformation that has been postulated is transactivation of proto-oncogenes by the *tax* protein of HTLV-1, such as c-*fos* and the platelet-derived growth factor gene.

Furthermore, in patients who have ATL, several chromosomal aberrations have been described. It is not clear whether these chromosome aberrations are induced by insertion of the HTLV proviral DNA.[2] [11] [19]

However, these hypotheses do not explain why it takes an average incubation time of 20–30 years to develop ATL or why only a small number of HTLV-1-infected people develop clinical manifestations of ATL. More research is required to answer these questions.

DIAGNOSTIC MICROBIOLOGY

The definite diagnosis of ATL is made by demonstrating the presence of HTLV-1 proviral DNA in the DNA of tumor cells using a PCR-based technique.

CLINICAL FEATURES

Human T-lymphocyte leukemia virus-1

Adult T-lymphocyte leukemia

Human T-lymphocyte leukemia virus-1 is considered to be the etiologic agent of ATL, a disease first recognized as a nosologic entity in 1977.[20] Several pieces of evidence established the causal relationship between HTLV-1 and ATL. First, ATL has an identical geographic distribution to that of HTLV-1, having a high incidence in south-western Japan, as was shown in seroepidemiologic studies. [21] Second, all ATL tumor cells contain one or more copies of the HTLV-1 provirus in their genomic DNA. Third, in-vitro infection of human T cells with HTLV-1 results in T-cell immortalization. Finally, HTLV-1 has been demonstrated to be oncogenic in animals.[19]

The development of ATL has been divided into four stages:

- the asymptomatic carrier state,
- the preleukemic state,
- smoldering (or chronic ATL), and
- acute ATL.

Asymptomatic carrier state

Patients in the asymptomatic carrier state are infected with HTLV-1 without any clinical manifestation or abnormal laboratory findings. The majority of HTLV-1-infected people are asymptomatic carriers. The lifetime chance of an infected person developing ATL is about 1%.[22] The first clinical manifestations of ATL generally occur 20–30 years after infection with HTLV-1. The median age of ATL onset is 52.7 years.[23]

Preleukemic state

The preleukemic state is defined by one or more of:

- leukocytosis,
- morphologic abnormalities of the lymphocytes (Fig. 221.5), or
- detection of HTLV-1 provirus by PCR.

Smoldering adult T-lymphocyte leukemia

Smoldering or chronic ATL is characterized by skin lesions and low levels (<5%) of leukemic cells. Patients in this stage may progress towards the acute stage of ATL. The median survival time in chronic ATL is 24 months.

Acute adult T-lymphocyte leukemia

Acute ATL is characterized by high levels (>5%) of leukemic cells, skin lesions, general lymphadenopathy, hepatosplenomegaly and hypercalcemia and immunodeficiencies. Hypercalcemia correlates with poor prognosis and is a result of osteoclast proliferation mediated by IL-1a and a parathyroid-mimicking hormone, both of which are produced by the HTLV-1-infected cells. The median survival of patients with acute ATL is approximately 6 months.

Tropical spastic paresis

Infections with HTLV-1 have also been associated with a neurologic syndrome called tropical spastic paresis, also known as HTLV-1-associated myelopathy (HAM). This disorder is characterized by a

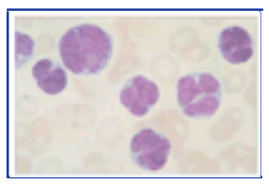

Figure 221-5 Typical 'clover leaf' appearance of nuclei of HTLV-1 induced adult T cell leukemic cells. *Courtesy of Steven M Opal.*

slowly progressive symmetric myelopathy combined with high titers of antibodies to HTLV-1 in plasma and cerebrospinal fluid (CSF). The myelopathy primarily affects the pyramidal tract. The mechanisms by which HTLV-1 infection causes HAM is unclear, but patients show signs of an activated immune system with high levels of immunoglobulins and increased numbers of activated T cells in the blood and CSF, which suggests an immunologic (possibly an autoimmunologic) pathogenesis. There have been reports that patients who have HAM respond to corticosteroids but this is always short-lived and unfortunately no form of therapy has been shown to have lasting benefit.[2] [11]

Ophthalmologic complications

Human T-lymphocyte leukemia virus-1 infections have also been associated with ophthalmologic complications, which are frequently observed in patients suffering from ATL or HAM. These include a wide range of neoplastic, infectious and noninfectious vascular or inflammatory lesions.[24] However, ocular lesions have also been found in patients who are positive for HTLV-1 antibodies but who have no other clinical manifestation of HTLV-1 infection. In a recent study of 93 patients who had HTLV-1 infection (23 asymptomatic and 70 patients who had HAM tropical spastic paresis), 48.4% of the patients were diagnosed with keratoconjunctivitis and 16.1% with uveitis.[25]

Arthropathy

Finally, HTLV-1 infections have been associated with chronic inflammatory arthropathy, both in the presence and in the absence of clinical ATL. Polyarthritis may be the presenting manifestation of HTLV-I-associated ATL. It has been demonstrated that the synovial fluid of patients who have HTLV-1-associated arthritis contains high titers of anti-HTLV-1 antibodies and atypical lymphocytes.[2] [11]

Human T-lymphocyte leukemia virus-2

Human T-lymphocyte leukemia virus-2 infections have been associated with T-cell malignancies, predominantly hairy T-lymphocytic leukemia and chronic lymphatic leukemia. Neurologic complications similar to those seen in HAM or tropical spastic paresis have also been described.

MANAGEMENT

The therapy for ATL usually consists of combined antineoplastic chemotherapy. However, antineoplastic therapies have proved to have only a limited ability to improve the prognosis of ATL. In most patients, resistance of the leukemic cells to the drugs is believed to be the prominent reason for failure to induce a complete remission. However, two promising novel strategies to improve the prognosis of ATL are under investigation. In one study using a combination of zidovudine and interferon-a, a prolonged survival in previously untreated patients was reported. [26] The other a therapeutic approach is directed against the IL-2 receptor on the leukemic cells. Lymphocytes in ATL express high levels of the IL-2 receptor, in contrast to normal resting, non-HTLV-1-infected lymphocytes. A favorable response has been reported in patients treated with antibodies against the IL-2 receptor that are armed with toxins or emitting radionuclides.[27]

HUMAN IMMUNODEFICIENCY VIRUSES

NATURE

The human immunodeficiency viruses HIV-1 and HIV-2 are members of the family of Lentiviruses. Both HIV-1 and HIV-2 are the causative agents of AIDS. For detailed information regarding the clinical manifestations of HIV infection and AIDS (see Chapter 122 , Chapter 124 , Chapter 125 , Chapter 126 , Chapter 127 , Chapter 128 , Chapter 129 , Chapter 130 , Chapter 131 , Chapter 132 , Chapter 133), antiretroviral therapy (see Chapter 139 and Chapter 204) and

Figure 221-6 HIV-1 virion.

therapy evaluation and vaccine strategies (see Chapter 118). This chapter describes viral structure, pathogenesis and epidemiology of HIV.

Virion structure

The electron microscopic view of human immunodeficiency retroviruses shows an electron-dense cone-shaped core. The viral p24 capsid protein functions as a shell for the condensed core, which contains the two identical genomic RNA strands in close association with RT (Fig. 221.6). The viral genome is approximately 9200 bases long and contains nine genes (see Fig. 221.3). Previously it was believed that the p6 protein was also located in the viral core, but this protein does not seem to co-purify with the core structure, suggesting another localization.[28] The viral protein Vpr (in HIV-1) and Vpx (in HIV-2) is also found in the virion and is probably located outside the core.[29] The Vif protein may also be present in the viral particle in close association with the viral core.[30] More research is required to increase our knowledge on the structure of the viral particle and to determine the exact localization of p6, Vpr/Vpx and Vif. The inner part of the viral membrane is covered with a myristylated p17 core protein, which provides the matrix for the viral structure. Glycoprotein spikes project from the virion surface and are anchored into an envelope that consists of a phospholipid bilayer derived from the host cell membrane. The spikes contain two viral glycoproteins (gp), gp120 and gp41. The gp41 acts as a transmembrane protein and its central portion binds to the external surface gp120. In addition to gp41 and gp 120, the viral envelope can contain various proteins derived from the host cell.

Replication cycle

Infection starts with the binding of gp120 glycoprotein to the cellular surface CD4 molecule, which acts as a high-affinity receptor. Recently, two secondary or co-receptors have been identified: CXCR4 (also known as fusin) and CCR5.[31] These co-receptors are members of a cellular transmembrane chemokine receptor family. All HIV strains tested to date use CXCR4 or CCR5, or both, as a co-receptor. However, several other co-receptors for HIV have also been identified, one of which is encoded by the cytomegalovirus. Co-receptor usage determines the cell tropism of the HIV strain. The CCR5 co-receptor is used by HIV strains that in vitro do not cause cell fusion (syncytia) in T-cell lines (non-syncitium-inducing (NSI) strains). Syncytium-inducing (SI) HIV variants use both co-receptors CXCR4 and CCR5. In general, NSI variants are found throughout the complete course of HIV infection, whereas SI variants emerge

only in a later stage of HIV infection. The presence of SI variants in a patient is associated with a more rapid CD4 decline and faster disease progression (see below).

A route of infection independent of the CD4 molecule may also be possible. A variety of host cells lacking the CD4 receptor have been successfully infected in vitro, although infection of CD4 cells seems to be a very inefficient process. The in-vivo significance of the CD4-independent route of entry is yet to be determined.

After binding, HIV enters the cell through fusion of the viral and host cell membranes. Subsequently, the viral core, containing the genome, is released in the cytoplasm of the cell; this involves a process of internalization and uncoating.

During the replication cycle, the first synthesized transcription products are the viral regulatory proteins *nef*, *tat* and *rev* (for a review see Greene *et al.*[32]). The *tat* protein will bind to the transactive response element region on the proviral DNA and, as a consequence, high-level expression of all viral genes occurs. The *nef* protein is required for high-level viral replication in vivo (see Pathogenesis, below), and it decreases CD4 on the cell membrane. The *nef* protein may enhance the efficiency of reverse transcription, but its precise functions have not been completely elucidated.

Through the action of *rev* a switch may occur toward the synthesis of late regulatory and viral structural proteins. The *rev* protein facilitates the nuclear transport of unspliced and incompletely spliced RNA transcripts that contain the *rev*-responsive element, located in the *env* gene. In addition it promotes translation of messages containing the *rev*-responsive element. It remains unclear to what extent the relative amounts of each of these regulatory proteins and their interaction with cellular factors can determine whether the infection of a cell results in a productive cycle or merely a viral latent state.

The *gag* and the *pol* open reading frames (ORFs) overlap. The *pol* ORF is positioned in the -1 frame relative to the *gag* ORF. In the unspliced, full-length mRNA, both reading frames are present. Translation starts at the beginning of the *gag* ORF and continues in most cases until the end of the ORF, and a 55kDa *gag* precursor protein (p55), containing p17, p24, p7, p2, p1 and p6, is made. During translation of full-length mRNA, approximately 5–10% of the ribosomes slip back one nucleotide (frame shift) and gain access to the *pol* ORF, and translation continues. A partial *gag* precursor protein is fused to the *pol* polyprotein, resulting in a *gag-pol* polyprotein. The *pol* gene encodes for three proteins: protease, RT and integrase. Cleavage of the *gag-pol* protein generates protease, RT and integrase. The 99-amino acid protease is coded for at the 5' end of the *pol* gene. HIV protease is active only as homodimer, which is generated by an autolytic process. It is possible that aggregation of two *gag-pol* proteins is required to generate the active form, thereby limiting activation to the budding site. Both *gag* and *gag-pol* polyproteins are post-translationally modified by a covalent attachment of a lipophilic myristyl group onto their aminoterminal glycine by a host cell-derived myristyl transferase. Myristylation may be required for intracellular transport to the cell membrane because, in the absence of myristylation, no infectious particles are produced.

The *gag* precursor protein is cleaved by viral protease into four structural proteins (p17, p24, p7 and p6) and two smaller proteins (p2 and p1). The protein p2 may be important for proper assembly of the virions. The *gag* precursor protein may also play a role in the packaging of viral RNA into the virus particle, specifically through the action of the nucleic acid binding protein p7. This protein binds to a sequence at the 5' end of the viral genome, possibly through the interaction of so-called cystine-histidine motifs. The p6 protein has been shown to be rich in proline, and through binding to p6, Vpr is incorporated in the viral particle. Viruses with a mutation in p6 are not released from the cell surface.

The accessory genes *vif*, *vpr* and *vpu/vpx* influence the viral assembly and budding process, and alterations in these genes leads to a decrease in infectivity. These proteins may be more important for replication in macrophages and primary lymphocytes than for T-cell lines. The protein Vpr can cause cell cycle arrest in the G2 phase, and it is as yet unclear whether this phenomena plays a role in viral replication. The protein Vpu interacts with CD4 and may cause CD4 degradation.[2] [11] The Vif protein is considered to enhance infectivity and the underlying mechanism is still under investigation.[32]

EPIDEMIOLOGY OF HIV AND VIRAL SUBTYPES

Twenty-six nonhuman primates in Africa have been reported to be infected with the retrovirus simian immunodeficiency virus (SIV). Two of these viruses are the cause of AIDS in humans. It has been estimated that they have been transmitted to humans on at least seven different occasions.[33]

The global HIV-1 epidemic is seen as a composite of infections from at least nine genetically distinct subtypes or clades of virus, designated A to H.[34] Together they form the M group.[35] These subtypes can be distinguished on the basis of sequence information of the *env* gene (30% difference) and *gag* gene (15% difference). Two

isolates that are highly divergent from group M have been fully sequenced. The results show that viruses from the new group O are almost as close to HIV-2 as to HIV-1. The distribution of certain HIV-1 subtypes is still geographically limited, but geographic dispersion will contribute to the growing pandemic (see Chapter 115). The distribution of subtypes within countries as well as throughout the world shows that there is no evidence for host specificity for certain subtypes.[35] Dual infection with two subtypes and hybrids between two subtypes have been described in infected individuals.

Five distinct subgroups have been identified for HIV-2, and in analogy with HIV-1 these were designated A to E. The observed viral variation has clear implications for vaccine development and has also implications for development of drugs or treatment of patients. The non-nucleoside RT inhibitors (NNRTIs) inhibit RT activity through binding various amino acids of RT, the most important amino acid being the tyrosine residue at codon 181 for HIV-1 RT. Selection of drug-resistant HIV-1 isolates both in vitro and in vivo results in a substitution at codon 181 of a cysteine. The cysteine substitution gives a considerable increase in the 50% inhibitory concentration for all NNRTIs. Sequence analysis of several HIV-2 RT genes has shown that at codon 181 the cysteine is normally present. The presence of the cysteine variant makes HIV-2 viruses naturally resistant to the NNRTIs.

The *env*-based classification of widely divergent HIV-1 strains into sequence subtypes is also supported by nucleotide sequence analysis of the *gag* genes. The distinction between SI and NSI viruses, conferred by gp120 described in clade B, is also present among other HIV-1 subtypes. Detailed information is available on the prevalence of the different subtypes for certain areas in the world. Information on the prevalence of different clades in a region may give interesting information on the spread of the infection and the possible transmission routes. For instance, in Thailand it has been shown that type A is mainly spreading through sexual intercourse, whereas type B is transmitted among intravenous drug users. Monitoring the prevalence of different clades around the world and searching for possible new clades is important for the use and development of diagnostic procedures. For instance, some screening assays for HIV antibodies have been shown to be relatively insensitive for clade O viruses. The use of diagnostic PCR procedures, especially in children born to mothers who have HIV infection, may be complicated by sequence variation in the region where the primers have to anneal to their substrate. The quantitative molecular assays may also vary in their

sensitivity for different clades. From the perspective of vaccine development, it will also be extremely important to continue to generate information on the worldwide prevalence and geographic distribution of the various clades (see also Chapter 115).[36]

PATHOGENICITY

Transmission

The three major routes of transmission of HIV are by sexual contact or blood or blood products or vertically through maternal-fetal transmission. The first step in infection is binding of the viral particles to submucosal dendritic cells (H). These cells which normally process antigens and present them to immune cells, express a protein termed DC-SIGN. The viral gp120 binds to DC-SIGN with high affinity; subsequently the viral particles are internalized and presented again at the cell surface after the dendritic cells have migrated to the regional lymph tissues and present viral particles to the T cells (see Chapter 120).

It is very likely that the amount of HIV in the inoculating material is the most important factor determining the risk of transmission. The amount of virus is, at least in the blood of the donor, determined by disease stage and antiretroviral therapy. In contrast, data on the relation between the amount of HIV in semen and disease stage is contradictory.[37] Modeling of the epidemic supports the notion that viral load may be the major factor for determining the rate of infection. It has been demonstrated that people who have a primary infection are an important source of transmission.[38] The amount of virus in the blood of people who have a primary infection is generally very high (see below). A prospective study showed that the transmission rate within heterosexual couples tended to increase when the index case was in a more advanced stage of disease, again pointing at an inoculum effect.[39]

Two recent studies showed that the risk of heterosexual transmission is dependent on the HIV RNA concentration in the peripheral blood of the positive partner.[40] [41] In one cohort no cases of transmission were noted if the seropositive partners had HIV RNA concentrations under 1500 copies/ml. In this cohort of 415 couples there was a clear dose-response relation of increased transmission with increasing viral load.[40]

The rate of transmission may also be determined by biologic properties of the virus. Transmission of HIV-2 seems to be considerably lower than of HIV-1 in western Africa. In addition, infection with HIV-2 seems to protect against infection with HIV-1. In a prospective study among commercial female sex workers in Senegal, the HIV-1 infection rate was lower in those workers who were already infected with HIV-2.[42] [43]

Other protective host factors may also play a role, such as the integrity of mucocutaneous membranes of the urogenital tract. Among heterosexual couples the risk of transmission increases when the negative partner had a genital infection.[39] [40]

It has been demonstrated that protection against transmission is also offered by a 32bp deletion in the *CCR5* gene, encoding a cellular co-receptor for HIV (see Replication cycle, above). The CCR5 allele with the 32bp deletion (CCR5 32) is common in the Caucasian population with a frequency of 8080 per 100,000 individuals (13.3% heterozygous, 1.4% homozygous). The CCR5 32 is not found among Asians and Africans. In 1252 homosexual males of the Multicenter AIDS Cohort Study from Chicago none of the HIV-infected participants was homozygous for the CCR5 32 allele, whereas 3.6% of the at-risk but uninfected Caucasian participants were found to be homozygous.[44] This suggests that homozygosity for the CCR5 32 allele is an important protection factor. Heterozygosity has not been found to protect against infection, although it is associated with a delayed disease progression (see below).[44]

Finally, a study among a group of 25 seronegative subjects who had a history of multiple exposures to HIV-1 showed that the $CD4^+$ lymphocytes in a subgroup of patients had a relative resistance to infection with clinical isolates in vitro.[45] These $CD4^+$ lymphocytes produced more chemokines — RANTES, macrophage inflammatory protein (MIP)-1a, MIP-1ß — than sensitive $CD4^+$ lymphocytes. Addition of recombinant chemokines to sensitive $CD4^+$ lymphocytes increased their resistance to infection. These chemokines are the natural ligands of chemokine receptors CCR5 and CXCR4, which have been identified as HIV co-receptors. It has been hypothesized that chemokines compete with HIV for the receptor binding sites, thus inhibiting the efficiency of HIV infection.

Studies addressing transmission from mother to baby have also shown that the risk of vertical transmission increases with a higher viral load in the mother at the time of delivery (as measured as by HIV p24 antigen, HIV-1 RNA, proviral DNA or PBMC viral titer) and with lower $CD4^+$ lymphocyte counts. [46] The current opinion is that the majority of infections of the child occur late during pregnancy and most commonly during delivery, because elective cesarean section lowers the transmission rate by approximately 50%. [47] This notion is supported by the outcome of a multicenter, randomized, placebo-controlled trial of the efficacy and safety of zidovudine in reducing the risk of vertical transmission.[48] A protective effect of treatment was seen despite the fact that the treated women received the study drug only for a median of 11 weeks before giving birth. Moreover, the risk of transmission increases when the fetal membranes rupture more than 4 hours before delivery.[49] [50] This also suggests that most transmissions occur late in pregnancy or during delivery (see Chapter 134).

Incubation period and viral replication

Initially, it was believed that during the asymptomatic or clinically latent phase the amount of viral replication would be very low and the amount of virus present in the body minimal. It has been shown over the past few years that this concept was seriously flawed. Prospective studies show that in most people during the asymptomatic phase of the infection a gradual decline of the $CD4^+$ lymphocytes is paralleled by a gradual rise in viral HIV-1 RNA in the peripheral blood. Moreover, it has been shown that in the asymptomatic phase, virus replicates in the lymphoid tissue in those people who lack cell-free virus in their peripheral blood. Analysis of the viral burden in the peripheral blood compared with the burden in lymphoid tissues shows that the viral load in lymphoid tissues is 1 log higher than in blood. In-situ hybridization studies and electron microscopic analyses have shown that the lymph nodes from asymptomatic carriers can contain high quantities of HIV.[51] Viral particles covered with antibody and complement are trapped by the follicular dendritic cells in the germinal center of the lymph nodes. Thus, the incubation period is characterized by ongoing viral replication.

Viral dynamics and $CD4^+$ lymphocyte depletion

The effects of therapy with two protease inhibitors (ritonavir (10 patients) and indinavir (8 patients)) and a NNRTI (nevirapine (4 patients)) were investigated.[52] In addition to measuring the response of HIV RNA and $CD4^+$ lymphocytes, this study also measured the appearance of drug-resistant mutations in both plasma and PBMCs. The viral clearance rate was calculated (using three methods) and found to range between 1.8 (±0.9) days and 3.0 (±1.7) days. There were no differences observed in viral clearance rates with the three different drugs. In both studies the clearance rate constants were independent of the initial viral loads and the $CD4^+$ lymphocyte counts, suggesting that the viral clearance rate constant is independent of the stage of HIV infection. Monitoring the appearance of drug-resistant mutations over time led to an estimated

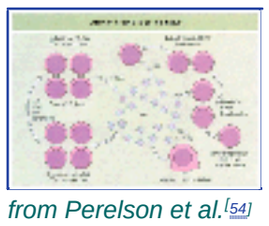

Figure 221-7 Dynamics of HIV-1 infection in vivo. Shown in the center is the cell-free virion population that is sampled when the viral load in plasma is measured. *Adapted from Perelson et al.*[54]

doubling time of approximately 2 days, in accordance with the estimated half-life for HIV in plasma.

In agreement with previous results, an estimate of 2×10^9 $CD4^+$ lymphocytes (about 5% of the total $CD4^+$ lymphocyte population) has been calculated to be produced and destroyed daily. In other studies data have been generated with zidovudine and lamivudine that support the observations described above.[53]

All the data together show that HIV-1 infection is a highly dynamic process in which billions of viruses are being produced (Fig. 221.7). The vast majority of the high number of circulating viruses is derived from continuous rounds of new infections that take place on a daily basis. [54] The contribution of long-living, chronically virus-producing cells is very small. In a review, these insights were placed in the context of genetic variation, pathogenesis and therapy.[55] Our current understanding of the kinetics of HIV infection has changed our views on antiretroviral therapy.

Relationship of viral load and $CD4^+$ lymphocyte levels to disease progression

Several approaches have been developed to obtain information on the amount of virus present in a person with HIV infection and to relate the amount of virus to the duration of the incubation period, rate of disease progression and survival. Both the amount of provirus and the amount of virus in the peripheral blood have been evaluated using quantitative culture techniques and quantitative molecular approaches.

The first quantification of virus was carried out by determination of viral capsid antigen in serum using the HIV p24 or antigen assays. Later, quantitative virus culture assays were developed to measure the amount of culturable virus in serum or plasma.[56] [57] In the first studies, the mean titers ranged from 30 tissue culture infective doses (TCID) for asymptomatic infection to 3200 TCID in patients who have AIDS, but a later study reported higher titers in a small number of patients.[58] Several cross-sectional studies showed a relationship between a more progressed disease stage, lower $CD4^+$ lymphocyte counts and higher plasma titers. Antiretroviral therapy lowers the plasma titers and cellular viral titers.[59] [60] The costs and the need for fast transport of plasma to the laboratory have prevented widespread use of quantitative cultures for estimating the risk of fast disease progression as well as for therapy evaluation. [61]

The amount of provirus has been measured by two methods:

- quantification of the viral titer in patient PBMCs; and
- quantification of the amount of proviral DNA using various PCR-based techniques.

A correlation has been found between a high frequency of positive cells or an increase in the number of positive cells and disease progression in all studies that have addressed the relationship between proviral DNA levels and disease progression, either by comparing patients in different disease stages cross-sectionally[62] [63] [64] [65] [66] [67] [68] or by following patients over time who progressed clinically.[64] [69] [70] [71] The increase observed over time was relatively small (range of 1–2 log). In one longitudinal study of seroconverters, a relationship was found between a high proviral load from the moment of seroconversion and a rapid progression to disease. [70] During the incubation time, the increase in proviral load was relatively small, indicating that the set point obtained around seroconversion determined the subsequent outcome. Similar observations have been made with HIV RNA levels in seroconverters.[72] [73] Two studies were carried out to analyze the amount of proviral DNA in patients infected with HIV-2.[74] [75] The numbers obtained were not significantly different from those in patients infected with HIV-1.

In a recent study the amount of HIV viral DNA was compared between HIV-specific memory cells and other memory cells.[76] It was shown that the HIV-specific memory $CD4^+$ cells contained significantly more HIV viral DNA at all stages of disease, indicating indeed that HIV-specific $CD4^+$ cells are preferentially infected by HIV in vivo.

Several studies have determined the amount and pattern of viral mRNA expression and have correlated these with disease progression and decline in $CD4^+$ -lymphocyte counts.[77] The outcomes of all these studies are remarkably similar. In all studies, independent of the disease stage, viral transcription can be detected. Furthermore, these studies indicate that in patients who show immunologic or clinical deterioration, a shift takes place from a predominantly spliced mRNA pattern to a predominantly unspliced pattern. It has been suggested that this may be caused by post-translational replication block, a model suggesting true in-vivo latency. However, the observed differences in the relative abundance of the different mRNA species may also be caused by de-novo viral replication.[77] Until this type of study is performed on single cells, it will be difficult to find out to what

---

extent latency in cells on the basis of post-transcriptional block is a frequent event. The authors of some of these studies advocate the use of quantitative mRNA measurements and pattern analysis as tools for clinical management. It is very unlikely, however, that this type of assay will show an advantage over the well-established methods for quantifying the amount of genomic RNA copies in serum or plasma.

The development of quantitative assays for the determination of viral RNA in serum has revolutionized the field of antiretroviral therapy and our insights into the pathogenesis of disease. The first cross-sectional studies showed that HIV-1 RNA could be detected in all stages of disease and that levels as high as 10^7 copies/ml could be measured.[78] [79] [80] In general, there is a significant correlation between HIV RNA levels and the other quantitative parameters for cell-free virus (extracellular virions), such as HIV p24 antigen, although these parameters are often undetectable.[81] [82] Furthermore, a strong correlation has been found between cell-free HIV RNA levels and cellular RNA levels in PBMCs.[72] The sensitivity and dynamic range of the HIV RNA measurements is much greater, however, and therefore more information has been obtained on the significance of viral load for pathogenesis and therapy evaluation by using the HIV RNA measurements.

Currently, several longitudinal studies on the relationship between HIV RNA load patterns over time and disease progression or $CD4^+$ -lymphocyte decline on four different cohorts of seroconvertors have been performed.[72] [73] [83] [84] [85] These studies showed that a plateau phase or set point is obtained a couple of months after acute HIV infection. This plateau phase is stable during the course of years. A clear variation (2–3 log) was observed, however, in the height of the set point, and this value, obtained some months after seroconversion, was directly related to the ultimate clinical outcome.

With the introduction of the highly active antiretroviral therapy it has become possible to inhibit viral replication completely in some treated individuals. This, however, does not lead to eradication of the infection because pretherapy infected cells not undergoing a full viral replicative cycle can persist. Currently it is not clear how long these latent reservoirs may persist, but most studies estimate that these reservoirs could persist for life.[86]

Indeed, even patients who have supressed their viral replication for as long as 5 years experience a rebound in viral replication if they interrupt their therapy.

This indicates that for eradication of HIV infection alternative strategies need to be developed. The challenge will be to find a way to eliminate the provirus from the T-memory cells, which are currently assumed to represent reservoir cells with the longest survival.

Factors that determine the duration of the incubation period

Presently, it is not clear why the incubation period can greatly differ between individuals and why the decline in $CD4^+$ lymphocyte counts is typically a gradual process (40–80 cells/mm^3 /year).[87] It is likely, however, that multiple factors are involved in determining the time to disease progression. Some factors have been identified. These factors can be divided into viral and immunologic (host) factors (see also Chapter 120).

To get more insight into the factors influencing the incubation period and pathogenesis of HIV infections, studies have been performed on patients with HIV infection who have not shown clinical progression and who have moderate immunologic deterioration, or none at all during long-term follow up (generally up to 10–15 years after

infection).[88] [89] These so-called long-term survivors or long-term nonprogressors seem to have some characteristics in common. The viral burden and proviral burden in the peripheral blood was found to be several orders of magnitude lower than the levels normally found in subjects who have progressive disease.[88] [89] The lymph nodes showed significantly less activation (germinal center formation) than the lymph nodes of control subjects with progressive disease, and furthermore the germinal centers did not show signs of involution and lymphocyte depletion.[89] Viruses could nevertheless be cultured from the mononuclear cells in the lymph nodes, indicating that HIV in these individuals was replication competent.[89]

Three viral factors have been found that seem to play a role in the duration of the incubation time. First, deletions in the *nef* regulatory gene causing a decrease in virulence have been shown to be present in a group of six long-term survivors, all of whom were intravenously infected by blood products from the same donor. However, in another study it was demonstrated that 91.1% of the *nef* genes of 10 long-term nonprogressors had no such deletions. The events described in all cases in which a *nef* deletion was observed are remarkably similar to the events described in rhesus monkeys inoculated with a derivative of the pathogenic SIV containing a 183bp deletion in *nef*. These animals became persistently infected but had low viral burden and normal $CD4^+$ -lymphocyte counts and did not show any sign of disease progression.[90]

Recently, a detailed analysis of a long-term survivor was published. [91] This patient, also infected via a blood transfusion, harbored viruses with only a low frequency of defective *nef* genes, but in contrast the viral population contained inactivating mutations in several other accessory genes (*vif, vpr, vpu, tat* and *rev*).

Thus, some studies show that, in at least in some long-term nonprogressors, specific virologic changes in their HIV cause a decrease in virulence, which may account for their sustained incubation period.

The second viral property that contributes to the rate of disease progression comes from studies that compared the rate of disease development between patients infected with HIV-1 and those infected with HIV-2.[45] [92] These studies suggest that people infected with HIV-2 have a reduced rate of developing a $CD4^+$ lymphocyte count below 400 cells/mm^3 and reduced disease progression compared with people infected with HIV-1. The limitation of this type of data is that the differences may be caused by differences in duration of infection between the HIV-1 and HIV-2 groups. The mechanism responsible for the reduced virulence of HIV-2 needs further research.

A third virologic factor that contributes to the duration of the incubation period is the capacity of HIV to induce syncytia in a MT-2 cell line ex vivo. Prospective studies in the Amsterdam cohort have shown that untreated subjects who switch in viral phenotype from NSI to SI isolates develop a more rapid decline in $CD4^+$ -lymphocyte counts and show a faster progression to AIDS than those who have persisting NSI phenotypic isolates.[93] The SI isolates appeared 2 years before the progression to AIDS.

Several host factors seem to contribute to the duration of the incubation time. The immune response to HIV plays a crucial role in controlling HIV replication in long-term nonprogressors. The cytotoxic T-lymphocyte activity to HIV antigens is believed to protect against disease progression. Recently, several studies have shown that heterozygosity for a deletion of 32bp in the gene encoding the CCR5 HIV co-receptor predicts delayed disease progression. In one study it was shown that 30 months after seroconversion CCR5 32 heterozygotes had a 1.5-fold slower decline in $CD4^+$ T-cell count and a 2.6-fold lower plasma viral load than CCR5 wild-type homozygotes. The predictive value of the CCR5 genotype for disease progression was independent of high HIV RNA plasma load, low $CD4^+$ T-cell counts, low T-cell functionality and the presence of SI variants of HIV.[94]

CLINICAL FEATURES

The hallmark of HIV infection is a selective reduction in the number of $CD4^+$ T cells, resulting in a progressive loss of cellular immunity

and development of AIDS, which is characterized by opportunistic infections and the development of opportunistic malignancies. In addition, several organs may be directly affected by HIV, including the gastrointestinal tract, bone marrow and the central nervous system, resulting in wasting, AIDS dementia, neuropathy and thrombocytopenia. The incubation period of primary HIV infection is approximately 4 weeks. Primary HIV infection is symptomatic in up to 70% cases and is associated with fever, arthralgia, adenopathy, myalgia, truncal (and facial) maculopapular rash and neurologic symptoms, including neuritis, myelopathy and aseptic meningoencephalitis (see Chapter 122). Primary HIV infection is followed by an asymptomatic carrier state of variable duration (median 10 years), after which most patients develop AIDS. The asymptomatic phase of HIV infection is frequently characterized by a persistent generalized lymphadenopathy. On histologic examination, lymph nodes of asymptomatic HIV carriers who have persistent generalized lymphadenopathy show follicular hyperplasia with endothelial cell proliferation, and HIV is found in large amounts on the follicular dendritic cells. Clinical progression toward AIDS is reflected by a rapid decrease in $CD4^+$ lymphocytes and deterioration of the lymph node architecture, from follicular hyperplasia to follicular involution and follicular depletion. The many symptoms and complications of AIDS are beyond the scope of this chapter. For a detailed discussion of the clinical manifestations during late-stage HIV disease, see Chapter 124 Chapter 125 , Chapter 126 , Chapter 127 , Chapter 128 , Chapter 129 , Chapter 130 , Chapter 131 , Chapter 132 , Chapter 133 .

MANAGEMENT

In a majority of patients with HIV infection, highly active antiretroviral therapy consisting of two RT inhibitors and one protease inhibitor results in profound and sustained suppression of HIV replication, increasing $CD4^+$ lymphocyte counts and preventing AIDS-defining illnesses and death. Reduction of plasma HIV RNA concentrations below the level of detection can be achieved for up to 2 years. For a review of the general principles and details of antiretroviral therapy, see Chapter 138 , Chapter 139 , and Chapter 204 .

Chapter 222 - Zoonotic Viruses

David Brown
Graham Lloyd

INTRODUCTION

Zoonotic infections are infections of animals that can naturally infect humans. More than 400 viruses cause clinically important zoonoses and infection is acquired by several different routes. Humans can be infected directly from the host animal species, for example following the bite of a rabies-infected animal, or through inhalation of rodent urine (hantavirus) or by direct contact with rodent urine (Lassa fever). However, the majority of zoonotic infections are spread by arthropod vectors and are classified as arboviruses.

The geographic distribution of the infections described in this chapter depends on many factors and changes over time. Recent examples include West Nile fever, which has recently spread to and become established across the USA. Nipah and hendra viruses, newly recognized causes of encephalitis in humans, have been identified in Australia, Malaysia, Singapore and India. Congo-Crimean hemorrhagic fever has re-emerged in Kosovo, following social dislocation resulting from conflict. Other important zoonotic infections include DNA viruses, such as poxviruses and herpes B virus, and RNA viruses, such as rabies. A number of rare occupational viral zoonoses have been described, including foot and mouth disease, vesicular stomatitis virus and swine vesicular disease.[1] [2]

ARBOVIRUSES

Over 400 viruses that cause human disease are classified as arboviruses. These are distributed worldwide because of their close association with lower vertebrates and insects and their wide host range. Most arbovirus infections are caused by RNA viruses and include members of the togaviruses, bunyaviruses and reoviruses.

Many arboviruses that infect humans cause non-specific symptoms such as acute fever. Three broad clinical patterns are recognized with arbovirus infection:

- fever, rash and arthritis or retinitis;
- encephalitis; and
- viral hemorrhagic fevers (VHFs).

Several comprehensive reviews are available.[3] [4]

The key features of the clinically important arboviruses transmitted to humans by hematophagous arthropod vectors, such as mosquitoes, ticks and *Phlebotomus* flies (sandfly), are given in Figure 222.1 .

Most arboviruses are maintained in complex life cycles that involve nonhuman vertebrate hosts with or without a primary vector. Mosquitoes are the most important arbovirus vector, followed by ticks, sandflies (*Phlebotomus* spp.) and midges (*Culicoides* spp.). These arbovirus life cycles only become evident when humans are bitten directly by the natural enzootic focus, or when they are exposed to a virus that has escaped the primary cycle via a secondary vector or vertebrate host. Many arboviruses have several vertebrate hosts and many can be transmitted by a number of vectors.

Viruses such as urban dengue, urban yellow fever and occasionally urban St Louis encephalitis cause significant viremia and represent the simplest form of epidemic transmission cycle, in which the virus is transmitted directly between mosquitoes and humans (see Fig. 222.1). In some cases the introduction of a secondary vector may allow the transmission of the virus to other nonhuman vertebrate reservoirs (sylvatic cycle), many of which can be regarded as blind-end hosts (Fig. 222.2). Prime examples of sylvatic cycles with multiple hosts are the encephalitides such as Western equine encephalitis, eastern encephalitis and St Louis encephalitis. Many arboviruses are maintained in arthropods, through transovarial transmission. Amplification of the cycle occurs by spread to and from small mammals (Fig. 222.3). The flavivirus infections are discussed in Chapter 23 . The key features of the clinically important arboviruses transmitted to humans by hematophagous arthropod vectors, such as mosquitoes, ticks and *Phlebotomus* flies (sandfly), are given in Table 222.1 . Yellow fever is an example of a mosquito-borne zoonotic virus infection.

YELLOW FEVER

Nature

Yellow fever has historically been one of the great killers of humans. Regrettably, this mosquito-borne virus continues to exact a considerable toll on human populations living in endemic areas even today. Yellow fever is principally responsible for the failure of the French to successfully complete the Panama Canal in the 1880s as the work force was decimated by epidemics of yellow fever. Yellow fever was the first virus shown to be transmissible by a mosquito vector. Pioneering work by Carlos Finlay and Walter Reed are credited with this important discovery, which led to mosquito control efforts and dramatic reductions in the incidence of yellow fever. Yellow fever remains a considerable public health risk to travelers and inhabitants in endemic regions of South America and Africa.

Epidemiology

The World Health Organization (WHO) reported that between 1987 and 1991 there were 18,735 cases of yellow fever worldwide, with 4522 deaths.[5] This represented the greatest number of reported cases over a 5-year period since active reporting began in 1948. Yellow fever primarily occurs in jungle regions of the world and it is estimated that the incidence of yellow fever is grossly under-reported. The WHO estimates that perhaps as many as 200,000 cases of yellow fever occur annually. [6] Countries reporting active cases of yellow fever as of January of 1999 are indicated in Figure 222.4 .[7] Yellow fever has caused significant outbreaks in recent years; in Guinea in 2000, Peru in 2001 and Senegal in 2002. The value of mass vaccination for controlling an outbreak was demonstrated in Guinea. [8]

There are two transmission cycles of yellow fever. The first and most common today is the jungle (or sylvatic) cycle of yellow fever. The jungle transmission cycle consists of a natural reservoir of disease in nonhuman primates with transmission by forest-dwelling mosquitoes. In South America the mosquito primarily responsible for yellow

Figure 222-1 Maintenance of arbovirus cycle involving humans as the primary vertebrate host (e.g. urban dengue and urban yellow fever).

Figure 222-2 Sylvatic cycle of Western equine encephalitis (WEE) and St Louis encephalitis (SLE).

fever transmission to humans is the *Haemagogus* sp. mosquito. In sub-Saharan Africa yellow fever is transmitted in rural areas primarily by *Aedes africanus*. The urban (or epidemic) cycle of yellow fever is related to urban outbreaks transmitted by the human-adapted mosquito *Aedes aegypti*.

All susceptible populations appear to be equally at risk for disease yet most cases occur in children or young men (particularly those involved in the logging industry or construction in heavily forested areas). The increased incidence of yellow fever recently may reflect population expansion and economic development of rainforest areas and inadequate distribution of yellow fever vaccine in regions of the

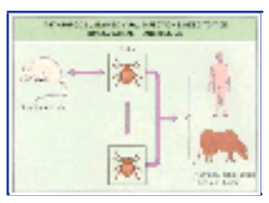

Figure 222-3 Arthropod sustained viral infection linked to tick transovarial transmission.

world where yellow fever remains endemic. Expanding commercial trade and international travel increases the risk of yellow fever outbreaks in nonendemic regions of the world in which the mosquito vector is found. Competent vectors for yellow fever are found in southern USA where the risk for yellow fever outbreaks remains a public health concern.[9]

Pathogenesis

Yellow fever is a prototypic mosquito-borne viral hemorrhagic fever. The virus is a 38nm ssRNA virus with a genome of approximately 4×10^6 Da. The virus is injected into humans during the course of a mosquito bite as the salivary contents of the mosquito contaminate the bite site. Local replication of the virus takes place in human skin and regional lymph nodes followed by viremia and dissemination to multiple organs of the body.

Major pathologic findings are found in the liver, kidney, heart and gastrointestinal tract. The virus infects the liver and causes massive hepatic necrosis. The characteristic pathologic finding is that of mid-zone necrosis with sparing of hepatocytes around the central vein and portal triads (Fig. 222.5). Another characteristic finding is that of Councilman bodies within degenerating hepatocytes (Fig. 222.6). Councilman bodies are acidophilic cytoplasmic deposits and not viral inclusion bodies. Diffuse areas of petechial hemorrhage are found throughout the body with the most marked changes found in the brain, kidney and gastrointestinal tract.

Prevention

The most important preventive measure is to avoid the mosquito vector within endemic regions where yellow fever exists. This can be accomplished by environmental control measures that remove mosquito habitats from areas of human habitation. There is a highly effective preventive vaccine against yellow fever. This is a live attenuated yellow fever vaccine known as vaccine strain 17-D.[10] The vaccine is highly efficacious and results in a prolonged neutralizing antibody response that will persist in the circulation for more than 10 years after immunization. Travelers to yellow fever endemic areas and residents within these areas should be vaccinated to prevent yellow fever.

Diagnostic microbiology

The virus can be isolated from a number of cell lines including Vero cells and AP-61 cells. Virus isolation represents an extreme biohazard and should only be attempted in specialized laboratory facilities.

Serodiagnosis is possible within 1 week of onset of infection with IgM antibodies detectable using enzyme-linked immunoabsorbent assay (ELISA), hemagglutination inhibition or plaque reduction neutralization tests. Virus detection can also be accomplished using reverse transcriptase semi-nested polymerase chain reactions (PCRs) from blood as well as tissue samples.[11]

Clinical manifestations

Human infection with yellow fever follows three discrete phases. The first phase of infection last approximately 72 hours and is initiated by headache, malaise, weakness, nausea and vomiting. The virus is replicating rapidly and high titers of infectious virus are found in the body fluids of patients at this point. This initial period of infection is followed by a brief period of remission where fever and symptoms remit. After 24–48 hours, symptoms recur and are dominated by symptoms of acute hepatic failure and renal failure. Patients develop jaundice and very high fever (hence the name yellow fever) and begin developing clinically overt signs of a hemorrhagic diathesis with petechiae, mucosal hemorrhages and gastrointestinal bleeding. A characteristic physical finding is marked bradycardia in the face of high fever (Fagetis' sign). Patients develop delirium, seizures, coma, acute renal failure and death within 7–10 days of illness. The mortality rate may be as high as 50% in some outbreaks and as low as 5% if optimal medical care is available. [12]

Management

The management of yellow fever remains primarily supportive. Intravenous fluids, blood product support and management of hepatic and renal insufficiency are the mainstays of therapy. Ribavirin does not appear to be effective and no other antiviral

Figure 222-4 Distribution of reported cases of yellow fever, 1 January 1999. Dark purple areas show the worldwide distribution of reported cases.

agent has been shown to be useful to treat yellow fever thus far. Patients should be isolated as their blood and body secretions may contain viral particles. Transmission to health care workers, particularly after needlestick injuries, has been described.

WEST NILE VIRUS

Recently human and horse West Nile virus (WNV) infection have been identified in new temperate regions of Europe and North America. Clinical presentation is variable, but severe infection is characterized by encephalitis and a significant mortality rate in humans and horses as well as certain domestic and wild birds. The virus was first isolated from the blood of a febrile women in the West Nile district of Uganda in 1937[13] and was subsequently isolated from patients, birds and mosquitoes, in Egypt in the early 1950s.[14] The

Pathology of tropical and extraordinary diseases. Volume 1. Washington DC: Armed Forces Institute of Pathology; 1976.*

WNV was first recognized as a cause of human meningoencephalitis in Israel in 1957 and as a cause of equine disease in Egypt and France in the early 1960s.

Virology

The WNV is an RNA virus belonging to the family Flaviviridae (genus flavivirus). It is a member of the Japanese encephalitis complex, which also includes Kunjin, Murray Valley encephalitis and St Louis encephalitis. The WNV virus strains can be divided genetically into two lineages. Only members of lineage 1 have been associated with clinical human encephalitis. Lineage 1 has been isolated from Africa, India, Europe, Asia and North America. Among lineage 1 WNV causing the recent human and equine outbreaks throughout Europe and Asia are closely related to the WNV (strain ROM96) first isolated in Romania and subsequently in Kenya in 1998. The virus

responsible for the outbreak in the USA (NY99) is genetically distinguishable from ROM96, but it is closely related to the virus circulating in Israel form 1997 to 2000 (Isi98). Only the USA and Israel have reported illness and death in humans and animals caused by the WNV strains Isi98 and NY99. The close relations between these strains suggest that the virus causing the outbreak in the USA was imported from the Middle East.

Epidemiology

Since the original isolation of WNV, outbreaks have occurred infrequently in humans, those in Israel (1951–4 and 1957) and South Africa (1974) being the most noticeable. Since the mid-1990s there have been three distinct epidemiologic trends.

First, there has been an increase in disease frequency in humans, notably in Romania,[15] Czech Republic and Russia. Epizootics of disease in horses have occurred in Morocco where 42 of 94 affected horses died, Italy (14 cases in 1998, six died), USA (1999–2002) and the Camargue region of France.

Second, there has been a noticeable increase in severity of human disease, with large outbreaks with significant mortality rates, especially in temperate urban areas. They include Bucharest, Romania (1996, over 400 cases, 17 deaths); Volgograd, Russia (1999, over 800 human cases, 40 deaths); New York City (1999–2000, 83 human cases, nine deaths); and Israel (2000, over 300 human cases, 29 deaths). [16] Since the introduction of WNV into the USA in 1999[17] it has been responsible for the identification of an increased number of cases (1999–2001, 149 human cases, 18 deaths; during the first a months of 2002, 2369 human cases, 139 deaths). The WNV has now been responsible for the spread of human disease westward, found in 34 states of the USA in less than 3 years.

Finally, high avian death rates accompanying human outbreaks have been a significant feature of WNV outbreaks in the USA and Israel.

The principal vectors are mosquitoes, predominantly of the genus *Culex* (*C. pipiens* and *C. restuans*), and the principal amplifying hosts are wild birds. Humans and horses are considered 'end-hosts' or 'incidental hosts'. A striking feature of the initial human epidemic in New York City 1999 was the high number of avian deaths among American crows (*Corvi brachrhynchos*) and other corvids.

Clinical manifestations

The incubation time in humans is reported to be 3–14 days. Symptoms generally last 3–6 days. Reports from earlier outbreaks describe a mild form of WNV infection presenting as a febrile influenza-like illness with sudden onset. This is often accompanied by malaise, anorexia, nausea, vomiting, rash, myalgia, lymphadenopathy and retro-orbital pain. A small proportion of cases (<1%) develop severe illness, such as acute encephalitis, aseptic meningitis or Guillain-Barré syndrome. In the recent outbreak in the USA those patients hospitalized with severe disease reported fever, weakness, gastrointestinal symptoms and flaccid paralysis. A minority of patients with severe disease develop a maculopapular rash or morbilliform rash involving the neck, trunk, arms or legs. Neurologic presentations include ataxia and extrapyramidal signs, cranial nerve abnormalities, myelitis, optical neuritis and seizures, and are more common in those over 50 years of age and in young children.

Diagnostic microbiology

Diagnosis of patients with WNF encephalitis or meningitis is made by the detection of IgM antibody to WNV in serum or cerebrospinal fluid (CSF) collected within 8 days of illness using the IgM antibody capture ELISA (MAC-ELISA). As IgM does not cross the blood-brain barrier, IgM antibody in the CSF strongly suggests central nervous system (CNS) infection. Therefore, the laboratory diagnostic confirmation strategy involves the serologic detection of IgM or IgG ELISA in CSF and serum with subsequent plaque reduction neutralization test (PRNT) confirmation. In addition, highly sensitive reverse transcriptase (RT)-PCRs have been described. Virus isolation on acute CSF samples provides an alternative approach. Antigenic cross-reactivity with other closely related flaviviruses is a major problem in serologic testing, and this underlines the need for confirmation with PRNT. It should be noted that samples from patients recently vaccinated against or recently infected with related flaviviruses (e.g. yellow fever, Japanese encephalitis) may give positive WNV MAC-ELISA results.

Management

There is no specific therapy or vaccine available and management is supportive.

ARENAVIRIDAE

Nature

Members of the Arenaviridae have been isolated from diverse species of rodents, which are their natural hosts, in a wide range of geographic locations. Two arenavirus complexes are recognized — the complex of lymphocytic choriomeningitis virus and Lassa virus (LCMV-LASV), or old world arenaviruses, and the Tacaribe complex, or new world arenaviruses.[18] This broad antigenic classification is supported by more detailed phylogenetic comparisons. The important arenavirus infections of humans are listed in Table 222.2 .

Arenavirus virions range from spheric to pleomorphic and have a mean diameter of 110–130nm. Particles are characterized by a variable number of electron-dense ribosomes (diameter 20–25nm) within the virus particles. They have a lipid membrane with glycoprotein spikes that project 8–10nm from the surface (Fig. 222.7).

TABLE 222-2 -- Arenaviruses known to cause human disease.

ARENAVIRUSES KNOWN TO CAUSE HUMAN DISEASE			
Virus	**Host in nature**	**Geographic distribution**	**Main features of human disease**
Lymphocytic chorio-meningitis virus (LCMV)	*Mus domesticus, Mus musculus*	Europe, Americas, perhaps elsewhere	Isolated 1933; causes lymphocytic choriomeningitis, which usually presents as an aseptic meningitis with a mortality rate <1%
Lassa fever	*Mastomys* spp.	West Africa	Isolated 1969; causes Lassa fever, a severe systemic illness; severe cases suffer shock and hemorrhages; mortality rate 16%
Junin virus	*Calomys musculinus*	Argentina	Isolated 1958; causes Argentine hemorrhagic fever (AHF), which causes a similar illness to Lassa but hemorrhage and CNS disease more frequent; mortality rate up to 30%
Machupo virus	*Calomys callosus*	Beni region of Bolivia	Isolated 1963; causes Bolivian hemorrhagic fever; similar clinical picture to AHF; mortality rate 25%
Guanarito virus	*Zygodontomys brevicauda: Sigmodon aistoni*	Venezuela	Isolated 1990, similar to AHF; mortality rate 25%
Sabia virus	Unknown	Brazil	Isolated 1990; only three human cases described, one fatal; clinical picture probably similar to AHF

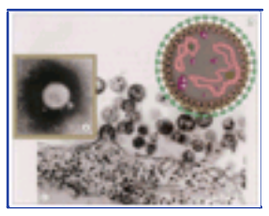

Figure 222-7 Arenaviruses. (a) Negative contrast electron micrograph of Lassa virus. (b) Arenavirus particle showing coiled nucleocapsid ribosomes and glycoprotein spikes. (c) Thin sections of infected Vero cells, showing extracellular virus, budding particles and intracellular inclusions. *Courtesy of G Lloyd, B Dowsett and ASR Featherstone.*

The genome consists of two ssRNA molecules, L (large) and S (small). The L and S RNAs of arenaviruses have an ambience coding arrangement; nucleocapsid (N) is encoded in the viral-complementary sequence corresponding to the 5' half of segment S, whereas the viral glycoprotein precursor (GPC) is encoded in the viral-sense

sequence corresponding to the 3' half of S.[18]

The N protein, which is the most abundant polypeptide, is non-glycosylated and forms a ribonucleoprotein (RNP) complex with the genomic RNA. Two glycosylated proteins, GP-1 and GP-2, are derived by post-transitional cleavage from the GPC. The L segment codes for the L protein, which is an RNA polymerase, and the Z protein, a putative zinc binding protein. a-Dystoglycan has recently been identified as a receptor for LCMV and Lassa fever virus.[19] This belongs to a highly conserved family of proteins found in epithelial, muscle and neurologic cells in humans.

Pathogenesis

In their natural rodent hosts, arenavirus infections occur in two distinct patterns: during the neonatal period, a chronic viremic infection is established; in adult rodents the infection is transient and self-limiting. This lifelong infection does not have major clinical sequelae for the infected rodent. [18]

In humans several arenavirus infections cause severe illness, including meningoencephalitis and hemorrhagic fever, with significant mortality rates. The pathogenesis is not fully understood, and microscopic changes found at autopsy are modest and do not account for the severity of illness. Petechial hemorrhages of the skin are found, and multiple hemorrhages and focal necrosis may be present in internal organs. Serous effusions and interstitial pneumonia have been described. Hemorrhages are more common with South American arenavirus infections. In contrast to these modest pathologic lesions, the physiologic changes are extensive. The state of shock characteristic of severe disease reflects an increase in vascular permeability. The mechanism involved is not fully understood, but it may be an indirect effect of immune mediators

Figure 222-8 Distribution of pathogenic human arenavirus infection in South America and Africa, and year of first isolation of each virus.

on endothelial cells produced by infected macrophages and monocytes, rather than direct viral damage.

Epidemiology

The epidemiology of individual arenaviral disease in humans is dependent on the geographic distribution of infected rodents and the nature of their contacts with humans (Fig. 222.8).

Several distinct patterns are seen. In Lassa fever, which is a common human infection, the reservoir host is *Mastomys* spp., which is a peridomestic rodent found in sub-Saharan Africa. The rodents are persistently infected and contaminate the environment with the virus, which generates infectious aerosols on drying. Other

routes of transmission include direct contact with rodent excretions during the capture and killing of these animals for consumption. The host of junin virus, the cause of Argentine hemorrhagic fever, is *Colomys musculinus*. The natural habitat of this rodent is the hedgerow and transmission occurs at harvest time, presumably because of aerosol transmission during mechanical harvesting.

Infection by LCMV is found worldwide, wherever its natural hosts *Mus domesticus* or *Mus musculus* are infected. The burden of disease is not well established, but LCMV infection is linked with up to 10% of CNS disease of suspected viral origin. Antibody studies show a prevalence of 5% in urban populations in the USA,[20] 9% in urban populations in Germany, and 2.2% in Argentina. An increase in the number of cases is reported in the autumn, which may result from the reservoir host moving into homes for the winter.

Lassa fever is a serious public health problem in West Africa, in two distinct hyperendemic areas — Sierra Leone, Guinea and Liberia and Nigeria. Identification of a recent case in Côte D'Ivoire indicates that infection may be distributed more widely in West Africa.[21] Infections are found throughout the year, but a peak incidence is seen in the dry season. Lassa fever is a more common infection than previously thought, with estimates of up to 400,000 human cases annually and an overall mortality rate of 2%.[22] More severe hospitalized cases have a mortality rate of 16%.[23]

Several hundred cases of Argentine hemorrhagic fever are identified each year, and are associated with the harvest. Most cases occur in adult males.

Bolivian hemorrhagic fever was first identified in 1963–4, when it caused an extensive outbreak in San Joaquin that resulted in 113 deaths. [24] This followed the rodent host entering the small town. However, the disease has since been uncommon, with occasional cases reported in rural communities in those more likely to come into contact with the infected rodent host.

Prevention

Two strategies have been proposed to prevent arenaviral disease in humans — rodent control and vaccination. Rodent control was important in controlling the Bolivian hemorrhagic fever outbreak, by the eradication of *Colomys callosus*. The house mouse, *Mus domesticus*, can be effectively eliminated from homes, thus reducing exposure to LCMV. However, its value in controlling other arenavirus infections has not been established. *Mastomys natalensis* is widespread and it has not proved practical to control rodent populations with living conditions found in West Africa. Both *C. callosus* and *C. musculinus* inhabit rural areas and control is not feasible.

A live, attenuated junin vaccine (Candid-1) has been developed and its efficacy demonstrated in a trial of 6500 volunteers.[25] It is now used for high-risk workers.

Lassa fever is the most important human arenavirus infection and vaccination seems to be the best hope for control. Killed and live vaccines have been developed and evaluated in animal models, and the most promising candidate vaccine is a vaccinia recombinant containing the Lassa virus glycoprotein gene. In challenge experiments this vaccine prevented death from Lassa challenge in guinea pigs and nonhuman primates. No human studies have been performed.[18]

Diagnostic microbiology

All arenavirus infections present similar diagnostic problems; the virus can be isolated early in the disease and this is followed by the later development of IgM and IgG antibody responses. There has been relatively little development of diagnostic assays for these agents because they are relatively rare and geographically localized.

Infection by LCMV is generally diagnosed by the detection of specific antibody. Usually immunofluorescence is used, but an ELISA test has been described. For virus isolation, blood and CSF samples are the most useful. Mice and guinea pigs are the most sensitive culture system, but isolation in Vero cells is more practical.

Lassa fever and several of the South American hemorrhagic fevers cause severe infections and can be transmitted by aerosol. Consequently, they have been classified as biohazard level 4 viruses and work on these agents is confined to the few high-containment laboratories worldwide.

The early clinical diagnosis of Lassa fever is difficult, and because ribavirin is an effective treatment if started early in the disease course, laboratory confirmation of infection is important. For rapid diagnosis either virus culture in Vero E6 cells or genome detection by RT-PCR are used on acute blood samples. Now RT-PCR is the first-line diagnostic test because it enables same-day diagnosis, and the use of guanadinium to extract RNA also inactivates viral infectivity, which makes the sample safe to work on outside the containment laboratory. In a recent study all Lassa fever patients were diagnosed by RT-PCR within 3 days of admission (Fig. 222.9).[26] Detection of Lassa-specific antibody by immunofluorescence is widely used, but antibody rises late in clinical disease and is often not detectable until the second week of illness, which is often too late to effect patient management. Baculovirus-expressed nucleoprotein (NP) has been used for serologic diagnosis and avoids the need to culture virus. Quantitative real-time PCR has now been applied to the diagnosis of Lassa fever, and the results obtained on sequential samples from a recent case are illustrated in (Fig 222.10). The ability to quantify and monitor viral load may have prognostic value and help to guide treatment, but substantive studies are required.

The South American arenaviruses can be cultured from acute blood samples in newborn mice and hamsters or Vero cells. The detection of virus-specific IgG and IgM

by immunofluorescence is widely used, and more recently ELISA using baculovirus-expressed viral proteins to detect antibody and RT-PCR tests have been described.

Clinical features

Arenavirus infections are often mild or subclinical. Even in severe infections, early illness is characterized by non-specific

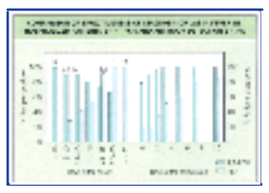

Figure 222-9 Comparison of effectiveness of diagnosis of Lassa fever in hospitalized patients by reverse transcriptase polymerase chain reaction (RT-PCR) and antibody detection by immunofluorescent antibody (IFA). (a) Samples from all patients were stratified with respect to the time since the onset of disease. The number of serum specimens in each group is indicated. (b) Samples were analyzed on a patient-by-patient basis with respect to time since admission to the hospital. *Adapted from Demby et al.* [26]

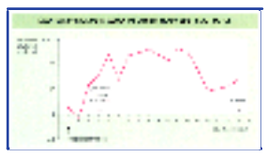

Figure 222-10 Lassa fever viral load in sequential samples from a case measured by real-time polymerase chain reaction.

symptoms, such as fever and myalgia, before the onset of severe systemic disease.

In LCMV infection headache, nausea or vomiting accompany the febrile prodrome. In the second week of illness CNS disease develops in a minority of cases and usually presents as an aseptic meningitis. In severe cases encephalitis can develop and this accounts for a significant minority of hospitalized cases. Full recovery is the most common outcome, but occasional deaths have been reported.

The incubation period of Lassa fever is about 10 days. It generally begins with a gradual onset of fever and malaise. As the disease progresses, abdominal pain, nausea and vomiting become more pronounced and an exudative pharyngitis and conjunctivitis are common. More pathognomonic signs and symptoms develop during the second week of illness, including facial edema, pleural edema, encephalopathy and shock. In severe cases illness is progressive, with shock followed by death. In survivors, defervescence is followed by recovery after 2–3 weeks. Hemorrhagic complications are not uncommon in severe cases and generally present with epistaxis, bruising and conjunctival hemorrhage. In the convalescent period pericarditis has been described. Deafness is now recognized as a late complication.[27] It can be unilateral or bilateral and is not related to the severity of disease; it may be immune mediated.

Argentine and Bolivian hemorrhagic fever present with a similar clinical picture. The progression of illness is more rapid than in Lassa fever, with severe prostration developing 3–4 days after onset. In more severe cases mucous membrane hemorrhage and bruising at intravenous injection sites are seen, which indicate a poor progress. In a few cases substantial neurologic involvement leads to convulsions. Recovery usually starts at the end of the second week of illness.

Management

Lassa fever has caused nosocomial infections in Africa and is the biohazard level 4 agent most commonly imported into nonendemic countries. Consequently, many countries have developed containment guidelines for the management of suspected Lassa fever cases to prevent secondary transmission.[28] [29] Transmission is through direct contact with infected body fluids and little evidence suggests that airborne transmission is important. The guidelines follow a similar approach based on an initial patient-risk assessment, which leads to different levels of investigation, containment and monitoring of close contacts, depending on risk (see also Chapter 183 and Chapter 186a).

Ribavirin, a guanosine analog, is effective in vitro against arenaviruses, but its mode of action is unknown. Ribavirin has been evaluated for the treatment of severe Lassa fever cases and dramatically reduces the mortality rate.[30] Its use for prophylaxis of contacts with Lassa fever cases and for the treatment of other arenavirus infections has been proposed, but no trial reports are yet published.

Treatment of Argentine hemorrhagic fever infections with convalescent human plasma is effective in reducing the mortality rate from 15–30% to <2% if given during the first 8 days of illness. Convalescent plasma could potentially play a role in Lassa fever treatment, but this has not been established in practice. Patient management of arenaviral infections requires general supportive care, with particular attention to fluid balance.

HANTAVIRIDAE

Nature

Hantavirus is the most recently described genus in the Bunyaviridae family and comprises a growing number of isolated viruses, including those that cause hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS). [31] [32] Some recently recognized probable species that have been identified by molecular genetic analysis have not yet been isolated (Table 222.3). Hantaviruses contain a tripartite, single-stranded, negative-sense RNA genome. The three segments are designated as small (S), medium (M) and large (L), and encode for the nucleocapsid (N) protein of 50–53kDa, the two envelope proteins (G1 and G2) of 65 and 74kDa, respectively, and an associated virus of 200kDa.[33]

Epidemiology

The epidemiology of hantavirus disease in humans is dependent on the geographic distribution of persistently infected rodent hosts.[34] The hantaviruses linked with HFRS are associated with specific rodent hosts, each named for the region in which they were first isolated:

- *Apodemus agrarius* (the striped field mouse) for the hantavirus;
- *Rattus norvegicus* (the Norway rat) and *Rattus rattus* (the black rat) for the Seoul virus; and
- *Apodemus flavicollus* (the yellow neck field mouse) for the Dobrava virus.

The hantavirus from Korea, Russia and China and the Dobrava virus from the Balkan countries of Europe (Bosnia, Croatia, Yugoslavia, Albania, Greece and Bulgaria) are associated with the severe form of HFRS, with an estimated mortality rate of 5–15% (see Table 222.3). [35] A moderate form of HFRS is caused by the Seoul virus, which (along with its host) is found virtually worldwide. Serologic evidence for infection with Seoul-like hantaviruses has been found in rodents in major cities within the USA.

TABLE 222-3 -- Characteristics of some known hantaviruses found in Europe, Asia, Russia and India.

CHARACTERISTICS OF SOME KNOWN HANTAVIRUSES FOUND IN EUROPE, ASIA, RUSSIA AND INDIA					
Species	**Human illness**	**Pathology**	**Mortality rate (%)**	**Reservoir**	**Geographic virus distribution**
Hantaan (HTN)	Severe: HFRS, EHF, KHF	Renal	5–15	*Apodemus agrarius* (striped field mouse)	China, Russia, Korea
Dobrava/Belgrade (DOB)	Severe: HFRS	Renal	5–15	*Apodemus flavicollis* (yellow neck mouse)	Balkans
Seoul (SEO)	Moderate: HFRS	Renal	1	*Rattus norvegicus* (Norway rat)	Worldwide

Puumala (PUU)	Mild; NE	Renal	1	*Clethrionomys glareolus* (bank vole)	Europe, Russia, Scandinavia
Khabarovsk (KHB)	?	?	?	*Microtus fortis* (reed mole)	Russia
Tula (TUL)	?	?	?	*Microtus arvalis* (European common vole)	Europe
Thailand (THAI)	?	?	?	*Bandicot indica* (bandicoot rat)	Thailand
Thottapalayan (TMP)	?	?	?	*Suncus murinus* (musk shrew)	India
Topografov (TOP)*	?	?	?	*Lemmus sibircus* (Siberian lemming)	Siberia
? Not yet documented					
EHF, epidemic hemorrhagic fever; HFRS, hemorrhagic fever with renal syndrome; KHF, Korean hemorrhagic fever; NE, nephropathia epidemica.					

* Virus not yet isolated/molecular analysis suggests they are probable hantavirus species

A mild form of HFRS, caused by the Puumala virus, is responsible for nephropathia epidemica (NE) in Scandinavia, the European regions of the former USSR and south of this through much of Europe to France, Spain and Portugal.

The hantavirus associated with HPS, Sin Nombre virus (SNV), has been recognized throughout the USA since its discovery in 1993.[36] Molecular biologic studies have identified similar viruses — Black Creek Canal (BCC), New York, Bayou (BAY) and Andes — that are also associated with HPS illness, that extend their geographic distribution from North America to Mexico and South America (Table 222.4). The distribution of specific host species throughout the Americas suggests a wider distribution of hantaviruses, which potentially could cause further clinical cases.

All rodent hosts are persistently infected with specific hantavirus strains that apparently cause no illness. In wild rodent populations, most infections occur through age-dependent horizontal routes, predominately in mature males. Horizontal transmission among cage mates was experimentally demonstrated via the aerosol route at median infectious doses of 1.0 plague forming units (pfu) for each virus tested. However, although rodents are susceptible to hantavirus through the aerosol route, their susceptibility is increased by inoculation (median infectious doses 0.003–0.016pfu). Vertical transmission from dam to pup has proved negligible or absent, both in wild and experimental settings.

Hantavirus disease, irrespective of strain, is a seasonal disease. This seasonality is associated with population dynamics of the rodent hosts that maintain each virus and their interaction with local human populations. Rodent population cycles vary according to climatic changes and interspecies competition. Rural-associated HFRS in Asia and Europe is linked to human rodent contact during the planting and harvesting of crops (late autumn and early winter). Similarly, in Scandinavia Puumala virus causes most cases of NE during the same period. Both Puumala outbreaks in Scandinavia and the original HPS outbreak in America were associated with increases in the natural rodent population followed by rodent migration from the fields to buildings in response to adverse weather conditions. Alternatively, in Greece, HFRS is observed predominately in the warmer months as a result of increased human outdoor activities, including camping. These cases point to higher risk being experienced by people such as forestry workers and shepherds. In China HFRS induced by Seoul virus appears to be most common in the spring.

The aerosol route of infection is regarded as the most common means of transmission among rodents and to humans. Rodent bites cannot be excluded as a way of maintaining the disease among rodents or occasionally resulting in human infection. Epidemiologic investigations link virus exposure to farming activities, sleeping on the ground and military exercises. Indoor exposure has been linked to rodent infestation of homes during cold weather or to nesting rodents in or near dwellings. Many hantavirus infections are identified among people who live in poor housing conditions or in those who pursue recreational activities such as camping and various water sports. Human-to-human transmission is rare and consequently hantaviruses do not pose a risk to hospital workers. However, recent outbreaks of HPS in South America suggested that minimal exposure to body fluids of infected patients resulted in apparent person-to-person spread.

The annual incidence of HFRS involving hospitalization throughout the world is estimated to be between 150,000 and 200,000 cases. More than half these cases predominate in the endemic center of epidemic hemorrhagic fever in the Chinese provinces of Hubei, Heilongjiang, Jiangxi, Jilin and Shanxi. Annual incidence rates here range from 0.05 to 3.0/1000. Russia and Korea also report hundreds to thousands of cases of HFRS each year. Most of the remaining cases (a few hundred) are reported from Japan, Finland, Sweden, Belgium, The Netherlands, Greece, Hungary, France and the Balkan countries formally constituting Yugoslavia. Mortality rates range from less than 0.1% for HFRS caused by Puumala to approximately 5–10% for HFRS caused by hantavirus.

Several hundred cases of HPS have been reported throughout North and South America (see Table 222.4). [37] Most of the identified cases in America and Canada were caused by SNV. Cases of HPS in south-western USA and South America are caused by molecularly identified strains that include BAY, BCC and Andes viruses.

A number of hantavirus infections have caused several laboratory-associated outbreaks of HFRS, all of which were traced to persistently infected rodents obtained from breeders, to wild-caught naturally infected rodents or to experimentally infected rodents. No illness has been associated with laboratory workers using cell-culture adapted viruses, although asymptomatic seroconversions have been documented.

Pathogenesis

The process by which hantaviruses cause multisystem organ dysfunction syndrome is unclear. Thrombocytopenia, defects in platelet function, transient disseminated intravascular coagulation (DIC) and increased vascular fragility are all thought to play a key role in the

TABLE 222-4 -- Some known hantaviruses found in North and South America.

SOME KNOWN HANTAVIRUSES FOUND IN NORTH AND SOUTH AMERICA					
Species	**Human illness**	**Pathology**	**Mortality rate (%)**	**Reservoir**	**Geographic virus distribution**

HPS, hantavirus pulmonary syndrome.

* Virus not yet isolated/molecular analysis suggests they are unique hantavirus strains

early stages of the disease. Hantavirus disease is mainly microvascular in nature and endothelium is the predominant cell type involved. The presence of hantavirus antigen has been demonstrated by immunochemistry in vascular endothelial cells of fatal HFRS infections, experimentally infected rodents and endothelium of lung capillaries in the highly lethal form of HPS.[38] Endothelial damage or dysfunction leads to capillary engorgement, leakage of erythrocytes and increased permeability.

Recent studies implicated the disease process as being immunologically based, with lymphocytes playing a key role, especially T cells. The CD4:CD8 ratio is greatly decreased, although abundant $CD4^+$ and $CD8^+$ lymphocytes have been reported in the lung interstitium of HPS patients.[38] Lymphocyte induction of migrating macrophages and other inflammatory cells results in the production of cytokines, such as tumor necrosis factor (TNF)-a, interleukin (IL)-1 and IL-2, and interferon (IFN)-?, which in turn increases vascular permeability.

Prevention

Prevention of hantavirus infection is dependent upon reducing contact between humans and infected rodents. However, many rodent control programs in known highly endemic areas, such as China, have been ineffective. Guidelines in the USA to control HPS infections have been aimed at reducing rodent access to homes, clean up recommendations of buildings with heavy rodent infestations, and precautions for workers exposed to rodents and for campers and hikers in infected areas.

Although a number of candidate (inactivated, recombinant) vaccines against hantaviruses are under development, none are currently available.

Both wild-caught rodents introduced into laboratories and laboratory-bred colonies have caused a number of laboratory-based infections. Current recommendations directed at the manipulation of hantaviruses call for handling at biosafety containment levels 2 and 3, dependent on the strain. Work with infected laboratory rodent colonies that may lead to the generation of infectious aerosols in urine or feces should be undertaken in facilities that have suitable room ventilation and high-efficiency particulate air (HEPA) filtration, primary containment of animals, and personal protective equipment at a minimum of biosafety containment level 3. Precautions should also ensure suitable decontamination of animal bedding, cages and animal waste.

It is prudent to introduce hantavirus screening of laboratory-bred and wild-caught rodents and cell lines that originate from rodent tissue before use. Such animals and cells should be segregated from other animals, with care being taken to prevent possible aerosolized spread of infectious virus.

Diagnostic microbiology

Diagnosis of hantavirus infection relies upon the recognition of characteristic clinical features, a history consistent with the epidemiology of the disease and serologic confirmation.[37]

Direct isolation of hantavirus from acutely ill patients is prolonged and often unsuccessful and consequently of little diagnostic value. Similarly, the success of antigen-capture ELISA or the application of RT-PCR on acute blood samples is of no practical value for the diagnosis of human infection.

Although the immunofluorescence assay is regarded as a useful diagnostic tool, the method of choice to diagnose acute hantavirus infection is an IgM antibody assay of high sensitivity and specificity.[39] Currently two alternatives are available:

- M antibody capture IgM enzyme immunoassay (EIA) based on the use of cell-culture grown hantavirus antigen; and
- M antibody capture IgM EIA based on baculovirus or *Escherichia coli* expressed full-length nucleocapsid protein.[40]

Both in humans and rodents IgG antibodies persist for life, and therefore the presence of IgG seropositivity may not reflect a recent infection. In addition, a rise in IgG has not always been observed in recent clinical cases. The IgG ELISA or immunofluorescent antibody (IFA) test is well suited for epidemiologic studies, whereas determination of the specific infecting virus is best achieved by focus reduction neutralization tests.

Other methods are also under development to investigate hantavirus:

- hantavirus recombinant immunoblot assay (RIBA), which uses recombinant and synthetic peptides; and
- application of RT-PCR and immunohistochemical staining of antigen contained in formalin-fixed autopsy tissues.[41]

TABLE 222-5 -- Main characteristics of the two severe forms of hantavirus disease.

MAIN CHARACTERISTICS OF THE TWO SEVERE FORMS OF HANTAVIRUS DISEASE		
Characteristics	**Hemorrhagic fever with renal syndrome (HFRS)**	**Hantavirus pulmonary syndrome (HPS)**
Primary target organ	Kidney	Lung
Acute phase	Febrile	Febrile 'prodrome'
Later phases	Shock, hemorrhage	Shock, pulmonary edema
Disease progression	Hypotensive, oliguric, diuresis, convalescence	Diuresis, convalescence
Other clinical and laboratory features	Thrombocytopenia, leukocytosis, proteinuria, hematuria, creatinine >100mmol/l, hemoconcentration, raised transaminases	Thrombocytopenia, leukocytosis, hemoconcentration, shortness of breath, abnormal respiratory rate, lung infiltrates
Mortality rate (%)	1–15	=50

Clinical manifestations

Although HFRS has been clinically recognized and reported in Asia, Russia and Scandinavia for the past century, the causative agent, hantavirus, was not isolated until 1978.[42] The HFRS complex comprises three distant clinical diseases, each infection being caused by a specific hantavirus. [34] [36] The spectrum of disease ranges from non-apparent infection to fulminant hemorrhagic fever with renal failure (sometimes having a fatal outcome). Depending on which hantavirus is responsible for the illness, HFRS can appear as a mild, moderate or severe disease. Fatality rates range from less than 1% for HRFS caused by Puumula virus to approximately 5–10% for HFRS caused by hantavirus (Table 222.5).

The clinical course of pathogenic hantavirus infection comprises an acute febrile illness characterized by variable degrees of hemorrhagic and renal dysfunction. More severe disease involves five overlapping stages — febrile, hypotensive, oliguric, diuretic and convalescent.

The onset of the disease is abrupt and characterized by high fever of 102.2–104°F (39–40°C), chills, intensive headache, malaise, myalgia, dizziness and anorexia. A petechial rash may also appear on the face, neck and trunk. The main laboratory findings include normal-to-elevated white blood count (WBC), decreasing platelets, rising hematocrit and rising proteinuria.

As the febrile phase ends, hypotension can abruptly develop and last for a few hours or days. Prominent features are tachycardia, falling arterial pressure and narrowing pulse pressure, and in severe cases classic shock. Laboratory findings include leukocytosis with a left shift, thrombocytopenia and prolonged bleeding times. Urinalysis shows heavy proteinuria, mild hematuria and hyposthenuria. About one-third of fatalities occur during this phase.

The oliguric phase lasts 3–7 days, during which blood pressure returns to normal or is slightly raised because of hypervolemia. Laboratory findings include normal WBC and platelet counts, initially normal and then depressed hematocrit, continual marked hematuria and elevated blood urea nitrogen and creatinine. Hyponatremia, hyperkalemia and hypocalcemia result from renal failure. Pulmonary edema may occur and fluid management should be handled with care. Almost half of the deaths occur during this phase, often from pulmonary edema or infection, electrolyte imbalance, late shock, or hemorrhage into the brain.

Clinical recovery is signaled by the diuretic phase, with improved renal function and normal clotting. Diuresis over a few hours or days is evident, with an output of 3–6 liters. Fluid management must be maintained to prevent negative fluid balance that may lead to shock. The final (convalescent) phase can last weeks to months before recovery is complete.

Seoul virus infections (mild HFRS) are less severe than those caused by hantavirus. Typically the phases are shorter and difficult to recognize or even absent. The disease is characterized by fever, anorexia, chills and nausea, and vomiting. Palatal injection is common, although other hemorrhagic signs (epistaxis, melena, hematemesis) are observed in fewer than 30% of patients. Laboratory findings include lymphocytosis, thrombocytopenia, microscopic hematuria and proteinuria, and elevation of serum transaminase. Renal involvement is less severe and fatalities are uncommon.

Puumula virus infection (NE) is characterized by a sudden onset of fever accompanied by headache. Characteristically, by the fourth day of illness nausea, vomiting, petechiae in the throat and soft palate, and facial flush and petechial rash have occurred. A mild thrombocytopenia can be observed. Hypotension may be found, but evidence of shock is rare. Onset of oliguria or recognition of renal failure around the sixth day of disease is the main cause of hospital admission. Serum creatinine levels rise and dialysis may be required in 10% of cases. As with other hantavirus infections, the onset of polyuria indicates the recovery process.

First recognized as a severe, often fatal respiratory illness in adults, HPS was characterized as a severe, systemic illness with a non-specific onset, fever, myalgia, cough or dyspnea, gastrointestinal symptoms and headache that typically lasted 3–5 days.[43] Rapid and abrupt onset of noncardiogenic edema, hypotension (systolic blood pressure "80mmHg) then follow, resulting in shock and death in over half of the recognized cases (see Table 222.5). Laboratory findings indicate leukocytosis, an increase in polymorphonuclear leukocytes, left shift, increased hematocrit, thrombocytopenia, prolonged prothrombin and partial thromboplastin time, elevated serum lactate dehydrogenase, decreased serum protein concentrations and proteinuria. Increases in hematocrit and thromboplastin time are considered to be predictors of death. Radiographic examinations show bilateral pulmonary infiltrates and evidence of pleural effusions in the majority of hospitalized patients. Histopathologic features seen in lung tissue reveal mild-to-moderate interstitial pneumonitis with variable degrees of congestion, edema and mononuclear infiltrates. The virus has been identified extensively within endothelial cells of the pulmonary microvasculature, spleen and lymph nodes.

Current understanding of the disease indicates little evidence of renal damage as a feature of this hantavirus infection. The extensive pulmonary endothelial involvement and severe pulmonary edema make clinical management difficult.

Management

Effective management of HFRS and HPS requires early diagnosis, knowledge of disease course and prompt hospitalization. Aggressive clinical management is essential to improve survival. Care should be phase specific, with special attention given to fluid management. Ribavirin can be efficacious in the treatment of HFRS patients, but its treatment of HPS is not proved.

FILOVIRIDAE

Nature

The family Filoviridae consists of two distinctive species, Marburg and Ebola, which cause severe and often fatal hemorrhagic disease in humans and monkeys (see Chapter 183). The viruses have a distinctive filamentous morphology under the electron microscope with a genome that consists of a nonsegmented, negative stranded RNA

Figure 222-11 Filoviruses. (a) Filovirus particle in cross-section (not to scale) showing glycoprotein surface projections, nucleocapsid core inside the envelope. (b) Negative contrast micrograph of Ebola (Reston). (c) Intracellular filamentous particles showing nucleocapsid core. (d) Sections of Ebola (Republic of Congo, formerly Zaire) infected Vero cells, showing extracellular virus, budding particles. *Courtesy of G Lloyd, B Dowsett and ASR Featherstone.*

approximately 19kb in length (Fig. 222.11). Several features of their molecular organization and structure have linked these viruses to members of the Paramyxoviridae and Rhabdoviridae under the taxonomic order Mononegavirales.[41] The virions are composed of a central core formed by an RNP complex, which is surrounded by a lipid envelope derived from the host cell plasma membrane. The RNP is composed of a genomic RNA molecule bound by the NP, virion structural protein 30 (VP30), VP35 and the L protein (RNA transcriptase polymerase). The three remaining structural proteins are membrane-associated — GP, VP24 and VP40 are located on the inner side of the membrane. Among the newly isolated Ebola viruses are differences in molecular structure, pathogenicity and virulence in humans.[44]

Marburg and Ebola were first detected in 1967[45] and 1976,[46] [47] respectively, although human infections since then have been rare. Fresh outbreaks of Ebola infections were identified in Côte d'Ivoire (1994, 1995), Republic of Congo, (formerly Zaire; 1995),[48] and Gabon (1996, 1997, 2001) and Uganda (2000). In addition, importation of Ebola-infected monkeys into the USA (1989–1990, 1996) and Italy (1992) attracted extensive worldwide media coverage and raised public concerns about the potential public health threat of these pathogens through international travel and commerce.[49] [50]

Pathogenesis

The precise mechanisms by which filoviruses cause the most severe forms of VHF are unclear, but there is marked hepatic involvement, DIC and shock, producing extremely high fatality rates (30–90%). In the early stages of infection laboratory findings, such as high aspartate transaminase/alanine transaminase (AST/ALT) ratios, and marked lymphopenia followed by a marked neutropenia with left shift, suggest other extrahepatic targets affected by the virus. As with other VHF infections (HFRS, Lassa, dengue) fluid imbalance and platelet abnormalities indicate endothelial cell and platelet damage

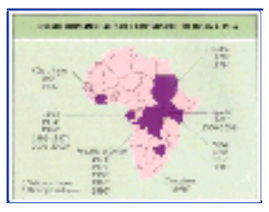

Figure 222-12 Distribution and dates of filovirus outbreaks in Africa.

or dysfunction. Human monocytes and/or macrophages, fibroblasts and endothelial cells support virus replication. Infected monocyte and/or macrophages have been shown in in-vitro models to secret the cytokine TNF-a, which has the ability to increase vascular endothelial cell damage.[51] The data currently available support mediator-induced vascular damage that leads to increased permeability and shock observed in severe cases. Hemorrhage is likely to be caused by reticuloendothelial system damage that cannot be repaired because of platelet and coagulation malfunctions.

Epidemiology

The natural history and reservoirs of filoviruses remain a mystery, as does a detailed understanding of their pathogenesis. In 1967, a fulminating hemorrhagic fever,

Marburg disease, occurred in Marburg and Frankfurt, Germany, and Bosnia, Croatia and Yugoslavia among laboratory workers handling blood and tissue from a shipment of African Green Monkeys (*Cercopithecus aethiops*) soon after being imported from Uganda via London. Among the 31 human cases, 25 of which were primary infections, there were seven (23%) deaths.[45] None of the secondary cases died. Since then, sporadic cases have been reported from South Africa and Kenya (Fig. 222.12).

In 1976, the first known cases of Ebola hemorrhagic fever were identified in southern Sudan (Table 222.6) and in a simultaneous outbreak in northern Republic of Congo (formerly Zaire), with fatality rates of about 60 and 90%, respectively.[46] [47] A further smaller outbreak occurred in the same region of Sudan in 1979, when 22 (65%) of 34 infections proved fatal. Lack of community co-operation hampered control efforts and investigations during an outbreak of Ebola in the Republic of Congo during 2002. Recent instances of Ebola infection were the severe illness of a Swiss zoologist working with infected chimpanzees (*Pan troglodytes verus*) in the Taï National Park in Côte d'Ivoire, West Africa, in late 1994 and a major epidemic in Kikwit, Bandundu Province, Republic of Congo (formerly Zaire), in 1995. Of 315 recorded cases of Ebola hemorrhagic fever a total of 244 died (77% mortality rate).[51] In the later part of 1995 further cases were identified in the Côte d'Ivoire among refugees who originated in Liberia. Finally, three reportedly independent human outbreaks of Ebola have occurred in the forested areas found in northeastern Gabon (1994, February 1996, July 1996, December 2001). Subsequent investigations of the 2001–2 outbreak suggested that cases in villages north of Mekambo resulted from contact with a gorilla whose remains were found to be positive for Ebola virus. A severe outbreak occurred between August

TABLE 222-6 -- **Characteristics of some know filovirus infections in Africa.**

CHARACTERISTICS OF SOME KNOWN FILOVIRUS INFECTIONS IN AFRICA			
Date	**Filovirus Infections**	**Documented fatalities/total cases**	**Main characteristics**
		Marburg	
1967	Marburg, Germany	5/23	Infected through contact with African green monkeys imported from Uganda
1967	Frankfurt, Germany	2/6	Infected through contact with African green monkeys imported from Uganda
1967	Belgrade, Yugoslavia	0/2	Infected through contact with African green monkeys imported from Uganda
1975	Zimbabwe	1/3	Contracted by travelers entering region — source unknown
1980	Mount Elgon, Kenya	1/2	Contracted by travelers entering region — source unknown
1987	Mount Elgon, Kenya	1/1	Contracted by travelers entering region — source unknown
1999	D.R. Congo	52/76 (estimates)	Gold miners near Durba
Total mortality rate		**62/113 (54.5%)**	
		Ebola (Africa)	
1976	Yambuku, D.R. Congo	280/318	Virus when introduced into hospital amplified disease
1976	Maridi, Sudan	151/284	Virus when introduced into hospital amplified disease
1976	England	0/1	Laboratory acquired
1977–8	Tandala, D.R. Congo	1/1	Child infected
1979	Nzara & Yambio, Sudan	22/34	Amplified by nosocomal transmission in hospital
1994	Taï Forest, Côte d'Ivoire	0/1	Worker infected after autopsy of chimpanzee-repatriated to Switzerland
1994	Gabon	32/44	Origin gold mining camps at Mekokou and Andcock. Primarily reported as yellow fever
1995	Kikwit, D.R. Congo	244/315	Included laboratory confirmed cases. Rapid transmission among unprotected health care workers
1995	Taï Forest, Côte d'Ivoire	0/1	Case originated in Liberia ? four additional cases in Liberia
1996 (January–March)	Mayibout, Gabon	21/37	Contact with dead chimpanzees
1996 July & January 1997	Booué & Libreville, Gabon	45/61	Index case hunter living in forest area — infected chimpanzees identified
1996	South Africa	1/1	Epidemiologically linked with outbreak in Gabon. Fatal case — nosocomial infection of nurse by patient transferred from Gabon
2000–1	Uganda	225/425	Occurred in Gulu, Misindi & Mbarara districts of Uganda. Spread associated with attending funerals, community nursing and medical care without personal protective measures
2001–2	Gabon	53/65	Community outbreak evidence suggest contact with dead nonhuman primates (gorilla)
2001–2	Republic of Congo		Outbreak occurred over the border of Gabon and the Republic of the Congo
	Mboma district	20/32	
	Kelle district	23/25	
Total mortality rate		**1118/1645 (68%)**	

TABLE 222-7 -- Recorded filovirus (Ebola (Reston)) infections.

RECORDED FILOVIRUS (EBOLA (RESTON)) INFECTIONS			
Date	**Filovirus infections**	**Documented fatalities/total cases**	**Main characteristics (all isolates originated from same compound)**
1989	Richmond, Virginia, USA	0/4	Reston strain isolated from monkeys imported from Philippines. Serologic evidence of asymptomatic infection among animal workers
1990	Manila, Philippines	0/12	Serologic evidence of asymptomatic infection among animal workers
1992	Siena, Italy	No cases	Reston strain isolated from monkeys imported from Philippines
1996 (April)	Alice Texas, USA	No cases	Reston strain in monkeys imported from Philippines

Total mortality rate	**0/16 (0%)**	

2000 and January 2001 in Uganda (Gulu and Masindi districts) that recorded 423 cases with 225 fatalities.[52] A case from the 1996 infection was treated in South Africa and the source of a fatal nosocomial transmission to a health care worker. All three outbreaks were associated with the deaths of chimpanzees, also thought to be from Ebola virus infection.

Hence, since 1994 West Africa has been considered to be part of the African filovirus map (see Fig. 222.12). Although filovirus outbreaks are rare events, the public health importance lies in their high mortality rate rather than the total number of infections in the 30 years since they were first identified (Table 222.6 and Table 222.7).

Ebola virus has also appeared outside Africa, among shipments of imported cynomolgus monkeys in Reston, Philadelphia and Texas, USA, in 1989, 1990 and 1996, respectively, and Sienna, Italy, in 1992.[49] The monkeys involved in each epizootic event were imported from the Philippines and traced to the same handling facility, where the presence of the virus was also documented. The epizootics indicate that monkeys acutely infected with filoviruses present a major veterinary emergency and possibly could pose a serious hazard to other animals or humans if not recognized in the future. Although an Asian origin of these virus strains cannot be discounted, molecular biologic and serologic studies carried out to date suggest a close similarity with the original Ebola viruses isolated from the 1976 African outbreaks.

Prevention

The imposition of ecologic controls to prevent outbreaks is impossible until the natural history of the viruses has been discovered. It is important that health care workers in areas where hemorrhagic fever exists are aware of the high risk of nosocomial spread if patients are not recognized early and placed in complete isolation.[53] In non-endemic areas an awareness of the changing epidemiology associated with viral re-emergence or emergence should always be considered, bearing in mind the threat and consequences of importation. [54] High-risk patients are those who during the 3 weeks before illness had:

- traveled into areas where VHF occurred recently;
- been in contact with body fluids from a person with VHF; or
- worked in a laboratory environment handling the virus.

(See also Chapter 183 and Chapter 186a). Importantly, filovirus illness is a rare event if patients do not meet any of these criteria.

As nonhuman primates are responsible for the introduction of Marburg into Europe, and of Ebola into the USA and Italy, the management of transportation, quarantine facilities and animal husbandry must ensure that personnel understand the hazards of handling nonhuman primates, and thus reduce the risks of future human outbreaks.[55]

Clinical manifestations

The incubation period for Ebola ranges from 4 to 10 days and for Marburg from 3 to 9 days.[45] The shorter times have been associated with exposure to contaminated needles.[56]

Filoviruses enter the host through close contact with contaminated body fluids. Epidemiologic studies in humans indicate that infection is not readily transmitted by the aerosol route. Although studies in nonhuman primates have established that the aerosol transmission can cause infection,[57] extra care must be taken with contaminated body fluid, tissue, hospital material and waste.

Both Marburg and Ebola virus infections follow a similar pattern of illness. Following exposure, initial symptoms include an abrupt onset with fever, severe frontal headache, malaise and myalgia. Such symptoms are similar to those of many viral illnesses that originate locally and in tropical areas. The initial diagnosis of a filovirus infection is very difficult. Disease progression is characterized by pharyngitis, nausea, severe vomiting of blood and production of bloody stools. Uncontrolled bleeding follows, which can be seen from under the skin, from venepuncture sites and from other orifices of the body. A characteristic maculopapular rash occurs 7–10 days (range 1–21 days) after onset of the clinical disease. If fatal, death occurs 6–9 days after onset of the clinical disease and results from severe blood loss and shock. Convalescence is slow, taking many weeks, and is marked by weight loss, prostration and amnesia of the acute phase of illness. [58]

Clinical laboratory findings in the early acute phase include lymphopenia followed by neutrophilia, marked thrombocytopenia and abnormal platelet aggregation. Serum AST and ALT are elevated and characterized by an AST/ALT ratio of between 10 and 3:1.

Diagnostic microbiology

The clinical diagnosis of Ebola or Marburg should be considered in patients who show acute, febrile illness and have traveled in known epidemic or suspected endemic areas of rural sub-Saharan Africa and Asia, particularly when hemorrhagic signs are present. As the differential diagnosis in the early acute phase of illness is difficult, other causes (malaria, typhoid) should not be excluded and treatment delayed. Laboratory diagnosis carried out on patient specimens is undertaken by more than one procedure to guard against false positives.

Care should be taken when drawing or handling blood specimens at the acute stage of illness because they contain large amounts of infectious virus — the virus is stable for long periods at room temperature at this stage.

Although their morphologic appearance is similar by electron microscopy, Marburg and Ebola are immunologically distinct. The basic diagnostic tool for filovirus infection and the only one to date that has widespread acceptance for the diagnosis of human filovirus disease is IFA, although some epidemiologic serology based on this assay has been regarded as non-specific and unreliable. A rising antibody in paired serum or a high IgG titer (>64) and the presence of IgM antibody together with clinical symptoms compatible with hemorrhagic fever are consistent with a diagnosis of filovirus infection.

Filoviruses can be readily isolated from fresh or stored (-94°F) specimens of blood or serum collected during the acute phase of illness. Vero cells (clone E6) and MA104 have proved the most sensitive for the propagation and assay of Marburg and Ebola viruses. Primary isolation using tissue culture rarely produces a specific cytopathic effect; thus, evidence of infection is confirmed by immunofluorescence staining using antivirus specific monoclonal or polyclonal antibodies. Some strains of Ebola, such as Ebola Sudan, proved difficult to grow in tissue culture and success was improved through interperitoneal inoculation of young guinea pigs. The resultant febrile response coincides with high levels of virus in the blood, which can be easily recovered by tissue culture or examined directly by electron microscopy. The isolation or propagation of filoviruses should not be attempted outside a biosafety containment level 4 laboratory.

During recent epizootic and human African outbreaks, early detection of filovirus infections was considerably improved by the development of an antigen-capture ELISA, amplification of filovirus RNA by RT-PCR, and immunohistochemistry identification of Ebola in skin biopsies. Skin biopsies fixed in formalin can be safely transported to reference facilities for confirmation without the need for low temperature preservation. Recent advances in molecular biology have expressed the NP gene of Ebola virus in a baculovirus expression system. The noninfectious N protein can replace the need for inactivation of infectious virus used in many serologic assays (IFA and ELISA). The diagnostic capabilities of such a system are currently being evaluated.

Management

No specific treatment is available. Treatment is limited to the provision of intensive nursing and effective control of blood volume and electrolyte balance. Shock, renal failure, depletion of blood clotting factors, severe bleeding and oxygen depletion must be managed. Human interferon and human convalescent plasma have been used

to treat patients, but their efficacy is not proved. Ribavirin has no therapeutic value.

Patient management is further complicated by the need to isolate the patient and protect medical and nursing staff.[50] [53] Use of patient isolators is a requirement in many countries, whereas strict barrier nursing techniques are acceptable in others. The latter can be supplemented using high efficiency particulate air filter respirators for protection against aerosols if considered feasible. Particular emphasis should be placed on ensuring that high-risk procedures (such as handling blood, secretions, catheters and introducing intravenous lines) are undertaken under barrier nursing conditions. It is recommended that patients who die from the disease should be buried or cremated promptly.

NIPAH AND HENDRA VIRUSES

Epidemiology

Both Hendra virus (HeV; formerly called equine morbillivirus) and Nipah virus (NiV) are newly recognized hazard group 4 zoonotic viruses.

Two outbreaks of a new zoonotic disease affecting horses and animals in Australia were reported within 1 month of each other in Brisbane (southeast Queensland) and Mackay (central Queensland) in 1994. A third event involving a single fatal equine case occurred near Cairns (North Queensland) in 1999. To date, two humans and 16 horses have died from this disease with acute respiratory failure.[59] [60] [61] Within the subfamily Paramyxovirinae, the extent of nucleotide homology in the N gene between different viruses in the same genus ranges from 56 to 78%, whereas the extent of nucleotide similarity between viruses from different genera is 39–78%. The N genes of HeV and NiV have 78% nucleotide homology, but the two viruses have no more than 49% similarity with any other members of the Paramyxovirinae.[66] Phylogenetic analysis of the N gene sequences show that HeV and NiV form a distinct cluster within the subfamily Paramyxovirinae. The cause of the infection has been identified as HeV, a new member of the family Paramyxoviridae.[62]

Another member of the Paramyxoviridae (NiV) was responsible for an outbreak of severe febrile encephalitis in humans in Malaysia in 1998–9. The outbreak was associated with respiratory illness in pigs and was initially considered to be Japanese encephalitis. Of a total of 256 cases 105 were fatal. In March 1999, a cluster of 11 cases (one fatality) was described in Singapore in abattoir workers who handled pigs imported from the outbreaks regions in Malaysia.[63] Measures to control the concurrent outbreak of respiratory disease in pigs resulted in the culling of over one million pigs (almost half the national pig herd) and had major domestic and international trade implications.

The geographic distribution of both HeV and NiV is currently undefined although Australia and South East Asia are considered to be endemic areas on the basis of the known incidents reported in the literature. Fruit bats of the genus *Pteropus* are considered to be the natural hosts of HeV and NiV[64] and are found in north, east and south-east areas of Australia, Indonesia, Malaysia, Philippines and some of the Pacific Islands. Pigs were the apparent source of infection among most human cases in the Malaysian outbreak of NiV, but other sources, such as infected dogs and cats, cannot be excluded.

Virology

Nipah and Hendra are closely lelated and difficult to distinguish serologically, although they have a diverse geographical distribution.[61] [65] Both NiV and HeV share a nonsegmented, negative-stranded RNA genome and similar genome organization, replication strategy and domain structure in the polymerase proteins to members of the Filoviridae, Paramyxoviridae, Rhabdoviridae and Bornaviridae. While being related to these families they are closely related to the Paramyxoviridae and more specifically the morbilliviruses. The genome organization of NiV and HeV is the same as for the rest of the Paramyxoviridae. There are a total of six transcription units encoding six structural proteins. These are the nucleocapsid protein (N), phosphoprotein (P), matrix protein (M), fusion protein (F), glycoprotein (G) or attachment protein, and large protein (L) or RNA polymerase. They are found on the genome in the order 3'-N-P-M-F-G-L-5'. Evidence suggests that NiV and HeV forms a distinct group of viruses within the subfamily Paramyxovirinae.[65]

Clinical features

The emergence of NiV and HeV has raised clinical concerns in the management of individuals returning from Australia and South East Asia presenting with pyrexia and other non-specific signs and symptoms. The incubation period for NiV and HeV is generally from 4 to 18 days. Onset of disease is usually influenza-like with high fever and myalgia. Sore throat, dizziness, and drowsiness and disorientation have been described. The case fatality rate for clinical cases is about 50% and subclinical infections may be common.

Experimental studies have confirmed the possibility of transmission through close contact with infected body fluids and that aerosol transmission does not seem to be significant. Human-to-human transmission has not been reported and the risk of transmission from horse to human, neither of which are considered natural hosts for the viruses, is thought to be very low. The mode of transmission from animal to animal, and from animal to human is uncertain.

Laboratory diagnosis

Virus isolation has been an important primary diagnostic tool in early outbreaks.

Both NiV and HeV grow well in Vero cells. A cytopathic effect (CPE) usually develops within 3 days but two 5-day passages are recommended before virus isolation is considered to be unsuccessful. However, isolation should only be attempted in a containment level 4 laboratory.

Virus neutralization tests are considered to be the reference standard in the serologic identification of NiV and HeV infection. This procedure needs to be carried out at a containment level 4 laboratory. Sera are added into the media covering virus-inoculated Vero monolayers in a 96-well plate format. Positive results are demonstrated by the inhibition of CPE production by sera.[66]

To reduce the dependence on high containment facilities (CL4), both the indirect IgG and capture IgM ELISA NiV and HeV systems can use irradiated viral antigens purified from cell culture. The level of sample processing involved to make the antigen safe to use outside Advisory Committee on Dangerous Pathogens (ACDP) 4 containment reduces the specificity and sensitivity of the assay.

NiV-specific primers that amplify a 228bp segment of the N gene region of the virus will form the basis of the RT-PCR detection system that has proven of diagnostic value when used in conjunction with specimens (sera, tissue from humans and animals) implicated in HeV and NiV outbreaks.[67] In addition, another published primer pair that amplifies a 200bp region of the matrix (M) protein will form a proven alternative primer set for the RT-PCR detection of HeV originally designed by Halpin *et al.*[64]

Management

As there are neither vaccine nor antivirals for treatment and because the viruses are potentially able to transmit by the aerosol route, both HeV and NiV have been classified as hazard group 4 agents. Working with these agents requires the use of ACDP containment level 4 laboratories. Therefore, with the increasing movement of horses and travelers to endemic areas, both clinicians and veterinarians have increasingly expressed a need to consider these infections as part of the current differential diagnosis.

Chapter 223 - Prions

Dominique Dormont

Transmissible spongiform encephalopathies (TSEs) are a group of human and animal diseases. In humans, TSEs include Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker syndrome (GSS), kuru and fatal familial insomnia (FFI). In animals, scrapie in sheep and goats, feline spongiform encephalopathy, mink transmissible encephalopathy, chronic wasting disease in wild ruminants, and bovine spongiform encephalopathy (BSE), which appeared in the UK in the mid-1980s, [1] belong to the TSE group. These diseases are all transmissible among individuals of the same species and in some cases they may pass from one species to another.

Unconventional micro-organisms known as TSE agents or prions induce TSEs. These agents have biologic and physicochemical characteristics that differ significantly from those of other micro-organisms; for example, they are resistant to inactivation processes that are effective against conventional viruses. Today, the exact nature of TSE agents or prions remains unknown even though it is likely that they consist of protein only. Transmissible spongiform encephalopathies are characterized by the accumulation, within the central nervous system (CNS) of the infected individual, of an abnormal isoform of a particular protein from the host organism, namely the prion protein (PrP).[2]

A dual causality, 'infectious' and 'genetic', of these diseases can be inferred from the various current theories. Indeed, the genetic basis of the familial forms in humans has now been confirmed. Furthermore, transmissibility has been proved in natural situations such as the outbreak of CJD among patients treated with pituitary-derived hormones and the appearance in 1986 of BSE that affected UK cattle. The fact of the transmissibility of TSEs requires strict compliance with safety regulations in sterilization, in the preparation of biologic products for therapeutic use and in the prevention of risks associated with graft processes.

NATURE

The nature of TSE agents is unknown. However, because TSEs are transmissible between different species, there are several animal models. The most common are scrapie in mice and hamsters and most of the experiments have been conducted using these two models, including attempts to isolate and to characterize TSE agents or prions.

The size of TSE agents or prions has been evaluated by utrafiltration to be between 15 and 40nm.[3] These agents aggregate easily because of their hydrophobicity; this could explain the variations in size and density that have been reported in the literature.

The inactivation processes that have been demonstrated to be effective against scrapie agents are those that denature or hydrolyze protein components: treatment with high doses of proteinase K, trypsin[4] or SDS. Diethylpyrocarbonate, guanidium thiocyanate or urea alters infectivity. Conversely, procedures that interact with nucleic acids do not modify infectivity titers: nucleases, ultraviolet treatment, Zn^{2+} hydrolysis[2] and psoralens. Therefore, one may hypothesize that TSE agents either consist of protein only or harbor a small nucleic acid that is protected within a shell that may have a lipidic or lipoproteic nature.

Because numerous experimental data indicate the absence of specific nucleic acid in the infectious fractions, the theory of a self-propagating proteic agent, or 'prion' (for proteinaceous infectious particle), was proposed at the end of the 1970s.[2] Prusiner has purified a 27–30kDa protein specifically associated with infectivity, the PrP^{SC} . This protein is present in the brains of infected individuals in proportion to the level of infection. In 1985, it was demonstrated that PrP^{SC} is an abnormal isoform of a host-encoded normal component of the host,[5] PrP^{C} , that accumulates as a result of a post-translational mechanism in the brains of infected individuals. Differences between PrP^{C} (isolated from normal individuals) and PrP^{SC} (isolated from infected individuals) have been investigated. Because the amino acid sequences of the two proteins are identical, the differences between PrP-c and PrP-res are thought to be at the level of conformation. The sensitivity to proteolytic enzymes varies; PrP^{C} is totally degraded by proteinase K concentrations that only partially degrade PrP^{SC} (Fig. 223.1); and PrP^{SC} is insoluble in detergents, although PrP^{C} is soluble. It is impossible to remove PrP^{SC} from infectious fractions without rendering them noninfectious.[6] The amount of PrP^{C} is 50 times greater in brain than in other organs; this may be a critical parameter of the pathogenesis of TSEs.[5] Other investigators have identified fibrillary structures specific for spongiform subacute encephalopathies in detergent-treated brain extracts from infected individuals, namely scrapie-associated fibrils (SAFs),[7] which are polymers of PrP^{SC} . PrP^{C} is anchored at the cell membrane, in rafts, through a glycosyl phosphatidyl inositol (GPI); its half-life at the cell surface is 5 hours, after which the protein is internalized through a caveolae-dependent mechanism and degraded in the endolysosome compartment. Conversion between PrP^{C} and PrP^{SC} occurs likely during the internalization process; this explains why PrP^{SC} is only detectable in the cytoplasm.

Prion protein amino acid and gene sequences are now well known. In humans, PrP is a 253 amino acid protein. It has two hexapeptides and repeat octapeptides at the *N*-terminus, a disulfide bond and is associated at the *C*-terminus with a GPI, which enables it to anchor to the external part of the cell membrane (Fig. 223.2). The fragment of PrP that is resistant to proteinase K digestion (PrP-res) in infected individuals is between amino acid residues 90 and 233 (molecular weight 27–30kDa). PrP^{C} has two putative sites of glycosylation; thus, three glycoforms of PrP can be described. The relative proportions of these glycoforms and the size of the unglycosylated PrP-res fragment are dependent on the strain of prion.[8] Infrared spectroscopy and circular dichroism have shown that the secondary structure of PrP^{C} is mainly composed of a-helices, whereas PrP^{SC} is mainly ß-sheets;[9] transconformation of a-helices into ß-sheets has been proposed as the structural basis by which PrP acquires pathogenicity in TSEs. Recently, the three-dimensional structures of a normal murine, bovine and hamster PrP have been published:[10] [11] [12] the protein is made of a globular domain (amino acids 121–231), which includes three a-helices and two small antiparrallel ß-sheet

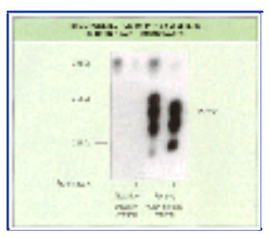

Figure 223-1 Immunodetection of PrP by Western blot in brain homogenates.

structures, and a long flexible tail whose conformation depends on the biophysical parameters of the environment (Fig. 223.3). Crystals of the globular domain of PrP have been obtained; their analysis suggest a possible dimerization of the protein through the three-dimensional swapping of the *C*-terminal helix 3 and rearrangement of the disulfide bond.[13] In-vitro conversion of PrP^{C} into PrP^{SC} is possible in acellular experimental system, and at least one of the biochemical strain characteristics of PrP^{SC} , resistance to PK digestion, can be 'transmitted' to PrP^{C} .[14]

The PrP gene (*PRNP*) is located on the short arm of chromosome 20 in humans (Fig. 223.4). It consists of two exons and one large 10kb intron. The entire coding sequence is within the second exon. The promoter of the PrP gene resembles those of housekeeping genes. Prion protein RNA is 2.1kb in length and is detected at various levels in almost all organs: brain, lung, spleen, heart, etc. (lowest expression level in liver and testicle).[5] Gene expression level is not modulated during TSEs.

Even among the most recent hypotheses, none gives a definite and complete account of the biologic, epidemiologic and clinical observations. Several hypotheses have been advanced:

- the virino hypothesis,[15] which suggests that the agent consists of a nucleic acid, which codes only for its own replication surrounded by host-encoded PrP (thus accounting for the lack of an immune response);
- the unknown conventional virus hypothesis; current concepts of microbiology indicate that this is most unlikely; and
- the protein-only hypotheses that include the seeding model, the chaperone-disease model and the prion theory.

The protein-only hypotheses are supported by the most recent results from transgenic experiments and molecular biology. In these theories, PrP^{SC} is the agent or a major constituent of the infectious fractions.[2] The prion theory postulates that pathogenicity is enciphered into the tertiary structure of PrP^{SC} . Propagation of the abnormal conformation results from the ability of PrP^{SC} to form dimers with PrP^{C} ; this heterodimerization induces a transconfor-mation of PrP^{C} into PrP^{SC} and, therefore, the propagation of this abnormal isoform of PrP (i.e. PrP^{SC}). Recently, it has been suggested that PrP^{C} transconformation into PrP^{SC} requires a host-encoded cellular factor, factor X,[16] which is thought to be a chaperone (Fig. 223.5).

Other theories involving chaperoning molecules[17] or nucleation have also been proposed;[18] in this latter hypothesis, the transformation of PrP^{C} into PrP^{SC} is reversible, PrP^{SC} being stable only when aggregated. Then, binding of PrP^{C} to PrP^{SC} aggregates results in PrP^{C} transconformation. The size of the aggregate then increases until the limit of cohesion of the aggregate, above which a dissociation occurs, giving birth to small seeds efficient for PrP^{C} transconformation. Moreover, the excess of ß-sheet measured in PrP^{SC} could be the consequence of aggregation through the globular domains which could trap a part of the flexible tail inside the aggregate and therefore induce a ß-sheet conformation of a part of the molecule that was not structured before. If demonstrated, this mechanism would not require any transconformation process of PrP.

There are major uncertainties that hinge on the nature of the agent and on the precise level at which the host's genetic background is implicated. The presence of sporadic diseases and familial forms suggests that several diseases probably co-exist under the same designation; some are of infectious origin, whereas others are probably of a metabolic and/or genetic origin. It might therefore be advisable to refer to Creutzfeldt-Jakob syndrome rather than disease in the strict sense of the word.

EPIDEMIOLOGY

Human TSEs are rare diseases, CJD being the most common. Creutzfeldt-Jakob disease can be sporadic (85–90% of cases), familial (10–15% of cases) or iatrogenic (<1%). Its incidence does not differ significantly in countries in which epidemiologic surveillance is performed;[19] incidence ranges between 1 and 1.7 per million inhabitants per year. To date, no link has been described with animal TSE except for the new variant of CJD (vCJD), which occurred mainly in the UK and is thought to

be caused by the BSE agent.[20] Several clusters of CJD have been described in the past, especially in Slovakia and Israel. Progress in molecular genetics has demonstrated that these clusters were in fact inherited forms of CJD. It should be noted that all forms of human TSEs are transmissible, including the genetic diseases.

PATHOGENICITY

Incubation and transmission

Natural and experimental TSEs are characterized by a long incubation phase without clinical symptoms; this silent phase may last as long as 40 years in humans with kuru or infected through extracted growth hormone treatment. Once started, the clinical course of the disease evolves slowly without remission. No inflammatory process is identifiable in blood or cerebrospinal fluid (CSF); none of the usual immunologic stigma or specific signs of chronic viral infections are observed in infected individuals. No virus-like or micro-organism-like structure is identifiable in the brains of infected patients, regardless of which microscopic technique is used. Transmission can be achieved by injecting ultrafiltrates of some organ extracts from infected individuals. The CNS is by far the most infectious; the spleen is also highly infectious in sheep and rodents, but at least 1000 times less so than the brain. In a given genetic background, infectivity depends on the amount injected, the strain of TSE agent and the route of infection; the intracerebral route is the most effective and the oral route the least effective (1 intracerebral route infectious unit = 125,000 oral route infectious units).[21] This has been demonstrated in experimental models, but natural disease-associated agents, especially the BSE agent, may behave differently and be more infectious by a peripheral route (including oral exposure). In-vivo, there are no alterations of the B, T and non-T non-B

Figure 223-2 Human PrP. Representation of the 253 amino acid primary sequence of the human prion protein. Stop tranfert effector (STE) is a sequence that facilitates integration of the protein into the cell membrane.

cells (quantitative or functional) and no antibody against PrP has been detected in natural or experimental diseases; therefore, there is no test available for screening asymptomatic infected individuals. These diseases are always fatal.

Transmissibility is easy in the same species, but is also possible between different species. The strength of the species barrier is variable; for example, BSE is not transmissible to hamsters although it can be transmitted to mice. Several species have never been infected with any TSE agent despite extensive attempts (e.g. rabbit or dog). The major molecular determinant of the species barrier is the homology between the PrP gene of the donor and the PrP gene of the recipient. Other genes play minor roles in TSE agent or prion susceptibility, for example major histocompatibility genes. In humans, the PrP gene exhibits a polymorphism at codon 129; either valine or methionine can be encoded, 50% of the general population being homozygous. Homozygosity at codon 129 has been associated with susceptibility to sporadic and iatrogenic CJD;[22] methionine/methionine homozygosity has also been reported in all the cases of vCJD so far described.

The role of the prion protein

The kinetics of PrP-res accumulation has been studied in a number of experimental animal models. Results have confirmed that

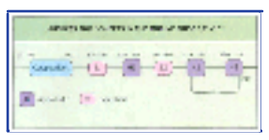

Figure 223-3 a-**Helices and** ß-**sheets in the murine PrP-c 121–231 fragment.** *Adapted from Riek et al.*[11]

accumulation follows the increase in infection. The TSE agent is detectable in the spleen of infected animals soon after a peripheral inoculation; it then appears in the CNS during the second half of the total duration of the experimental disease. In the CNS the infection develops almost exponentially until the appearance of clinical signs and death.

These facts illustrate two main characteristics of the spongiform subacute encephalopathies:

- certain organs of the infected individual, particularly the brain, spinal cord and retina, are heavily infected before clinical signs appear (Table 223.1);[23] and
- these diseases develop without interruption, that is, without any latency of the infectious agent during the asymptomatic phase.

This must be taken into consideration for the safety of biologic products and grafting processes.

The immune system plays a role during the pathogenesis of peripheral infection with TSE agents. It has been demonstrated that immune cells (most probably dendritic cells and macrophages) can be the first site of replication of these agents. In lymphoid structures, infectivity is associated with follicular dendritic cells (FDCs). Neuroinvasion then occurs through the nerve endings that are present in lymphoid organs. It is not known whether PrP^{SC} propagates in the peripheral nervous system (PNS) via a retroaxonal transport or through a propagation of abnormal conformation following a 'domino model' at the surface of the axon; the presence of PrP^{C} is required for agent propagation in the PNS.

The precise function of PrP in healthy individuals remains unknown. Several results obtained in transgenic animals indicate that PrP^{C} might play a role in long-term potentiation, in aging of the Purkinje cells of the cerebellum, in sleep physiology, in oxidative burst compensation (PrP can fix 4 Cu^{++} through its octarepeat domain), in interactions with the extracellular matrix (PrP^{C} can bind to the precursor of the laminin receptor, LRP),[24] in apoptosis and in signal transduction (co-stimulation of PrP^{C} induces a modulation of Fyn kinase phosphorylation).[25]

In TSE-affected individuals, PrP has a determinant role in the incubation time and in the species barrier[26] and its role in pathogenesis is now well established. Transgenic mice lacking *PRNP* expression (i.e. knockout mice that do not express any PrP) are not susceptible to TSE agent or prion infection, demonstrating the key role of PrP in the subacute spongiform encephalopathies.[26] Susceptibility to TSE agents or prions thus depends upon the presence of PrP^{C} on the cell membrane of the host; prions do not propagate in brains that lack PrP^{C} .[27] Moreover, in transgenic animals that express large numbers of *PRNP* copies, it has been demonstrated that incubation time is inversely correlated with PrP-c expression; that is, susceptibility to infection and prion propagation depend on the amount of PrP-c available in the host. Finally, transgenic animals with a PrP gene

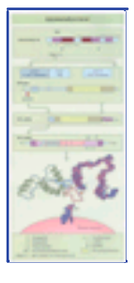

Figure 223-4 Gene structure of the PrP.

mutation equivalent to one described in human familial disease spontaneously exhibit a spongiform encephalopathy that is transmissible under certain conditions.[28]

Neuropathology

Neuropathology of TSEs consists of neuronal death, spongiosis and gliosis with hyperastrocytosis. The precise mechanisms that lead to brain cell damage are not known. Nevertheless, several experimental

TABLE 223-1 -- **World Health Organization classification of risk associated with scrapie.**

WORLD HEALTH ORGANIZATION CLASSIFICATION OF RISK ASSOCIATED WITH SCRAPIE		
Category	**Infectivity**	**Tissue/body fluid**
I	High	CNS (brain, spinal cord)
II	Medium	Spleen, tonsil, lymph nodes, ileum, proximal colon, placenta
IIIa	Some	Sciatic nerve, pituitary, adrenal, distal colon, nasal mucosa
IIIb	Minimal	CSF, thymus, bone marrow, liver, lung, pancreas, white blood cells
IV	None detectable	Skeletal muscle, heart, mammary gland, colostrum, milk, blood clot, feces, kidney, thyroid, salivary gland, ovary, uterus, testis, seminal vesicle
(Blood might be in category IIb).		

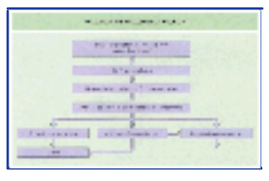

Figure 223-6 Molecular and cellular pathogenesis.

mental results indicate that neuronal death can occur in two ways: by accumulation of PrP^{SC} in vacuoles that fuse and induce cell death through a toxic mechanism; and by apoptosis of noninfected neurons induced by PrP. Indeed, exposure of primary neuronal cell cultures to peptides derived from the 106–126 domain of the PrP molecule induces apoptosis.[29] This apoptosis requires the presence of microglial cells and the presence of PrP^{C} at the cell surface; apoptotic pathway requires NMDA receptor activation. Microglial cells exposed to PrP 106–126 or to PrP^{SC} secrete interleukin(IL)-1ß, IL-6 and other neurotoxic mediators that could participate in neuronal death observed during TSEs. On the other hand, exposure of primary astrocyte cell culture to PrP^{SC} in liposomes induces astrocyte activation and hyperexpression of the glial fibrillary acidic protein (GFAP) gene, which is a biochemical hallmark of natural and experimental TSE (unpublished data). Thus, molecular pathogenesis of brain damage can be summarized as follows (Fig. 223.6).

- PrP^{C} transconformation occurs through direct contact with PrP^{SC} .
- Because of its resistance to proteolysis, PrP^{SC} accumulates in the cytoplasm of infected cells.
- Neuronal death is induced by PrP^{SC} accumulation and PrP^{sc} is released into the extracellular compartment.
- Contact with PrP^{SC} induces either apoptosis of noninfected neurons or infection.
- Contact with PrP^{SC} induces microglial cell activation and release of neurotoxic metabolites.
- Exposure of astrocytes to PrP^{SC} induces activation and hyper-expression of GFAP characteristic of gliosis.

PREVENTION

Several iatrogenic contaminations (Table 223.2) have been reported in the literature.[30] All of them have implicated the CNS as the 'donor tissue' of prions. They have occurred mainly after treatment with extracted pituitary hormones (growth hormone, gonadotropins), dura mater transplantation and the use of surgical instruments contaminated with prions. In several of these cases, transmission has been precisely documented.

In medical practice TSE-associated risk may be, theoretically, at different levels:

TABLE 223-2 -- Iatrogenic contaminations with Creutzfeldt-Jakob disease agent.

IATROGENIC CONTAMINATIONS WITH CJD AGENT			
Mode of infection	**Number of patients**	**Route of entry into brain**	**Mean incubation period**
Instruments			
Neurosurgery	4	Intracerebral	20 months
Stereotactic EEG	2	Intracerebral	18 months
Tissue transfer			
Corneal transplant	2 (+1?)	Optic nerve	18 months
Dura mater implant	115	Cerebral surface	33 months
Tympanic transplant	1	Auditory nerve	48 months
Tissue extract transfer			
Growth hormone	>120	Peripheral	15 years
Gonadotropin	5	Peripheral	13 years

- tissue grafting, including blood transfusion;
- products used in therapy that are extracted from humans, sheep or cattle, including products derived from human blood (drugs and medical devices); and
- hospital sterilization.

The appearance of vCJD in the UK and its possible link with the BSE agent also raises the risk of human contamination by the BSE prion through food or the use of bovine-derived products that are utilized in medicine.

The existence of TSEs has a number of consequences for safety in the use of biologic products in therapy. Such products must be evaluated for the potential risk of transmission of TSE agents; safety will depend on the screening of the donor or the animal source, the purification process (which may include several steps that can inactivate or eliminate TSE agents), the dose and the administration route of the final product (the intracerebral route being the most risky), and the indication for which the product is used. The replacement of biologic products with synthetic/recombinant molecules is desirable whenever possible. For biologic and synthetic molecules a precise evaluation of the therapeutic risk/benefit ratio should be performed.

Patient who have subacute encephalopathy should not be considered as graft or blood donors. Patients belonging to families with cases of familial CJD, GSS or FFI should also be excluded. Finally, it is strongly recommended that individuals with a medical history of treatment with pituitary-derived hormones or dura mater graft be excluded from blood and organ or tissue donation.

Risk associated with vCJD must also be considered, at least in countries in which exposure of the human population to the BSE agent is highly suspected. Although infectivity is restricted to the CNS and retina in classic CJD (sporadic and familial), PrP^{SC} and infectivity can be detected in lymphoid organs of vCJD patients (tonsils, lymph nodes, appendix) in all cases. This implication of the lymphoid system raises several questions, two of which are as follows.

- Are there infectious particles in blood? If so then what is the infectious load?
- Is any surgery involving contact with lymphoid tissue 'at risk' of prion transmission?

These problems are under evaluation at present and the public health consequences of vCJD will depend upon the future number of cases. Nevertheless, precautionary measures have been taken for blood transfusion and the use of plasma-derived products. Some European countries have introduced a systematic leukodepletion of blood donations; in several countries, individuals who spent more than 6 months in the UK between 1980 and 1996 are excluded from blood donation, and British plasma is no longer used for plasma derivative product purification.

Special attention must be given to the sterilization protocols that are currently used in hospitals. Transmissible spongiform encephalopathy agents or prions resist almost all of the physical and biochemical procedures generally used to inactivate conventional viruses. The resistance to disinfectants of TSE agents is exceptional. A level of decontamination compatible with viral safety may be obtained by:

- autoclaving at 273–277°F (134–136°C) for 20 minutes, but susceptibility to autoclaving varies depending on the strain of agent;[20]
- treatment with sodium hydroxide 1 or 2mol/l for 1 hour at 68°F (20°C); and
- treatment with sodium hypochloride (2% available chlorine at least) for 1 hour at 68°F (20°C).

Risks depend on the nature of the patient and/or the type of surgery. High-risk patients include CJD patients, all neurosurgical patients, patients who have a history of treatment with pituitary-extracted hormone and patients from families with documented familial CJD. High-risk procedures include neurosurgery and ophthalmology and otorhinolaryngology surgery. In all these cases (high-risk patients and/or high-risk surgery) decontamination should include at least one of the procedures recommended by World Health Organization. [23] Several countries in Europe stipulate that two of these procedures be applied consecutively. Of course, the definition of 'high-risk patients' may evolve depending upon the spread of vCJD in the human population.

DIAGNOSTIC MICROBIOLOGY

Because the nature of the TSE agent is unknown and because of the lack of a detectable immune response to infection, there is as yet no routine test that permits the diagnosis of infection in asymptomatic individuals or in patients with subacute encephalopathies. Therefore, diagnosis of TSE is most often post mortem. Neuropathology, immunohistochemistry of PrP-res accumulation in the brain and Western blot detection of proteinase K-resistant PrP (see Fig. 223.1) are the most common diagnostic tests that can be used in medical practice. Electron microscopy detection of SAF can also be used for diagnosis. Transmissibility to primates or to rodents can be helpful, but it requires a high level of safety in animal care facilities; moreover, incubation times during primary interspecies passages are often very long.

It is worth noting that neuropathology can be very discrete and that PrP^{SC} accumulation can be undetectable in several parts of the brain; a negative result is inconclusive.

Protein 14-3-3, a protein associated with neuronal death, is detectable in the CSF of human TSE-affected patients.[31] Although not specific of CJD, a positive 14-3-3 test in CSF is a strong argument in favor of a CJD diagnosis when the clinical picture is compatible and when neopterin is normal. It must be kept in mind that 14-3-3 is not elevated in all vCJD and growth hormone-related CJD cases.

CLINICAL MANIFESTATIONS

Creutzfeldt-Jakob disease is a degenerative illness of the CNS (see Chapter 26). It is characterized by a clinically silent latent stage, which may evolve over a period of 20 years or more. Clinical manifestations can vary at the onset of the disease and may include memory loss, abnormalities in movement co-ordination and psychiatric abnormalities. At the full-blown stage of the disease, the clinical picture consists of a severe dementia associated with ataxia, extrapyramidal and pyramidal syndromes, and myoclonia. All of the clinical signs are related to the CNS degeneration. It must be pointed out that few of the clinical symptoms usually associated with infectious diseases (e.g.

fever) are observed in CJD patients. Routine serological testing and nuclear magnetic resonance imaging (except for vCJD) are of little assistance; for example, there are no abnormalities in blood or CSF chemistry or cell populations, except for the frequent detection of neuron-specific enolase and protein 14-3-3 in the CSF. Conversely, the electroencephalogram exhibits pseudoperiodic abnormalities that are constituted by 1–1.5Hz triphasic sharp waves in all derivations in 75% of patients. The evolution of the disease is subacute and always fatal; patients die after a short period of coma. Creutzfeldt-Jakob disease lasts an average of 6 months in adults, but may reach more than 1 year in infants or young adults with iatrogenic disease or with CJD.

MANAGEMENT

No curative or palliative treatment for CJD or other TSEs currently exists. Only a few drugs have proved relatively effective when administered at the time of the experimental infection; they are Congo red, dextran sulfate, polyoxometalates from the tungstoantimoniate family, and amphothericin B and its derivatives.[32] [33] Polyene antibiotics seem the most promising class of drugs that may be suitable for therapy; in experimental scrapie, positive effects on survival are correlated with PrP-res accumulation delay in the brain. This underlines the key role of PrP in the pathogenesis of TSEs.

Unfortunately, none of these drugs are effective once the first clinical signs have appeared; therefore, no drug is suitable for human use.

Recently, treatment with anti-PrP antibodies has been reported as capable of curing infected cells in vitro.[34] Moreover, transgenic animals for anti-PrP antibody have been demonstrated to be less susceptible to peripheral infection than the wild-type controls.[35] This may be the proof of the principle of such a therapeutic approach and may support the possibility of a vaccine against TSEs in the future.

Chapter 224 - Staphylococci and Other Micrococcaceae

Jan Verhoef
Ad C Fluit
Franz-Josef Schmitz

NATURE

Staphylococci were first observed and cultured by Pasteur and Koch but the first thorough studies on staphylococci were made by Ogston in 1881 [1] and Rosenbach in 1884.[2]

The genus *Staphylococcus* was given its name by Ogston in 1881 when he observed grape-like clusters of bacteria in pus from human abscesses.[1] Three years later, Rosenbach [2] was able to isolate and grow these micro-organisms in pure culture. He gave them the specific epithet *Staphylococcus aureus* Rosenbach because of the yellow-to-orange pigmented appearance of their colonies.[2] Rosenbach showed that *S. aureus* was responsible for wound infections and furunculosis, and that *Staphylococcus epidermidis* was a normal colonizer of the skin. Ever since Rosenbach first described the growth of this 'golden' coccus, surgeons have feared staphylococcal wound infections after surgery.[3] Staphylococci also caused life-threatening disease after trauma and fatal pneumonia during the influenza season, killing young people in the prime of their lives.[4] Therefore, in the pre-antibiotic era, *S. aureus* was known as a major life-threatening pathogen.

Because of penicillin's important contribution to the fight against *S. aureus* disease, the period between 1946 and 1950 was referred to as 'a golden age' for the treatment of staphylococcal disease. However, the rapid spread of resistant staphylococci soon led to a return of this major pathogen.

An excellent up-to-date review on staphylococci is provided by Crossley and Archer.[5]

Taxonomy

The family of Micrococcaceae consists of four genera:

- *Planococcus*;
- *Stomatococcus*;
- *Micrococcus*; and
- *Staphylococcus*.[6]

Planococci are not found in humans, whereas *Stomatococcus* and *Micrococcus* can colonize humans but rarely produce disease.

Staphylococci are Gram-positive nonmobile cocci that characteristically divide in different patterns to form irregular grape-like clusters (Fig. 224.1). They usually produce catalase. They are facultative anaerobes but grow better under aerobic than under anaerobic conditions. Traditionally, they have been divided into coagulase-positive and coagulase-negative staphylococci. The coagulase-negative staphylococci can be subdivided at present into 32 different species (Fig. 224.2). Of the large number of staphylococci, only three are commonly associated with human disease:

- *S. aureus*;
- *S. epidermidis*; and
- *Staphylococcus saprophyticus*.

In addition, *Staphylococcus lugdunensis* and *Staphylococcus schleiferi* must be mentioned since these two species are relatively aggressive and can cause a variety of infections, including foreign body infections, bacteremia, endocarditis, bone infections and abscesses in various organs.

At the genus level staphylococci are a homogenous group of bacteria. On the basis of DNA rRNA hybridization and comparative oligonucleotide analysis of 16S rRNA they appear to be related to the *Bacillus*, *Enterococcus* and *Listeria* cluster (Fig. 224.3).

The micrococci and stomatococci are more related to *Actinomycetes*, although their cytosine-guanine rates vary from 30% to 70%.

Anatomy of the staphylococcus

Capsular polysaccharides

Staphylococci are often surrounded by a loose-fitting polysaccharide capsule. This capsule can be used to identify serotypes. Serotypes 5 and 8 are the most common and many methicillin-resistant *S. aureus* (MRSA) belong to these serotypes.[7]

When isolated from infections, *S. aureus* expresses high levels of polysaccharide but rapidly loses it upon subculture in the laboratory. The function of the capsule is not clear. It may impede phagocytosis (see below) and may therefore contribute to the invasive character of *S. aureus*.

Peptidoglycan

The peptidoglycan layer is the major macromolecule present in the cell wall (Fig. 224.4). The glycan chains are built with approximately 10 alternating subunits of *N*-acetylmuramic acid and *N*-acetylglycosamine. Pentapeptide side chains are attached to the *N*-acetylmuramic acid subunits. The glycan chains are then cross-linked with peptide bridges between the side chains.

Protein A

The surface of all strains of *S. aureus* contains proteins that protrude through the peptidoglycan layer and are anchored covalently. One of these proteins, protein A (Fig. 224.5), has the capacity to bind the Fc fragment of immunoglobulin subclasses IgG1, IgG2 and IgG4.[8] Protein A is not produced by coagulase-negative staphylococci.

Teichoic acid

The teichoic acids are macromolecules of phosphate containing polysaccharides (Fig. 224.6). Teichoic acid is bound both to the peptidoglycan layer and to the cytoplasmic membrane. The polysaccharides are species specific; ribitol teichoic acids are present in *S. aureus* cell walls and glycerol teichoic acids are present in *S. epidermidis*.[9]

EPIDEMIOLOGY

Every human being is colonized with *S. epidermidis*. The normal habitats of these staphylococci are the skin and the mucous membranes. The major habitats of the most pathogenic species, *S. aureus*, are the anterior nares and perineum.

Neonates are readily colonized by *S. epidermidis* and often by *S. aureus*. Newborn infants usually acquire *S. aureus* first on the skin (umbilical area) and later in the nose.[10] [11] Soon after the neonatal period some individuals become permanent carriers, often with the

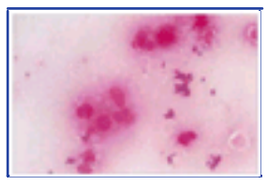

Figure 224-1 *Staphylococcus aureus* in a Gram stain of pus.

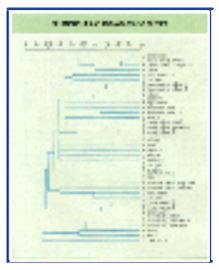

Figure 224-2 Relationship of *Staphylococcus* species. Dendrogram of the DNA relationships of *Staphylococcus* spp. and subspecies based on the relative percentage of DNA-DNA hybridization (reassociation) at optimal conditions. *Adapted with permission from Crossley and Archer.* [5]

same strain. Although some spread of *S. aureus* may occur within a family, generally the established flora of the nose prevents the acquisition of new strains.[12] However, colonization with other strains may occur when antibiotic treatment is given that leads to elimination of the susceptible carrier strain. Because this situation occurs in hospital, patients may become colonized with resistant staphylococci. Carriage rates of *S. aureus* in the nares of people outside hospital varies from 10% to 40%. Hospital patients and personnel have higher carriage rates. The carriage rates of patients may increase

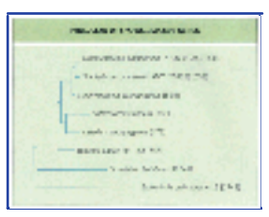

Figure 224-3 Phylogeny of *Staphylococcus* genus based on 16S rRNA sequences. *Adapted with permission from Crossley and Archer.*[5]

during their stay in hospital through colonization and nosocomial transmission. The rates are especially high in patients undergoing hemodialysis and in diabetics, drug addicts and patients who have a variety of dermatologic conditions.[13] [14]

The carrier state is clinically relevant because carriers undergoing surgery have more infections than noncarriers. This has led to the application of mupirocin (a local antibiotic) to the anterior nares in some centers just before open heart surgery to lower the incidence of postoperative wound infection.[15] Dispersers among the carriers are important because dispersers transmit staphylococci not only by direct contact but also by airborne transmission. Heavy perineal carriers almost always disperse large amounts of staphylococci. Staphylococci may accumulate rapidly on the clothes and bedding of dispersers and may disseminate when these fomites are disturbed. Dust particles containing staphylococci may be carried for considerable distances.

Since 1944, an increasing proportion of hospital-acquired *S. aureus* strains have developed resistance to penicillin because of their ability to produce ß-lactamase. By 1950, approximately 80% of hospital-acquired infections were caused by these penicillinase producers.[16] In the mid-1950s, penicillin-resistant *S. aureus* of a new phage type (the so-called phage type 80, see below) was first detected in Australia and then spread rapidly, causing a major pandemic of hospital-acquired infections.[17] Because of the 'resistance advantages' of the new *S. aureus* strain, referred to as 'hospital staph', there were again outbreaks on hospital wards. In 1959, the British Ministry of Health published guidelines for the prevention of further spread of the multiresistant — penicillin-streptomycin-tetracycline-erythromycin (PSTE)-resistant — *S. aureus* strains.[18]

A temporary respite in the war against resistant *S. aureus* occurred in the early 1960s, when Rolinson and Stevens discovered a ß-lactamase-stable penicillin (methicillin).[19] In the following years the introduction of the semisynthetic penicillins (methicillin, oxacillin, flucloxacillin) and the application of infection control measures probably contributed to the spontaneous decrease in the epidemic spread of *S. aureus* strains. However, coinciding with the disappearance of PSTE strains was the appearance of MRSA.

Early MRSA epidemics were reported in the UK in the early 1960s. [20] Later, two surveillance studies conducted by the Cross Infection Reference Laboratory in London showed that the frequency of methicillin resistance in clinical isolates from London hospitals and

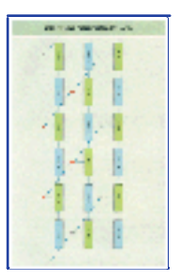

Figure 224-4 Structure of the peptidoglycan layer. The peptidoglycan layer consists of three integral parts. The glycan chains are built with 10–12 alternating *N*-acetylglucosamine (Glu) and *N*-acetylmuramic acid (Mur) subunits jointed with ß-1,4 glycosidic bonds. Vertical pentapeptide side chains are linked to the muramic acids subunits, and the side chains are in turn cross-linked with diagonal intrapeptide bridges. For example, the glycan chains in *Staphylococcus aureus* are cross-linked with pentaglycine bridges attached to L-glycine in one pentapeptide chain and D-alanine in an adjacent chain.

from hospitals in south east England increased until 1963, when it was followed by a stationary phase (below or around 1%) until 1968.[21] The rate of methicillin resistance rose sharply in the period 1968–69 (up to 5%). After another decline in major MRSA epidemics, the first serious hospital outbreaks were reported in 1970. The early MRSA epidemics could be controlled by aminoglycosides. In the late 1970s, however, resistance to gentamicin emerged in *S. aureus* and led to a new wave of hospital outbreaks. [22] Since then the MRSA strains have spread all over the world,[23] not only in hospitals but also in the community.[24] In the USA, the percentage of MRSA in all hospitals in the National Nosocomial Infection Survey system increased from 2.4% in 1975 to 29% in 1991. The incidence varied according to hospital bed capacity, with hospitals of less than 200 beds reporting 14.9% of *S. aureus* isolates as MRSA, and hospitals of 500 beds reporting a 38.3% frequency. [25] Meanwhile, the incidence has increased to nearly 40% MRSA in the USA and 6% in Canada. Within European countries a systematic survey of 27 laboratories documented a wide variation in incidence ranging from less than 1% in northern European countries to over 30–50% in Spain, France and Italy. [26]

Patients at highest risk for MRSA infection are:

- those in large tertiary-care hospitals, particularly the elderly and immunocompromised;
- those in intensive care units;
- burns patients;
- those who have surgical wounds; and

¦ patients who have intravenous lines.

Duration of hospitalization, previous antibiotic treatment and proximity to a patient colonized or infected with the organism also predispose to MRSA infection. In acute care and nursing facilities, colonized and infected patients are the major MRSA reservoir. Person-to-person transmission of MRSA usually occurs via the hands of health care workers.[14]

Typing of staphylococcal isolates

Nosocomial infections caused by *S. aureus*, especially by MRSA, are an increasing problem in hospitals. Quick and reliable typing methods are required to obtain information about the relatedness of individual *S. aureus* isolates in order to implement hygienic measures faster and more effectively. The epidemiologic goal of bacterial typing is to accurately identify the source, extent and mechanisms of transmission of outbreaks of infection. Investigations are typically triggered by an increase in the prevalence of *S. aureus* infection or by noting the appearance of isolates with a distinctive antibiotic susceptibility pattern. A convenient basis for classifying typing methods is to divide them into:

¦ phenotypic techniques — those that detect characteristics expressed by the micro-organisms, such as biotyping, antimicrobial susceptibilities, serotyping, bacteriophage typing, immunoblotting and multilocus enzyme electrophoresis; and
¦ genotypic techniques — those that involve direct DNA-based analyses of chromosomal or extrachromosomal genetic elements, such as plasmid restriction digests, ribotyping, Southern blot analysis, pulsed-field gel electrophoresis (PFGE) and polymerase chain reaction (PCR)-based methods.[27]

Bacteriophage typing (Fig. 224.7) has played an important role in the study of many epidemics of *S. aureus* infection.

The temperate bacteriophages of *S. aureus* have a narrow host range, lysing only some strains of the same species, and are therefore useful as typing phages. When phage typing became widespread, it became clear that some phage types were more endemic than others.[28]

Also, molecular typing methods are now being introduced into the study of *S. epidermidis* and *S. aureus*, particularly MRSA. Plasmid analysis has been used extensively with success but it has the disadvantage that plasmids can easily be lost and acquired and are therefore inherently unreliable. Methods designed to recognize restriction fragment length polymorphisms (RFLP) using a variety of gene probes, including rRNA genes (ribotyping), have had limited success in the epidemiology of MRSA. In this technique the choice of both the restriction enzyme used to cleave the genomic DNA and the probes is crucial.

Although there is no definitive typing technique for staphylococci, the preponderance of data indicate that PFGE is currently the single most useful and reliable reference method. This technique, in which genomic DNA is cut with a restriction enzyme that generates large fragments of 50–700kb,[29] is a variation of agarose gel electrophoresis because the orientation of the electric field across the gel is changed periodically. This change of orientation in the electric field enables DNA fragments as large as several megabases to be separated effectively by size. The restriction profiles often demonstrate remarkable

Figure 224-5 Structure and sorting of protein A. Structure of the cell wall anchor of surface proteins in *Staphylococcus aureus* and other Gram-positive bacteria. (a) Cell wall sorting of surface proteins consists of four distinct steps, which lead to the proteolytic cleavage of the polypeptide chain between threonine (T) and glycine (G). The carboxyl of threonine is subsequently amide-linked to the free amino group in the pentaglycine cross-bridge of the staphylococcal cell wall. The cell wall linkage of surface proteins in *S. aureus* (b) is compared with that proposed for other Gram-positive bacteria such as *Streptococcus pyogenes* (c) and *Listeria monocytogenes* (d). Figure 224-6 Structure of teichoic acid and linkage unit attaching teichoic acid to peptidoglycan in *Staphylococcus aureus*. The C2 and C4 positions of the ribitol residues are substituted by D-alanyl and *N*-acetylglucosamine residues. *Adapted with permission from Crossley and Archer.*[5]

variation among different strains, greatly facilitating the analysis and comparison of multiple isolates.

The most obvious 'challengers' to PFGE as the current standard for typing staphylococci are systems based on the PCR. The essential feature of PCR is the ability to replicate a particular DNA sequence rapidly and exponentially. Several different approaches have been proposed (i.e. restriction digestion of PCR products, PCR based on repetitive chromosomal sequences, arbitrarily primed PCR).

The application of molecular techniques to staphylococcal typing has provided a powerful set of new tools that can facilitate both epidemiologic investigations and patient management.[27]

Coagulase-negative staphylococci

The high prevalence of coagulase-negative staphylococci on the skin and the frequent implantation of foreign devices during hospitalization provide these bacteria with an ideal opportunity to cause infection.

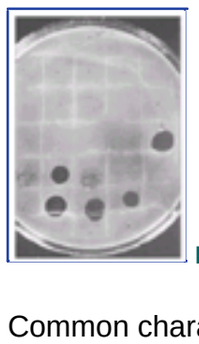

Figure 224-7 Phage type III of *Staphylococcus aureus.*

Common characteristics of coagulase-negative staphylococci infections are as follows.

¦ They are usually nosocomial.
¦ *S. epidermidis* is the most common species involved.
¦ They are associated with implanted foreign devices such as intravascular catheters, prosthetic heart valves or cerebrospinal fluid shunts.

Evaluation of the hospital reservoir of coagulase-negative staphylococci remains problematic because these bacteria form part of the normal skin flora. Although several typing systems have helped to elucidate their epidemiology,[30] evaluate their transmission and define outbreaks of nosocomial infection, little is known about the hospital reservoir of coagulase-negative staphylococci, including that of methicillin-resistant strains (MR coagulase-negative staphylococci). Such strains also serve as a reservoir for antibiotic resistance genes that may be transferred to other Gram-positive organisms, including strains of *S. aureus*. The National Nosocomial Infection Survey (NNIS) of the USA found that, between 1980 and 1989, the incidence of coagulase-negative staphylococci as a cause of nosocomial bacteremias increased from 9% to 27% to become the single most common cause of these infections. Furthermore, NNIS data revealed that during this period the proportion of MR coagulase-negative staphylococci increased from 20% to 60%. Data from the worldwide SENTRY study indicated that, independent of geographic origin, 70–75% of coagulase-negative staphylococci are nowadays resistant to methicillin. Most of these strains were also resistant to multiple additional antimicrobial agents. [26] There is therefore an association between the dramatic increase of coagulase-negative staphylococci as a cause of nosocomial infections and the resistance of these

pathogens to antimicrobial agents.[31]

STAPHYLOCOCCUS AUREUS

PATHOGENICITY

The pathogenesis of *S. aureus* infections is determined by the interaction of *S. aureus* surface-associated and extracellular proteins with host cell determinants. The pathogenesis of staphylococci is multifactorial[32] and therefore it is difficult to determine precisely the role

TABLE 224-1 -- Staphylococcal virulence factors.*

STAPHYLOCOCCAL VIRULENCE FACTORS		
Enzymes	**Toxins**	**Other**
Coagulase	Cytotoxins (a, ß, d, ? leukocidin)	Slime production
Catalase	Exfoliative (epidermolytic) toxin	Capsule
Hyaluronidase	Toxic shock syndrome	Cell wall
Fibrinolysin	Enterotoxin (A–F)	
Lipase		
Nuclease		
Penicillinase		
Overview of enzymatic, toxic and other staphylococcal virulence factors that may participate in the etiology of staphylococcal disease. Several enzymes and toxins are known to play a role in the pathogenesis of staphylococcal infection.

of each individual staphylococcal component in the etiology of staphylococcal disease (Table 224.1).

Adherence

In order to initiate infection, the pathogen must gain access to the host and attach to host cells or tissues (adherence). The *S. aureus* cells express surface proteins that promote attachment to host proteins such as laminin, fibronectin, elastin, vitronectin, fibrinogen and many other molecules that form part of the extracellular matrix. These surface proteins of *S. aureus* are called extracellular matrix binding proteins.[34]

The extracellular matrix molecules are present on epithelial and endothelial surfaces as well as being a component of blood clots. The receptor that promotes attachment to collagen is particularly associated with strains that cause osteomyelitis and septic arthritis.

Antibodies against a fusion protein encompassing a-galactosidase and the domains of fibronectin binding protein may be protective by blocking the binding of *S. aureus* to fibronectin, suggesting a possible therapeutic approach.[35]

Role of adherence in infections associated with medical devices

Staphylococcus aureus and *S. epidermidis* can cause infections associated with indwelling medical devices ranging from simple intravenous catheters to prosthetic joints and replacement heart valves. Soon after biomaterial is implanted in the human body it becomes coated with a complex mixture of host proteins and platelets (Fig. 224.8). Extracellular matrix binding proteins also play a role in the binding of *S. aureus* and *S. epidermidis* to biomaterials. Interbacterial adherence leads to biofilm formation. Recently, a polymer from *S. epidermidis* has been characterized that is involved in the intracellular adhesion between cells, leading to the formation of large cell clusters following the attachment of cells to a plastic surface during biofilm formation. The polymer, known as polysaccharide intracellular adhesin, is a linear homopolymer of ß-1,6-linked glucosamine residues, 80–85% of which are *N*-acetylated.[36]

In addition, *S. aureus* can adhere to the surface of endothelial cells and become internalized by a phagocytosis-like process. It is not clear whether attachment involves a novel receptor or a known surface protein of *S. aureus*. Some researchers think that *S. aureus* can initiate endocarditis by attaching to the undamaged endothelium. Others believe that trauma, even if very minor, is required to promote attachment of bacteria.

Invasion

As soon as microbes invade the tissues, circulating polymorphonuclear leukocytes (PMNLs) are activated. They adhere to endothelial

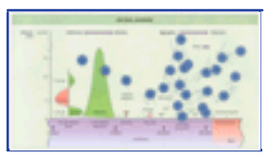

Figure 224-8 Bacterial adherence. The figure illustrates the events associated with bacterial (B) adherence to a biomaterial in relation to time and the molecular sequence in bacterial attachment, adhesion, aggregation and dispersion at substratum surface. A number of possible interactions may occur depending on the specificities of the bacteria or substratum system, the distance from the biomaterial and the stage of adherence. The attachment stage is mediated by non-specific forces. Adhesion is driven by specific adhesin-receptor interactions. The final aggregative step results in a bacterial macrocolony on the biomaterial surface in which the bacteria are firmly adherent to the biomaterial and each other. Bacterial exopolysaccharide blankets the macrocolony and may serve to improve the nutritional microenvironment and protect the bacteria from host defenses. In the dispersion phase, bacteria disaggregate, break loose from the macrocolony and drift free into the bloodstream. *Adapted with permission from Gristina AG. Biomaterial centered infection: microbial adhesion versus tissue integration. Science 1987;237:1588. © 1987 American Association for the Advancement of Science.*

cells and move through the endothelial barrier (chemotaxis). While leukocyte migration occurs, the microbes are opsonized and the microbial surface is coated with antibodies and complement factors for recognition by PMNLs.[37]

Encapsulated *S. aureus* is much more difficult to opsonize than unencapsulated strains. Four mechanisms of opsonization of unencapsulated *S. aureus* strains have been described (Fig. 224.9):

- interaction of PMNLs with *S. aureus* through antibodies against peptidoglycan;
- interaction through antibodies and C3b;
- interaction through C3b generated by direct interaction of peptidoglycan with complement (classic pathway); and
- interaction through direct activation via the alternative pathway.

Opsonization of encapsulated *S. aureus* is largely mediated by antibodies against the *O*-acetyl group of the capsular polysaccharide.[38]

Antibodies bound to specific antigens on the cell wall of bacteria (mostly peptidoglycans) serve as ligands for the attachment of bacteria to PMNLs. Antibodies against

peptidoglycan are opsonic.[39] Peptidoglycan is able to activate the complement system, leading to deposition of C3b on the surface of the bacteria. During *S. aureus* infection, antibodies are also produced against teichoic acid. Their role in opsonization is questionable and is probably indirect via activation of the complement cascade. Antipeptidoglycan antibodies promote phagocytosis in vitro but their opsonic capacity in vivo is unclear as most strains grown under in-vivo conditions contain a capsule (Fig. 224.9 Fig. 224.10 Fig. 224.11).

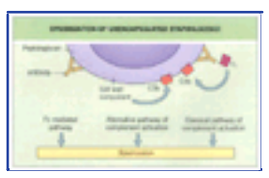

Figure 224-9 Opsonization of unencapsulated staphylococci. Opsonization through complement activation is primarily a function of C3b and iC3b. When antibody (ab) molecules bind to antigen, the antigen-antibody complex activates the first complement component, C1. C1 is then converted into an esterase, initiating the classical pathway. Additionally, some cell-wall components can activate the alternative pathway.

Although the acidic polysaccharides are not activators of the complement pathway by themselves, in the presence of anticapsular antibody they may become activators of the classic and alternative complement pathways, and binding sites for C3b may be created

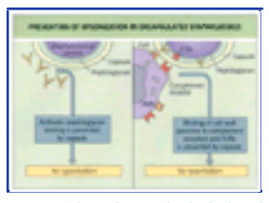

Figure 224-10 Prevention of opsonization in encapsulated staphylococci. (Left) The capsule of *Staphylococcus aureus* prevents binding of antibodies to peptidoglycan: no opsonization. (Right) The capsule prevents binding of opsonins on the cell wall of *Staphylococcus aureus* to complement and Fc receptors on PMNLs.

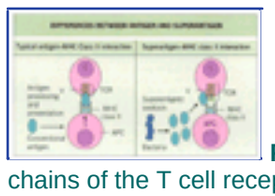

Figure 224-11 Differences between antigen and superantigen. Staphylococcal enterotoxin and TSST-1 act as superantigens, binding directly to MHC class II and the Vß chains of the T cell receptor (TCR) without the need for normal antigen processing.

within the capsular matrix so that these antibodies and C3b finally act as opsonins (see Fig. 224.9).[40]

Opsonization

Opsonization in the absence of antibody and complement

Some bacteria are able to adhere to PMNLs in the absence of antibodies and/or complement through the help of extracellular matrix molecules. These molecules may act as a bridge between PMNLs and bacteria, thus facilitating phagocytosis in the absence of specific opsonins. How important fibronectin is as an opsonin, for example, is not yet known. It is likely that optimal phagocytosis only occurs in the complement process.[41]

Evasion of opsonization

Many staphylococci have developed a defense against opsonophago-cytosis and are therefore able to escape phagocytosis by PMNLs. The most important antiphagocytic defense of staphylococci is an enveloping capsule (see Fig. 224.10). These capsules protect the microbes against PMNLs by interfering with opsonization. Two other cell wall components that help microbes evade the phagocytic defense of the host are peptidoglycans and protein A. Indeed, two mechanisms have been described to explain why encapsulated strains resist phagocytosis in the absence of type-specific anticapsular antibodies (see Fig. 224.10). The capsule shields the peptidoglycan macromolecule from reacting with antibodies and C3b, thereby preventing opsonization. No antibody reaction with peptidoglycan occurs and no complement is activated. It is also possible that, although peptidoglycan reacts with antibodies and iC3b is generated on the peptidoglycan moiety, the capsule prevents the interaction of C3b and IgG on peptidoglycan with the receptors in the membrane of PMNLs.[37]

Protein A probably plays a triple antiphagocytic role in the bacteria-cell recognition process by its binding to the Fc portion of IgG.

- ¦ Extracellular soluble protein A can react with the Fc terminal of IgG molecules of human serum, thereby producing immune aggregates that consume complement, which leads to depletion of complement needed for phagocytosis.
- ¦ Extracellular protein A can bind to the Fc portion of specific anti-staphylococcal antibodies coating the micro-organism with their Fab fragment, thereby preventing further interaction of the complex with the Fc receptor of phagocyte.
- ¦ Cell-bound protein A binds to the Fc fragment of any IgG molecule in its neighborhood, thus eliminating non-specific and specific antibodies.[42]

It has been shown that strains with high levels of protein A are less able to activate complement than strains with low levels of protein A.[43] Indeed, mutants of *S. aureus* lacking protein A are more efficiently phagocytosed in vitro, and studies with mutants in infection models suggest that protein A enhances virulence.

After opsonization, staphylococci are phagocytosed and killed. Some bacteria are usually able to escape killing and are able to survive inside PMNLs. Some strains of *S. aureus* with a special coagulase genotype may be better able to survive inside the PMNL.[33]

Toxins

Staphylococcus aureus can express several different types of protein toxin, which are probably responsible for some symptoms during infections.[44]

a-Toxin

The most potent membrane-damaging toxin of *S. aureus* is a-toxin. It is produced by a large percentage of strains and is expressed as a monomer that forms cylindric oligomeric heptamers and binds to the membrane of susceptible cells. Susceptible cells have a specific receptor for a-toxin that allows low concentrations of toxin to bind resulting in small pores through which monovalent cations can pass. At higher concentrations the toxin reacts non-specifically with membrane lipids, resulting in larger pores through which divalent cations and small molecules can pass. a-Toxin is toxic to a wide range of mammalian cells and animals and is dermonecrotic and neurotoxic.

ß-Toxin

This toxin is a sphingomyelinase that damages membranes containing sphingomyelin. Lysis of sheep erythrocytes by *S. aureus* is caused by ß-toxin. The majority of human isolates of *S. aureus* express ß-toxin but its role in disease is poorly understood. It is produced in high concentration, especially in animal strains, suggesting that it must provide some form of selective advantage to the microbe. This is supported by the fact that ß-toxin-deficient mutants are less virulent. It may play a role in the pathogenesis of bovine mastitis.

?-Toxin and Panton-Valentine leukocidin

Staphylococcus aureus strains produce bicomponent toxins composed of two independently secreted nonassociated proteins. These toxins, ?-toxin and Panton-Valentine leukocidin (PVL), are synergistically

toxic to PMNLs and monocytes and macrophages, and ?-toxin is additionally lytic for red cells from a variety of mammalian species. Recently it was shown that PVL-producing *S. aureus* strains cause rapidly progressive, hemorrhagic, necrotizing pneumonia, mainly in otherwise healthy children and young adults. This pneumonia is often preceded by influenza-like symptoms and has a high mortality rate. [45]

d-Toxin

A variety of features have been attributed to d-toxin.

- It can damage a variety of cell types as a result of its action on cell membranes.
- It causes dose-dependent damage to the bowls of guinea pigs, leading to speculation that it is a mediator of staphylococcal membranous enterocolitis.
- It increases vascular permeability in guinea pig skin, inhibits water absorption and activates adenylate cyclase.
- It has many other effects on various cell systems, such as activation of membrane phospholipase A_2 , stimulation of prostaglandin synthesis, release of lysozyme and ß-glucuronidase from PMNL granules and activation of the acetyltransferase.

Enterotoxins and toxic shock syndrome toxin-1

The enterotoxins, of which there are several serotypes (A, B, C[1] [2] [3] , D, E, G, J, K) cause diarrhea and vomiting when ingested and are responsible for staphylococcal food poisoning. Systemically, enterotoxins can cause toxic shock syndrome (TSS). First described in 1978 in association with severe infections with *S. aureus* among children, the major symptoms of TSS are high fever, generalized exanthema, hypotension, multiorgan failure and desquamation of the skin. Menstruation-related TSS is much more common than non-menstruation-related TSS. Most *S. aureus* isolates from patients who have TSS produce toxic shock syndrome toxin (TSST)-1. Enterotoxins B and C cause 50% of nonmenstrual TSS. The TSST-1 is responsible for 75% of TSS, including all menstrual cases.

The TSS can occur as a sequela to any staphylococcal infection if an enterotoxin or TSST-1 is released systemically and the host lacks appropriate neutralizing antibodies. Tampon-associated TSS is not a true infection; rather it is caused by growth of *S. aureus* in a tampon and absorption of the toxin into the bloodstream. The incidence of TSS rose sharply with the introduction of superabsorbent tampons and, although the number of such cases has decreased dramatically, they still occur despite the withdrawal of certain types of tampon from the market.

The enterotoxins and TSST-1 are superantigens. Superantigens (see Chapter 1) stimulate T cells non-specifically without normal antigenic recognition (see Fig. 224.11). Up to one in five T cells may be activated, whereas only 1 in 10,000 are stimulated during normal antigen presentation. It has been postulated that this massive activation of lymphocytes results in cytokine release, which may contribute to some of the features of TSS.

Epidermolytic (exfoliative) toxin

The epidermolytic toxin (ET) causes scalded skin syndrome in neonates, with widespread blistering and loss of the epidermis. The two antigenically distinct forms of the toxin are ETA and ETB. These toxins have protease activity. They have a sequence similarity with the *S. aureus* serine protease, and the three most important amino acids in the active site of the protease are conserved. Changing the active site of serine to a glycine completely eliminates toxin activity. It is therefore possible that the target of the toxins is a very specific protein involved in maintaining the integrity of the epidermis. Recent data indicated that the gene coding for ET is located on a phage and that isolates displaying ET activity are often clonally related.

Other extracellular proteins

Coagulase

Coagulase is an extracellular protein that binds to prothrombin to form a complex called staphylothrombin. The protease activity of thrombin is then activated, resulting in the conversion of fibrinogen to fibrin. This reaction is the basis of the tube coagulase test, in which a clot is formed in plasma after incubation with the *S. aureus*. Coagulase is the classic marker for distinguishing *S. aureus* from *S. epidermidis* in the clinical laboratory. Although there is no direct evidence that coagulase is a virulence factor, it is reasonable to speculate that the bacteria protect themselves from host defenses by causing localized clotting.

Staphylokinase

Many strains of *S. aureus* express a plasminogen activator called staphylokinase. A complex formed between staphylokinase and plasminogen activates plasmin-like proteolytic activity, which causes dissolution of fibrin clots. The mechanism is identical to that of streptokinase, which is used to treat patients who have coronary thrombosis.

Another enzyme produced by staphylococci is catalase, which converts hydrogen peroxidase into nontoxic H_2 O and O_2 . Catalase may contribute to virulence because its production allows staphylococci to evade the killing mechanism of PMNLs.

Regulation of virulence factors

Whole genome sequencing of *S. aureus* strains provided valuable new insights into potential virulence factors and their control. Many staphylococcal products can be involved in the pathogenesis of disease. [33] The expression of these genes is controlled by a number of different global regulators. Best known among these are the *agr* (accessory gene regulator) and *sar* (staphylococcal accessory regulator) loci. The regulation of the expression of various virulence factors is poorly understood but highly complex.

A global regulator may upregulate the expression of one group of virulence factors, downregulate the expression of a second group and have no influence on a third. However, the expression of these genes may also be influenced by other global regulators. Indeed, the expression of one regulator may be influenced by the expression of another. In addition, this regulation network responds to stimuli from the environment (e.g. adhesion to epithelial cells, adhesion to catheter material, presence of other staphylococcal cells). Unraveling this highly complex regulation network may help to explain the different clinical manifestations seen in *S. aureus* infections.

CLINICAL MANIFESTATIONS

Staphylococcal infections are characterized by intense suppurative inflammation of local tissues with a tendency for the infected area to become encapsulated, leading to abscess formation.[46]

Furuncle

The most common staphylococcal infection is the furuncle or boil, which is a localized painful superficial skin infection that develops in a hair follicle or gland. Similar infections at the base of the eyelashes are the common styes. The most common sites for boils are the neck and the buttocks, often as a result of wearing tight clothes. The infected patient is often a carrier of the staphylococcus that causes the infection, usually in the anterior nares. A total of 65% of furuncles, especially those on the head and neck, are caused by a strain indistinguishable from that in the patient's nose, and there are indications that perineal carriage is associated with furuncles on the legs. No specific pathogenicity factors are responsible for the pathology of furuncles. Although about 50% of strains involved in carbuncles and

furuncles have been found to produce PVL, only 2% of all *S. aureus* are producers. The course of infection is usually benign. No specific treatment is needed and most often the infection resolves after spontaneous drainage of the pus or surgical incision.

Chronic furunculosis

Approximately 2–3% of the population have chronic furunculosis, in which repeated attacks of boils are often caused by the same phage type of *S. aureus*. The most appropriate management of patients who have recurrent furunculosis includes a course of an oral antibiotic combined with chlorhexidine washes and the use of an antistaphylococcal intranasal ointment.

Carbuncle

Staphylococcal infection may spread from a furuncle to the deeper subcutaneous tissues, resulting in the development of one or more abscesses known as carbuncles. These abscesses occur mostly on the back of the neck, but may involve other skin sites. They may result in bloodstream invasion.

Bullous impetigo

Certain strains of *S. aureus* can cause bullous impetigo. This is characterized by small bullae, which form and burst. When this occurs in infants it may be described as pemphigus neonatorum.

Bullous impetigo is a highly contagious superficial skin infection characterized by large blisters containing many staphylococci in the superficial layers of the skin. Bullous impetigo is seen most often in infants and children under conditions where direct spread can occur (e.g. sharing of contaminated towels). Impetigo mainly occurs on the face and limbs. Extensive atypical bullous impetigo is associated with HIV infection.

The strains often produce exfoliative toxin and impetigo can therefore be considered as a localized form of scalded skin syndrome. The bullae are the result of epidermolytic toxins, which are serine proteases.

Botryomycosis

Botryomycosis is a rare chronic skin infection that resembles mycetoma or actinomycosis. The lesions may be nodular or granulomatous and may have draining sinuses.

Secondary cutaneous infection

The most common secondary infection occurs in people who have eczema, especially atopic dermatitis. Colonization of lesions in adults approaches 100%; children are colonized only slightly less often. Skin ulcers, especially those of the legs in the elderly, may also become heavily colonized by *S. aureus*. Similarly, hidradenitis suppurativa, a chronic suppurative disease of the skin that occurs in areas bearing apocrine glands, most often the axilla and groin, also yields *S. aureus*.

Paronychia

Another common *S. aureus* infection is paronychia, which involves the soft tissue around the nails.

Deep lesions

Staphylococcus aureus can cause a wide variety of deep tissue, often metastatic, infections. These infections include osteomyelitis, arthritis, endocarditis and cerebral, pulmonary and renal abscesses, and breast abscesses in nursing mothers.

Staphylococcus aureus can also cause bacterial pneumonia, which is almost always secondary (e.g. after influenza or other viral infections).

In many of these situations, diabetes mellitus, leukocyte defects or a general reduction of host defenses by alcoholism, malignancy, old age or corticosteroid or cytotoxic therapy are predisposing factors. Severe *S. aureus* infections, including endocarditis, are particularly common in intravenous drug abusers.

Wound infections

Staphylococcus aureus is a notorious cause of wound infection. Infections can be major complications following surgery. The source may be the patient's own carrier state, other carriers (e.g. doctors or nurses) or other infected patients. Whether a staphylococcal wound infection occurs following surgery depends upon a complex interaction between:

- ¦ host factors, including the status of the immune system and the presence of diseases such as diabetes mellitus;
- ¦ surgical factors, such as the disruption of tissue perfusion that accompanies the surgical procedure and whether foreign bodies are used;
- ¦ staphylococcal factors, including substances that mediate tissue adherence and invasion or that enable staphylococci to survive the host defenses and antibiotics in the tissues; and
- ¦ the use of antimicrobial prophylaxis.

Staphylococcal infections at the site of intravenous lines can result in bacteremia with metastatic infection.

Staphylococcal scalded skin syndrome

This term refers to a group of primarily cutaneous diseases (e.g. generalized scalded skin syndrome, staphylococcal scarlet fever and bullous impetigo) caused by the staphylococcal exfoliatin toxins exfoliatoxin A and exfoliatoxin B.

Toxic epidermal necrolysis (Lyell's disease) is also known as generalized scalded skin syndrome. It results from the production of exfoliatin toxin in a staphylococcal lesion, which can be quite minor. The toxin is absorbed into the bloodstream, and intraepidermal desquamation may occur at remote sites from which *S. aureus* cannot be isolated. The disease is most common in neonates and in children under 8 years of age, and epidemics may occur in nurseries. The face, axilla and groin are most often affected first but the erythema, bullous formation and subsequent desquamation of epithelial sheets can spread to all parts of the body. Generalized scalded skin syndrome is the most severe manifestation of exfoliatin-producing staphylococcal infections.

Milder versions of the same disease are staphylococcal scarlet fever, in which erythema occurs without desquamation, and bullous impetigo, in which there is only local desquamation.

Toxic shock syndrome

Toxic shock syndrome is a serious disease associated with *S. aureus*. As mentioned above it has been most commonly seen in young women during or immediately after menstruation and is associated with the use of highly absorbent intravaginal tampons. In such cases, *S. aureus* grows in large numbers in and around the tampon and liberates TSST-1. The disease is characterized by the development of high fever, vomiting, diarrhea, sore throat and muscle pain. Within 48 hours it may progress to severe shock with evidence of renal and hepatic damage. A skin rash may develop, followed by exfoliation at a deeper level than in scalded skin syndrome. Blood cultures are usually negative.

Staphylococcal food poisoning

Staphylococcal food poisoning results from the production of staphylococcal enterotoxin in food before ingestion. It is an intoxication, not an infection. Because of the heat resistance of the toxin, toxicity persists even if the food is heated to boiling. Ingestion of the food results in acute vomiting and diarrhea within 1–5 hours. There is prostration but usually no fever. Recovery is rapid, except sometimes

in the elderly and in those with other diseases. The diagnosis is suspected on the basis of exposure history and of the typical symptoms (nausea, vomiting, abdominal cramping and diarrhea). Worldwide, 30% of cases of food-borne illness are caused by staphylococci.

DIAGNOSIS

Most staphylococcal lesions contain numerous PMNLs and large numbers of *S. aureus*. These findings are readily demonstrated by a direct Gram smear of pus. This method is also advised for sputum samples from cases of staphylococcal pneumonia and stool specimens from patients who have staphylococcal enterocolitis.

Staphylococci grow aerobically on blood agar and typical colonies of 2mm or more in diameter develop overnight. Rapid and accurate identification of *S. aureus* is important. Rapid methods commonly used by laboratories to differentiate *S. aureus* from other staphylococcal species are:

- the slide coagulase factor reaction; and
- latex agglutination assays.

In the latter, latex particles coated with fibrinogen and IgG are used to detect protein A and clumping factor ('bound coagulase') on the cell surface of *S. aureus*. However, decreased sensitivity has been reported for several tests, especially in identifying MRSA.[47] An additional penicillin binding protein is produced by MRSA that is absent from susceptible strains. It is termed PBP2a or PBP2' and has reduced affinity to ß-lactam antibiotics. Therefore, latex agglutination assays have been developed in order to detect PBP2a. In addition, methods of DNA amplification such as the PCR are becoming increasingly useful for the specific and sensitive detection of *S. aureus* in clinical specimens. In most laboratories the presence of coagulase, coded for by the *coa* gene, is used to identify *S. aureus*. Polymerase chain reactions have been described in which staphylococcus-specific sequences have been amplified for species identification. In these studies DNA was extracted from preincubated colonies or single colonies were picked from agar plates and transferred directly to a PCR assay.[48]

Blood cultures from untreated bacteremia patients are usually positive after overnight incubation.

Deep staphylococcal infection such as osteomyelitis or endocarditis poses special diagnostic problems when the lesion cannot be aspirated. Antibodies to staphylococcal products such as hemolysin, nuclease and cell wall ribitol-teichoic acid can be detected by a variety of immunologic techniques. However, the sera of many individuals who do not have deep staphylococcal infections may also contain such antibodies and there is considerable overlap in the antibody titers of those who are and those who are not infected. Consequently, these assays have a low predictive value and are not cost-effective. These assays are ancillary at best and their results must be interpreted with caution.

MANAGEMENT

Superficial staphylococcal lesions are generally adequately treated by simple drainage of the lesion. Drainage is also important in the treatment of chronic staphylococcal infections.

Acute serious staphylococcal infections (e.g. pneumonia or bacteremia) require immediate antibiotic therapy. Antibiotic susceptibility tests should always be done because of unpredictive staphylococcal susceptibility patterns. A penicillinase-resistant penicillin or cephalosporin is normally used pending the results of a susceptibility test. Infections proved to be caused by strains susceptible to benzylpenicillin are best treated with that antibiotic. There is synergy between cell-wall-active antibiotics and the aminoglycosides when the staphylococcus is susceptible to both. Combinations of a ß-lactamase-stable semisynthetic penicillin and an aminoglycoside are often used for severe systemic infections, particularly in the immunocompromised host. Other antibiotics with good antistaphylococcal activity include clindamycin, rifampin (rifampicin) and fusidic acid.

Some chronic or recurrent infections of the compromised host can be controlled by administration of an oral preparation of one of the penicillinase-resistant penicillins over months or years.

As mentioned, an additional penicillin binding protein, PBP2a, is produced by MRSA. It has reduced affinity to ß-lactam antibiotics. The 2kb gene encoding PBP2a, *mec*A, is carried on a 40–60kb segment of DNA inserted into the staphylococcal chromosome. The added DNA often contains genes encoding resistance to other antimicrobials, insertion-sequence-like elements and genes regulating the expression of *mec*A. Methicillin-resistance of *S. aureus* mediates clinically inadequate susceptibility to all currently available ß-lactam antibiotics, and MRSA is typically resistant to several other antimicrobial agents, including aminoglycosides, chloramphenicol, clindamycin, fluoroquinolones and macrolides. Multiple resistance varies greatly geographically, so in planning treatment it is imperative to carry out susceptibility testing.[49] So far most clinical isolates have been susceptible only to vancomycin, which consequently has become the agent of choice for MRSA infections, although recently several investigators have described clinical isolates of *S. aureus* with diminished sensitivity to vancomycin. In the laboratory, vancomycin resistance has been transferred from *Enterococcus faecalis* to *S. aureus* and is stably expressed.[50] In addition, the first vancomycin-resistant *S. aureus* isolate has been detected in the USA. Probably the *van*A gene, coding for vancomycin resistance, was transferred from enterococci to *S. aureus*.

In addition, *S. aureus* isolates with reduced vancomycin susceptibility were described worldwide (GISA isolates, isolates with reduced susceptibility to glycopeptides). As far as has been studied, all these isolates contained thickened cell walls. Furthermore, all of them, with the exception of the Illinois isolate, showed reduced cross-linking when compared to isogenic revertants. Interestingly, only some of them showed a reduction in D-glutamic acid amidation. The data described so far on GISA strains seem to indicate that, depending on the strain studied, several independent mutations have been accumulated in these strains, which in various combinations lead to the observed resistance phenotype.

Probably, the following mechanisms are associated with the appearance of GISA strain:

- accelerated cell wall synthesis, which leads to a thickened cell wall that is capable of affinity trapping large amounts of vancomycin and shielding the membrane associated lipid II target molecules; and
- most probably caused by the accelerated cell wall synthesis, modifications of the nascent wall precursors, as amidation of the D-glutamic acid cannot be ensured as completely as under nonaccelerated conditions. The same may apply to the cross-linking reaction, although cross-linking will also be reduced because nonamidated precursors are poor substrates for the staphylococcal transpeptidation reaction.

Since lower nonamidation and lower cross-linking both lead to even higher consumption of vancomycin per unit of cell wall weight, they also contribute positively to the GISA resistance phenotype.

Should vancomycin resistance and reduced susceptibility to glycopeptides become widespread, alternative MRSA therapies will be urgently needed. Careless prescription of drugs active against MRSA will inevitably lead to the emergence of resistance and the permanent loss of a valuable agent. Responsible antibiotic prescription therefore mandates close and frequent consultation between the prescribing physician, the medical microbiologist and the infectious disease specialist.

Recently, new antimicrobial substances have been introduced that are valuable antistaphylococcal agents. Synercid® is a new, injectable, water-soluble semisynthetic derivative of pristinamycin. It is composed of a streptogramin B, quinupristin and a streptogramin A, dalfopristin, combined in a 30:70 ratio. Both compounds bind to the 23S RNA of the 50S ribosomal subunit. They act synergistically to inhibit protein synthesis and show good activity against MSRA. The new oxazolidinone linezolid clearly demonstrates an in-vitro activity against MRSA equal to that of vancomycin. In addition to this invitro potency, linezolid also possesses other promising features, most noticeably its lack of cross-resistance with any other mechanisms. Linezolid has been shown to possess a mechanism of action unique among Gram-positive organisms by inhibiting protein synthesis by binding to the 50S ribosomal subunits.

PREVENTION

For patients who have recurrent infection such as chronic furunculosis, preventive measures are aimed at controlling re-infection and, if possible, eliminating the carrier state. For adults, the use of chlorhexidine or hexachlorophene soaps in showering and washing increases the bactericidal activity of the skin. For those individuals or medical personnel found to be a source of infection to patients, anterior nasal carriage can be reduced and often eliminated. Although many different agents and drug

combinations have been used for eradicating nasal carriage of *S. aureus*, there is a consensus that topical mupirocin is presently the regimen of choice.[51] The high-level mupirocin resistance rate is less than 5%. Attempts to remove nasal carriage of MRSA with local antiseptics (e.g. chlorhexidine or povidone iodine) or antibiotics (e.g. bacitracin) have frequently failed. Chemotherapeutic agents for elimination include topical antimicrobials and antiseptics applied directly to the nares or other sites of carriage, systemic agents that achieve adequate concentrations in these sites, and antiseptic soaps for bathing.

Chemoprophylaxis is usually considered mandatory for surgical procedures such as hip and cardiac valve replacements, in which infection with coagulase-positive or coagulase-negative staphylococci can have devastating consequences for the prosthesis and for the patient. Brief high-dose chemoprophylaxis is given around the time of surgery with the intention of preventing superinfections, which often complicate longer periods of antibiotic administration.

More than 30 years have passed since methicillin resistance was first detected in *S. aureus*. Now hospitals worldwide experience MRSA as a major nosocomial pathogen. Three possible strategies in the control of epidemics of staphylococci, especially those of MRSA, have been proposed. [52] They include:

- the 'search and destroy' strategy;
- the *S. aureus* limitation technique (SALT) strategy; and
- the Scutari strategy.

The 'search and destroy' strategy has become the major tactic for MRSA control in countries where the MRSA threat was recognized in the 1980s. In the UK, the Hospital Infection Society and the British Society for Antimicrobial Chemotherapy published MRSA control guidelines in 1986 that were revised in 1990.[53] Included in these guidelines is the installation in hospitals during an outbreak of a dedicated isolation unit. Patients who have MRSA should be nursed in separate rooms or wards by designated personnel using special barrier techniques: the use of gloves and handwashing with an antiseptic detergent, disposable gowns, masks and strict environmental hygiene. This last point is especially important as MRSA is extremely resistant to drying and can survive anywhere (e.g. in tourniquets, mattresses, air-conditioning systems).[54] These guidelines were followed to control the three MRSA epidemics that occurred in the Utrecht University Hospital in The Netherlands.[55]

The SALT strategy stresses the isolation of MRSA-infected patients, whereas MRSA-colonized patients are nursed with precautions for infections only. This would be a rational strategy if one could assume that MRSA carriers do not spread MRSA and that MRSA from infection sites are more virulent. However, there is no indication that MRSA strains differ in virulence. Nevertheless, the SALT strategy may be the only manner in which hospitals with high rates of MRSA can achieve some degree of control.

The Scutari strategy was named after the hospital where Florence Nightingale worked during the Crimean War (1854–1856) and is based on simple hygiene such as handwashing and barrier nursing. This strategy, however, is insufficient to combat MRSA in hospitals. Nevertheless, these general guidelines of simple hygiene can be applied in other settings, such as nursing homes.

Is it worth spending so much time and money to try to prevent the spread of MRSA, a bacterium that often colonizes patients but only causes infections in a minority of cases, most of which can be treated? In those countries where the incidence is still low the answer should be 'yes'. Several authors have proposed that the carriage of MRSA poses an increased risk of infection over the carriage of methicillin-susceptible *S. aureus* (MSSA). Among patients on continuous ambulatory peritoneal dialysis, MRSA carriers have a higher risk for MRSA infections than noncarriers. Perioperative colonization with MRSA significantly increases the risk for postoperative MRSA infection in patients on the intensive care unit. Studying the rate of bacteremia in patients admitted to the intensive care unit, patients colonized with MSSA in the nares had a significantly increased risk for the development of *S. aureus* bacteremia but patients colonized with MRSA had a much higher risk. It seems clear that MRSA carriage constitutes a greater risk for the development of *S. aureus* infection than MSSA carriage.[56] Several studies have failed to show a difference between MRSA and MSSA in terms of virulence. It is therefore most likely that the increased infection rate observed in carriers of MRSA is primarily due to the selection of a more vulnerable group of patients who become carriers of MRSA.

Furthermore, time is running out for the treatment of MRSA infections. Already, the first vancomycin-resistant MRSA has been reported. Increased use of mupirocin as a topical therapy for MRSA carriage may also result in increased mupirocin resistance.[57]

Vaccines and new approaches to combating nosocomial infections

No vaccine is currently available to combat staphylococcal infection. Hyperimmune serum from human volunteer donors or humanized monoclonal antibodies directed toward surface components (e.g. capsular polysaccharide or surface protein adhesions) could both prevent bacterial adherence and promote phagocytosis of bacterial cells. A prototype vaccine based on capsular polysaccharide from *S. aureus* has been administered to volunteers to raise hyperimmune serum, which could be given to patients in hospital before surgery. A vaccine based on fibronectin-binding protein induces protective immunity against mastitis in cattle and might also be used as a vaccine in humans.[58]

STAPHYLOCOCCUS EPIDERMIDIS

PATHOGENICITY

Coagulase-negative staphylococci are frequently isolated from various clinical specimens in the clinical microbiology laboratory. In the past, these isolates were often discarded as contaminants. This situation has radically changed during the past two decades, with coagulase-negative staphylococci now being recognized as an important cause of nosocomial infections.[59]

Intravascular catheters, cerebrospinal fluid shunts, peritoneal dialysates, prosthetic cardiac valves and blood cultures frequently yield coagulase-negative staphylococci. Every isolate from such sources must be carefully evaluated for its clinical significance, although interpretation of the culture remains a challenge to all physicians, even in combination with the clinical presentation of the patient.

In general, coagulase-negative staphylococci become potentially pathogenic as soon as the natural balance between micro-organisms and the immune system is disturbed. This is exemplified in immunocompromised patients such as oncology patients and premature neonates in whom coagulase-negative staphylococcal infections frequently occur in association with the use of intravascular devices. The increase in incidence of infections with coagulase-negative staphylococci is probably related to the increased use of intravascular devices. Furthermore, the presence of large numbers of coagulase-negative staphylococci on the skin, their ability to adhere to biomaterial surfaces and the selection of resistant strains by the use of broad-spectrum antibiotics in hospital have all been cited as possible reasons for the increased rate of infection with coagulase-negative staphylococci.

Of all coagulase-negative staphylococci, *S. epidermidis* is the most frequently isolated species associated with catheter-related infections. The main adhesins responsible for binding *S. epidermidis* to catheters are:

- a capsular polysaccharide; and
- a protease-sensitive surface constituent from the slime-producing strains of *S. epidermidis*.

In addition to promoting adherence to foreign bodies, these adhesins may also protect coagulase-negative staphylococci against phagocytosis and prevent reaction of antibodies to cell-wall components. Specific antibodies to these adhesins may neutralize this shield and are often needed for efficient opsonization of the bacteria. Monoclonal and polyclonal antibodies against *S. epidermidis* adhesins facilitate phagocytosis of homologous *S. epidermidis* strains and protect animals against endocarditis.[60] Most important in the pathogenesis of foreign-body-associated infections is the ability of these bacteria to colonize the polymer surface through the formation of a thick, multilayered biofilm. Biofilm formation takes place in two phases. The first phase involves the attachment of the bacteria to polymer surfaces, which may be either unmodified or coated with host extracellular matrix proteins. In the second phase, the bacteria proliferate and accumulate into multilayered cell clusters embedded in an extracellular material.

The major PMNL receptor for *S. epidermidis* opsonins is the FcRIII receptor.[61] For strains that have a hydrophobic surface structure, however, antibodies alone are not sufficient for opsonization. Either C3b or iC3b is also needed, but deposition or transformation of C3 into the opsonic-active C3b on the surface of *S. epidermidis* is largely facilitated by antibodies. In hypogammaglobulinemic preterm babies, C3b generation by *S. epidermidis* may therefore be impeded and the antibody deficiency state may contribute to the persistence of *S. epidermidis* bacteremia in very-low-birth-weight infants.[62]

CLINICAL MANIFESTATIONS

Catheter-related infections

Staphylococcus epidermidis is the most frequently isolated coagulase-negative staphylococcal species in catheter-related infections, especially in children.[63] These infections have been reported in association with central hyperalimentation catheters, peripheral intravenous catheters, subclavian catheters, Hickmann and Broviac central lines and Swan-Ganz catheters. As can be seen in Figure 224.12 , there are

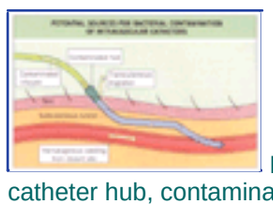

Figure 224-12 Potential sources for bacterial contamination of intravascular catheters. Bacteria gain access to the catheter by the following routes: contamination of the catheter hub, contamination of the infusate, transcutaneous migration and hematogenous seeding.

different potential sources for bacterial contamination of intravascular catheters.

The diagnosis of a catheter-related infection is often a physician's nightmare. Catheters may be colonized without local signs of infection (i.e. without gross evidence of purulence or erythema at the insertion site of the catheter). Furthermore, blood cultures may yield *S. epidermidis* without the patient showing major clinical symptoms.

A diagnosis of catheter-related infection is based on a proper collection of at least three blood cultures from different sites of venepuncture within 24 hours. In addition, culture of the intravascular catheter segment should be performed according to current standards. In most clinical microbiology laboratories, the intravascular segment of the catheter is cultured according to the method of Maki and colleagues.[64] Catheter segments are cultured after being 'rolled' over a blood agar plate and, after incubation for 18 hours at 98.6°F (37°C), the number of colony-forming units (cfu) are counted. Cultures yielding more than 15cfu/blood agar plate are associated with catheter-related bacteremia (see also Chapter 57).

Cerebrospinal fluid shunt infections

Both *S. epidermidis* and *S. aureus* strains are the most frequently encountered isolates in cerebrospinal fluid shunt infections. Infections usually occur within 2 weeks of implantation or manipulation of the shunt. Clinical manifestations are usually non-specific (see Chapter 28).

Peritonitis

About 40% of patients who have continuous ambulatory peritoneal dialysis develop peritonitis during the first year (overall incidence ranging from 0.6 to 6.3 episodes/patient-year). Criteria for diagnosis include a combination of:

- abdominal pain;
- cloudy fluid containing more than 100 white blood cells/mm^3 (the majority of which are PMNLs); and
- a positive dialysate culture.

Staphylococcus epidermidis is by far the most frequently isolated organism in patients who have peritonitis associated with continuous ambulatory peritoneal dialysis.

Endocarditis

Infections of native cardiac valves with coagulase-negative staphylococci are uncommon, accounting for only about 5% of all cases of infective endocarditis. However,

for the majority of cases of nosocomial infective endocarditis. These bacteria are the single most common cause of infections of prosthetic cardiac valves, and *S. epidermidis* is the cause of approximately 40% of cases of prosthetic valve endocarditis (see Chapter 57).

In more than 80% of patients, *S. epidermidis* valve endocarditis is associated with valve dysfunction or persistent fever during therapy. The infection is most frequently located in the valve sewing ring, resulting in complications such as dehiscence, dysrhythmia and obstruction of the valve orifice. Fever usually persists during therapy because the valve ring abscess is relatively protected from antibiotics. *Staphylococcus epidermidis* prosthetic valve endocarditis shows an indolent clinical picture without the classic endocarditis findings such as peripheral emboli and multiple positive blood cultures.

Valve dysfunction and fever are the most frequent symptoms. Most patients are infected at the time of cardiac surgery but the incubation period can vary, with a latency of 2–13 months before symptoms arise.

Orthopedic implant infections

Although the incidence of infection of indwelling prostheses is only 1–5%, such infections are devastating. Usually, infected prostheses must be removed, which may result in organic defects. Fewer than 10% of prosthetic hip and knee infections have been treated successfully without removing the prosthesis. Prosthetic joints may become infected either by local introduction of organisms or by hematogenous seeding. Staphylococci are the most frequently isolated pathogens, causing more than 70% of prosthetic joint infections (see also Chapter 53).

Infections in immunocompromised patients

The coagulase-negative staphylococci have emerged as pathogens in immunocompromised hosts, notably patients on neonatal intensive care units and oncology patients. Most coagulase-negative staphylococci infections in these patients are related to the use of foreign devices, especially central intravascular catheters (see Chapter 100).

Urinary tract infection

Among the coagulase-negative staphylococci, *S. saprophyticus* can cause spontaneous acute urinary tract infection in previously healthy people. With a few exceptions these are women aged 16–25 years. The disease appears soon after the woman becomes sexually active and the symptomatology closely resembles that of urinary tract infection caused by *Escherichia coli* (see Chapter 67).

Chapter 225 - Streptococci and Related Genera

Ellen M Mascini
Stig E Holm

INTRODUCTION

The genus *Streptococcus* consists of round or slightly oval Gram-positive cocci with a diameter of <2µm. The cocci are often in pairs or chains. The detection of cytochrome enzymes with the catalase test distinguishes members of the catalase-positive family of Micrococcaceae from the members of the family of Streptococcaceae, which are catalase negative. Most of these micro-organisms are facultative anaerobes, but some need carbon dioxide for growth and others may be strictly anaerobic. The major representatives of the genus *Streptococcus* include *Streptococcus* and *Enterococcus*.[1] The further division of streptococci has been the topic of an extensive taxonomic re-evaluation and we still lack a complete picture of the genetic relationship between different subgenera and species. Some of the older classification systems are therefore still in use despite access to more accurate genetic taxonomic methods.

The traditional division of streptococci into a-streptococci, ß-streptococci and ?-streptococci on the basis of the capacity of the bacterial colony to hemolyze erythrocytes in the blood agar medium is still considered the first step in the classification of streptococci. The clear zone produced by lysis of the erythrocytes around the colony is typical of the ß-hemolytic streptococci, but the zone may vary considerably in size (Fig. 225.1). Colonies of a-hemolytic streptococci are surrounded by a zone that is usually green (Fig. 225.2), whereas no color changes (and no hemolysis) are seen around the colonies of ?-streptococci on blood agar plates.

In addition, the colony size of the ß-hemolytic streptococci is sometimes used as a taxonomic tool. Thus, ß-hemolytic streptococci belonging to Lancefield groups A, C and G can be separated into large-colony (>0.5mm diameter) and small-colony (<0.5mm diameter) streptococci. The large-colony forms are usually designated 'pyogenic streptococci'; the small ones are representatives of the *Streptococcus milleri* group.

The further classification of streptococci involves biochemical analysis, including carbohydrate fermentation and detection of enzymatic activities. During the past 10 years genetic methods have been applied increasingly to taxonomic studies of streptococci and related organisms, for instance DNA-DNA and DNA-rRNA hybridization analysis, and small subunit (16S) rRNA sequencing. The latter technique has become the most powerful approach for delineating the phylogenetic interrelation of micro-organisms. Whereas the pyogenic streptococci (groups A, C and G) phylogenetically cluster together, the a-hemolytic streptococci fall into several different phylogenetic groups.

DIAGNOSTIC MICROBIOLOGY

Streptococci can be identified (Table 225.1) on the basis of:

- their hemolytic qualities;
- rapid antigen detection tests;
- serologic assays for detection of cell wall or capsular antigens;
- physiologic and biochemical tests; and
- molecular biologic tests.[2]

Streptococci are catalase negative and fermentation of carbohydrates is accompanied by the production of lactic acid. Streptococci are oxidase negative, a property that, together with the Gram stain, differentiates streptococci from *Neisseria* spp. Nutritional requirements are high; medium containing blood or serum is necessary for their growth (Fig. 225.3). Streptococcal colonies on blood agar can appear as mucoid mat or glistering. This appearance relates to the amount of hyaluronic acid capsule produced by the streptococci. Some of the oral streptococci may form bactericidal substances, so-called bacteriocins, which might inhibit the growth of other (ß-hemolytic) streptococcal species in the surrounding area (Fig. 225.4). [3]

The surface structure of the pyogenic streptococci (groups A, C and G), together with the highly biologically active toxins and enzymes released by the cells, forms the basis of the pathogenesis of these streptococci. The cell wall is composed of a framework of peptidoglycan similar to that found in other Gram-positive bacteria. The group-specific polysaccharide is fixed to peptidoglycan through phosphate bridges, composed of one or several units of glycerol and glycerol rhamnoside.

A rapid, preliminary diagnosis of infections caused by streptococci can be achieved by Gram stain of properly obtained specimens (e.g. sputum, cerebrospinal fluid, pus). The presence of Gram-positive cocci in chains or pairs associated with leukocytes is indicative of the diagnosis of streptococcal infections (Fig 225.5 and Fig 225.6). The skin is not normally colonized by streptococci, but streptococci are part of the commensal oropharyngeal flora; their presence in respiratory specimens collected from patients with pharyngitis has poor predictive value.

Further identification of streptococci may be achieved using extended biochemical and physiologic tests. For this purpose, diagnostic microbiologic laboratories can use standardized, commercially available laboratory kits such as API-20 Strep and Rapid Ig 32 Strep (Fig. 225.7). [4] Generally, these tests have high stability and good reproducibility between different laboratories and there is a database for interpretation of the reaction patterns.

For special epidemiologic purposes, molecular biologic typing techniques may be employed but these are not yet used in routine diagnosis.

ß-Hemolytic streptococci

The ß-hemolytic streptococci have long been considered the main pathogenic streptococci. Table 225.2 illustrates the characteristics of ß-hemolytic streptococci in groups A, C and G, as well as those of streptococci in groups B and F, which may also produce ß-hemolytic colonies on blood agar plates.[2] [5]

Serologic analysis is based on differences in group-specific antigens, which are either carbohydrates or teichoic acids on the cell wall. This allows separation of streptococci into 20 different serogroups (the Lancefield grouping system).[6] Grouping involves a two-stage procedure with rapid acid or enzymatic antigen extraction, followed by immunospecific precipitation or agglutination reactions.

Figure 225-1 ß-**Hemolytic streptococci group A on a blood agar plate.** Note the clear ß-hemolytic zone.

Figure 225-2 a-**Hemolytic streptococci on a blood agar plate.** Note the small greenish zone surrounding the colonies, which is a characteristic of viridans streptococci.

TABLE 225-1 -- Commonly used methods for typing streptococci.

COMMONLY USED METHODS FOR TYPING STREPTOCOCCI		
Serologic methods	M typing and T typing	
	R typing	
	OF typing (inhibition of the opacity reaction) group A streptococci	
	Polysaccharide antigen typing combined with protein antigen typing in group B streptococci	
	Latex agglutination	
Molecular methods	DNA fingerprinting	• M genotyping
		• pulsed-field gel electrophoresis
		• multilocus sequence typing
		• amplified fragment length polymorphism
	Ribotyping	
Other methods	Multilocus enzyme electrophoresis	
	Whole cell protein analysis	
Rarely used methods	Bacteriophage typing	
	Bacteriocin typing	

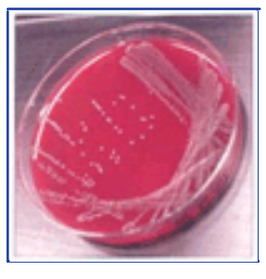

Figure 225-3 ?-**Streptococci on a blood agar plate.** Note the absence of hemolysis.

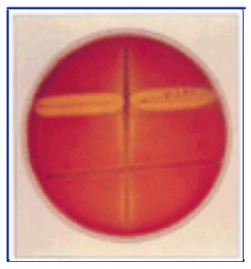

Figure 225-4 Bacterial interference. Inhibition of growth of ß-hemolytic streptococci by an a-hemolytic *Streptococcus* sp. No such inhibition is seen with other streptococci.

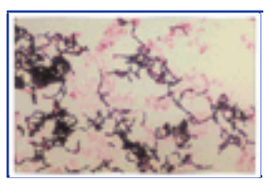

Figure 225-5 Gram-stain of ß-hemolytic streptococci group A.

Commercial kit systems in which group-specific antisera (usually containing A, B, C, D, F or G antibodies) are coupled to latex beads are now widely used for identification of ß-hemolytic streptococci.[7] In a positive test the latex particles clump together; in a negative test they stay separate, giving the suspension a milky appearance (Fig. 225.8).

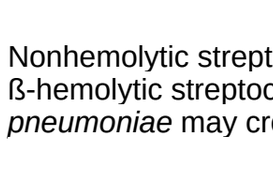

Figure 225-6 Gram stain of a sputum sample infected with *Streptococcus pneumoniae.*

Nonhemolytic streptococci do not possess Lancefield cell wall grouping antigens, but some strains may possess similar antigens that show cross-reaction with ß-hemolytic streptococcal group-specific antisera. Thus, proper assessment of hemolysis is essential for the reliability of the test because, for instance, *Streptococcus pneumoniae* may cross-react with group C latex reagent.

Group A streptococci

Cell wall antigens

From the blood agar plates, suspected hemolytic streptococcal colonies are subjected to Lancefield grouping as described above. Typing of group A streptococcal isolates is reserved mainly for laboratories specializing in streptococcal diagnostics and research. The cell wall proteins of group A streptococci that are used in strain typing include T protein and M protein. T protein is used for classification purposes, although it does not contribute to streptococcal pathogenesis. All group A streptococci carry one or more T antigens, which have a correlation with the M protein. The presence or absence of opacity factor divides the streptococci into two groups, which further facilitates a final typing by the T agglutination test. M antigen, a potent virulence factor, is the basis for the further serologic and genetic identification of more than 100 types.[8] Using specific antisera against these M proteins and sequence typing, more than 90% of fresh isolates of group A streptococcal isolates can be typed. Thus, subclones within group A streptococci carrying the same M protein have been described. However, the discriminatory power of these sera depends on the quality of the antisera and the size of the serum panel. This means that many isolates will be registered as 'nontypable'. This is also true for isolates that have lost the M protein or express only very low amounts of M protein on their surface.

Streptococcal typing by M-genotyping has been useful not only as a tool for general epidemiologic studies but also in analyses of correlation between streptococcal types and a clinical condition (see Clinical manifestations, below). Further discrimination between isolates belonging to the same M-type may be achieved by pulsed-field gel electrophoresis, multilocus sequence typing or amplified fragment length polymorphism.

Rapid antigen detection tests

Nonculture rapid antigen kits for direct detection of group A streptococci in patient samples are widely used.[9] The grouping antigen is extracted from the throat swab using nitrous acid or enzymatic treatment, followed by a procedure to detect the antigen. Most assays use latex agglutination or other immunoassays for antigen detection. It has been shown that these tests have high specificity (>95% in most kits) but variable sensitivity (50–90%) compared with culture techniques. False-negative results are common in the nonhospital setting; specimens from patients with clinical signs of pharyngitis and a negative antigen detection test should undergo routine culturing for streptococcal identification.

The use of rapid diagnostic tests eliminates the need for further epidemiologic analysis and streptococcal surveillance, but the costs of the kits and the extra clinical time spent on carrying out the tests limit their usefulness.

Serology

Determination of antistreptococcal antibodies may be helpful for diagnosing recent streptococcal infections. Streptolysin O is a strong immunogen and antibodies against this factor can be determined for demonstration of a recent infection with group A streptococci.[10] Streptolysin O binds easily to cholesterol and this binding eliminates its hemolytic and immune-stimulating activities. Therefore, in contrast to other streptococcal infections such as pharyngitis, infection in the skin often gives poor immune response to streptolysin O. Deoxyribonuclease (DNase) is produced by group A streptococci in four different antigenic variants, designated A, B, C and D. Most strains produce the B type and antibodies against this can be determined routinely to complement the antistreptolysin O determination in streptococcal infections of the skin; anti-DNase B antibodies appear after exposure to both dermal and respiratory infections. Ideally, two serum samples (acute-phase serum and convalescent serum) are tested for antistreptolysin O and anti-DNase B; a 4-fold increase in the titer is suggested as being significant. However, antibody responses may be depressed in patients receiving early antibiotic treatment for the infection.

The group A streptococci also produce other enzymes such as nicotinamide adenine dinucleotidase (NADase) and hyaluronidase. Antibodies are developed against both these enzymes and anti-hyaluronidase determination can be used in parallel with antistreptolysin O determination to detect a previous streptococcal infection.

Biochemical and enzymatic assays

Streptolysin S, which is heat stable, is responsible for the ß-hemolysis that occurs around the streptococcal colonies in blood agar. The so-called pyr test demonstrates the presence of pyrolidonylamidase, which is almost exclusively produced by ß-hemolytic streptococci of group A and is often used for biochemical characterization of streptococci. It should be mentioned, however, that ß-hemolytic colonies of enterococci can also produce this enzyme. The differentiation between these micro-organisms is often easily done by their differences in colony size and morphology.

The Vogues-Proskauer (VP) test for demonstration of ascetoin production helps to differentiate the small colony forming ß-hemolytic streptococci belonging to the *S. milleri* group, which carry the polysaccharide antigens of Lancefield groups A, C, F and G, from the large colony forming pyogenic streptococci of these serologic groups.

Group B streptococci

Cell wall antigens

The group B streptococci can also be divided into several types based on the differences in the polysaccharide capsule of the organism. These types are designated 1a, 1b and 2–10. These capsular polysaccharides are high molecular weight polymers with straight backbone structures containing short side chains. The composition of the polysaccharide varies but contains galactose, glucose, *N*-acetylgucosamin and *N*-acetylneuraminic acid (sialic acid).[11] The

Figure 225-7 API-20 Strep tests for the identification of streptococci. (a) *Streptococcus equisimilis* ATCC 35666. (b) *Enterococcus faecium* ATCC 35667. (c) *Streptococcus mutans* ATCC 35668. (d) Interpretation scheme.

group B streptococci also have several protein antigens on the surface (designated C, R and X), which can be used to characterize the different serotypes. Their functional significance has not been defined.

Rapid antigen detection tests

Group B streptococci can be diagnosed in cerebrospinal fluid, serum and urine by agglutination assays, in which antibodies against group-specific antigens attached to latex particles recognize the group B streptococcus. These assays cannot be used to screen pregnant women for carriage of group B streptococci. Rapid tests to screen pregnant women include enzyme immunoassays, but because they are not yet sensitive and specific enough, their clinical use is limited.[12]

Biochemical and enzymatic assays

The CAMP assay is used for identification of group B streptococci. It is based on the production of an extracellular protein, the so-called CAMP (Christie, Atkins and Munck-Pedersen) factor. This factor has the capacity to lyse erythrocytes in the presence of staphylococcal ß-lysin. A ß-lysin-producing strain of *Staphylococcus aureus* is streaked at right angles to a streak of the suspected group B streptococci on a sheep blood agar plate. After incubation at 95°F (35°F)

overnight, an arrowhead-shaped zone of ß-hemolysis will be seen in the area where staphylococcal ß-lysin and CAMP factor meet (Fig. 225.9). Otherwise, group B streptococci can be distinguished by hydrolysis of hippurate or by growth on selective media (e.g. new Granada medium).[13]

Group C and G streptococci

Group C isolates can be differentiated into species on the basis of their capacity to ferment carbohydrates (see Fig. 225.4). However, genetic analysis of group C and G streptococci has shown that human isolates of the group C species *Streptococcus equisimilis* are closely related to group G large colony human isolates and may therefore be classified in the same species. Furthermore, molecular studies have indicated that *Streptococcus zooepidemicus* probably is a subspecies of *Streptococcus equi*.[14] The large colony forming ß-hemolytic streptococci belonging to the Lancefield groups C and G have a disease spectrum and an epidemiology similar to those of the group A streptococci.[15] [16] [17] It should be added that these streptococci are not identified with the quick tests usually employed today to aid streptococcal diagnosis in primary health care. This means that if culture is not performed the diagnosis of throat infections caused by these micro-organisms will be missed.

Group D streptococci (enterococcal and nonenterococcal species)

It is now generally accepted that enterococci are sufficiently different from the other members of the *Streptococcus* genus to represent a separate genus, *Enterococcus*. This is based on the genetic information on *Streptococcus faecalis* and *Streptococcus faecium*, but further analysis by DNA-DNA and DNA-RNA hybridization as well as sequencing by 16S RNA indicate that at least 11 more species should be incorporated into this genus.

Biochemical and enzymatic assays

Most enterococci produce an a-hemolytic (greenish) zone on the blood agar plates but also nonhemolytic colonies as well as complete lysis of the blood around the colonies may be produced by some species (Fig. 225.10). Other characteristics of the enterococcus group, such as growth in broth containing 6.5% sodium chloride and hydrolysis of esculin in the presence of 40% bile salts (bile-esculin medium), help to distinguish between streptococci and enterococci. Furthermore, all strains produce leucinaminopeptidase. In most cases it is possible to extract a cell wall-associated glycerol-teichoic acid, which is identical to the streptococcal group D antigen. The physiologic characteristics of the enterococcus group mentioned above are not restricted to the genus *Enterococcus* and it is now accepted that a number of other micro-organisms may have several or all of these characteristics, including most species of the genus *Pediococcus* and several species of the genus *Leuconostoc* (see Fig. 225.8). *Leuconostoc* spp. can, for example, grow in a bile-esculin milieu and in high salt concentrations, and the group D antiserum test is also positive. However, they show intrinsic resistance to vancomycin, which is not usually the case with *Enterococcus* spp. Additionally, *Streptococcus*

Figure 225-10 *Enterococcus faecalis* on a blood agar plate.

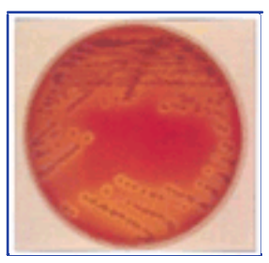

Figure 225-11 Mucoid *Streptococcus pneumoniae* on a blood agar plate.

bovis and *Streptococcus equinus*, of which the primary hosts are animals, belong to the nonenterococcal group D streptococci. *Streptococcus bovis*, unlike the enterococci, does not grow in 6.5% sodium chloride.

a-Hemolytic streptococci

Streptococcus pneumoniae (or pneumococci) are facultative anaerobic bacteria that are usually found as lancet-shaped cells in diploid form or in short chains. In order to be reliable, sputum specimens tested for the presence of pneumococci should be devoid of saliva containing epithelial cells and viridans streptococci, the most prevalent organisms among the oral flora.

Cell wall antigens

Differences in the capsular polysaccharide structure among the isolates allow discrimination between 84 different pneumococcal serotypes. The appearance of pneumococcal colonies depends on the degree of encapsulation; heavily encapsulated strains form larger colonies and appear very mucoid (Fig. 225.11). In Gram stains the capsule is visible as a pink halo or a nonstaining zone around the bacteria. On prolonged incubation, colonies on blood agar plates typically appear as checker pieces surrounded by an intensely greenish color (the a-hemolytic zone).

Rapid antigen detection tests

Soluble pneumococcal capsular polysaccharides can be rapidly detected in infected body fluids by very sensitive immunologic assays. This is especially beneficial in patients who have pneumococcal meningitis. In about half of meningitis patients, cultures may be negative after the administration of even a single dose of antibiotics, yet the antigen detection tests will remain positive.

Biochemical and enzymatic assays

Pneumococci are fastidious and some strains also need carbon dioxide for good growth. They produce an autolytic enzyme (L-alanine-uramylamidase), which has a capacity to hydrolyze the cell wall. This enzyme is activated by detergents such as bile, which results in the lysis of the cell. Optochin (ethylhydrocupreinhydrochloride) inhibits the growth of most pneumococci, in contrast to other a-hemolytic streptococci, and is thus an easy method for distinguishing between these species.

Serology

In routine diagnosis, serologic tests for pneumococcal infections are of limited clinical value because acute and convalescent sera are usually not available and only a limited number of antigens can be used. However, using the C polysaccharide and pneumolysin as antigens, antibody tests have been developed. Unfortunately, antibodies against C polysaccharide develop poorly in children, but in adults an enzyme-linked immunosorbent assay (ELISA) technique based on the C polysaccharide has been valuable for the diagnosis of pneumococcal pneumonia. Determination of antibodies against pneumolysin by ELISA has been applied successfully to establish the pneumococcal etiology in adult patients with pneumonia.

Molecular biology

Development of rapid DNA diagnostic tests such as polymerase chain reaction (PCR) for detection of pneumococci in middle-ear fluid are in progress. [18]

Viridans group streptococci

Traditionally, the name viridans streptococci was given to a-streptococci isolated from the oral region but lacking the Lancefield grouping antigen. The term viridans is not quite correct as this group of streptococci are also nonhemolytic (not producing a green zone of hemolysis in the agar medium around the colonies).

Because viridans group streptococci are capable of inducing significant infections, especially in some high-risk patients, efforts should be made to obtain specimens free of contamination by the normal flora. Determination of the clinical significance of each isolate must be made with caution because such determinations influence the need to direct therapy against these organisms.

Because the viridans streptococci give poor and variable reactions in serologic and conventional physiologic tests and, in many cases, are of relatively low virulence, they have been studied less extensively than the ß-hemolytic streptococci. In selected cases of bacteremia or endocarditis it may be clinically helpful to identify viridans streptococci. The taxonomic classification of these streptococci has caused confusion for a long time but was substantially simplified by a scheme worked out by Facklam and Washington (Table 225.3).[5] The identification of these streptococci has long since been recognized as unsatisfactory, with the result that a significant proportion of these isolates remain misidentified or unidentified. [4] [19] [20]

Biochemical and enzymatic assays

Although they are named viridans, these organisms do not all produce a-hemolysis; the property of green coloration on blood agar is affected by the growth medium used.[4] Commercially developed kits may be of great help in the species identification of viridans streptococci, but misidentification or lack of identification of members of the *S. milleri* group, *Streptococcus oralis*, *Streptococcus mitis*, *Leuconostoc* spp. and other *Streptococcus*-like organisms is a significant

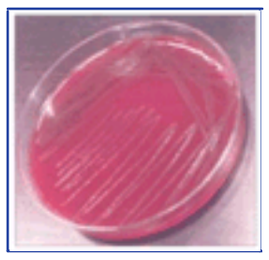

Figure 225-12 *Leuconostoc* on a blood agar plate.

problem. Five species or groups of species can be identified on the basis of various biochemical tests or fermentation capacities (Table 225.4 ; Fig 225.12). [1] [5] [21] *Streptococcus milleri* produces small, pinpoint colonies on blood agar, among which a-hemolytic and a-hemolytic strains and nonhemolytic strains with or without identifiable Lancefield antigens (A, C, F and G) are represented. At least seven distinct species in the *Streptococcus mutans* group are recognized, including *Streptococcus sobrinus, Streptococcus rattus*, and *Streptococcus cricetus*, besides the cariogenic *S. mutans.* The sanguis group, which was formerly designated *Streptococcus sanguis* I, consists of *Streptococcus sanguis, Streptococcus gordoni, Streptococcus parasanguis* and *Streptococcus crista*.

Molecular biology

Molecular biology-based analyses, such as DNA-DNA or RNA-DNA hybridization and restriction fragment length polymorphism analysis of rRNA genes (ribotyping), have helped to clarify the taxonomy of viridans streptococci.[22] The streptococci belonging to the *S. mitis* group were earlier recognized as *Streptococcus mitior, S. sanguis II* and *Streptococcus oralis*. In the *S. milleri* group, the species *Streptococcus anginosus, Streptococcus intermedius* and *Streptococcus constellatus* are now listed, based on similarities found in genetic studies.

Nutritionally variant streptococci (Abiotrophia)

A subgroup of the viridans streptococci has been isolated from patients who have endocarditis and otitis media. These are nutritionally deficient, being dependent on pyridoxal or vitamin B6. They are also designated thiol-dependent streptococci and symbiotic streptococci.[23] These bacteria will not grow on ordinary media, which usually lack pyridoxal, but they will grow in the vicinity of other micro-organisms that produce this substance (e.g. *Staphylococcus aureus, Escherichia coli* and members of several enterobacter groups). Like other viridans streptococci they are normal inhabitants of the oral flora. Nutritionally variant streptococci should be suspected when Gram stains of specimens reveal the presence of cocci but cultures are negative. [24]

Streptococcus-like organisms

Streptococcus-like organisms can be found in the genera *Aerococcus, Facklamia, Pediococcus* and *Leuconostoc*. They have a particular resemblance to the viridans streptococci and share many characteristics with the viridans group of streptococci (Table 225.5). These micro-organisms have a low pathogenic potential but can be found in immunocompromised patients and especially in patients with endocarditis. They can be recovered from wounds, urine and saliva and should be recognized because they may be resistant to vancomycin; this is true for *Pediococcus* and *Leuconostoc* spp. The identification of *Facklamia* spp. is problematic because none of the biochemical testing systems currently include them in their databases.

EPIDEMIOLOGY

Streptococci are widely distributed in nature and can be found in animals and humans as part of the normal flora in the respiratory tract as well as the gastrointestinal and urogenital tracts. They are

TABLE 225-5 -- Characterization of viridans streptococcus-like bacteria.

also the causative agents of various types of infections with or without late sequelae. [25] [26] [27]

ß-Hemolytic streptococci of groups A, C and G

ß-Hemolytic streptococci of groups A, C and G are often found in the upper respiratory tract, especially in children aged between 5 and 15 years, although people of all ages may be infected. The frequency of streptococcal-induced upper respiratory tract infections and especially pharyngitis and tonsillitis is higher during the early autumn months and the spring.[25] [26] [27] This seasonal variation is fairly constant over the years but fluctuations between years have been noted, especially before the antibiotic era when it was easy to follow the fluctuation in scarlet fever epidemics, which varied widely. Infections in the upper respiratory tract are transferred to the surroundings via droplets and also directly through physical contact; a higher number of streptococcal upper respiratory tract infections is found in highly populated areas in narrow localities. Spread among family members and in classrooms is therefore a common finding. In residential schools and detention centers pharyngeal carriage rates approach 50%. Except in epidemics, skin carriage is not common. However, in certain geographic areas where streptococcal pyoderma is common, skin colonization rates may be as high as 40%. Colonization rates are higher in patients who have skin diseases, such as eczema and psoriasis, and wounds. Children who have streptococcal pharyngitis may excrete this organism in their feces or carry it in the perianal region, which may be the cause of wide-spread streptococcal infections in closed facilities.

Large numbers of pyogenic streptococci are shed in the immediate environment, where the bacteria may be cultivated from clothing as well as sheets and mattresses belonging to the infected person. This is important, especially in the treatment of patients who have skin infections such as impetigo. Recurrent streptococcal throat or skin infections is a common finding within families or institutions. In the search for sources, pets as well as family members are usually incriminated. Generally, pets are not a common source of reinfection because group A streptococci are highly host specific. Otherwise, group C streptococcal infections can be acquired by close contacts with infected horses and group G streptococci can be obtained from dogs, in which group G streptococci are the dominant cause of streptococcal pharyngitis (see Chapter 91).

In a given population only a limited number of M types are prevalent and the population gradually seems to acquire immunity to these. New types seem to enter the population when the immunity against these diminishes below a certain level.

Scarlet fever used to be a frightening disease, but during the past few decades it seems to have had a mild course in the Western world. However, since the mid-1980s a worldwide increase in the incidence of severe group A streptococcal disease has been reported, including rheumatic fever, cellulitis, necrotizing fasciitis and other invasive forms. These serious infections were reported as being associated with the reappearance of M1 and M3 strains and the production of pyrogenic exotoxins A and B although subsequently other exotoxins have also been implicated.[26] [28] [29] Food-borne epidemics (especially carried by milk) were common before pasterurization and were usually caused by group A streptococci, but groups C and G streptococci were also implicated on occasion. Food-borne infection can cause epidemic outbreaks of streptococcal infections such as scarlet fever and pharyngitis.

Recently, *Streptococcus iniae*, a fish pathogen that produces ß-hemolytic colonies on blood agar, has been reported as an additional cause of cellulitis and invasive soft tissue infections.[30]

Group B streptococci

Group B streptococci are less commonly found in the upper respiratory tract, but their presence in the vagina of women aged between 15 and 45 years is rather common. Their numbers fluctuate and are higher before the monthly menstrual period and in pregnancy.[3] [31] [32] Isolation frequencies as high as 30–35% have been recorded in some surveys. During delivery, vaginal colonization causes transmission to the infant in 50–75% of cases. A small number of these infants will develop symptoms of disease (see Clinical manifestations, below).

Enterococci

Enterococci are the most prevalent aerobic cocci in the bowel. Resistance against glycopeptides is emerging, especially in *E. faecium* isolated in intensive care units and nursing homes. This increase in resistance is thought to be associated with the administration of high doses of glycopeptides. In many hospitals, the increasing prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) was accompanied by a similar increase in the prescription of vancomycin. In addition, glycopeptides have been used as growth promoters in the livestock industry, thus inducing resistant enterococci in poultry products for human consumption.

Streptococcus pneumoniae

Streptococcus pneumoniae is an obligate parasite in humans, who may be colonized at a very early stage of life. The pneumococcus is a regular inhabitant of the nasopharynx in humans, especially among children, although adults are also frequently colonized. In certain populations carrier rates of 70% are found. In general, the rate of disease in a population depends on the frequency with which invasive serotypes are carried in the nasopharynx. [33] Nasopharyngeal carriage is often accompanied by the development of protection against infection by the same serotype. Carriage rates are inversely related to age and the levels of anticapsular antibody, and thus it is clear that the immune status of the host is an important determinant of the prevalence and longevity of carriage.[33] Like the ß-hemolytic streptococci, pneumococci are spread from person to person by sneezing and coughing. Of the 84 capsular types in the pneumococci, some seem to be more invasive than others (e.g. type 3 is among the most invasive strain types). [34] The capsular types 6a, 6b, 14, 19a, 19f and 23f are the dominant types found in pneumococcal

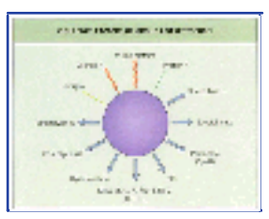

Figure 225-13 Virulence factors of group A streptococci. Spe, streptococcal pyrogenic exotoxins; SIC, streptococcal inhibitor of complement-mediated lysis; Ssa, streptococcal superantigens.

infection during the first 2 years of life, whereas in adults these types and the types 1, 3, 4, 7f, 8, 9, 10a, 11a, 12f, 14, 15b, 17f, 18c, 20 and 22f seem to cause the greatest number of bacteremic infections recorded in the USA.

A viral infection may predispose to a pneumococcal infection; this seems to be the case in children, who very often get pneumococcal otitis media 1–2 weeks after a virus infection. Support for this theory might be the finding in vitro that certain strains of adenovirus enhance the adherence of pneumococci to human respiratory tract epithelial cells.[31] Consequently, pneumococcal infections vary with the season in relation to the frequency and type of virus infections.

Certain penicillin-resistant pneumococcal clones may have a strong epidemic potential owing to their relative resistance to penicillin and other commonly used antibiotics, showing a facilitated spread in subpopulations regularly exposed to both the pneumococcus and to numerous antibiotics.[35]

Viridans group streptococci

Viridans group streptococci are fairly constant in the upper respiratory tract and dominate the aerobic normal flora in this region in the same way that enterococci dominate the aerobic normal flora in the gut. Viridans group streptococci are part of the normal flora of human mucous membranes in the mouth and upper respiratory tract as well as in stool samples.

PATHOGENESIS

Group A streptococci

The virulence factors of group A streptococci comprise both surface structures and proteins released from the cells during growth (Fig. 225.13).

Cell wall antigens

According to some scientists the M protein is a prerequisite for the binding of group A streptococci to epithelial cells in the skin, and F protein, another surface protein, is responsible for the binding to the epithelial cells in the airways, probably by binding to fibronectin.[32] Biochemically, M protein is an a-helicoidal structure similar to some muscle proteins such as myosin and tropomysin (Fig. 225.14 and Fig. 225.15). [36] The M protein has also been shown to cross-react

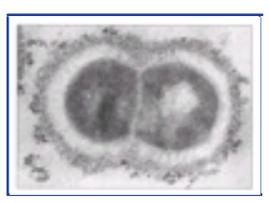

Figure 225-14 Electron microscopy of group A streptococcus. The fuzzy M protein layer can be seen protruding from the cell wall.

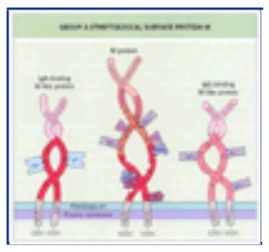

Figure 225-15 Group A streptococcal surface protein M. A, B and C represent various regions of the M protein characterized by different degrees of variability of the protein structure. H, S, A and Fib denote human serum albumin and fibrinogen binding structures, respectively.

immunologically with these contractile proteins.[36] [37] [38] It has been speculated whether this is of significance for the pathogenesis of rheumatic fever. A type-specific immunity is induced during the streptococcal infection and it has been shown in vaccination experiments[38] that purified M protein can be used to induce immunity. Because these antibodies cross-react with human heart muscle proteins, there has been a reluctance to proceed with these experiments in humans. Lately it has been shown that M proteins may also function as superantigens and this has further emphasized that the proteins in the M-protein family may be important virulence factors.[39]

The amount of M protein on the surface of streptococci varies within wide ranges and in some streptococci this antigen cannot be demonstrated. M-negative streptococci are phagocytosed quickly in serum milieu after being opsonized via the alternative complement pathway in the absence of antibodies against the M antigen, whereas M-positive streptococci resist phagocytosis in the absence of type-specific antibodies. The inability of M-positive streptococci to bind to phagocytosing cells efficiently indicates that C3b is not deposited on the surface of the streptococci or it is not accessible to the C3b receptor on the streptococci. The deposition of

C3b is probably regulated by factor H, for which the M antigen has a high affinity. [40]

Several other M-like factors have been identified on the surface of group A streptococci. These have been shown to bind immunoglobulins such as IgG and IgA as well as several other serum proteins, including fibrinogen, plasmin, $ß_2$ microglobulin and factor H. It has also recently been shown that some group A streptococcal strains have the ability to inhibit the activation of complement via the classic pathway by binding C4b to M-protein like structures. The way in which all these factors influence the virulence of the streptococci is not clear at present, but these factors can be seen as an expression of the complex interplay between the host and the micro-organism in group A streptococcal infections.[39] [40]

Another example of this is C5a peptidase, which is a surface protein that by its specific ability to cleave C5a hinders the activation of polymorphonuclear leukocytes and thereby contributes to the protection of the bacteria against phagocytosis. [41]

Extracellular products, toxins and enzymes

Group A streptococci produce a great number of extracellular products (see Fig. 225.13). Streptolysin O is an oxygen-labile hemolysin that is biologically closely related to pneumolysin, tetanolysin and hemolysins from some other micro-organisms. Intravenous injections of this toxin in animals have demonstrated a cardiotoxic effect. It also inhibits chemotaxis, the mobility of neutrophils and the phagocytosis by the macrophages.

Streptokinase (fibrinolysin) is produced by groups A, C and G streptococci. Streptokinase binds to plasminogen in the blood, forming a complex that transforms plasminogen to plasmin, which has a fibrinolytic activity. Purified streptokinase from group C streptococci is commonly used clinically to treat thrombosis in the coronary vessels and the deep veins of the leg. The plasmin formed by the plasminogen-streptokinase complex also activates complement via the alternative pathway. It has been proposed that streptokinase from certain so-called nephrogenic streptococcal strains is related to the nephrogenic capacity of some of these isolates (Fig. 225.16). This explanation of the pathogenesis of nephrotoxicity in these organisms has recently been challenged in an experimental animal model.[42]

The pyrogenic exotoxins (scarlatina toxins) have been proposed as being responsible for the scarlatina erythema. Numerous different toxins are produced; they are designated streptococcal pyrogenic exotoxin (Spe)A, SpeC, SpeF, SpeG, SpeH, SpeJ, SmeZ, mitogenic factor (MF) and streptococcal superantigen (Ssa). (SpeB is now known to be a constitutive cysteine protease and SpeE and MF have been shown to be identical.) Most group A strains produce more than one of these toxins. Several biologic effects have been attributed to the toxins, including pyrogenicity, a decrease in the blood-brain barrier permeability, cardiotoxic effect, T-cell activation and potentiation of the effects of endotoxin. The toxins may be responsible for the development of the shock syndrome that sometimes appears after streptococcal infections.[43] [44] It has been suggested that this reaction, like many of the biologic effects, is induced by the release of cytokines because these toxins function as very active superantigens and thereby stimulate a high level of proliferation of T cells (Fig. 225.17). Patients who develop the toxic shock syndrome have been shown to have very low or undetectable levels of neutralizing antibodies against one or more of these toxins.[44] Development of the streptococcal toxic shock syndrome might be hindered if toxin-neutralizing antibodies could be administered at a very early stage (see Chapter 56).

Groups C and G streptococci

The species *S. equisimilis* (a group C streptococcal species) produces streptolysin O as well as streptokinase, and *S. zooepidemicus* and *S. equi* (also group C streptococci) form hemolysins that differ from streptolysin S and O. Group C streptococci often have a very strong

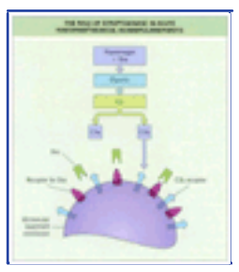

Figure 225-16 The role of streptokinase in acute poststreptococcal glomerulonephritis. Theoretic model of the pathogenesis of acute post-streptococcal glomerulonephritis as induced by streptokinase. The affinity of the streptokinase isotypes (Ska) is probably dependent on differences in the amino acid composition. This model explains the early deposition of C3b in the glomeruli that is typical of the early phase of acute post-streptococcal glomerulonephritis. Ska, streptokinase from Group A streptococci.

antiphagocytic hyaluronic capsule similar to that of group B streptococci. Group C streptococci, like group G streptococci, have not been isolated from patients who have rheumatic fever, but both can cause bacteremia and sepsis. Like the group A streptococci, they have an antiphagocytic M protein on their surface and form several enzymes. They should be regarded as pathogens.

Group B streptococci

Vaginal colonization with group B streptococci is common among adult women and transmission to the infant during childbirth occurs in 50–75% of cases. A small proportion of these infants will be infected (see Chapter 65). This indicates that particular strains or a defect in the immunity of the host play a role in the establishment of infection. It has long been known that antibodies against the capsular polysaccharide are a crucial factor for protection against group B streptococcal infections.[45] [46] In-vitro studies indicate that phago-cytosis and killing by polymorphonuclear leukocytes require the presence of both antibodies and complement. The capsular polysaccharide types 1a, 1b, 2 and 3 are clinically the most important, as they are responsible for infections during the early weeks after birth. Nonencapsulated mutants of group B streptococci belonging to type 3 have been demonstrated to lack virulence in an experimental neonatal rat model. The significance of the capsular polysaccharide for the virulence of group B streptococci was further strengthened by the finding that transplacentally acquired maternal antibodies to the group B streptococcal polysaccharides conferred protection against infection of the baby. Consequently, human experiments have been performed with

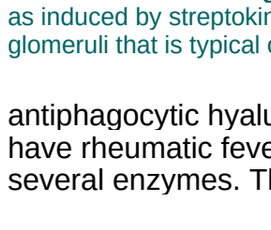

Figure 225-17 Pathogenesis of streptococcal toxic shock syndrome. In this model, patients who have opsonizing antibodies against the M antigen are protected against infection. In the absence of these antibodies, they may develop a serious infection if they are also lacking neutralizing antibodies against the streptococcal pyrogenic exotoxins which, as superantigens, may induce a cytokine cascade. This process will be hindered by the presence of toxin-neutralizing antibodies. The affinity of the toxins to the class II major histocompatibility complex of antigen presenting cells (APC) and T-cell receptors of specific Vß (variable region of ß chain of the T cell receptor) bearing T cells determines the outcome in each individual patient.

polysaccharide-protein conjugate vaccines, which were capable of inducing opsonizing antibodies and killing group B streptococci.[47] The significance of sialic acid as part of the capsular polysaccharide in the inhibition of complement activation adds to the importance of the capsule in the pathogenesis of group B streptococcal disease.

Group B streptococci also produce other potential virulence factors, such as the CAMP factor, hemolysins and neuraminidase. Although these substances may contribute to the pathogenesis, their exact role awaits further studies.

Enterococci

Although members of the genus *Enterococcus* cause many different infections in humans, very little is known about the pathogenic mechanisms involved and the virulence factors carried by these micro-organisms are less well understood than those of many other streptococci. It is clear, however, that infections caused by enterococci are often found in patients who have various types of immunodeficiencies, in patients using mechanically compromising devices, such as intravascular lines and urinary catheters, and in seriously ill patients. The increasing importance of enterococci as nosocomial pathogens may in part be explained by their natural

ability to acquire and exchange extrachromosomal elements encoding virulence traits or antibiotic resistance. Adherence to host tissue may be mediated by enterococcal aggregation substance, fibronectin-binding protein and surface carbohydrates. Extracellular toxins such as cytolysin may also contribute to the pathogenesis.[48]

Streptococcus pneumoniae

Pneumococci are a perfect example of the significance of the role that the mucous lining plays in the inhibition of potentially pathogenic micro-organisms. Thus, pneumococcal infections often occur after a respiratory tract viral infection that has damaged the epithelium, thereby helping the pneumococci to establish themselves in the mucous membranes. Factors that disrupt the normal clearing process in the airways predispose patients to pneumococcal infections in the lungs. Defects in systemic host defenses (i.e. HIV infection, asplenia, immunoglobulin deficiency) may also contribute to pneumococcal infections in the respiratory tract, sometimes causing invasive infections such as bacteremia, meningitis and endocarditis.

The virulence of *S. pneumoniae* is associated with an antiphagocytic capsular polysaccharide.[49] Thus, laboratory strains that have lost the ability to produce a capsule are nonpathogenic. The virulence capacity of pneumococci is neutralized by complement-dependent opsonizing antibodies. Protection is afforded by type-specific antibodies with opsonizing capacity. [34] [49] Not all types of pneumococci are equally invasive. Thus, during the first 2 years of life about 50% of the pneumococcal infections are caused by six serotypes (6A, 6B, 19A, 19F and 23F) and in adults these six types together with 15 others are responsible for 80% of pneumococcal bacteremia in the USA.

Besides polysaccharide, the pneumococci produce a hemolysin similar to the streptolysin O of group A streptococci, as well as hyaluronidase and a neuraminidase. None of these seems to play a direct role in the disease process.[33]

Viridans group streptococci

Viridans group streptococci can be divided into those that have a tendency to induce endocarditis and those that do not. The endocarditis-related species usually produce dextrans and this is true for the species mutants, *S. sanguis* and *S. mititor*, as well as *S. bovis*. A prerequisite for the endocarditis-inducing capacity seems to be a capacity to adhere to endothelial cells in the endocardium and this is in turn related to dextran production. In contrast, *S. salivarius* produces levan as its exopolysaccharide and is usually not related to endocarditis. Dextran production is probably not the only virulence factor because these micro-organisms can cause several other types of infections (see Chapter 59).

Patients undergoing intensive cytotoxic treatment that results in neutropenia are predisposed to severe infections with viridans streptococci, the so-called viridans shock syndrome. The mechanism is not well understood (see Chapter 100).

CLINICAL MANIFESTATIONS

Groups A, C and G streptococci

Group A streptococcus, or *Streptococcus pyogenes*, is considered the most pathogenic species of ß-hemolytic streptococci. Group A streptococci are involved in a wide variety of clinical syndromes, which can be roughly divided into:

- uncomplicated superficial infections,
- severe invasive infections, and
- postinfectious autoimmune sequelae.

Depending on climate and portal of entry, the infections are preferentially related to the upper airways or to the skin.

Uncomplicated superficial infections

Uncomplicated respiratory infections

Group A streptococci are the most prevalent cause of bacterial pharyngitis and tonsillitis, especially in school children aged between 5 and 15 years; however, people of all ages can be affected. Typically in streptococcal pharyngitis, after 1–5 days of incubation, the first clinical symptom is general malaise with excessive tiredness, headache and fever. The tonsils are swollen and red, showing exudates and deposits together with local petechiae. The patient may have

TABLE 225-6 -- Clinical manifestations of sore throat.

CLINICAL MANIFESTATIONS OF SORE THROAT	
Typical streptococcal pharyngitis	**Atypical streptococcal pharyngitis**
Temperature >100°F (38°C)	Cough
Acute throat pain	Hoarseness
Tender lymph nodes in the neck	Watery nose secretion
Redness in pharynx	Conjunctivitis
Tonsillar exudate	
Petechiae	
Sore nose	
Scarlatina	

difficulty in swallowing. Tenderness and enlargement of the anterior cervical lymph nodes are common findings. Based on the symptoms and signs, streptococcal pharyngitis is not easily differentiated from viral infections (Table 225.6). Cough is not a usual finding in streptococcal pharyngitis but is not uncommon in viral infections (see Chapter 31).

When the infecting strain produces one of the so-called pyrogenic (or erythrogenic) exotoxins, scarlet fever may be a complication of streptococcal pharyngitis. Although there are no scarlatinogenic streptococcal types the disease has a higher prevalence in streptococcal infections caused by M types 1, 3, 4, 6, 12, 18, 22 and 66. Group A streptococci are the main causative agents in scarlet fever, but streptococci of groups C and G are isolated from a small number of patients. As well as the signs observed in pharyngitis, scarlet fever is characterized by a diffuse erythematous rash over the trunk, the neck and face and the limbs. The area around the lips is generally free of erythema (circumoral palor). The rash is a diffuse light erythema that blanches on pressure. A white coating on the tongue develops and then resolves, leaving red swollen papillae, the so-called 'strawberry tongue'. Patients usually recover within about 5–7 days. The rash disappears within 10 days, followed by a characteristic discoloration of the skin during the following week. This desquamation is most pronounced on the palms and soles. In certain cases, progression of infection is observed locally causing sinusitis, otitis media, and retropharyngeal or peritonsillar abscesses.

The symptoms of group A streptococcal respiratory infections in young children may have a different clinical appearance. Young children under 3 years usually present with (mucopurulent) nasopharyngitis, which tends to a prolonged course and may be complicated by sinusitis and otitis media.

Uncomplicated skin infections

Streptococci can cause skin infections of various forms and the clinical features are determined by which skin layers are infected:

- infections immediately below the stratum corneum result in impetigo;
- infections in the epidermis can give rise to ecthyma; and
- infections in the dermis give rise to erysipelas and cellulitis.

Pyoderma (impetigo) is most common in young children and is associated with warm, moist climates and poor hygiene (Fig. 225.18). Colonization of the skin occurs first and this is followed by an infection in sites where the integrity of the skin is lost (e.g. in scratches, pierced ear lobes, paronychia or insect bites). Streptococcal infections in more superficial lesions usually result in an impetigenous type of infection, starting with small red papules and developing into vesicles with clear yellow contents. The vesicles change into pustules which, when broken, are covered with a honey-colored crust. Underneath the crust there is a slightly red, blistering surface. The lesions contain numerous bacteria and tend to spread over the body

Figure 225-18 Impetigo in a child.

Figure 225-19 Erysipelas. Note the sharp demarcation of the affected skin.

surface, resulting in a multitude of lesions. The name 'impetigo contagiosa' indicates the contagious tendency of this infection, which is especially apparent in closed institutions such as day care centers and in overcrowded conditions. The lesions may heal spontaneously after some weeks and they usually heal without scarring. Strict hygiene precautions are necessary to prevent further spread of the disease.

Erysipelas is an acute superficial cellulitis of the skin that most often involves the face or the limbs (Fig. 225.19). Erysipelas is sharply demarcated and the affected skin is painful and appears red and swollen, with lymphatic involvement. Erysipelas occurs mostly in young children and older adults and is often accompanied by generalized symptoms such as fever and rigors and sometimes by nausea and vomiting. This is usually a relatively mild disease with few complications, but some patients develop pronounced septic symptoms and local complications such as skin necrosis or necrotizing fasciitis (see below; also see Chapter 9 and Chapter 10).

Figure 225-20 Necrotizing fasciitis caused by group A streptococci. There is only moderate erythema but at surgery there was extensive soft tissue damage.

Invasive infections

Invasive group A streptococcal infections occasionally occur. Examples are sepsis (including puerperal sepsis), pneumonia, meningitis and lymphangitis. Puerperal sepsis usually occurs as an ascending genital infection in the postnatal period after obstetric manipulation in combination with poor hygiene. Additionally, group A streptococcus is the second most common cause of nongonococcal septic arthritis after *Staphylococcus aureus*.[29] [50]

Remarkably, the most severe infections, such as necrotizing fasciitis (Fig. 225.20) with or without the toxic shock-like syndrome (analogous to the toxic shock syndrome caused by *Staphylococcus aureus*), have been increasingly seen since the mid-1980s.[26] [28] [29] [43] [44] The skin serves as the main portal of entry, followed by the mucous membranes of the throat, but in many cases the portal of entry is unknown. Early clinical features of group A streptococcal infections, before the development of toxic shock, may be flu-like in nature, with fever, sore throat, vomiting and diarrhea. Sometimes there is a history of blunt trauma. Necrotizing fasciitis is often difficult to diagnose; although redness and bullae may be visible, edema is sometimes the only superficial sign. Discrepancy between the unimpressive clinical observations and the extremely severe pain indicated by the patient is then the only clue to the correct diagnosis. Subsequent surgery may reveal massive tissue necrosis along the fascial planes. In the course of hours or days, toxic shock with hypotension and multiple organ failure may develop. A faint erythematous rash may be seen mainly on the chest. Clinically this disease resembles the staphylococcal toxic shock syndrome (Table 225.7) and it is interesting to note that streptococcal pyrogenic exotoxin A and the enterotoxin B of *Staphylococcus aureus* have a similar molecular structure. Despite adequate antibiotic treatment and intensive care, these infections are characterized by a high mortality rate of between 30% and 80% with up to 50% of the survivors having to have limbs amputated and requiring major debridement of tissue (see Chapter 10). [26] [28] [29]

Autoimmune sequelae

In some cases, streptococcal disease is followed by autoimmune sequelae, either acute rheumatic fever or acute glomerulonephritis.

Rheumatic fever (see also Chapter 60)

Rheumatic fever is seen predominantly during fall and winter in children aged between 5 and 15 years, who also show the highest incidence of streptococcal pharyngitis. Clinical manifestations may

TABLE 225-7 -- Definition for streptococcal toxic shock-like syndrome.

DEFINITION FOR STREPTOCOCCAL TOXIC SHOCK-LIKE SYNDROME
I. Isolation of GAS from:
A. a normally sterile site (e.g. blood, cerebrospinal, pleural or peritoneal fluid, tissue biopsy, surgical wound, etc.)
B. a nonsterile site (e.g. throat, sputum, vagina, superficial skin lesion, etc.)
II. Clinical signs of severity
A. Hypotension: systolic blood pressure=90mmHg in adults or <5th percentile for age in children
and
B. =2 of the following signs
1. Renal impairment: creatinine =177µM for adults or =2 × the upper limit of normal for age. In patients with pre-existing renal disease, a =2-fold elevation over the baseline level.
2. Coagulopathy: platelets =100 × 10^9 /l or disseminated intravascular coagulation defined by prolonged clotting times, low fibrinogen level and the presence of fibrin degradation products.

3. Liver involvement: alanine aminotransferase, aspartate aminotransferase or total bilirubin levels =2 × the upper limit of normal for age. In patients with pre-existing liver disease, a =2-fold elevation over the baseline level.
4. Adult respiratory distress syndrome defined by acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure or evidence of diffuse capillary leak manifested by acute onset of generalized edema or pleural or peritoneal effusions with hypoalbuminemia.
5. A generalized erythematous macular rash that may desquamate.
6. Soft tissue necrosis, including necrotizing fasciitis or myositis or gangrene.
An illness fulfilling criteria IA and II (A and B) is defined as a *definite* case. An illness fulfilling criteria IB and II (A and B) is defined as a *probable* case if no other etiology for the disease is identified.

vary from mild to highly aggressive. The disease is largely self-limiting. Most patients give a history of preceding pharyngitis. Acute rheumatic fever is a clinical syndrome; there is no specific diagnostic test. Guidelines for the diagnosis of initial attacks of acute rheumatic fever are described in the Jones criteria (Table 225.8). The presence either of two major criteria or of one major criterion and two minor criteria is suggestive of rheumatic fever if a case history of preceding group A streptococcal infection can be documented. Typically, patients present 10–25 days after the preceding streptococcal infection with fever, tachycardia and nonsuppurative inflammatory changes of the joints, heart, skin and subcutaneous tissue. Migratory arthritis is the most common manifestation and can be diagnosed in 70% of patients; carditis is found in about 50% of patients. There is an inverse relationship between the severity of joint involvement and the risk of developing carditis. The carditis is a pancarditis, which means that the pericardium, the myocardium and the endocardium can all be affected. Although carditis may be asymptomatic, clinical symptoms can include:

- heart murmurs,
- arrhythmias,
- cardiac enlargement,
- congestive heart failure,
- pericardial friction rubs, and
- pericardial effusion.

Repetitive group A streptococcal infections tend to cause relapses in these patients, resulting in chronic progressive damage to the cardiac valves. Carditis is the only manifestation of rheumatic fever that has the potential to cause long-term disability or death. In order to prevent valvular destruction, these patients should receive prophylactic penicillin (or alternative antibiotic) therapy.

TABLE 225-8 -- Revised Jones criteria for the diagnosis of poststreptococcal rheumatic fever.

REVISED JONES CRITERIA FOR THE DIAGNOSIS OF POSTSTREPTOCOCCAL RHEUMATIC FEVER		
Major manifestations	**Minor manifestations**	
Carditis	Clinical	Previous rheumatic fever or rheumatic heart disease
Polyarthritis		Arthralgia
Chorea		Fever
Erythema marginatum	Laboratory	Acute phase reactants
Subcutaneous nodules		Leukocytosis
Positive throat culture		Elevated erythrocyte sedimentation rate
Increased titer(s)		Elevated C-reactive protein
Recent scarlet fever		Prolonged P-R interval on electrocardiogram
	Supporting evidence of streptococcal infection	
The presence of two major criteria or of one major and two minor criteria is highly suggestive of rheumatic fever, if supported by evidence of preceding group A streptococcal infection		

Firm, painless, subcutaneous nodules may appear in association with severe carditis, usually over bony surfaces and tendons. Erythema marginatum, a nonpruritic erythematous eruption, may appear on the trunk or the proximal extremities.

In addition, the central nervous system (CNS) may be affected with emotional lability, muscular weakness and rapid, uncoordinated movements (Sydenham's chorea or St Vitus' dance). About 10% of patients develop chorea after a latent period of 3–12 months. The specificity of this disease in relation to rheumatic fever is a matter of controversy. The general distribution of the chorea is interesting. The frequency is equal between the sexes before puberty but after puberty chorea disappears in males and is not seen in military epidemics. In contrast, pregnancy aggravates and exacerbates the disease.

Strains of certain M types are strongly associated with rheumatic fever, especially strains that appear mucoid on blood agar plates. Other equally prevalent serotypes fail to initiate the disease or even to reactivate it in susceptible hosts. Rheumatic fever is associated with pharyngeal strains carrying M proteins of types 1, 3, 4, 5, 6, 12, 14, 18, 19 and 24.

In the developed world, the incidence of rheumatic fever has declined throughout the 20th century, probably owing to improved living conditions, effective antibiotic treatment of upper respiratory tract infections and good health care. However, rheumatic fever is still a problem in developing countries, where it is still the most common cause of acquired heart disease (Table 225.9).

Acute glomerulonephritis

Acute glomerulonephritis is diagnosed on the basis of the clinical presentation in combination with evidence of a recent infection (in the previous 1–3 weeks) with *S. pyogenes*. This syndrome of acute inflammation of the glomeruli comprises oliguria, hematuria, proteinuria, hypertension and edema, but the presentation may be mild. The laboratory findings include proteinuria, hematuria and reduced renal function as evidenced by renal function tests. Decreased serum complement is an important parameter to support the diagnosis.

The toxic effect of streptokinase is thought to be involved in the pathogenesis of acute glomerulonephritis. Autoimmune reactions caused by shared components between glomeruli and streptococcal membranes may also play a role. While the significance of these presumed mechanisms awaits further proof, autoantibodies to glomerular connective tissue components have been identified in patients who have streptococcal glomerulonephritis.

The prognosis in young adults is usually favorable, but sporadically acute disease is followed by chronic glomerulonephritis and subsequent renal failure. The incidence of glomerulonephritis is lower in Western Europe than in the USA, as is the incidence of pyoderma. The

TABLE 225-9 -- Rheumatic heart disease in school-age children in various regions of the world.

RHEUMATIC HEART DISEASE IN SCHOOL-AGE CHILDREN IN VARIOUS REGIONS OF THE WORLD		
Location	**Prevalence per 1000**	**Year(s) of report(s)**
USA	0.6	1965
Latin America	1.0–17.0	1968–1980
Asia	0.4–21.0	1970–1979

Africa	0.3–15.0	1970–1985
Pacific region (except Japan)	1.0–18.6	1978–1985
Japan	0.7	1979

attack rate varies within wide ranges but it seems to decrease substantially in the developed world and many cases can only be detected by slight proteinuria and confirmed by renal biopsies.

Glomerulonephritis is observed more in connection with skin isolates of M types M2, M49, M55, M57, M59, M60 and M61, and throat isolates of M1, M4, M12 and M25. Although the incidence of rheumatic fever has declined dramatically in the developed world, it is still a major concern in developing countries.

Groups C and G streptococci

Groups C and G streptococci can induce similar infections to those caused by group A streptococci, such as pharyngitis. They have been recognized as part of the normal flora of the pharynx, skin, intestinal tract and vagina.[51] [52] Group C streptococci are a common cause of infection in animals, including mastitis in cows. Human infections regularly develop after contact with animals or animal products.[16] [52] Groups C and G streptococci have occasionally been reported as the cause of nosocomial and opportunistic infections, including endocarditis, arthritis, puerperal sepsis and septic abortion, neonatal sepsis, pleuropulmonary infection, peritonitis, meningitis and cellulitis.[51] [52] [53] Malignancy, diabetes, cardiovascular disease and alcoholism are important host determinants of invasive streptococcal infections.[26] [28] [29] [51] [52] [53] [54]

Group B streptococci

Neonatal disease

Group B streptococci (*Streptococcus agalactiae*) are a leading cause of bacteremia and meningitis in neonates (see Chapter 65).[55] Most group B streptococci infections are thought to be transmitted to the infant from the maternal genital tract during delivery.[45]

Early-onset group B streptococcal infection (up to 5 days of age) is associated with a high mortality rate and occurs predominantly in immature neonates whose deliveries have been characterized by complications predisposing to infection (premature onset of labor, rupture of membranes for more than 24 hours before delivery, maternal fever or anogenital colonization of the mother).[55]

With rapid diagnosis, including screening of pregnant women, and better supportive care, mortality has decreased and is now between 15% and 40%. A substantial proportion of children with group B streptococcal sepsis develop meningitis and lumbar punctures should therefore be performed in all infants with suspected sepsis. Pulmonary involvement occurs in 40% of neonates with group B streptococcal sepsis, which cannot be distinguished from hyaline membrane disease on the basis of clinical or radiologic findings.[55]

Late-onset disease (occurring at 7 days of age or older) is infrequently associated with obstetric complications, but is acquired from exogenous sources (e.g. the mother or another infant). Typically, septic patients present with fever, poor feeding and irritability; 80% have meningitis. Death rates are much lower than in early-onset disease, but survivors of meningitis may have permanent neurologic sequelae, including central diabetes insipidus, thermal dysregulation, cortical blindness, deafness, mental retardation and generalized spasticity.[55]

As with group A streptococci, a correlation has been found between certain clinical conditions and the streptococcal type causing the infection. In early-onset neonatal infections, all four of the first serotypes are isolated at about the same frequency, whereas in the late-onset type 3 streptococci are the most prevalent.

Adult disease

In recent years, group B streptococci have been recognized with increasing frequency as a substantial cause of morbidity and mortality among adults. [56] [57] Two groups of adults are at increased risk of group B streptococcal infection: pregnant women and patients with serious underlying disease (e.g. diabetes mellitus, malignancy). [55] [57] The spectrum of group B streptococcal disease in adults includes:[55] [57]

- bacteremia with or without sepsis,
- cellulitis and other soft tissue infections,
- pneumonia,
- arthritis,
- meningitis,
- osteomyelitis,
- pyometritis,
- endocarditis, and
- urinary tract infection.

Mortality is 30–35% and is associated with advanced age (over 60 years).[56] [57]

Postpartum sepsis is generally seen as endometritis or wound infection. Because most young mothers are in good health, the prognosis is excellent when appropriate therapy is started.

Enterococci

Enterococci are the most common aerobic, Gram-positive cocci found in the bowel flora and lower female genital tract of humans and other animals. Initially thought of as merely harmless commensals because of their low intrinsic virulence compared with other organisms such as group A streptococci, enterococci have become the second most common nosocomial pathogen overall. This appears to have been caused by selection of these organisms by the widespread use of broad-spectrum antibiotics, such as the cephalosporins, which lack enterococcal activity, and acquisition of new mechanisms of antibiotic resistance.[58] [59]

Enterococci are commonly associated with urinary tract infections, particularly in patients who have indwelling catheters and are recovered from abdominal and pelvic wound infections and abscesses. However, most clinical studies suggest that patients who have normal host defenses are resistant to enterococcal infections. [58] Furthermore, there is a low frequency of enterococcal bacteremia originating from an intra-abdominal source when antimicrobial agents that do not cover enterococci are used.[58] Enterococcal bacteremia in surgical patients is almost always associated with the ongoing or previous use of antimicrobial agents that are not specific for enterococci.

The most frequently seen infections are infections of the cardiovascular system, with bacteremia related to an intravascular catheter being the most common, [58] [59] although endocarditis also occurs. Other types of infection caused by enterococci include: [59] [60] [61]

- intra-abdominal infections;
- soft tissue and skin infections;
- bone and joint infections, especially in prosthetic joints;
- infections of the CNS associated with shunts;
- deep surgical wound infections;
- urinary tract infections; and
- endometritis.

Classically, enterococcal endocarditis is a disease of older people, with a male predominance as a result of obstructive urinary tract disease; it can also affect those who have prosthetic valves.[59] Enterococcal meningitis is rarely seen; it is associated with underlying disease, immunosuppressive therapy and CNS trauma or

surgery.[61]

It has been reported that 60% of enterococcal infections are nosocomial, with half of them occurring in intensive care units. *Enterococcus faecalis* is responsible for 80–90% of enterococcal infections and *Enterococcus faecium* for 10–20%.[58] [59] [60]

Streptococcus bovis infections are most often manifest as bacteremia or endocarditis. In addition, there is a strong association with underlying colonic malignancy (up to 50% in some series), so all patients with *S. bovis* bacteremia should undergo colonoscopy.

Streptococcus pneumoniae

Streptococcus pneumoniae is an important agent of human disease at the extremities of age and in those who have underlying disease.[62] [63] [64] Pneumococcal disease is most commonly associated with an antecedent viral respiratory infection such as influenza or with chronic conditions such as chronic obstructive pulmonary disease, diabetes mellitus, congestive heart failure, renal failure, smoking and alcoholism. Immunodeficiency such as that caused by splenic dysfunction or splenectomy is an additional risk factor for the development of severe pneumococcal disease because of decreased bacterial clearance and defective production of antibodies.

Streptococcus pneumoniae is the causative agent of the majority of cases of community-acquired pneumonia and otitis media, one of the three most common pathogens in bacterial meningitis and an important cause of sepsis and sinusitis.[33] [62] Bacteremia occurs in 25–30% of patients who have pneumococcal pneumonia and in more than 80% of patients who have pneumococcal meningitis. Children with sickle cell disease and individuals with hypogamma-globulinemia or who have had a splenectomy are at greatly increased risk of fulminating pneumococcal sepsis, which has a high mortality.

Pneumococcal pneumonia

Pneumococcal pneumonia is characterized by an abrupt onset with chills and high fever. Most patients complain of a productive cough with blood-tinged sputum, and chest pain (caused by pleurisy) is common. Physical examination may reveal decreased expiratory excursion as a result of pain, and dullness to percussion. Crackles

are present in nearly all cases. Infiltrations on chest radiograph vary between occupying less than a full segment to lobar consolidation. Empyema, endocarditis, pericarditis, peritonitis and brain abscess are rare complications.[62] [65] Because the disease is related to aspiration, the infection is generally localized in the lower lobes of the lungs.

Recovery is usually rapid after initiation of appropriate antibiotics, with complete resolution in 2–3 weeks. Despite antibiotic therapy, the case fatality rate of pneumococcal pneumonia is about 5–7% in the developed world [33] and can be higher in disease caused by serotype 3, in elderly patients and in cases of bacteremia (see Chapter 34).

Pneumococcal meningitis

Pneumococcal meningitis may follow otitis, sinusitis or bacteremia. It is an infrequent cause of neonatal meningitis, but it is responsible for 15% of cases of meningitis in children and for 30–50% of cases in adults. Mortality and severe neurologic sequelae are more frequent with disease caused by *Strep. pneumoniae* than with the other common causes of bacterial meningitis (see Chapter 22).

Viridans group streptococci

Viridans group streptococci are usually found as normal inhabitants of the oral cavity, the upper respiratory tract and the bowel.[66] When these organisms gain access to the bloodstream, people who have damaged heart valves are at increased risk of endocarditis.[20] Infection is usually endogenous and is preceded by disease, dental extraction or trauma to a mucosal surface. It is often associated with an immunocompromised condition. [67] [68] However, blood cultures that are positive for a-hemolytic streptococci or nonhemolytic streptococci have no clinical relevance in many cases.[69] If the same strain is isolated from more than one blood culture bottle or is isolated on repeated occasions, the assumption of clinical relevance is strengthened (see Chapter 59).

Viridans group streptococci are the most frequent cause of endocarditis and are generally associated with a better clinical outcome than endocarditis caused by staphylococci, enterococci or fungi.[20] A special population prone to develop infections with viridans streptococci is those with hematologic malignancies, who are treated with cytotoxic drugs with high cytotoxicity for mucosal surfaces. The course of infection in these patients may vary from mild to highly severe, with shock, adult respiratory distress syndrome and death.[67]

Streptococcus milleri is a cause of abscesses in association with previous surgery, trauma, diabetes and immunodeficiency. [24] The digestive tract has been recognized as the most likely portal of entry.[70] A notable feature is the preponderance of reported cases of infection in men.[66] [71] [72] *Streptococcus milleri* has been isolated in association with:[24] [66] [70] [71]

- periodontitis,
- odontogenic abscesses,
- sinusitis,
- intracranial abscesses,
- pleuropulmonary abscesses and empyema,
- abdominal infections, including hepatic abscesses, and
- subcutaneous sepsis following human bite wounds.

These bacteria are an infrequent cause of endocarditis and pharyngitis.

Streptococcus bovis can be isolated from patients who have endocarditis and bacteremia. There is a strong association between bacteremia caused by this micro-organism and adenocarcinoma of the colon, as well as neonatal sepsis and meningitis.[73]

The nutritionally variant streptococci (pyridoxal-dependent streptococci) can also cause endocarditis. These bacteria, which are part of the normal oral flora, account for up to 5% of endocarditis cases.[23] [74] These bacteria are the cause of much higher rates of treatment failure, relapse and mortality in endocarditis than other streptococci. [74]

Infections caused by *Leuconostoc* spp. are mostly nosocomial, occurring in immunocompromised patients or neonates. Previous antibiotic therapy or interrupted integrity of the skin or mucosal barriers are usually additional risk factors in patients infected with these micro-organisms. [75] [76]

MANAGEMENT

Groups A, B, C and G streptococci

Penicillin is the traditional first-choice therapy for infections caused by groups A, B, C or G streptococci or pneumococci. *Streptococcus pyogenes* is still extremely sensitive to penicillin and erythromycin is a good alternative in case of penicillin allergy. However, an increase in the prevalence of erythromycin-resistant group A streptococcal strains has been reported in several areas. Resistance occurs in relation to an increased macrolide consumption and may reach 40%.[77]

Acute streptococcal pharyngitis should be treated; amoxicillin is an appropriate choice in the outpatient setting. Generally, there is no need to treat carriers. Persistent oropharyngeal carriage after a complete course of penicillin therapy can occur in up to 30% of patients. ß-Lactamase production by pharyngeal flora as well as penicillin tolerance of the group A streptococci have been suggested as causes of failure of penicillin in the eradication of group A streptococci.

Septic scarlet fever should be treated in order to prevent suppurative and late complications. Again, penicillin is the first-choice therapy but a synergistic effect can be

achieved by addition of an aminoglycoside. In cases of allergy, erythromycin, clindamycin and vancomycin appear to be adequate alternatives.[51]

The object of therapy in patients who have acute rheumatic fever is to reduce inflammation, to decrease fever and toxicity and to control cardiac failure. Depending on the clinical condition of the patient, treatment varies from analgesia to anti-inflammatory drugs (aspirin-like agents or, in severe cases, corticosteroids). Antibiotic treatment of streptococcal infections effectively prevents development of acute rheumatic fever and minimizes the possibility of transmission of rheumatogenic streptococcal strains. On the other hand, a favorable effect of penicillin on prevention of acute glomerulonephritis has never been demonstrated. However, in order to eradicate the nephritogenic streptococcal strain, penicillin should also be administered to these patients. Thus, it is essential to distinguish acute post-streptococcal nephritis from other forms of glomerulonephritis. In fact, no form of treatment is known that influences the generally favorable outcome of acute post-streptococcal glomerulonephritis. Therefore, therapy is symptomatic and usually confined to salt and fluid restriction to prevent circulatory overload. Sometimes, additional treatment including diuretics or antihypertensive therapy is indicated.

In life-threatening infections, such as necrotizing fasciitis and streptococcal toxic shock, a rapid diagnosis immediately followed by adequate treatment is essential. Surgery (debridement of necrotic tissue or even amputation) is the key event in the treatment of necrotizing fasciitis.[26] [28] [29] [43] The combination of penicillin and clindamycin is the therapy of choice. Preliminary data suggest that the addition of intravenous immunoglobulin preparations may be efficacious, although convincing clinical trial data are lacking. Supportive therapy in the intensive care unit, including fluid replacement, inotropics, hemodialysis and resuscitation, is also required (see Chapter 10).

In immunocompromised patients who have serious group C and G streptococcal infections, such as endocarditis, meningitis or septic arthritis, penicillin-aminoglycoside combinations are used.[51] [52] [53]

Failure of antibiotic therapy should prompt investigation to discover underlying disease or undrained foci of infection.

Group B streptococci

Group B streptococci remain susceptible to penicillin G. However, the MIC of penicillin G for group B streptococci is considerably higher (average 0.04µg/ml) than that observed for group A streptococci.[55] Susceptibility to ampicillin and cephalosporins is also uniform, whereas resistance to erythromycin and clindamycin occurs in 1–18% of isolates and tetracycline resistance is seen in 85–92% of recent isolates.[55] [56] Resistance to aminoglycosides is uniform, but the combination of penicillin and gentamicin has synergistic activity and accelerates the killing of group B streptococci *in vitro*.

Because of the inoculum-like effect and the direct relation between delayed sterilization of the CNS and the occurrence of neurologic sequelae, initial therapy of suspected group B streptococcal meningitis should include increased dosages of penicillin to ensure efficacy.

Although the duration of therapy is relatively arbitrary, most investigators recommend parenteral penicillin G for 10 days for bacteremia, 2–3 weeks for meningitis and 3–4 weeks for osteomyelitis or endocarditis.[55]

Enterococci

Antimicrobial therapy for enterococcal infections is complicated because most antibiotics are not bactericidal at clinically relevant concentrations. Combination therapy with a cell wall agent plus an aminoglycoside improves the outcome of enterococcal endocarditis and probably of enterococcal meningitis, but it may not improve the outcome in bacteremia.[59] [61] [78] High-level aminoglycoside resistance, ß-lactamase production, vancomycin resistance and high-level ampicillin resistance are increasing in prevalence.[58] [59] [78]

Enterococcus faecium is typically high-level penicillin and ampicillin resistant and this type of resistance has been reported as a

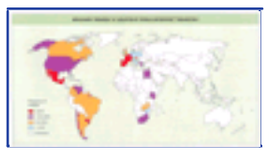

Figure 225-21 Worldwide frequency of isolation of penicillin-resistant pneumococci. Strains with MIC 0.1–2.0µg/ml are said to be intermediate resistant and high-level penicillin-resistant strains are defined as MIC > 2.0µg/ml.

significant predictor of lack of cure.[58] [59] [78] Therapy of enterococcal infections caused by vancomycin-resistant *E. faecium* is very difficult because these organisms are usually resistant to alternative antibiotics currently available.[58] [59] Several types of glycopeptide resistance phenotypes are now known.[58] The VanA phenotype is associated with acquired inducible resistance to both vancomycin and teicoplanin. VanA, which is carried on a transposon (a mobile genetic element), is transferrable to other susceptible enterococci by conjugation. The VanB phenotype, which is chromosomally mediated, inducible and transferrable by conjugation, mediates inducible resistance to vancomycin but not to teicoplanin (see Chapter 189 and Chapter 199). [58]

There has been some interest in the use of quinolones against vancomycin-resistant enterococci. Ciprofloxacin displays bacteriostatic activity against enterococci and synergistic bactericidal activity has been demonstrated in vitro when combined with ampicillin or gentamicin. However, in-vitro activity does not guarantee in-vivo success.[78] The newly developed streptogramins (quinupristin and dalfopristin) and oxazolidinones (linezolid) appeared promising against vancomycin-resistant enterococci.[79] Nitrofurantoin is active against many strains of vancomycin-resistant enterococci and should be useful for urinary tract infections.[78]

Streptococcus bovis should be differentiated from the enterococci because it is usually susceptible to penicillin alone, and both endocarditis and meningitis due to *S. bovis* have a better prognosis.[73]

Streptococcus pneumoniae

Penicillin used to be the first-choice therapy for pneumococcal disease, and in penicillin-sensitive strains it still is. For patients who have penicillin allergy, cephalosporins and erythromycin are valuable alternatives.

Resistance to penicillin is increasing in many parts of the world (Fig. 225.21) and is associated with a decreased affinity of the antibiotic for penicillin-binding proteins present in the bacterial cell wall. Penicillin resistance is thought to be due to horizontal transfer of

genes of altered penicillin-binding proteins with lowered affinity to penicillin and other ß-lactams.

At least 30% of the pneumococcal strains in the USA show intermediate resistance to penicillin (MIC 0.1–2.0µg/ml). Except for meningitis patients, these are readily treatable with increased doses of penicillin.

Of more concern is the appearance of pneumococcal isolates that are regarded as highly resistant to penicillin (MIC =2.0µg/ml). It is suggested that the extended consumption of oral cephalosporins contributes to pneumococcal resistance to penicillin. If these strains are circulating, it might be more reliable to treat severe pneumococcal infections with vancomycin.[65] However, the rate of resistance to other commonly used antibiotics such as erythromycin, tetracycline and trimethoprim-sulfamethoxazole is much greater in penicillin-resistant strains than in penicillin-sensitive strains (see Chapter 189).[35] [62] [80]

Viridans group streptococci

Viridans group streptococci have long been considered uniformly susceptible to ß-lactams, macrolides, lincosamines, rifampin (rifampicin) and vancomycin.[67] Occasionally, however, mostly under the pressure of long-term penicillin therapy, serious infections due to penicillin-resistant or penicillin-tolerant strains have been

reported.[68] [81] In endocarditis, high-dose penicillin in combination with an aminoglycoside is recommended. If MIC values are below 0.12µg/ml, the duration of this combination therapy may be limited to 14 days, but alternatively penicillin monotherapy can be given for 4 weeks. In cases of penicillin allergy, vancomycin is a good alternative.[23] [67] [74] [81] (See also Chapter 59).

Surgical drainage remains central to the management of abscesses (caused by *S. milleri*) and is often augmented by antibiotics.[70] The antibiotic of choice for infections caused by *S. milleri* is penicillin, to which all but a few strains are very sensitive.[66] [70] [71] [72] Suitable alternatives include erythromycin, clindamycin and cephalosporins.[66] [70] [71]

Leuconostoc and *Pediococcus* spp. are vancomycin resistant but are generally susceptible to clindamycin, carbapenems and gentamicin, and most are susceptible to penicillin as well.[75] [82]

PREVENTION

Several of the infections caused by streptococci are followed by complications of such a serious nature that preventive measures should be instituted. Preventive measures can include several modes of action:

- improved hygiene,
- antibiotic prophylaxis, and
- vaccination.

The choice of method should be based on the pathogenicity of the micro-organisms and the reactivity of the host. Special attention should be paid to those patients who have previously known disorders in organs that could be the focus of infection.

Group A streptococci

Resurgence of severe group A streptococcal disease in the USA during the late 1980s has renewed interest in preventive measures for patients who have rheumatic fever. As a new group A streptococcal throat infection can cause further deterioration in an already diseased heart, preventive measures must be undertaken to hinder the further progression of the disease. Penicillin or erythromycin prophylaxis has usually been recommended. Carefully controlled trials in patients who have rheumatic fever have demonstrated convincingly that a monthly intramuscular dose of benzathine penicillin produces a statistically significant reduction in the frequency of recurrent streptococcal infections and subsequent attacks of rheumatic fever. Where benzathine penicillin is no longer available, procaine penicillin may be a suitable alternative. The intramuscular route of penicillin injection is preferred to the oral route because of the higher compliance rates associated with it. The recommended dose is benzathine penicillin intramuscularly 1.2 million units every 4 weeks or penicillin V orally 250mg q12h. It is not clear how long prophylaxis should be continued, but presumably it should be for life.

In contrast, a favorable effect of penicillin prophylaxis in cases of glomerulonephritis has never been demonstrated, and relapses of glomerulonephritis occur at such a low frequency that prophylaxis is not warranted. In rare cases, patients who have streptococcal cellulitis or erysipelas with frequent recurrences should be considered for penicillin prophylaxis.

No vaccine is at present available for protection against group A streptococcal infections, but intensive research is ongoing.

Group B streptococci

Group B streptococci colonize the vagina, vulva and rectum of about 25% of fertile women. This micro-organism therefore represents a threat of bacterial sepsis to the newborn baby, especially in those cases where obstetric complications or prematurity are likely. Although the incidence of serious infections, such as septicemia and meningitis, is only around 1%, antibiotic prophylaxis has been recommended for patients who have obstetric complications, especially if earlier pregnancies have been complicated by group B streptococcal infections. Studies have clearly demonstrated that intrapartum administration of penicillin or ampicillin reduces the transmission of group B streptococci from the mother to the infant, and at least 80% of early-onset group B streptococcal disease can be prevented in this way.[83] Local prophylactic regimens have also been suggested, including vaginal washing with various antiseptics during the last month of pregnancy and at delivery, although the effect of this is still controversial (see Chapter 65).

Another approach is based upon the observation that antibodies toward the capsular polysaccharide of group B streptococci are protective in animal models and appear to correlate also with human immunity. Thus, efforts have been made to prevent group B streptococcal infections by passive or active immunization. Administration of antibodies to the mother before delivery has not given unequivocal results, but the use of vaccine produced by single or multiple group B streptococcal type polysaccharide antigens in many cases has induced protective antibodies. However, the results are often erratic and, although they are promising overall, vaccination against early-onset group B streptococcal neonatal infection is not routinely used. The use of conjugated group B streptococcal capsular polysaccharide-based vaccines may be a step forward.[47]

Streptococcus pneumoniae

In order to control the spread of (penicillin-resistant) pneumococci, restrictive antibiotic policies, isolation facilities and vaccination are indispensable. The currently available pneumococcal vaccines are composed of a mixture of 23 pneumococcal capsular polysaccharides; antibodies against these polysaccharides are protective.[84] However, the 23 vaccine serotypes do not cover more than 63% of the streptococcal types responsible for pneumococcal infections in other parts of the world. The response rate in the healthy adult population is variable.[33] [85] The majority of vaccinated adults respond by producing antibodies against about 75% of the 23 antigens. The poor immunogenicity of the polysaccharide vaccine in people at risk for pneumococcal disease is a major problem; an insufficient response is observed in asplenic or elderly people and in young children. Antibody levels subside with time and may no longer be detectable after 5 years in older adults. Therefore, patients who are

prone to develop pneumococcal disease should be vaccinated every 3–5 years. [62] [63] [85] [86]

The pneumococcal types most commonly found in children are those that seem to be less immunogenic than other types. Furthermore, polysaccharide vaccines do not evoke an antibody response in children aged under 2 years. This problem can at least be partly overcome by preparation of conjugate vaccines, in which the polysaccharides are bound to a protein carrier such as bacterial toxoids, thereby inducing a T cell-dependent immunoreactivity. Further research along these lines is presently being performed. Pneumococcal protein antigens, such as pneumolysin and surface proteins, are currently being examined as candidates for a pneumococcal vaccine, together with the polysaccharide vaccine.

Prevention of endocarditis

There is an obvious risk of endocarditis in patients undergoing dental, surgical or interventional procedures that might induce transient bacteremia. In certain high-risk groups the bacteria can adhere to the heart valves and give rise to endocarditis. This is often the case in patients who have congenital heart failure, rheumatic heart disease, valve prostheses or earlier incidences of endocarditis. In many countries, amoxicillin as a single dose 1 hour before the intervention and ampicillin combined with an aminoglycoside in extended operative procedures are recommended. The prophylaxis is mainly directed against viridans group streptococci when the intervention is localized to the oral cavity and against enterococci if the intervention is directed to the gut or the urinary tract (see Chapter 59).

Chapter 226 - Aerobic Gram-positive Bacilli

Robert Bortolussi
Timothy Mailman

INTRODUCTION

The aerobic Gram-positive bacilli are a heterogeneous group of bacteria whose members cause a wide variety of infections in both healthy and immuno-compromised individuals, and several organisms have been implicated in outbreak infections. The major pathogens are *Listeria monocytogenes*, *Bacillus anthracis*, *Corynebacterium diphtheriae*, *Erysipelothrix rhusiopathiae* and *Nocardia* spp. Other organisms discussed are *Arcanobacterium*, *Oerskovia*, *Rhodococcus*, *Rothia* and other corynebacteria.

LISTERIA MONOCYTOGENES

NATURE

Listeria monocytogenes is a short, motile, Gram-positive, non-spore-forming bacillus that is the causative agent in a spectrum of human disease ranging from gastroenteritis to invasive infections — notably in neonates, the elderly and immunocompromised patients. In addition to its importance as a human pathogen, it has a significant association with abortion and encephalitis in sheep and cattle.

The genus *Listeria* is described in *Bergey's Manual of Determinative Bacteriology* as a non-spore-forming, non-acid-fast and nonencapsulated Gram-positive regular short-rod occurring singly or in short chains.[1] *Listeria* is divided into six species based on biochemical properties and DNA relatedness. *Listeria monocytogenes* is distinguished by its ability to produce acid from the sugars L-rhamnose and a-methyl-D-mannoside, lack of acid production from D-xylose and by narrow zones of ß-hemolysis on blood agar. The organism exhibits a positive Christie, Atkins and Munch-Petersen (CAMP) test using *Staphylococcus aureus* or *Rhodococcus equi* as the second indicator hemolytic strain. A positive CAMP test for *L. monocytogenes* differs from that seen for *Streptococcus agalactiae* by producing a rectangular, rather than arrow shaped, zone of accentuated hemolysis (Fig. 226.1a). Other key tests for the identification of *L. monocytogenes* include a positive catalase reaction, tumbling motility when viewed microscopically at room temperature, and an 'umbrella' pattern of motility in soft agar incubated at room temperature (Fig. 226.1b).

Growth of the organism occurs between 39°F (4°C) and 98.6°F (37°C), with fastest growth between 86°F (30°C) and 98.6°F. Cold enrichment techniques or selective agar may be used to isolate *L. monocytogenes* from contaminated specimens but are generally of limited value in the clinical laboratory.

Only *L. monocytogenes* and *Listeria ivanovii* have been associated with significant infection in humans. Six serovars of *L. monocytogenes* have been described and are distinguished on the basis of somatic O and flagellar H antigens. Serovars 1/2a, 4a and 4b are the most common isolates from animals and humans with clinical disease. In the USA, serovars 4b and 1/2a account for 95% of strains, serotype 4b being the most common overall. In Canada serovar 1/2a occurred in 42% of clinical isolates in 1988. Other serovars originate from soil or other environmental sources but are rarely seen as clinical pathogens.

EPIDEMIOLOGY

Reservoir

Listeria monocytogenes is commonly present in soil, decayed matter, wood and other material and is widespread in the natural environment.[2] [3] Spoiled silage appears to be a source of infection to animals. Fecal carriage of *L. monocytogenes* in animals allows recontamination of soil, with subsequent ingestion of contaminated silage to complete the cycle in animals.

Recent evidence suggests that almost all human cases of *L. monocytogenes* are acquired through ingestion of contaminated food. In the early and mid 1980s large outbreaks of *L. monocytogenes* occurred in both pregnant women and immunocompromised hosts. The first outbreak that demonstrated indirect transmission from an animal reservoir was reported from the Atlantic maritime provinces of Canada.[4] In this outbreak, *Listeria*-contaminated sheep manure was used to fertilize cabbages that were placed in cold storage over the winter; clinical disease developed in pregnant women and immunocompromised patients who subsequently consumed the cabbages. Outbreaks of infection attributed to consumption of many foods, including inadequately pasteurized dairy products and contaminated processed meats, have been reported since.[5]

The improved ability to culture *L. monocytogenes* with selective media provides an opportunity to examine food eaten by patients who have sporadic listeriosis. Evidence that most sporadic listeriosis cases result from ingestion of contaminated food was provided by the Listeriosis Study Group at the Centers for Disease Control and Prevention (CDC).[6] [7] Their studies implicated undercooked chicken and soft cheeses as significant sources of disease and are supported by subsequent sampling surveys performed by food regulatory agencies.

Fecal carriage of listeriosis is uncommon but ranges from 1% in hospitalized patients to 26% in household contacts of patients who have listeriosis. In the Canadian outbreak fecal surveys demonstrated carriage in approximately 5% of family contacts.[4] Several studies have shown that fever and gastroenteritis are clinical features of *L. monocytogenes* infection[5] after ingestion of contaminated food. *Listeria monocytogenes* may also cause a self-limited symptomatic gastrointestinal infection.

Occurrence

Active surveillance in the USA suggests an annual incidence of 0.7 cases per 100,000 population,[8] resulting in 1700 cases of listeriosis per year in the USA, with a mortality rate of 40%. Slightly lower figures have recently been reported from Europe. Risk of listeriosis varies among segments of the population. Immunocompromised patients and those at the extremes of age — neonates and the elderly — appear to be at highest risk. Immunocompromised patients comprise two-thirds of adult listeriosis cases. This parallels

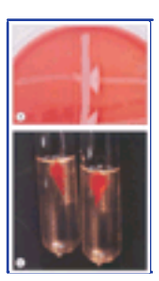

Figure 226-1 Tests for the identification of *Listeria monocytogenes.* (a) CAMP test. Enhanced hemolysis patterns for *L. monocytogenes* (left) and *Streptococcus agalactiae* (right) colonies are shown; these are growing adjacent to a streak of *Staphylococcus aureus* colonies in the center. (b) Demonstration of motility of *L. monocytogenes* grown in semisolid agar at room temperature. Note that the migration of the organism from the central stab is more pronounced at the surface of the soft agar, forming the typical umbrella-shaped pattern in both tubes.

animal models, in which risk of listeriosis is increased by administration of corticosteroids, ciclosporin A and prostaglandins. Renal transplantation appears to be a particularly significant risk factor and a nosocomial outbreak in this population has been reported. Patients who have AIDS have an estimated 1000-fold risk of acquiring invasive listeriosis. Alcoholism, diabetes, cirrhosis, hemochromatosis and decreased gastric acidity are additional risk factors. Community-acquired listeriosis, however, often occurs in patients who have no apparent predisposing conditions.

Incidence of neonatal listeriosis in the USA is approximately 13 per 100,000 live births — approximately 30% of the total number of cases of reported listeriosis. A similar incidence has been reported in studies from Europe. Epidemics of food-borne listeriosis have disproportionately involved perinatal cases. No differences in carriage rates between pregnant women and nonpregnant individuals have been found in fecal and vaginal specimens. Fecal carriage may lead to vaginal colonization and the development of 'late-onset' infection in infants born to healthy mothers.

While most large outbreaks of listeriosis have occurred in the community, case clusters of nosocomial listeriosis in both newborn infants and adults have been described. In infants, the index case typically presents with 'early-onset' infection within 1 week of birth, and subsequent cases develop 'late-onset' listeriosis after the 7th day of life. A dramatic nosocomial outbreak occurred in Costa Rica when an infant who had 'early-onset' listeriosis was bathed in mineral oil that became contaminated with the epidemic strain. A cluster of 'late-onset' disease then erupted after other infants were bathed with the same oil.[9]

PATHOGENICITY

Intracellular growth

Since the 1960s, it has been known that *L. monocytogenes* can survive within macrophages in the liver and spleen. In the late 1980s

Figure 226-2 *Listeria monocytogenes* can invade both 'professional' phagocytic cells — polymorphonuclear leukocytes and monocytes — and nonphagocytic cells. Attachment of the bacteria to the surface of nonphagocytic cells may be determined by heparin sulfate recognition proteins on the surface of the organism. Once internalized, the bacterial product listeriolysin O will lyse the phagosome, liberating the bacteria into the cytoplasm, where they proliferate. After a few hours, actin filaments polarize at one end of the bacterium, propelling it to the internal membrane surface. The organism will break through the membrane to enter the exterior of the cell or an adjacent cell.

it was also appreciated that *Listeria* can infect nonphagocytic cells — epithelial, hepatocellular and fibroblast cell lines — thus providing the organism with an intracellular environment temporarily sheltered from more hostile host defense forces.[10]

Microbial attachment to host cells is the initial step in cell invasion (Fig. 226.2). Recent work has shown that interaction with a heparin sulfate peptidoglycan receptor on the surface of cells is involved in *L. monocytogenes* adhesion.[11] The stage is then set for internalization of the organism. A family of surface proteins known as internalins are secreted in large amounts by all strains of *Listeria* capable of invading host cells.[12] Although these proteins may be an important factor associated with entrance into epithelial cells and hepatocytes, they do not explain intracellular spread and multiplication. The intracellular survival of *Listeria* requires synthesis of a specific hemolysin, termed listeriolysin O. Listeriolysin enables the organism to escape from the phagosome by lysing the phagosomal membrane. Release of *L. monocytogenes* from intracellular vacuoles precipitates both intracellular growth and polymerization of actin of the host cell around *Listeria*. Actin polymerization is important in the cell-to-cell transfer of *L. monocytogenes* and is encoded by the *actA* gene. The liberated organism thrives in the cytoplasm, which provides more abundant growth conditions. Through these mechanisms *Listeria* can enter, grow and spread inside a wide variety of cells including renal epithelial cells, fibroblasts, vascular endothelium, hepatocytes and enterocytes. By producing ActA, *Listeria* causes host-cell actin to assemble into filaments at one end of the bacterium. This 'rocket tail' provides the propulsive force for the organism to move through the cytoplasm. When the bacteria reach the cell membrane, they form filopods that become ingested by adjacent cells.

Acquired immunity

Some 3–4 days after infection begins there is normally a decrease in viable bacteria in the monocyte/macrophage phagocytic system. This heralds the onset of the immune T-cell-dependent stage of antilisterial defense, termed 'acquired resistance'.

The process leading to acquired immunity to *Listeria*, cell-to-cell interaction, cytokines and cytolytic activity is now partially elucidated (Fig. 226.3 and Fig. 226.4). In adult immunocompetent animals, *Listeria* are phagocytosed by 'professional' phagocytes —

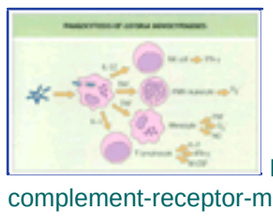

Figure 226-3 Phagocytosis of *Listeria monocytogenes*. Opsonized *L. monocytogenes* is phagocytosed by professional phagocytic cells through a complement-receptor-mediated process. Once ingested into a phagosome of a monocyte or macrophage, most bacteria are quickly killed by oxidative radicals (O_2^-), lysozyme, nitric oxide (NO) and other products of the cell. Tissue macrophages produce a variety of protein products essential for the activation of natural killer (NK) cells (interleukin(IL)-12), T cells (IL-1) and polymorphonuclear (PMN) leukocytes and other monocyte/macrophages (tumor necrosis factor (TNF)-a). These cells in turn produce cytokines, interferons (IFN), interleukins that cause cell proliferation (IL-2; macrophage colony stimulating factor (M-CSF)) or further activation of cell populations involved in elimination of the organism and of infected nonprofessional cells.

macrophages and monocytes; and by 'nonprofessional' phagocytic cells — fibroblasts, hepatocytes, etc. Macrophages take up and process listerial proteins and produce interleukin (IL)-12 and IL-1. Peptides resulting from digestion of *Listeria* are actively processed by the macrophage in the endoplasmic reticulum, where the peptides bind to major histocompatibility complex (MHC) class I molecules.[12] The *Listeria*-peptide-MHC complex is transported to the cell surface, where it is recognized by cytotoxic T cells ($CD8^+$ phenotype) and helper T-cells (Th). In the presence of IL-12, naive Th cells differentiate into Th1 cells, which proliferate, producing IL-2, interferon (IFN)-? and lymphotoxin. [13] Interleukin-12 also stimulates activation and proliferation of natural killer (NK) cells and ?/d T cells. Both cell clones produce IFN-?. Cytotoxic T cells interact with cells bearing *L. monocytogenes* antigen, causing them to lyse. Natural killer cells are further stimulated by IFN-?, inducing an enhanced ability of these cells to lyse infected fibroblasts and hepatocytes (Fig. 226.4).

Cytokines such as macrophage colony-stimulating factor (M-CSF) and tumor necrosis factor (TNF)-a also appear during the first 5 days and have been implicated as mediators of listerial clearance. Peak immunity to *Listeria* is expressed at about the sixth day of infection, which coincides with maximal T-cell synthesis of IFN-?. The role for endogenous IFN-? for resolution for *L. monocytogenes* infection has been clearly shown. [14] Tumor necrosis factor-a enhances a variety of antibacterial or antiparasitic resistance mechanisms. Several cells produce TNF-a, including NK cells; however, monocytes/macrophages are probably the most abundant source. Endotoxin (lipopolysaccharide) and other agents including mitogens, viruses, protozoa and cytokines such as M-CSF, IL-1, IL-2 and IFN-? have been identified as inducers of TNF-a. When administered before infection, TNF-a induces enhanced resistance of the host to bacterial infection. Endogenously produced TNF-a during sublethal *Listeria* infection in adult animals appears to function as an inducer of resistance,[15] suggesting that TNF-a-dependent mechanisms limits intracellular infection early in the course of infection. Down-modulation of the immune

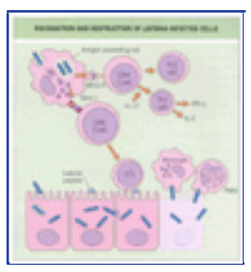

Figure 226-4 Recognition and destruction of *Listeria*-infected cells. Cytotoxic T lymphocytes and NK lymphocytes migrate to the site of infection and recognize and destroy *Listeria*-infected cells by the presence of listerial peptides on the surface of such cells. Intracellular bacteria are then exposed to the extracellular environment. Organisms in the extracellular space are efficiently phagocytosed and killed by polymorphonuclear leukocytes (PMN) and monocytes that have been primed or activated by cytokines (TNF-a, M-CSF, IL-8) and IFN-?.

response is mediated by ?/d T cells, an important role for such cells in controlling unregulated proinflammatory cytokines.[14]

Perinatal listeriosis

The pathogenesis of fetal listeriosis is not clear. Since the heaviest foci for neonatal infection are lung and gut, the fetus is probably infected by swallowing contaminated liquid as well as through the transplacental hematogenous route.[16] An ascending pathway from the lower genital tract may occur; however, infection via the transplacental route is favored by most authors. *Listeria monocytogenes* chorioamnionitis diagnosed by transabdominal amniocentesis (free from vaginal bacterial contamination) has been reported, supporting a maternal-to-newborn blood-borne route of infection.

Host response in the neonate

In newborn animals, susceptibility to *Listeria* is increased and is associated with delayed activation of macrophages. Studies on the afferent and efferent arms of the immune system in newborn mice have shown that macrophage-T-cell interaction is impaired and macrophage activation does not occur. [17]

Natural killer cells also contribute to the early response to *L. monocytogenes* infection. The proportion of mononuclear cells expressing NK cell phenotype and NK cell

activity is decreased at birth, particularly for premature infants. Both NK cell phenotype and function increase rapidly in the weeks after birth.

In adult animals, IFN and agents that induce or augment IFN production confer protection against lethal listeriosis. Synthesis of IFN, IL-2, IL-4 and IL-12, all of which modulate the immune response

and macrophage activation, is deficient in newborns. Although production of these factors may be defective, newborn animals do respond to exogenous IFN; pretreatment with IFN or its inducers protects against subsequent infection.

The ontogeny of cytokine-related host defense mechanisms has not been studied in depth. Tumor necrosis factor is decreased among newborn rats challenged with *L. monocytogenes*.[18] In this study of *L. monocytogenes* infected newborn rats, TNF-a was detected only among animals over 8 days of age. The age at which TNF-a becomes measurable corresponds to the approximate age at which increased resistance to *L. monocytogenes* occurs.

PREVENTION

Food-borne outbreaks of listeriosis are unpredictable and may occur in a wide geographic area. Therefore, reporting of sporadic cases of listeriosis to public health authorities may be the only method of distinguishing sporadic from epidemic disease. The epidemic threshold is unknown and may only be determined in retrospect. Recent studies suggesting that sporadic listeriosis is also food-borne have important public health implications.

Sampling of foodstuffs associated with sporadic cases of listeriosis is not warranted. Case-control studies to determine potential vehicles of transmission in outbreaks may help to define the source, and environmental sampling may be an important part of such outbreak investigations. Strains of *Listeria* from clinical and environmental isolates should be forwarded to a reference laboratory for appropriate epidemiologic typing. At a minimum, serotyping, phage-typing and multifocus enzyme electrophoresis typing should be performed to characterize the epidemic strain.

During an outbreak of listeriosis, high-risk groups such as pregnant women or those who have AIDS who develop a flu-like illness should be empirically treated with ampicillin and an aminoglycoside after appropriate cultures of blood, cerebrospinal fluid (CSF), sputum, rectum and vagina have been obtained. In pregnant women, amniocentesis for diagnosis of chorioamnionitis may be appropriate. If membranes have ruptured and contamination is suspected, use of selective media may enhance the isolation of *Listeria* from these patients.

Identification of early- or late-onset listeriosis in a newborn nursery should prompt appropriate epidemiologic and clinical history taking from the mother as well as postpartum cultures of rectum and vagina. Infection control precautions with gowning, gloves and careful hand-washing will prevent nosocomial transmission between infected infants and is consistent with current procedures for all forms of neonatal sepsis.

The recognition that sporadic cases of listeriosis are primarily food-borne has also prompted publication of preventive guidelines by the CDC (Table 226.1).

DIAGNOSTIC MICROBIOLOGY

Serologic evaluation

The agglutination reaction (Widal test) demonstrates antibodies against somatic O and flagellar H antigens of the various *Listeria* serovars. Unfortunately, because of the antigen complexity of *L. monocytogenes*, no agreement has been reached as to the interpretation of agglutination reactions for diagnostic purposes.

Attempts to demonstrate complement-fixing *Listeria* antibodies date back to the 1930s. In one study, serum samples collected from 32 mothers who had perinatal *Listeria* infection were compared with 128 samples from matched controls.[20] The sensitivity and specificity of the complement fixation test were shown to be 78% and 91%, respectively; however, the positive predictive value was only 75%. Thus,

TABLE 226-1 -- Dietary recommendations for preventing food-borne listeriosis.*

DIETARY RECOMMENDATIONS FOR PREVENTING FOOD-BORNE LISTERIOSIS
• Thoroughly cook raw food from animal sources (e.g. beef, pork and poultry)
• Thoroughly wash raw vegetables before eating
• Keep uncooked meals separate from vegetables, cooked foods and ready-to-eat foods
• Avoid consumption of raw (unpasteurized) milk or foods made from raw milk
• Wash hands, knives and cutting boards after handling uncooked foods
Additional recommendations for people at high risk
• Avoid soft cheeses (e.g. Mexican-style, feta, Brie, Camembert, blue-veined cheeses). There is no need to avoid hard cheeses, cream cheese, cottage cheese or yogurt
• Reheat leftover foods or ready-to-eat foods (e.g. hot dogs) until steaming hot before eating
• Although the risk for listeriosis associated with foods from delicatessen counters is relatively low, pregnant women and immunosuppressed persons should avoid these foods or thoroughly reheat cold cuts before eating
People at high risk are those who are immunocompromised as a result of illness or medications, pregnant women and the elderly.

** Adapted from Centers for Disease Control.*[19]

the complement fixation test can be regarded as reliable only in some patients who have acute *Listeria* infection.

Detection of antibodies to listeriolysin O has been used to diagnose human listeriosis. Sensitivity and specificity of the test were over 90%. Although these results were impressive, the technique is not available commercially and results have not yet been confirmed in other centers.

Isolation of the organism

Cultivation of *L. monocytogenes* is the only reliable means of proving that the cause of an infection is due to *Listeria*. Culture of venous blood, ascitic and other fluids, cervical material, urine, amniotic fluid, lochia and meconium and tissues at biopsy or autopsy offer the best chances for identifying *Listeria* in persons who have an infection. Culture of the stool is not helpful. Feces are positive for *Listeria* in 1–5% of healthy adults.

Microscopic diagnosis may be attempted by use of Gram's stain only in specimens that normally do not contain bacteria — CSF, meconium and tissue smears. The finding of short (sometimes coccoid, and in pairs) Gram-positive rods strongly supports a suspicion of listeriosis and is indicative of this infection (Fig. 226.5). *Listeria monocytogenes* may not Gram stain as well as other Gram-positive organisms. Particularly with longstanding disease or when the patient has received antibiotics, the organisms may appear Gram-negative and be confused with *Haemophilus influenzae* when observed in the CSF. In other instances, *Listeria* has been mistaken for pneumococci or corynebacteria.

The submission of clinical specimens for culture may be facilitated by the use of transport-enrichment fluid. It is, however, advisable to submit specimens such as blood, sputum, CSF and pus without any additives. For patients who have received antibiotics, the use of a commercial antibiotic-removing device in sterile body fluid cultures is useful.

CLINICAL MANIFESTATIONS

The clinical features of listeriosis have considerable variability and may mimic other infections or other disease states. Based on the most common clinical manifestations, four or more clinical groups may be distinguished.

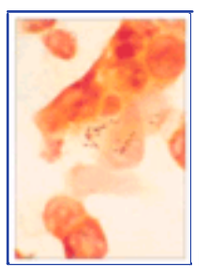

Figure 226-5 Gram stain of clinical specimen showing intra- and extracellular Gram-positive bacilli.

Listeriosis during pregnancy

Susceptibility to *L. monocytogenes* is markedly increased in pregnant animals. The predilection of *Listeria* for the fetoplacental unit and intrauterine infection is well documented.[21] [22] Maternal listeriosis can be transmitted to the fetus by an ascending or transplacental route. Early gestational listeriosis is associated with septic abortion; however, most cases of perinatal listeriosis are found after the fifth month of pregnancy, with premature delivery of a septic or stillborn infant the result.

Maternal influenza-like illness with fever and chills, fatigue, headache and muscle pains often precedes delivery by 2–14 days. Although symptoms in the mother may subside before delivery, infection and fever precipitating delivery is common. Blood cultured from such women can yield *Listeria* at the time of initial symptoms or later. Premature labour in mothers who have listeriosis is common; approximately 70% deliver newborns at less than 35 weeks of gestation. The mortality rate, including stillbirth and abortion, is 40–50%. Early treatment of *Listeria* sepsis in pregnancy, however, can prevent infection and its sequelae.

Listeriosis in the newborn infant

Neonatal listeriosis has become recognized as the most common clinical form of human listeriosis. Infection in the neonatal period is usually divided into two clinical groups defined by age: early- and late-onset infection.

Some clinical and laboratory manifestations of early-onset neonatal listeriosis are outlined in Table 226.2 , which is compiled from clinical cases in which early and late forms of the disease could be differentiated. Classically (as illustrated in Table 226.2), early-onset neonatal listeriosis develops within 1–2 days of life. However, in one outbreak involving 10 infants who had nosocomially acquired listeriosis, an atypical clinical picture was described.[9] Nine of these infants were bathed shortly after birth with mineral oil contaminated with *L. monocytogenes*. Clinical features of infection developed 4–8 days later and were similar to those seen in late-onset infection, insidious onset of illness with fever and meningitis being common.

Evidence of preceding maternal illness is often described in infants who have early-onset disease. Although some symptoms in mothers are vague and non-specific — malaise, myalgia — others are sufficiently

TABLE 226-2 -- Clinical and laboratory features of early-onset listeriosis.

CLINICAL AND LABORATORY FEATURES OF EARLY-ONSET LISTERIOSIS		
Feature		**Proportion of cases (%)**
Male sex		64
Preterm infants (gestation age <35 weeks)		63
Mortality (of live-born infants)		15
Features in infants	Meconium stain	69
	Pneumonia	62
	Anemia	62
	Thromobocylopenia (<150 × 10^9 /l)	35
	Meningitis	21
Source of isolate	Blood	73
Maternal features	Flu-like illness	45
	Blood isolate	35
Age at onset for early-onset listeriosis is under 7 days, but most cases occur at less than 2 days of age. Anemia is defined as hemoglobin less than 14g/dl and/or hematocrit less than 45. Meningitis is based on compatible clinical or autopsy findings or observation of the organism on Gram stain of the CSF. Flu-like illness is defined as the presence of respiratory symptoms, myalgia and fever occurring from 3 days to 1 month before delivery. Blood isolates are defined as of *Listeria monocytogenes* from mother's blood at any time before delivery of the infant.		

distinctive — fever, chills — to alert physicians to the risk of prenatally acquired listeriosis. Blood cultures from such mothers are often positive for *Listeria*.

Although early-onset disease may occur up to 7 days of age, most cases are clinically apparent at delivery, with meconium staining, cyanosis, apnea, respiratory distress and pneumonia. Meconium-stained liquor is a common feature in such infants and may occur at any gestational age, even less than 32 weeks. Pneumonia is also common, but radiographic features are not specific — peribronchial to widespread infiltration. In more longstanding infection, a coarse, mottled or nodular pattern has been described. Assisted ventilation is frequently necessary in such infants. Persistent hypoxia in spite of ventilatory assistance is seen in severely affected infants. Laboratory features are non-specific; a leukocytosis with presence of immature cells may be seen or, if infection is severe, neutropenia. Similarly, thrombocytopenia may also occur. Many infants are anemic, which is perhaps attributable to hemolysin produced by the organism. These laboratory and clinical features will not help to distinguish listeriosis from early-onset group B streptococcal or other bacterial infection.

In severe infection a granulomatous skin rash has been described (Fig. 226.6). Slightly elevated, pale patches measuring 1–2mm in diameter with a bright, erythematous base are seen. If such areas are biopsied, a leukocytic infiltrate with multiple bacteria is found.

Neonatal listerial infection that occurs after 7 days of life is termed late-onset infection. Although there is some overlap between early- and late-onset forms of listeriosis, the clinical pattern of the two is usually distinct. The common clinical and laboratory features of late-onset neonatal listeriosis are shown in Table 226.3 . By far the most common form of *Listeria* infection over this period is meningitis, which is present in 94% of late-onset cases. In many centers, *Listeria* ranks second only to group B streptococci as a cause of bacterial meningitis in this age group, causing approximately 20% of such infections.

Clinical features do not distinguish listerial meningitis in this age group from other causes. A striking predominance of males has been noted in most series. Fever and irritability are predominant clinical

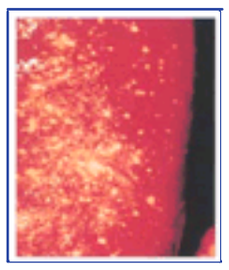

Figure 226-6 Skin rash on premature infant who has sepsis due to *Listeria monocytogenes.* This form of infection, known as granulomatosis infantisepticum, is characterized by disseminated microabscesses on the skin, spleen and liver. The elevated pale patches (1–2mm in diameter) on the skin are clearly seen in contrast to the bright erythema of surrounding skin.

TABLE 226-3 -- Clinical and laboratory features of late-onset listeriosis.

CLINICAL AND LABORATORY FEATURES OF LATE-ONSET LISTERIOSIS		
Feature		**Proportion of cases (%)**
Male sex		67
Signs at presentation	Fever	94
	Irritability	75
	Diarrhea	Occasional
Isolates	CSF	94
	Blood	17
Mean age is 12–20 days.		

features. Often, infants do not appear excessively ill and may therefore elude diagnosis for several days.

Laboratory features of late-onset infection are not specific. Cell count in the CSF is usually high, with a predominance of polymorphonuclear and band forms. Occasionally, in longstanding disease, a relatively high number of monocytes may be seen. Gram stain of CSF may not always suggest a diagnosis, both because the organism may be rare and because the morphology is atypical. Variable decolorization of Gram's crystal violet-iodine stain may result in organisms appearing as Gram-negative rods. The appearance of organisms as illustrated in Figure 226.5 is characteristic of listeriosis in the early phase of severe infection.

Mortality in late-onset newborn infection is generally low, unless diagnosis is delayed by more than 3–4 days after onset of infection. Long-term sequelae and morbidity are uncommon.

Central nervous system infection

Bacteria invade the central nervous system through a variety of mechanisms. For *L. monocytogenes*, invasion of the central nervous system may be mediated by bacterial invasion of endothelial cells at the blood-brain interface followed by cell-to-cell spread of the organism in microvascular endothelial cells. Some investigators have also speculated on a 'Trojan horse' mechanism, whereby monocytes or neutrophils infected with *L. monocytogenes* transport organisms to the central nervous system, where they are released when these cells are lysed.[23] Among adults who have central nervous system infection, a high incidence of prolonged ataxia, hydrocephalus and cerebellar atrophy visualized via computerized tomography (CT) have been reported. Rhombencephalitis and brain abscess have also been seen and appear to have a good prognosis.[22]

Other clinical forms of infection

Papular cutaneous lesions are often observed in newborns when listeriosis is disseminated. These are to be distinguished from the primary skin lesions caused by *Listeria* observed in adults, which are the result of direct contact, such as the handling of a cow's placenta after abortion by a veterinarian or farmer.

In the course of the septicemic form, accompanying conjunctivitis is sometimes observed. Other unusual forms of listeriosis such as endocarditis and septic arthritis have been described in adults but appear to be rare in infants.

THERAPY

Listeria remains susceptible to antibiotics commonly used in its treatment. However, the high mortality rate and risk of relapse have prompted a search for newer therapeutic regimens, including fluoroquinolones, trimethoprim-sulfamethoxazole (co-trimoxazole) and rifampin (rifampicin). Transferable plasmid-mediated antibiotic resistance has been reported, conferring resistance to chloramphenicol, tetracycline and erythromycin.

In-vitro studies

Conflicting reports of in-vitro activity of antibiotics against clinical isolates of *L. monocytogenes* probably reflect a variable pattern of susceptibility for strains as well as differences in laboratory technique. Two large in-vitro studies of antibiotic susceptibility of human clinical isolates of *L. monocytogenes* have been reported, using broth dilution susceptibility methods.[24] [25] Both studies found that the strains represented a homogeneous population susceptible to ampicillin, penicillin, erythromycin and tetracycline. In-vitro results, however, are greatly influenced by methodology — inoculum size, media and definition of end points. As reported in these two studies, the minimal bactericidal concentration (MBC) of antibiotics is often much higher than levels attainable clinically. Thus, most antibiotics tested are bacteriostatic but not bactericidal. Although bacteriostatic antibiotics have been used in the past, bactericidal antibiotics have a potential advantage for patients who have impaired host defense mechanisms, including neonates. Results of cephalosporin antibiotic in-vitro and in-vivo studies have been consistently disappointing. The organism is uniformly highly resistant to all the cephalosporin antibiotics tested.

In-vivo studies

Several combinations of antibiotics have been compared for their bactericidal activity against *L. monocytogenes* in vivo. Animal models appear to provide the only practical method of assessing therapeutic regimens, since large clinical studies in humans are not available. Murine models employing normal adults or immunodeficient animals have been reported.[26] [27] A rabbit model using animals injected intracisternally with *Listeria* has also been described. The model most analogous to neonatal disease has also been described.[28]

In the in-vivo model of neonatal listeriosis, the combination of ampicillin with gentamicin gave significantly better eradication of organisms in spleen than ampicillin alone.[28] Similarly, the combination of trimethoprim and sulfamethoxazole was superior to either drug alone. Reports of efficacy of other antibiotics in vivo are conflicting. Rifampin has been found by some authors to be highly effective in eradicating organisms, while others have found it to be ineffective. Sensitivity of individual strains to rifampin may account for the widely discrepant results. Also, rifampin resistance may develop in vivo when it is used as a single drug. The use of ciprofloxacin

in animal models has not suggested any therapeutic advantage over ampicillin.

Clinical reports

There have been no prospective clinical trials reported for *L. monocytogenes* human infection. Anecdotal reports of single cases or reviews of outbreaks support the conclusions drawn from in-vivo models. In one review of clinical management of 119 cases of listeriosis from three centers in the USA, excellent therapeutic results

were seen for patients treated empirically with penicillin or ampicillin; all had a reduction of fever and clinical improvement. However, patients treated initially with cephalosporins had persistent fever and infection.[2] In the largest assessment of treatment regimens during a single outbreak,[29] lower mortality was reported for children given ampicillin (16% of 57 children) compared to those treated with chloramphenicol, tetracycline or streptomycin (33% of 82 children). Nevertheless, in the absence of controlled clinical trials, a definitive recommendation for treatment cannot be made.

SUGGESTED MANAGEMENT

Listeriosis during pregnancy

If amnionitis is present, initial treatment should be given by intravenous route to assure adequate tissue levels — ampicillin 4–6g per day (divided into four equal doses) plus an aminoglycoside. If amnionitis is not present or if acute symptoms of amnionitis have subsided, then oral antibiotics are probably adequate — amoxicillin 2–3g per day (divided into four equal doses). In both situations, treatment should continue for 14 days. If the patient has a significant allergy to ampicillin, therapeutic options are limited. Erythromycin may be given. The estolate form of this drug should be avoided since there is increased liver toxicity during pregnancy. Trimethoprim-sulfamethoxazole should not be used, since premature delivery of the infant may occur as a consequence of infection, in which case the drug may cause displacement of bilirubin from protein and increase the potential for toxicity in the infant.

Neonatal listeriosis

Ampicillin in combination with an aminoglycoside is the preferred management for early-onset infection. For infants with a body weight under 2000g, administer 100mg/kg per day (divided into two equal doses) for the first week of life. For infants with a body weight over 2000g, administer 150mg/kg per day (divided into three equal doses) for the first week of life. For the second week of life the appropriate daily dosages are 150mg/kg and 200mg/kg for infants under and over 2000g body weight, respectively. Aminoglycoside doses vary with the agent chosen.

For gentamicin the suggested dosages are 5mg/kg per day (divided into two equal doses) for the first week of life and 7.5mg/kg per day (divided into three equal doses) for the second week of life. A treatment duration of 14 days is recommended for early-onset neonatal sepsis due to *L. monocytogenes*; however, a 3-week course of treatment should be given in the uncommon event of early-onset neonatal listeriosis with meningitis.

Listeriosis in infants and adults

Meningitis is commonly present in the late-onset type of neonatal listeriosis and in listeriosis in adults. Delayed eradication of the organism may be seen in such cases. Ampicillin 200–400mg/kg per day (divided into 4–6 equal doses for 3 weeks), in combination with an aminoglycoside, is recommended. [22] Lumbar punctures should be repeated daily until the organism has been cleared. In the event of delayed clearance (more than 2 days), further investigations are indicated and should include CT scan or cranial ultrasound (in infants) to assess for the presence of cerebritis, abscess, rhombencephalitis or intracranial hemorrhage. Treatment should be prolonged to 6 weeks if cerebral pathology is identified.

If the organism persists in the CSF the addition of rifampin or use of trimethoprim-sulfamethoxazole may be considered if the organism is sensitive in vitro. Experience with rifampin and trimethoprim-sulfamethoxazole in the neonatal period and with this organism is limited. Cephalosporin antibiotics have no role in treatment since the organism is uniformly resistant. Vancomycin has been used successfully in patients who are allergic to penicillin.[22]

BACILLUS ANTHRACIS

NATURE

The genus *Bacillus* comprises a variety of Gram-positive, spore-forming bacilli that are differentiated from *Clostridium* spp. by a positive catalase test and the ability to produce endospores in the presence of oxygen. *Bacillus* spp. are found worldwide as inhabitants of soil, water and airborne dust. Some species are part of the normal intestinal flora of humans and animals. Endospores resistant to extremes of heat, pH and salinity are able to survive harsh environmental conditions.

Bacillus anthracis was the first bacterium proved to cause a specific disease when, in 1877, Robert Koch induced anthrax in experimental animals by injecting them with pure cultures of the organism. Today, three well-defined cycles are recognized for the organism: spore multiplication in soil; infection of herbivorous animals; and human infection. Spore multiplication is favored in moist, alkaline soils rich in organic matter. As spore density increases, infection of grazing animals can occur. Human disease is often associated with animal outbreaks. Spores can survive in the soil for decades and contribute to persistence in a geographic area.

Bacillus anthracis can be differentiated from other *Bacillus* spp. by its lack of motility, absence of ß-hemolysis on sheep blood agar and penicillin susceptibility.

EPIDEMIOLOGY

Anthrax is a zoonotic disease of herbivores endemic to many rural areas of the world. Although anthrax spores have been found in soil samples worldwide, the disease has been controlled in most developed countries through animal immunization programs. Human infection occurs incidentally by contact with infected animals or animal products such as hides, hair or wool. Most human cases are related to occupational exposure by agricultural workers, veterinarians or those in the textile industry where animal hides and hair are frequently handled. Transmission to humans usually occurs by direct inoculation of spore-containing material to skin abrasions (cutaneous anthrax) but also via spore aerosolization (inhalational anthrax or 'wool sorter's disease') and ingestion (gastrointestinal anthrax). Accidental infections have occurred in laboratory workers. Person-to-person transmission has not been documented. The incubation period is generally 1–7 days following exposure. Suggestions that delayed onset of disease may occur following exposure to aerosolized spores has led to the current recommendation for a 2-month course of antibiotic prophylaxis following inhalational exposure.[30]

Anthrax remains enzootic in parts of Africa and Asia, despite its decreasing prevalence in the developed world. Multiple epidemics of human disease have been associated with epizootics in agricultural herds. More than 10,000 human cases occurred in Zimbabwe between 1979 and 1985 following an outbreak in cattle.[31] An outbreak in Chad during 1988 resulted in 716 human cases and 88 deaths.[32] Other outbreaks have occurred in the Middle East, South East Asia and the

Indian subcontinent. While most cases have been of cutaneous disease, clusters of inhalational and gastrointestinal anthrax have been reported.[33] Anthrax is probably under-reported in developing nations because of the difficulty in diagnosing gastrointestinal disease and limited public health statistics.

In developed countries, outbreaks have mostly been associated with the handling of imported animal products. An epidemic in a textile factory in Switzerland involved 24 cutaneous cases and one case of inhalational anthrax. The infections were traced to goat hair imported from Pakistan.[34] In North America, intermittent outbreaks occur among wildlife herds but domestic human disease is rare.

The development of anthrax as a biologic warfare and bioterrorism agent has drastically heightened global awareness of the disease. Japan, the USA, the UK, Iraq and the Soviet Union are among countries known to have worked on military applications of anthrax. Its subsequent use in terrorist acts has dissolved the perception of anthrax as merely an uncommon and occupational disease. Health care workers and public health agencies have been re-educated to recognize patterns of illness suggestive of anthrax and to develop contingency plans for epidemics. The lethal inhalational dose for anthrax spores is a millionth of a gram, yielding the potential for a small amount of aerosolized spores to devastate urban populations. These concerns were foreshadowed in April 1979 when anthrax spores were accidentally released from a military microbiology facility in the central Russian city of Sverdlovsk.[35] An anthrax epidemic occurred among people who lived or worked downwind of the site. The 96 cases and 64 deaths that ensued constituted the largest documented outbreak of inhalational anthrax in history. Livestock up to 50km from the site perished from anthrax.

PATHOGENICITY

The virulence of *B. anthracis* is largely mediated by the production of anthrax toxin and encapsulation. Anthrax toxin is an exotoxin composed of three thermolabile proteins, protective antigen (PA), lethal factor (LF) and edema factor (EF), which mediate most of the pathologic findings of anthrax. A capsule containing poly-D-glutamic acid assists the organism in evading phagocytosis. Production of toxin and capsule is mediated by the plasmids pX01 and pX02, respectively.[36]

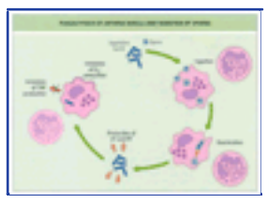

Figure 226-7 Phagocytosis of anthrax bacilli and ingestion of spores. Vegetative bacilli are relatively resistant to phagocytosis by polymorphonuclear leukocytes and monocytes, whereas spores are readily ingested. Once ingested by polymorphonuclear leukocytes or macrophage cells, however, the spores germinate into vegetative forms, which are able to reduce the normal production of bactericidal oxidative radicals by the cell. *Bacillus anthracis* produces lethal toxin (LT) and edema toxin (ET), which are cidal to cells and inhibit TNF-a production and oxidative radical production by phagocytic cells.

Anthrax usually begins by the introduction of spores from the organism through the skin, gastrointestinal tract or respiratory epithelium. Spores may be phagocytosed by tissue macrophages and remain at the site of inoculation or be transported to regional lymph nodes. In either case, spores germinate to vegetative bacilli, which are capable of toxin production. Local damage to tissue results from toxin-mediated edema and tissue necrosis. Toxin, organisms or both may spread via the vascular system to produce systemic disease.

When organisms release anthrax toxin, the PA component binds specific cell-surface receptors, forming a membrane channel that enables EF and LF to enter the cell.

Edema factor is an adenylate cyclase, similar to the adenylate cyclase toxin of *Bordetella pertussis*. Recent studies have demonstrated that activation of EF depends on binding to calmodulin.[37] It combines with PA to form *edema toxin*. In experimental models, cells treated with edema toxin exhibit increased intracellular cyclic adenosine monophosphate (cAMP). In monocytes and macrophages, cAMP regulates TNF-a production and as cAMP rises TNF production decreases. The ensuing cytokine dysregulation produces edema and destruction of local tissues.

Lethal factor combines with PA to form *lethal toxin*, the dominant virulence factor and major cause of death in infected animals. Following entry of lethal toxin into host cells, calcium influx occurs and cellular synthetic pathways are disrupted. Apoptosis and necrosis occur, mediated by protein phosphatases. Cell lysis follows. These tissue effects are seen clinically as the black necrotic lesions of cutaneous anthrax, the hemorrhagic mediastinitis of inhalational anthrax and the necrotic ulcers of pharyngeal or gastrointestinal disease.

Together, lethal toxin and edema toxin contribute to the inhibition of phagocytosis. If ingestion does occur, lethal toxin and edema toxin inhibit the oxidative burst of neutrophils and prevent intracellular killing of ingested bacteria (Fig. 226.7).

PREVENTION

Public health measures for preventing the spread of anthrax have focused on the identification and destruction of diseased animals and quarantine of potentially

infected livestock. Repeated outbreaks in Africa have illustrated that reservoirs of disease in wildlife herds can

be a source of re-introduction to domestic animals. Animal vaccines are available but require annual re-vaccination to maintain efficacy.

Control of anthrax in humans can be achieved by surveillance and control of industrial and agricultural sources of *B. anthracis* by public health authorities. International controls on the export of contaminated animal products has contributed to a decrease in industrial cases of anthrax. Both a live attenuated and a killed vaccine have been developed. The former vaccine has undergone large trials in the former Soviet Union, which demonstrated good protective efficacy. In North America, a cell-free vaccine, BioThrax®, is mandated for all US military personnel and is available for persons who have an occupational risk of acquiring anthrax. The vaccine contains purified protective antigen and can significantly reduce the occurrence of cutaneous anthrax in adults. Protection against aerosol challenge has not been evaluated.[38] Vaccine safety and efficacy have not been evaluated in a postexposure setting.

Postexposure prophylaxis against gastrointestinal and inhalation anthrax has been effective with several antibiotics. In one animal study, antibiotics such as penicillin, ciprofloxacin or doxycycline significantly improved survival when administered after aerosol exposure but before onset of symptoms.[39] Prophylactic antibiotics have also been effective after ingestion of contaminated food. The potential for genetically manipulated strains of military or terrorist origins to exhibit penicillin resistance has made ciprofloxacin or doxycycline the preferred prophylactic options in patients who have such inhalational exposures. The duration of prophylaxis for inhalational anthrax is 60 days.[40]

DIAGNOSTIC MICROBIOLOGY

Diagnostic specimens from patients suspected to have anthrax must be handled in biosafety cabinets to minimize the risk of transmission to laboratory workers. Laboratories should refer presumptive isolates to a reference laboratory capable of the appropriate biosafety containment level and notify public health authorities immediately.

Bacillus anthracis can be isolated from blood, sputum, CSF, vesicular fluid or eschar, gastric aspirates and stool (gastrointestinal anthrax). Blood cultures should be part of the evaluation for all forms of anthrax. Gram staining of clinical specimens may reveal Gram-positive 'boxcar-shaped' *B. anthracis* organisms. M'Fadyean's or India ink stains may be used to visualize the capsule. Direct fluorescent antibody (DFA) testing and polymerase chain reaction (PCR) have been used for rapid diagnosis in clinical specimens but are unavailable in most clinical laboratories.

Bacillus spp. can be cultured on standard media without special nutrient supplementation and typically produce flat, spreading colonies. The filamentous outgrowths from *B. anthracis* colonies are described as forming a 'Medusa-head' appearance. Colonies are gray-white and tenacious. Encapsulation is lost on standard media but may be demonstrated on nutrient agar with 0.8% sodium bicarbonate after overnight incubation in 5% CO_2 . Isolation of *B. anthracis* from non-sterile sites may be achieved with selective media such as polymyxin B-lysozyme EDTA-thallous acetate (PLET) agar or spore selection techniques using heat or alcohol treatment of specimens to kill vegetative cells.

Bacillus anthracis is included with the *Bacillus cereus* group (*B. cereus*, *B. anthracis*, *Bacillus mycoides* and *Bacillus thuringiensis*), whose members are distinguished by production of egg yolk lecithinase. One potential algorithm for *B. anthracis* identification is outlined below.

Presumptive identification criteria

1. From clinical samples such as blood, CSF or skin lesion (vesicular fluid or eschar): large encapsulated Gram-positive rods lacking ß-hemolysis on sheep blood agar;
2. From growth on sheep blood agar: large spore-forming Gram positive rods;
3. Non-motile; and
4. Non-hemolytic on sheep blood agar.

Confirmatory criteria

1. Visualization of capsule; and
2. Lysis by gamma-phage; or
3. DFA assay.

While wild strains of *B. anthracis* are penicillin-susceptible, the potential for genetically altered strains to exhibit penicillin resistance makes this a less reliable trait. Commercial test strips are also available to assist in differentiating *B. anthracis* from other *Bacillus* spp.

Serology has a limited role in acute diagnosis but is useful for epidemiologic studies and as a confirmatory test when the organism has not been isolated. Both an enzyme-linked immunosorbent assay (ELISA) and an electrophoretic immunotransblot (EITB) method have been found to be reliable for detection of antibodies to the capsule and PA respectively. Demonstration of a 4-fold rise in titer between the acute and convalescent phases or a single titer greater than 1:32 is required for confirmation of infection.[38]

Since bacteriologic confirmation is achieved in less than half of anthrax cases, a skin test of cell-mediated immunity to anthrax was developed as a complementary diagnostic tool. An evaluation in the former Soviet Union found the test to have a sensitivity of 81.8% in the first 3 days of illness, 97–99% during the second and third weeks of illness and a sensitivity over 72% up to three decades following recovery — providing a useful method of retrospective diagnosis. [41]

CLINICAL MANIFESTATIONS

Three primary forms of human anthrax are recognized: cutaneous, gastrointestinal and inhalational. Cutaneous anthrax accounts for over 95% of naturally occurring anthrax cases; gastrointestinal anthrax ranks second. Inhalation anthrax is rare. Prior to the outbreak in the Soviet Union in 1979, only 30 inhalational cases had been described.[42]

Clinically, cutaneous anthrax usually begins as a small, pruritic, painless papule 1–10 days after direct contact with infected material. The papule generally develops into one or more vesicles surrounded by a ring of erythema and edema (Fig. 226.8). The vesicles may rupture, exposing an ulcer covered with a black eschar. The word 'anthrax' is derived from the Greek word for coal, in reference to the eschar's dark appearance. Regional lymphadenopathy is also evident and may be severe. Untreated cutaneous anthrax has a fatality rate of 10–20%. However, antibiotic treatment drastically reduces the mortality rate and sequelae.

Gastrointestinal anthrax is associated with ingestion of contaminated meat products that are raw or incompletely cooked. Early symptoms include nausea, vomiting and fever. Severe abdominal pain and bloody diarrhea develop within 2–3 days. Toxemia, shock

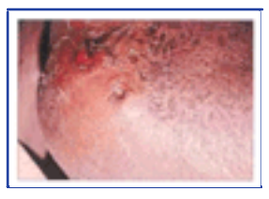

Figure 226-8 Cutaneous anthrax, demonstrating marked erythema, edema and vesicle rupture.

and death can develop shortly after the start of severe symptoms. Lesions can be found anywhere from the oropharynx (pharyngeal anthrax) to the large bowel, with the cecum being frequently involved. Pathologically, a hemorrhagic enteritis is noted, with necrotic ulcerations of the mucosa.

Respiratory anthrax was well characterized during the 1979 outbreak at Sverdlovsk and in more recent cases in the USA.[42] Initial symptoms include sore throat, fever, myalgias and fatigue. Rapid progression to dyspnea, cough, headache, vomiting, chills, weakness, abdominal pain and chest pain is typical. Respiratory failure and shock develop in most patients. The presence of infiltrates is variable on chest radiograph but a widened mediastinum with pleural effusions is a key diagnostic finding and reflects the underlying pathology of hemorrhagic mediastinitis.

In the Sverdlovsk cases, onset of symptoms was typically 3–14 days following exposure. Hospitalized patients were treated with penicillin or other antibiotics, antianthrax globulin, steroid and artificial ventilation. The average hospital stay was 1–2 days for fatal cases and approximately 3 weeks for survivors. Historical data suggest that the mortality rate for untreated inhalational anthrax is approximately 97%. With modern antibiotic treatment and intensive care support, the fatality rate remains at least 75%.

Meningitis may develop following dissemination of cutaneous, gastrointestinal or respiratory anthrax but occurs in fewer than 5% of cases.

MANAGEMENT

Given the potential severity of disease, patients who have suspected anthrax should receive empiric therapy pending diagnostic tests. Historically, penicillin G has been the treatment of choice. Doses of two million units given intravenously every 2 hours have been used in adults. The addition of an aminoglycoside such as gentamicin may confer some improvement in response to treatment. All naturally occurring strains of *B. anthracis* have been sensitive to erythromycin, chloramphenicol, gentamicin and ciprofloxacin. As noted previously, in potential bioterrorism or biowarfare settings, penicillin susceptibility cannot be assured and doxycycline or ciprofloxacin should be used. One recent review has recommended treatment with intravenous ciprofloxacin (400mg q8-12h).[43] Supportive therapy for shock, fluid volume deficit and ventilatory assistance may also be needed (see also Chapter 185). [43]

CORYNEBACTERIUM DIPTHERIAE

NATURE

Corynebacterium diphtheriae is a member of a group of irregular nonspore-forming aerobic Gram-positive bacilli characterized by an ability to grow in the atmosphere of air, lack of endospores and an irregular shape on Gram-stained smears. This group includes human, plant and animal pathogenic species, the human pathogens including *Oerskovia*, *Rothia*, *Actinomyces*, *Arcanobacterium*, *Propionibacterium*, *Arachnia* and *Gardnerella* spp. in addition to *Corynebacterium* spp.

The genus *Corynebacterium* is characterized by pleomorphic Gram-positive bacilli that tend to stick together in parallel groupings and bend when dividing to create 'Chinese letter' arrangements (Fig. 226.9). They are all catalase- and cytochrome-oxidase-positive and can grow in facultative anaerobic conditions.[44]

EPIDEMIOLOGY

Diphtheria, the disease caused by *C. diphtheriae*, was first described in manuscripts of the 6th century AD but was not recognized as a specific

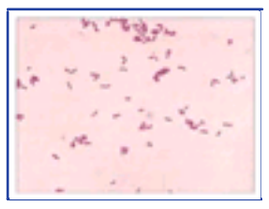

Figure 226-9 Chinese letter and picket-fence appearance of *Corynebacterium* spp. on Gram-stained smears.

disease until Bretonneau defined it in 1826. In the 1880s the bacillus was discovered by Klebs and soon after Koch's postulates were fulfilled. The first successful diphtheria immunization was performed in 1913 by von Behring, at a time when epidemics in Europe and the UK made diphtheria the leading cause of death in children 4–10 years of age. Mass immunization was introduced in the early 1940s, by which time the numbers of cases were already declining. The introduction of diphtheria toxoid immunization was associated with a substantial decrease in reported cases in both Europe and North America for 25 years. A study of an immunization program in Toronto, Canada from 1926–9 showed a 75% reduction in cases of diphtheria in immunized children compared with controls who were unimmunized.[45]

Outbreaks of diphtheria in recent years have been rare. In 1990 an epidemic that began in Moscow rapidly spread to the newly independent states of the former Soviet Union, first in the cities and later into rural areas. Poor immunization practices may have created a large population of susceptible hosts. Toxigenic strains that had not circulated in this part of Europe for about 25 years were finally able to colonize a pool of susceptible hosts large enough to start an epidemic.

Prior to childhood immunization programs, epidemics among European school-aged children occurred about every 25 years through the 17th, 18th and 19th centuries. Speculation that the resurgence of this infectious disease might be due to cyclic intrinsic factors of the micro-organism itself evolved from evidence that non-toxigenic oropharyngeal colonizing strains of *C. diphtheriae* can be made toxigenic by introduction of toxin genes by bacteriophages. Perhaps immunization with diphtheria toxoid does not prevent colonization with non-toxigenic strains of this organism, allowing natural cycling of more virulent strains into a population with waning immunity. The epidemic in the former USSR largely involved the adult population. Poor socio-economic conditions and mass population movements during the dissolution of the Soviet Union may have also contributed to the development of this epidemic. A total of 47,808 cases of diphtheria were reported in the former Soviet Union from 1990–5.[46] Spread of cases by travelers has occurred in western Europe. This is confirmed by the fact that isolates from Finland showed the same prevalent *C. diphtheriae* var. *gravis* strain belonging to the same G1 ribotype as in 91% of a series isolated in northern Russia during this epidemic.[47]

Transmission is generally through contact with infected respiratory droplets or skin wounds. Raw milk and milk products and clothing have been associated with diphtheria transmission. It is transmissible for 2–4 weeks in untreated individuals but with antibiotic treatment the risk of transmission is greatly reduced after the first 48 hours.

PATHOGENICITY

Corynebacterium diphtheriae is not an invasive organism but causes disease by colonizing the skin and upper respiratory epithelium, inducing a mild inflammatory reaction and releasing a potent exotoxin

Figure 226-10 Molecular action of *Corynebacterium diphtheriae.* The B subunit of diphtheria toxin (DT) binds to host cell receptor. Proteolytic cleavage of the B subunit from the A subunit (the active DT) in cell endosome. The DT-A subunit escapes from the endosome into the cytoplasm, where it inhibits the transfer of triple code from mRNA to growing polypeptide at the ribosomes on the endoplasmic reticulum. It does this by modifying the enzyme elongation factor (EF)-2 that catalyzes this mRNA transfer.

that, when taken up by animal cells, inhibits protein synthesis. Locally, the toxin causes tissue necrosis. If circulating toxin antibodies are not present, it will be absorbed into the circulation and transported to distant sites, causing extensive end-organ damage, especially to the kidneys, brain and heart.

On a molecular level, the diphtheria toxin (DT) is synthesized as a 62kDa polypeptide comprising a B subunit that binds to cell receptors and an A subunit that is the active moiety. The DT binds to the host animal cell receptor via its B subunit and is taken up by cellular endosomes at clathrin-coated pit sites (Fig. 226.10). Proteolytic cleavage of DT occurs releasing the A subunit (DT-A; see Fig. 226.10). The acidic condition of the cell's endosome causes conformational change in the B subunits, resulting in opening of cation channels in the endosome membrane and release of the active DT-A moieties into the cytoplasm. There, DT-A inhibits cellular protein synthesis by adenosine diphosphate (ADP)-ribosylation of diphthamide in elongation factor 2-GTP, thus inactivating it. This elongation factor 2 (EF-2) is important for catalyzing the transfer of triple code from messenger RNA to the developing amino-acid polypeptide sequence via transfer RNA at the ribosome. In this way, DT-A acts as a polypeptide chain terminator of host cell protein synthesis, causing an inability of the cell to repair its own membranes and cellular cytotoxicity (see Fig. 226.10). Toxin production by *C. diphtheriae* is induced by a lysogenic bacteriophage ß that co-infects certain strains of this colonizing organism. It is also known that this toxin has DNA fragmentation capabilities and can cause cell cytotoxicity by a mechanism other than inhibition of protein synthesis.[48]

The localized tissue destruction initially forms a gray exudate of dead host cells and white blood cells, which may be removed. Later, with the addition of fibrin and red blood cells, a tough gray-brown pseudomembrane is produced that is difficult to remove and bleeds after such attempts. If the membrane is extensive, it may lead to respiratory tract obstruction. The underlying submucosa is often very edematous. Secondary invasion of bacteria, especially *S. aureus* and *Streptococcus pyogenes*, can occur. End-organ toxin-mediated damage can initiate a myocarditis with edema, mononuclear cell infiltration and fatty changes of heart myofibrils and its conducting system, neuritis and nerve demyelinization and acute tubular necrosis of the kidney.[49]

PREVENTION

The best form of prevention is an active immunization program of children and adults that covers over 90% of the population. Immunization coverage of less than this target leaves enough susceptible people to cause spread in an enclosed population. Infants should receive a primary series of diphtheria toxoid immunization with

other childhood immunizations at 2, 4 and 6 months of age and booster shots at 18 months, 4 years and every 10 years thereafter through adulthood.

Because of an excess of local and systemic reactions, the adult vaccine dosage is usually decreased to 2 Lf units in those over 7 years of age. In an outbreak situation in older children and adults, if no immunization was previously administered, the primary series can be given in two doses 4 weeks apart and the third 6 months later.

Carriers or close contacts of a case of diphtheria should receive not only vaccination with diphtheria toxoid but erythromycin or penicillin prophylaxis for 7 days to prevent subsequent spread of the organism. Eradication of asymptomatic pharyngeal colonization is slow and difficult, with many people excreting organisms for more than 1 month despite antibiotic therapy.[50]

DIAGNOSTIC MICROBIOLOGY

Corynebacterium diphtheriae colonizes the respiratory tract of humans alone. Isolation of the organism requires specialized media containing potassium tellurite (Tinsdale agar) to inhibit other normal flora, including non-*diphtheriae Corynebacterium* spp. After 24–48 hours of incubation at 35°C, gray-black colonies are seen with a surrounding brown halo due to the precipitation of a tellurium sulfide secondary to cysteine breakdown utilizing the bacteria's cysteine desulfatase. Methylene-blue-stained smears will show the pleomorphic club-shaped nonsporulating rods. The organism's name is derived from the Greek word *korynee*, meaning 'club', and *diptheria,* meaning 'leather pouches', referring to the thick, leather-like pharyngeal membranes this organism produces. Other normal flora, *Neisseria* and *Staphylococcus* spp. can also occasionally appear black on this specialized media but have a different morphology on stained smear. In addition, specimens should be streaked onto a blood agar plate to detect *S. aureus* and ß-hemolytic streptococci, which can co-infect tissues with this organism. If transportation to the laboratory is delayed for more than 24 hours, the specimens should be streaked onto a specialized Loeffler transport media agar slant, leaving the swab on top, for later delivery to the laboratory.[51]

Corynebacterium diphtheriae can be distinguished from other *Corynebacterium* spp. biochemically as it is catalase, cysteinase and nitrate reaction-positive; urease, esculin, pyrazinamidase and gelatin hydrolysis reaction-negative; and uses glucose and maltose but not mannitol or xylose sugars for growth requirements.[44] A modification of the normal concentrations of biochemical substrate concentrations and the use of an enriched basal media can allow for rapid 1 hour

identification from a pure subculture of a 18- to 24-hour growth of the organism. [52] A commercial API-Coryne® strip of 20 biochemical substrates may identify this and other *Corynebacterium* spp. within a 24-hour period.

Subdivision of this organism into three biotypes — *gravis*, *mitis* and *intermedius* — can be done using colony size, blood agar hemolysis, morphology on stained smear and biochemical tests. It is also important to establish bacterial toxin production because biotype *mitis* is usually non-toxigenic. Treatment is generally reserved for people carrying toxigenic strains.[44] Recently, in Germany, toxin-producing *C. diphtheriae* var. *mitis* strains have been described that cause invasive disease.[53] Toxin can be demonstrated using the Elek plate, on which the organism and controls are streaked perpendicular to an antitoxin-impregnated filter paper strip embedded in the agar, causing immunoprecipitin lines to form if the organism is a toxin-producer (Fig. 226.11). The PCR technique may be more sensitive by directly detecting toxin genes.[54]

Antimicrobial susceptibility testing of isolates has shown that they are generally susceptible to penicillin, vancomycin and erythromycin but they are methicillin-resistant. Recent isolates from France and Vietnam show that multiresistant strains are becoming increasingly common. Erythromycin resistance was seen in 15% and tetracycline resistance in 20% of 88 strains from Vietnam between 1992 and 1996. [55] Isolates from France between 1987 and 1993 showed a 19% resistance to rifampin.[56]

Multilocus enzyme electrophoresis and ribotyping techniques can be used in molecular characterization of strains of these clinical bacterial isolates to determine whether an outbreak is occurring from a particular clone introduced into a population.[57] Other laboratory diagnostic tests have more limited value and include the Schick test and serology testing to the diphtheria toxin to detect previous exposure to the organism either in the form of a vaccine or infection. The Schick test is an intracutaneous inoculation of a small amount of purified diphtheria toxin. If the subject has circulating antitoxin antibodies, there will be an absence of the redness, tenderness and induration of greater than 10mm that occurs 5 days later. This test is not useful for acute diagnosis of diphtheria, and a negative result does not necessarily indicate that the antitoxin antibody levels present are protective against acquisition of this disease.[49] Indeed, serology testing for antitoxin antibody levels is problematic because protective levels have not been well defined. It is believed that antibody levels of 0.01–0.09IU/ml or more provide some protection.[58]

Figure 226-11 Detection of diphtheria toxin production. The Elek test detects DT production in a bacterial clinical isolate. A paper strip soaked in diphtheria antitoxin is placed perpendicular to a horizontal streak of bacterial growth. If it produces toxin, an arrow-shaped precipitin line develops in the agarose plate.

CLINICAL MANIFESTATIONS (see also Chapter 178)

Respiratory tract disease

After a 2- to 4-day incubation period, colonizing toxigenic strains start producing toxin locally and signs and symptoms of disease start to occur. In nasal disease, typically seen in infants, the illness appears similar to the common cold but then progresses to a serosanguinous and mucopurulent rhinitis. Excoriation of the nares and upper lip and a white septal pseudomembrane may been seen. Spread of the disease to the pharynx occurs next, causing a sore throat, tonsillitis, low-grade temperature and a white to gray pseudomembrane extending from the tonsils to the posterior pharyngeal pillars and nasopharynx. As toxin production continues, there is profound malaise, weakness, cervical lymphadenitis, soft tissue swelling of the neck, causing a 'bull neck', and occasionally palatine paralysis and upper respiratory obstruction with stridor. Further spread of the disease downward to the larynx, causing hoarseness, dyspnea and stridor and later a tracheobronchitis with edema and membrane formation in the lower respiratory tract, will often precede respiratory failure.[49] Indeed, about 60% of 42, mostly middle-aged, adults who died in a review of 1860 cases of diphtheria in St Petersburg, Russia in 1994 had simultaneous involvement of throat, nose and bronchi clinically. Unlike the mortality rate of about 2% for this Russian outbreak, which was mostly in adults, [59] the mortality rate for respiratory tract diphtheria in the USA and Sweden of late, in which more cases of children were involved, has been 10% and 18%, respectively. Clinical manifestations of toxin dissemination after respiratory tract diphtheria occurs as the localized disease is waning. Cardiac toxicity is the next most prevalent cause of death after respiratory failure and neurotoxicity is generally a much later phenomenon that adds to the morbidity from this disease.

Cutaneous disease

Diphtheria involving the skin usually is more common in tropical climates and is associated with infection of pre-existing skin lesions, lower mortality, an indolent and mild course, and superinfection with *Staphylococcus aureus* and *Streptococcus pyogenes*. This disease is characterized by chronic, nonhealing, sharply bordered ulcers that have an adherent gray pseudomembrane over the top of them. Despite their mild clinical course, they produce good protective antitoxin antibodies, do not respond to antitoxin therapy and act as reservoirs for respiratory tract illness, can contaminate objects in the environment and are shed for longer periods of time than pharyngeal colonization. Cutaneous diphtheria is seen in outbreaks among the poor, homeless and alcoholics with close-confined living arrangements. This form of disease may be an important means of person-to-person transmission of diphtheria and is thought to be the means of starting outbreaks of respiratory tract diphtheria.

Myocardial toxicity

When the local disease is improving, 1–2 weeks from onset, up to two-thirds of patients have electrocardiographic evidence of myocardial toxicity, with ST wave alterations and first-degree heart block, but most of them are asymptomatic. Heart failure and arrhythmias occur in up to one-quarter of patients who have severe disease, increasing mortality by three to four times compared with those who do not have these manifestations. Such patients present with dyspnea, weakness, diminished heart sounds, a gallop rhythm, a dilated heart, low cardiac output and conductive disturbance arrhythmias.

A rather uncommon but often fatal cardiac complication of diphtheria is endocarditis. Most reported cases were in patients who had *C. diphtheriae* bacteremia. A total of 33 cases were reported between 1893 and 1993, and at least 20 of those reported since 1950 are associated with non-toxigenic strains. Non-toxigenic strains have been

thought not to be associated frequently with invasive disease but this increased incidence may be due to an increasing prevalence of patients in whom intravenous drug usage is a pre-existing risk factor. Almost half of these cases were children aged 16 years and younger, and a high incidence of septic arthritis and mycotic aneurysms of the lower extremities occurred. Although most patients had a known predisposing factor for endocarditis, such as intravenous drug abuse, valvular heart disease or congenital heart disease, one-third occurred in patients who had no known predisposition. The mitral valve is the most commonly affected heart valve. The mortality rate was about 40%. Very few of these patients received surgical therapy in conjunction with antibiotic therapy and it is unclear whether early surgical intervention would have improved the prognosis of this disease.[60]

Neuronal toxicity

Up to two-thirds of severely involved cases of diphtheria show evidence of neuronal toxicity, presenting early as palatine and pharyngeal paralysis and then cranial palsies involving muscles of the eye, face, pharynx and larynx, causing dysphagia and predisposing these patients to aspiration. The ocular manifestations of diphtheria include blurred vision and failure of accommodation. Later, several weeks after the sore throat, a peripheral motor demyelinating neuritis occurs, starting in the proximal extremities and progressing distally. Generally, there is slow and total resolution of the limb weakness.

MANAGEMENT

The management of a clinical case of diphtheria is described in Figure 226.12 (see also Chapter 178).

Hyperimmune diphtheria antitoxin

This product is made from immunized horses and, because up to 10% of the population shows hypersensitivity to horse serum, this preparation must be diluted 1:1000 with saline and a test dose of 0.1ml administered intracutaneously. An area of redness at the administration site greater than 10mm requires epinephrine (adrenaline) to be given, followed by a desensitization regimen.[49] If no hypersensitivity to horse serum is found, 20,000–40,000 units for pharyngeal or laryngeal disease of less than 48 hours duration, 40,000–60,000 units for nasopharyngeal pseudomembrane formation and 80,000–100,000 units for extensive disease of 3 or more days duration or with neck swelling should be administrated intravenously (or some suggest a spit between intramuscular and intravenous administration) over 60 minutes, as recommended by the American Academy of Pediatrics Red Book Committee. Repeat administrations are of no benefit and may increase the risk of anaphylaxis to horse serum protein.[50]

Antibiotic therapy

Antibiotics do not seem to alter the course of clinical disease but are administered in an effort to terminate toxin production and extension of local disease and prevent spread of the organism to other people. Erythromycin 40mg/kg per day (maximum 2g/day) intravenously or orally in four divided doses has been shown in some studies to be more efficacious than penicillin G (procaine penicillin G 25–50,000U/kg per day intramuscularly in two divided doses for 14 days). Elimination of the organism should be documented by three negative daily cultures after antibiotic therapy before strict isolation is discontinued. Communication of the organism to others can occur up to 4 days after commencement of antibiotic therapy.[50]

Supportive therapy

Strict bed rest is usually advocated during the maximum period of myocardial toxicity, the first 2–3 weeks from onset of illness. Serial

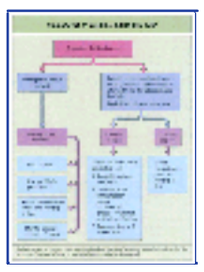

Figure 226-12 Management of a clinical diphtheria case. *Adapted from Farizo.*[61]

electrocardiograms may be useful for earlier detection of this complication. Tracheostomy equipment should be placed by the bedside to be prepared for acute upper airway obstruction. Nasogastric tube feeding may be required to prevent aspiration in the patient who has palatine or pharyngeal paralysis. Long-term immunity is unusual in cases of diphtheria and adequate immunization is required to prevent recurrence of this disease. This is given in the convalescent phase.[50]

OTHER *CORYNEBACTERIUM* SPECIES

Corynebacterium jeikeium

This species is the most commonly isolated *Corynebacterium* sp. from human blood and sterile body fluids. It is a pleomorphic, nonsporulating, aerobic Gram-positive bacillus that forms nonhemolytic, small, whitish colonies on blood agar after 24 hours of incubation. It requires lipid to grow and is unable to reduce nitrate or hydrolyze urea. In addition, it is resistant to most antibiotics, with the exception of being sensitive to vancomycin.[62]

This organism has emerged as a cause of serious nosocomial infections in immunocompromised patients. Predisposing factors for this infection include neutropenia, prior multiple antibiotic usage, prolonged hospitalization and disruption of the skin by surgery or an indwelling catheter. *Corynebacterium jeikeium* heavily colonizes the skin (axillary, inguinal and rectal) of about one-third to one-half of oncology patients for weeks to months but only lightly colonizes the

skin of healthy individuals. The spectrum of infection includes central-line-related septicemias, wound and soft tissue infections, prosthetic joint infection, prosthetic valve endocarditis, continuous ambulatory peritoneal dialysis (CAPD)-related catheter peritonitis, pneumonia, CSF shunt infections and liver abscesses.[63] Recently, there have been reports of infections in immunocompetent patients with this organism.[64]

Treatment involves intravenous vancomycin or ciprofloxacin and the removal of the prosthetic material or catheter.

Corynebacterium urealyticum

Corynebacterium urealyticum (CDC Group D2) is an aerobic Gram-positive bacillus that is similar to *C. jeikeium* in growth characteristics, microbiology and multiple antibiotic resistance profile (often only sensitive to vancomycin) but is rapidly urease-reaction-positive and does not ferment carbohydrates. It is a common cause of alkaline-encrusted cystitis, [65] in which ammonia produced from these urea-splitting bacteria combines with magnesium phosphate. At high pH, ammonium magnesium phosphate crystals precipitate out in the walls of an already damaged bladder and cause ulceration. *Corynebacterium urealyticum* has also been associated with kidney infections and struvite kidney stone production in renal transplant recipients.

Microbiologists should be aware of this organism and not discard urine plates after 24 hours in patients predisposed to such infections (immunosuppressed, urologic or renal transplant patients, especially if they have had repeated urinary tract infections); the plates should be re-examined at 48 hours, when these slow-growing organisms may first become noticed.

Vancomycin is considered the drug of choice to treat this infection. [63]

Corynebacterium pseudodiphtheriticum

This organism is part of the normal oropharyngeal flora, looks like *C. diphtheriae* but does not produce a toxin and, unlike *C. diphtheriae*, possesses both urease and pyrazinamidase enzymes and does not ferment carbohydrates. It has been found to cause endocarditis, necrotizing bronchitis and pneumonia in patients who have chronic disease. Rare case reports of urinary tract infection following renal transplantation, suppurative arthritis and osteomyelitis have been reported.[63]

Corynebacterium minutissimum

Corynebacterium minutissimum has been associated with erythrasma a red-brown pruritic macular skin rash usually found in the intertriginous regions of toes, fingers and axillae. Both the superficial skin lesions and the organism's minute colony growth are noted for their coral-red-orange fluorescence under ultraviolet light produced by a Wood's lamp.[51]

Corynebacterium ulcerans

This organism is morphologically similar to *C. diphtheriae* and is found in the pharynx of persons who drink unpasteurized cows milk or who have had contact with milking cows. In cattle and horses it is part of the normal flora and causes mastitis. This organism can be cultured from the throats of asymptomatic people and occasionally from patients who have an exudative pharyngitis[63] and diphtheria-like illness, in whom the bacterium has been found to produce diphtheria and dermatonecrotic toxins. [66] Both colony morphology and Gram stain of isolates growing on Tinsdale selective medium are indistinguishable from *C. diphtheriae* but the colonies, unlike *C. diphtheriae*, show a narrow zone of hemolysis on blood agar and have a positive urease reaction. The antibiotic susceptibility profile of this organism is similar to that of *C. diphtheriae* in that it is sensitive to most ß-lactam antibiotics and erythromycin.[63]

ERYSIPELOTHRIX RHUSIOPATHIAE

NATURE

Erysipelothrix spp. are short, slender, non-spore-forming Gram-positive rods. While two species of the genus are recognized, *Erysipelothrix rhusiopathiae* and *Erysipelothrix tonsillarum*, only *E. rhusiopathiae* has been described as a pathogen in humans. The organism inhabits soil and water worldwide and has been found in mammals, birds, fish and shellfish, presumably following ingestion of contaminated matter. In 1886, *E. rhusiopathiae* was established as the cause of 'swine erysipelas', and the organism continues to have economic importance as a cause of septicemia in swine, calves, lambs, turkeys and other farm animals.[67] Animals may exhibit asymptomatic carriage or disease. Domestic pigs appear to be the major reservoir.

EPIDEMIOLOGY

Infection with *E. rhusiopathiae* occurs worldwide and is considered to be a zoonosis. Transmission to humans usually occurs by direct cutaneous contact with infected fish or animals and manifests as erysipeloid, a localized cellulitis that appears 2–7 days after exposure. Most human infections follow occupational exposure. While persons who handle fish or shellfish appear to be at highest risk, erysipeloid is also more common in abattoir workers, butchers, farmers and veterinarians. The frequent occurrence of erysipeloid in whalers earned it the title 'whale finger'. Systemic *E. rhusiopathiae* infection has been reported following ingestion of undercooked pork. Human-to-human transmission has not been reported.

PATHOGENICITY

Infection of laboratory animals with *E. rhusiopathiae* leads to production of specific antibodies that are protective against re-infection. The virulence of *E. rhusiopathiae* appears to be related to resistance to phagocytosis and to multiplication and survival within cells after uptake. One group described the presence of a capsule on virulent strains when the organism was viewed by electron microscopy.[68] The presence of a capsule appeared to be associated with virulence. Mutant strains lacking the capsule were less virulent than parent strains.[68] Strains with a capsule were relatively resistant to phagocytosis by polymorphonuclear leukocytes unless the organism had been opsonized with organism-specific antiserum.

Virulent *E. rhusiopathiae* can also survive, and subsequently replicate, within macrophages when ingested in the presence of nonimmune serum. Survival within the macrophage appears to be associated with the organism's ability to reduce the production of reactive oxidative products. [69]

DIAGNOSTIC MICROBIOLOGY

In patients who have erysipeloid, organisms are found only in deeper parts of the skin, requiring aspiration or biopsy specimens that include the entire dermal thickness for optimal results. Blood cultures may isolate the organism in patients who have systemic disease. *Erysipelothrix rhusiopathiae* is a short, slender, non-spore-forming Gram-positive rod that grows best on routine blood agar plates in an atmosphere of 5–10% CO_2 at 92°F (35°C). Microscopically, they appear straight or slightly curved and occasionally form long filaments over 60µm long.[70] Unlike *Listeria*, *Bacillus* and *Corynebacterium*, *Erysipelothrix* spp. are catalase-negative. Colonies are small and translucent with a or no hemolysis. Two major discriminatory tests are the production of H_2 S on TSI slants (highly suggestive of *E. rhusiopathiae*) and a 'pipe cleaner' pattern of growth in gelatin stab cultures inoculated at 71.6°F

(22°C). The organism is typically vancomycin-resistant — an uncommon trait among Gram-positive rods. The ability of *E. tonsillarum* to ferment saccharose distinguishes it from *E. rhusiopathiae*. [70]

CLINICAL MANIFESTATIONS

Human infections with *E. rhusiopathiae* have three patterns of presentation: erysipeloid (a localized skin lesion), multiple skin lesions with or without systemic symptoms, or bacteremia/endocarditis.

Erysipeloid constitutes the majority of *E. rhusiopathiae* infections and presents as a subacute cellulitis. Most lesions occur on hands or other areas of the body exposed directly to infected fish or animals. The diagnosis is suggested by a nonsuppurative, insidious cellulitis with severe disproportionate pain — usually in a person who has an occupational exposure. The incubation period is typically 2–7 days. Lesions are usually well demarcated, slightly raised, erythematous and accompanied by swelling of the surrounding tissue. Regional painful lymphadenopathy or lymphangitis may occur. Low-grade fever and arthralgias are present in a minority of cases. Erysipeloid usually resolves within 3–4 weeks of onset without treatment and earlier with appropriate antibiotic treatment.

Untreated, erysipeloid occasionally spreads proximally from the initial lesion to producing multiple noncontiguous lesions. Lesions developing at sites remote from the initial inoculum have also been described, presumably via hematogenous dissemination.

Bacteremia due to *E. rhusiopathiae* is unusual; however, the organism has been identified as a cause of persistent bacteremia and endocarditis in adults.[71] The vast majority of serious infections due to *E. rhusiopathiae* have occurred in men who had a history of occupational exposure such as farming or animal handling.[72] Patients with a history of alcohol abuse or immunosuppression have occasionally been seen with only mild fever in the presence of bacteremia due to *Erysipelothrix*. The possibility of a carrier state of infection in such patients has been proposed.[71] Bacterial endocarditis, particularly involving the aortic valve, has been described. In one review, 40% of patients who have endocarditis had an antecedent erysipeloid cutaneous lesion. Overall mortality due to *E. rhusiopathiae* endocarditis is approximately 40%. The one case of neonatal septicemia that has been described was attributed to cutaneous contamination shortly after birth.[73]

MANAGEMENT AND PREVENTION

Erysipelothrix rhusiopathiae is susceptible to penicillin but resistant to vancomycin.[74] Vancomycin resistance is notable since this drug is commonly used as empiric treatment for bacteremia due to Gram-positive organisms. Therefore, a high index of suspicion for this organism should be maintained for patients who have unusual cutaneous sites of infection or animal exposure. Penicillin is the drug of choice for serious infection caused by *E. rhusiopathiae*; however, the organism is also highly susceptible in vitro to cephalosporins, clindamycin, imipenem and ciprofloxacin.[75]

Prevention is achieved mainly through the use of protective gloves in high-risk occupations.

ARCANOBACTERIUM HAEMOLYTICUM

NATURE AND DIAGNOSTIC MICROBIOLOGY

Arcanobacterium haemolyticum is often overlooked in clinical specimens, as organisms appear similar in morphology to *Corynebacterium* spp. that are resident normal flora of the skin and oropharynx. In fact, the organism was originally named *Corynebacterium haemolyticum*. The name of the genus is derived from the Greek word *arcanus*, meaning 'secretive' or 'mysterious'. Colonies are small, gray-white and take 24–48 hours to appear on sheep blood agar, displaying a narrow zone of ß hemolysis that may not appreciated until a colony is picked off of the plate. A colony Gram stain shows pleomorphic short V- and club-shaped Gram-positive bacilli that, with older growth, appear beaded and streptococcus-like in appearance. The ß-hemolysis and lack of catalase activity distinguish them from *Corynebacterium* spp. In addition, they ferment glucose, lactose, maltose and sucrose but do not reduce nitrate or hydrolyze urea, esculin or gelatin. They are nonmotile and produce a reverse CAMP test with inhibition of the ß-hemolysin activity of *S. aureus*.[76] [77]

EPIDEMIOLOGY

Humans appear to be the primary host for this organism, which causes pharyngitis in teenagers and young adults,[78] as well as cellulitis[79] and chronic skin ulcers, mostly in tropical countries.[80] Although it can be associated with symptomatic pharyngitis, this is uncommon. Pharyngitis associated with this organism is predominantly found in females aged 15–22 years. Rarely, this organism has been found as a cause of septicemia, meningitis, endocarditis, osteomyelitis, sinusitis and cavitary pneumonia in adults who have underlying chronic diseases.[81] One study showed an increase in isolation of this bacterium from throat swabs in spring and autumn.[82] Person-to-person spread by fomites is thought to be the predominant mechanism of transmission, although this has not been adequately studied.

PATHOGENICITY

Evidence that *A. haemolyticum* is a cause of pharyngitis in adolescents and young adults is derived from studies showing its presence in the throats of symptomatic but not asymptomatic subjects. However, some investigators dispute this conclusion. *Arcanobacterium haemolyticum* has been isolated singularly and in association with *S. aureus* and ß-hemolytic streptococci; however, insufficient data exist to rule out concomitant infection with viruses or *Mycoplasma* spp. In a study of seven volunteers who had a pure culture of this organism applied to their pharynx, none became symptomatic in 6 weeks of follow-up despite having heavy pharyngeal colonization.[77] Indeed, several studies have shown an association of *A. haemolyticum* pharyngitis with Epstein-Barr virus infection. Preceding viral colonization may be required in the pharynx before symptomatic infection can occur.[83]

This organism produces phospholipase A and D, lipase, hemolysin and a dermotoxin when injected into the skin of a guinea pig.[77] Occasionally a serologic response has been found in patients who have either skin or pharyngeal infection. The organism can persist intracellularly.[84] Skin biopsies of two patients who had concomitant scarlatiniform-like rash, often seen with the pharyngeal infection, showed no organism or immunoglobulin deposits but a mild lymphocytic perivascular infiltration.[85] This indicates that the rash may be due to a toxin-mediated event similar to the scarlet fever rash of group A streptococci.

CLINICAL MANIFESTATIONS

The signs and symptoms of pharyngitis due to *A. haemolyticum* are listed in Table 226.4 [82] [83] [86] and are similar to those of group A streptococcal pharyngitis with the exception of the rash and presence of more upper respiratory symptoms of dry cough and hoarseness. The rash appears 1–4 days after the onset of pharyngitis and is usually scarlatiniform, appearing first on extensor surfaces of the extremities and then spreading to trunk and chest, sparing palms and soles. It often persists for more than 2 days.[86] Unlike streptococcal scarlet

TABLE 226-4 -- Signs and symptoms of pharyngeal *Arcanobacterium haemolyticum* infection.

SIGNS AND SYMPTOMS OF PHARYNGEAL *A. HAEMOLYTICUM* INFECTION	
Sign or symptom	**Frequency (%)**
Sore throat	97–100
Tonsillar exudate	50–70
Fever	60–80
Dry cough/hoarseness	40–60
Cervical lymphadenopathy	40–67
Rash	50

fever, circumoral pallor does not occur. Less frequently, the rash is maculopapular or urticarial. Skin infections with *A. haemolyticum* were first described in US military personnel stationed in South Pacific islands and have been described as ecthyma, resembling chronic ulcers. Cellulitis and wound infections in these tropical environments often have mixed bacterial infections with this organism.

MANAGEMENT

Arcanobacterium haemolyticum isolates are highly susceptible to erythromycin with MICs of less than 0.01µg/ml. As a result, erythromycin is considered the drug of choice for pharyngitis. As a bacteriostatic compound it is generally inappropriate for therapy of bacteremia. Penicillin is bactericidal but the MICs are more variable and tolerance and antibiotic failure have been documented.[81] Clinical evidence of antibiotic efficacy is anecdotal and largely involves the use of intravenous penicillin to treat *A. haemolyticum* septicemia.

RHODOCOCCUS SPECIES

NATURE

Rhodococcus are aerobic Gram positive bacilli similar to *Nocardia* in that they produce a substrate mycelium in soil environments that fragments into bacillary and coccoid forms. Also like *Nocardia*, *Rhodococcus* is partially acid-fast using the modified Kinyoun stain, because of its mycolic-acid-containing cell wall. Unlike *Nocardia*, it does not produce aerial mycelia and its cell wall composition is different. There are 15 species in this genus and *Rhodococcus equi*, formerly *Corynebacterium equi*, is the predominant pathogen in humans.[87] [88]

EPIDEMIOLOGY

Rhodococcus equi causes bronchopneumonia in foals, cattle, pigs and felines.[89] [90] It is found in soil and herbivore manures[90] and is not part of the normal bacterial flora in healthy humans. Transmission occurs via the respiratory tract and appears to be through contact with soil and animals. Human disease usually occurs in patients who have disturbances of cell-mediated immunity such as AIDS, cancer, transplantation or chronic disease.[91] Human-to-human transmission has not been documented. Many investigators suggest that infection with this organism should warrant testing for concomitant HIV infection.

PATHOGENICITY

Both animals and humans acquire this infection via respiratory tract. There, organisms are taken up by alveolar macrophages, in which they grow intracellularly and cause a granulomatous inflammatory response. This progresses to caseous necrosis of lung tissue. Later there may be hematogenous dissemination from a focal lung infection to brain, liver, kidney, skin, muscle or bone.[92]

DIAGNOSTIC MICROBIOLOGY

Rhodococcus equi produces large, mucoid, salmon-pink colonies on blood agar. Initial Gram staining may reveal Gram-positive coccobacilli. As colonies age, longer Gram-positive bacilli are formed that demonstrate branching and fragmentation into both coccoid and bacillary forms. *Rhodococcus equi* are partially acid-fast, nonmotile and have positive catalase and urease reactions.[87] [88]

CLINICAL MANIFESTATIONS

The overwhelming majority of *R. equi* infections involve the lung. As noted, most patients have an underlying condition such as AIDS or post-transplant immunosuppression that impairs their cell-mediated immunity. Clinical presentation may be insidious, with onset of fatigue, fever and nonproductive cough over several weeks. Chest radiographs often show nodular or cavitary lesions in the upper lung lobes that may mimic lesions due to *Mycobacterium tuberculosis* or *Nocardia* spp.[93] The underlying pathology is a necrotizing pneumonia and *R. equi* lesions have a propensity to show air-fluid levels, which are rarely seen in tuberculosis. Bacteremic pneumonia occurs more frequently in patients who have AIDS and their mortality rate is higher than that of patients who are not infected with HIV.

Fewer than 10% of patients present with extrapulmonary disease, usually abscesses in skin or soft tissues, osteomyelitis, meningitis or endophthalmitis. Recently, several cases of *Rhodococcus* infections have been found associated with medical devices such as central lines, ventriculoperitoneal shunts and chronic ambulatory peritoneal dialysis catheters.[92] [93] [94]

MANAGEMENT

As large numbers of organisms exist both intracellularly in macrophages and in abscesses in patients who have impaired cell mediated immunity, treatment of such infections may be problematic. *Rhodococcus* spp. are commonly resistant to penicillins and cephalosporins or will rapidly develop resistance during therapy. They usually are sensitive to erythromycin, clindamycin, rifampin, vancomycin, imipenem, aminoglycosides, chloramphenicol and fluoroquinolones, [84] but antibiotic therapy alone may not be successful without surgical excision and drainage. Reduction in immunosuppression where possible (i.e. reduction of corticosteroid or ciclosporin dosage).

Antibiotics with enhanced intracellular penetration and concentration abilities such as the macrolide antibiotics and rifampin appear to be the most potent and act synergistically to kill these intracellular bacteria.[95] Duration of therapy is not established but most patients require long courses of at least two antibiotics, even after surgical excision and drainage.

NOCARDIA SPECIES

NATURE

The genus *Nocardia* is a member of the order Actinomycetales, found in soil, plants and decomposing organic material. These organisms are also present in the gastrointestinal tract, oropharynx and skin of animals.

The taxonomy of Actinomycetales has been controversial. In recent editions of *Bergey's Manual of Determinative Bacteriology*, several new species have been recognized, and others reclassified.[96]

Nocardia was first described by Nocard in 1889 and is now divided into several species, only a few of which cause disease in humans — *Nocardia asteroides*, *Nocardia brasiliensis*, *Nocardia otitidiscaviarum*, *Nocardia transvalensis*, *Nocardia farcinica* and *Nocardia nova*. *Nocardia asteroides* accounts for the vast majority of clinical nocardial infection in humans.[97] Ribotyping has been proposed as a tool for taxonomic classification of this organism.[98]

EPIDEMIOLOGY

The incidence of systemic *Nocardia* infection in humans is probably underestimated since there is no comprehensive reporting system. However, based on a survey of US infectious disease physicians, the incidence in the mid-1970s was estimated at between 500 and 1,000 cases annually (2–4/10^6 people).[97] Since immunocompromised patients are profoundly susceptible to the development of nocardiasis, it is likely that the incidence of the disease in the 2000s is far greater than this estimate would suggest. Over the past 20 years there has been a marked increase in the number of immunocompromised patients due to aggressive chemotherapeutic management of cancer and to the epidemic of AIDS.[99]

Although immunosuppression is a major predisposing factor for infection, *Nocardia* spp. may occasionally cause disease in the absence of any predisposing factor. Cases may go undiagnosed because appropriate investigations are not undertaken before antimicrobial therapy is prescribed.

PATHOGENICITY

Nocardia elicits an inflammatory response in the host characterized by infiltration of polymorphonuclear leukocytes, activated lymphocytes and monocytes at the site of infection.

Although the pathogenic mechanisms contributing to elimination of *Nocardia* spp. from the body are poorly understood, a model of nocardiasis in mice shows many similarities to intracellular parasites such as *Listeria monocytogenes* and *Toxoplasma gondii*.[100] In the murine model of *Nocardia* infection, the organism persists for 3–4 weeks in high concentrations in the spleen and liver of intravenously or intraperitoneally infected animals. A large number of macrophages are seen in infected granulomas. Electron microscopic studies demonstrate that these macrophages contain organisms within the cytoplasm in various stages of degeneration. When compared with control cells, macrophages isolated from *Nocardia*-infected animals produce high amounts of TNF-a after ex-vivo stimulation with lipopolysaccharide. Since TNF-a and other cytokines upregulate the phagocytic system, this finding suggests that macrophage activation occurs during *Nocardia* infection. In support of this is the observation that animals treated with TNF-a antibodies fail to eliminate the organism from their liver when this would normally occur. Eradication of the organism from the body therefore appears to depend on TNF-a or its effects on the immune system.

DIAGNOSTIC MICROBIOLOGY

Diagnosis of invasive nocardial infection usually depends on demonstrating the organism in tissue. Specimens of sputum, bronchial wash, exudate, tissue biopsy or CSF should be collected for culture and staining in suspected cases. Gram's stain and a modified Kinyoun stain are recommended. Because the clinical picture is often unclear, clinical material should be examined for other potential pathogens including acid-fast bacilli and fungi.

Although *Nocardia* resemble fungi morphologically, producing a mycelial-like hyphae growth, they exhibit cellular characteristics of bacteria including the presence of procaryotic cellular organization. *Nocardia* spp. grow slowly on laboratory-enriched media. Specimens should be maintained for at least 2–4 weeks before being called negative. *Nocardia* grows well on enriched media such as blood or brain heart infusion agar. However, the microscopic morphology of *Nocardia* is best demonstrated by examining colonies grown on minimal medium such as tap water agar or cornmeal agar without dextrose. A period of 2–3 weeks of cultivation is needed before growth is evident on such media (Fig. 226.13). Colonies may have a smooth, chalky-white appearance; however, gross morphology is variable and may depend on the medium of cultivation and length of inoculation time. The color of *N. asteroides* colonies varies from salmon-pink to orange, while other *Nocardia* spp. vary from orange to tan colored.

The organisms are Gram-positive with short, extensively branched vegetative hyphae that break up into short rods and are less than 1µm in diameter (Fig. 226.14). Aerial hyphae may only be evident when viewed microscopically. Short chains of conidia may be found on the aerial hyphae. Most isolates of *Nocardia* in cultured material are weakly acid-fast by the modified Kinyoun stain.

Although some studies have proposed the use of a complement fixation serologic test to aid in the diagnosis, this is typically available only in research settings. The clinical value of this and other serologic or skin testing remain uncertain.

CLINICAL MANIFESTATIONS

The clinical manifestations of nocardial infection vary from localized to disseminated.

Nocardia spp. are recognized as pathogens among severely immunosuppressed patients such as those who have severe systemic lupus erythematosus,[101] transplant recipients [102] or patients who have advanced HIV infection. [99] Although nocardiasis has been described in patients who have AIDS, it remains relatively uncommon. The clinical manifestations of nocardiasis in HIV-infected patients are nonspecific, with fever, productive cough and weight loss most common. About two-thirds of patients who have systemic nocardial infection with AIDS have the lung as the primary site of infection.

Radiographic features of pulmonary nocardiosis at the time of presentation include unilateral involvement (18 of 22 AIDS patients) with an alveolar pattern (14 out of 22).[100] The upper lobe was most commonly affected. CT scans of patients who have pulmonary

Figure 226-13 Colonies of *Nocardia asteroides,* showing a smooth, chalky-white appearance.

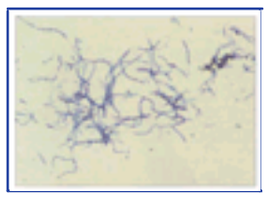

Figure 226-14 *Nocardia asteroides* on Gram stain, showing extensively branched vegetative hyphae that break into short rods.

infection show enlarged nodules or other masses (83%), cavitation (33%), consolidation (33%) and pleural thickening (29%).[104] Among patients who have severe immunosuppression such as AIDS, evidence of cavitation is seen more commonly.

Primary cutaneous infection may be caused by *N. asteroides*, *N. brasiliensis* or *N. otitidiscaviarum*.[104] [105] In contrast to pulmonary or disseminated nocardiasis, cutaneous nocardial infection commonly occurs in immunocompetent individuals. Four clinical types of cutaneous nocardiasis have been described: mycetoma, lymphocutaneous involvement, superficial cellulitis and cutaneous involvement with disseminated disease. Primary cutaneous nocardial infection usually results from traumatic inoculation with the organism. Cutaneous lesions are characteristically painless, slowly progressive and localized (Fig. 226.15).

Rarely, localized infections may become invasive. Such infections have been described both in immunocompetent and immunocompromised subjects and may occur secondary to trauma or direct spread from adjacent anatomic sites.

A total of 131 patients who had *N. asteroides* brain abscess have been described.[106] Only about a third of these patients had a history of an underlying disease or treatment that might have affected the immunocompetence of the subjects. Co-existent *Nocardia* infection outside the central nervous system is common (71%). CT scans using contrast enhancement characteristically show single or multiple ring-enhancing brain abscesses. Most abscesses are located in the supratentorial space. Solitary brain abscess was present in 71 of 121 cases. Patients who had single abscesses had a lower mortality (32%) than those who had multiple abscesses (66%).

MANAGEMENT

In most clinical settings *Nocardia* can be managed effectively with antibiotic therapy. Recommendations for antibiotic therapy of localized or systemic nocardial infection are problematic since no large clinical trials have been undertaken. Moreover, the clinical relevance of in-vitro susceptibility testing has not yet been established. The most commonly used testing method has been the gradient strip diffusion test (E-test, AB Biodisk, Solna, Sweden). Susceptibility testing guidelines have been published by the National Committee for Clinical Laboratory Standards.[107] The most active parenteral

Figure 226-15 Primary cutaneous nocardial infection is characteristically painless, localized and slowly progressive. (a) There is marked swelling and erythema in this child's finger. (b) However, because the finger was painless the child was not brought to medical attention until the infection had progressed to involve the entire finger.

agents for *N. asteroides* are amikacin (95% susceptible), imipenem (88%), ceftriaxone (82%) and cefotaxime (82%). The most active oral agents are sulfonamides (100%), minocycline (100%) and amoxicillin (40%). In many studies the combination of trimethoprim-sulfamethoxazole has been found to be synergistic in vitro. Since both drugs penetrate tissue, including CSF, and are usually well tolerated, the combination of trimethoprim and sulfamethoxazole is often recommended as the first line of therapy.[97] Other drug combinations, such as amikacin-imipenem and amikacin-ceftriaxone, have been proposed for severe infection requiring parenteral therapy.

Nocardial brain abscesses should be managed with a combination of medical and surgical techniques. The largest review on this subject recommended conservative medical treatment if the brain abscess is less than 2cm in diameter. [106] For patients who had larger abscesses or deteriorating conditions, stereotactic aspiration to confirm the diagnosis and decompress the lesion was advocated.

MISCELLANEOUS AEROBIC GRAM-POSITIVE BACILLI

ROTHIA DENTOCARIOSA

This pleomorphic, aerobic Gram-positive bacillus is catalase-reaction-positive, hydrolyzes esculin and forms coccoid spherules in broth culture and branching slender rods on solid agar. It is found as part of the normal flora in the oropharynx, where it has been associated with dental caries and chronic periodontal disease in the immunocompetent host and septicemia, pneumonia and infective endocarditis in the immunocompromised host. This organism remains susceptible to most ß-lactam antibiotics, erythromycin and vancomycin.[108]

OERSKOVIA SPECIES

These aerobic, non-sporulating Gram-positive bacteria are found in soil. They form yellow colonies without aerial mycelia and produce a substrate mycelium that fragments into non-acid-fast, motile rods. They resemble *Nocardia* spp. in their ability to hydrolyze casein, xanthine and hypoxanthine to a varying degree. They have been associated with bacteremias, endocarditis, catheter-associated infections and infections after direct trauma involving soil contact, especially, but not exclusively, in immunocompromised hosts.[109]

Chapter 227 - Neisseria

Jacob Dankert

INTRODUCTION

The genus *Neisseria* was named after Albert Neisser who observed diplococci in leukocytes in urethral exudates from patients who had gonorrhea in 1879.[1] Three years later Leistikow and Loeffler were able to cultivate the bacterium, termed gonococcus, in pure culture.

Although various species within the Neisseriaceae family can cause disease in humans and various animals, the two well-known pathogenic species for humans are *Neisseria gonorrhoeae*, or gonococcus, and *Neisseria meningitidis* or meningococcus.

Neisseria gonorrhoeae causes gonorrhea, a sexually transmitted disease. Gonorrhea was named by Galen in AD130 after the Greek words *gonor* (seed) and *rhoia* (flow), suggesting that the disease was related to the flow of semen. In the 13th century Maimonides recognized that the urethral discharge of male gonorrhea patients was not semen, but a sexually transmitted disease. Gonorrhea was not clearly distinguished from syphilis until the 19th century. In 1885 Bumm proved the causal relationship between the bacterium and the onset of gonorrhea by inoculating gonococci into volunteers. Although it was known that untreated infection healed spontaneously, treatment was warranted because reinfections were common. Effective therapy became available in the 1930s when sulfonamides were developed and in 1943 when penicillin was produced. Sulphonamide resistance occurred early and rapidly in gonococci. Penicillin-resistant gonococci due to penicillinase production were documented in various parts of the world in 1975 and 1976. The prevalence of strains resistant to penicillin and other antibiotics has risen steadily worldwide. Therefore, the pathogenesis of gonorrhea, the host response to infection and the molecular biology of the gonococcus have been studied intensively over the past two decades.

Neisseria meningitidis is a cause of endemic and epidemic disease in developed and developing countries. Epidemic meningococcal meningitis was first described by Vieusseaux in 1805 in Geneva.[2] Throughout the 19th century periodic epidemics occurred, involving mainly young children and military men in recruit camps. In 1887 Weichselbaum isolated the meningococcus from six of eight cases of primary sporadic community-acquired meningitis. Kiefer described the nasopharyngeal meningococcal carrier state among healthy people in 1896. Recognition of an association between increasing rates of meningococcal carriage and the onset of epidemic disease stimulated studies of the epidemiology and prevention of meningococcal infection. Serum therapy, used by Flexner and Jobling in 1908, resulted in survival from a previously fatal disease. The outcome of meningococcal disease improved drastically by treatment with sulfonamides in 1937. In addition, sulfonamides to eradicate the carrier state were used as prophylaxis to prevent epidemics. Nevertheless, an epidemic in two military bases in California in 1963 could not be aborted by sulfonamide prophylaxis because of the occurrence of sulfonamide-resistant meningococci. This led to the development of vaccines derived from selected meningococcal capsular polysaccharides. Such vaccines have been successfully used in military recruits and have also been given to civilian populations.

A successful vaccine that prevents infection caused by *N. meningitidis* serogroup B, which causes most cases of disease in temperate countries, has not, however, been developed. The absence of a group B vaccine limits the effective control of meningococcal disease. Other problems of meningococcal infection are:

- enhanced susceptibility of certain age groups;
- mechanisms involved in the upper respiratory carrier state leading to invasion of the meningococcus into the bloodstream; and
- reasons for the fulminant nature of the infection in certain patients.

NATURE

Taxonomy

In the 1984 edition of *Bergey's manual of systemic bacteriology*,[3] the family of the Neisseriaceae included the following four genera:

- *Neisseria*,
- *Moraxella*,
- *Kingella*, and
- *Acinetobacter*.

The taxonomy of the family has been extensively revised over the past decade. This has led to the renaming of certain genera and species, as well as the addition of new ones.

The genus *Neisseria* contained 11 species considered as 'true *Neisseria*' recovered from human sources and three animal species called the 'false *Neisseria*'. The genus *Moraxella* had two subgenera — the subgenus *Moraxella* with six species and the subgenus *Branhamella* with four species. The genus *Kingella* contained three species and the genus *Acinetobacter* was made up of various phenotypes.

Studies of the family Neisseriaceae making use of DNA-rRNA hybridization, DNA-DNA hybridization and 16S rRNA sequence analysis have revealed substantial differences between the genera and certain species within each of the four genera.[4] [5] The family Neisseriaceae, as defined in *Bergey's manual of systematic bacteriology*, is genetically heterogeneous. Its members cluster in two separate rRNA superfamilies that exhibit no significant levels of relatedness. The true Neisseriaceae and two *Kingella* spp. belong to the ß-subclass of the Proteobacteria. Because the false *Neisseria, Moraxella, Branhamella* and *Acinetobacter* genera belong to the ?-subclass of the Proteobacteria, recommendations have been made to remove them from the family Neisseriaceae. Molecular genetic techniques have demonstrated that the genera *Eikenella, Simonsiella* and *Alysiella* and four CDC groups (EF-4a and 4b, M-5 and M-6) are close genetic relatives of the true *Neisseria* and two *Kingella* spp.[5] The newly amended family Neisseriaceae, containing true *Neisseria* spp. from humans as well as false *Neisseria* spp., is shown in Table 227.1 . The taxonomic status of the false *Neisseria* is debated, but they are considered as *Neisseria* spp. from animal origin.

Neisseria weaveri and *N. elongata* subspp. *nitroreducens* are the former CDC groups M-5 and M-6, respectively. The true *Neisseria* and both *Kingella* spp. form a cluster with 91% or more DNA homology,

but are rather distantly related (Fig. 227.1). The relationship between *Neisseria* spp. is as follows:

- *N. gonorrhoeae* and *N. meningitidis* are very closely related;
- *N. lactamica, N. polysaccharea* and *N. cinerea* are related to *N. gonorrhoeae* and to each other more distantly;
- saccharolytic Neisseriaceae (*N. subflava, N. sicca* and *N. mucosa*) are more distantly related to the other Neisseriaceae; and
- species of animal origin are still more distantly related.

The closest neighbors of the family of Neisseriaceae are the genera *Chromobacterium* and *Aquaspirillium*.

General characteristics of the amended family of Neisseriaceae are that the micro-organisms are coccal, coccoid or rod shaped or exhibit a multicellular micromorphology (*Simonsiella* spp. and *Alysiella* spp.).[4] [5] They are Gram-negative. Several species possess capsules and are fimbriated (piliated). Endospores are not found, and flagella are absent. Members of the genus *Simonsiella* and *Alysiella* show gliding motility. Some *Neisseria* spp., including *N. meningitidis*, may show surface-bound twitching motility. All species are aerobic, but *Kingella* and *Eikenella* spp. also grow under anaerobic conditions. The optimum growth temperature is 89.6–98.6°F. The guanine-plus-cytosine

content of DNA ranges from 41 to 58mol %. Most species are not pathogenic and their main habitat is the mucosal surface of the nasopharynx and oropharynx of humans and various mammals.

Neisseria gonorrhoeae and *N. meningitidis* are primarily pathogens of humans. Both *Kingella* spp. and *Eikenella corrodens* are occasionally isolated from human infections, and are discussed in Chapter 229 .

General characteristics

The genus *Neisseria* is composed of 10 species that may be isolated from humans and 10 species that may be cultured from various animals.[6]

The *Neisseria* spp. are the only true coccal members of the family Neisseriaceae, with the exception of *N. elongata* and *N. weaveri*, which are medium-to-large plump rods that sometimes occur in pairs or short chains. *Neisseria* spp. grow best aerobically in an atmosphere containing 5–10% carbon dioxide at a temperature of 89.6–98.6°F and pH of 7–7.5. The micro-organisms are Gram-negative cocci that typically appear in pairs (diplococci) and occasionally in tetrads or clusters. Diplococci have flattened opposing sides, imparting the characteristic kidney or coffee bean appearance seen in stained smears. Cell size ranges from 0.6 to 1.5µm depending upon the species source of the isolate and the age of the culture.

Neisseria spp. can be grown on several kinds of media, though growth may be inhibited by fatty acids in the medium. Inhibition can be eliminated by adding starch or blood. Blood agar medium or chocolate medium (blood heated at 176–194°F) are suitable media for growing *Neisseria* spp.

Colonies of *N. gonorrhoeae* vary in diameter from 0.5 to 1µm. Colonies of *N. meningitidis* are usually larger (1–µm in diameter) and flatter than those of *N. gonorrhoeae*. Colonies of *N. flavescens* are yellow and opaque and colonies of *N. elongata* have a dry claylike appearance. Colonies of the other nonpathogenic *Neisseria* spp. are similar in size, appearance and consistency to those of the two pathogenic *Neisseria* spp., except those of the saccharolytic *Neisseria* spp. (*N. subflava, N. sicca* and *N. mucosa*). Colonies of these species are larger (1–3µm in diameter), more convex and smooth (*N. mucosa*). Colonies of *N. subflava* and *N. sicca* are opaque and have varying consistency. *Neisseria sicca* adhere to the agar surface and become wrinkled with prolonged incubation. Some nonpathogenic *Neisseria* spp. form a yellow pigment (*N. flavescens*) or a greenish-yellow pigment (*N. mucosa, N. subflava*).

Neisseria spp. are oxidase positive and catalase positive, except *N. elongata*, which is catalase negative.

All species produce acid from a few carbohydrates by oxidation. The ability to produce polysaccharide from sucrose, to produce catalase and deoxyribonuclease, to reduce nitrate and nitrite, and to oxidize the tributyrin fatty acid are also used to identify *Neisseria* spp.

Habitat and prevalence

Neisseria spp. are normal inhabitants of the nasopharyngeal and oropharyngeal mucous membrane of humans and various mammals. [2] [6] *Neisseria meningitidis* is usually carried in the nasopharynx without causing disease. [7] Colonization may persist for many months. One-third of the carriers have chronic carriage for more than 16 months. Carriage may also occur on anogenital mucosal membranes. In children under 4 years of age the carriage rate is 1% or less. Carriage rates rise progressively through the first two decades of life to peak at about 20–25% in late teenage and early adult life, and then slowly decline. During carriage the expression of capsule polysaccharide is absent or low. Therefore, nongroupable (capsular polysaccharide absent) meningococci are predominantly cultured from the nasopharynx of carriers. Meningococcal carriage may not be confined to the mucosal surface.[8] Carriage rate among patients undergoing tonsillectomy as assessed by nasopharyngeal swabbing

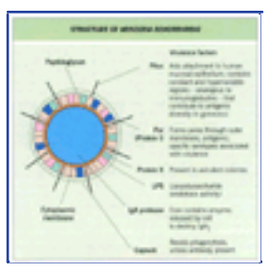

Figure 227-2 Structure of *N. gonorrhoeae.* *(Adapted from Mims et al. [9])*

was 10%, whereas meningococci detected by immunohistochemical methods were present within the epithelial layer and tonsillar tissues from 45% of such patients. These findings show that the conventional swabbing method to determine carriage rate is an insensitive procedure, assuming that the majority of the subepithelial meningococci are viable cells. Carriage induces bactericidal antibodies. Since the development of such antibodies increases progressively at a young age when carriage of meningococci is low, other bacteria with cross-reaction most likely induce bactericidal antibodies. *Neisseria lactamica* carriage elicits bactericidal antibodies against various meningococcal serogroups and serotypes. Carriage of *N. lactamica* is higher than that of *N. meningitidis* in infancy and in young children and is approximately 4% by 3 months of age and peaks at 21% by 18–24 months of age.[7]

Both children and adults can be colonized either by strains of the sucrose-positive *Neisseria* spp. (*N. mucosa, N. perflava, N. sicca*) or by several other *Neisseria* spp. Both patterns of colonization are stable and generally persistent for many months.

Neisseria gonorrhoeae strains are always considered to be pathogenic, in contrast to *N. meningitidis*, of which only some strains can cause meningococcal disease. Gonococci infect those surfaces which are lined with columnar epithelial cells: endocervix, urethra, anogenital and oropharyngeal mucous membranes and conjunctiva.

Both *Kingella* spp. are part of the normal upper respiratory and genitourinary tract flora. *Eikenella corrodens* is a commensal of the human oropharynx and upper respiratory tract.

Structure

Neisseria spp., like other Gram-negative bacteria, possess an inner cytoplasmic membrane, a thin peptidoglycan layer and an outer membrane containing proteins, phospholipids and a lipo-oligosaccharide (LOS), as shown in Figure 227.2 for *N. gonorrhoeae*.[9]

Capsules

Neisseria gonorrhoeae is covered with a loosely adherent capsular-like structure containing high-molecular weight polyphosphate. Its function is unknown.[6]

Neisseria meningitidis also produces polyphosphate loosely adherent to the surface. In contrast to gonococci most meningococci have a polysaccharide capsule.[6] On the basis of structural differences in the polysaccharide, meningococci can be divided into at least 12 serogroups (A, B, C, 29E, H, I, K, L, X, Y, Z and W135). Meningococcal disease-associated serogroups B, C, Y and W135 all have *N*-acetylneuraminic or sialic acid (a common constituent of eukaryotic cell membranes) in their capsular polysaccharide. Sialic acid confers resistance to host complement-mediated attack mechanisms. The disease-associated serogroup A capsule contains *N*-acetyl-mannosamine-1-phosphate. This serogroup causes most of the major epidemics, particularly in less developed countries. Serogroups B and C generally cause endemic disease and occasionally epidemic outbreaks worldwide.

Meningococcal capsular polysaccharides induce specific bactericidal antibodies. Therefore, capsular polysaccharide antigens are used as vaccine materials. The B-polysaccharide is poorly immunogenic, probably because of immunotolerance due to cross-reactivity between this polysaccharide and polysialic acid expressed on host neural cell adhesion molecules.

In the absence of opsonizing antibodies the various capsules render meningococci resistant to phagocytosis. The genetic material responsible for capsule polysaccharide synthesis can be exchanged between meningococci.[10] Serogroup B can thus switch to C or vice versa.[11]

Pili

Pili are hair-like filamentous proteins consisting of repeating peptide subunits (pilin). Pathogenic *Neisseria* spp. have long pili (4300nm in length) protruding through the capsular structures (see Fig. 227.2). Nonpathogenic *Neisseria* spp. have short pili (175–210nm in length) and long pili.

Neisseria gonorrhoeae has pilin protein subunits that have an apparent molecular weight of 16.5–21.5kDa. Gonococci produce one type of pilus; the main subunit is Pil E. CD 46 has been identified as the pili receptor.[12] Pili undergo both phase variation and antigenic variation. Expression of pili is a function of the *pil* gene complex.

Gonococci contain one copy of *pil E* and multiple copies of *pil S*, which are transcriptionally silent. *pil C* encodes a protein involved in pilus assembly. Phase variation involves several mechanisms. Deletions and frame shift mutations produce truncated pilin and a stable P^- -phenotype. Reversible phase variation can be due to changes in the *pil C* region.

Colonial morphology is associated with piliation: cells from small domed colonies are piliated (P^+ and P^{++} colonies) in contrast to cells from large, flat colonies (P^- colonies).

Freshly isolated gonococci from patients carry pili. Initially grown on culture media, gonococci form colony types P^+ and P^{++} . P^- colonies lacking pili predominate after 20 hours of growth. This shift between P^+ or P^{++} to P^- colony types is due to pili phase variation. *In vitro* the frequency of phase variation is high, being 10^{-2} to 10^{-4} , and usually occurs in only a fraction of the bacterial population.

Antigenic variation of pili is due to the variability of pilin sequences residing primarily in the C-terminal half of the protein. The genome of the *pil* gene complex contains many incomplete sequences, which can be recombined with expressed loci on the same chromosome. Lysing gonococci release transforming DNA, which can recombine effectively with partly homologous regions. The frequency of antigenic pili variation may be *in vitro* as high as 10^{-3} per cell in a fraction of the bacterial population.

Neisseria meningitidis expresses two different classes of pili (either class I or class II), which are antigenically and structurally distinct. During infection pili undergo rapid phase shifts and antigenic variation.[13] Unlike gonococci, piliated meningococci form colonies that are indistinguishable from their nonpiliated isogenic forms.

Pili are essential for adhesion to epithelial and endothelial cells and impart tissue tropism.[14] Piliated *Neisseria* spp. adhere to susceptible cells and can initiate infection. Pili can overcome the electrostatic repulsion between the negatively charged mucosal surfaces and also play a role in transformation (the acquisition of homologous and heterologous DNA from the environment).[15] Neisserial competence for transformation is much greater in piliated cells than in nonpiliated cells. Pil E and Pil C are required for DNA uptake.[15]

Outer membrane proteins

The outer membrane proteins of gonococci and meningococci are similar. For both species various proteins are present within or on the surface of the outer membrane.[16] The trimeric proteins provide channels or porins, allowing low-molecular nutrients to diffuse through the outer membrane.

Neisseria gonorrhoeae porin protein is termed Por (formerly protein I). There are two different antigenic forms of Por (Por A and Por B) with molecular weights of 32kDa to 36kDa. Por is LOS associated and shows stable interstrain variation. The antigenic heterogeneity is the basis for serologic typing schemes of gonococci. Strains expressing Por IA are associated with resistance to normal human serum and disseminated gonococcal infection.

Neisseria gonorrhoeae can also express a family of other membrane proteins called protein II (20–28kDa). Colonies of bacteria expressing protein II have a more opaque surface than those not expressing PII. Therefore, PII is designated as an opacity (Opa) protein.[17] Each of the 10–12 Opa proteins is produced from its own *opa* gene. Expression of Opa varies, in contrast to Por, due to high-frequency variation in the *opa* gene because of translational frame shifting. The expression of each gene can be independently switched on and off. These phase transitions occur frequently, yielding expression of up to three different Opa types at one colony (Opa^- , Opa^+ , Opa^{++}). Antigenic variation among the Opa proteins of a strain also occurs.

Opa proteins have an important role in bacterial adherence. Heparin-related compounds[18] and CD 66[19] have been identified as Opa receptors. Cell tropism is determined by the variable expression of the Opa proteins.

Neisseria meningitidis is able to express two porins simultaneously: a class 1 protein, or Por A (44–47kDa), and either a class 2 (40–42kDa) or class 3 (37–39kDa) protein, Por B. [16] Por A is cation selective, whereas class 2 and 3 porins are anion selective. Class 2 and class 3 porins are the equivalent of the gonococci Por protein. The antigenic differences between class 2 and class 3 proteins of different strains are used for serotyping meningococci.

Neisseria meningitidis possesses an outer membrane protein, class 5 protein (26–30kDa), known as opacity protein. So far five variants of protein 5 are known, and from none to all five may be expressed by a single strain. There is no relationship between colonial opacity and the expressions of these proteins in contrast to *N. gonorrhoeae*. As in gonococci, the Opa proteins can undergo antigenic variation during natural infection. Two proteins, Opa and Opc, play a role in attachment of the

bacteria to tissue. CD66e and heparin sulfate proteoglycan are their receptors, respectively. [20] [21] The variable expression of these proteins represents an important cell tropism determinant. The outer membrane of both *Neisseria* spp. also contains a protein which increases in molecular weight upon treatment with a reducing agent. This reduction modifiable protein (Rmp) in *N. gonorrhoeae* is designated as protein III and in *N. meningitidis* as class 4 protein. The protein is immunologically conserved. Rmp antibodies interfere with the bactericidal activity of antibodies directed to other surface antigens. Therefore Rmp antibodies are so-called blocking antibodies. Both *Neisseria* spp. also have a number of environmentally regulated outer membrane proteins. These proteins may

be expressed depending upon the bacterial growth conditions. The iron-regulated proteins are essential for survival of gonococci and meningococci *in vivo*. The transfer-binding proteins (Tbp-1 and Tbp-2) and the lactoferrin-binding proteins (Lbp) mediate internalization of iron into the bacterium.

Lipo-oligosaccharide

Approximately 50% of the outer membrane is LOS. Gonococcal and meningococcal LOS lack the multiple repeating sugars of enterobacterial lipopolysaccharide (LPS). Therefore the neisserial LPS has been termed LOS. Lipo-oligosaccharide is composed of lipid A and a short sugar chain of 8–12 saccharide units, the core oligosaccharide. The lipid A portion anchors LOS in the outer membrane and is the active moiety of endotoxin. The core oligosaccharide is divided into an inner and outer core region. The inner core has a common structure. Lipo-oligosaccharide outer core sugars undergo high-frequency phase and antigenic variation[22] [23] during the course of infection and are used for immunotyping of meningococci.

The terminal structure of LOS is the target for sialylation by bacterial sialyltransferase. Gonococci utilize cytidine-5-monophospho-*N*-acetylneuraminic accid (CMP-NANA) present in the host tissues and add NANA to the LOS. Meningococci synthesize the CMP-NANA. Sialylation protects against the bactericidal activity of normal serum and generates a structure that mimics a structure present on host tissue cells. The neisserial outer membrane continuously sheds vesicles, which occur as blebs. These blebs contain DNA, protein and high levels of LOS, including lipid A. The latter component is implicated in the onset of shock if bacteria gain entrance into the circulation.[24]

Peptidoglycan

The peptidoglycan layer of *N. gonorrhoeae* and *N. meningitidis* may contribute to the inflammatory response, especially in gonococcal disease. In addition, peptidoglycan causes complement activation.

Typing of *N. gonorrhoeae* and *N. meningitidis*

Studies of the pathogenesis and epidemiology of gonorrhea and meningococcal meningitis have been enhanced by the availability of appropriate typing methods.

Characterization of *N. gonorrhoeae* is based on auxotyping and serotyping.[6] Gonococcal strains that have specific requirements for certain nutritional growth factors are known as auxotypes and include prototrophic (none requiring), proline-requiring and arginine-, hypoxanthine- and uracil-requiring (AHU) strains. *Neisseria gonorrhoeae* can be subdivided in 35 auxotypes. Arginine, hypoxanthine and uracil auxotypes are more likely to cause asymptomatic infection and more subtle inflammatory signs than other auxotypes.

Serotyping for *N. gonorrhoeae* is performed using a panel of monoclonal antibodies directed against epitopes on Por (protein I). Strains are divided into two major serogroups, Por IA and IB strains. Subdivision into serovars is based on patterns of reaction with specific protein IA and protein IB antibodies. In total there are at least 55 serovars. Typing systems have been used in epidemiological studies of gonorrhea in communities and in analyzing patterns of antibiotic resistance. Strain typing is also done by analysis of DNA sequence variations, by Opa typing or DNA sequencing of the *por* gene.

The phenotypic classification of *N. meningitidis* is based upon serologic methods to detect antigenic differences on four surface antigens:

- capsular polysaccharide,
- epitopes on class 2 and 3 outer membrane proteins,
- epitopes on the class 1 outer membrane, and
- LOS epitopes.

The 12 serogroups are recognized on the basis of the immune reaction of the polysaccharide capsule. Serotyping is based on the difference in the class 2 and 3 proteins (Por B). Strains are further subdivided into serosubtypes based on differences in the class 1 protein, Por A.

Lipo-oligosaccharides can also be used as typing antigens, giving rise to immunotypes L1, L2, L3, etc. Six different gonococcal LOS immunotypes and 12 different meningococcal LOS immunotypes have been recognized. Among meningococcal serogroups B and C immunotypes L1–9 are found, and in serogroup A immunotypes L10–12. Double epitopes may be recognized depending upon phase variation or the presence of incomplete epitopes on the same bacterium. Using the current typing scheme, a meningococcus is characterized as follows:

- B: serogroup, the capsular polysaccharide composition;
- 15: serotype, class 2/3 (Por B) protein antigen;
- P1.7, 16: serosubtype, class 1 (Por A) protein antigen;
- L 3,7: immunotype, LOS antigen.

Characterization of gonococcal and meningococcal immunotype is relevant for pathogenetic studies. Meningococcal serogroup, serotype and serosubtype characterization are of great value in epidemiologic surveillance.

In addition to the serologic classification of meningococci, other typing methods are used.[25] Multilocus enzyme electrophoresis gives the electrophoretic type (ET). Multilocus sequence typing has been used to show that specific complexes of related hypervirulent strains have caused epidemics.[26] DNA restriction analysis, randomly amplified polymorphic DNA (RAPD), restriction fragment length polymorphism (RFLP) and ribotyping are also used.

EPIDEMIOLOGY

Gonorrhea

Gonorrhea caused by *N. gonorrhoeae* is a common sexually transmitted disease and a worldwide public health problem. Its incidence reflects the lifestyle of the human community. The incidence in most Western European countries is lower than in the USA, with approximately 200 cases/100,000 population in 1992.[27] In the 1995 survey the incidence in the USA was 124 cases/100,000 population.[28] The highest incidence is in countries of the developing world, ranging from 4000 to 10,000/100,000 population. Commonly the highest attack rates occur in 15–25-year-old men and women.

Gonococci are obligate human pathogens. They cannot spontaneously infect animals or reside free in the environment. Gonorrhea is commonly transmitted by sexual intercourse with an infected partner. The risk of acquiring the urethral infection for men is approximately 20% after a single exposure to vaginal intercourse with an infected woman, rising to 60–80% after four or more exposures.

The transmission rate from male to female is approximately 50% per contact, rising to 90% after three exposures. Gonococci may also be transmitted by orogenital contact or rectal intercourse. Perinatal transmission may also occur.

Although gonococci can survive for brief periods outside the human reservoir, transmission is extremely rare. Transmission of purulent vulvovaginitis in prepubescent girls through a contaminated washing glove has been reported, but currently children who have gonorrhea are considered to be victims of sexual abuse by an infected adult.

The major reservoir for continued spread of gonorrhea is the asymptomatic patient. Among infected women 30–50% are asymptomatic or show no symptoms associated with a sexually transmitted disease. Among infected men only 5–10% are asymptomatic. Asymptomatic women and men remain infectious for months. In

addition, people who have symptoms that they ignore may continue

to spread the disease. The rate of transmission of gonococcal infection varies with the type of sexual practice.

The incubation period for gonorrhea is on average 2–7 days, but may vary between 1 and 14 days.

Meningococcal disease

Meningococcal disease is a major worldwide health problem.[29] [30] Among populations of meningococci, different patterns of epidemiological behavior are recognized. These disease patterns are termed endemic, hyperendemic, epidemic and pandemic. The five serogroups A, B, C, Y and W135 account for almost all the disease-causing isolates.

In western Europe and the Americas, endemic meningococcal disease is caused mainly by serogroup B or C organisms occurring at a low level affecting 1–3/100,000 people.[30] [31] Sporadic increases of disease incidence, termed hyperendemic are often localized to a small area or restricted to a particular population or community. For example, hyperendemic outbreaks due to group B have been reported in Brazil, The Netherlands and the UK.[25] [32] Recently, increasing proportions of cases due to serogroup C have been reported from various European countries.[31] [33] Serogroups A and C predominate in China, the Middle East and parts of Africa. In the African 'meningitis belt', disease occurs as major periodic epidemics occurring every 5–12 years and is caused by serogroup A with attack rates of 500/100,000 population or higher.[25] [30] Occasionally, particularly virulent strains arise that cause pandemic outbreaks across continents.[25] [29]

In the USA, Israel and Sweden, disease due to serogroup Y has increased in recent years.[30]

Serogroup B and C generally cause endemic cases and small outbreaks; in addition, distinct groups of genetically related serogroup B and C organisms have been recognized, which spread worldwide. Young adults who socialize frequently at discos and parties may particularly be at higher risk if they smoke.[34] These clusters may contain both serogroup B and C organisms, presumably because of horizontal gene transfer of capsule synthesis genes. As only a small fraction of the clones colonizing the throat of healthy individuals can cause disease, there is a difference in virulence potential of different meningococcal strains.[26]

In the mid-1970s, ET-5 complex serogroup B strains resulted in an increased incidence of meningococcal disease in north west Europe and Central and South America.[25] In other countries in Western Europe, ET-5 (serogroup B) strains were also isolated, although the increase in incidence was much lower. Strains of this cluster caused a severe epidemic in Cuba starting in the 1980s, followed by outbreaks in Florida in 1981 and 1982. The ET-5 strains were isolated only sporadically in North America in the following years, until in 1994 this complex was associated with an increased incidence in the states of Washington and Oregon. In Brazil and Chile the incidence of meningococcal disease rose due to strains of this complex in the mid-1980s and ET-5 strains were isolated in countries in Africa and Asia.[25]

Another cluster that has been identified worldwide is the lineage III. The first strain was isolated in The Netherlands.[32] Since 1980, the number of lineage III isolates has risen in The Netherlands, simultaneously with an increased incidence of disease. Most strains of this genotype are characterized by the serosubtype P1.4 (mostly B:4:P1.4), although lineage III strains with different serosubtypes and nonlineage III strains with P1.4 have been found. Since then B:4:P1.4 strains have been identified in many other European countries, resulting in an increased incidence of disease in Belgium and England and an ongoing epidemic in New Zealand. [25] Meningococci of the ET-37 complex cause much of group C cases worldwide as well as the international outbreaks of W135 disease among pilgrims returning from the Hajj and their close contacts.[35]

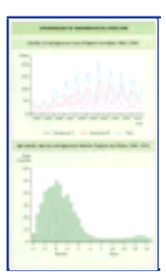

Figure 227-3 Epidemiology of meningococcal infection. *(Adapted from Jones.[36])*

Meningococcal disease irrespective of the serogroup involved is often seasonal in nature. Serogroup A and C disease increases during the dry season in Africa. The number of serogroup B and C cases peaks during the winter months in the developed countries (Fig. 227.3). [36] The reasons for the different epidemiological characteristics of the different serogroups and the cyclic nature of outbreaks are poorly understood.

The incidence of meningococcal disease appears to predominate in children under school age in the Western world (see Fig. 227.3).[36] Infants and children aged between 1 and 4 years account for approximately 50% of the cases. In the meningitis belt young school-aged children represent the peak age group.

Transmission of meningococci is by respiratory droplets, requiring close contact. The attack rate among family members of a clinical case is 1000-fold higher than in the general population. *Neisseria meningitidis* has a particular preference for the nasopharyngeal mucosal membrane.[7] Humans are the only natural host, but the incidence of disease cannot be attributed simply to acquisition of any strain. Invasive disease can be produced by:

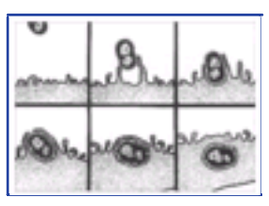

Figure 227-4 Steps in the pathogenesis of *N. gonorrhoeae* infection. *(Reproduced with permission from Weel.[40])*

- a pathogenic organism;
- a susceptible host;
- the influence of a coincidental viral or mycoplasma upper respiratory tract infection; or
- most frequently, a combination of all four.

Although there can be sudden and large changes in the rates of meningococcal acquisition and carriage, there is in general much less variation in rates of carriage than in rates of disease.

PATHOGENESIS

Gonorrhea

Gonococci primarily infect columnar or cuboidal epithelium. In males the anterior urethra is the primary site of infection and in females the endocervix. Colonization may occur, often followed by infection once the mucosal membrane of the genitourinary tract, rectum, oropharynx or eyes has been reached by gonococci. In most cases infection remains restricted to the initial site of colonization, although certain gonococcal strains have the ability to spread to distant sites. The infective dose for the male urethra is over 10^3 gonococci and for the female cervix ranges from 10^2 to more than 10^7 gonococci. [27]

Histopathologic examination of infected mucosa shows gonococci attached to the epithelial cell surface and within the epithelial cells, and occasionally in the submucosal tissue. Fulminant infection is characterized by a vigorous neutrophil response, sloughing of the epithelium, development of (sub)mucosal microabscesses and exudation of pus with gonococci inside polymorphonuclear cells. Several weeks after the start of the infection gonococci can no longer be observed histologically

or recovered by culture.

The first step in the pathogenesis of gonorrhea is the attachment of gonococci to mucosal surfaces and the ability of the gonococci to remain attached despite the continuous flow of body fluids (Fig. 227.4). Gonococci attach to microvilli of nonciliated columnar epithelial cells. Nearly all attached gonococci are piliated. Shortly after initial attachment gonococci become more tightly anchored to the epithelial cell surface. This second stage of binding is in part mediated by the gonococcal PII or Opa proteins to their cell receptors.[18] [20] Opa also mediates the binding of gonococci to each other to form microcolonies, probably aiding the initial colonization.

After attachment there is a critical interaction between gonococci and host defenses.[37] Gonococci have multiple mechanisms by which the bacteria resist innate defense as well as the defense by antibodies elicited by a previous infection. Sialylation of LOS may limit or alter complement binding.[38] The binding of cross-reactive blocking antibodies to Rmp (protein III) hinders the binding of bacterial antibodies. [39] *Neisseria gonorrhoeae* varies its surface proteins, especially pili antigens, by phase variation and antigenic variation.[22] In the case of pili, gonococci have an antigenic repertoire that may be as large as one million different antigenic variants. The antigenic repertoire for protein II (Opa) is smaller. The LOS composition is also changed due to antigenic variation.

Gonococci secrete an IgA protease that specifically cleaves IgA_1 in the hinge region. In response to environmental conditions gonococci synthesize iron-repressed gonococcal outer membrane proteins, which bind lactoferrin and transferrin, providing iron internalization. Cell damage is caused by LOS shed from viable bacteria and peptidoglycan fragments liberated from lysed bacteria.

In vitro it has been shown that after attachment gonococci invade epithelial cells as a result of endocytosis[40] (see Fig. 227.4). Whether this process represents a normal feature of uncomplicated mucosal infection is unclear. Cellular invasion is an important factor in the pathogenesis of a complicated infection such as salpingitis or disseminated infection. Invasion of gonococci is characterized by the formation of intimate contacts between the bacteria and the cell membrane, the zipper mechanism. Por and certain Opas facilitate invasion. Por is inserted into the plasma membrane of eukaryotic cells, probably making pores. Inside the cells the porin protein binds to calmodulin. As a result of this, microfilament-dependent processes are modified.

Por IB variant strains inserting into the host cell membrane remain localized, whereas Por IA variants translocate and are associated with disseminated gonorrhea. In addition, gonococci produce Yop-like substances, that interfere with host cell signal transduction systems and affect the host cell cytoskeleton. Bacteria-mediated rearrangement of actin is associated with forced endocytosis.

Inside the cells gonococci are transported within vacuoles, which coalesce to form larger vacuoles. Por prevents phagolysome fusion. Sheltered from innate host defenses, the gonococci multiply. Vacuoles fuse with the basement membrane. Although the majority of phagocytosed gonococci die, the viable gonococci are discharged into the subepithelial connective tissue.

As gonococci do not produce exotoxins, tissue damage results from the bacterial cell wall components such as LOS and peptidoglycan. Both constituents induce the production of tumor necrosis factor (TNF)-a. The inflammatory reaction is most likely responsible for the local symptoms.

A prominent feature of gonococcal infection is the intimate association with granulocytes, intracellularly as well as extracellularly. Opa+ gonococci adhere to granulocytes, bypassing phagocytosis and killing.[37] Also pili have antiphagocytic properties and sialylation of LOS reduces the opsonization of bacteria. The gonococci are able to resist oxidative killing inside phagocytes and may survive inside the granulocytes by binding of Por to calmodulin and upregulation of catalase production.

Certain strains have the ability to spread. Strains isolated from the fallopian tube lack Opa (protein II). Gonococci from other distant sites have the Por IA type protein. Host factors also play a role in the dissemination of gonococci. People who have terminal complement deficiencies have a high risk of developing bacteremia.[41]

Meningococcal disease

Infection due to *N. meningitidis* commonly results from asymptomatic nasopharyngeal carriage.[7] At any time approximately 10–20% of the population may be carriers of meningococci. Protective antibodies are evoked within 1 week by the meningococcal carrier state. Susceptibility to infection has been shown to correlate with the absence of specific antibodies. Another important host factor playing

a role in the pathogenesis of meningococcal disease is the complement system.[42]

The pathogenic effects of meningococci lie in the ability of the organism to traverse the epithelial lining of the respiratory tract, evade the host immune system and invade the bloodstream (Fig. 227.5).[43] [44] Meningococci either disseminate further into the subarachnoid space or remain circulating in the bloodstream. The mechanisms by which this occurs are only partially understood. *In vitro* studies have shown that meningococci adhere to the host cell receptor CD46, a complement regulatory protein[45] of the microvilli on nonciliated epithelial cells via type IV pili and class 5 proteins. [14] [20] [21] Nonencapsulated strains adhere better than capsulated parent strains. Adherent meningococci cause ciliostasis at a distance, probably due to the induction of TNF-a or interleukin (IL)-1 by bacterial cell wall constituents. Meningococci produce $sIgA_1$ protease, which is though to help bacterial survival on the mucosal membranes. After mucosal adherence meningococci may initiate a bacterial-directed endocytosis.[46] Nonencapsulated meningococci traverse the cytoplasm, whereas encapsulated meningococci are transported in phagocytic vacuoles. The IgA1 protease and PorB may promote the survival of meningococci in the epithelial cell.[30]

In the migration from the mucosa to the deeper tissues the pili are downregulated. However, *in vitro* studies have shown that piliated meningococci associate with endothelial cells more readily than their nonpiliated counterparts. The presence of pili is also associated with a greater degree of cytopathic effects, including disruption of intercellular junctions and rounding up of cells.[43] It is not known why in an unknown percentage of colonized persons pathogenic meningococci are not adequately contained by the local host defenses and traverse the endothelial lining of the vascular bed, probably through widened intercellular junctions.[44] In the bloodstream meningococci may:

- be inactivated by the combined actions of antibody, complement and granulocytes; or
- reach the subarachnoid space; or
- multiply within the circulation.

Little is known of this early bacteremic phase and dissemination to the subarachnoid space. It is thought that there are at least three potential mechanisms by which bacteria may gain access to the subarachnoid space:[44]

- paracellular transport after disruption of tight junctions of the blood-brain barrier in the chord plexus;
- transport within circulating phagocytic cells, such as monocytes; and
- transcellular transport within endothelial cell vacuoles.

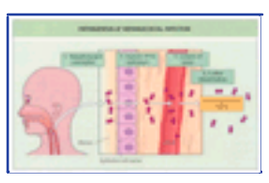

Figure 227-5 Pathogenesis of meningococcal infection. *(Adapted from Virji.[43])*

Systemic meningococcal infection is a bacteremic disease. The number of bacteria/ml of blood has been correlated with the severity of clinical presentation, probably due to the quantity of LOS.[24] Indeed, there is a correlation between clinical outcome and strains of meningococci that shed large amounts of LOS from surface blebs. The subsequent tissue injury is related to the host inflammatory response to LOS; circulating levels of proinflammatory mediators TNF-a, IL-1 and interferon-? at admission are strongly correlated with outcome.

Pathophysiologic sequelae of meningitis are also due to host responses to the presence of bacteria within the subarachnoid space. Host responses are elicited by intact bacteria as well as bacterial constituents such as LOS and peptidoglycan. They include the influx of leukocytes into the subarachnoid space (Fig. 227.6) and the release of soluble inflammatory mediators such as various cytokines, prostaglandins and platelet-activating factor.

Individuals who have inherited deficiencies in the late complement components (C6–C9) have a greatly increased risk of developing meningococcal infection.

Intriguingly, however, they acquire the infection at a much later age, have frequent recurrences and the fatality rate is much lower than for normocomplementemic individuals.[42]

Other genetic defects such as polymorphisms in the mannose-binding lectin[47] [48] and TNF-a may also alter susceptibility to the disease.[49]

PREVENTION

Gonococcal infection

Condoms provide a high degree of protection from acquisition of gonorrhea, as well as other STDs. Other important approaches for prevention of gonorrhea are early diagnosis and treatment, partner notification and screening and case finding. A new approach is the use of topical microbicides for intravaginal or intrarectal use.

Attempts to develop a gonococcal vaccine have been hampered by the high degree of antigenic variability in pili, Opa and LOS of gonococci during the natural course of infection. Porin (protein I), antigenically stable, inducing specific antibodies, is a preferred protein to produce a vaccine.[50]

Meningococcal disease

Prevention of meningococcal disease is based on two different approaches: chemoprophylaxis and the use of vaccines.[30] [51]

Chemoprophylaxis

The aim of chemoprophylaxis is to reduce secondary cases of meningococcal disease and to arrest outbreaks. The risk of a secondary case among close contacts of the index case in the household setting is 150–1000 times higher than that in the general population. Children are at greatest risk, but secondary disease can occur at all ages. Risk is maximal in the week following recognition of the index case but extends for several weeks.

Many of the antibiotics that are useful in treating infection do not effectively eradicate or prevent carriage of meningococci because of their inability to achieve adequate levels in oropharyngeal secretions. A number of agents, however, have been shown to be effective.[30] [52] Minocycline, a tetracycline, can eradicate meningococcal carriage, but its use is associated with an unacceptably high incidence of side-effects, particularly vestibular problems causing vertigo. Rifampin (rifampicin) is widely used as a chemoprophylactic agent now. Carriage is eradicated in 70–95% of the contacts after a 2-day course. Failures may be due to the emergence of meningococci resistant to rifampin. Side-effects include discoloration of soft contact lenses, interference with the oral contraceptive pill and red urine and it is contraindicated during pregnancy. Two other antibiotics have also been shown to effectively eradicate meningococcal carrier status. Ceftriaxone, in a single intramuscular dose, was 97% effective in household contacts after 1–2 weeks after infection. The advantage of ceftriaxone is that it can be used in pregnancy and to small children.

Ciprofloxacin and ofloxacin as a single oral dose have an efficacy of 93–97% in eliminating carriage.[52]

Chemoprophylaxis is recommended for close household contacts of cases and other intimate contacts. In addition, patients who have meningococcal disease should receive chemoprophylaxis before discharge from the hospital, because parenteral antibiotic treatment of meningococcal disease (except ceftriaxone) is unreliable in eliminating meningococci from the nasopharynx.

Vaccines

In the past two decades, increasing effort has been put into the development of new meningococcal vaccines, in particular against serogroup B disease. Two main approaches have been taken, based on polysaccharide or outer membrane protein (OMP) components.

Polysaccharide vaccines

These vaccines have been used successfully to reduce the incidence of infection among military recruits, to reduce the progress of epidemics of group A disease and to protect individuals known to be susceptible because of various complement deficiencies.[53] The vast majority of antibodies appear to bind to epitopes that are affected when the polysaccharide is de-O-acetylated, indicating that O-acetyl groups are critical in a polysaccharide vaccine.[54] However, immunity provided by polysaccharide vaccines is short-lived in adults (as no T-helper response occurs) and no protection is achieved in young children. Polysaccharide vaccines are used by travelers visiting countries with a high incidence of meningococcal disease and in these cases the short duration of the immune response is immaterial. A drawback of polysaccharide vaccines is that there is no vaccine in use against serogroup B meningococci, which causes most cases of disease in temperate countries. Early studies with serogroup B polysaccharide vaccines failed to show evidence of antibody response in human volunteers. There was a reluctance to include the group B polysaccharide in further vaccination approaches because of the possibility of inducing an autoimmune response.[51]

Conjugate vaccines

Following the success of the conjugate vaccines to prevent *Haemophilus influenzae* type b meningitis, serogroup A, C, Y and W135 meningococcal polysaccharides have been conjugated to carrier proteins.[51] Such polysaccharide protein vaccines are immunogenic in young infants. They induce a T cell-dependent response, prime immunologic memory and result in long-term protection. Initial field trials of these vaccines yielded encouraging data. In the United Kingdom meningococcal group C conjugate vaccine was introduced in health care programs in late 1999.[33] Rates of disease caused by serogroup C meningococci fell rapidly in the vaccinated age group.[55]

Age-specific vaccine efficacy had been estimated to be 88% in young children and 95% in young adolescents. Carriage of serogroup C meningococci studied in the vaccinated young adolescents group showed a reduction by 66%.[56] Meningococci have the capacity to exchange genes that induce the enzymes involved in capsular synthesis.[10] [11] It has been documented that the bacteria can switch from serogroup C to serogroup B or vice versa. Capsule switching, replacement by strains having capsular groups not contained in the vaccine providing serogroup specific protection, and replacement by nongroupable strains having the genetic material encoding the capsule but downregulating the capsule expression may occur with the widespread use of monovalent serogroup conjugate vaccines, but have not been established yet.

Bivalent A plus C polysaccharide conjugate vaccines have been assessed in clinical trials. Multivalent polysaccharide A,C,Y and W135 protein conjugate vaccines are being developed.[51]

Outer member protein vaccines

The observation that outer membrane components stimulated cross-reactive antibodies and promoted complement-mediated, bactericidal killing of capsulated strains led to alternative approaches to vaccination against serogroup B disease. The first experimental outer membrane vaccines used membrane preparations as close to the native membrane structure as possible. Detergent extraction was used to remove LOS from outer membrane vesicles obtained from a common disease-causing strain. Such vaccines were used in clinical trials and showed efficacies in the range of 50–80%. However, young children were not protected. There are a variety of novel OMP-based meningococcal vaccines currently under investigation,[51] such as construction of multivalent vaccine strains based on common variants of Por A;

OMPs complexes with group C polysaccharide; immunization with synthetic peptides; use of other organisms as vehicles for the delivery of a meningococcal OMPs; and investigation of vaccine potential of iron-regulated proteins (Tbp-1 and Tbp-2). The rational design of OMP-based vaccines must take into account the antigenic variability of circulating meningococcal strains to determine the most appropriate epitopes for inclusion in a vaccine. Therefore, new vaccine candidates on the basis of conserved antigens are being identified.

Novel vaccine candidates

The completion of the genomic sequencing of a serogroup B meningococcus made it possible to find open reading frames encoding novel surface-exposed proteins. [57] These proteins and those derived from a serogroup A meningococcus and a gonococcus (*N. gonorrhoeae*) were compared to identify similar conserved surface-exposed proteins. Such proteins were cloned, expressed in *Escherichia coli* and antisera were prepared to the recombinant proteins. Genome-derived antigens inducing antibodies which bind to the serogroup B meningococcal surface and eliciting bactericidal activity against serogroup B meningococcus may be vaccine candidates for providing broad protection. [57]

CLINICAL FEATURES

Gonococcal infection

Neisseria gonorrhoeae usually causes an infection of the urethra (urethritis) and cervix (cervicitis).[27] The bacterium may spread to the upper urogenital tract or may disseminate.

In addition, gonococci may cause localized infections at sites outside the urogenital tract.

Urogenital gonococcal infection of men

Acute anterior urethritis

This is the most common manifestation of gonorrhea (Fig. 227.7). It is characterized by a purulent urethral discharge and dysuria.

Acute epididymitis

This is the most common local complication of gonococcal infection and usually presents as gradually increasing unilateral scrotal pain.

Urogenital gonococcal infection of women

Cervicitis

The endocervix is the primary site of urogenital gonococcal infection. The infection is characterized by (muco)purulent discharge and intermenstrual bleeding, but is often asymptomatic.

Acute anterior urethritis

Urethral infection is present in 70–90% of women who have gonococcal cervicitis.

Abscess formation in glands adjacent to the vagina

About 35% of the women who have genital tract gonococcal infection have an infection of Bartholin's glands or Skene's ducts, by which abscess formation may occur.

Ascending gonococcal infection

Endometritis or acute salpingitis develops in 10–20% of women who have lower urogenital gonococcal infection. The high frequency of the asymptomatic infection of the endocervix is an important factor in the development of these complications because the initial infection is neither recognized nor treated. Symptoms of this clinical syndrome of pelvic inflammatory disease (PID) include lower abdominal pain abnormal cervical discharge and bleeding, fever and peripheral leukocytosis. The onset of salpingitis due to gonococci occurs early rather than late in infection and either during or shortly after menstruation. Obstruction

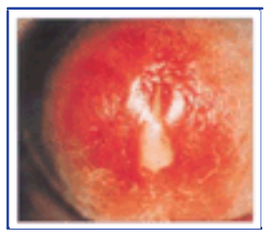

Figure 227-7 Gonococcal urethritis. *Courtesy of J Clay. (Reproduced with permission from Mims et al.[9])*

of the fallopian tubes leading to infertility occurs in 10–20% of patients who have PID after a single episode of gonorrhea.

Gonorrhea in pregnancy

In pregnant women gonorrhea is associated with an increased risk of spontaneous abortion, premature labor, early rupture of fetal membranes and perinatal infant mortality. Pelvic inflammatory disease is uncommon after the first trimester.

Gonorrhea in children

Historically gonococcal infection in children included only ophthalmia neonatorum (acute gonococcal conjunctivitis). Recently, studies have shown that children can acquire gonococcal infection by sexual contact with an infected person. Such infection therefore indicates sexual abuse. In girls the infection often produces a vulvovaginitis. Complications affecting the internal genital organs are rare.

Localized gonococcal infection outside the urogenital tract

Proctitis

Anorectal gonorrhea is present in up to 5% of women who have gonorrhea, although gonococci can be cultured from the anorectal region of 40% of women with gonorrhea. A similar proportion of homosexual men have positive rectal cultures for gonococci. Proctitis is manifested by anal pruritus, tenesmus, purulent discharge or rectal bleeding.

Pharyngeal gonorrhea

Pharyngeal infection occurs in 10–20% of women who have gonorrhea and in 10–25% of homosexual men who have the infection and in 3–7% of heterosexual men.

The infection is due to orogenital sexual exposure. Most cases are asymptomatic and resolve spontaneously.

Acute conjunctivitis

Ocular gonococcal infection is seen in neonates. Ophthalmia neonatorum is acquired during passage through an infected birth canal. In adults ocular infection usually results from autoinoculation of the conjunctiva in a person who has the infection. Gonococcal conjunctivitis is usually severe, with an overt purulent exudate and corneal ulceration.

Disseminated gonococcal infection

In 0.5–3% of infected individuals gonococci invade the bloodstream, resulting in disseminated gonococcal infection.

Dermatitis-arthritis-tenosynovitis syndrome

This infection is characterized by fever, hemorrhagic painful skin lesions, primarily on the hands or feet, tenosynovitis, polyarthralgias and frank arthritis (Fig. 227.8).

Monoarticular septic arthritis

In 30–40% of patients who have disseminated gonococcal infection, gonococci are localized in one joint and cause a purulent arthritis.

Figure 227-8 Disseminated gonococcal infection. (a) Skin lesions. *Courtesy of JS Bingham.* (b) Arthritis. *Courtesy of TF Sellers Jr. (Reproduced with permission from Mims et al.[9])*

The elbows, wrists, fingers and knee or ankle joints are commonly involved.

Perihepatitis

Acute perihepatitis (Fitz-Hugh-Curtis syndrome) occurs by direct extension of gonococci from the fallopian tube, lymphangitic spread or bacteremic dissemination to the liver capsule.

Endocarditis and meningitis

These complications are reported in 1–2% of patients who have disseminated gonococcal infection.

Meningococcal infection

On presentation 60% of cases have had symptoms for less than 24 hours and 12–20% for less than 2 days. Meningococcal disease may be manifested in various forms.[24] [30] [58]

Meningitis

The most frequent form of meningococcal infection is acute pyogenic meningitis due to inflammation of the meninges. Meningitis may occur with or without meningococcemia. Of patients who have meningococcal disease 75% have meningitis; 40% of them also have bacteremia.

Meningococcemia

Meningococcemia may occur with or without meningitis and may be transient, occult or result in severe sepsis. Bacteremia without meningitis occurs in 7–10% of patients. A distinguishing factor of meningococcemia is the appearance of skin lesions (Fig. 227.9). Initially these lesions appear on the mucous membranes and conjunctivae. Three patterns may be seen:

- a maculopapular rash.
- petechiae, and
- ecchymotic hemorrhagic or necrotic lesions or purpura fulminans.

However, skin lesions may be atypical, evanescent or even entirely absent in patients who have blood culture-positive meningococcal sepsis. Meningococcal sepsis may progress to disseminated intravascular coagulation characterized by increasing petechiae or purpura fulminans, resulting in extensive areas of tissue destruction secondary to coagulopathy, rapid onset of hypotension and adrenal hemorrhage (Waterhouse-Friderichsen syndrome).

Figure 227-9 Typical rash of meningococcal sepsis. Fine erythematous macules and petechiae are present in some areas.

Chronic meningococcemia

Persistent meningococcal bacteremia is associated with low-grade fever, rash and arthritis (arthritis-dermatitis syndrome).

Respiratory infection

Meningococci are implicated as the etiologic agent in approximately 5–14% of patients who have community-acquired pneumonia. Pharyngitis is associated with recent contact with individuals who are colonized by meningococci and is often a prior symptom and sign of serious meningococcal disease.

Other infections

Neisseria meningitidis may cause other infections as a result of hematogenous spread. Infections due to blood-borne dissemination include endocarditis, pericarditis, arthritis, endophthalmitis, osteomyelitis, conjunctivitis and peritonitis. Arthritis is particularly common with an incidence of 11% in adults and 5% in children.

LABORATORY DIAGNOSIS

Gonococcal infection

Because *N. gonorrhoeae* can cause infection at a variety of body sites, collection of appropriate specimens for diagnosis depends upon the clinical manifestations and the sites exposed. In men suspected of having gonorrhea, urethral exudate is the best specimen. In females cervix swabs are preferred over urethral or vaginal specimens. Swabs coated with charcoal to absorb toxic substance are transported to the laboratory in specific transport media (Stuart's or Amies's). Specimens from the male urethra or the female endocervix should be collected from all cases of suspected gonococcal infection. Both specimens are taken for direct examination and culture. A finding of neutrophils containing Gram-negative cocci in the Gram-stained smear is presumptive evidence of gonococcal infection (Fig. 227.10). Gram stain is highly sensitive and specific for diagnosing genital gonorrhea in men. Gram-stained smears made from endocervix specimens from symptomatic women have a sensitivity of only 40–60% relative to culture, but a high predictive value. In asymptomatic women Gram stain has a low predictive value and is not useful.

Direct nonculture tests are also used. An enzyme-linked immunosorbent assay test detects gonococcal antigen. A nucleic acid probe test is also available. The polymerase chain reaction has also been applied for direct detection of gonococci in clinical specimens. The ligase chain reaction using highly sensitive nucleic acid amplification is used on urine and urogenital specimens. It has proved to be as

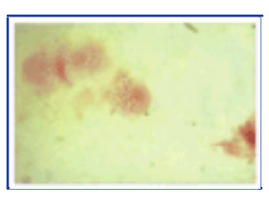

Figure 227-10 Gram stain of a urethral discharge from a male who has gonorrhea. Note the intracellular Gram-negative diplococci with neutrophils.

sensitive and specific as culture. Ligase chain reaction has the advantage of requiring only a freshly voided urine sample, avoiding invasive sampling of the endocervix and urethra.

Culture is used for making a diagnosis of gonococcal infection of the urethra, the endocervix or an extragenital site. Depending upon sexual practices, samples are also collected from the rectum and/or pharynx. In cases of disseminated gonococcal infection blood cultures are obtained and biopsies from skin lesions and joint fluid aspirates are cultured. Maximal recovery of gonococci from infected sites is obtained when specimens for culture are plated directly onto growth medium. If this is not possible or practical, various commercial nonnutritive transport media are available.

Diagnosis of gonococcal infection is made at two levels: presumptive and confirmed. Antimicrobial treatment may be started based on the results of the presumptive tests, but additional tests have to be performed to yield a confirmatory diagnosis.

A variety of enriched selective media are available to grow gonococci. Commonly used media (Thayer-Martin medium and Martin-Lewis medium) contain lysed or heated blood (chocolate agar) supplemented with growth factors and a variety of antimicrobials to suppress the growth of other bacteria and yeast. Specimens taken from sites that are normally sterile are cultured on antibiotic-free media because occasional strains of gonococci are susceptible to the antibiotics added to the growth media. Growth media are placed in a carbon dioxide incubator or candle jar at 95–98.6°F. After incubation for 24–48 hours colonies of gonococci have a characteristic appearance. Isolates on primary culture media are predominantly of the P^{+} and P^{++} (piliated) colony types, being small, glistening and raised. After subculture P^{-} (nonpiliated) colonies appear. They are larger and flatter than P^{+} colonies and there is no glistening. Smears are prepared from suspicious colonies and examined with Gram stain and the oxidase and catalase tests. Gramnegative diplococci that give a positive oxidase and catalase test may be *N. gonorrhoeae*.

For confirmatory identification of gonococci other types of *Neisseria* spp. as well *Branhamella* and *Kingella* spp. have to be considered. Certain characteristics differentiate between species of the genera.

Confirmatory identification tests include carbohydrate utilization test, monoclonal antibody fluorescence test, coagulation test, chromogenic detection of specific enzyme activities or the DNA probe culture confirmation test. Gonococci oxidize glucose (but not maltose, sucrose and lactose). Serologic tests are not used, because none has sufficient sensitivity and specificity for clinical use.

Meningococcal infection

Cerebrospinal fluid (CSF), blood, skin biopsies and aspirates are relevant specimens for the diagnosis of meningococcal disease. Additionally, synovial fluid, sputum and conjunctival and nasopharyngeal swabs may be cultured if clinically indicated. Because meningococci, like gonococci, are susceptible to desiccation and temperature extremes, specimens should be cultured as soon as possible after collection.

For presumptive diagnosis appropriate specimens are examined by Gram stain. Gram-stained smears are made from uncentrifuged CSF if the CSF is cloudy and from centrifuged CSF if the CSF is clear. The probability of detecting Gram-negative diplococci, typically present inside as well as outside polymorphonuclear cells, depends on the number of bacteria present. The majority of the smears will be positive when the CSF bacterial count is 10^5 bacteria per ml or greater. Smears from CSF containing 10^3 bacteria per ml or less will be positive in only 25%; on average 60–90% of cases of CSF specimen will have a positive Gram stain, since the bacterial number per ml CSF ranges from 1.5×10^2 to 6×10^5 (mean 1.3×10^5). Gram-stained smears from petechial skin lesions due to meningococcemia may detect meningococci in more than 70% of cases.

Direct examination of CSF to detect meningococcal capsular polysaccharides can be done by performing direct antigen tests. Currently direct antigen tests contain a polyclonal antibody for serogroups A, C, Y and W135 and a reagent for serogroup B. Using latex agglutination and coagglutination tests, 0.02–0.05mg antigen per ml CSF from infected patients can be detected. The sensitivity of the tests is only about 50%.

The mean CSF leukocyte count is higher in patients who have meningitis than in patients who have meningococcemia. The proportion of polymorphonuclear cells in CSF from patients who have meningitis ranges from 49% to 98% with a mean of 86%. Other CSF abnormalities include low glucose concentration and an elevated protein concentration. In patients partially treated with antibiotics for meningococcal disease the CSF leukocyte count, glucose and protein concentration and the antigen tests remain abnormal for several days, whereas bacteria are not evident on smear and CSF culture is often negative. Blood cultures are positive in only 50% of the patients with meningococcal disease. In those who have received antibiotics prior to the collection of blood for culture, blood cultures are sterile. A nasopharyngeal swab from young children can provide worthwhile information in cases of suspected meningococcal disease. Meningococci are rarely recovered from healthy young children. Therefore, a well-capsulated serogroup B or C meningococcus grown from a throat swab is strong evidence that a meningococcus is the cause of disease.[58]

The aforementioned tests should be accompanied by a culture of specimens on nonselective growth media in order to isolate *N. meningitidis*. It is noteworthy that CSF cultures may be positive even when other tests are negative. Such a finding is encountered particularly in early meningococcal meningitis and in patients who have meningococcemia without clinical evidence of meningitis. Appropriate nonselective media are 5% sheep blood agar (in contrast to gonococci, meningococci grow well on this medium) and chocolate agar. Selective media used to culture nasopharyngeal specimens are the same as those mentioned for gonococci. Most blood culture media support the growth of meningococci, although liquid sodium polyanethole sulfonate (SPS)-containing media may be toxic for some meningococcal strains.

After inoculation, meningococci will grow quite rapidly on agar media in a 3–7% carbon dioxide-enriched atmosphere with rather high humidity at 95–98.6°F. After 18–24 hours of incubation flat, gray-brown, translucent, smooth, 1–3mm in diameter colonies of *N. meningitidis* are present. Mucoid colonies are often serogroup A

or C strains. If sufficient growth is present a presumptive diagnosis is made with a Gram stain, an oxidase test and a catalase test. The finding of Gram-negative diplococci that are oxidase and catalase positive grown from appropriate specimens may be sufficient to initiate antibiotic treatment for meningococcal disease. For confirmatory identification other species of *Neisseria, Kingella* and *Branhamella* have to be taken into account. Characteristics that differentiate *N. meningitidis* from

these species are the production of acid from glucose and maltose. Gonococci acidify only glucose, and *N. lactamica* produces acid from glucose, maltose and lactose, though a number of commensal *Neisseria* spp. may be misidentified as *N. meningitidis* on the basis of carbohydrate oxidation. In order to specify *N. meningitidis* enzyme substrate tests are also used. Meningococci produce ?-glutamylaminopeptidase. In addition, the polysaccharide from sucrose test differentiates between *N. polysaccharea* (polysaccharide positive) and *N. meningitidis* (polysaccharide negative).

A polymerase chain reaction test has been used for the detection of meningococci in CSF or blood. This test may be useful to confirm the diagnosis in patients who have had antibiotic treatment prior to collection of CSF and whose CSF Gram stain, antigen test and culture are negative.

MANAGEMENT

Gonorrhea

Data from the pre-antibiotic era indicate that in males the urethral infection subsides after 2–3 months. Repeated infection, if untreated, leads to stricture of the urethra. Such sequelae are now rare, because the signs of urethritis bring most men to diagnosis and treatment.

In 10–20% of women gonorrhea results in ascending genital infection and PID, manifested by endometritis, salpingitis, tubo-ovarian abscess and pelvic peritonitis. Infertility due to fallopian tube obstructions is the most serious sequela of PID and occurs in 15–20% of women after a single episode and in 50–80% of women after three or more episodes.[27] In addition, disseminated gonococcal infections may occur. In the pre-antibiotic era *N. gonorrhoeae* was a frequent cause of endocarditis and meningitis.

In 1937 sulfonamides were introduced for treatment of gonorrhea. Sulfonamide-resistant strains emerged rapidly and penicillin was traditionally used to treat gonorrhea. Before 1976 *N. gonorrhoeae* was not generally tested for its antimicrobial susceptibility, although gonococcal isolates with a decreased sensitivity for penicillin (MIC >0.1mg/1) had been recovered. This chromosomally encoded penicillin insensitivity is the result of a number of mutations at the *pen A, pen B env* and *mtr* genes. Mutations in the *pen* genes alter penicillin-binding proteins, reducing their affinity for penicillin. The mtr locus is an efflux pump. Mutations of *mtr* and *env* alter the permeability of the gonococcal membrane. Gonococci with this form of penicillin resistance were designated chromosomally resistant *N. gonorrhoeae* (CMRNG). These strains represent 1–6% of all gonococci in the Western world. In 1976 strains of gonococci that were totally resistant to penicillin due to ß-lactamase production were recovered.[27] These isolates contain a plasmid (Pc^r) that carries the genes for a TEM-1 type ß-lactamase. Although the prevalence of such penicillinase-producing *N. gonorrhoeae* (PPNG) remains stable at about 5–10% in Western Europe and the USA, it is no longer common practice to treat patients who have gonococcal infection with penicillin. One of the reasons for this is that failure to cure a case of gonorrhea has implications for the infected patient as well as for public health, because of the possibility for transmission of the disease and the resistant gonococcus. Therefore, antibiotic regimens for gonorrhea require high patient compliance and an efficacy of 100%. In addition, the antibiotic regimens for gonorrhea should have potential efficacy for a concurrent sexually transmitted disease (STD) infection, such as syphilis and STD due to *Chlamydia trachomatis*. Many studies have shown that *C. trachomatis* can be recovered from 15–30% of men who have gonococcal urethritis and from 35–50% of women who have endocervical gonorrhea.[59] In 1985 *N. gonorrhoeae* strains were isolated that showed high-level tetracycline resistance, designated TRNG, so tetracycline is also no longer recommended for the primary treatment of uncomplicated gonococcal infections. This type of tetracycline resistance is due to a conjugative plasmid into which the *tetM* transposon has been inserted. The *tetM* determinant is readily transferable to other gonococci and various other micro-organisms. The prevalence of TRNG among gonococci in Western Europe and the USA is about 5–8%.

Present recommendations for treatment of uncomplicated gonorrhea are based on regimens that provide high efficacy, have potential, efficacy against concurrent sexually transmitted bacterial infections, particularly *Chlamydia trachomatis*, and that can be given as a single dose in order to obtain maximal patient compliance. Typical regimens are ceftriaxone (one intramuscular dose) or a single oral dose of cefixime, ciprofloxacin or ofloxacin.[60] Each of the therapies also includes a single oral dose of azithromycin or doxycycline for 1 week for the treatment of co-infecting *C. trachomatis*. One oral dose of azithromycin is active against both gonococci and *C. trachomatis*. Ciprofloxacin, ofloxacin and doxycycline are contraindicated during pregnancy. Pregnant women who have gonococcal infection are treated with ceftriaxone followed by 7–10 days of erythromycin. In the past decade gonococcal isolates with decreased sensitivity to ciprofloxin and ofloxacin have been isolated, [61] particularly in South East Asia and Africa. The high-level resistance (MIC >1–16mg/l) is chromosomally mediated, mainly due to mutations in *gyr A* (DNA gyrase) and *par C* (topoisomerase IV). The rapid emergence of such resistant strains most likely requires reassessment of ciprofloxacin and ofloxacin for the treatment of gonorrhea in the near future.

Treatment of PID has been performed with a large number of antibiotic combinations. The important role of both gonococci and *C. trachomatis* in producing PID has been elucidated and, although the role of various anaerobes in PID is not ascertained, many studies have shown that anaerobic cover is essential for treatment of PID patients. The recommended regimens now include intravenous cefotetan or cefoxitin plus doxycycline.[60] An alternative regimen is clindamycin or metronidazole plus gentamicin or tobramycin, followed with oral doxycycline or clindamycin to complete 14 days of treatment. The recommended regimen for treatment of outpatients is a 2-week combination of oral ofloxacin and clindamycin or metronidazole. Amoxicillin-clavulanic acid together with doxycycline will also cover the major pathogens responsible for PID.[59] Azithromycin in combination with amoxicilin-clavulanic acid may also give excellent activity against *N. gonorrhoeae*, anaerobes and *C. trachomatis*.

Complicated gonococcal infection in males (acute epididymitis) is treated with a single dose of ceftriaxone plus doxycycline for 10 days or ofloxacin. [60] Treatment of disseminated gonorrhea is always started with ceftriaxone.[60] This treatment is not changed into doxycycline or ciprofloxacin if arthritis or meningitis is present. Children who have gonococcal infection are also treated with ceftriaxone.

Meningococcal disease

The overall case fatality rate of meningococcal disease is 9–12% and has remained fairly stable over the last decades.[30] Approximately 5% of patients who have meningitis, and 25–35% of patients who have meningococcal sepsis, will die. Of the survivors, 11–19% have serious sequelae, such as loss of hearing, scars after skin necrosis and cranial nerve palsies.

After the introduction of the sulfonamides, meningococcal disease could be treated by chemotherapy. Now sulfonamides have no role in the treatment of meningococcal infection, because resistant strains appeared in 1963. The mainstay of treatment for patients who have meningococcal disease is benzylpenicillin.[52] [58] For most cases of uncomplicated meningococcal meningitis a 7-day course is adequate.[58] Since the etiology is not known at admission, ceftriaxone or cefotaxime is used for the first 24–48 hours to cover the possibility of other bacterial pathogens.[58] Routine susceptibility testing is not indicated,[30] although ß-lactamase producing strains have occasionally been recovered. These strains harbor the same plasmid as many PPNG. In addition, there are *N. meningitidis* strains that are not ß-lactamase positive but have decreased sensitivity to penicillin. This diminished sensitivity is due to reduced affinity of penicillin to penicillin-binding proteins 2 and 3, resulting from an altered *pen A*. Although the frequency of relatively penicillin-resistant meningococci is low, continued surveillance is necessary. Cefotaxime or ceftriaxone is used when relatively penicillin-resistant strains are isolated.

A novel approach to treat children with severe meningococcal sepsis is the use of bactericidal/permeability-increasing protein (BPI). BPI is a cationic protein contained within granules of polymorphonuclear leukocytes. Since BPI binds endotoxin, a recombinant fragment of BPI ($rBPI_{21}$) was used to treat children with severe meningococcemia. The results of the first clinical trial showed a beneficial effect of $rBPI_{21}$ in decreasing complications of meningococcal disease. [62]

INFECTIONS CAUSED BY OTHER *NEISSERIACEAE*

The so-called nonpathogenic *Neisseria* spp. colonize the human nasopharynx and oropharynx. They comprise eight species (*N. lactamica, N. cinerea, N. polysaccharea, N. sicca, N. subflava, N. flavescens, N. musosa* and *N. elongata*), which do not grow on the enriched media containing antibiotics used for the isolation of gonococci and meningococci.

Strains of *N. lactamica, N. subflava, N. cinerea* and *N. polysaccharea* can be isolated from the selective media and must be differentiated from meningococci and gonococci. *Neisseria* spp. may be differentiated by their patterns of acid production. Rapid methods have been developed to detect acid production. Without additional tests including chromogenic enzyme substrate tests and serologic tests, however, the eight species may be misidentified as meningococci or gonococci.

Neisseria lactamica, which produces acid from lactose and can thus be differentiated from meningococci, has been isolated from cases of meningitis or sepsis in both adults and children.[63]

Four true *Neisseria* spp., *N. sicca, N. subflava, N. flavescens* and *N. mucosa*, have been reported most frequently with native and prosthetic endocarditis.[63] Most

patients who had endocarditis had underlying heart abnormalities. In many cases the use of intravenous drugs was a risk factor: oral secretions are used as a solvent for the drug or to clean or lubricate the needle before injection, or result in infection of the valve.

Neisseria sicca is associated with cases of native and prosthetic valve endocarditis. It has also been isolated from meningitis cases. It is a rare cause of pneumonia and osteomyelitis.

Neisseria subflava has been isolated from a small number of patients who have endocarditis, meningitis and sepsis.

Neisseria flavescens, producing yellow-pigmented colonies, has been isolated once in association with an outbreak of meningitis. Occasionally this species is the cause of sepsis resembling chronic meningococcemia.

Neisseria mucosa forms large mucoid colonies adherent on the agar and is isolated as an unusual cause of endocarditis, meningitis, ocular infections, cellulitis, pneumonia and empyema.

Neisseria cinerea colonies may resemble gonococcal colonies on selective media. Occasionally this species is recovered from genital sites and may be associated with syndromes similar to those caused by gonococci, such as conjunctivitis in newborns (ophthalmia neonatorum), proctitis and lymphadenitis. Meningitis occurred in a patient who had facial trauma. Pneumonia in immunodeficient patients has also been reported.

Neisseria polysaccharea grows on the selective media and resembles *N. meningitidis* because acid is produced from glucose and maltose. Infections due to this species have not been reported.

Neisseria elongata, a rod-shaped *Neisseria* spp., has been cultured from blood specimens of patients who have endocarditis or sepsis. It has also been associated with wound infections, and osteomyelitis after oral surgery.[63]

The six false *Neisseria* spp. are common inhabitants of the oropharynx of various animals. *Neisseria canis*, first recovered from a healthy dog, is a normal commensal in the upper respiratory tract of cats and has been cultured from wounds due to cat bites.

Neisseria weaveri, a rod-shaped *Neisseria* spp., was formerly called CDC group M-5 and is part of the oropharyngeal flora of dogs. It has been isolated from human wounds due to dog bites.

N. denitrificans and *N. iguanae* are present in the oropharynx of guinea pigs and iguanas, respectively, and have not been associated with human disease.

Centers for Disease Control and Prevention groups EF-4a and 4b are normal inhabitants of the oropharynx of cats and dogs. Most human infections follow dog and cat bites.[63]

In general the commensal *Neisseria* spp. are susceptible to penicillin, ampicillin and tetracyclines. Only *N. mucosa* is penicillin resistant and sensitive to chloramphenicol. Some strains of *N. lactamica* have an altered penicillin-binding protein 2 similar to the penicillin-binding protein 2 in relatively penicillin-resistant *N. meningitidis*. Rare strains of *N. sicca, N. flavescens* and *N. subflava* are penicillin resistant because of production of ß-lactamase. Such strains are a potential source of ß-lactamase genes that are transferable to meningococci and gonococci.

Chapter 228 - Enterobacteriaceae

Maja Rozenberg-Arska
Maarten R Visser

INTRODUCTION

Enterobacteriaceae are ubiquitous organisms that are found worldwide in soil, water and vegetation, and they are part of the normal flora of the gastrointestinal tract of most animals, including humans. Some members of the family Enterobacteriaceae are more frequently associated with disease in humans (e.g. *Shigella*, *Salmonella*, *Yersinia* spp.) than others (e.g. *Escherichia coli, Klebsiella* spp., *Proteus* spp.). These others are members of the normal commensal flora, which in some situations can cause human disease ranging from mild symptoms to severe infections with fatal septicemia. Infections can be of exogenous (e.g. *Salmonella* and *Shigella* spp.) or endogenous origin (e.g. *E. coli*).

NATURE

Taxonomy and nomenclature

The nomenclature and classification of Enterobacteriaceae has always been confusing, with many changes over time. Micro-organisms previously grouped on the basis of biochemical and antigenic properties in certain families may in fact not be closely related.[1]

In recent years, however, techniques of nucleic acid hybridization and nucleic acid sequencing have provided powerful tools that can enable better definition of the evolutionary relationships of all micro-organisms[2] and the relationships of the organisms in one family. Indeed, it is the application of this technology that has led to the current nomenclature.

In addition, molecular information on the complete genome of *E. coli*[3] will provide further valuable insight into the taxonomy of bacteria and will be used to refine current classification schemes.

In 1986, Ewing proposed dividing the family of Enterobacteriaceae into eight tribes that are associated with human diseases (Escherichiae, Edwardsiellae, Citrobactereae, Salmonellae, Klebsiellae, Proteae, Yersiniae, Erwiniae and a group of miscellaneous genera).[4] This tribal concept has been used in some recent descriptions of the Enterobacteriaceae[5] [6] but others have not used it because of lack of diagnostic and taxonomic significance.[2] [5] [7] [8] The classification that is used in this chapter is based on the current bacterial names of the Enterobacteriaceae (see Table 228.4 , Table 228.5 , Table 228.6 , Table 228.7 , Table 228.8 , Table 228.9 , Table 228.10 , Table 228.11 , Table 228.12 , Table 228.13).

Members of the family Enterobacteriaceae show many common properties. They are all Gram-negative, non-spore-forming bacilli, and they are all relatively small (2–3µm × 0.4–0.6µm). They are either motile by peritrichous flagella or nonmotile (e.g. *Shigella* and *Klebsiella* spp.). Some of them are encapsulated.

Enterobacteriaceae grow rapidly on ordinary laboratory media under aerobic and anaerobic conditions. All species utilize glucose fermentatively, often with the formation of either acid or acid and gas. They are oxidase-negative and, with only a few exceptions (certain biotypes of *Pantoea agglomerans* and some *Serratia* spp.), catalase-positive. They reduce nitrates to nitrites.

Anatomy of Enterobacteriaceae

As shown in Figure 228.1 and Figure 228.2 , the major structural compounds of cell wall of Enterobacteriaceae are:

- an inner cytoplasmic membrane;
- the peptidoglycan layer; and
- an outer membrane consisting of two layers — a phospholipid protein layer and an outer lipopolysaccharide (LPS) layer.

Many organisms, such as *Klebsiella* spp. and a number of *E. coli* strains, possess an additional capsular layer (the capsule).

Some Enterobacteriaceae possess flagella, proteinaceous structures that give mobility to the bacteria. In addition, the presence of pili and fimbriae, also proteinaceous in nature, is an important factor in bacterial attachment or adherence to mucosal surfaces.

Cell wall

The cytoplasmic membrane is an important part of the cell envelope, is the boundary between the cytoplasm and environment, and is primarily responsible for regulating the flow of nutrient and metabolic products into and out of the cell. The cytoplasmic membrane is involved in almost every aspect of bacterial growth and metabolism. The chemical units of peptidoglycan, LPS and phospholipids are synthesized by enzymes within this membrane.[9]

Peptidoglycan forms a thinner layer in Gram-negative bacteria than in Gram-positive bacteria. Peptidoglycan consists of a network in which linear amino-sugar chains containing alternating *N*-acetyl-glucosamine and *N*-acetyl muramic acid residues are linked to tetrapeptides. The peptidoglycan layer maintains the shape of bacteria.[10]

The periplasm, or periplasmatic space, lies between the inner and the outer membranes. A number of processes that are vital for the growth and the viability of the cell occur within this compartment.

Changes in the outer membrane or in the LPS allow the release of periplasmatic enzymes and binding proteins, which play a role in protection and interaction of the bacteria and the host defenses.[11]

The outer membrane of Enterobacteriaceae forms an asymmetric bilayer of phospholipids[12] and LPS.[12] [13] The hydrophobic parts of the LPS molecules face the environment and the hydrophilic part interacts with the hydrophilic part of the phospholipid. The LPS molecules generally have three regions: the O-specific polysaccharide chain, the core region and lipid-A moiety.

The O-specific polysaccharide chain is chemically unique for each type of organism and LPS, and it confers serologic specificity on an organism. The O-specific chain normally consists of 20–40 repeating units of oligosaccharides, each containing between two and eight different monosaccharides interlinked with glycosidic bonds. At least 160 different chemical arrangements of O-antigens have been identified in *E. coli* alone.[13] [14] Based on the presence or absence of the O-specific chain, bacterial endotoxin can be smooth (S) or rough (R), named after the appearance of the bacterial colonies on agar plates.

There is uncertainty about the part played by the O antigen in the virulence of the Enterobacteriaceae; however, most of the isolates

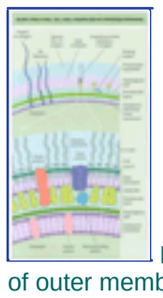

Figure 228-1 Major structural cell wall compounds of Enterobacteriaceae. The figure also illustrates the molecular organization of the outer membrane, and the most likely positions of outer membrane constituents are indicated. Lipopolysaccharide and phospholipid molecules are the major constituents of the asymmetric bilayer. Divalent cations (not indicated) are believed to play important roles in interactions of LPS: Only three types of protein are shown: the pore proteins (LamB protein not shown), OmpA protein and lipoprotein (their interactions with peptidoglycan and lipoprotein are not shown — that such interactions occur cannot be excluded). Several O-antigen chains are much longer than shown here. Enterobacterial core antigen has been omitted for simplicity. The P pili and fimbriae are discussed and illustrated in more detail in Chapter 1 .

from infected sites have smooth LPS. Epidemiologic surveys have demonstrated association between certain O types and clinical infections.[15] It is now generally felt that the O serogroup may act primarily as a marker for a specific cluster of virulence properties needed for a certain infectious process. Certain serogroups possess adhesive factors that are important specifically in urinary tract infection, whereas other serogroups possess colonization factors and toxins that are necessary for the organism to cause gastroenteritis.

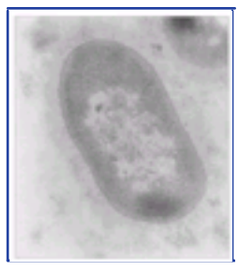

Figure 228-2 Longitudinal section of *Escherichia coli.* The bacterial cell is surrounded by a visible cell wall (outer membrane, cytoplasmic membrane and — in between — periplasm).

The core polysaccharide region of outer membrane, which shows much less variability than the O-specific chain and is often identical in large groups of Gram-negative bacteria, contains deoxy-sugar, 2-keto-deoxyotonic acid and heptose. The core region connects the polysaccharide chain and lipid-A components.

Lipid-A is the most conserved part of LPS and the basic structure is similar in various Gram-negative bacteria. Lipid-A consist of a glucosaminyl-ß-(1–6) glucosamine backbone, which is substituted with six or seven fatty acid residues, all of them saturated. Lipid-A is responsible for the biologic properties of endotoxin. However, lipid-A-associated protein and polysaccharide side chains exert modifying effects and separately may exhibit biologic activities.[16]

Capsule

Two types of capsular polysaccharides are found in Enterobacteriaceae. The M antigen (mucous antigen) or colanic acid is produced by most enteric bacteria, presumably by means of protection against desiccation. Mucous antigen is non-specific and serologically cross-reactive among different micro-organisms. In contrast, K antigen polysaccharides have structures specific to each serotype within a species and presumably help these bacteria to evade phagocytosis.[17] [18]

The presence of K antigen is determined by means of the bacterial agglutination test. It can block the agglutination by specific O antisera; however, these strains become agglutinable when the cells are heated. Two important examples of K antigens are the Vi antigen of *Salmonella typhi* and the K1 antigen of *E. coli,* which is associated with neonatal meningitis and urinary tract infection.[19] [20] Classification of K antigen is now based on electrophoretic mobility, reflecting differences in charge and molecular size.[17]

Flagella

Many members of the Enterobacteriaceae possess proteinaceous structures called flagella, which provide bacteria with mobility.[21]

There are some similarities between several flagellar proteins and proteins involved in either the expression of virulence genes or the export of virulent proteins, or both (e.g. in *Salmonella* spp.).[21] Flagella carry the heat-labile H antigen. The H antigen is dominant to the O antigen; therefore, O-antigen reactivity requires prior denaturation of the H antigen by heating or treatment with acid or alcohol.[17]

Fimbriae

The presence of fimbriae (pili) in bacteria is an important factor for attachment or adherence to the mucosal surfaces of the alimentary, respiratory or genitourinary tract and to red blood cells (causing hemagglutination). These adhesive properties of piliated bacteria play an important role in bacterial colonization of epithelial surfaces and are therefore referred to as colonization factors.[22]

PATHOGENICITY

Normal host defenses limit the majority of bacterial interactions. Therefore, infections caused by members of the Enterobacteriaceae are determined by several virulence factors in the pathogenic strains and the state of the host defenses. Most of the infections are preceded by: colonization of the mucosal site and adherence; evasion of host defenses; multiplication; and host damage.

Virulence factors

Adherence

In order to initiate infection, bacteria must enter the host and attach to host cells. Among Enterobacteriaceae, adhesion is mediated by both fimbrial and nonfimbrial adhesins that are encoded on plasmids and on the bacterial genome (Table 228.1).[23] [24] [25] [26] Most Enterobacteriaceae express the common fimbriae, which can attach to a number of cells; however, the role of this molecule in disease is still unknown.

Fimbriae have been characterized in two different ways, one antigenic and the other functional. Type 1 fimbriae, together with colonization factor antigens CFA/I and CFA/II, are present in enterotoxigenic *E. coli* (ETEC) and are responsible for adherence to the small bowel mucosa[29] ; bundle forming pili (Bfp) are responsible for adherence of enteropathogenic *E. coli* (EPEC) to the small intestine; GvvPG fimbriae mediate adherence of enteroaggregative *E. coli* (EAEC) to the small intestine. Intemin is an adhesin that causes the intimate association found among EPEC and enterohemorrhagic *E. coli* (EHEC). This is associated with the 'attachment and effacement' (E/A) phenomenon, which leads to destruction of the intestinal surface cells[27] [28] of the small as well as the large intestine. The role of nonfimbrial adhesions, other than in uropathogenic *E. coli* (UPEC), are less defined and their role in adherence is not yet clear. The P-fimbriae adhesion factors, known for their ability to bind to P blood group antigens on urinary tract cells, are associated with *E. coli* responsible for urinary tract infections, in particular pyelonephritis and urosepsis.[23] [27] The S-fimbriae, which recognize O-linked sialo-oligosaccharides of glycophorin A, are associated with sepsis and meningitis in neonates.[28]

Phase variation of all fimbrial antigens protects the bacteria from immune-mediated clearance.

The role of adhesins in the pathogenesis of infections caused by Enterobacteriaceae other than *E. coli* is not well characterized. Types 1, 3 and 6 fimbriae have been found in *Klebsiella* spp. but their function as a virulence factor remains largely unknown.[30]

Capsule

The surface of Gram-negative bacteria can play an important role in the protection of the bacterium in a hostile environment. A number of surface antigens appear to be acid polysaccharides; these include the Vi antigen, some of the K antigens of *E. coli* (Table 228.2) and the capsular polysaccharides of *Klebsiella* spp. The capsule provides bacteria with a mechanism for avoiding non-specific host defenses.[31] The K antigen polysaccharides enhance the virulence of invasive bacteria because they counteract the bactericidal action of complement by inhibiting the alternative pathway.

Because the alternative pathway accounts for much of the bactericidal activity of serum and for opsonization in the absence of specific antibodies, it has been suggested that strains with K antigen avoid host defenses more easily, particularly in the early course of infection before the antibody response is mounted. In addition, the capsule may act as a physical barrier to phagocytosis by preventing contact between the bacterium and the phagocytic cell, a result of the anionic and hydrophobic nature of its constituent polysaccharide.[31] [32] Moreover, some of the K antigens are poor immunogens and activators of complement. However, the presence of K antigen alone does not appear to account fully for the virulence of an organism.

Bacterial toxins

Exotoxins

A number of enterotoxins have been identified in Enterobacteriaceae (Table 228.3). Heat-labile enterotoxin (which resembles the cholera toxin) acts by way of activation of cyclic adenosine monophosphate (cAMP), leading to increased electrolyte and fluid secretion and inhibition of resorption. This results in increased fluid in the small intestine. This toxin is produced by enterotoxigenic *E. coli* and occasionally by *Klebsiella* and *Salmonella* spp.[33] [34]

Heat-stable enterotoxin acts via the activation of cGMP in the intestinal epithelium, leading to changes in ion transport, which also result in increased fluid and electrolytes in the intestinal lumen. This toxin is produced by enterotoxigenic *E. coli* and occasionally by *Yersinia enterocolitica* and *Citrobacter freundii*. [33] [35]

Shiga toxin produced by *Shigella flexneri* may elicit a diarrheal prodrome that often precedes bacillary dysentery; however, its role in human disease remains to be defined.[36] Shiga toxin from *Shigella dysenteriae* type 1, a potent cytotoxin, causes capillary dysfunction and focal hemorrhage. This toxin is associated with the hemolytic-uremic syndrome (HUS).[36] Closely related to the Shiga toxin from *S. dysenteriae* type 1 are toxins expressed by enterohemorrhagic *E. coli*. [36]

Hemolysins are present in many species and can cause cell destruction that is not limited to red cells but extends to white cells and other cell types. By killing host cells, hemolysins make iron more available by releasing hemoglobin-bound iron from lysed cells. To release this iron from the host-binding proteins (transferrin and lactoferrin) *E. coli* produces siderophores. a-Hemolysin is produced by pathogenic *E. coli* belonging to a restricted set of O serogroups that are associated with extraintestinal infection.[37]

Endotoxins

As discussed above, Gram-negative bacteria express various macromolecules at their surface. Of these, LPS are of particular microbiologic, immunologic and medical significance.[12] [13] Lipopolysaccharides have been implicated as major factors in the pathogenesis of serious Gram-negative infections (see Chapter 56).[38]

Lipopolysaccharides are released from the bacterial outer membrane during rapid bacterial growth and are released in large quantities on bacterial lysis and death. In animal studies and human volunteer studies,[39] intravenous administration of purified LPS can induce pathophysiologic changes similar to those associated with Gram-negative sepsis and septic shock, including hypotension, metabolic acidosis, coagulation disorders and the progressive failure of multiple organs. These pathophysiologic changes ultimately lead to death.

TABLE 228-1 -- Bacterial adhesins promoting colonization and infections by Enterobacteriaceae.

BACTERIAL ADHESINS PROMOTING COLONIZATION AND INFECTIONS BY ENTEROBACTERIACEAE		
Virulence factor	**Action**	**Organism, site affected and disease**
Bacterial adhesins	Adherence to mucosal surfaces	
P fimbriae		*Escherichia coli* (UPEC): urinary tract infections, pyelonephritis
Type 1 fimbriae		*E. coli*: respiratory tract infections, sepsis
		E. coli (ETEC): gastroenteritis
		Klebsiella pneumoniae: cystitis
Type 3 fimbriae		*Klebsiella* spp.: cystitis, urinary tract infections
Type 6 fimbriae		*Klebsiella* spp.: diseases uncertain
S fimbriae		*E. coli*: sepsis and meningitis in neonates
Bundle-forming pili (Bfp)		*E. coli* (EPEC): gastroenteritis, watery diarrhea
Colonization factor antigens (CFA/I, CFA/II)		*E. coli* (ETEC): gastroenteritis, watery diarrhea in infants and travelers
AAF/I and II fimbriae		*E. coli* (EAEC/some strains): persistent diarrhea in young children, traveler's diarrhea, no inflammation, no fever
Intimin		*E. coli* (EPEC): gastroenteritis, watery diarrhea
		(EHEC): bloody diarrhea
AFA-I; AFA-III; Dr adhesin		*E. coli* (UPEC)
Outer membrane protein		*E. coli* (EIEC)?
		E. coli (EPEC)?
		Proteus mirabilis: urinary tract infection?
		E. coli (EAEC)?
Afimbrial adhesions	Tight binding to host cells	*Klebsiella pneumoniae*: urinary tract infection, infection of cerebrospinal fluid
EAEC, enteroaggregative *Escherichia coli*; EHEC, enterohemorrhagic *E. coli*; EIEC, enteroinvasive *E. coli*; EPEC, enteropathogenic *E. coli*; ETEC, enterotoxigenic *E. coli*; UPEC, uropathogenic *E. coli*.

BACTERIAL CAPSULES AND INFECTION BY ENTEROBACTERIACEAE		
Virulence factor	**Action**	**Organism and disease**
Bacterial capsules	Inhibition of opsonization, prevention of phagocytic uptake	

K antigen		*Escherichia coli* K1: meningitis and sepsis in neonates *Escherichia coli*: invasive extraintestinal infections in adults

The effects of LPS are ascribed to several inflammatory mediators that result from the interaction of LPS with components of both cellular and humoral limbs of the host defense system. Monocytes and macrophages respond to LPS by secreting cytokines, such as tumor necrosis factor and interleukins, that heighten host defense but at the same time activate inflammatory processes that lead to organ failure. Neutrophils play a role in the defense against bacteria but may contribute to the damaging effect of exposure to LPS by enhanced production of oxygen radicals, secretion of proteases and increased cellular adhesiveness.[40] It has been established that the lipid-A part of LPS is responsible for the toxicity.

PREVENTION

Enterobacteriaceae are primarily spread in the hospital from person to person via the hands of hospital personnel.

Escherichia coli diarrheal disease is best controlled by preventing fecal hand-mouth transmission, by stressing the importance of improved hygiene and by introducing appropriate infection-control procedures.

Prevention of *E. coli* infections is difficult because most of the infections (with the exception of intestinal infections) are caused by endogenous bacteria (e.g. community-acquired urinary tract infection) or bacteria acquired during the hospital stay (nosocomial infections). Use of antibacterial chemoprophylaxis in neutropenic patients has reduced the morbidity and mortality attributable to Enterobacteriaceae, especially *E. coli*. [41] For the prevention of nosocomial infections certain risk factors (e.g. the unrestricted use of antibiotics, the unnecessary use of urinary catheters) should be avoided. Unfortunately, many of these factors tend to be found in patients at greatest risk for infections (e.g. immunocompromised patients and patients in intensive care units).

DIAGNOSTIC MICROBIOLOGY

Members of most genera form 'coliform-type' colonies on simple media (i.e. the colonies are circular with a diameter of 1–3mm and have a low convex, smooth-surfaced, colorless to gray and translucent appearance).

For recovery of the Enterobacteriaceae from the specimens containing mixed flora (e.g. fecal samples) several media are used: nonselective media (e.g. blood agar; Fig. 228.3), selective or differential media (e.g. MacConkey agar, *Salmonella-Shigella* agar; Fig 228.4 and Fig 228.5) and enrichment broth to enhance the growth of certain bacteria while inhibiting the growth of other, unwanted bacteria.

On MacConkey (lactose-containing) media (see Fig. 228.4) the colonies may be pink, indicating that the organisms ferment lactose

TABLE 228-3 -- Bacterial toxins and infections by Enterobacteriaceae

BACTERIAL TOXINS AND INFECTIONS BY ENTEROBACTERIACEAE		
Virulence factor	**Action**	**Organism and disease**
Exotoxins		
	Cell destruction	
Hemolysins a, ß	Cell lysis, often leading to cytokine release and inflammatory response	*Escherichia coli*: extraintestinal infection, urinary tract infections, pyelonephritis
Enterotoxins		
Heat-stable toxins (Sta; STb)	Hypersecretion of fluid and electrolytes	*E. coli* (ETEC): gastroenteritis (noninvasive, no inflammation, no fever)
Heat-stable toxins (LT-I; LT-II)		Watery diarrhea in infants and travelers
Verotoxin (VT1 and 2)	Intestinal mucosal destruction	*E. coli* (EHEC): hemorrhagic colitis, diarrhea; hemolytic—ureic syndrome
Enteroaggregative heat-stable toxin (EAST)?		*E. coli* (EAEC), diarrhea
Endotoxin		
Lipoplysaccharide	Complement activation, liberation of cytokines, leukocyte mobilization and degranulation, platelet and coagulation pathway activation	Enterobacteriaceae: fever, sepsis, shock with multiorgan failure

rapidly, or pale, indicating that the organisms either do not ferment lactose or that they cause 'late' fermentation after several days of incubation.[8] This procedure makes possible an immediate presumptive distinction between colonies (e.g. between true intestinal pathogens such as *Salmonella* or *Shigella* spp. and common intestinal commensals). These findings need to be confirmed by other tests.

Differences in biochemical activities provide the main means of differentiating the genus and species.[42] A number of identification methods are readily available from commercial sources (e.g. API-20E system — bioMérieux, 'sHertogenbosch, The Netherlands; Fig. 228.6). These methods give a range of simple biochemical tests, and the biochemical profile for a high percentage of bacterial species can be obtained within 24 hours of incubation at 98.6°F (37°C).[43] The biochemical profile is translated into a numeric code, which can be read from a profile index. Computer-based identification services for unusual organisms are available. The rapid API-20E system allows the identification of Enterobacteriaceae by detection of preformed enzymes in suspension of the test organisms. The rapid system gives a result in 4 hours. Fully automated identification systems, such as Vitek2 (bioMérieux) and Phoenix (BD Diagnostic Systems Europe, France) are also available.

With *E. coli* infections the problem is generally to characterize the pathogenic types from the commensal types. For the isolation of *E. coli* from sterile body sites where its presence indicates infection, such as blood or urine, the standard technique can be used. With the emergence of EHEC as an important pathogen, special media were developed to identify those from feces and food. Most commonly used is sorbitol MacConkey agar, on which some but not all EHEC will appear as nonfermenting colonies, while most other *E. coli* ferment sorbitol.

The diagnosis of diarrheagenic *E. coli* strains depend on identification of virulence characteristics of those strains. This may include in-vitro phenotypic assays that correlate with the presence of specific virulence traits, such as adherence, toxins or the detection of genes encoding those traits. Molecular diagnostic methods are developed to diagnose diarrheagenic *E. coli* strains. These methods allow the differentiation of diarrheagenic strains from nonpathogenic strains of the stool flora and also to make it possible to distinguish one category from another. Nucleic-acid-based probes as well as polymerase chain reaction (PCR) techniques can be applied to isolated bacteria but also directly to fecal samples.[25] [44]

Molecular methods can be used for clinical purposes to detect and identify pathogenic Enterobacteriaceae in order to be able to treat patients and also to perform epidemiologic studies.

CLINICAL MANIFESTATIONS

Escherichia coli is a normal inhabitant of the human gastrointestinal tract that can cause infections under certain conditions. The development and the severity of the infection depends strongly on both the virulence of the bacteria and the state of the host's defense mechanisms. Different strains are associated with different diseases. The versatility of *E. coli* is due to the fact that different strains have acquired different sets of virulence genes. Most of the infections caused by *E. coli*, with the

exception of intestinal infections, are endogenous.

Urinary tract infection (see Chapter 67)

Escherichia coli is a leading cause of urinary tract infection (UTI) in humans.[45] Infecting strains originate from the gastrointestinal tract and several virulence factors have been found to be involved in the pathogenesis of UTI. The most important of these virulence factors are the O-K serotypes, hemolysins and the presence of adhesins for uroepithelial cells.[46] [47]

Urinary tract infections generally start with the colonization of the urethra by *E. coli* strains from the colon or vagina. The bacteria have the ability to adhere to uroepithelial cells. A number of adhesins of uropathogenic *E. coli* strains have been identified.

Type 1 fimbriae may mediate adherence to the bladder cells, and they contribute to virulence in the urinary tract when expressed against the background of a fully virulent uropathogen.[48] These strains do not appear to be specific for uropathogenic strains. The most important type of adhesin, particularly in strains that cause pyelonephritis, are P-fimbriae.[49] They bind specifically to the P blood group antigen, which is present not only on red cells but also on the uroepithelial cells of approximately 99% of people. Uropathogenic strains also have adhesins that are not pili. Some examples are the afimbrial adhesins (AFA I, AFA III) and hemagglutinin that bind to Dr blood group antigen.

Figure 228-5 *Salmonella-Shigella* agar plate showing growth of *Salmonella typhimurium* (pale colonies with black pigmentation indicating hydrogen sulfide production).

Figure 228-6 API-20E strip after 24 hours incubation at 95°F (35°C).

Some uropathogenic *E. coli* strains also produce an extracellular toxin, hemolysin.[37] Hemolysin acts generally as a membrane-damaging toxin, leading to the lysis of the cell with subsequent release of cytoplasmic components.

Another important virulence factor is the ability of *E. coli* to acquire iron for growth, and uropathogenic *E. coli* strains have multiple iron-sequestration systems, including a siderophore-based system. Many uropathogenic *E. coli* are encapsulated. [20]

Neonatal meningitis

Some strains of *E. coli* with a capsular antigen (K1) are uniquely associated with neonatal meningitis.[50] The severity of the disease is directly related to the presence, amount and persistence of K1 antigen.[51] The presence of K1 antigen interferes with phagocytosis and, in combination with certain O antigens, shows increased resistance to the bactericidal effect of serum complement.

Escherichia coli K1 antigen is composed of sialic acid residues and shows cross-reactivity with the group B meningococcal polysaccharide capsule. Although colonization of infants with *E. coli* at the time of delivery is common, disease is relatively infrequent.

Intestinal infections (see Chapter 43)

Certain *E. coli* strains are associated with intestinal infections in infants and adults. Most of these strains are the cause of 'traveler's diarrhea'. A characteristic feature of diarrheagenic *E. coli* is their ability to colonize the host's intestinal surface despite host defenses such as gastric acid, peristalsis and competition from other microbial gut flora. This is partly attributed to surface fimbriae for mucosal adherence. Diarrheagenic *E. coli* possess specific fimbrial antigens that increase their ability to colonize the intestine and adhere to the small bowel mucosa — a site that is not normally colonized[25] [52] — once colonization is established. The virulence factors are distinct for each of the groups of diarrheagenic *E. coli.* The versatility of the *E. coli* genome is conferred mainly by two genetic configurations: virulence-related plasmids and chromosomal pathogenicity islands.

There are six main categories of diarrheagenic *E. coli.*[33] Although these categories are quite distinct, they have certain underlying similarities with respect to pathogenesis:

- their virulence properties are encoded on the plasmids;
- they have a characteristic interaction with the intestinal mucosa; and
- they produce enterotoxins or cytotoxins.

Within each category the strains tend to fall within certain O:H serotypes.

Before the availability of DNA techniques, knowledge of the epidemiology of enterodiarrheagenic *E. coli* was based on immunoassays and bioassays for identification of virulence factors such as toxins. These assays were cumbersome and time-consuming. Recent advances in DNA techniques have provided a new approach to

screening a range of virulent genes of *E. coli.*[40] Six major categories of *E. coli* that cause diarrhea have been identified:[33]

- enterotoxigenic *E. coli* (ETEC);
- enteroinvasive *E. coli* (EIEC);
- enterohemorrhagic *E. coli* (EHEC);
- enteropathogenic *E. coli* (EPEC);
- enteroaggregative *E. coli* (EAEC, also known as EaggEC); and
- diffusely adherent *E. coli* (DAEC).

Enterotoxigenic Escherichia coli

Enterotoxigenic *E. coli* causes 'travelers' diarrhea' (in developing countries) by colonizing the small intestine and producing one or more enterotoxin, giving rise to a net secretory state.[29] [53] The heat-labile enterotoxin (LT) is structurally similar to *Vibrio cholera* toxin and, by activation of adenylate cyclase, leads to hypersecretion of fluids and electrolytes into the small intestines. The heat-stable enterotoxin (ST) activates guanylate cyclase and stimulates fluid secretion.

Besides the enterotoxins, three other factors have been used to identify and characterize ETEC: O serogroup, H serogroup and CFAs.[29] The mechanism by which ETEC adheres to small bowel enterocytes is mediated by surface fimbriae (pili). The ETEC fimbriae confer the species specificity of the pathogen; human ETEC possess an array of colonization fimbriae, the CFAs (CFA/I rod-shaped fimbriae; CFA/III; a Bfp CFA/II and CFA/IV). The CFA genes are usually encoded on plasmids, which typically also encode the enterotoxins ST and/or LT.[54]

Infection by ETEC, after an incubation period of 1–2 days, is characterized by diarrhea, nausea and vomiting but usually no fever; the symptoms are usually mild and self-limiting, with a duration of 3–4 days.

Enteroinvasive Escherichia coli

Enteroinvasive *E. coli* causes a dysenteric form of diarrheal illness.[55] Strains of EIEC closely resemble *Shigella* spp. Like *Shigella* spp., they are capable of invading and proliferating within epithelial cells of the large intestine, eventually causing death of the cell. The invasive capacity is dependent on the presence of plasmid coding for the production of several outer membrane proteins involved in invasiveness.[56] Among the genes responsible for invasion are the *mxi* and *spa* loci, which encode a so-called type III secretion apparatus.[56] [57] In addition, both EIEC and *Shigella* spp. elaborate one or more secretory enterotoxins, which may play a role in diarrheal pathogenesis. They do not form enterotoxins, like ETEC. Clinically, the illness is marked by watery diarrhea, often with mucus and leukocytes, a scant bloody stool, severe abdominal cramps and fever. The symptoms are usually self-limiting.

Enterohemorrhagic Escherichia coli

Enterohemorrhagic *E. coli*, also called verocytotoxin-producing *E. coli*, is associated with two syndromes: hemorrhagic colitis, with abdominal pain and bloody diarrhea; and hemolytic-uremic syndrome (HUS), characterized by hemolytic anemia, thrombocytopenia and acute renal failure.[58] [59] *Escherichia coli* O157:H7 has been associated most frequently with hemorrhagic colitis and HUS; however, several other serotypes have also been associated with disease.

Both plasmid-encoded adherence factors for distinct fimbriae and cytotoxin production are important factors in the pathogenesis of disease.[60] Enterohemorrhagic *E. coli* as well as EPEC have the ability to induce a characteristic 'attacking and effacing' (A/E) histopathology on gut enterocytes characterized by localized destruction of brush border microvilli, intimate bacterial adhesion and gross cytoskeletal reorganization.[26] [61] A/E lesion formation is essential for full EPEC and EHEC pathogenicity.

The genes encoding for the A/E histopathology are contained on a 35.6kb pathogenicity island called the locus of enterocute effacement (LEE). The EHEC LEE contains genes encoding intimin type III secretion pathway and some other protein O. Enterohemorrhagic *E. coli* and EPEC strains use the LEE type III secretion system — secretion of virulence factors, some of which are injected (translocated) directly from the pathogen's cytoplasm into the host cell cytosol — to secrete several LEE-encoded proteins. All contacts stimulate the expression of LEE-encoded proteins and the assembling of a protein translocation apparatus (translocon) that provides a continuous channel from the bacterial cytoplasm to the host cell cytosol. The translocon is used to translocate receptor into the host cell, where it becomes inserted into the host membrane; excreted effector proteins are now probably able to make cytoskeletal changes and as a result form A/E lesions.

There are 'typical' EHEC strains, such as O157:H7, that produce stripe-like (Stx) toxins and A/E lesions and possess the 60MDa plasmid; and 'atypical' EHEC strains that do not produce A/E lesions and/or do not possess the 60MDa EHEC plasmid.[25] The development of HUS involves direct cytotoxic action of Stx on renal endothelial cells, but cytokines are probably also indirectly involved in this process.[62]

The symptoms are usually self-limited. They vary in severity from mild symptoms of nonbloody diarrhea to severe hemorrhagic colitis, sometimes ending in death (especially in children and the elderly).

The use of antibiotics for the treatment of severe infection is controversial and a recent study[63] showed that patients treated with antibiotics are at greater risk of developing HUS. The harmful potential is explained by lysis of bacteria and an increase in release of toxins. Recent outbreaks of EHEC disease have raised public concern about the safety of the food supply.[64]

Enteropathogenic Escherichia coli

Enteropathogenic *E. coli* plays a role in infant diarrhea and can also be associated with chronic diarrhea in young children.[65] Plasmid-encoded adhesiveness is the most important factor in the pathogenesis of the disease.[66] Strains of EPEC are responsible for different clinical signs of the infection, depending on the diffuse and localized adherence to cells. The clinical signs range from mild nonbloody diarrhea to more severe diarrhea.

The hallmark of infections due to EPEC is the A/E histopathology similar to that of EHEC (see above), characterized by effacement of microvilli and intimate adherence between the bacteria and the epithelium cell membrane.[26] [61]

In the first step of infection, localized adherence to epithelial cells mediated by Bfp occurs. Bfp is encoded on plasmids called EAF plasmids. In the second step adherence induces a variety of signal induction pathways. Genes responsible for this signal transduction are encoded on a 35kb pathogenicity island (LEE). Intimate adherence of EPEC to epithelial cells is mediated by a 94–97kDa outer membrane protein called intimin. At least four proteins are secreted extracellularly by EPEC and three of them are essential for A/E histopathology.

As with other diarrheal pathogens, the treatment of EPEC diarrhea is to prevent dehydration by correcting fluid and electrolyte imbalances. Antibiotic treatment had been used in many patients, with good results, but multiple antibiotic resistance is common for EPEC.[67]

Enteroaggregative Escherichia coli

Enteroaggregative *E. coli* are an increasingly important cause of diarrhea.[68] They cause nonbloody, watery diarrhea that is often persistent and can be inflammatory. Enteroaggregative *E. coli* have been implicated in sporadic diarrhea in children and adults in both

developing and developed countries, and recently have been reported to cause 'traveler's diarrhea'.

Enteroaggregative *E. coli* are characterized by their ability to adhere to epithelial cells in a characteristic 'stacked-brick' pattern but are otherwise highly heterogeneous. The adherence consist of two phenotypes — diffuse and aggregative. The exact mechanism of pathogenesis is not completely known but adhesins, toxins and several other factors contribute to disease.

Adhesins (plasmid-encoded) are aggregative adherence fimbria I (AAF/I), which is shown to mediate aggregative adherence to epithelial cells and Hep-2 hemagglutination, and to be involved in formation of biofilm. The other type of fimbria, AAF/II, is more associated with diarrhea in children. Other virulence factors include invasion and plasmid-encoded toxin production, but these factors were shown to be present only in some strains. The general problem with *E. coli* infections is

to distinguish the pathogenic from the commensal types.

Diffusely adherent Escherichia coli

Diffusely adherent *E. coli* are now recognized by most authors as an independent category of potentially diarrheagenic *E. coli*. In a number of studies DAEC was associated with endemic pediatric diarrhea lasting longer than 2 weeks. The diffuse adherence to Hep-2 cells is mediated by a unique fimbrial structure known as the F1845 fimbria, which can be found on either bacterial chromosome or a plasmid.

BACTEREMIA AND NOSOCOMIAL INFECTIONS

As a group, Enterobacteriaceae are the most frequent bacterial isolates recovered from both inpatient and outpatient clinical specimens. In 1990–2 Enterobacteriaceae accounted for 30% of pathogens isolated from all infection sites in the Centers for Disease Control and Prevention (CDC) and National Nosocomial Infection Surveillance system.[69]

In the past few years, with the increased use of invasive devices and broad-spectrum antibiotics, Enterobacteriaceae, specifically *E. coli*, have become somewhat less prevalent than Gram-positive cocci as a cause of nosocomial infection. Nevertheless, *E. coli* is still an important cause of hospital-acquired infections despite adequate antibiotic therapy and supportive care.

The increasing antibiotic resistance among *E. coli* resulting in nosocomial infections is a major cause of concern in hospitals. There are several factors that predispose hospitalized patients to such infections: the use of antibiotics that eradicate normal flora, impaired skin and mucous membranes, intubation, intravenous and bladder catheters and surgical procedures. These infections, including UTIs, wound infections, pneumonia, intra-abdominal abscesses and peritonitis, are often followed by bacteremia. However, bacteremia without primary focus is sometimes detected in immunocompromised patients.

Bacteremia

Escherichia coli is the most common cause of nosocomial bacteremia. In 1979 it had an incidence of 2.7 per 10,000 hospital charges.[70] The most common portal of entry of infection for both community-acquired and nosocomial *E. coli* bacteremia is the urinary tract.[71] The overall mortality rate from *E. coli* bacteremia is approximately 20%. Bacteremia that does not originate in the urinary tract tends to have a worse outcome.

Bacteremia is frequently due to pulmonary infections in intubated patients receiving ventilation therapy or to UTIs caused by indwelling urinary catheters. Patients with granulocytopenia due to leukemia, cancer or chemotherapy are at high risk of bacteremia.

Septic shock

Septic shock occurs in approximately 40% of patients with Gram-negative bacteremia. The high frequency of septic shock in bacteriemia caused by Enterobacteriaceae is attributed to the toxic effect on the circulatory system of endotoxin (LPS).[38] [40] Endotoxin within the circulatory system has multiple and complex effects on neutrophils, platelets, complement, clotting factors and the inflammatory mediators in the blood. These complex effects may result in multiple organ failure and eventually in death. Mortality rates from Gram-negative shock range from 40% to 70%.

Urinary tract infections

Urinary tract infections are the most common hospital-acquired infections and *E. coli* is a leading pathogen, implicated in about 25% of all nosocomial UTIs.[69] Recognized major risk factors for hospital-acquired UTIs include urinary catheterization and obstruction to urine flow.

Other sites of hospital-acquired infection

The lungs are a common site of hospital-acquired infection, although it is often difficult to discriminate between *E. coli* colonizing the upper airways and *E. coli* causing pulmonary infection.

Approximately a quarter of surgical infections are caused by Enterobacteriaceae, among which *E. coli* accounts for about 8%.

Nosocomial central nervous system infections occur mainly in neurosurgical patients, neonates and patients undergoing procedures that penetrate the central nervous system. Of postsurgical meningitis, 69% is caused by Gram-negative bacilli, with a majority (70%) of these due to *E. coli.*

MANAGEMENT

Antibiotic therapy for infections with *E. coli* and other Enterobacteriaceae must be guided by an in-vitro susceptibility test and by clinical experience. Although most strains of *E. coli* are still susceptible to the commonly used antibiotics, resistance, especially in hospital-acquired infections, is increasing.

The treatment of infective diarrhea is oral fluid and electrolyte replacement. Antibiotics are generally not recommended and only in chronic or life-threatening infections should antibiotic treatment be considered.[72] The duration and breadth of antimicrobial treatment in other infections caused by *E. coli* or other Enterobacteriaceae depend on the site and severity of the infection. For example, uncomplicated cystitis in otherwise healthy women can be often managed with a single dose of antibiotic, whereas sepsis requires about 10 days' therapy, and prostatitis or deep-seated renal infection requires as much as 6 weeks' treatment.

Conventional approaches to control nosocomial infections caused by Enterobacteriaceae are not always successful. Therefore, antibiotic prophylaxis has been studied to prevent colonization and nosocomial pneumonia in the critically ill, and selective decontamination of the gastrointestinal tract has been investigated as a method of preventing infections by Enterobacteriaceae in ventilated patients in intensive care units.[73] A recent meta-analysis of 22 randomized trials demonstrated that selective decontamination reduced the incidence of respiratory tract infection by 63%.[74] However, in most studies, even when pneumonia rates were reduced, selective decontamination had no effect on the mortality rate or hospital stay. The development of antibiotic resistance is the most feared complication of selective decontamination.[75]

MEDICALLY IMPORTANT GENERA OF ENTEROBACTERIACEAE

Escherichia

Escherichia coli makes up the largest proportion of aerobic Gram-negative bacteria of the intestinal tract. It is a non-spore-forming rod

and is often motile by means of peritrichous flagella. It can grow aerobically as well as anaerobically.

Most strains ferment lactose rapidly, and the colonies on MacConkey medium are smooth, glossy and translucent in appearance and rose pink in color. On blood agar the colonies of some strains are surrounded by zones of hemolysis. Most strains of *E. coli* attack carbohydrates fermentatively, with the production of acid and gas; a few strains will produce acid but not gas. Although most strains of *E. coli* ferment lactose rapidly, there are some strains with a slow fermentation pattern or that are non-lactose-fermenting. Furthermore, *E. coli* is characterized by the ability to reduce nitrates to nitrites. Most of the strains produce indole, give a positive methyl-red reaction and the Voges-Proskauer test is negative. *Escherichia coli* strains do not hydrolyze urea or produce hydrogen sulfide, and phenylalanine deaminase activity is absent. *Escherichia coli* cannot use citrate as the sole source of carbon and will not grow in the presence of potassium cyanide.[2] [42]

Although conventional approaches to identification (e.g. sugar fermentation) are still valid and useful, there are several other methods available now. For example, there are commercially available tests that use rapid chromogenic enzyme substrates, such as the API system or automated methods.[43] Together with growth on selective or differential media, colonial characteristics and cell morphology on a Gram stain, identification can be completed.

Escherichia coli can be subdivided into serogroups, serotypes and biotypes.[1] Two *E. coli* surface compounds form the basis for the serologic classification system: heat-stable somatic O antigen of LPS, and heat-labile flagella H antigen (H stands for *hauch*, the German word for 'breath', because of the mist-like effect around the bacterium caused by the presence of flagella; O denotes *ohne*, 'without', i.e. lacking flagella). The O antigen identifies the serogroup of a strain and the H antigen identifies its serotype. The biotype is determined by the biochemical profile.

To date, 173 different serogroups have been identified, and there are at least 56 identified serotypes.[17] There is some correlation between serogroup and virulence. For example, O86 is commonly found on members of the residual colonic microflora, and members of this serogroup rarely cause disease; on the other hand, group O55 is rarely found in the residual microflora and is almost always associated with disease. If the bacteria is enveloped by a capsule, a capsular (K) antigen is also used for classification. Only a few of the 80 distinct K antigens isolated from natural populations are associated with invasive *E. coli* disease.[18] Strains classified as K1, for example, are a common cause of systemic disease in infants.[17]

Escherichia fergusonii, *Escherichia hermannii* and *Escherichia vulneris* (Table 228.4) are occasionally isolated from patients, but their clinical significance is not well defined. *Escherichia blattae* has been recovered from cockroaches but its role in human infections has not been established. [76]

Shigella

The genus *Shigella* is closely related to the genus *Escherichia*, as shown by genetic analysis. The genetic relationship is so close that it has been advocated that both genera form a single genetic species. However, the distinction between the two genera remains useful from a clinical point of view. The *Shigella* organisms differ from a typical *Escherichia coli* strain in that they are nonmotile, do not ferment lactose and do not produce gas from glucose. One member of the genus *Escherichia*, *E. coli* inactive (formally called 'Alcalescens-Dispar'), has many characteristics similar to those of *Shigella* organisms and they be considered to be a species in between Escherichiae and Shigellae.

Four species of medical importance are traditionally described within the genus *Shigella*: *S. dysenteriae*, *S. flexneri*, *Shigella boydii* and *Shigella sonnei* (see Table 228.4). Members of the species are hard to differentiate from each other by biochemical testing. Using serologic methods, *S. dysenteriae* makes up group A, *S. flexneri* group B and *S. boydii* group C. Each group can be further subdivided into different serotypes, and this is useful for epidemiologic purposes. Serologic cross-reactions with *E. coli* strains and other members of the family of Enterobacteriaceae do occur. *Shigella sonnei* (group D) can be separated from the other *Shigella* spp. by a positive ornithine reaction; this species may show lactose fermentation after incubation for more than 48 hours.

Dysentery caused by *Shigella* spp. occurs worldwide. The annual number of *Shigella* episodes is estimated to be 163.2 million in developing countries and 1.5 million in industrialized countries.[77] In industrialized countries, person-to-person transmission, perhaps via hands, is the most common form of transmission, and *S. sonnei* is now the most frequently isolated species of the Shigellae in these countries.[77] In developing countries, the predominant species is *S. flexneri* and the mode of transmission is often by contaminated water, food or perhaps flies. The low inoculum (less than 200 viable bacteria) needed for disease is often assumed to be one of the factors responsible for the high secondary attack rate during outbreaks. Long-term excretion is uncommon but does occur. Long-term excreters are probably important as a reservoir; in these people, carriage of the *Shigella* strains is often in the colon.

Salmonella

The classification of *Salmonella* organisms has been controversial over the years.[42] Biochemical and genetic studies show so much similarity between *Salmonella* and Arizona group that all strains may belong to a single species. For epidemiologic purposes, serotyping of O antigens (type A, B, C and so on) and of H (flagellate) antigens has resulted in more than 2000 distinct serotypes, which are often named as if they were species (e.g. '*Salmonella typhimurium*' rather than '*Salmonella* serotype *typhimurium*' or even '*Salmonella choleraesuis* subsp. *choleraesuis* serotype *typhimurium*').

The genus *Salmonella* can be subdivided into different groups.[2] More than 99% of clinical isolates belong to subgroup 1 (*S. choleraesuis* subsp. *choleraesuis*; Table 228.5). Other subgroups include *S. choleraesuis* subsp. *salamae* (subgroup 2), *S. choleraesuis* subsp. *arizonae* (subgroup 3a), *S. choleraesuis* subsp. *diarizonae* (subgroup 3a), *S. choleraesuis* subsp. *houtenae* (subgroup 4) and *S. bongori* (subgroup 5). Subgroup 6 has been proposed to contain the subspecies *indica*. The name *Salmonella enterica* has been used by bacteriologists and has caused confusion in the nomenclature of *Salmonella*. [78]

A presumptive identification of '*S. typhi*' can often be made biochemically because these strains are mostly citrate-negative, produce hydrogen sulfide slowly, are ornithine-decarboxylase-negative, do not produce gas from glucose and do not ferment arabinose and rhamnose, in contrast to most other strains of *Salmonella*.

Salmonella gastroenteritis and enteric fever occur worldwide. The reservoir for the serotypes *typhi* and *paratyphi* A, B and C are human, but the other Salmonellae are widely distributed among animals. Some strains are associated with particular animals (e.g. subspecies *arizonae* with reptiles), but exchange of strains between animals is frequent. Transmission is mostly by contaminated water and food, and perhaps by insects such as flies, although direct person-to-person transmission has been described.

Citrobacter

The name *Citrobacter* is derived from the ability of these strains to use citrate as a source of carbon. *Citrobacter* organisms are widely found in environmental samples. Eleven species in this genus have now been listed (Table 228.6). [7] *Citrobacter freundii* is frequently

isolated from nosocomial infections, including hospital-acquired pneumonia, bacteremia, UTIs and wound infections. Nosocomial transmission may be related to antimicrobial resistance; many strains of *C. freundii* produce an inducible broad-spectrum ß-lactamase.[79] In addition, *C. freundii* has been associated with gastroenteritis.[2] [5] New species, formally within the *C. freundii* complex, include *Citrobacter braakii*, *Citrobacter rodentium*,[80] *Citrobacter sedlakii*, *Citrobacter werkmanii*, *Citrobacter youngae*, *Citrobacter gillenii* (genomospecies 10) and *Citrobacter murliniae* (genomospecies 11). [81] Identification of newly described *Citrobacter* spp. by commercial systems has been studied.[82]

Citrobacter koseri (formerly designated *C. diversus*) may be a causative agent of sepsis, meningitis and brain abscesses, especially in young children.[83] Transmission from mother to newborn has been described.[84] Many strains of *C. koseri* produce an inducible class A ß-lactamase, as does *Proteus vulgaris*,[79] although other strains may produce a class C ß-lactamase like *C. freundii*. *Citrobacter amalonaticus* is rarely involved in human disease. It has recently been proposed that melibiose-positive variants of *C. amalonaticus* (biotype 1) should be named *Citrobacter farmeri*.[2]

Klebsiella

The current classification of the genus *Klebsiella* recognizes five species with several subspecies (Table 228.7). All the species are nonmotile. *Klebsiella* strains can be found in the feces of healthy adults.[85] *Klebsiella pneumoniae* is well known as the cause of Friedländer's pneumonia and nosocomial infections. Strains of this species often grow as mucoid lactose-positive colonies on MacConkey agar. The subspecies *rhinoscleromatis* is Voges-Proskauer-negative and does not ferment lactose or several other sugars. It is the causative agent of rhinoscleroma, a granulomatous

diseases of the nose and associated tissues.[86] *Klebsiella ozaenae* is another biochemically less active subspecies, which is associated with ozena, an atrophic condition of the nasal mucosa. *Klebsiella planticola*, *Klebsiella terrigena* and *Klebsiella ornithinolytica* are uncommon isolates in the clinical setting,[87] and the genus name *Raoultella* has been proposed for these species.[88] Indole-positive strains of *Klebsiella* are classified as *Klebsiella oxytoca*; these strains may cause infections similar to those caused by *K. pneumoniae*. Most strains of *K. pneumoniae* and *K. oxytoca* produce a chromosomal class A ß-lactamase that renders them resistant to ampicillin but susceptible to ß-lactamase inhibition by clavulanic acid and analogues. Since 1982, extended-spectrum ß-lactamases have been described that are mutations of the TEM or SHV type of ß-lactamase; these have increased hydrolytic activity against third-generation cephalosporins or are less inhibited by clavulanate.[79] Genetic information for these enzymes is carried on plasmids, often in combination with other resistance factors such as aminoglycoside-modifying enzymes, and this type of resistance may spread relatively rapidly in settings of increased antibiotic use.

Enterobacter

The species in the genus *Enterobacter* are listed in Table 228.8 . *Enterobacter cloacae* is a common clinical isolate. It is a frequent cause of opportunistic infections and is often acquired in hospital. Antibiotic resistance is frequent, especially against third-generation cephalosporins, by means of an inducible chromosomal ß-lactamase.[89]

Another frequently isolated species in this setting is *Enterobacter aerogenes*. Because this motile strain resembles the genus *Klebsiella* more than other *Enterobacter* organisms, it has been proposed that this species be renamed *Klebsiella mobilis*. [42] A yellow pigment is produced by *Enterobacter sakazakii*, a species that has been described as causing neonatal infections. [90] Another yellow-pigmented species, *Enterobacter agglomerans*, has recently been renamed *Pantoea agglomerans* (see below). *Enterobacter hormaechei*, *Enterobacter cancerogenus* ('*Enterobacter taylorae*'), *Enterobacter intermedium*, *Enterobacter asburiae* and *Enterobacter gergoviae* are among the less common *Enterobacter* spp. that have been isolated from blood cultures and various other specimens from patients with infections.[91] [92] [93] *Enterobacter amnigenus* has also been isolated from human tissue but it is unclear whether it causes disease. [2]

Enterobacter kobei is a recently proposed species[94] that closely resembles *E. cloacae*. Many *Enterobacter* spp. are resistant to second-generation and third-generation cephalosporins by virtue of

TABLE 228-7 -- The genus *Klebsiella*.[7]

an inducible broad-spectrum cephalosporinase encoded by genetic information on the chromosome. These strains may seem susceptible at first isolation, but subsequent isolates may show resistance to these agents.[79] [89]

Serratia

The genus *Serratia* consists of nine species (Table 228.9). [7] *Serratia marcescens* is the one most commonly associated with nosocomial infections, in part because it is often resistant to commonly used ß-lactam antibiotics and in part because it is not fastidious in its growth conditions. This species and other *Serratia* spp. have been

implicated in ocular infections associated with soft contact lenses. [95] Red pigment is formed under suitable conditions by some strains of *S. marcescens*, as well as by *Serratia plymuthica* and *Serratia rubidaea*, two other opportunistic pathogens.[96] [97] Two other species, *Serratia liquefaciens* and *Serratia odorifera*, are less frequently associated with clinical infections.[98]

Serratia grimesii, *Serratia proteamaculans* subsp. *proteamaculans* and *Serratia proteamaculans* subsp. *quinovora* are closely related to *S. liquefaciens*.[5] *Serratia ficaria* and *Serratia fonticola* are rarely involved in human disease.[99]

Proteus

The genus *Proteus* once contained many species but currently only three are listed: *Proteus mirabilis*, *Proteus penneri* and *Proteus vulgaris* (Table 228.10). Characteristics of *Proteus* spp. include their tendency to display swarming motility during growth on nonselective media and their strong urease reaction.[100] This urease activity has been associated with the formation of kidney stones, as UTIs are commonly caused by *Proteus* spp. *Proteus mirabilis* is indole-negative and often susceptible to most common antibiotics, with the exception of nitrofurantoin, whereas indole-positive *P. vulgaris* is more resistant to ß-lactam antibiotics. *Proteus penneri* is closely related to *P. vulgaris* but is indole-negative and can be distinguished from *P. mirabilis* by its negative ornithine reaction. The name *Proteus hauseri* has been proposed for *P. vulgaris* biogroup 3.[101]

Morganella

Morganella morganii is currently the only species in the genus (see Table 228.10). Two subspecies (*morganii* and *sibonii*) can be distinguished by the ability to ferment trehalose.[102] Urinary tract infections and other opportunistic infections are associated with this species. *Morganella morganii* was originally part of the genus *Proteus*.

Providencia

Members of the genus *Providencia* are a diverse group of organisms (see Table 228.10). The two species *Providencia rettgeri* and *Providencia stuartii* may be urease positive (*P. rettgeri* more often

TABLE 228-8 -- The genus *Enterobacter*.[7]

than *P. stuartii*), and both are a frequent cause of UTIs and other opportunistic infections.[103] *Providencia alcalifaciens* has been implicated in gastrointestinal infections in children.[104] *Providencia rustigianii* has rarely been isolated from humans.[2]

Yersinia

The genus *Yersinia* includes three species that can cause a variety of infections in the host (Table 228.11).[105] *Yersinia pestis* is the causative agent of plague.[106] [107] The plague bacillus grows slowly on conventional media. Like infections with other *Yersinia* spp., plague is a zoonosis. The natural reservoir are small animals, and transmission occurs through bites of fleas from these animals, by handling contaminated parts of the animals and by human-to-human transmission from patients with pneumonic plague. Plague has been implicated as a potential biologic weapon, and recommedations for measures to be taken by medical and public health professionals have been developed. [108] *Yersinia pseudotuberculosis* closely resembles *Y. pestis*, and it has even been suggested that the two are a single species. *Yersinia pseudotuberculosis* is associated with mesenterial lymphadenitis, which simulates appendicitis, mainly in children and adolescents. Sepsis with *Y. pseudotuberculosis* has mainly been described in patients with liver disease and other chronic illnesses. *Yersinia enterocolitica* can cause mesenterial lymphadenitis, gastroenteritis, infections in many other tissues and sepsis. Notorious sources of infections include blood transfusion products,[109] in which *Y. enterocolitica* can proliferate at storage temperatures of 39°F (4°C). Serotypes 3 and 9 are most common in Europe, whereas serotype 8 is more frequently encountered in the USA.[76] Complications of *Y. enterocolitica* infection include polyarthritis, erythema nodosum and Reiter's syndrome.

Yersinia frederiksenii, *Yersinia intermedia* and *Yersinia kristensenii* have recently been separated from *Y. enterocolitica*. As with *Yersinia bercovieri*, *Yersinia mollaretii* and *Yersinia rohdei*, their association with human disease is less clear.[110] For a fuller description of the microbiology of *Yersinia* spp. see Chapter 231 .

Edwardsiella

In nature, *Edwardsiella* spp. are found in many cold-blooded animals. *Edwardsiella tarda* has been the cause of liver abscesses, bacteremia and infections in various other tissues.[111] In addition, it has been associated with gastrointestinal infections. It produces large amounts of hydrogen sulfide in culture. The association of *Edwardsiella ictaluri* and *Edwardsiella hoshinae* with human disease is less clear.

Hafnia

Hafnia alvei is presently the only species within the genus *Hafnia*. Fewer carbohydrates are fermented than in *Enterobacter* spp.

TABLE 228-9 -- The genus *Serratia*.[7]

THE GENUS *SERRATIA*	
Name	**Synonym**
Serratia ficaria	
Serratia fonticola	
Serratia grimesii	*Serratia liquefaciens*
Serratia liquefaciens	*Enterobacter liquefaciens*
Serratia marcescens	
Serratia odorifera	
Serratia plymuthica	
Serratia proteamaculans subsp. *proteamaculans*	*Serratia liquefaciens*

Serratia proteamaculans subsp. *quinovora*	*Serratia liquefaciens*
Serratia rubidaea	

TABLE 228-10 -- The genera *Morganella*, *Proteus* and *Providentia*[7]

THE GENERA *MORGANELLA, PROTEUS* AND *PROVIDENTIA*	
Name	**Synonym**
Morganella morganii subsp. *morganii*	*Proteus morganii*
Morganella morganii subsp. *sibonii*	*Proteus morganii*
Proteus mirabilis	
Proteus penneri	*Proteus vulgaris* indole negative
Proteus vulgaris	
Providencia alcalifaciens	*Proteus inconstans*
Providencia rettgeri	*Proteus rettgeri*
Providencia rustigianii	*Providencia alcalifaciens* biogroup 3
Providencia stuartii	*Proteus inconstans*

TABLE 228-11 -- The genus *Yersinia*.[7]

THE GENUS *YERSINIA*	
Name	**Synonym**
Yersinia aldovae	
Yersinia bercovieri	*Yersinia enterocolitica* biogroup 3b
Yersinia enterocolitica	*Pasteurella enterocolitica*
Yersinia frederiksenii	
Yersinia intermedia	
Yersinia kristensenii	
Yersinia mollaretii	*Yersinia enterocolitica* biogroup 3a
Yersinia pestis	*Pasteurella pestis*
Yersinia pseudotuberculosis	*Pasteurella pseudotuberculosis*
Yersinia rohdei	

The organism has been isolated from environmental samples, infected wounds and other tissues, and has been implicated in gastroenteritis.[112] [113] [114] [115]

Pantoea

Pantoea agglomerans was until recently a member of the genus *Enterobacter*. Strains produce a yellow pigment. This species became notorious because of an outbreak of nosocomial bacteremia associated with contaminated intravenous fluids.[116]

TABLE 228-12 -- Miscellaneous enterobacterial genera.[71]

MISCELLANEOUS ENTEROBACTERIAL GENERA	
Name	**Synonym**
Budvicia aquatica	
Buttiauxella agrestis	
Buttiauxella noackiae	CDC enteric group 59
Cedecea davisae	CDC enteric group 15
Cedecea lapagei	
Cedecea neteri	*Cedecea* sp. 4
Cedecea sp. 3	
Cedecea sp. 5	
Edwardsiella hoshinae	
Edwardsiella ictaluri	
Edwardsiella tarda	
Ewingella americana	CDC enteric group 40
Hafnia alvei	*Enterobacter hafniae*
Kluyvera ascorbata	CDC enteric group 8
Kluyvera cryocrescens	
Kluyvera georgiana	CDC enteric group 36/37
	Kluyvera sp. group 3
Leclercia adecarboxylata	*Escherichia adecarboxylata*
	CDC enteric group 41
Leminorella grimontii	CDC enteric group 57
Leminorella richardii	
Moellerlla wisconsensis	CDC enteric group 46
Pantoea agglomerans	*Enterobacter agglomerans*
Photorhabdus luminescens	*Xenorhabdus luminescens*
Rahnella aquatilis	
Tatumella ptyseos	CDC group EF-9
Yokenella regensburgei	*Koserella trabulsii*

	CDC enteric group 45

TABLE 228-13 -- The newer Enterobacteriaceae genera and their distinguishing reactions.[*]

THE NEWER ENTEROBACTERIACEAE GENERA AND THEIR DISTINGUISHING REACTIONS		
Newer genus	**Related genus**	**Selected differentiating reactions**
Buttiauxella	*Escherichia*	Citrate
Cedecea	*Serratia*	DNAase, gelatin, lipase
Ewingella	*Pantoea*	Xylose, arabinose
Kluyvera	*Escherichia*	Citrate
Leclercia	*Escherichia*	Adonitol, lysine, malonate
Leminorella	*Proteus*	Urease, phenylalanine, arabinose
Moellerella	*Providentia*	Lactose, phenylalanine
Rahnella	*Pantoea*	Phenylalanine
Tatumella	*Pantoea*	Mannitol, phenylalanine
Trabumella	*Salmonella*	Ortho-nitrophenyl-ß-galactosidase, dulcitol
Yokenella	*Hafnia*	Voges-Proskauer

** Adapted from Koneman et al.* [5]

Miscellaneous other Enterobacteriaceae

Newer members of the family Enterobacteriaceae have been described in recent years and many have been associated with human diseases.[116] [117] [118] [119] [120] [121] [122] Table 228.12 and Table 228.13 list the newer genera, together with other genera that are closely related and selected reactions to distinguish these strains. In addition to the genera mentioned in these figures, other new genera include *Budvicia*, which are mainly isolated from water sources, *Erwinia*, which are mostly plant pathogens,[123] and *Photorhabdis*. Chapter 229 - Pseudomonads and Miscellaneous Gram-negative Bacilli

Eugénie Bergogne-Bérézin

INTRODUCTION

Strictly aerobic Gram-negative bacilli have become increasingly important as human pathogens over the past 20 years.[1] [2] Dominated by *Pseudomonas aeruginosa*, which is well known for its significant pathogenicity for the human host, this large group of saprophytic organisms has undergone confusing taxonomic changes for many years. New definitions of species and genera using modern genotyping analysis, together with reliable identification methods, have resulted in a better knowledge of these bacteria and a significantly increased awareness of their pathogenic role in hospitals and in rare cases of community-acquired infection. In descending order of importance the following are commonly isolated in nosocomial infections:

- *P. aeruginosa*;[1]
- *Acinetobacter baumannii*;[3]
- *Stenotrophomonas maltophilia*;[4] and
- *Burkholderia cepacia*.[5]

Species of *Flavobacterium*, *Comamonas* and *Alcaligenes* groups have only recently (late 1980s) been recognized as potential pathogens. A few other groups less frequently colonize or infect patients (as compared with *P. aeruginosa* and the other groups cited above) in intensive care units (ICUs).[6]

EPIDEMIOLOGY

Because of their ability to grow in environments providing limited nutrients, pseudomonads and other aerobic Gram-negative bacilli are saprophytic organisms and are found in water, soil and various other origins, plants, vegetables, insects and sewage. They may survive in hostile conditions, dry, cold or warm environments, and in a variety of foods such as dairy products, poultry and frozen foods. As nonfastidious organisms, most aerobic Gram-negative bacilli can use a wide variety of substrates as sole carbon and energy sources.[1] [2] [3] Their presence as saprophytes in the human environment, industrial environment (agricultural, food, cosmetic industries) and medical environment (pharmaceutical preparations, antiseptics, warm ICU humidifiers and ventilators) is unavoidable and they have been particularly successful at adapting themselves to new environments created by human activities.

PATHOGENIC ROLE

Aerobic Gram-negative bacilli can be carried as transient commensals in the human body. Although considered as low-virulence organisms, *Pseudomonas* spp. behave as opportunistic pathogens, being responsible for severe infections in hospitals, and are recognized as important human pathogens worldwide.[7]

ANTIBIOTIC THERAPY

Aerobic Gram-negative bacilli are frequently multiresistant to major antibiotics and this contributes to their prominent role in the morbidity and mortality of patients hospitalized in ICUs, oncology units, burn centers and surgery wards.[7] [8] [9] Various mechanisms of resistance have been recognized. Combination antibiotic therapy is often recommended for treatment, on the basis of careful antibiotic susceptibility testing. This chapter deals with *P. aeruginosa* and other potentially pathogenic aerobic Gram-negative bacilli. (Species that are animal or plant pathogens are not included in this review.)

PSEUDOMONAS AERUGINOSA

NATURE

Taxonomic classifications of *Pseudomonas* spp. have evolved considerably over the years. As the traditional phenotypic classifications based on morphologic, biochemical and antigenic characteristics have been replaced by the genotypic classification systems, these groups of bacteria are now much easier to understand. However, divisions and subdivisions based on genetic homologies, DNA hybridizations and rRNA sequence comparisons have undergone designation changes; new genera have been identified such as *Burkholderia* spp. (previously included in *Pseudomonas* spp.).[5] One of the most significant examples of taxonomic changes is the recent conversion of the species initially designated *Pseudomonas maltophilia* in 1961[8] and then *Xanthomonas maltophilia* in 1983[10] to *Stenotrophomonas maltophilia* (Table 229.1).

EPIDEMIOLOGY

The large majority of *Pseudomonas* spp.[7] [11] are ubiquitous organisms and are widely distributed in nature. Their increasing involvement in infections in humans results from multiple factors but mainly the development of antibiotic usage and the resulting selective pressure in favor of inherently or potentially resistant Gram-negative species from the environment.[12] [13] Hospitals, ICUs, immunodepressed patients, invasive procedures and antibiotic usage have provided opportunities for emergence, persistence and transfer of *P. aeruginosa* between patients or from patients to staff and to inanimate reservoirs.

Pseudomonas aeruginosa is also a saprophyte in the normal individual and is by far the predominant aerobic Gram-negative bacillus causing illness in patients who have risk factors and immunosuppressed defense mechanisms. Recent studies using molecular typing methods have shown a variety of environmental sources in hospitals and nursing homes: *P. aeruginosa* isolates from sinks, wash basins and toilets were similar (*exotoxin A* typing) to those isolated from the hands of staff and the urinary tracts of paraplegic patients, and transmission over a 6-month period in an ICU for newborns has been related to a source implicating air valves in the ventilator tubes. It is well recognized that *P. aeruginosa* can be present on surgical and medical material, in antiseptic (quaternary ammonium compounds) or contact lens cleaning solutions, and in ventilatory equipment in ICUs.[7] [11] In humans, few intestinal carriers are found in the general population (about 4%) but they are much more

TABLE 229-1 -- Current nomenclature of non-Enterobacteriaceae, nonfermentative Gram-negative bacilli.

CURRENT NOMENCLATURE OF NON-ENTEROBACTERIACEAE, NONFERMENTATIVE GRAM-NEGATIVE BACILLI

The list is limited to those potentially involved in infections.[1] [6] [7]		

common among hospital patients (i.e. up to 18% on average for all hospital populations). Intestinal carriage of *P. aeruginosa* is significantly increased after gastrointestinal surgery, and can reach 73% of patients.[14] Many other carriage sites have been described in hospital patients, including the respiratory tract, genitourinary tract and skin, which can also be the source of dissemination of *Pseudomonas* strains as well as the origin of endogenous contamination (Table 229.2).

TABLE 229-2 -- Carriage in human flora.

CARRIAGE IN HUMAN FLORA				
Organisms	**Respiratory tract**	**Gastrointestinal tract**	**Genitourinary tract**	**Skin, ear, eye, miscellaneous**
Pseudomonas aeruginosa	2+	1+	0	0
Other *Pseudomonas* spp.	0	1+	0	0
Acinetobacter spp.	2+	1+	1+	2+
Burkholderia cepacia	1+	0	0	1+
Alcaligenes faecalis	0	1+	0	1+
Weeksela virosa	0	0	1+	0
Incidence of carriage of aerobic Gram-negative bacilli in human flora (quantitative presence).[2] [15] 2+, frequently isolated; 1+, rarely isolated; 0, not typically isolated.				

PATHOGENICITY

Pseudomonas aeruginosa is responsible for a variety of infections in patients who have many risk factors such as:

- surgery;
- immunosuppression; and
- prolonged hospital stay, mainly in an ICU.

TABLE 229-3 -- Predominant sites and incidences of nosocomial infections.

PREDOMINANT SITES AND INCIDENCES OF NOSOCOMIAL INFECTIONS			
		Hospital wide (%)	**Intensive care unit (%)**
Pseudomonas aeruginosa	Sepsis	18.2*	-
	Nosocomial pneumonia	16.9†	20.8–36.4
	Urinary tract infection	12.0–18.8	11.3
	Surgical wound	8.2	9.5
	CF respiratory infection	70–90% of CF cases	
	Burns — SSTI	15.4	
Stenotrophomonas maltophilia [16] (total 3.7% of 2569 *S. maltophilia* strains)	Sepsis, endocarditis	1.4	
	Surgical wound	15.8	
	Secondary meningitis	-	
	Nosocomial pneumonia	66.4	
	Urinary infection	8.7	
	CF	About 7% of CF lung infections	

Burkholderia cepacia [17] (of 786 strains)	Blood culture	1.8	
	Respiratory infection	78.8	6–20% of CF cases
	Miscellaneous fluids and pus	7.8	
	Urine	3.7	
	Environment	7.6	
Acinetobacter baumannii [18] (of total *Acinetobacter* spp.)	Nosocomial pneumonia		25–29
	Urinary infections		21–30
	Bacteremia, endocarditis		6–9
	Burn infections, wounds		2–12
	CF respiratory infections		Rare
Chryseobacterium meningosepticum [19] (rarely pathogenic)	Neonatal meningitis, sepsis	Predominant sites in neonates	
	Surgical wound, nosocomial pneumonia	Occasional	

Predominant sites of nosocomial infections due to aerobic Gram-negative bacilli and incidences (% of total organisms).[2] [3] [6] [7] CF, cystic fibrosis; SSTI, skin and soft tissue infection.

* % of all Gram-negative bacteremia.[7]

† % of all bacterial species including Gram-positives.[19]

Pseudomonas aeruginosa possesses many virulence factors and various resistance mechanisms, which confer upon it a predominant role as a nosocomial pathogen. Recent surveys have shown that *P. aeruginosa* is responsible for between 10% and more than 20% of all nosocomial infections[7] and that the predominant site of infection is the respiratory tract, although there are many other infection sites (Table 229.3).[13] [14]

PATHOGENESIS

Pseudomonas aeruginosa is pathogenic as a result of toxigenic and invasive properties. It produces many virulence factors that have been characterized and some of them have already been cloned (Table 229.4).[20] The pathogenic factors may act at or away from the site of infection.

At the site of infection

The adhesion factors (pili in nonmucoid strains and/or alginate in mucoid strains) and exoenzyme S play a significant role in the pathogenesis of most respiratory infections; they are particularly involved in pulmonary invasion in cystic fibrosis (CF). Nearly all strains produce pili under favorable conditions; they are uni- or bipolar in distribution and are composed of pili protein (molecular weight 18kDa).[20]

Local enzymatic activities at the site of infection are those of proteases, neuraminidase and phospholipases. They disrupt epithelial cell membranes, phospholipids and protecting cell surface proteins, resulting in tissue damage. Proteases appear to contribute to necrotic skin lesions (ecthyma gangrenosum). Elastolytic activities disrupt the elastin of blood vessels, resulting in hemorrhages. All enzymes contribute to the invasiveness of *P. aeruginosa*. [11] [20] [21]

TABLE 229-4 -- *Pseudomonas aeruginosa* virulence-associated factors.[20] [21] [22]

***PSEUDOMONAS AERUGINOSA* VIRULENCE-ASSOCIATED FACTORS**		
Nature		**Human effects**
Constitutive	Lipopolysaccharide	Cascade of inflammatory events
	Endotoxin	Septic shock
	Mucopolysaccharide capsule in mucoid	Bacterial adhesion to epithelial cells
	Pseudomonas aeruginosa (alginate: polymer of ß-1, 4-D-mannuronic and L-glucuronic acid)	Barrier to antibiotics
		Increased viscosity of bronchial secretions (cystic fibrosis)
	Pili (fimbriae)	Act as adhesins
	Cytoplasmic lectins	PAI specific for D-galactose
	PAI, PAII	PAII specific for D-mannose
Exoproducts	Proteases (alkaline and neutral metalloproteinase)	Damage tissues (active on elastin, collagen, fibrin)
		Digestion of protecting proteins serving as host defenses
	Neuraminidase	Enhances pilin-mediated adherence
	Phenazine pigment (pyocyanin)	Ciliary disruption
	Elastolytic activity (two enzymes Las A, Las B)	Breakdown elastin of blood vessels, hemorrhages
	2 Hemolysins: phospholipase C glycolipid-rhamnolipid (heat-stable)	Disruption of phospholipids of cell membranes, hydrolysis of lung surfactant and ciliostatic action
	Siderophores (pyochelin and pyoverdin)	Help growth in iron-limited condition
		Generation of toxic oxygen-free radicals
	Exotoxin A	Causes tissue damage
		Similar to diphtheria toxin
		Inhibits phagocytes
		Inhibits protein synthesis
	Exoenzyme S (functions as adhesin)	Binding specificity for glycolipids (glycososphingolipid)
	Cytotoxin: leucocidin	Cytopathic effects on leukocytes and alteration of phospholipids of cell membrane
	Antibiotic-inactivating enzymes	ß-Lactamases
		Aminoglycoside-inactivating enzymes

Away from the site of infection

The invasive properties are those of:

- lipopolysaccharide (LPS), an endotoxin responsible for septic shock;
- cytotoxins, which have cytopathic effects on leukocytes; and
- exotoxin A, produced by approximately 90% of strains, which exhibits cytotoxicity by inhibiting protein synthesis, causing intense tissue damage and inhibiting phagocytic activities.

Exotoxin A acts by a similar mechanism to that of diphtheria toxin, but has a different receptor (a 300kDa glycoprotein) on host cells. It is encoded by a single copy of a structural gene, *tox*A, regulated by two genes, *reg*A and *reg*B. It is remarkable that, whereas most Gram-negative bacilli are pathogenic via an endotoxin, *P. aeruginosa* also produces an exotoxin, which enhances the virulence of this pathogen.

Risk factors in patients

A wide variety of *P. aeruginosa* infections of varying severity have been observed. Predominant sites of infections and patient risk factors are directly related to:

- immune status;
- underlying pathologies; and
- hospitalization in an ICU.

Specific factors that determine the site and the severity of *Pseudomonas* infection include:

- extended burns;[23]
- CF in children;[24]
- prosthetic heart valves; and
- intubation or tracheostomy.[13] [25]

PREVENTION

Prevention plays a major role in controlling *Pseudomonas* infections. Preventive measures are based on the identification of sources and modes of transmission of the pathogens (Table 229.5). Numerous guidelines have been established in the USA and in European countries. Isolation policies, administrative and regulatory measures and hospital epidemiology surveillance are increasingly applied to control outbreaks involving *P. aeruginosa*. Among the main guidelines, the aims of three approaches can be summarized as follows:

- elimination of endogenous nosocomial *P. aeruginosa* and reduction of oropharyngeal, intestinal and skin colonization in ICU patients;
- prevention of cross-contamination and control of various sources of *P. aeruginosa* that can be transmitted from patient to patient or from personnel to patient (i.e. proper disinfection and care of catheters, respiratory equipment, humidifiers, endotracheal tubes, dialysis systems, etc.); and
- prevention of contamination in burns patients, surgical wounds and the oropharyngeal area in ventilated patients (i.e. antibiotic prophylaxis in postoperative high-risk patients; for burns patients either systemic antibiotics or local antibiotics or disinfection could be recommended; and aerosolized polymyxin B and/or endotracheal aminoglycosides to prevent *Pseudomonas* pneumonia, which has the highest fatality rate).[13] [24] [25]

In addition, selective digestive decontamination[34] has been advocated in ICU patients; this should prevent colonization of the oropharynx and the gut by potentially pathogenic bacteria, as the digestive tract can be an important reservoir for multiresistant *P. aeruginosa*, and so prevent nosocomial infection. Topical chemoprophylaxis includes nonabsorbable antibiotics, generally polymyxin E, tobramycin (or norfloxacin) and amphotericin B (the latter to control fungal colonization). Most investigations have included coadministration of systemic ceftazidime but a clear consensus about the effectiveness of selective digestive decontamination has not been established, possibly because of the heterogeneous groups of patients and varying oral regimens involved and the inconsistent addition of systemic cefotaxime or ceftazidime (see Chapter 84).

DIAGNOSTIC MICROBIOLOGY

Bacteriology of *Pseudomonas aeruginosa*

Microscopy

Pseudomonas aeruginosa is a thin, motile Gram-negative bacillus that moves relatively fast considering that it has only a single polar flagellum.[1] [11] [15]

It grows easily on simple agar medium and produces characteristic pigments. Its phenotypic characteristics, such as motility, pigment production and positive oxidase reactions, mean that it can be

TABLE 229-5 -- Sources, methods of contamination and risk factors for nosocomial infections due to aerobic Gram-negative bacilli.

SOURCES, METHODS OF CONTAMINATION AND RISK FACTORS FOR NOSOCOMIAL INFECTIONS DUE TO AEROBIC GRAM-NEGATIVE BACILLI			
Organisms and reference	**Settings**	**Mechanism (source)**	**Risk factor/comments**
Pseudomonas aeruginosa[15] [23]	SICU/MICU, HU, BU	Contaminated equipment, solutions, antiseptics; endogenous	Cross-contamination; exposure to broad-spectrum antibiotics; severely ill patients; burns outbreaks
Pseudomonas putida, *Pseudomonas fluorescens*[1] [15] [23]	SICU	Contaminated blood and blood byproducts, antiseptics	Few in wound infections; rare cases of opportunistic infections
Stenotrophomonas maltophilia [2] [15] [16] [27]	Surgery, SICU	Contaminated devices, disinfectants, catheters	Dialysis fluids; exploratory procedures; neutropenia; respiratory devices (CF); tracheostomized patients; backflow from nonsterile tubes
Burkholderia cepacia[2] [15] [17]	ICU	Airborne transmission; contaminated skin preparations, ventilator, thermometer, antiseptic solutions	CF patients; hand carriage; calibration bath (contaminated with 10^5 cfu/ml); immunodepressed patients
Chryseobacterium meningosepticum (*Flavobacterium* spp.)[19] [28] [29]	NICU	Contaminated water, ice, disinfectants, humidifiers	Bacteremia; neonatal meningitis; infected wounds
Alcaligenes xylosoxidans[30] [31] [32]	ICU, HDU	Contaminated chlorhexidine solution, dialysis fluid, aerosols, respirators	Aqueous source; hemodialysis; peritonitis; bacteremia; meningitis; severe underlying disease
Acinetobacter spp.[3] [33]	MICU/SICU	Contaminated ventilators, moist devices, burns; endogenous	Severely ill patients; cross-contamination; outbreaks
BU, burns unit; HDU, hemodialysis unit; HU, hematology unit; MICU, medical intensive care unit; NICU, neonatal intensive care unit; SICU, surgical intensive care unit.			

Figure 229-1 Key to identification of nonfermentative aerobic Gram-negative bacilli. Note that *Burkholderia mallei* has no flagella and is nonmotile; *Pseudomonas aeruginosa* is monotrichous; oxidase-negative organisms use carbohydrates (activity of a-glucosidase, ß-glucosidase, ß-galactosidase, ß-xylosidase); *Alcaligenes* spp. have degenerated peritrichous flagella, which are functional; *Chryseobacterium* spp. produce variably pigmented colonies due to yellowish-orange pigment; and *Stenotrophomonas* spp. (except nonpigmented mutants) produce yellow pigment.

rapidly identified. Details of diagnostic microbiology techniques are shown in Figure 229.1 , Table 229.6 and Table 229.7 .

Electron microscopy

Figure 229.2 clearly shows the very long, thin polar flagellum and the irregular surface of the bacillus.

Culture

Colonies of *Pseudomonas aeruginosa* on agar culture at 98.6°F (37°C) are smooth and flat (Fig. 229.3). The pigments (pyocyanin and fluorescein) give the characteristic blue-green pigmentation due to production of pyocyanin, which is enhanced by culture on King's A medium.

Epidemiologic markers

Reliable epidemiologic tools are needed to trace the geographic spread of strains (Table 229.8).

Conventional phenotypic methods

These are based on biochemical profiles, antibiotic susceptibility patterns, bacteriophage and bacteriocin susceptibilities; more recently developed are outer membrane protein profiles and multilocus

TABLE 229-6 -- Phenotypic identification of aerobic Gram-negative bacilli based on microscopy, pigments and oxidase.

PHENOTYPIC IDENTIFICATION OF AEROBIC GRAM-NEGATIVE BACILLI BASED ON MICROSCOPY, PIGMENTS AND OXIDASE		
Tests	**Characteristics**	
Microscopy	**Gram-negative bacilli**	
Morphology	Thin bacilli: *Pseudomonas aeruginosa*	Coccobacilli (diplobacilli): *Acinetobacter* spp.
Motility	Motile: *P. aeruginosa* (fast motion): *Pseudomonas* spp.	Nonmotile: *Acinetobacter* spp., *Flavobacterium* spp. (*Chryseobacterium*)
Flagella*	Monotrichous, polar unique: *P. aeruginosa; Pseudomonas stutzeri; Pseudomonas pseudoalcaligenes*	None (gliding motility)
	Lophotrichous polar: *Stenotrophomonas maltophilia; Burkholderia cepacia; Pseudomonas fluorescens: Burkholderia pseudomallei*	
	Peritrichous, nonpolar, degenerated: *Alcaligenes faecalis*	
Pigments (on nutrient agar)	*P. aeruginosa/Pseudomonas* spp.	*Flavobacterium* spp. (*Chryseobacterium*) (inconstantly produced)
	Pyocyanin: bluish-green	
	Phenazinic pigment: yellowish-orange (*Pseudomonas aureofaciens*)	Light-yellow, yellowish-orange or bright yellowish-orange; nondiffusible pigment
	Pyoverdin: greenish-yellow (*P. aeruginosa*, *P. fluorescens*, *Pseudomonas putida*)	
	Carotenoïd pigment (*P. stutzeri*)	
	Light-straw yellow pigment (*S. maltophilia*)	
	Yellow-purple (violacein) or brownish in 10% *B. cepacia*	
Oxidase†	Positive:	Negative:
	Pseudomonas spp.	*S. maltophilia* (or weakly and tardily positive)
	Alcaligenes spp.	*Acinetobacter* spp.
	Flavobacterium spp.	
	B. cepacia (rare strains negative)	

* Staining of flagella: Leifson's staining (tannic acid, basic fuchsin) or Rhode's silver-plating staining method.
† Oxidase reaction: on Mueller-Hinton agar, 1% solution of N-dimethyl paraphenylene-diamine (ready-to-use discs or solution prepared in the laboratory).

TABLE 229-8 -- Epidemiologic markers for *Pseudomonas aeruginosa* typing.

EPIDEMIOLOGIC MARKERS FOR *PSEUDOMONAS AERUGINOSA* TYPING				
Epidemiologic markers		**Principles and characteristics**	**Advantages**	**Drawbacks**
Phenotypic	Biotyping	Utilization of substrates, production of enzymes, biotyping schemes for identification	Rapid, easy to perform, API 20NE panel or automated (Vitek GNI), inexpensive	Unstable, variability of metabolic characters, poorly discriminating
	Resistance phenotype	Antimicrobial susceptibility pattern always carried out, multiple resistance markers	Rapid, easy to perform, standardized (National/International guidelines), early and useful during outbreak	Unstable profiles, plasmid acquisition or loss during an outbreak, derepression of inducible enzymes, mutations, poorly discriminating, unreliable
	Serotyping	Based on somatic O specific antigen (LPS), polyclonal/monoclonal antibodies, 20 serotypes, 17 antisera (IATS)	Rapid, early results, easy to perform, available reagents, inexpensive, most commonly used	50–70% of CF strains nontypable, polyagglutination of some CF strains, reproducibility of anti-LPS monoclonal antibodies is 75%
	Phage typing	Colindale set of 21 phages, cell surface receptors (OM, LPS, slime)	Limited requirements, inexpensive, available reagents	Lack of reproducibility, low discrimination, insensitivity of CF and LPS-defective strains
	Pyocin typing	R, F, S pyocins, specific lytic activity, 105 types, 26 subtypes	Limited requirements, inexpensive	Poor discrimination, complexity of the system, time-consuming technique
Genotypic	Plasmidotyping	Relatively rare plasmid in *Pseudomonas aeruginosa*, plasmids of 1.2–60MDa in 15% of strains	No advantage for *P. aeruginosa* typing	Low frequency, acquisition or loss during epidemics
	Genomic DNA, total DNA	Polymorphism of DNA, REA endonucleases (*Eco*R1, *Hin*dII, *Sma*I), conventional agarose electrophoresis	Good discriminatory power	Large number of fragments making resolution of bands difficult to interpret
	DNA RFLP	Detection of genes coding for exotoxin A (*exo*A). elastase (*las*B). alginate (*alg*D). two probes necessary	Good discriminatory power, good correlation with ribotyping	Laborious techniques, small numbers of isolates can be compared
	Ribotyping (ribosomal DNA)	Three genes coding for rRNA, probes for 16S and 23S RNA, restriction enzymes (*Eco*R1, *Cla*I, *Sal*I)	Universal, excellent reproducibility, stable ribotype patterns within outbreaks	Laborious techniques, sensitivity and specificity not established for *P. aeruginosa*
	Pulsotyping (PFGE)	DNA fingerprinting, restriction enzymes *Dra*I, *Spe*I (fragments >50kb requiring PFGE)	The most specific discriminant technique	Interpretation somewhat delicate, heavy workload
O serotypes internationally recognized; types O18 to O20 not validated yet.[22] [35] [36] IATS, International Antigenic Typing System; OM, outer membrane; PFGE, pulse-field gel electrophoresis; REA, restriction endonuclease analysis; RFLP, restriction fragment length polymorphism.				

perform, are cheap and little equipment is needed; they are useful in emergency situations and are a great help in laboratories with limited facilities.[15] [22]

Serotyping

Pseudomonas aeruginosa is serologically heterogeneous because it possesses many somatic and flagellar antigens. Based upon the

specificity of somatic antigen O (polysaccharide side chains of the LPS), an O antigenic scheme has been internationally recognized with agreement for 17 O serotypes in the International Antigenic Typing Scheme.

Limitations to serotyping include poor discriminating power, polyagglutination for some strains, failure of serotyping in LPS-defective strains and autoagglutination in CF strains. However, serotyping of *P. aeruginosa* remains useful and epidemiologically significant. For example, it has been shown that the most frequent serotypes involved in nosocomial infections are O6, O11, O1 and O3 and that serotype O12 is characterized by its exceptional multi-resistance pattern.[22]

Bacteriophage typing

A large number of bacteriophages active against *P. aeruginosa* attach to specific cell surface receptors: outer membrane proteins, LPS and slime polysaccharide. The

Colindale set of 21 phages is the most popular and constitutes the reference system, with more than 80% of isolates sensitive to these phages. Many *P. aeruginosa* strains are lysogenic and about 10 lysogenic phages may interfere with typing procedures.[22]

Phage typing lacks reproducibility and mucoid and LPS-defective strains are insensitive to phage typing.

Bacteriocin typing

Pyocin particles, identified as R, F and S pyocins (retractile, flexuous and soluble respectively), have been used for typing, on the basis of specific lytic activity, and permit identification of 105 types plus 26 subtype patterns. [37]

Although reproducible (90% of clinical strains typable), pyocinotyping is not a widely used method because of the complexity of the system and inadequate discrimination and reproducibility requiring strict standardization of inoculum and media (reagents are not commercially available).

Multilocus enzyme electrophoresis

This is based upon the electrophoretic motilities of a large number of cellular enzymes. One strain is characterized by a combination of alloenzymes (motility variants) designated 'zymotype'. When applied to *P. aeruginosa* this method has proved complex and time-consuming and is carried out only in specialized laboratories.[35]

Genotypic markers

The many drawbacks and limitations of phenotypic markers have led investigators to develop more reliable typing procedures based upon genomic DNA, and many new epidemiologic tools have become available in clinical laboratories.

Plasmid profile

This is a rapid and simple method for species carrying many plasmids but is relatively useless for *P. aeruginosa* because only 15–20% of the strains carry plasmids; the majority of clinical isolates lack demonstrable plasmids.[36]

DNA fingerprints

DNA fingerprints, which are restriction endonuclease digestions of genomic DNA, can use total chromosomal DNA, resulting in thousands of fragments ranging in size from 2kb to 25kb. The banding patterns for a series of isolates, visualized by ethidium bromide staining in gel, are compared either visually or by scanning densitometry and digitization. Because of the large number of fragments generated, it can be difficult to resolve the bands. DNA restriction fragment length polymorphism may be used to detect specific genes; good discriminatory power, using DNA probes specific for genes coding for exotoxin A (*exo*A), alginate (*alg*D), elastase (*las*B) or pilin (*PAK*), has been observed for differentiating isolates from different patients, provided that at least two DNA probes are used (5% of *P. aeruginosa* strains are deficient in the *exo*A gene).[35] [36]

Ribotyping

This is based on interspecies differences in genomic RNA sequences. Restriction fragment length polymorphisms are detected by differences in the banding pattern (three to six bands for *P. aeruginosa*). Although recognized as a stable and reproducible typing system for *Escherichia coli* and *Haemophilus influenzae,* it seems likely that its sensitivity and specificity are not well established for *P. aeruginosa*.[35] Ribotyping requires combination with another typing method, which involves a great deal of work.

Pulsotyping

Pulsed-field gel electrophoresis uses restriction endonucleases, which cut the chromosome infrequently, producing large fragments (5–800kb) resolved into 10–50 bands by field inversion gel electrophoresis or a contour-clamped homogeneous electric field. Field inversion gel electrophoresis and contour-clamped homogeneous electric field analyses are considered to be the most discriminant tools for establishing the relatedness of strains; isolates that differ by more than three bands are considered to be different, but pulsotyping requires careful interpretation and the techniques for typing require equipment, time and expense.[36]

Other typing procedures

Molecular biology techniques are evolving very rapidly and many new applications are being developed for typing. Polymerase chain reaction has been applied to comparative typing of *P. aeruginosa* — random primed or enterobacterial repetitive intergenic consensus sequences have been used. Both approaches were reproducible and discriminatory.[38] In addition, they require less work and expense than the methods discussed above, and so are becoming methods of choice for fingerprinting strains in the laboratory.

CLINICAL MANIFESTATIONS

Pseudomonas respiratory infections

Pseudomonas *pneumonia*

This generally occurs after endogenous aspiration from a colonized oropharynx, often in patients who have an underlying malignancy; these people carry *P. aeruginosa* in the oral flora more frequently (18–25%) than subjects who do not have malignancies (=5%).

Pseudomonas pneumonia usually occurs in hospitalized patients and the clinical features do not distinguish it from other Gram-negative nosocomial pneumonias. The clinical presentation and radiographic findings (nodular infiltrates, sometimes with cavitation and lesions, predominantly in the lower lobes) are not specific; various degrees of hemorrhagic edematous lung with scattered micro-abscesses and vascular involvement (thrombosis) are often seen on anatomic pathology. The microscopic appearances are of necrosis of alveolar septa (Fig. 229.4) and arterial walls, with areas of focal hemorrhage and, in intact areas, infiltration with macrophages, mononuclear cells and polymorphonuclear leukocytes.[13] [39]

Bacteremic Pseudomonas *pneumonia*

A different lung pathology has been described in bacteremic *Pseudomonas* pneumonia, which occurs in even more severely ill patients who have the risk factors listed in Table 229.9 . The pneumonia is diffuse and bilateral and there is a pleural effusion. On cut section, the lesions are either nodular, hemorrhagic with necrotic foci, or umbilicated nodules surrounded by dark hemorrhage. Intra-alveolar

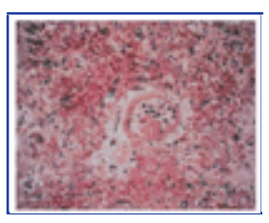

Figure 229-4 Anatomic pathology of *Pseudomonas aeruginosa* pneumonia showing acute inflammatory exudate, necrosis of alveolar membranes and fibrinous thrombosis in a venula. Hematoxylin-eosin stain. *Courtesy of Professor Groussard.*

hemorrhages with patchy alveolar septal necrosis are seen on microscopy. The lesions contain many bacteria but lack a leukocytic reaction. The pneumonia is

accompanied by bloodstream invasion that often spreads to metastatic sites of infection. The pneumonia rapidly progresses, resulting in pulmonary edema and necrotizing bronchopneumonia. The fatality rate is extremely high (up to 80–100% of cases).[20] [21] [39] [40]

Strategies for the treatment of *Pseudomonas* bacteremic pneumonia have emphasized the importance of early initiation of empiric appropriate therapy because the majority of fatal cases occur within the first 48–72 hours. Combination therapy is generally recommended (antipseudomonal ß-lactam and an aminoglycoside), but there is a poor correlation between clinical response and the in-vitro synergistic effects of antibiotics.[26] [41] [42]

Respiratory infections in cystic fibrosis patients

Pathogenesis

Cystic fibrosis is a congenital disease affecting exocrine gland secretions.[43] [44] A protein, the CF transmembrane conductance regulator, which is responsible for transporting chloride across membranes, is abnormal in CF patients and this decreases the electrochemical gradient for sodium ion movement into the CF duct cell. This results in abnormal sodium absorption in airway epithelium and mucous airway secretions contain decreased water and electrolyte concentrations, with twice the normal ratio of macromolecules (mucins) to electrolytes. These glycoprotein mucins form thick tenacious secretions, which obstruct the airways and contribute to the development of progressive suppurative pneumonia (see Chapter 33).

The leading cause of morbidity and mortality in patients who have CF is progressive pulmonary deterioration with chronic necrotizing bronchopneumonia. These pulmonary infections mainly involve *P. aeruginosa*. Cystic fibrosis also causes a wide range of other major organ deficiencies (diarrhea, malabsorption, pancreatic insufficiency) (see Chapter 40g).

Mucoid *Pseudomonas aeruginosa*

In the early 1960s the importance of mucoid variants of *P. aeruginosa* was recognized. Mucoid *P. aeruginosa* are morphologic and

TABLE 229-9 -- Infections due to *Pseudomonas aeruginosa* listed in descending order of incidence.[13] [20] [21] [26]

INFECTIONS DUE TO *PSEUDOMONAS AERUGINOSA* LISTED IN DESCENDING ORDER OF INCIDENCE		
Infection		**Associated factors**
Respiratory infections	*Pseudomonas* pneumonia (30–60% mortality rate)	Mechanical ventilation
		Endotracheal or tracheostomy tube
		Neurologic disease
		Nasogastric tube
		Prolonged stay in intensive care unit
		Broad-spectrum antibiotics
	Bacteremic *Pseudomonas* pneumonia (80–100% mortality rate)	Neutropenia
		Underlying malignant neoplasm
		Chronic bronchiectasis (terminal state)
		Diabetes mellitus
		Severe immunodepression
		Cytotoxic chemotherapy
		Coronary artery disease
		Severe burns
	Respiratory tract infections in people with cystic fibrosis (ultimately fatal unless a pulmonary transplant is carried out)	Presence of the lethal genetic disease cystic fibrosis
		Chronic colonization with *Pseudomonas aeruginosa*
		Progressive lung deterioration
		Altered immune response to *Pseudomonas* spp.
Bacteremia	Primary	Same factors as above
	Secondary	Leukemia, lymphoma
		Intravenous devices
		Intravenous drug abuse
		Trauma
		Prematurity
		Ulceration of the gastrointestinal tract
		Solid organ or bone marrow transplant
		Various endoscopic instrumentation procedures
Skin and soft tissue infections (50–78% mortality rate in burn wound sepsis)		Burn wound sepsis (78% *Pseudomonas* spp.)
		Wound infection
		Ecthyma gangrenosum
		Dermatitis, pyoderma
Urinary tract infections		Acute
		Chronic (obstruction)
Endocarditis		Intravenous drug abusers
		Prosthetic heart valves
Miscellaneous		Meningitis (secondary)
		Brain abscesses
		Bone and joint infections (chronic *Pseudomonas* osteomyelitis)
		Ear infections (otitis externa, malignant external otitis)
		Eye infections (*Pseudomonas* keratitis, endophthalmitis, contact lens keratitis)

functional variants of *P. aeruginosa* characterized by the ability to produce copious amounts of an exopolysaccharide, which is an acetylated polymer of D-mannuronic and L-glucuronic acids (alginate; see Table 229.4). Molecular weights of the polysaccharide vary from 100kDa to 480kDa. It should be distinguished from the 'slime' polysaccharide, which has different biologic properties and is found in nonmucoid *P. aeruginosa* as well as in mucoid *P. aeruginosa*. The controlling genes (*alg*) for the alginate biosynthetic pathway have

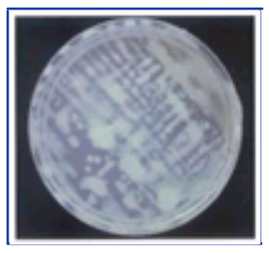

Figure 229-5 Mucoid colonies of a strain of *Pseudomonas aeruginosa* isolated from a patient who has cystic fibrosis. *Courtesy of Professor E Bingen.*

been partially cloned; multiple gene control of alginate production involves several enzymatically controlled steps.[43] It seems likely that most *P. aeruginosa* possess the genetic information for mucoid exopolysaccharide production. They are capable of producing mucoid exopolysaccharide when grown under appropriate environment conditions, such as those present in the CF lung. Figure 229.5 shows colonies of mucoid *P. aeruginosa*.

In vivo, in areas with impaired local defenses, such as in the airways of CF patients, the organism grows in microcolonies surrounded by the thick polysaccharide matrix. In autopsied lungs of people who had CF there are microcolonies adherent to the walls of larger airways and in the alveoli. Mucoid *P. aeruginosa* are present in abundance in foci of active inflammation in small bronchioles but not in destroyed parenchymal areas. This observation is consistent with the simultaneous role of bacterial growth in the active inflammatory process and of toxins produced by *P. aeruginosa* diffusing away from microcolonies. For instance:

- exotoxin A is one of the major factors responsible for tissue injury in the lungs of patients who have CF and they have high titers of antibodies to toxin A; and
- 86% of mucoid *P. aeruginosa* isolates produce proteases, elastase, collagenase and fibrinolysin.

In contrast it seems likely that mucoid *P. aeruginosa* LPS contributes little to the pathogenesis of lung injury but stimulates local inflammation.

Clinical features

The clinical signs, pulmonary functions and radiographic features seen in patients who have CF vary considerably according to the extent of the disease and the frequency of acute exacerbations. A chronic productive cough, wheezing, tachypnea and low-grade fever develop during acute exacerbations. As the pulmonary disease progresses, fever, chest pain and a cough producing abundant purulent viscous sputum are the predominant symptoms of infection. Lung damage results in pulmonary vascular obstruction and a deteriorating pulmonary function. Arterial hypoxemia is progressive and correlates with clinical pulmonary status. Chest radiographs show overaeration, peribronchial thickening, patchy atelectasia and pneumonia. These features are reversible during the early stages of the disease in the first year of infection.

Appropriate management of the disease and acute exacerbations with aggressive antibiotic therapy, chest physiotherapy and nutritional therapy may result in a symptomatic improvement and slow the inevitable progression of pulmonary deterioration.

Pseudomonas bacteremia

Of all nosocomial bacteremias, *P. aeruginosa* accounts for 20–35% of isolates.[13] [40] *Pseudomonas aeruginosa* is particularly common in

TABLE 229-10 -- Anatomic sites of primary infection in *Pseudomonas* bacteremia.*

ANATOMIC SITES OF PRIMARY INFECTION IN *PSEUDOMONAS* BACTEREMIA		
Infection	**Hospital acquired Gram-negative bacilli (%)**	**Community acquired (%)**
Urinary tract	18.8	5.2
Gastrointestinal tract	20.0	4.3
Skin/soft tissue infection	15.4	6.3
Respiratory tract	36.4	27.8
Other	4.8	6.7

** Adapted from MacCue.*[40]

series of patients who have hematologic malignancy or high risk factors (see Table 229.9).

Primary bacteremia

Pseudomonas bacteremia may occur following instrumentation procedures using contaminated equipment or solutions. Equipment used for endoscopic retrograde cholangiopancreatography, intra-aortic balloon pump placement and many other invasive exploratory investigations have been reported as sources of *Pseudomonas* bacteremia. Many cases of bacteremia have also occurred in narcotic addicts.[13] [26]

Secondary bacteremia

Pseudomonas bacteremia is most often related to focal infection (Table 229.10) and the most frequent source is the respiratory tract;[40] the skin and soft tissues, especially in burns patients, and urinary tract are also common sources. Less frequently, colonization of the gastrointestinal tract may precede infection, which develops in the presence of a variety of risk factors such as hospitalization in an ICU, the presence of neutropenia or treatment with cytotoxic chemotherapy; 50% of these patients develop intestinal carriage, which occurs in only 5–15% of the general population, and translocation of *P. aeruginosa* is the potential mechanism for blood invasion and metastatic infection, predominantly in the respiratory tract.

Endocarditis

Endocarditis due to *P. aeruginosa* occurs predominantly in intravenous drug abusers and in those who have prosthetic heart valves. The tricuspid valve is most frequently involved but the aortic or mitral valve and mural endocardium can also be affected.[26] Adherence mechanisms in *P. aeruginosa* (pili, exoenzyme S, alginate) are likely to play a role in the colonization of prosthetic valves, resulting in microcolonies embedded in polysaccharide material and therefore protected from host defenses and antibacterial agents. Similar mechanisms may occur in bacterial colonization of intravenous and intra-arterial catheters.[20] [44]

Skin and soft tissue infections

Burn wound sepsis

Pseudomonas aeruginosa is the most common cause of burn wound sepsis, which is the predominant form of skin and soft tissue infection complicating severe thermal injury. The mortality rate is high (50–78%) despite improvements in management and antibiotic therapy.[26] Colonization of the burned skin surface by *P. aeruginosa* may result from the patient's own flora or from environmental sources. The bacteria penetrate into the subcutaneous tissues via hair follicles and breaks in the burned skin, and may enter with the help of proteolytic enzymes they produce. Other virulence factors (see Table 229.4) make a significant contribution to the severity of the

Figure 229-6 Burned leg that has been superinfected with *Pseudomonas aeruginosa.* *Courtesy of Professor H Carsin.*

Figure 229-7 Burned abdominal wall that has been superinfected with *Pseudomonas aeruginosa.* *Courtesy of Professor H Carsin.*

burn infection, which can be the source of bloodstream invasion. Sepsis, which is clinically characterized by fever or hypothermia, hypotension, oliguria and abdominal distension in addition to the extensive burn eschar, requires specific management in burns centers. Figure 229.6 and Figure 229.7 show extensive burn lesions.

Ecthyma gangrenosum

This is a focal skin lesion that is often associated with *Pseudomonas* bacteremia. The lesion is characterized by an erythema surrounded by hemorrhage, necrosis of skin tissues and bacterial invasion. Other pseudomonal skin lesions may complicate *Pseudomonas* bacteremia, such as subcutaneous nodules, deep abscesses and cellulitis. These extensive and destructive lesions of the skin are particularly seen in neutropenic patients.

Wound superinfections with Pseudomonas aeruginosa

These occur occasionally and their characteristics were described early in the medical literature, particularly because of the blue-green exudate and the colored bandages due to the production of pyocyanin pigments.

Urinary tract infections

Most *Pseudomonas* urinary tract infections are hospital-acquired and associated with either catheterization or surgery or with any cause of obstruction or persistent site of infection (e.g. chronic prostatitis).

Pseudomonas urinary tract infections have no specific clinical presentation but tend to evolve with frequent recurrences and chronic evolution. A characteristic picture of ulcerative or necrotic lesions and multiple renal abscesses is seen in patients who have metastatic bacteremia with urinary tract invasion.[26]

Eye infections

Of all Gram-negative organisms, *P. aeruginosa* is the most common ocular pathogen, despite not forming part of the normal ocular flora. Ocular metastatic infection is rare and the most common source is exogenous. Ocular infections vary from mild (conjunctivitis) to extremely severe (orbital cellulitis). [45]

Keratitis

The most frequent manifestation is keratitis. The predominant predisposing factors of *Pseudomonas* keratitis are prosthetic devices (contact lenses), congenital abnormalities, burns or trauma, altered host defenses (people who have HIV infection) and prematurity. Viral keratitis (herpes simplex) may also be associated with a secondary bacterial infection. The corneal damage results from the exocellular products of *P. aeruginosa* and from strong adhesion to the exposed basement membrane of the epithelium; exotoxins, proteases and phospholipases degrade the corneal stroma, resulting in extensive loss of collagen fibers from the stroma.

Contact-lens associated Pseudomonas *keratitis*

This is common and is mainly observed in association with extended-wear contact lenses, inappropriate disinfecting regimens and poor hygiene. The bacteria may adhere to the lens, resulting in the development of a thick coat of mucopolysaccharide forming the same biofilm as on other prosthetic devices.

Endophthalmitis

This most often results from an endogenous origin, occurring by hematogenous spread from other infected sites. It may also occur after intraocular inoculation of *P. aeruginosa* by either trauma, burns or ocular surgery. Endophthalmitis is an acute fulminant disease, with pain and decreased acuity, which are potentially followed by panophthalmitis. The prognosis is poor without appropriate local and systemic management.[26] [45]

Miscellaneous

Central nervous system infections

These include meningitis and brain abscesses, which can result from either direct inoculation (head trauma, surgery), a contiguous infection (sinus, mastoid) or bloodstream infection. Other occasional sources are spinal anesthesia, lumbar puncture and cancer (the latter being one of occasional causes of central nervous system infections).

Bone and joint infections

These may result from contiguous spread, hematogenous origin or trauma. They occur predominantly in patients who have predisposing factors such as diabetes mellitus, intravenous drug abuse and chronic debilitation. Examples are:

- *Pseudomonas* osteomyelitis, which tends to have a chronic evolution;
- pyarthrosis, which frequently involves the sternoclavicular or sternochondral joints, in drug abusers;
- vertebral osteomyelitis in elderly patients in association with genitourinary instrumentation or surgery (*P. aeruginosa* has a particular affinity for cartilaginous joints of the axial skeleton); and
- *Pseudomonas* osteochondritis of the foot, which occurs in children following puncture wounds (this infection, like other fibrocartilaginous infection sites, involves cartilage, synovium, joint space and contiguous bone).

Pain, swelling, fever and other systemic signs are variable, depending upon the underlying diseases and the immune status of the patient.[20] [21] [26]

The management of bone and joint *Pseudomonas* infections is dependent upon the site of the infection and the immune status of the patient (see Table 229.9).

Ear infections

Pseudomonas aeruginosa is frequently isolated from the external auditory canal, particularly in infants. The significance of the presence of this potential pathogen is not always clear. In some cases, *P. aeruginosa* is involved in a superficial self-limited external otitis, which resolves spontaneously. Occasionally, the pathogen invades the epithelium between cartilage and bone in the lateral portion of the auditory canal, penetrating soft tissue, cartilage and bone.

Malignant external otitis

Malignant external otitis is a severe invasive necrotizing ear infection, clinically characterized by otalgia, otorrhea, early facial nerve paralysis and a swollen erythematous external auditory canal. Adjacent soft tissue is often involved. There is visible extension with cellulitis and bone erosions, the tympanic membrane is generally perforated and there is a purulent discharge.[26] [46]

Pseudomonas aeruginosa is isolated from the external auditory canal and from surgical specimens in all cases of malignant external otitis. Most cases occur in elderly people who have diabetes mellitus, but can occur in infants who have severe underlying diseases.

Management of this severe and extensive ear infection requires prolonged antibiotic therapy, surgical debridement and drainage.[46] The fatality rate is high (about 15–20%). Relapses are frequent and malignant external otitis requires prolonged follow-up.

MANAGEMENT

Antibiotic resistance in *Pseudomonas aeruginosa*

Paradoxically, although *P. aeruginosa* is the aerobic Gram-negative bacillus most frequently involved in nosocomial infection, it is not

TABLE 229-11 -- Resistance mechanisms in *Pseudomonas aeruginosa*.*

RESISTANCE MECHANISMS IN *PSEUDOMONAS AERUGINOSA*					
Antibiotics		**Percentage resistant**[47]	**Percentage resistant**[49]	**Mechanisms**	**Genetic bases**
Penicillins	Ticarcillin	30–40	12	Altered PBPs targets	Chromosomal
	Piperacillin	15–20	22	Altered PBPs targets	Chromosomal
Cephalosporins	Cefsulodin	12–15	-	Reduced permeability	Chromosomal
	Cefoperazone	15–20	-	Reduced permeability	Chromosomal
	Ceftazidime	2–8	6	ß-Lactamase inactivation (83%)	Chromosomal or plasmid mediated
	Cefpirome	5–8	-	ß-Lactamase inactivation (83%)	Chromosomal or plasmid mediated
Monobactams	Aztreonam	5–10	13	ß-Lactamase inactivation	
Carbapenems	Imipenem	10–15	2	Altered protein porin D2, imipenemase	Chromosomal
	Meropenem	10–15	-	Altered protein porin D2, imipenemase	Chromosomal
Aminoglycosides	Gentamicin	30–50	14	Reduced permeability, enzymatic inactivation	Chromosomal or plasmid mediated
	Tobramycin	25–35	4	Reduced permeability, enzymatic inactivation	Chromosomal or plasmid mediated
	Netilmicin	25–40	12	Reduced permeability, enzymatic inactivation	Chromosomal or plasmid mediated
	Amikacin	11–30	2	Reduced permeability, enzymatic inactivation	Chromosomal or plasmid mediated
Fluoroquinolones	Ciprofloxacin	10–50	28	Altered DNA gyrase target, efflux	Chromosomal
	Ofloxacin	10–50			
Fosfomycin		-	50–80	Altered transport system	Chromosomal mutation
Rifampin (rifampicin)		-	-	Altered DNA polymerase target	Chromosomal
Distribution of ß-lactamases in *P. aeruginosa*: plasmid mediated — PSE-1 to PSE-4 36%, OXA (1–10) 25%, TEM-1 and TEM-2 11.5%; inducible chromosomal cephalosporinase. Main modifying enzymes in *P. aeruginosa*: AAC (3)-I, AAC (3)-III; AAC (3)-IV, V; AAC (6')-I, AAC (6')-II; ANT (2''), AAC (6')-I + ANT (2''). PBP, penicillin-binding protein.					

** Data from Chen et al.,[6] Wiedemann et al.[47] and Li et al.[48]*

the most resistant organism among 'pseudomonads' and other aerobic Gram-negative bacilli. A number of ß-lactams considered to be 'antipseudomonal' drugs are still active against this species (Table 229.11). These drugs include:

- semisynthetic penicillins — carboxypenicillins (ticarcillin), ureidopenicillins (piperacillin);
- third-generation cephalosporins (ceftazidime, cefpirome, cefepime). For both penicillins and cephalosporins the percentages of susceptible strains were between 55% and 75% according to recent European[49] [50] and international surveys.[47]
- for carbapenems (imipenem), rates of susceptibility were about 80%; and
- for monobactams (aztreonam) — 70–80% susceptible strains.

Variations occur between countries in relation to different antibiotic usages. Besides natural resistance to many ß-lactam antibiotics, high resistance rates are seen in *P. aeruginosa* with aminoglycosides and fluoroquinolones. The incidence of plasmids in *P. aeruginosa* is relatively low and the major resistance mechanisms are chromosomally mediated. These mechanisms are mainly:

- altered outer membrane permeability (altered protein porins or lack of protein porin OprD);[51]
- production of chromosomally mediated ß-lactamases, inducible cephalosporinases or plasmid-mediated enzymes, including extended spectrum ß-lactamases;[50] [51] [52]
- aminoglycosides inactivating enzymes;[53] and
- active efflux mechanism pumping out different antibiotic classes from the cell.[54]

Resistance during therapy may develop and multiple resistance in *P. aeruginosa* is frequent, resulting in diminished permeability to ß-lactams, increased production of ß-lactamases, aminoglycoside-inactivating enzymes and efflux mechanisms pumping out fluoroquinolones, ticarcillin, aztreonam, cefsulodin, chloramphenicol and tetracyclines.[48] This results in strains with multiresistance profiles that are extremely difficult to eradicate and the choice of a potentially

TABLE 229-12 -- Antibiotic therapy for *Pseudomonas* infections.*

ANTIBIOTIC THERAPY FOR *PSEUDOMONAS* INFECTIONS		
Choices	**Drugs**	**Indications**

Monotherapy	Antipseudomonas penicillins: ticarcillin, piperacillin, azlocillin; Cephalosporins: ceftazidime, cefoperazone, cefpirome; Carbapenems: imipenem; Fluoroquinolones: ciprofloxacin	Limited to nongranulocytopenic patients, non-life-threatening infections, short courses, bacteriologic monitoring
Conventional combinations	Aztreonam, ticarcillin or ceftazidime plus clavulanate and/or sulbactam plus tobramycin; imipenem plus amikacin; ciprofloxacin plus ceftazidime; ciprofloxacin plus fosfomycin	Severe *Pseudomonas* infections — pneumonia, bacteremia, burns (plus topical), malignant external otitis media (plus surgery), central nervous system infection (plus local), cystic fibrosis (plus topical)
Alternatives	Antipseudomonas penicillin plus fluoroquinolone; aztreonam plus aminoglycoside; aminoglycoside plus fluoroquinolone	
Adjuvants	Burns — mafenide acetate (local), local debridement; Cystic fibrosis — mucolytics, passive immunization (anti-TNF MAb, IL-1); vaccines O-polysaccharide-based	
Anti-TNF MAb, monoclonal antibody to tumor necrosis factor; IL-1, interleukin-1.		

** Data from Pollack,[26] Bustamante et al.[41] and Figueredo and Neu.[55]*

efficient antibiotic therapy becomes limited. Serotype O12 has been recognized as one of the most resistant *P. aeruginosa* types; during an outbreak in a burns unit,[23] a serotype O12 strain was resistant to ticarcillin, ceftazidime, aztreonam, imipenem and ciprofloxacin, being only susceptible to amikacin. Paradoxically, 96% of these multiresistant strains were susceptible to fosfomycin.

Management of *Pseudomonas aeruginosa* infection

A summary of appropriate antipseudomonal treatments in various indications is given in Table 229.12 .

Conventional antibiotic therapy of* Pseudomonas aeruginosa *infections

Systemic severe infections, bacteremic pneumonia, life-threatening infections

The antibiotic therapy, either empiric or documented, is based upon an antibiotic combination, such as an aminoglycoside and a ß-lactam with antipseudomonal activity. Before laboratory data and antibiogram are available, a knowledge of local epidemiology of resistance in a particular ward or ICU and antibiotic susceptibilities as established in recent publications should be a great help in choosing a suitable combination.[41] [42] [56] Data shown in Table 229.11 and Table 229.13 indicate the current situation in terms of susceptibilities and minimum inhibitory concentrations (MICs) and should permit an empirical choice to be confirmed by the local clinical laboratory results.

Monotherapy

This has been documented using the following as monotherapy in moderately severe infections:[57]

- a third-generation cephalosporin, preferentially ceftazidime or cefpirome;
- imipenem/cilastatin; or
- a fluoroquinolone.

Agents such as ceftazidime or cefoperazone have been reported to achieve high serum bactericidal levels against bacteria isolated from patients who have *Pseudomonas* pneumonia.

Results from controlled clinical trials have shown that monotherapy is as good as combination therapy in nongranulocytopenic patients.

Antibacterial agents proposed as single-agent treatments of nosocomial pneumonia include imipenem and fluoroquinolones. Monotherapy with quinolones has narrow indications in severe *Pseudomonas* infection; short-term therapy is recommended when quinolones are used as monotherapy, and close bacteriologic monitoring is advised. Therapeutic results with quinolones against *Pseudomonas* infection were initially encouraging. Mild-to-moderate infections in CF patients have been controlled by oral ciprofloxacin when *P. aeruginosa* strains were resistant to ß-lactam agents and aminoglycosides. In some cases patients probably responded to therapy as a result of high tissue concentrations and a favorable ratio of quinolone concentration in vivo to the MICs for the pathogens.[56] However, the susceptibilities of hospital pathogens have evolved, and *Pseudomonas* systemic infections should be monitored carefully for antibiotic resistance.

The major risk of using single-agent treatment for *Pseudomonas* pneumonia is the possible emergence of antibiotic-resistant bacteria during therapy with quinolones or imipenem.

Indications for antibiotic combinations

In microbiologically documented cases of *Pseudomonas* infections, ß-lactam and aminoglycoside combinations offer a broad spectrum of antibacterial activity with synergistic bactericidal effect. Many reports have described in-vitro synergism, and in-vivo studies in animal models of *P. aeruginosa* pneumonia have confirmed the efficacy of such regimens.[58] However, in patients who have *Pseudomonas* nosocomial infections, there were frequent therapeutic problems due to the presence of multiresistant bacteria.[49] In a survey in our hospital, of 762 *Pseudomonas* strains:

- 39% were resistant to all ß-lactams;
- 21% were imipenem resistant;
- 21% were resistant to all aminoglycosides; and
- 37.5% were resistant to all fluoroquinolones.

Among imipenem-resistant strains, however, 41% were susceptible to ticarcillin and ceftazidime. The emergence of resistance has been prevented by using ciprofloxacin with ceftazidime or imipenem in *P. aeruginosa* pneumonia, but the in-vitro effect of combinations is additive or indifferent rather than synergistic. [41] An absence of correlation between in-vitro synergism and clinical outcome with a combination of ciprofloxacin and azlocillin has been observed.[42] When quinolones are combined with ß-lactam drugs (ureidopenicillins, ceftazidime or imipenem), the combination prevents or at least reduces the risk of emergence of resistance. Combinations of fluoroquinolones with fosfomycin have been found to be useful in preventing the emergence of resistant mutants[55] and to be generally synergistic.

Management of specific* Pseudomonas *infections

Central nervous system infections due to *Pseudomonas aeruginosa*

These require bactericidal antibiotics that reach high concentrations in cerebrospinal fluid (CSF) — in *Pseudomonas* meningitis a

combination of ceftazidime, which is highly concentrated in CSF when the meninges are inflamed, and an aminoglycoside (amikacin, which is the drug with the lowest resistance rates; see Table 229.11). If there is obstruction of the subarachnoid space the aminoglycoside may be instilled directly into the ventricular system. *Pseudomonas* brain abscess is treated surgically together with a similar prolonged antibiotic therapy.[26]

Malignant external otitis

Malignant external otitis, which is an extremely severe infection, must be treated with a combination of local surgical debridement and drainage together with a potent antibiotic therapy combining an aminoglycoside and antipseudomonal ß-lactam.[46]

Pseudomonas burn wound sepsis

This requires a combination of antibiotics, as mentioned above, although there is frequent emergence of resistance due to high bacterial counts and limited access of antibiotic to burn sites. Local measures with topical agents and surgical debridement of necrotic tissue are always applied in addition to systemic antibiotics.[26] [52]

Pseudomonas pneumonia in cystic fibrosis patients

Respiratory infections in CF are among the most serious types of infection, because they occur in children, who suffer for prolonged periods. Eradication of *Pseudomonas* spp. (or other pathogens) from the airways occurs provisionally only, whatever strategy is used. Proper management of acute exacerbations of *Pseudomonas* lung infection requires antibiotic combinations, usually aminoglycosides and ß-lactams (ceftazidime or piperacillin) at larger than usual doses. Although not recommended in children, fluoroquinolones have been used successfully and a combination of ciprofloxacin with fosfomycin has demonstrated in-vitro synergy.[55] Courses of aggressive antibiotic therapy every 3 months in combination with other measures such as mucolytics, antiproteases and topical antibiotic therapy and physiotherapy increase the 5- to 20-year survival of patients who have CF.

Topical antibiotic therapy for nosocomial *Pseudomonas* pneumonia in cystic fibrosis patients

Depending upon their physicochemical characteristics, many injected antibiotics do not achieve significant concentrations in the

lung. Administration of antibiotics directly into the tracheobronchial tree should therefore increase local antibiotic concentrations so that the free drug concentration exceeds the MIC of the pathogen.[59] [60] A good clinical tolerance has been reported for gentamicin, tobramycin and amikacin, although some reduction of the maximum expired volume per second has occasionally been observed. Carbenicillin and ceftazidime were also administered topically but poorly tolerated. Successful inhaled tobramycin therapy has been demonstrated recently in 69 CF centers in the USA.[59]

Among the drawbacks of this route of administration are:

- a low or heterogeneous deposition of antibiotic in lung areas where there is consolidation or atelectasis; and
- resorption of aminoglycoside from the respiratory tract to the blood resulting in a low antibiotic concentration that may promote the emergence of resistant bacteria (this has been observed in *P. aeruginosa* pneumonia when continuous local polymyxin B has been used for prophylaxis).[60]

Nosocomial *Pseudomonas* pneumonia

It has been suggested that parenteral conventional therapy should be combined with direct instillation of aminoglycoside into the respiratory tract via an endotracheal or tracheostomy tube. In a double-blind randomized trial, using endotracheal tobramycin versus placebo, pathogens were eradicated in 68% versus 31% respectively.[61]

OTHER *PSEUDOMONAS* SPECIES

EPIDEMIOLOGY

Among *Pseudomonas* spp. (see Table 229.1), a few may be involved in rare cases of opportunistic infection. Their common habitat is in the natural environment: water, soil and plants. Some of these species, in particular *Pseudomonas putida*, *Pseudomonas fluorescens* and *Pseudomonas stutzeri*, are widespread in the animal and human environment and are frequently found in the hospital environment; they occasionally contaminate antiseptic solutions, dialysis fluids, transfusion blood and blood byproducts.

DIAGNOSTIC MICROBIOLOGY

Characteristics differentiating *Pseudomonas* spp. are shown in Table 229.7 . This simplified scheme for identification of these bacteria is mainly based on morphologic features (flagella), pigment production and the main metabolic characteristics. The taxonomic status of non-*aeruginosa Pseudomonas* spp. has evolved significantly (see Table 229.1). Some species, such as *P. fluorescens* and *P. putida*, are heterogeneous and several biovars are recognized: five biovars in *P. fluorescens* (I–V) and two biovars in *P. putida* (A and B), which differ in a few metabolic properties.[1] [7] [11]

PATHOGENICITY AND CLINICAL MANIFESTATIONS

Some of these *Pseudomonas* spp. have been isolated from human clinical specimens (blood, urine, stools) and occasional cases of opportunistic infection occur as a result of transfusion, antiseptic use, dialysis and other mechanisms of transmission. *Pseudomonas fluorescens*, a psychrophilic organism, may grow at 39°F (4°C), which favors its presence in blood products.[15] Outbreaks of bacteremia, respiratory infections in CF patients, wound infections and rare cases of community-acquired pneumonia have been reported.[7] These *Pseudomonas* spp. have been also implicated in rare cases of endophthalmitis and keratitis, particularly *P. fluorescens*, *P. stutzeri* and *Pseudomonas paucimobilis* (the last species being rarely cited). Most

TABLE 229-14 -- Epidemiology and pathogenicity of the non-*aeruginosa Pseudomonas* species

EPIDEMIOLOGY AND PATHOGENICITY OF THE NON-*AERUGINOSA PSEUDOMONAS* SPP.		
Habitat and epidemiology	**Pathogenicity**	**Species**
Environment, water, plants; hospital environment; rare opportunistic pathogens	Occasional bacteremia (contaminated blood, solutions); rare cases	*Pseudomonas alcaligenes, Pseudomonas pseudoalcaligenes*
Soil, water, plants; hospital sinks, floor; food spoilage (eggs, meat, fish, milk); opportunistic pathogens	Rarely isolated from clinical specimens; rare cases of isolation in patients with cystic fibrosis, bacteremia, urinary tract infection, wounds	*Pseudomonas putida, Pseudomonas fluorescens*
Ubiquitous, soil, water, sewage water; hospital environment, antiseptics, injectable solutions; relatively more frequent than other non-*aeruginosa*	Outbreaks of pseudobacteremia; frequent isolation from pus, urine, blood, cerebrospinal fluid; contamination of bone marrow transplant	*Pseudomonas stutzeri*
Pseudomonas spp.; opportunist; more susceptible to antibiotics than other species		

cases occur in severely debilitated patients, and these *Pseudomonas* spp. behave as opportunistic pathogens in immunocompromised patients (Table 229.14).[15] [39] [26]

MANAGEMENT

Based on their in-vitro susceptibilities,[47] these organisms can be eradicated by using carbapenems (MICs 0.5–8mg/l) in combination with fluoroquinolones (ciprofloxacin MICs 0.5–16mg/l). Aminoglycosides have poor activity and management of infections due to *P. putida* or *P. fluorescens* is difficult. *Pseudomonas stutzeri* is more susceptible to antibiotics than other species.

ACINETOBACTER SPECIES

NATURE

Acinetobacter spp. are Gram-negative bacteria that are commonly present in soil and water as free-living saprophytes and are also isolated as commensals from skin, throat and various secretions of healthy people. They have emerged as important nosocomial pathogens in outbreaks of hospital infections and rank second after *P. aeruginosa* among aerobic Gram-negative bacilli nosocomial pathogens. The increasing number of these infections and the natural resistance of the strains has led to studies of epidemiology and resistance mechanisms in *Acinetobacter* spp.[3]

EPIDEMIOLOGY

In the natural environment

Acinetobacter spp. are widely distributed in nature and can be found in virtually 100% of soil and freshwater samples when appropriate culture techniques are used.[6] [62] They use a wide variety of substrates as

a sole carbon source. In freshwater samples, less than 1–7.9 × 10^4 cfu/100ml have been recorded, whereas in raw sewage effluents up to 10^6 cfu/100ml have been found. *Acinetobacter* spp. can also be isolated from food and form part of the normal flora of fresh meats; they may contribute to the spoilage process of refrigerated meats.

In the human environment

In hospitals

Acinetobacter spp. have been found in:

- moist situations such as room cold-air humidifiers, tap water, hand washbasins, waterbaths, moist respirometers and all types of ventilatory equipment, which are capable of aerosolizing the organism;
- angiography catheters;
- blood collection tubes; and
- plastic urinals.

The presence of *Acinetobacter* spp. in mattresses in burns units has been reported,[3] [62] and Acinobacter have caused considerable problems on some intensive care units.

Human carriage of Acinetobacter *species*

This has been demonstrated in normal individuals, indicating that the source of nosocomial infections might be endogenous as well as from the external environment. *Acinetobacter* spp. form part of the bacterial flora of the skin and are found in the axilla, groin and toe webs; they can colonize the oral cavity, the respiratory tract and the normal intestine (see Table 229.2).[62] However, the value of this approach has not been independently confirmed and is not widely used.

PATHOGENICITY

Pathogenesis of infections: virulence of *Acinetobacter* species

Several factors may be responsible for the virulence of *Acinetobacter* spp.:

- the presence of a polysaccharide capsule formed of L-rhamnose, L-glucose, D-glucuronic acid and D-mannose that makes the surface of strains more hydrophilic;
- the adhesiveness of *Acinetobacter* spp. to human epithelial cells in the presence of fimbriae and/or mediated by the capsular polysaccharide;
- enzymes (butyrate esterase, caprylate esterase and leucine arylamidase) potentially involved in damaging tissue lipids; and
- the LPS component of the cell wall and the presence of lipid A, which are likely to participate in the pathogenicity of *Acinetobacter* spp.[33]

Host predisposing factors

Susceptible patients include those who have severe underlying conditions such as malignancy, burns and immunosuppression or who have undergone major surgery. Age plays a role in the occurrence of nosocomial infections with *Acinetobacter* spp. in elderly patients and neonates. The settings for infection are medical or surgical ICUs, and renal and burns units. Tubes, catheters and all kinds of artificial devices act as portals of entry at the site of infection (see Table 229.5). In French hospitals, *Acinetobacter* spp. were found in 9.7% of nosocomial infections.[3]

DIAGNOSTIC MICROBIOLOGY

Acinetobacter strains are nonfermentative, nonfastidious, aerobic Gram-negative coccobacilli, usually found in diploid formation or in chains of variable length (Fig. 229.8). They are not motile (*akinetos* means 'unable to move' in Greek), but the cells display a 'twitching

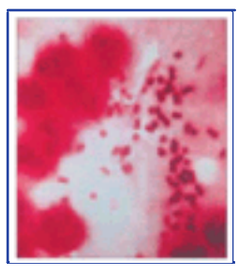

Figure 229-8 Morphology of *Acinetobacter baumannii* on Gram stain. Preparation from a lung infection in mice. *Courtesy of Dr ML Joly-Guillou.*

motility'. Strictly aerobic, they grow well on all common media at temperatures of 68–86°F (20–30°C), but for most strains the optimum is 91.4–95°F (33–35°C). A few species can grow at 105.8°F (41°C) and 111.2°F (44°C) and this is a discriminating character between species. Identification of *Acinetobacter* spp. is based upon:

- oxidase-negative, catalase-positive, indole-negative, nitrate-negative tests; and
- production or not of acid from D-glucose, D-ribose, D-xylose and L-arabinose (used oxidatively as carbon sources; Table 229.15).

Acinetobacter is the only genus with an oxidase-negative test among non motile aerobic Gram-negative bacilli.[3] [7]

Nomenclature of *Acinetobacter* species

This has undergone considerable taxonomic changes. By using modern methods of taxonomy (genetic transformations, DNA hybridizations and rRNA sequence comparisons), the classification proposed by Bouvet and Grimont[63] identified more than 15 genomic species including *Acinetobacter baumannii* (formerly *A. calcoaceticus* var. *anitratus* and *A. glucidolytica non liquefaciens*), *Acinetobacter haemolyticus*, *Acinetobacter junii*, *Acinetobacter johnsonii* and *Acinetobacter radioresistens*.

Species of clinical importance

Most studies have supported the initial observation that *A. baumannii* is the main species associated with outbreaks of nosocomial infection. Other species, *A. haemolyticus*, *A. junii* and *Acinetobacter lwoffi*, have been associated with clinical infections; they can be natural inhabitants of human skin and repeated isolation of non-*A. baumannii* species suggests that they are potential pathogens.[3]

CLINICAL MANIFESTATIONS

The main sites of infections are the respiratory and urinary tracts. Endocarditis, burn infections, and skin and wound sepsis may also occur (see Table 229.3).

Acinetobacter pneumonia

This is common in hospitals, especially in ICUs. Large outbreaks of *Acinetobacter* pneumonia have been described. All patients had severe underlying disease, assisted ventilation and tracheostomy or were intubated. *Acinetobacter* spp. represent 15.6% of the total Gram-negative bacilli involved in nosocomial pneumonia in France. [18]

Community-acquired cases of *Acinetobacter* pneumonia have been reported in middle-aged and elderly people who have a chronic underlying disease or are alcoholic.

TABLE 229-15 -- Identification of the most frequently isolated *Acinetobacter* species. [3] [63]

Genospecies	Growth at	Glucose (acidified)	Hemolysis	Gelatin hydrolysis	Utilization test*			
					β-alanine	DL-lactate assimilation	Citrate	Malonate

A. lwoffi 8/9	+/44.6°C	–	–	–	–	+	–	–
A. radioresistens 12†	+/44.6°C	–	–	–	–	–	+	+

* Eleven other assimilation tests of carbon and energy sources can be used[3]; data not shown for unnamed genospecies 10 and 11.
† Five other unnamed genospecies have been identified – 13, 14, 15, 16, 17 – and are being studied.

Red indicates a positive result, and white a negative result. The numbered genospecies are based on DNA-DNA hybridizations. *A. alcaligenes* is hemolytic.

Urinary tract infection

Several reviews[9] [18] [62] have described *Acinetobacter* spp. in 2–61% of nosocomially acquired urinary tract infections. A recent investigation in France has indicated an overall incidence of 30.5% of acquired urinary tract infection.[18]

Meningitis

Nosocomial meningitis is an infrequent manifestation of *Acinetobacter* infection. The first case report was in 1908 by Von Lingelsheim and the organism was designated *Diplococcus mucosus*, later renamed *Mima* by Debord (1939) because of its resemblance to *Neisseria meningitidis*. Cases of *Acinetobacter* meningitis have been reported after neurosurgical procedures, but rare cases of primary meningitis, especially in children, have also occurred.[3]

Miscellaneous

Skin and wound infections, abscesses, sepsis, endocarditis, peritonitis and burn wound infections have been reported.[3]

MANAGEMENT

Antibiotic resistance

Since 1980 successive surveys have shown increasing resistance in clinical isolates of *Acinetobacter* spp.[3] [9] [18] [64] High proportions of strains are resistant to most commonly used antibacterial drugs including aminopenicillins, ureidopenicillins, cephalosporins of the first generation (cephalothin) and second generation (cefamandole), cephamycins such as cefoxitin, most aminoglycosides, aminocyclitols, chloramphenicol and tetracyclines. Differences in susceptibilities of *Acinetobacter* isolates as a function of countries and areas could be attributable to environmental factors and different patterns of antibiotic usage.[3] [64] [65]

Management of *Acinetobacter* infections

Only a few antibiotics are active in the treatment of *Acinetobacter* spp. infections. A few ß-lactams might be used after careful in-vitro susceptibility testing:

- ticarcillin combined with sulbactam (the latter being a ß-lactamase inhibitor often active by itself against *Acinetobacter* spp.);[3] [66]
- ceftazidime; and
- most often imipenem, which is by far the most active drug for treating *Acinetobacter* infection.

Combination therapy is always recommended, combining a ß-lactam with an aminoglycoside, a fluoroquinolone or rifampin (rifampicin). The addition of ß-lactamase inhibitors, clavulanic acid to ticarcillin, or sulbactam to a third-generation cephalosporin, may significantly enhance the ß-lactam activity. In a recent study,[64] pneumonia and sepsis due to *A. baumannii* were treated using synergistic combinations of imipenem plus either amikacin or tobramycin (14 cases) or ampicillin-sulbactam with tobramycin and ticarcillin-clavulanate with tobramycin (four cases), underlining the importance of ß-lactamase inhibitors in combination therapy in *Acinetobacter* infections.

BURKHOLDERIA SPECIES

NATURE AND EPIDEMIOLOGY

Burkholderia spp. were transferred from the genus *Pseudomonas* (see Table 229.1). Three species are recognized as opportunistic agents involved in nosocomial infections:

- *Burkholderia cepacia* (type species),
- *Burkholderia gladioli*, and
- *Burkholderia pickettii*.

Two species are responsible for specific infections in horses (glanders) — *Burkholderia mallei* and *Burkholderia pseudomallei* — and are occasionally transmitted to humans, resulting in a disease named melioidosis (the organism was identified by Whitmore in 1913). [5]

All *Burkholderia* spp. are genetically related on the basis of DNA-DNA homologies, 16S rRNA sequences and phenotypic characters. They are ubiquitous organisms, being widespread in water, soil and plants, and are present in the human environment. *Burkholderia cepacia* is an environmental organism that has no specific nutritional requirements and survives for months in water, sinks, antiseptic solutions (chlorhexidine, quaternary ammoniums, povidone-iodine), pharmaceutical products, dialysis fluid and various injectable solutions. It may even survive on environmental surfaces[11] and may be found in nebulizers, ventilatory equipment and many other medical and dental devices (see Table 229.5).

PATHOGENICITY

Although weakly virulent with a limited invasive capacity, *B. cepacia* has become an important nosocomial pathogen. Clinical manifestations are dependent upon the source of contamination. Most cases and outbreaks of *B. cepacia* infection have been bacteremias with septic shock, nosocomial urinary tract infections, peritonitis (in dialysis units), endophthalmitis and keratitis, and nosocomial pneumonias.[26] [39] [44] [67] All infections due to *B. cepacia* have been described in immunocompromised patients, who have usually been hospitalized in ICUs. The predominant site of infection is the respiratory tract (see Table 229.3), mainly in patients who have CF.[44] [68] [69] [70]

Burkholderia cepacia in severe respiratory infections in cystic fibrosis patients

The pathogenesis of *B. cepacia* in severe respiratory infections in people who have CF has not been extensively studied. Virulence factors suspected in *B. cepacia* could be mainly exoproducts (proteases, lipases, exopolysaccharides), which act in addition to the LPS forming part of O antigen, responsible for severe pneumonia and sepsis in CF patients.[44] [17] Cases of fulminant and extensive necrotizing pneumonia with a rapidly fatal outcome have been observed.[71]

Other *Burkholderia* species

Burkholderia pickettii *and* Burkholderia gladioli

These are ubiquitous organisms that can be found in water and soil and may play a role as nosocomial pathogens. Rare outbreaks of infection have been described and emergence of multiresistance is a potential problem.[11] [70]

Burkholderia mallei *and* Burkholderia pseudomallei

These are environmental organisms predominantly found in Asia, Africa and South America. *Burkholderia mallei* is not motile but is genetically related to *B. pseudomallei*. The latter, an animal pathogen, can be transmitted to humans; sepsis with severe pneumonia and subacute pulmonary cavitating disease are the main human forms of melioidosis (see Chapter 175). These infections are severe and have high fatality rates.[26]

DIAGNOSTIC MICROBIOLOGY

Identification tests for *Burkholderia* spp. are summarized in Table 229.16 .

MANAGEMENT

The susceptibility of strains to aztreonam, ceftazidime, ceftriaxone and fluoroquinolones suggests the use of combinations of drugs belonging to these classes for treating these severe infections, particularly in people who have CF. Imipenem is not the most active ß-lactam (MICs 1 to =32mg/l) and aminoglycosides have variable efficacy (MICs 2 to >32mg/l). However, aminoglycoside plus imipenem may be a synergistic combination.[11] Highly multiresistant strains can be isolated from CF during exacerbations of pulmonary infection; consecutive sequences of antibiotic treatments[70] [71] may have exerted a selective pressure leading to a therapeutic 'dead end'. In those cases, inhaled antibiotic therapy[59] [60] associated with an intravenously administered antibiotic combination can control pulmonary exacerbation by *B. cepacia*.

STENOTROPHOMONAS MALTOPHILIA

NATURE AND EPIDEMIOLOGY

Stenotrophomonas maltophilia is an emerging opportunistic pathogen that belonged to the *Pseudomonas* genus, was transferred

TABLE 229-16 -- Diagnostic microbiology of *Burkholderia* species.

DIAGNOSTIC MICROBIOLOGY OF *BURKHOLDERIA* SPECIES			
Characteristics	*Burkholderia cepacia*	*Burkholderia mallei*	*Burkholderia pseudomallei*

to the *Xanthomonas* group[10] and then received a new designation, *S. maltophilia*, [4] belonging in the newly defined genus *Stenotrophomonas*. Isolated from soil, plants, water and raw milk, this ubiquitous bacterium is common in the hospital environment.[27] It has often been isolated from ventilatory equipment (thermal humidifying units) and from moist respirometers, as well as from dialysis fluids and antiseptic solutions (see Table 229.5).

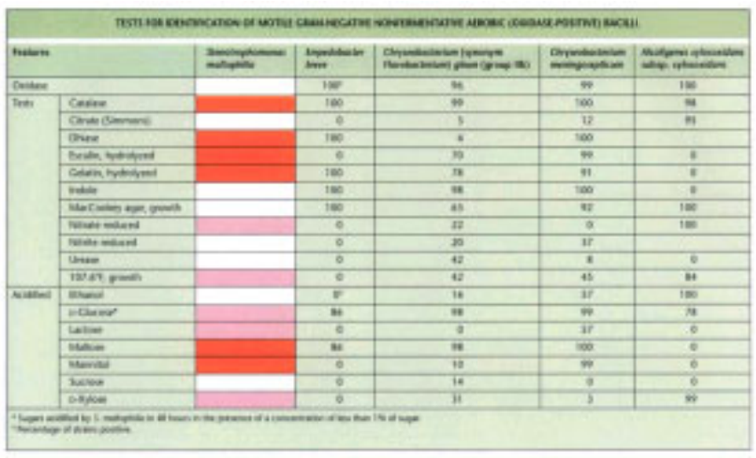
DIAGNOSTIC MICROBIOLOGY

These bacteria are characterized by the presence of a single or a small number of polar flagella (motile bacteria), frequently pigmented colonies (yellow or yellowish orange) and oxidase-negative reaction.[4] [11] [15] (Table 229.17 ; also see Fig. 229.1 and Table 229.6). *Stenotrophomonas maltophilia* acidifies sugars (except for rhamnose or mannitol) and is generally proteolytic. Its identification tests are shown in Table 229.17 .

CLINICAL MANIFESTATIONS

Stenotrophomonas maltophilia can be isolated from patients who have respiratory tract infections, endocarditis, bacteremia, meningitis and urinary tract infections, and can also be implicated in severe cutaneous infections (ecthyma gangrenosum similar to that due to *P. aeruginosa*), cellulitis and abscesses. It produces proteolytic enzymes and other pathogenic extracellular enzymes such as DNAse, RNAse, elastase, lipase, hyaluronidase, mucinase and hemolysin, which contribute to the severity of *S. maltophilia* infection in immunodepressed patients in ICUs.[2] [4] [27] There is a high incidence of infection with *S. maltophilia* in patients who have cancer, leukemia or lymphoma, and *S. maltophilia* is increasingly implicated in pulmonary superinfections in patients who have CF (see Table 229.3). It can be underlined that *S. maltophilia* is a rapidly developing agent of nosocomial infection, with an increasing incidence in respiratory infections in CF patients. Another species, identified as *Stenotrophomonas africana*, is an emergent pathogen, a strictly aerobic, nonproducer of oxidase close to *S. maltophilia*. It has been isolated in east Africa from the CSF of an HIV-positive patient with meningoencephalitis. This organism is one of the most resistant bacteria, susceptible only to ciprofloxacin and colistin.[72]

TABLE 229-17 -- Tests for identification of motile Gram-negative nonfermentative aerobic (oxidase-positive) bacilli.



Clinically important species of the genera *Stenotrophomonas*, *Chryseobacterium-Flavobacterium* group and *Alcaligenes* (*Stenotrophomonas maltophilia* is not in fact oxidase-positive). Genera and species of *Empedobacter breve, Chryseobacterium gleum* and *Chryseobacterium meningosepticum* are derived from the genus *Flavobacterium*. Red indicates a positive result, white a negative result and pink a variable result.[1] [2] [4]

Stenotrophomonas maltophilia is frequently associated with other bacterial species at sites of infection but is increasingly isolated as the sole pathogen.

MANAGEMENT

Resistance

Stenotrophomonas maltophilia is naturally resistant to most antibiotics as a result of chromosomally mediated mechanisms, poor permeability of the outer membrane and naturally produced inactivating enzymes. [6] [67]

- Many ß-lactamases have been described in *Stenotrophomonas maltophilia* and it is susceptible only to latamoxef and combinations of ticarcillin plus clavulanic acid or piperacillin plus tazobactam. It is naturally resistant to imipenem and meropenem as a result of carbapenemase production.
- Only a few strains are susceptible to gentamicin, neomycin and kanamycin. Resistance to aminoglycosides is probably plasmid-mediated. *Stenotrophomonas maltophilia* is poorly susceptible to quinolones.

- Resistance to quinolones is generally associated with resistance to chloramphenicol and to doxycycline in more than 50% of cases and is associated with alteration of outer membrane proteins.[16]
- An active efflux mechanism has been also demonstrated.[67]

Stenotrophomonas maltophilia is variably susceptible to minocycline, rifampin and trimethoprim-sulfamethoxazole.

Management of infections due to *Stenotrophomonas maltophilia*

Infections due to *S. maltophilia* require combination therapy including rifampin plus a fluoroquinolone or plus ß-lactams (mezlocillin, ceftazidime or cefotaxime; MICs 8, 128 and 16mg/l respectively). Combinations decrease the MICs of ß-lactams.[67] [73]

MISCELLANEOUS AEROBIC GRAM-NEGATIVE BACILLI

Many other aerobic Gram-negative bacilli either derived from the *Pseudomonas* group or originating from dispersed groups of environmental organisms have been identified. Some are increasingly involved in human infection.[5] [11] [72] [73] These genera and species have undergone many taxonomic changes; some have been identified recently, and the wide use of analysis of ribosomal 16S RNA gene sequences has allowed a clearer taxonomic position to be established for most aerobic Gram-negative bacilli. The following section includes a short description of the pathogenic role of those involved in human infections and of the management of these infections. For easy reading, the generic groups are described in alphabetical order (Table 229.18). Species cited in the list are those isolated from human infections (see also Table 229.1).

ACHROMOBACTER spp.

See *Ochrobacterium* spp.[74]

TABLE 229-18 -- Current and previous nomenclature of miscellaneous aerobic Gram-negative bacilli.

CURRENT AND PREVIOUS NOMENCLATURE OF MISCELLANEOUS AEROBIC GRAM-NEGATIVE BACILLI		
Main groups (genera)	**Current name**	**Previous name**
Achromobacter	*Ochrobactrum anthropi*	*Achromobacter* Vd
Aeromonas	*Aeromonas enteropilogenes*	*Aeromonas trota*
	Aeromonas ichtiosemia	*Aeromonas veronii*
	Aeromonas salmonicida	*Haemophilus piscium*
	Aeromonas caviae	-
Agrobacterium	*Agrobacterium radiobacter*	*Agrobacterium tumefaciens*
	Agrobacterium tumefaciens	
	Pantoea agglomerans	*Agrobacterium gypsophilae*
Alcaligenes (see Table 229.1)	*Alcaligenes faecalis type 1*	
Alcaligenes xylosoxidans	*Alcaligenes odorans*	
Achromobacter xylosoxidans		
Bergeyella	*Bergeyella zoohelcum*	*Weeksella zoohelcum*
Burkholderia (see Table 229.1)	*Burkholderia cepacia*	
Burkholderia mallei		
Burkholderia pseudomallei	*Pseudomonas kingii*	
Pseudomonas mallei		
Pseudomonas pseudomallei		
Calymmatobacterium	*Calymmatobacterium granulomatis*	*Klebsiella granulomatis*
Capnocytophaga	*Capnocytophaga ochracea*	*Bacteroides ochraceus*
	Capnocytophaga gingivalis	-
	Capnocytophaga sputigena	-
Chromobacterium	*Chromohalobacter marismortui*	*Chromobacterium marismortui*
Chryseobacterium (see Table 229.1)	*Chryseobacterium meningosepticum*	*Flavobacterium meningosepticum*
Chryseomonas (formerly *Flavobacterium*)	Chryseomonas luteola	Pseudomonas luteola
Comamonas	*Comamonas terrigena*	*Pseudomonas terrigena*
	Comamonas testosteroni	-
	Delftia acidovorans	*Comamonas acidovorans*
Ochrobactrum	*Ochrobactrum anthropi*	*Achromobacter* Vd
	Ochrobactrum intermedium	*Ochrobactrum* nov. sp.
Oligella	*Oligella urethralis*	*Moraxella urethralis*
Plesiomonas	*Proteus shigelloides*	*Plesiomonas shigelloides*
Ralstonia	*Ralstonia picketii*	*Burkholderia picketii*
	Ralstonia eutropha	*Pseudomonas/Alcaligenes eutrophus*
Shewanella	*Shewanella hanedai*	*Alteromonas hanedai*
	Shewanella putrefaciens	*Pseudomonas/Alteromonas putrefaciens*
Sphingobacterium (see Table 229.1)	*Sphingobacterium mizutae, S. multivorum*	*Flavobacterium* spp.
Stenotrophomonas	*Stenotrophomonas maltophilia*	*Xanthomonas maltophilia*
	Stenotrophomonas africana	-
Weeksella	*Bergeyella zoohelcum*	*Weeksella zoohelcum*
Only species seen as pathogenic in humans are listed. This table completes and/or modifies the taxonomic data in Table 229.1 .		

AEROMONAS spp.

Originally included in the Vibrionaceae group, *Aeromonas* spp.[70] [76] form their own family (the Aeromonadaceae). Their natural habitat is water, fish and other aquatic animals, and the gut of pigs, dogs and cats. At least seven species have been recognized, four of which are the most pathogenic for humans (see Table 229.18).

Microbiology

These organisms are motile, Gram-negative rods (one single polar flagellum), oxidase- and catalase-positive and facultatively anaerobic. They grow easily at low temperatures (between 41°F/5°C and 72–82°F/22.2–27.8°C) on nutrient agar. Selective growth media that contain ampicillin has been formulated, as ampicillin inhibits the growth of *Aeromonas* spp. at more than 32mg/l.

Pathogenic role

Aeromonas spp. isolated from contaminated water produce enteric infections with diarrhea, abdominal pain and fever. *Aeromonas* spp. present in the hospital environment may also be responsible for systemic infections, bacteremia, meningitis, peritonitis, cholecystitis and liver infections, all of which occur generally in patients who have severe underlying disease or immunodepression.

Aeromonas hydrophila strains have been involved in nosocomial infections. They may also be transmitted by sanguivorous leeches used in plastic or graft surgery, being responsible for severe cellulitis, osteitis and pyomyositis.

Management

Aeromonas spp. are resistant to most ß-lactams; they produce several ß-lactamases, including a carbapenemase, which confers resistance to imipenem. Infections are treated using third-generation cephalosporins, aminoglycosides, tetracyclines, fluoroquinolones and trimethoprim-sulfamethoxazole. [72]

AGROBACTERIUM spp.

Initially included in the group of *Alcaligenes* spp. (see Table 229.1), these bacteria are considered as emerging pathogens but only one species, namely *Agrobacterium radiobacter*, has been involved in human infections.[72] [73]

Microbiology

These phytopathogenic organisms, present in water, soil and environmental plants, are strictly aerobic coccobacilli, motile with peritrichous flagella (one to six). They grow easily on conventional media and produce oxydase and catalase; these bacteria are identified by using commercial identification kits.

Pathogenic role

Oncogenic in plants, *Agrobacterium* spp. have not been found to be oncogenic in humans, but they have been implicated in bacteremia, endocarditis, catheter infection, peritonitis and urinary tract infections. A limited number of cases have been cited in the literature.

Management

Agrobacterium spp. are susceptible to cephalosporins (second- and third-generation), ticarcillin, imipenem, tetracyclines, colistin, trimethoprim-sulfamethoxazole and fluoroquinolones, but outcomes of treatment depend on underlying pathologies in infected patients.

ALCALIGENES spp.

See Table 229.1 , Table 229.5 , Table 229.17 and Table 229.18 and Figure 229.1 .

Epidemiology

The natural habitat of *Alcaligenes* spp. is the same as that of *Pseudomonas* spp. In the hospital environment, *Alcaligenes faecalis* and *Alcaligenes xylosoxidans* can be isolated from various environmental sources, such as respirators, hemodialysis systems, intravenous solutions and disinfectants.[1] [2] [3] [30] [77]

Microbiology

These are short, Gram-negative rods (0.5–2.6µm), strictly aerobic and motile with one to eight peritrichous (nonpolar) flagella, usually described as degenerated (see Fig. 229.1 and Table 229.6). They are oxidase-positive and catalase-positive. *Alcaligenes faecalis, Alcaligenes piechaudii* and *A. xylosoxidans* subsp. *denitrificans* are not saccharolytic. The only saccharolytic species is *A. xylosoxidans* subsp. *xylosoxidans*. Not all *Alcaligenes* spp. possess specific physiologic or biochemical characteristics (see Table 229.17) and those most commonly involved in nosocomial infections are *A. faecalis* and *A. xylosoxidans*.

Pathogenic role

Alcaligenes spp. have been isolated from blood, feces, sputum, urine, cerebrospinal fluid, wounds, burns and swabs taken from throat, eyes and ear discharges. *Alcaligenes* spp. strains do not seem to possess any specific virulence determinants. They are infrequent causes of hospital-acquired infection in patients who have severe underlying disease. Rare cases of peritonitis, pneumonia, bacteremia, meningitis and urinary tract infections are found in the literature. In many instances the organism is considered to be a colonizer. Nosocomial outbreaks of infection are usually associated with an aqueous source of contamination.[30] Recent findings have underlined the fact that *Alcaligenes* spp. are predominantly isolated from respiratory tract specimens and that recovery of these organisms from the sputum of CF patients is associated with an exacerbation of pulmonary symptoms.[31]

Management

Alcaligenes spp. are resistant to aminoglycosides, chloramphenicol and tetracyclines; they are variably susceptible to trimethoprim-sulfamethaxazole and newer ß-lactams. *Alcaligenes xylosoxidans* has been shown to be susceptible to ureidopenicillins, latamoxef, imipenem and some fluoroquinolones (ciprofloxacin, ofloxacin). There have been several reports of multiple ß-lactam resistance to broad-spectrum penicillins in *A. xylosoxidans* due to constitutive ß-lactamase production; three different types of cephalosporinase and the presence of other ß-lactamases have been demonstrated. [32] [77] Treatment of *Alcaligenes* infection requires combination therapy including expanded-spectrum ß-lactams (piperacillin, imipenem) and recent fluoroquinolones (ciprofloxacin, sparfloxacin) or trimethoprim-sulfamethaxazole.

BERGEYELLA spp.

See *Weeksella* spp.

CALYMMATOBACTERIUM sp.

One known species, *Calymmatobacterium granulomatis*, an aerobic Gram-negative bacillus, remains of uncertain taxonomy. The only reservoir of the organism is humans and its main epidemiologic characteristic is its presence intracellularly in macrophages of the lesions in donovanosis (granuloma inguinale). This sexually transmitted disease is endemic in Asian countries, India, South America, Australia and Africa. *Calymmatobacterium* has not been cultured yet (only 15 successful isolations) since it does not grow on conventional media; knowledge on the microbiology of this organism is limited. The diagnosis is based on bacterial inclusions found in biopsies (Giemsa or Wright staining). Extensive granuloma inguinale is seen in pregnant women and in HIV patients. Antibiotic treatment requires lipid-soluble drugs that can penetrate intracellularly and the first-line therapy is a combination of trimethoprim-sulfamethoxazole, tetracycline or thiamphenicol. Additional options include lincomycin, chloramphenicol or gentamicin. [72] [78]

CAPNOCYTOPHAGA spp.

These Gram-negative, strictly aerobic organisms are oxydase- and catalase-negative (group DF-1) or positive (group DF-2). Group DF-1 includes three species — *Capnocytophaga ochracea, Capnocytophaga gingivalis* and *Capnocytophaga sputigena* (see Table 229.18) — found as commensals of the human oral cavity. They can be responsible for cervicofacial infections and, in patients who have valvular lesions or prosthetic valves, endocarditis and bacteremia. *Capnocytophaga canimorsus*, a commensal of the oral cavity of dogs, has been cited as responsible for human infection after dog bites (septicemia, endocarditis).

These bacteria grow easily on blood agar and identification is based on conventional tests. Treatment of infection uses penicillins, cephalosporins, clindamycin and fluoroquinolones but *Capnocytophaga* spp. are resistant to aminoglycosides.[72]

Figure 229-9 Colonies of *Flavobacterium-Chryseobacterium* group grown on Mueller-Hinton agar. *Courtesy of Professor H Monteil.*

CHROMOBACTERIUM spp.

These bacteria of uncertain taxonomic position and designation have a limited pathogenic role. They are motile by one to four subpolar flagella. Grown on agar plates, colonies are violet and the bacterium has some fermentative activities on sugars and is proteolytic. Found in soil and water in tropical countries, *Chromobacterium violaceum* is occasionally pathogenic in humans, causing occasional pyogenic or septicemic infection.[2] [15]

CHRYSEOBACTERIUM spp.

Chryseobacterium spp. (formerly *Flavobacterium* spp.; see Table 229.1) are ubiquitous organisms that can be found in the hospital environment. Epidemiologic studies have traced the bacterial source to contaminated water, ice machines and humidifiers. Phenotypic markers used for the delineation of outbreaks of *Chryseobacterium meningosepticum* infections were serology based on the O antigenic type; nine O serovars have been identified (A–H and K).

Microbiology

These organisms grow at between 41°F (5°C) and 86°F (30°C) and strains isolated from human specimens can grow at 98.6°F (37°C). On nutrient agar they produce colonies of 1–2mm in diameter, which are frequently pigmented light yellow or yellowish orange (nondiffusible pigment; Fig. 229.9). The metabolism is strictly aerobic and sugars are metabolized by the oxidative pathway — except for *Chryseobacterium odoratum (Myroides odoratus)* and *Sphingobacterium multivorum*, which do not acidify glucose. Indole-positive species (i.e. *Empedobacter breve, C. meningosepticum, Chryseobacterium gleum*) are usually strongly proteolytic; esculin, citrate and urease tests are variably positive (see Table 229.17). [15] [28] [29] [72] [73]

Clinical manifestations

Infections due to Chryseobacterium meningosepticum *and* Chryseobacterium indologenes

These have been isolated in sepsis, meningitis and endocarditis. Meningitis due to *C. meningosepticum* (still designated under its previous name, *Flavobacterium*) has been often observed in neonates but infrequently in immunocompromised patients.[28] [29] [19] *Chryseobacterium meningosepticum* has been isolated from adults suffering from pneumonia, postoperative bacteremia and meningitis, usually in patients who had severe underlying pathologies.[29] [19] Rare cases of community-acquired *C. meningosepticum* pneumonia have been cited in the literature.[79]

Infections with *Flavimonas oryzihabitans* (an emerging Gram-negative aerobic bacillus previously designated *Pseudomonas oryzihabitans* and closely related to *Chryseobacterium* spp.; see Table 229.1) have been reported.[80] *Chryseobacterium indologenes* has been cited in association with infections due to indwelling devices.[29] *Chryseomonas luteola* (previously designated *Pseudomonas luteola*), *Comamonas testosteroni* and *Comamonas acidovorans* have been implicated in bacteremia, catheter infections, prosthetic valve endocarditis and peritonitis in patients who are being treated with continuous ambulatory peritoneal dialysis.[72]

Management

These bacteria are generally resistant to aminoglycosides (MIC >16mg/l), third-generation cephalosporins, antipseudomonal penicillins (mezlocillin, piperacillin, ticarcillin), aztreonam, imipenem, erythromycin and tetracycline. The most active antibiotics are rifampin and clindamycin (MICs 1–4mg/l). Ciprofloxacin has proven effective for treating pneumonia in pediatric patients. Cases of neonatal sepsis have been treated with clindamycin combined with piperacillin.[73] [81] Susceptibility to ß-lactams can be recovered by combining ß-lactamase inhibitors with ß-lactam antibiotics.

COMAMONAS spp.

These aerobic Gram-negative oxydase-positive bacilli are seldom implicated in human infections. Rare cases of catheter-induced bacteremia (*C. testosteroni, Delftia acidovorans*), conjunctivitis (*C. testosteroni*) and otitis media (*D. acidovorans*) have been cited in the literature. These straight or slightly curved rods are motile by means of tuft of polar flagella. They grow easily on standard media and are susceptible to piperacillin, cefotaxime, imipenem and ciprofloxacin.[72]

OCHROBACTRUM spp.

Derived from the genus *Achromobacter*, two species have been recognized as having a medical role, *Ochrobactrum anthropi* and *Ochrobactrum intermedium*. These environmental organisms are considered as opportunistic pathogens. A few recent publications have pointed out their role in nosocomial infections, induced by contaminated catheters.[72] [82] Endocarditis, postoperative cases of endophthalmitis and necrotizing fasciitis have been cited as well. These nonfastidious bacteria are easily grown on conventional media and identified by using classical biochemical tests. The major problem regarding these organisms is their resistance to most ß-lactams, since they produce ß-lactamases of AmpC class 1. They are susceptible to imipenem, aminoglycosides and fluoroquinolones but strains of *O. intermedium* have been cited as resistant to tobramycin and colistin.

OLIGELLA sp.

This genus was created in 1987 and *Oligella urethralis* was derived from *Moraxella urethralis*. These small rods, often occurring in pairs, develop slowly on blood agar and exhibit a limited metabolic activity. They are oxidase- and catalase-positive. Their potential pathogenic role is limited to the genitourinary tract.[72]

PLESIOMONAS sp.

Only one species, *Plesiomonas shigelloides*, until recently designated *Proteus shigelloides*, is present in the environment (water, soil) in tropical and subtropical areas. Its pathogenic role in humans is controversial but rare cases of gastroenteritis, septicemia and neonatal meningitis have been cited in Japan and the USA. Raw oysters and contact with contaminated water or with aquatic animals have been implicated. *Plesiomonas* sp. is not a strictly aerobic organism and may grow on selective media used for isolation of Enterobacteriaceae. Its production of oxidase and other biochemical characteristics

permit its identification. Antibiotic testing of *P. shigelloides* shows a general resistance to penicillins and aminoglycosides but this organism is susceptible to cephalosporins, imipenem and fluoroquinolones, the latter antibiotics being very active in treating gastrointestinal infections.[83]

RALSTONIA spp.

Ralstonia picketii was derived from *Burkholderia picketii* or *Pseudomonas picketii,* and *Ralstonia eutropha* from *Alcaligenes eutrophus* (see Table 229.18). Both are emerging pathogens isolated from infections in immunodepressed patients or from respiratory tract infections in CF patients.[72] [73]

SHEWANELLA spp.

Derived from *Alteromonas* spp. or *Pseudomonas* spp., *Shewanella putrefaciens* belongs to the Vibrionaceae class but grows in media used for Enterobacteriaceae and produces SH_2 , which may result in confusions with *Salmonella* spp. or *Proteus* spp. This bacterium is present in the environment and has been isolated from otitis media, intra-abdominal infections and bacteremia, most cases occurring in immunodepressed patients. Treatment of these infections is based on third-generation cephalosporins, imipenem, ciprofloxacin, aminoglycosides, trimethoprim-sulfamethoxazole and tetracyclines. [72]

SPHINGOBACTERIUM spp.

Two species (see Table 229.18) of *Sphingobacterium* are derived from *Flavobacterium* spp. (see Table 229.1). They are characterized by colonies that develop a yellow pigment after a few days at room temperature. Their presence in the hospital environment and in most aquatic sources is frequent but their clinical significance is limited to rare cases of opportunist infection.

WEEKSELLA spp.

Designated currently *Bergeyella* spp. and deriving from *Flavobacterium* spp., these organisms include *Weeksella virosa* (see Table 229.1) and *Weeksella zoohelcum*. Both grow as pigmented colonies (brown or yellow). Their pathogenic role is doubtful and is limited to local infection after animal bites or genitourinary tract infection.[73]

Chapter 230 - Curved and Spiral Bacilli

Francis Mégraud
Steven FT Thijsen

INTRODUCTION

The curved and spiral bacilli are a heterogeneous group of bacteria that share little morphology.

Helicobacter pylori was previously called *Campylobacter pylori*[1] and in the first part of the 20th century *Campylobacter* was called *Vibrio. Campylobacter, Helicobacter* and *Vibrio* spp. all produce infections of the gastrointestinal tract. Moreover, they are all Gram-negative organisms and have a similar, curved shape. Using nucleic acid sequence determination of 16S rRNA, the genera *Campylobacter* and *Helicobacter* have been classified (together with *Arcobacter, Sulfurospirillum* and *Wolinella*) as members of the superfamily VI of Gram-negative bacilli (Table 230.1).[2] Only those bacteria belonging to this superfamily that are involved in human infections are discussed in this chapter.

Treponema, Borrelia and *Leptospira* are all members of Spirochaetales. These spirochetes are thin, helical, Gram-negative bacteria.

CAMPYLOBACTER SPP., *HELICOBACTER PYLORI* AND *VIBRIO CHOLERAE*

CAMPYLOBACTER SPP.

Nature

Campylobacter spp. are micro-aerophilic, Gram-negative, curved rods which obtain their energy by using fatty acids and amino acids rather than carbohydrates, and are adapted to life in mucus of the digestive tract. With the genera *Arcobacter* and *Sulfurospirillum*, they form the family *Campylobacteraceae*. At least 15 species and six subspecies have been differentiated. Not all, however, cause disease in humans.[3] *Campylobacter jejuni* and *Campylobacter coli* are responsible for enteric infections and are the most common Campylobacters found in humans. *Campylobacter fetus* is the third most frequently isolated, but is mostly involved in systemic diseases. The other species (*Campylobacter lari, Campylobacter upsaliensis*) occur only anecdotally. They also lead to enteric infections.

Epidemiology

Campylobacter spp. infections can be considered as zoonoses, because the primary reservoir for *Campylobacter* spp. is animals. These bacteria are essentially present in the digestive tract of animals, especially birds, where they do not cause disease. They can cause septic abortion in cattle. Humans can become infected by ingesting contaminated food or water or through contact with infected animals, including pets. The majority of *Campylobacter* spp. infections are sporadic, although outbreaks do occur. *Campylobacter* enteritis is generally more common than *Salmonella* and *Shigella* enteritis and is a major cause of travelers' diarrhea. Infections can be caused by the ingestion of undercooked, contaminated poultry or contaminated milk as well as by cross-contamination of foods which will be consumed raw. It has been estimated that there are 2.4 million cases annually in the USA.[4] Transmission of the disease from human to human has also been described but seldom occurs. In temperate countries there is a peak incidence in summer and early autumn, although infections occur throughout the year.[5] The highest incidence is found in infants and young children, with a second peak in young adulthood. The incidence in developing countries, with less hygienic living conditions, is even higher than in developed countries and direct transmission from poultry to humans seems to occur.

Pathogenesis

Campylobacter bacilli are acid sensitive. Because of the relative barrier imposed by the gastric acid environment, infection is more likely to occur when large numbers of bacteria are ingested. Histologic examination of gut biopsies obtained from patients who have *Campylobacter* enteritis reveals inflammation and edema of the mucosa, with infiltration of neutrophils in the lamina propria. Lesions are mainly restricted to the ileum and colon.

In vitro co-culture of epithelial cells with *C. jejuni* has shown that these bacteria can adhere and penetrate into the cells. Pili, flagellin (major antigen), outer membrane proteins and lipopolysaccharides (LPS) could play the role of adhesins. *C. jejuni* is also able to synthesize proteins which may play a role in internalization and cytoskeletal rearrangement. *C. jejuni* can survive in vacuoles and induce IL-8 synthesis. Its translocation may occur by transcellular as well as paracellular means.[6] In addition, *C. jejuni* produces a cytolethal distending toxin (cdt) acting on the cell cycle and leading to apoptosis. Nevertheless, the numerous pathogenicity studies performed have not determined a specific mechanism. Recent knowledge of the whole genomic sequence of *C. jejuni* [7] should bring insight to this field. The molecular mimicry of human ganglioside with the LPS molecules present in strains of *C. jejuni* expressing the O:19 antigen has been implicated in the association of *C. jejuni* infection with the Guillain-Barré syndrome.[8]

Immune persons in endemic areas, where infections are frequent, can become asymptomatic carriers. Infection can have a protracted course in the case of reduced resistance, such as in patients suffering from hypogammaglobulinemia. In HIV-infected patients, opportunistic infections with atypical *Campylobacter* spp. also suggest a role for cellular immunity.

An interesting mechanism to avoid elimination by the immune system has been discovered for *C. fetus*. Almost all *C. fetus* strains express a surface protein that abrogates complement C3b binding. This prevents opsonization, thereby conferring resistance to killing by phagocytes and adding to the pathogenicity of the species.[9]

Prevention

Preventive measures for *Campylobacter* spp. infections include adequate disinfection of drinking water supplies, adequate heating of contaminated food and reinforcement of hygiene in the kitchen in order to avoid cross-contamination. Eradication of the animal reservoir is impossible but adequate measures taken in poultry farms and abattoirs can decrease the level of contamination. Development of vaccines is an alternative. Research in this direction has been boosted

TABLE 230-1 -- Clusters of the rRNA VI superfamily of Gram-negative bacilli.*

CLUSTERS OF THE rRNA VI SUPERFAMILY OF GRAM-NEGATIVE BACILLI		
rRNA group I	**rRNA group II**	**rRNA group III**
Campylobacter jejuni	*Arcobacter butzleri*	*Helicobacter pylori*
Campylobacter coli	*Arcobacter cryaerophilus*	*Helicobacter acinonyx*
Campylobacter hyointestinalis	*Arcobacter nitrofigilis*	*Helicobacter bilis*
Campylobacter fetus	*Arcobacter skirrowii*	*Helicobacter bizzozeronii*
Campylobacter upsaliensis		*Helicobacter canis*
Campylobacter concisus		*Helicobacter cinaedi*
Campylobacter curvus		*Helicobacter felis*
Campylobacter gracilis		*Helicobacter fennelliae*
Campylobacter helveticus		*Helicobacter hepaticus*
Campylobacter hyoilei		*Helicobacter muridarum*
Campylobacter lari		*Helicobacter mustelae*
Campylobacter mucosalis		*Helicobacter nemestrinae*
Campylobacter rectus		*Helicobacter pametensis*
Campylobacter showae		*Helicobacter pullorum*
Campylobacter sputorum		CLO-3
Bacteroides ureolyticus		*Gastrospillum hominis*
		Wolinella succinogenes
B. ureolyticus is placed in this group based on 16S rRNA. CLO, *Campylobacter*-like organism.

by the discovery of an association between *Campylobacter* enteritis and the Guillain-Barré syndrome, because the latter can cause permanent disability in a significant number of cases. Vaccines using killed whole-cell preparations have been successful in animal models and experiments with humans are under way. [10]

Diagnostic microbiology

The curved motile rods can be demonstrated in a fecal sample using Gram staining or dark-field microscopy. Culturing *Campylobacter* spp. necessitates special conditions, sometimes difficult to implement.[11] Cultures are commonly performed with an atmosphere comprising 5% oxygen, 10% carbon dioxide and 85% nitrogen. Some species, such as *Campylobacter rectus* and *Campylobacter hyointestinalis*, also require hydrogen in the atmosphere for growth. Selective culture media contain antibiotics such as cefoperazone to suppress the growth of normal intestinal bacteria and blood or charcoal to neutralize inhibiting factors such as oxygen radicals. Commonly used media are Skirrow's, Butzler's, Campy (cefoperazone-vancomycin-amphotericin) agar and cefoperazone charcoal deoxycholate agar. An important disadvantage of selective media is that bacteria such as *C. hyointestinalis, C. fetus* and *C. upsaliensis*, which are sensitive to antibiotics used in these selective media, can be missed. To circumvent this problem, membrane filtration of feces can be performed to eliminate contaminants followed by culturing on nonselective media. However, this filtration technique is less sensitive than direct plating.

Although the most important species (i.e. *C. jejuni* and *C. coli*) grow at 107.6°F, some species (i.e. *C. fetus*) grow best at 98.6°F and will be missed when cultures are only incubated at 107.6°F. Typically, colonies with a gray color and growing flat and confluently are visible after 2–3 days of culture. Definite identification of suspect colonies is performed using standard biochemical tests showing positive oxidase and catalase tests for *C. jejuni* and *C. coli*.

Campylobacter jejuni is the only *Campylobacter* spp. that is capable of hydrolyzing hippurate, which is essential for its differentiation from other Campylobacters, especially *C. coli*. Growth at 77°F is essential for diagnosing *C. fetus*. Given the high level of resistance of Campylobacters to quinolones, the nalidixic acid susceptibility test is no longer a key test in *Campylobacter* identification. Molecular identification (PCR, sequencing) is now being performed more frequently in this group of bacteria.

The presence of *Campylobacter* spp. can also be determined using PCR directly on feces. Typing of isolates is important for epidemiologic studies. More than 60 serotypes of *C. jejuni* and *C. coli* have been identified with the Penner O typing system but molecular typing methods are now commonly used, including PCR-RFLP of *fla* genes, macrorestriction of the genome and AFLP.[12] Serology can also be helpful in diagnosing a *Campylobacter* spp. infection because serum IgG and IgM levels start to rise in response to infection 5 days after infection and reach a peak 2–4 weeks later. This is the essential method to diagnose the Guillain-Barré syndrome due to *C. jejuni*. Immunoglobulin A is also produced and excreted in the gut lumen.

Clinical features

Most *Campylobacter* spp. infections manifest as acute enteritis.[13] The ensuing diarrhea can vary from modest to voluminous stools that may be watery or bloody. The infection can also run a subclinical course, especially in hyperexposed populations. Disease will develop 1–3 days after ingestion of the bacilli and symptoms usually disappear after 1 week. Stool samples typically remain positive for *Campylobacter* spp. for several weeks. In most cases, *Campylobacter* enteritis is a self-limiting disease and it tends to be more severe in patients at the extreme ends of age. Fever, malaise and abdominal pain may precede diarrhea or may be the most predominant signs. Infection with *Campylobacter* spp. gives rise to inflammation of the gut mucosa. The accompanying pain and fever may also lead to disease resembling Crohn's colitis or ulcerative colitis. When pain is the major feature of the infection, differentiation from appendicitis may be difficult. When fever is the major feature, differentiation from *Salmonella* enteritis may be difficult. *Campylobacter jejuni* can grow in bile and can occasionally cause acute cholecystitis and pancreatitis. [14]

Only a few patients who have a *C. jejuni* infection develop systemic disease. Bacteremia can occur, but this is considered rare and generally occurs in patients who have an underlying disease.[15]

As with other pathogenic bacteria, a postinfectious syndrome may occur after *C. jejuni* infection. One is an acute reactive arthritis which is very similar to the complication seen after enteritis caused by *Salmonella* spp., *Shigella* spp. or *Yersinia* spp. and is associated with the presence of the HLA-B27 antigen.

Another important complication of *Campylobacter* enteritis is the Guillain-Barré syndrome. This syndrome is an acute demyelinating disease affecting the peripheral neurons and is characterized by an ascending paralysis. [8] *Campylobacter jejuni* enteritis is the infection most frequently observed before Guillain-Barré syndrome and occurs in 20–40% of cases. The risk of developing Guillain-Barré syndrome after *Campylobacter* spp. infection is estimated at 1 per 2000 infections. Major neurological sequelae exist in 20% of the cases.

Campylobacter coli infections are very similar to infections with *C. jejuni*, but they tend to follow a less severe course.

Infections with *C. fetus* tend to disseminate from the intestine, especially in patients who have conditions that cause impaired immunity, such as chronic alcoholism, diabetes mellitus, malignancies and HIV infection, and in the elderly. Systemic *C. fetus* infections can lead to endocarditis, thrombophlebitis, meningitis and septic abortion.

Campylobacter upsaliensis, C. lari and *C. hyointestinalis* can also cause enteritis. *Campylobacter consisus, C. gracilis, C. curvus, C. mucosalis, C. rectus, C. showae, C. sputorum* and *Bacteroides ureolyticus* can be associated with periodontal infections.

Management

Disease management is primarily symptomatic. Depending on the severity of the diarrhea, fluid replacement can be performed with oral rehydration fluids or with saline infusions. Antibiotic intervention is especially effective early in the disease and is of benefit in cases of prolonged illness, recurrent disease and secondary sepsis, for example in patients who have reduced resistance. The first-choice antibiotic is erythromycin (500mg q6h orally for 2 weeks) or another macrolide, resistance being low for this class of antibiotics. Ciprofloxacin (500mg q12h orally for 2 weeks) can also be used, but a high incidence of resistance to quinolones exists (see Chapter 43). Other alternatives include tetracycline and amoxicillin-clavulanic acid. Gentamicin in association with amoxicillin-clavulanic acid is the antibiotic of choice for systemic diseases.

HELICOBACTER PYLORI

Helicobacter pylori was cultured for the first time in 1982, from the stomach which was previously thought to be sterile. [16] Currently this bacterium is considered to be the most important bacterium responsible for chronic infections. It is also the first bacterium known to be involved in a cancer in humans.

Nature

Helicobacter spp. are spiral-shaped, Gram-negative bacilli with between five and seven terminal flagella. They are micro-aerophilic and use amino acids and fatty acids rather than carbohydrates to obtain their energy. At present, about 17 species of *Helicobacter* have been identified, only eight of which cause disease in humans (Fig. 230.1). *Helicobacter pylori* is the third bacterium for which the entire genome has been sequenced[17] and the first for which the genome of two strains has been sequenced.[18]

Epidemiology

The prevalence of an *H. pylori* infection is strongly linked to the socio-economic level of the community.[19] The infection rate decreases as the socio-economic level increases. Infection usually occurs in childhood and the bacilli persist in the stomach for decades and possibly for life. The socio-economic level of the family into which a child is born and raised is a more important risk factor than his or her socio-economic status in adult life. The corresponding risk factors are poor sanitation, poor education and sharing a bed.[20] Given the substantial improvement in socio-economic conditions in

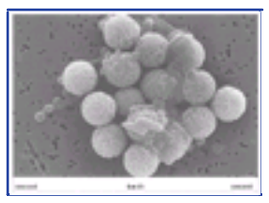

Figure 230-1 Cultured *H. pylori* in coccoid and bacilli forms, bound to immunomagnetic beads. *Adapted from Murray et al.* [106]

developed countries during recent decades, there has been a gradual decrease in the acquisition of the infection. Because the infection is lifelong, a cohort effect is present: the oldest people in a population are infected more often than the youngest. [21]

The current prevalence of *H. pylori* infections in the 20–29 year age group in Europe shows a gradient decreasing from east to west and from south to north. The prevalence in young adults in Western countries does not exceed 20%. The incidence of *H. pylori* infection is low in adulthood (less than 0.5%), but higher in developing countries than in the West. Although the source of the infection is known (i.e. the stomach of humans), the mode of transmission remains uncertain: it may be fecal-oral or oral-oral. Vomiting may play an important role.

Pathogenesis

Helicobacter pylori is adapted to the acid milieu of the stomach: it produces urease, which breaks down the urea diffusing from the mucosa and buffers the pH around the bacterium. *Helicobacter pylori* moves into the mucus and produces different kinds of adhesins that allow it to adhere very specifically to mucus cells. *Helicobacter pylori* appears in the duodenum when metaplasia of these mucus cells is present and disappears from the stomach when intestinal metaplasia is present.

Helicobacter pylori can persist by escaping host-defense mechanisms. For example, it synthesizes catalase and superoxide dismutase enzymes, which destroy bactericidal products from inflammatory cells. Moreover, urease increases the pH of the phagolysosomal compartment, thereby disturbing phagocyte function. It has also been proposed that the large amount of released antigens could saturate local antibodies. In addition, *H. pylori* triggers a response from T helper (TH)l lymphocytes with IgG production and inflammation, whereas a TH2 lymphocyte response would be more appropriate.[22]

Helicobacter pylori strains do not all share the same virulence factors; some produce the vacuolating cytotoxin A (VacA) and some possess a pathogenicity island. VacA may be responsible for the epithelial cell damage observed in *H. pylori* infection. The main action of VacA is on the mitochondria, vacuole formation being the consequence of the late endocytosis compartment when weak bases are present, in this case, NH_4 Cl. [23] The sequence of the *vacA* gene is not homogeneous. There are two main regions of variation: the signal sequence (s) and the midregion (m). Typing has been proposed: s1-ml, s1-m2 and s2-ml, corresponding to high, low and no production of toxin, respectively. The pathogenicity island is named *cag* and has the *cagA* gene as a marker. It is a 40kB fragment containing 27–31 open reading frames. Six of them have sequence similarities to genes coding for a type IV secretion system, i.e. a complex protein structure that allows the bacterium to inject compounds into eukaryotic cells. The CagA protein is one of them which is phosphorylated and leads to a reorganization of the actin cytoskeleton. The other effect associated with the *cag* pathogenicity island is an increased production of IL-8 via an NF?B pathway.[24] Nevertheless, *cag*-negative *H. pylori* also induce inflammation, which stresses the fact that other factors present in all *H. pylori* strains may also be involved. Lipopolysaccharide moieties of the outer membrane of *H. pylori* may be identical to Lewis x and y antigens. Such antigen mimicry could confer autoimmunity and play a role in the pathogenesis of, for example, gastric atrophy.[25]

Prevention

Because the route of transmission is unclear, it is difficult to take preventive measures. The first attempts at developing a vaccine using recombinant urease as the only antigen have not been successful in humans. Other vaccine candidates antigens are under study. Mucosal administration seems to be the most popular route.

Diagnostic microbiology

Invasive methods for diagnosing *H. pylori* infection depend on endoscopy to obtain biopsies. These biopsies can then be processed for histological examination and stained with hematoxylin-eosin, Giemsa stain or silver stain. *Helicobacter pylori* is usually abundant and its typical morphology and the presence of polymorphs make diagnosis easy. The use of immunoperoxidase staining can be considered when atypical bacilli are detected. The examination of a smear is quick and can be performed in the endoscopic ward using either dark-field examination of a wet smear or Gram staining.

Because *H. pylori* is a fragile organism, transport conditions are extremely important for culture. Biopsies can be transported in saline for 3–4 hours, but (commercially) available transport medium must be used if preservation up to 24 hours is necessary. The media must be maintained at a low temperature (<50°F) before plating. Biopsies must be ground with a homogenizer and plated on media enriched with 5–10% blood and antibiotics to inhibit growth of nonrelevant bacteria. The plates must then be incubated for up to 10 days in a micro-aerobic atmosphere. Growth usually occurs within 3–4 days. *Helicobacter pylori* colonies are easily identified by their morphology and their urease, catalase and oxidase activities.

The urease test is specific for *H. pylori*. A color change is observed if *H. pylori* urease is present when the biopsy is introduced into a medium containing urea and a pH indicator. Tests using semisolid agars show an optimal sensitivity after 24 hours. In contrast, strip tests show a high sensitivity after just 2 hours.

Polymerase chain reaction for diagnosing *H. pylori* infection does not require specific transport conditions and can be performed with a urease test kit sent by mail. Several genes can be targeted: urease, 16S rRNA, 29kDa antigen, *cagA* gene or *vacA* gene. Recently a real-time PCR has been developed which allows detection of both *H. pylori* and its resistance to macrolides. Primers target the 23S rRNA gene and the dissociation curve of the hybrids indicates the mutation present.

Less invasive methods for obtaining material are aspiration of gastric juice or a capsulated string. Diagnosis can also be made using noninvasive tests. The urea breath test measures urease production by *H. pylori*. Samples of breath air are collected by having the patient blow into a tube before and 30 minutes after ingestion of ^{13}C-labeled urea. The tubes can be maintained for months and sent by mail to a laboratory that has a mass spectrometer in order to measure the ^{13}C:^{12}C ratio.

Antibodies are mainly detected by enzyme-linked immunosorbent assay (ELISA). There are numerous kits commercially available. Immunoblot methods can also be used.

Detection of specific antibodies has also been proposed but shows a lower sensitivity than in blood. It is also possible to detect *H. pylori* antigens in stools using ELISA. Polyclonal antibodies were first used as a reagent. A second generation of tests employs monoclonal antibodies and gives excellent results.

Since none of the tests are perfect in terms of sensitivity, a combination of tests is recommended.[26] All these tests have a comparable sensitivity except for the smear examination, the agar-based urease and rapid serology tests which are inferior. The urea breath test is ideal for follow-up after eradication therapy. Serology cannot be used for this purpose because the antibody titer may be high for months after the disappearance of *H. pylori*.

Clinical features

The presence of *H. pylori* in the stomach is always accompanied by inflammation of the mucosa. However, this infection is not always symptomatic. Duodenal ulcer, gastric ulcer, gastric carcinoma, gastric lymphoma and some nonulcer dyspepsia syndromes can develop. Symptoms of these diseases (e.g. epigastric pain and dyspepsia) are not specific.

Duodenal ulcer

Duodenal ulcer occurs in subjects who are infected by *H. pylori* and also have gastric metaplasia in the duodenal bulb, which will be colonized with *H. pylori*.[27] Hyperproduction of acid following a decrease in somatostatin, and an increase in gastrin production are observed. Antral gastritis is the usual pattern of histological lesions. Smoking and infection with *cag*-positive *H. pylori* strains are important risk factors.

Gastric ulcer

In contrast, gastric ulcer occurs in patients who have multifocal gastritis or pangastritis leading to a decreased acid production by the corpus. The lesions have been

explained by a retrodiffusion of hydrogen ions in the gastric wall. A vascular factor is also probably important. Gastric ulcer in Western countries is about five times less frequent than duodenal ulcer and occurs in older people. Smoking, dietary factors (e.g. high salt intake) and infection with *cag*-positive *H. pylori* strains are important risk factors. In some instances, gastric ulcer may be a precursor of gastric carcinoma, motivating endoscopic follow-up.

Gastric carcinoma

The incidence of gastric carcinoma is currently decreasing in developed countries. This decrease has been attributed to a decrease in the rate of *H. pylori* infection. Indeed, gastric carcinoma is virtually absent when gastric mucosa is normal.[28] Most gastric carcinomas are of the intestinal type and are thought to result from chronic gastritis followed by atrophy, intestinal metaplasia and dysplasia ultimately leading to carcinoma. These events occur over several decades. They can be reproduced in an animal model, the Mongolian gerbil infected with *H. pylori*. [29] A very early acquisition of the bacterium, infection with *cag*-positive strains and dietary factors (e.g. high salt consumption and low vitamin intake) are risk factors for this evolution. The diffuse type of gastric cancer does not follow the pattern described above, but it is associated with *H. pylori* infection.

Gastric lymphoma

Gastric lymphoma involves mucosa-associated lymphoid tissue (MALT). The stomach is normally free of lymphoid follicles; they only occur when *H. pylori* is present.[30] T cells stimulated by *H. pylori* antigens trigger a monoclonal B-cell proliferation, giving rise to lymphoid follicles. *H. pylori* infection is responsible for 80% of gastric MALT lymphoma.

Nonulcer dyspepsia

Nonulcer dyspepsia occurs in dyspeptic patients in whom no organic lesion is found at endoscopy. *Helicobacter pylori* is found in about 50% of the cases in Western countries. In most of these cases, however, the presence of *H. pylori* is probably incidental, with only about 10% of cases being the consequence of *H. pylori* infection.[31]

Other diseases

Helicobacter pylori infection has been implicated in children's diseases including iron deficiency anemia, growth retardation and recurrent abdominal pain. It may also be a risk factor for myocardial infarction, possibly because of the long-lasting chronic inflammation induced.[32]

Management

Eradication of *H. pylori* in duodenal ulcer and gastric ulcer avoids relapses, increases the healing process and normalizes the mucosa and gastric physiology. In low-grade gastric MALT lymphoma, eradication

---

leads to a disappearance of the lesions. Nevertheless, follow-up is needed for several years. Eradication of *H. pylori* at an early stage can have a positive effect in gastric carcinoma. Nevertheless, surgery and other cancer treatments remain essential.

The optimal regimen to eradicate *H. pylori* consists of two orally administered antibiotics for 7–10 days with an antisecretory drug. The combinations favored are:

- clarithromycin (500mg q12h) and amoxicillin (1g q12h), or
- clarithromycin (250mg q12h) and metronidazole (500mg q12h).

Most studies have been performed with omeprazole. However, lansoprazole and pantoprazole and rabeprazole are also effective. A double dose of proton pump inhibitors is also usually given.[33] Currently, resistance to amoxicillin is seldom found, whereas resistance to macrolides occurs in up to 20% of the strains and resistance to metronidazole in 10–80%. Follow-up is performed 4–6 weeks after treatment has been stopped.

In case of failure, the recommended second-line treatment is a quadruple therapy with metronidazole, tetracycline, bismuth salts and a proton pump inhibitor for a week, or the use of the new compound ranitidine-bismuth citrate, plus two antibiotics.[33] The use of dual therapy (e.g. a proton pump inhibitor with amoxicillin or clarithromycin) is no longer recommended. The main risk factors for treatment failure are the resistance of *H. pylori* and lack of patient compliance (see Chapter 42 for further discussion on gastritis).

VIBRIO CHOLERAE

Nature

Vibrio cholerae is a Gram-negative, comma-shaped rod belonging to the family *Vibrionaceae*. Its natural habitat consists of fresh-water and salt-water environments. Based on differences in the composition of the major cell wall antigen (O), 139 serotypes have been differentiated. *Vibrio cholerae*, which belongs to either serogroup O1 or serogroup O139, has been associated with epidemic cholera. *Vibrio cholerae* serogroup O1 can be subdivided into El Tor and classic biotypes as well as the Ogawa, Inaba and Hikojima serotypes. Other serogroups of *V. cholerae*, in addition to nontoxigenic *V. cholerae* O1 or O139, do not cause epidemic cholera; they may, however, cause individual cases of diarrhea (see Chapter 43).

Epidemiology

Cholera has raged in seven pandemics since 1817. It is possible that an eighth is superimposed on the seventh. The fifth and sixth pandemics have been explored and were caused by the classic biotype and originated in the Indian subcontinent. The seventh and current one is caused by the El Tor strain and began in 1961 in Indonesia. It has gradually affected most of Asia and Africa and is found incidentally in parts of Europe. In 1991, this pandemic reached South America and has since spread throughout Latin America (Fig. 230.2).[34] Persons who have blood group O are at higher risk of El Tor cholera than those with blood group A, B or AB.[35] This is particularly important for Latin America, where 73% of the population carries the blood type O. An episode of classic cholera protects nearly entirely against recurrent cholera of either biotype, but an episode of El Tor cholera does not protect against future attacks. In 1992, a novel *V. cholerae* variant O139 (synonym Bengal), which has the same origin as the El Tor strain, emerged in southern Asia. This 1992 epidemic was the first one caused by a serogroup other than O1, and it occurred in populations assumed to be largely immune to *V. cholerae* O1. The impact of a *V. cholerae* O139 infection on the risk of a subsequent *V. cholerae* infection, either O1 or non-O1, has not yet been determined. The Bengal strain has the potential to spread pandemically. It has now affected areas throughout the Indian subcontinent, neighboring states and other

Figure 230-2 Spread of the *Vibrio cholerae* O1 El Tor pandemic in Central and South America, 1991–94. *(Adapted from Tauxe et al. [35])*

parts of Asia. Cases occurring as far away as the USA and Western Europe have also been described.

V. cholerae, including serogroups O1 and O139, exist as natural inhabitants of aquatic ecosystems and are therefore facultative human pathogens. Within the marine environment they attach to zooplankton and are able to form biofilm, facilitating environmental persistence. It was suggested but largely debated that *V. cholerae* can switch into a viable but nonculturable state. It is likely that the aquatic environment harbors different virulence-associated genes scattered among environmental vibrios, which possess a lower virulence potential than the epidemic strains. The clustering of such genes in a proper combination could lead to the emergence of new *V.*

cholerae strains with epidemic potential.[36]

Pathogenesis

Infection starts with ingestion of water or food contaminated with *V. cholerae*. The infectious dose is high due to the acid sensitivity of the bacteria. Persons who have impaired gastric acidity or who take acid-suppressing medication have an increased risk of infection. In addition, *Helicobacter pylori* gastritis is also associated with an increased risk of cholera.[37] The surviving bacteria adhere to and colonize the small intestine epithelial cells, producing the cholera toxin and causing acute watery diarrhea. In the intestine *V. cholerae* is faced with growth inhibitory substances like bile salts and defense factors like complement, defensins, against which it has developed survival strategies. The powerful enterotoxin then released is a 68kDa protein consisting of an active (A) subunit and five binding (B) subunits. These B subunits attach to the GM1 ganglioside receptor at the lining of the mucosal cells (Fig. 230.3). The A subunit triggers a cascade of reactions involving cyclic adenosine monophosphate, prostaglandins, 5-hydroxytryptamine and calmodulin.[38] This results in an increased level of intracellular cAMP leading to an increase in intestinal chloride secretion and a decrease in sodium chloride absorption. The outcome is a passive watery excretion that leads to diarrhea. The volume typically exceeds 1 liter per hour in adults and 10ml/kg/h in children. Since cholera results from a locally acting enterotoxin, it is not accompanied by systemic manifestations caused by a cytokine-induced acute-phase reaction.

Molecular knowledge of pathogenesis has recently improved. The most important colonization factor was identified as a type IV pilus named toxin-coregulated pilus (TCP). The genes required for TCP synthesis are located on a pathogenicity island (PI) named Vibrio PI.[39]

Figure 230-3 Mechanism of action of *Vibrio cholerae* toxin. The toxin binds to the GM1 ganglioside receptor on the intestinal mucosal cell membrane via the binding (B) subunits (a). The active portion of the A subunit enters the cell and activates adenyl cyclase (b), which results in the accumulation of cyclic adenosine monophosphate (cAMP), derived from adenosine triphosphate (ATP), along the cell membrane (c). The cAMP causes active secretion of sodium (Na^+), chloride (Cl^-), potassium (K^+), bicarbonate (HCO_3^-) and water (H_2O) out of the cell into the lumen of the intestine (d). *Adapted from Murray et al.*[106]

The genes encoding the cholera toxin are enclosed by a phage named CTX integrated into the large chromosome of the two *V. cholerae* chromosomes.[40] The surface antigens (capsule, LPS, outer membrane proteins) are important virulence factors.

A unique regulatory system co-ordinates the expression of TCP and cholera toxin. Interestingly, it was recently shown that quorum sensing systems control virulence genes in *V. cholerae*.[41]

The complete genome sequence of the two chromosomes of *V. cholerae* O1 El Tor, now available,[42] will help further dissection of cholera pathogenesis.

Prevention

Cholera is difficult to eradicate from water and is likely to remain a serious threat to public health for some time. Measures to prevent cholera include separating sewage and drinking water systems, disinfection of drinking water and food, hygiene measures (e.g. handwashing with soap), active case finding and effective case management with the use of oral rehydration. Breast-feeding provides important protection to infants, not because of transmission of maternal antibodies but because of the lower exposure to contaminated food and water. During epidemics, the bodies of persons who died of cholera should be disinfected and buried rapidly and the consumption of food at gatherings, including funerals, should be discouraged. The currently licensed, parenteral, killed cholera vaccine is no longer recommended by the World Health Organization because of its limited protective efficacy. To induce mucosal immunity, oral vaccines, both inactivated (whole cell/B-subunit) and live (CVD103-HgR), have been developed; these show no side effects and a longer lasting protection than the parenteral vaccine.[43] Vaccines that include the B-subunit of the toxin provide cross-protection against heat-labile enterotoxigenic *Escherichia coli*, a result of the close relationship between the two toxins. CVD103-HgR produces higher resistance to the homologous classic strain than to the El Tor strain. Attenuation of El Tor has led to several new candidate vaccines that have proven safe and highly effective against El Tor cholera.[44] Because immunity against the O1 type is not protective against O139, *V. cholerae* O139 type vaccines are urgently needed. To date, one live, attenuated candidate vaccine, Bengal-15, has shown a protective efficacy as high as 83%.

Diagnostic microbiology

The diagnosis of cholera is confirmed when *V. cholerae* is identified in a stool culture on thiosulfate citrate bile salts sucrose agar directly or after enrichment, taking advantage of *V. cholerae*'s tolerance to alkaline conditions. For rapid diagnosis, dark-field examination of a fresh, unstained stool specimen is highly sensitive and specific: a characteristic finding is the 'shooting star' phenomenon caused by the motility of the single polar flagellum of the organism. Once identified at the species level, additional tests include serotyping for O antigens and the 3 antigen variants recognized, as well as biotyping to differentiate classic and El Tor biotypes. A rapid, colorimetric immunodiagnostic method is available for the detection of *V. cholerae* O1. The immunochromatographic strip test may be the simplest, most rapid and most sensitive and specific test for the detection of *V. cholerae*. Two rapid immunodiagnostic test kits based on the use of monoclonal antibodies have been developed for the direct detection of *V. cholerae* O139: a coagglutination test and Bengal DFA (a direct fluorescent-antibody test). In epidemic settings in developing countries, a bacteriological diagnosis is not indicated in all suspected cases because the management of dehydrating diarrhea is guided by the extent of fluid loss rather than by the nature of the infecting organism. In contrast, the diagnosis should be confirmed in individual cases of suspected cholera in the developed world.

Clinical features

In Latin America, well-established case management has kept fatality rates low (at about 1%). In contrast, cholera in Africa has been sporadic and as a result less well recognized. The fatality rates there also tend to be higher (about 10%).[45] Children are more likely to have only subclinical infection or mild diarrhea, whereas adults tend to develop more severe disease and require hospitalization. Cholera is in principle a self-limiting disease if dehydration is sufficiently remedied. Cholera gravis is a voluminous painless watery diarrhea that can lead to dehydration and even death within a few hours. The case fatality rate for untreated cholera gravis is 50%. Symptoms include nausea, vomiting (especially early in the illness) and muscle cramps, followed by signs of hypovolemic shock.

Cholera stool is not malodorous and is often described as 'rice water' in character because it contains small flecks of mucus but little fecal matter; bloody stool is not suggestive of cholera. Because *V. cholerae* does not invade the epithelial lining of the intestine, there is little inflammatory response and hence the stool contains few if any leukocytes and patients are afebrile. The degree of dehydration is based on physical signs and measuring stool, vomit and urine output.

Complications from cholera (e.g. acute tubular necrosis) are mostly due to inadequate rehydration. Metabolic abnormalities may also occur, including hypokalemia as the result of potassium loss, acidosis from both bicarbonate loss and increased lactate production resulting from anaerobic glycolysis, and hypoglycemia due to deficient gluconeogenesis resulting in seizures and other neurologic abnormalities. Hyperventilation (Kussmaul breathing) may occur as a result of the metabolic acidosis. Shock from cholera can precipitate abortion in pregnant women, although this is less likely to occur if rehydration is prompt.

Management

The management of cholera patients consists of two components:

- rehydration, which is critical; and
- antimicrobial therapy, which is optional and intended to shorten the duration of the illness and prevent spread of the disease.

Effective fluid replacement can be expected to reduce mortality to less than 1% of the severely affected individuals. Mild and moderately dehydrated patients can be treated using oral rehydration solution (ORS), which has three basic components: sugars, salts and water. Physiologically, the sugar acts as the vehicle whereby salts can be absorbed by the mucosal cell; water follows passively.[46] Patients on ORS should remain on ORS until the diarrhea stops. Severely dehydrated patients should be treated intravenously. When intravenous solutions and equipment are not available, severely dehydrated patients may be treated through a nasogastric tube.

Antibiotic treatment serves to shorten the illness and save rehydration fluids. Incomplete courses have contributed to antibiotic resistance. Options are guided by local sensitivity patterns. These are tetracycline 250mg q12h for 7–10 days or amoxicillin 250mg q6h for 5 days. Tetracyclines and quinolones are not recommended during pregnancy. During epidemics, prophylactic antibiotics should be used for the immediate family only and should be limited to a single-dose therapy.

In conclusion, it can be said that during the last decade of cholera research two important findings have emerged: the characterization of a novel serogroup (O139) which circumvented established immunity against O1 and the discovery that cholera toxin genes were encoded on the genome of a bacteriophage. These two characteristics illustrate how bacterial pathogens can rapidly evolve through the acquisition of horizontally transferred genetic elements.[47]

Other pathogenic *Vibrio* spp.

Vibrio parahaemolyticus is a halophilic, or salt-requiring, *Vibrio* sp. that has been related to food poisoning and ingestion of raw or inadequately cooked seafood. The epidemiology results from the ubiquitous presence of the organism in coastal waters. The median incubation time is estimated at 23 hours with a range of 5–92 hours; secondary cases are rare. Preventive measures include the use of boiled water for cooking food. It is not known whether clinical disease confers immunity. There is no effective vaccine available. Stool culture on selective thiosulfate citrate bile salts sucrose agar demonstrates distinct opaque green colonies; final identification is made using standard biochemical tests. The clinical picture ranges from mild, watery diarrhea with low-grade fever to frank dysentery. Specific treatment is not required in most cases because the illness is self-limiting and no benefit has been established from antimicrobial agents.

Other less common halophilic *Vibrio* spp. include *Vibrio vulnificus, V. alginolyticus, V. fluvialis, V. hollisae* and *V. damsela*. Molecular methods, especially PCR, can be used for identification or detection of these species, including in the environment. In contrast to the *Vibrio* spp. discussed so far, *V. vulnificus* and *V. alginolyticus* are more associated with soft tissue wound infection and sepsis than with diarrhea.[48] *Vibrio vulnificus* may be considered an emerging pathogen and its virulence is the strongest among the noncholera *Vibrio* spp. Pathogenicity is generally reserved for the immunocompromised host and is related to disease states that exhibit high serum iron levels, including liver disease. Prevention involves avoidance of contaminated salt water. Immunocompromised patients should be warned against the ingestion of raw oysters and shellfish.[33] At higher latitudes, severe *V. vulnificus* infections have been reported in association with very hot weather conditions and seawater temperatures above 68°F. A vibrio polysaccharide conjugate vaccine may be useful in the management of *V. vulnificus* infections. Antibodies that react with the capsular polysaccharide of the organism are detectable in infected patients and in persons without known exposure to the organism, suggesting that cross-reacting antibodies are present in the general population.

Vibrio vulnificus infections present as two main clinical syndromes:

- primary sepsis secondary to ingestion of raw oysters; and
- localized infection from wound exposure to salt water in which the organism lives.

Both syndromes demonstrate characteristic skin lesions of the trunk and extremities. These present as hemorrhagic bullae and progress to necrotic ulcerations. Necrotizing fasciitis of the foot associated with *V. vulnificus* can cause death within 48 hours and has an overall mortality rate of 50%, even with appropriate antibiotic and surgical treatment.[49] Besides these two syndromes, *V. vulnificus* may also cause acute diarrhea in those on antacid therapy. Early suspicion is critical, because *V. vulnificus* is not always susceptible to aminoglycosides, and tetracycline is the first-choice treatment.

Vibrio alginolyticus may cause bacteremia and death in immunocompromised hosts. Among immunocompetent hosts, it may cause cellulitis and otitis media in swimmers and fishermen.

Vibrio mimicus, a nonhalophilic vibrio, produces a clinical spectrum that is indistinguishable from that of *V. parahaemolyticus*. The epidemiology of *V. mimicus* reflects a global distribution; outbreaks have been associated with heavy contamination of water sources. Prevention involves adequate purification of water sources and proper cooking practices. The diagnosis is confirmed by identifying the agent on thiosulfate citrate bile salts sucrose agar and subsequent specific antiserum testing. Treatment is limited to fluid and electrolyte replacement.

TREPONEMA SPP., *BORRELIA* SPP. AND *LEPTOSPIRA* SPP.

The order of the Spirochaetales is divided into the families Spirochaetaceae and Leptospiraceae. These families include, among others, the genera *Treponema, Borrelia* and *Leptospira* (Table 230.2).

TREPONEMA SPP.

Nature

The genus *Treponema* includes *Treponema carateum*, the causative agent of pinta, and *Treponema pallidum*. The latter species is subdivided into;

- *T. pallidum* subsp. *pallidum*, the causative agent of human venereal and congenital syphilis;
- *T. pallidum* subsp. *pertenue*, the cause of yaws; and
- *T. pallidum* subsp. *endemicum*, the cause of bejel.

Treponemata are motile, thin, spiralliform bacteria (Fig. 230.4).

Treponema pallidum

Epidemiology

In the majority of cases, *T. pallidum* subsp. *pallidum* is transmitted by sexual intercourse, with a moderate to high probability of transmission

TABLE 230-2 -- Order Spirochaetales.

ORDER SPIROCHAETALES			
Spirochaetaceae		**Etiologic agent**	**Human disease**
Family	Genus *Cristispira*		None
Spirochaetaceae	Genus *Serpulina*		None
	Genus *Spirochaeta*		None
	Genus *Treponema*	*Treponema pallidum* subsp. *pallidum*	Syphilis
		Treponema pallidum subsp. *endemicum*	Bejel
		Treponema pallidum subsp. *pertenue*	Yaws
		Treponema carateum	Pinta
	Genus *Borrelia*	*Borrelia recurrentis*	Epidemic relapsing fever
		Many *Borrelia* spp.	Endemic relapsing fever
		Borrelia burgdorferi, Borrelia garinii, Borrelia afzelii	Lyme borreliosis
Family	Genus *Leptonema*		None
Leptospiraceae	Genus *Leptospira*	*Leptospira interrogans*	Leptospirosis
The genera *Treponema, Borrelia* and *Leptospira* contain pathogens associated with human infections. The genera *Cristispira, Serpulina, Spirochaeta* and *Leptonema* are not known to cause disease in humans.			

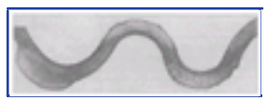

Figure 230-4 Helical structure of *T. pallidum* with the periplasmic flagella. *From Binford and Connor.*[107]

during contact between susceptible and infectious sexual partners (see Chapter 75). It can also be transmitted by kissing, transfusion of fresh blood, placental passage or during birth. Patients are most contagious early during the illness when fresh lesions exist. As a sexually transmitted disease, syphilis has the highest incidence among young adults.

A high incidence was observed in homosexual men until the mid-1980s when, in response to the threat of HIV infection, changes in sexual behavior (e.g. increased condom use) led to a lower incidence. During the 1990s, a resurgence of syphilis among male homosexuals occurred because the tenets of safe sex education gave way to the reacceptance of risky behavior. This, combined with the uncertainty of immunity to reinfections, helps ensure the long-term persistence of syphilis. [50] All patients who have syphilis should be screened for other sexually transmitted pathogens because many patients carry more than one.

Pathogenesis

Treponema pallidum passes through the abraded skin or mucous membrane and spreads throughout the body. The incubation time is proportional to the size of the inoculum. The immunoevasiveness of *T. pallidum* is largely the result of its unusual molecular architecture; its outer membrane contains a paucity of poorly immunogenic proteins, the *T. pallidum* rare outer membrane proteins (TROMPS), whereas its highly immunogenic lipoproteins are anchored predominantly in the periplasmic leaflet of the cytoplasmic membrane.[51]

The presence of granulocytes and macrophages can be demonstrated in a primary chancre, and CD8+ cytotoxic lymphocytes are found in both primary and secondary lesions.[52] The pathologic hallmark of syphilis is endarteritis obliterans, which consists of concentric endothelial and fibroblastic proliferation. In late syphilis, endarteritis affects the vasa vasorum and leads to the formation of gummas with their typical necrotic, coagulated center, most notably in the ascending aorta and the meningeal arteries.

Prevention

Along with individually oriented strategies, such as case finding, partner notification and presumptive treatment, the use of epidemiologic information is recommended when designing community-oriented, population-based strategies, which should include (but not be limited to) selective mass treatment in high-prevalence populations.[53] Widespread treatment of syphilis with penicillin in the USA, beginning in the mid-1940s, led to a decline of more than 85% in its incidence. The increased incidence seen after 1955 was attributed to the relaxation of control measures and increased sexual promiscuity. Surveillance data from Switzerland suggest that the incidence of infection with *Neisseria gonorrhoeae*, *T. pallidum* and *Chlamydia trachomatis* has declined notably since the 1980s. This is a result of population-based strategies, which include more widespread treatment with specific antibiotics and changes in behavior education, leading to a major increase in safe

sex practices, including condom use, in combination with the control of drugs and alcohol abuse. The cost effectiveness of antenatal screening for syphilis has been shown in various settings.[54] A vaccine for syphilis is not available for public health purposes.

Diagnostic microbiology

The lack of a method for *in vitro* culturing of *T. pallidum* necessitates the use of alternative methods (e.g. animal inoculation, dark-field microscopy or serology). Serologic tests, divided into two classes, do not become positive until several week after the appearance of the lesion. The nontreponemal tests detect antibodies to cardiolopin; examples include the Venereal Disease Research Laboratory (VDRL) test, the rapid plasma reagin (RPR) test, the automated reagin test (ART) and the syphilis screen. Because of their ease of use and low cost, these tests are applied for screening purposes. Reactivity in these tests generally indicates host tissue damage that may not be specific for syphilis. False-positive tests may occur in the elderly, drug addicts and patients who have chronic infections and autoimmune disease. Confirmation is required with treponemal tests such as the fluorescent treponemal antibody absorbed (FTA-ABS) test and the *T. pallidum* hemagglutination (TPHA) test. The TPHA and FTA-ABS are good markers for screening potential blood donors who have high-risk sexual behavior because they are more sensitive than the reagin tests. Syphilis Screen is claimed to be an alternative for the TPHA method.[55] After 3 months and following treatment, the non-specific cardiolipins begin to decline, whereas the FTA-ABS remains positive for life. In suspected neurosyphilis, VDRL should be performed on the cerebrospinal fluid (CSF); in unexpected cases, a positive FTA-ABS should be confirmed by a second sample. A number of direct antigen, ELISA and PCR techniques

are currently being developed.[56] Recently, a specific and highly sensitive reverse transcriptase PCR was developed for detecting very low numbers of organisms. Syphilis serology findings (both RPR and TPHA) may be altered in the presence of HIV infection, although in at least one study the serologic response to therapy was similar in HIV-positive and HIV-negative patients.[57] The high prevalence of neurosyphilis in HIV-infected patients who have syphilis warrants examination of the CSF regardless of the stage of illness.

Congenital syphilis is often a presumptive diagnosis based on serology, because confirmation requires the identification of *T. pallidum* in fetal or neonatal tissue or in the placenta, by either histopathology or PCR.

Clinical features

Local symptoms develop as primary syphilis following an incubation period of 10–90 days. This involves a painless, indurated or firm, sharply demarcated chancre (ulcus), usually distinctly different from the more painful, soft and bleeding ulcers caused by *Haemophilus ducreyi* (chancroid). The most common site is the coronal sulcus or prepuce in males and the labia or cervix in females. Primary lesions may also occur on the lips, breasts, mouth and anus. These local lesions heal in 3 months. These symptoms may be followed by regional lymphadenopathy.

Figure 230-5 Secondary syphilis with typical skin rash. *(Reproduced with permission from Habif.[58])*

TABLE 230-3 -- Treatment options for treponematosis.

TREATMENT OPTIONS FOR TREPONEMATOSIS				
		Antibiotic regimen		
Bacterium	**Clinical features**	**First choice**	**Second choice**	**Third choice**
Treponema pallidum subsp. *pallidum*	Syphilis, all stages except neurosyphilis	Benzathine penicillin G 2.4MU once weekly im for 3 weeks	Doxycycline 200mg q12h po for 2–4 weeks	Erythromycin 500mg q6h po for 2–4 weeks
	Neurosyphilis	Penicillin G 2MU q4h iv for 2 weeks	Ceftriaxone 1000mg q24h iv or im for 2 weeks	Doxycycline 200mg q12h po for 2–4 weeks
Treponema pallidum subsp. *pertenue*	Yaws (frambesia)	Benzathine penicillin G 1.2MU single dose im	Doxycycline 100mg q12h po 10–14 days	
Treponema pallidum subsp. *endemicum*	Bejel	Benzathine penicillin G 1.2MU single dose im		
Treponema carateum	Pinta	Benzathine penicillin G 1.2MU single dose im	Doxycycline 100mg q12h po 10–14 days	

If the primary infection is untreated, secondary syphilis may develop 2–8 weeks later, manifesting as a generalized, dry, nonpruritic rash that persists for 2–6 weeks. Patients are highly contagious during this stage (Fig. 230.5). The rash heals spontaneously, but it relapses in 25% of cases and may be accompanied by condylomata lata in the axillae or anogenital region and by mucous patches in the mouth, pharynx and cervix. Concurrent symptoms of secondary syphilis include generalized lymphadenopathy, low-grade fever, arthralgia, malaise, hepatitis, nephritis and pleuritis. As such, secondary syphilis may mimic other infectious diseases (e.g. brucellosis, rickettsiosis and certain viral diseases).

The rash and the other symptoms may disappear gradually in 1–3 months, marking the beginning of tertiary syphilis or the latent stage. Approximately one-third of the patients go on to develop granulomatous inflammation (gummas) in various organs, cardiovascular lesions (classically an aortic aneurysm), Charcot joints and the involvement of the central nervous system (neurosyphilis).

Management

Penicillin G is the drug of choice. A recent study showed that the addition of amoxicillin and probenecid did not improve the outcome, whether or not patients were co-infected with HIV.[59] Current recommendations for the management of early syphilis remain unchanged and a lumbar puncture is not necessary unless neurologic signs or symptoms are present. Because the effectiveness of the nonpenicillin alternative treatment regimens for syphilis (tetracycline or erythromycin) has not been well studied and because these regimens require the patient to comply with 15–30 days of oral therapy, desensitization of penicillin-allergic patients and treatment with penicillin rather than the use of oral therapy is preferred. Tetracycline-resistant bacteria have been increasingly found since the early 1950s. Treatment options are summarized in Table 230.3 . *Treponema pallidum* infection in the fetus during early pregnancy can be successfully treated by maternal treatment. The same treatment recommendations apply to pregnant women with penicillin as the preferred agent.

Nonsyphilitic treponematoses

Nature and epidemiology

Treponema pallidum subsp. *pertenue, T. carateum* and *T. pallidum* subsp. *endemicum* are morphologically indistinguishable from *T. pallidum* and cause yaws, pinta and bejel, respectively. The distribution of yaws spans the warm and humid tropics; pinta is limited to equatorial America and bejel is prevalent in arid subtropical and temperate climates. The prevalence of yaws decreased from 50–100 million

Figure 230-6 The papillomatous skin lesions of yaws. *(Reproduced with permission from Peters & Giles.[60])*

infected people during the 1950s to fewer than 2 million during the 1970s because of a mass treatment campaign sponsored by the World Health Organization. Yaws has been virtually eliminated in the Americas but it has re-emerged in western Africa and areas of the western Pacific. Pinta is limited to remote areas of Colombia, Central America and Mexico. Bejel is prevalent in parts of Africa and western Asia (see Chapter 156).

Pathogenesis and prevention

The treponemata that cause these three diseases are transmitted by direct contact among children living under unhygienic circumstances. The contacts of patients may be treated with antibiotics. Vaccines for public health use are not available.

Diagnostic microbiology and clinical features

Yaws is characterized by early papillomatous skin lesions and periostitis, late destructive skin lesions (including hyperkeratosis) and bone and skin gummata (Fig. 230.6). As in syphilis, the diagnosis can be confirmed directly by dark-field microscopy or fluorescent antibody staining, or serologically by the VDRL test, the RPR test, the treponemal FTA-ABS test or the specific microhemagglutination antibody tests. The incubation period is 3–5 weeks.

Pinta is suspected in patients from endemic areas who present with papulosquamous or depigmented skin lesions. The diagnosis is confirmed by dark-field microscopy or serologic tests (VDRL, FTA-ABS) that become positive after the lesions appear. The incubation period is about 1–3 weeks.

Bejel is suspected in patients from endemic areas who present with early mucous membrane and skin lesions and late gummata of skin and bone.

Management

Long-acting penicillin G is recommended for patients and their contacts in a single dose of 1.2 million units for those over age 10 years and 600,000 units for children below 10 years of age (see Fig. 230.6).

BORRELIA SPP.

Lyme disease

Borrelia spp. have gained importance during the past 25 years. This genus has become a well-known pathogen to many medical specialists since the first description of Lyme disease and the discovery that *Borrelia* spp. are the causative agents.

Nature

All *Borrelia* spp. are loosely coiled, left-handed bacteria characterized by the presence of a protoplasmic cylinder that is surrounded by a cell membrane, a periplasmic flagellum and an outer membrane (Fig. 230.7). The genome has been sequenced and is relatively small, with 150 megabases comprising a linear chromosome and plasmids. Three

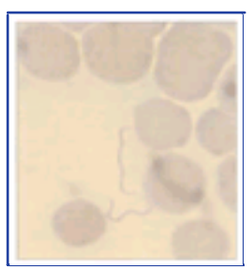

Figure 230-7 Giemsa stain of blood with *B. burgdorferi.* *Adapted from Murray et al.[106]*

species have been associated with disease in humans: *B. burgdorferi sensu stricto, B. afzelii* and *B. garinii*, which together form the *Borrelia burgdorferi sensu lato* complex.[61] In Europe, *Borrelia afzelii* and *Borrelia garinii* are predominant but *B. burgdorferi sensu stricto* can also be encountered. In North America, only infections with *B. burgdorferi sensu stricto* have been observed.

Epidemiology

Lyme disease surveillance data, collected since 1982, show that it is the commonest vector-borne infection in the USA. *Borrelia burgdorferi* is transmitted by ticks of the *Ixodes ricinus* complex. The principal vector in Europe is *I. ricinus*, in north-eastern and mid-west USA *Ixodes scapularis*, in the western coastal states *Ixodes pacificus*, and in Asia *Ixodes persulcatus*. Deer serve as hosts for *I. ricinus*. Small rodents, rats and mice serve as transitional hosts for the tick in its larval and nymph stages. Humans are more or less accidental hosts. The total developmental cycle from egg to adult takes 2 years. The tick is active during the summer and early autumn. In their larval stage, 1–4% of ticks are infected; in their nymph and adult stages, up to 25% are infected. In endemic areas Lyme disease is an important health problem in school-aged children, with a reported incidence of clinical Lyme disease of 10.1 cases per 1000 person-years and a reported incidence of asymptomatic *B. burgdorferi* infection of 3.8 cases per 1000 person-years.

Pathogenesis

Most tick bites do not cause infection and if they do, serious illness is rare. Early during the illness, the distribution of the spirochete is widespread. This is facilitated by the capacity of *B. burgdorferi* to resist elimination by phagocytes, to adhere to epithelial and brain cells, to cross intracellular junctions and penetrate cytoplasm, and to induce tumor necrosis factor (TNF)-a and interleukin (IL)-1b.[62] *Borrelia burgdorferi* actively attaches to, invades and kills human B and T cells. The cellular immune response seen locally in erythema migrans is mainly composed of $CD4^+$ lymphocytes, $CD8^+$ lymphocytes and macrophages. The immune response is suppressed initially, but it is heightened 3–6 weeks later at the peak of the specific IgM response, which is usually directed toward the spirochetal 41kDa flagellar antigen. This IgM response is associated with polyclonal B-lymphocyte activation, including elevated total serum IgM levels, cryoglobulins, circulating immune complexes, rheumatoid factor and antinuclear antibodies or anticardiolipin antibodies. After a further 6–8 weeks, a specific IgG response develops to different spirochetal antigens. At this stage, affected tissues show lymphocyte and plasma cell infiltration and signs of vascular damage.

Prevention

Preventing tick-borne diseases such as Lyme disease can be accomplished by tucking trousers into socks, covering the neck and head (especially of small children) and inspection of the body for ticks after a possible exposure. The use of environmental modifications (e.g. removal of leaf litter, deer fencing or eradication, and the application of insecticides around residential areas) are all effective for various periods of time. Since no scientific evidence is present supporting antibiotic prophylaxis after exposure, adverse affects and resistance development should discourage this approach.[63] The Food and Drug Administration approved in 1998 the LYMErix

(Glaxo Smith Kline) vaccine for persons 15–70 years of age. The vaccine is composed of recombinant OspA (outer surface protein A) and aims at the elimination of the spirochete in the gut of the tick before entry in the host.[64] Efficacy in preventing Lyme disease was 49% and 76% after two and three injections, respectively.[65] A theoretical concern is the induction of inflammatory arthritis by vaccination although no proven cases have been documented. All strains in the USA have been shown to express the same OspA variant; in Europe, however, a polyvalent vaccine will be obligatory.[66] [67]

Diagnostic microbiology

Lyme disease is primarily a clinical diagnosis for which erythema migrans is pathognomonic (Fig. 230.8). [68] It should be suspected in young patients from endemic areas who present with facial palsy or unexplained heart block. Because of the scarcity of organisms, infection can rarely be proven from samples other than the skin on histologic staining. Culturing *B. burgdorferi* from erythema migrans lesions or infected ticks is relatively easy. *Borrelia burgdorferi* grows as fastidious microaerophilic bacteria, at 91–92% F in Barbour-Stoenner-Kelly II medium. Serologic tests serve only as an adjunct to the clinical diagnosis because false positivity may occur. Enzyme-linked immunosorbent assays are preferred to the indirect fluorescent antibody staining method because of their higher sensitivity and reproducibility.[69] False-positive results and considerable variation within and between laboratories have been reported. Despite these shortcomings, the CDC has developed criteria for a two-step approach to determine antibodies against *B. burgdorferi* using ELISA and Western blotting.[65] These criteria apply only for the situation in the USA since antibody production against *Borrelia* spp. other than *B. burgdorferi sensu stricto* is less predictable. None of the laboratory tests can be used to estimate the extent of infection, its prior duration or its prognosis. In general, antibody response is slow and may persist for many years after treatment.

Figure 230-8 Typical erythema migrans rash. *Adapted from Murray et al.*[106]

Borrelia burgdorferi DNA has been demonstrated with PCR in skin biopsies from patients who have erythema migrans and acrodermatitis chronica atrophicans, in CSF from patients who have neuroborreliosis and in synovial fluid and synovial tissue from patients who have Lyme arthritis. [70] Urine is an important source of *Borrelia* DNA in patients who have erythema migrans, acrodermatitis chronica atrophicans, neuroborreliosis and Lyme arthritis.[71] In general, molecular diagnostics for Lyme disease should be reserved for patients with a high clinical probability in the early phase of disease before seroconversion.[72]

Clinical features

Although erythema migrans, the major presenting feature of the illness, is similar in all parts of the world, differences in disease manifestations, disease severity and frequency occur. These differences may reflect regional variation in the prevalence of genospecies of *B. burgdorferi*. In general, a wider spectrum of disease presentations has been noted in Europe than in North America. Borreliosis may evolve in three clinical stages.[73] The clinical heterogeneity results in the tendency to overdiagnose Lyme disease. Stage 1 may remain asymptomatic, whereas stages 2 and 3 may not occur in sequence or may not develop at all. A summary of the clinical manifestations is given in Table 230.4 .

Stage 1 (localized infection)

Three days to a month after the tick bite, a flu-like illness develops together with erythema migrans. Erythema migrans may also be the sole presenting feature. It begins at the site of the tick bite, expands from a macule or papule to a large circular lesion of 3–60cm diameter and fades spontaneously in the course of weeks. Most commonly, the lesions are found on the trunk or lower extremities. Differential diagnoses for erythema migrans include streptococcal and staphylococcal cellulitis, hypersensitivity reactions to arthropod bites, plant dermatitis, tinea and granuloma annulare.

Stage 2 (early dissemination)

Multiple secondary lesions may occur several days after the first lesion of erythema migrans and result from the spread of the organism. Lymphadenopathy and malaise may be evident. After an interval of weeks or months, neurologic abnormalities occur in 10–15% of cases. The cranial nerves can be affected, particularly the facial nerve, resulting in a Bell's palsy. Lymphocytic meningitis develops in 5% of cases. Even less frequent complications include meningoencephalitis, chorea, myelitis, radiculitis and peripheral neuritis. A lymphocytoma, which is sometimes painful, especially when exposed to cold, may also develop. These symptoms may disappear spontaneously or become chronic or relapsing. Transient arthritis or arthralgia may occur as well. At this stage, 10% of the patients develop myocarditis, with atrioventricular blocks of various degrees, which may resolve spontaneously or require a temporary pacemaker.

Stage 3 (persistent infection)

Months to years after the primary exposure, 50% of the patients who have not received adequate treatment develop monoarthritis or oligoarthritis, which becomes chronic in 10–20% of cases. Late complications may also include chronic encephalomyelitis, uveitis and acrodermatitis chronica atrophicans.

Management

Stage 1 and mild manifestations of stage 2 can be treated with oral doxycycline or amoxicillin for 2–3 weeks; early treatment may prevent the development of antibodies.[76] Treatment with doxycycline has the advantage that human granulocytic ehrlichiosis (HGE) is treated as well. Cefuroxime axetil can serve as an alternative for patients allergic to doxycycline or amoxicillin. Macrolides should only

TABLE 230-4 -- Clinical features of Lyme borreliosis.*

CLINICAL FEATURES OF LYME BORRELIOSIS			
System	**Localized (stage 1)**	**Early infection, disseminated (stage 2)**	**Late infection, persistent (stage 3)**
Skin	Erythema migrans	Secondary erythema migrans, lymphadenosis benigna cutis	Acrodermatitis chronica atrophicans
Musculoskeletal		Migratory pain in joints, tendons, muscle, bone; brief attacks of arthritis	Prolonged attacks of arthritis, arthritis, peripheral chronic enthesopathy, joint subluxation below the lesions of acrodermatitis chronica atrophicans
Neurologic		Meningitis, cranial neuritis, Bell's palsy, motor or sensory radiculoneuritis, encephalitis	Chronic encephalomyelitis, spastic parapareses, mental disorders, dementia
Heart		Atrioventricular block, myopericarditis, pancarditis	
Lymphatic	Regional lymphadenopathy	Regional or generalized lymphadenopathy	
Eyes		Conjunctivitis, iritis	
Liver		Hepatitis	
Respiratory		Nonproductive cough	
Renal		Microscopic hematuria or proteinuria

TABLE 230-5 -- Treatment options for borreliosis.*

TREATMENT OPTIONS FOR BORRELIOSIS				
		Antibiotic		
Bacteria	**Clinical features**	**First choice**	**Second choice**	**Third choice**
Borrelia recurrentis	Recurrent fever	Doxycycline 100mg 1 dose po	Erythromycin 500mg 1 dose po	Tetracycline 500mg 1 dose po
Borrelia spp.		Doxycycline 100mg q12h po 5–10 days	Erythromycin 500mg q6h po 5–10 days	
B. burgdorferi	Stage 1	Doxycycline 100mg q12h 14–21 days	Amoxicillin 500mg q8h 14–21 days	Cefuroxime axetil 500mg q12h 14–21 days
	Stage 2 and 3 mild Cranial nerve palsy, 1st or 2nd degree heart block, arteritis	Doxycycline 100mg q12h 14–28 days	Amoxicillin 500mg q8h 14–28 days	Cefuroxime axetil 500mg q12h 14–28 days
	Stage 2 and 3 serious disease Meningitis, radiculopathy, 3rd degree heart block	Ceftriaxone 2g once daily 14–28 days	Cefotaxime 2g q8h 14–28 days	Penicillin G 18–24 million units iv/d given q4h 14–28 days

** Adapted from Speelman et al.[106]*

be used when patients are intolerant to the aforementioned drugs. The more serious complications of stage 2 and stage 3 such as meningitis, radiculopathy and third-degree atrioventricular heart block will require parenteral antibiotics such as ceftriaxone. Intravenous penicillin G or cefotaxime can serve as an alternative. Oral doxycyline is probably equally effective for the treatment of neuroborreliosis (Table 230.5).[77] Prophylactic treatment is not recommended, especially if the tick has been attached for less than 24 hours.

Borrelia recurrentis

Nature and epidemiology

The louse-borne epidemic relapsing fever, caused by *Borrelia recurrentis*, is transmitted by the human body louse and is associated with unhygienic living circumstances. The tick-borne endemic relapsing fever is caused by different *Borrelia* spp. and is transmitted by the *Ornithodorus* tick.

Pathogenesis and prevention

When lice are crushed, *B. recurrentis* is released and penetrates the skin or mucous membranes. Organisms can be detected in the blood when the patient has a fever. They sequester in internal organs in the afebrile periods. Mutational changes in the antigenic properties of the organism and consequent antibody production account for the relapses, which end when sufficient borrelicidal antibody has been developed.

Preventive measures are similar to those recommended for Lyme disease and involve the elimination or avoidance of the

spirochete vector. A vaccine is not yet available for public health purposes.

Diagnostic microbiology

Diagnosis is based on the clinical presentation and detection of the bacteria in the blood. Spirochetes are found in the majority of wet or stained blood smears. They have also been detected in the CSF of patients who have signs of central nervous system involvement. Up to 10% show positive serologic tests for syphilis.

An early clinical diagnosis of louse-borne relapsing fever is not difficult during epidemics. In contrast, the initial differential diagnosis in an isolated case includes many different diseases such as malaria, typhoid fever, leptospirosis and dengue fever.[78]

Clinical features

Epidemic louse-borne relapsing fever and endemic tick-borne relapsing fever have very similar clinical manifestations; heterogeneity reflects differences in, for example, spirochete strains and the condition of the patient. Louse-borne relapsing fever and tick-borne relapsing fever both have a very acute onset of high fever with chills and muscle and joint aches. Headache and lethargy may be accompanied by neurologic findings, including meningitis and seizures leading to coma. Photophobia and iridocyclitis may develop, causing permanent damage to the sight. Coughing may result from bronchitis or pneumonia. A 2-day truncal rash may occur at the end of the first febrile period. Abdominal tenderness with enlargement of liver and spleen may be associated with jaundice, lymphadenopathy and hemorrhagic diathesis.

The first bout of fever usually lasts 3–6 days, sometimes with fatal complications including myocarditis, cerebral hemorrhage and hepatic failure. The fever may suddenly reappear after a 7–10-day interval. Louse-borne disease typically has a longer incubation period and a more elongated cycle of febrile and afebrile periods, and it is associated with a single relapse. Tick-borne disease manifests with multiple relapses that taper off in duration and intensity.

Management

First-choice antibiotic is doxycycline 100mg q12h for 5–10 days. One 500mg dose of erythromycin is the second-choice option. Antibiotic treatment may be accompanied by a Jarisch-Herxheimer reaction that cannot be prevented by prior corticosteroid therapy.[79] and that reflects clearance of the spirochetemia. It may be advisable to give the first dose of antibiotics at a lower dose (e.g. erythromycin 250mg) to limit the severity of the Jarisch-Herxheimer reaction (see Chapter 182 for further management guidelines).

LEPTOSPIRA INTERROGANS SPP.

Nature

Leptospira interrogans spp. are thin, motile, coiled bacilli. The serotypes of the *Leptospira interrogans* sp. group include *icterohaemorrhagiae, canicola, pomona, autumnalis, grippotyphosa, hebdomadis, ballum* and *australis*. [80] Each of these has a different natural habitat. For example, *L. interrogans* serotype *icterohaemorrhagiae* is most commonly found in rats, *L. interrogans* serotype *canicola* in dogs and *L. interrogans* serotype *pomona* in pigs.

Epidemiology

Leptospirosis is a zoonosis that occurs worldwide (see Chapter 181). In the USA, rats are the most common vector for human infection, followed by dogs, livestock,

rodents, wild mammals and cats. Humans are dead-end hosts because person-person transmission is very rare. The peak incidence is during the summer and early autumn; young adult men often become infected, for example, after recreational exposure to contaminated water. Leptospirosis has long been considered an occupational disease affecting farmers, veterinary surgeons and abattoir workers through indirect contact with infected animals via urine-contaminated water or soil. [81]

Pathogenesis

Leptospira spp. penetrate the intact mucous membranes or abraded skin, enter the bloodstream and spread to all parts of the body, including the CSF and eyes. Liver damage is subcellular and may lead to jaundice. Renal failure may result from a direct toxic effect of the leptospires on the tubules. Meningeal irritation may occur when the leptospires enter the CSF. They are abundant during the early stage of the meningeal disease and disappear when serum antibodies develop. A chronic or recurrent uveitis may result from leptospires persisting in the corpus vitrium of the eye. Myalgia, particularly of the calves, may be an early sign, and pathologic changes such as polymorphonuclear infiltration of the muscle occur late.[82]

Prevention

Effective control of leptospirosis is difficult because leptospires can establish a symbiotic relationship with many hosts, even if they have been vaccinated, and persist in the renal tubules (with excretion in the urine) without causing illness or pathologic changes in the kidneys. In addition, wild animals represent a reservoir from which domestic animals are continually infected. Widespread vaccination of livestock and pets in the USA has reduced the incidence of infection in some species, although adequately vaccinated dogs can still infect humans.[83] Immunization of rice fieldworkers in China with polyvalent vaccines has been practiced. In France a vaccine against serovar *icterohaemorrhagiae* is available for human use.[84] Prohibition of recreational activities in contaminated waters and measures to reduce the number of rats have been successful in reducing the incidence of disease. Prevention can be considered using 200mg doxycycline once a week for heavily exposed individuals such as soldiers who train in the jungle.[85]

Diagnostic microbiology

Isolating the organism from patient material or the detection of seroconversion confirms the clinical suspicion of leptospirosis. Leptospires can be isolated from blood or CSF during the first 10 days of illness. During the second week, they appear in the urine and can be detected in biopsies from various organs. Tween 80-albumin is viewed as the best available medium.[86] Cultures should be maintained in the dark for up to 6 weeks at 82–86°F. Leptospires grow in semisolid media in a ring 0.5–1cm below the surface, appearing 6–14 days after inoculation. They remain viable in heparinized blood for more than 1 week and can be mailed to a reference laboratory for identification.

The laboratory technique most commonly used to diagnose leptospirosis is a two-step serologic procedure, although antibiotic treatment may interfere with antibody development and account for false-negative results.

Macroscopic slide agglutination is used for screening purposes, followed by microscopic agglutination test (MAT) with live antigens for determining antibody titers and identifying serotypes. Both tests use pools of antigens representative of most serogroups. Nevertheless, cross-reactions often occur and serologic tests cannot accurately identify the serotype responsible for infection. Currently, the sensitivity and specificity necessary for reliable clinical diagnosis is best achieved using a battery of 23 antigens. The presumptive diagnosis may be based on a microscopic agglutination titer of 1:100 or greater or on a positive slide agglutination test. Agglutinins appear after 1 week of illness and decline after the third or fourth week. For areas in the world where laboratory resources are limited a dipstick

assay using a broadly reactive leptospiral antigen on a solid support for the detection of IgM antibodies was demonstrated to have satisfactory specificity and sensitivity. [87]

Other techniques to identify leptospires include dark-field examination and silver staining. Polymerase chain reaction has proven valuable as a rapid, sensitive and specific means of diagnosing leptospiral infection, especially during the first 10 days of illness when the clinical expression of the disease may be confusing. [88]

Clinical manifestations

Leptospirosis may evolve subclinically or clinically. It has an incubation period of approximately 7–12 days; clinical illness typically follows a biphasic course. During the initial phase of 4–7 days, patients present with sudden onset of fever, severe general malaise, muscular pain, especially in the calves, conjunctival congestion and leptospires can be isolated from most tissues. Two days without fever follow. During the second phase of up to 30 days, leptospires are still detectable in the urine, kidney and vitreous body. Circulating antibodies emerge and meningeal inflammation, uveitis and rash develop.[89]

Icteric leptospirosis, or Weil's disease, occurs in 10% of the clinically ill patients; 90% remain anicteric. Icteric leptospirosis can be caused by any type of leptospire including *L. interrogans* subtype *icterohaemorrhagiae*. Prominent features are renal and liver malfunction, hemorrhage and impaired consciousness; the mortality rate is 5%.[90] The combination of a direct serum bilirubin level of less than 20mg/100ml (342mmol/l), a marked elevation in serum creatine phosphokinase and an elevation in transaminase (SGOT and SGPT0 of less than 200 units is suggestive of the diagnosis.[91] Hepatocellular necrosis rarely occurs and no residual hepatic dysfunction ensues. Hepatomegaly is found in 25% of cases. The severity of the illness probably reflects the degree of the vasculitis.

Anicteric leptospirosis is a more common and less severe form of leptospirosis. It has a sudden onset and is accompanied by remittent fever and chills, persistent headache, severe myalgia, malaise, prostration and abdominal pain with nausea and vomiting lasting up to 7 days. During the following so-called immune stage, the fever virtually subsides. Delirium and meningism, however, may develop. Several organ systems can be affected, including the lungs, which may show pulmonary infiltrates, and the eyes.[92] A rash may develop as well. Distinct erythematous pretibial lesions can be found in the Fort Bragg fever syndrome, which is caused by *Leptospira interrogans* serotype *autumnalis*.

Management

Severely ill patients should be treated with intravenous penicillin or amoxicillin for 7 days (Table 230.6). [93] Less severely ill patients should receive oral doxycycline for 7 days.[94] Severe disease is not limited to adults but may also affect children, who benefit from antibiotics even late during the illness.[95] Careful monitoring and supportive therapy are important in order to prevent possible complications, including renal failure, hypotension and major hemorrhage.

SPIRILLUM MINUS

Rat-bite fever can be caused by either *Streptobacillus moniliformis* or *Spirillum minus*. The first description of the spirillum dates back to 1888 when Carter reported a spiral organism which he called *Spirillum minor* in the blood of wild rats. Later the organism was named *Spirocheta morsus muris* and in 1924 the organism was renamed *Spirillum minus*.[96]

Nature

The literature on *Spirillum minus* is very puzzling since largely conflicting properties of the organism have been reported. The basic

TABLE 230-6 -- Treatment options for leptospirosis.*

TREATMENT OPTIONS FOR LEPTOSPIROSIS		
	Antibiotic	
Bacteria	**First choice**	**Second choice**
Leptospira icterohaemorrhagiae, copenhageni (Weil's disease)	Penicillin G 1 MU q4-6h iv for 7 days	Doxycycline 100mg q12h po for 7 days
Leptospira hardjo (Milker's disease)	Alternative: Amoxicillin 500mg q6h for 7 days	
Leptospira grippotyphosa		

** Adapted from Speelman et al.*[106]

problem lies in the fact that the description of the organism is purely morphological. [97] No biochemical properties or nucleotide sequence data are available. *Spirillum minus* is a Gram-negative spiral microorganism. It measures 0.2–0.5µm in width and 3–5µm in length. It possesses two to three windings and is actively motile by means of bipolar tufts of flagella.

Epidemiology and pathogenesis

Spirillum minus can be detected in the oropharynx of rats and small rodents. Infections occur throughout the world. Data on incidence are lacking so the widely held belief that infections with *S. minus* are more often seen in the Pacific region cannot be substantiated. Transmission from human to human has not been documented.

Prevention

No studies have been reported on the use of prophylactic antibiotics after a rat bite.

Diagnostic microbiology

The spiral bacteria can be made visible using dark-field microscopy or Giemsa staining of blood smears, smears from eschars or lymph node aspirates. *Bergey's manual of determinative microbiology* states that the organism cannot be cultured on artificial media but can be detected in the blood of mice or guinea-pigs 3 weeks after intraperitoneal injection of clinical samples.[97] A practical problem concerning this approach is the fact that these animals are the natural reservoir of these spirilla. Animal inoculation studies should include control animals and preinoculaton evaluation for spirilla.[98] Most reports in the literature do not describe if such controls were performed. Diagnosis of *S. minus* infection in the literature is based on either clinical presentation, [99] direct visualization of the organism[100] or animal inoculation.[98] These spirilla could not be cultured on artificial media. Other reports indicate an easily cultivable *S. minus* as an etiologic agent for endocarditis[101] [102] and recurrent fever.[103] These spirilla could be cultured on simple media such as blood agar and an antibiogram could be established. Further characterization of the spirilla is warranted to determine if we are dealing with one or multiple species or even genera.[104] No specific serological test can be used; however, the VDRL is positive in 50% of cases.

Clinical features

Spirillum minus rat bite fever is also called sodoku: 'so' means rat and 'doku' means poison in Japanese.[96] The initial lesion of the rat bite usually heals promptly. One to 36 days after the exposure the patient becomes ill and develops fever. At the site of the bite, the wound reactivates and an eschar develops. Regional lymphadenitis is present in

the majority of cases. A violaceous maculopapular rash on palms and soles, very similar to the one seen in syphilis, is a common feature. If untreated, relapsing fever will develop. As compared to the rat-bite fever caused by *Streptobacillus moniliformis*, sodoku has a longer incubation period and arthritis is not a frequent event.

Management

Penicillin is the treatment of choice although no clearcut guidelines can be presented about dose and duration. A Jarisch-Herxheimer reaction can occur after initiation of antibiotic therapy. Tetracycline can be used for patients with an allergy for penicillin.

Chapter 231 - Gram-negative Coccobacilli

Mary PE Slack

INTRODUCTION

The Gram-negative coccobacilli that are important human pathogens include *Bordetella*, *Brucella*, *Francisella*, *Haemophilus*, *Legionella*, *Pasteurella* and *Yersinia* spp. *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella* and *Moraxella* (*Branhamella*) spp. occasionally cause human disease. All of these genera except *Yersinia* are fastidious, requiring special nutrients and growth factors for isolation. *Yersinia* spp. are members of the Enterobacteriaceae and are not exacting in their growth requirements.

The genera *Brucella*, *Francisella*, *Pasteurella* and *Yersinia* cause zoonotic infections in humans. *Legionella* infections are acquired through exposure to environmental contamination. *Haemophilus* and most *Bordetella* infections arise through person-to-person transmission. Rarely *Bordetella bronchiseptica*, an animal pathogen, produces opportunistic human infections.

BORDETELLA SPECIES

NATURE

Bordetella spp. are minute Gram-negative coccobacilli. They often demonstrate bipolar staining. They may be nonmotile or motile by means of peritrichous flagella. They are strictly aerobic and the optimum temperature for growth is 95–98.6°F (35–37°C). No acid is produced from carbohydrates. There are seven species in the genus; these differ in their fastidiousness and growth requirements. *Bordetella pertussis* is the most exacting and requires special media for isolation. *Bordetella parapertussis* is slightly less exacting. *Bordetella bronchiseptica* and *Bordetella avium* will grow on ordinary laboratory media. *Bordetella pertussis* and *B. parapertussis* show homogenous clonality. *Bordetella avium* is a distinct species, the G + C content of its DNA being 62mol%, whereas the other species have a G + C content of 66–70mol%. The mol% of guanine and cytosine (G + C) bases in the DNA is the measurement of the genetic unrelatedness of bacterial species. The relatedness of the newly identified species *B. hinzii*, *B. holmesii* and *B. trematum* to *B. pertussis* has not yet been determined.

Bordetella pertussis and *B. parapertussis* are human pathogens of the respiratory tract causing pertussis or whooping cough. *B. bronchiseptica* and *B. avium* are primary respiratory tract pathogens of birds and mammals. *B. bronchiseptica*, *B. avium*, *B. hinzii*, *B. holmesii* and *B. trematum* may infrequently cause infections in humans, particularly in the immunocompromised host.

EPIDEMIOLOGY

Pertussis is highly contagious, being transmitted via aerosolized droplets of respiratory secretions, and in the prevaccine era nearly all children became infected between the ages of 1 and 5 years. Attack rates range from 50% for school contacts to 80–90% for close family contacts. Patients disseminate organisms for weeks or months and are highly infectious in the non-specific catarrhal and early paroxysmal stages of the infection. It is therefore easy for the infection to spread to susceptible individuals before the possibility of whooping cough is considered. There is little evidence of asymptomatic carriers.

Whooping cough is still a major disease worldwide and an important cause of death in malnourished children. It is estimated that there are over 51,000,000 cases each year worldwide and 600,000 deaths.[1] In most populations the disease is endemic, with epidemics occurring every 4 years in late winter and spring. There is no animal reservoir.

With the use of whole-cell pertussis vaccine the incidence of pertussis in children aged 1–5 years declines sharply but there is an increase in the incidence of the disease in children younger than 1 year. Unfortunately, these young children are those at greatest risk of morbidity and mortality from pertussis. Females are more likely to be infected than males.[2] Adults with waning vaccine-induced immunity are increasingly also suffering from pertussis, which often goes undiagnosed because the infection may be atypical. It has been suggested that up to 30% of adults with a prolonged cough may be suffering from pertussis.

There are three serotypes of *B. pertussis* pathogenic for humans, which contain agglutinins 1,2; 1,2,3; and 1,3. Strains may switch serotype both in vitro and in vivo. For this reason, a genotypic method of classification, based on techniques such as restriction fragment length polymorphism (RFLP) or pulsed-field gel electrophoresis (PFGE) is preferable.

PATHOGENICITY

Bordetella spp. possess a common cell wall somatic O antigen. There are 14 capsular polysaccharide types or factors. Factor 7 is found in all species of *Bordetella*. Factors 1–6 are specific to *B. pertussis*. Factor 1 is a lipo-oligosaccharide; it may be involved in attachment. Pertactin is an outer membrane protein that is also involved in adhesion. *Bordetella pertussis* produces a number of other factors that may play a part in pathogenesis [3] [4] (Table 231.1).

Filamentous hemagglutinin is a protein that is involved in the binding of *B. pertussis* to receptors on respiratory cilia. Pertussis toxin is a four-polypeptide toxin with many biologic activities. It acts as a histamine-sensitizing factor and a lymphocytosis-promoting factor, enhances insulin secretion and is also a potent adjuvant. It is composed of two subunits, A and B. Subunit B mediates binding of the toxin and subunit A carries out the biologic activities of the toxin. Pertussis toxin acts by activating adenyl cyclase, which results in increased cyclic adenosine monophosphate (cAMP) in the host cell. The toxin is only expressed by *B. pertussis*. *Bordetella parapertussis* and *B. bronchiseptica* contain the toxin gene but it is not expressed. Adenylate cyclase toxin is an extracytoplasmic protein that can enter leukocytes. Once inside the cells, adenylate cyclase toxin is activated by calmodulin to catalyze the production of cAMP from adenosine triphosphate (ATP). The increased cAMP interferes with leukocyte function. Dermonecrotic toxin is a heat-labile toxin

TABLE 231-1 -- Virulence factors of *Bordetella pertussis.*

VIRULENCE FACTORS OF *BORDETELLA PERTUSSIS*			
Toxin	**Synonyms**	**Composition**	**Action**
Filamentous hemagglutinin	FHA	Protein	Adhesion
Pertactin	PRN	Protein (outer membrane)	Adhesion
Pertussis toxin	PT	Protein	Activation of cAMP, HSF, LPF, IAP
			Impairs leukocyte function
			?Adhesion
Adenylate cyclase toxin	ACT	Protein	Activation of cAMP
			Interference with leukocyte function
			Hemolytic
Dermonecrotic toxin	DNT, heatlabile toxin	Polypeptide	Vascular smooth muscle contraction
			Focal necrosis
Tracheal cytotoxin	TCT	Glycopeptide	Ciliostasis
			Inhibition of DNA synthesis
			Lethal to ciliated epithelial cells
Lipopolysaccharide	LPS	Lipopolysaccharide	Endotoxin
Agglutinogens	Fimbriae, FIM	Protein	Adhesion
With the exception of pertussis toxin, similar toxins are expressed in *B. parapertussis* and *B. bronchiseptica*. cAMP, cyclic adenosine monophosphate; HSF, histamine sensitizing factor; IAP, islet-activating protein; LPF, lymphocytosis promoting factor.			

that can cause vascular smooth muscle contraction resulting in focal ischemic necrosis. Tracheal cytotoxin is a peptide derived from the bacterial peptidoglycan. It causes ciliostasis, inhibits DNA synthesis and kills ciliated epithelial cells, which are then sloughed off. The lipopolysaccharide (LPS) of *B. pertussis* probably also plays a part in pathogenicity.

Following inhalation, *B. pertussis* adheres to the ciliated epithelium of the trachea and bronchi. Adhesion is mediated by filamentous hemagglutinin, pertactin and

possibly pertussis toxin. The bacilli then begin to multiply, producing pertussis toxin, which disrupts cell function; tracheal cytotoxin, which inhibits ciliary motion; and adenylate cyclase toxin, which interferes with phagocytosis. The dermonecrotic toxin causes local necrosis. The organisms remain localized on the respiratory epithelium. They do not invade.[5] [6]

PREVENTION

Prevention of pertussis depends on immunization. The vaccines generally used are killed suspensions of whole bacterial cells adsorbed with aluminum hydroxide, which acts as an adjuvant and also results in fewer adverse reactions. The vaccine should be administered routinely to infants. To be effective the vaccine must contain all three agglutinogens, 1, 2 and 3. Pertussis vaccine was introduced into the UK during the 1950s and resulted in a steady decline in the size of pertussis epidemics until the mid-1970s.

Many concerns have been voiced about the safety of whole-cell vaccines and fears of possible neurologic sequelae. In the UK these fears resulted in a dramatic fall in the rate of vaccine uptake and three large epidemics of pertussis occurred in the late 1970s (Fig. 231.1). Since that time, parental confidence in the vaccine has gradually been restored and the number of cases has again declined. There is no strong evidence that whole-cell pertussis vaccine does produce long-term adverse effects but it may trigger the appearance of pre-existing neurologic problems. A severe adverse reaction to a previous dose of vaccine is a contraindication for further doses. Vaccination should be delayed in children who are unwell.

Acellular pertussis vaccines have been developed. They contain inactivated pertussis toxin and filamentous hemagglutinin. Some also contain fimbrial agglutinogen. Acellular vaccines are currently licensed and being used in the UK, USA, Japan, Germany and Italy. They appear to be safe and effective and may soon replace whole-cell

Figure 231-1 Whooping cough notifications — cases and deaths. Figures are for England and Wales 1940–2000. *Data supplied by the Public Health Laboratory Service Communicable Disease Surveillance Centre.*

vaccines.[7] [8] Because the incidence of pertussis in older children and adults is increasing there may be a case for using acellular pertussis vaccine to boost waning vaccine-induced immunity in older age groups.

DIAGNOSTIC MICROBIOLOGY

With careful sampling and culture techniques *B. pertussis* can be recovered for up to 3 months after the onset of the illness. Ideally, a flexible pernasal swab should be used to collect material. This is far superior to 'cough plates' and postnasal swabs. The material collected should be plated immediately on a suitable medium. If this is not possible it should be placed in a charcoal transport medium.[9] The traditional Bordet-Gengou agar, a potato infusion agar containing 10% glycerol and 20% sheep blood, has the disadvantage of a short shelf life. Better growth is obtained on charcoal blood agar, which can be made selective by the addition of cephalexin.

Figure 231-2 Colonies of *Bordetella pertussis* on charcoal blood agar.

TABLE 231-2 -- Differentiation of species of *Bordetella* found in clinical material.

DIFFERENTIATION OF SPECIES OF *BORDETELLA* FOUND IN CLINICAL MATERIAL				
Species	**Growth on blood agar**	**Motility**	**Oxidase**	**Urease**
Bordetella pertussis	-	-	+	-
Bordetella parapertussis	+	-	-	+
Bordetella bronchiseptica	+	+	+	+

Cultures should be incubated in a moist aerobic atmosphere at 98.6°F (37°F) for at least 5 days. After 3–5 days of incubation, typical 'bisected pearl' colonies appear (Fig. 231.2). Suspect colonies should be checked by Gram-staining and identified using slide agglutination with type-specific antisera. *B. pertussis* and *B. parapertussis* can be differentiated by a series of simple tests (Table 231.2). *B. bronchiseptica* can be identified using a commercial galley test kit such as API 20NE.

Direct immunofluorescence can be applied to respiratory secretions to give a rapid diagnosis.[9] False-negative results may occur because of host antibody adsorbed to the organism. The sample must therefore be pretreated with enzymes. False-positive results may be obtained because of cross-reactions with other organisms such as staphylococci. A polymerase chain reaction (PCR) method may be used to improve the diagnosis of pertussis[10] and has the advantage that it can give a positive result even in the absence of viable organisms.

Immunoglobulin (Ig)M and IgG antibodies in serum or IgA in respiratory secretions can be assayed using an enzyme-linked immunosorbent assay (ELISA) technique. A diagnosis of whooping cough relies on a rising titer of IgG and IgM antibody in two samples collected at least 5 days apart, or a single raised level of IgM or IgG antibodies. However, the antibody response may be slow and weak, especially in young children. Cross-reactions with other organisms and the long-term persistence of pertussis antibodies can produce false-positive results.

CLINICAL MANIFESTATIONS

In a typical case, after an incubation period of 7–14 days, the patient develops red eyes, a runny nose, a mild cough and sneezing ('catarrhal stage'); this is a picture indistinguishable from many viral upper respiratory tract infections. After about 1 week the cough becomes more severe and the patient experiences paroxysmal bouts of a severe, hacking cough. A paroxysm consists of repeated coughing followed by an inspiratory gasp as the patient finally breathes in. This is the characteristic 'whoop'. Paroxysms may be triggered by a variety of stimuli, including cold air and loud noises. The child may become cyanosed during a paroxysm and can suffer fatal hypoxia. Often the child vomits at the end of a paroxysm and is left exhausted. The 'paroxysmal stage' may last for 1–4 weeks. This is followed by a lengthy 'convalescent stage' as the paroxysms decline and the patient slowly recovers. Many cases, but not all, develop a lymphocytosis. Pertussis is most severe in very young infants. In this age group the presentation may be atypical, with no characteristic paroxysmal whooping. Similarly, partially immunized children and adults may have an atypical form of pertussis.[11] [12]

The principal complications of pertussis are secondary infections, notably pneumonia and otitis media, and mechanical damage, including subconjunctival hemorrhage and diaphragmatic herniation during paroxysms. Encephalopathy and fits may also occur.

Bordetella parapertussis is a cause of acute bronchitis or pertussis-like infections in children.[13]

Bordetella bronchiseptica may rarely cause pneumonia, meningitis or whooping cough in highly immunocompromised patients.[14]

MANAGEMENT

The most important aspect of management is supportive care, ensuring that the patient is adequately hydrated, oxygenated and fed. Erythromycin is the antibiotic of choice and appears to reduce the severity and duration of the disease. Trimethoprim-sulfamethoxazole (co-trimoxazole) is an alternative for older patients who are unable to tolerate erythromycin. Corticosteroids may be indicated in infants who have life-threatening disease. Secondary bacterial infections should be treated with appropriate antibiotics.

BRUCELLA SPECIES

NATURE

Brucella spp. are small, nonmotile, nonsporing, noncapsulated Gram-negative coccobacilli. They are aerobic, but some strains require 5–10% carbon dioxide for primary isolation. Growth on culture media is improved by the addition of serum or blood. Growth in vitro is slow and primary isolation may require up to 4 weeks incubation. *Brucella* spp. are catalase-positive but oxidase activity, urease activity and hydrogen sulfide production are variable. They are facultative intracellular parasites that infect a wide variety of domestic and wild animals. The G + C content of DNA is 58–59mol%. DNA-DNA hybridization shows more than 95% homology between all types of *Brucella*. They are to be regarded as a single species, *Brucella melitensis*, with multiple biovars. In practice it is more useful to refer to separate species, which have differing host specificities. Thus, there are six species of *Brucella*, four of which can infect humans (Table 231.3). *B. melitensis* is the most virulent and is responsible for the majority of human infections. Both *Brucella abortus* and *Brucella suis* cause considerable morbidity in countries where brucellosis persists in domestic animals.

EPIDEMIOLOGY

Brucella spp. can infect a wide variety of domestic and wild animals. Brucellosis is a true zoonosis because humans acquire the infection directly or indirectly from infected animals. About 500,000 cases of human brucellosis are reported annually worldwide but this almost certainly is a gross underestimate of the true incidence of the disease.

Brucellosis is prevalent in Mediterranean countries, the Middle East, the Gulf of Arabia, the Indian subcontinent and Central and South

TABLE 231-3 -- Species of *Brucella* pathogenic to humans.

SPECIES OF *BRUCELLA* PATHOGENIC TO MAN			
Species		**Primary host**	**Humans as secondary host**
Brucella abortus (biovars 1–6, 9)		Cattle	+
Brucella melitensis (biovars 1–3)		Goats, sheep, camels	+
Brucella suis	biovars 1–3	Pigs	+
	biovar 4	Reindeer	+
	biovar 5	Small rodents	+
Brucella canis		Dog, fox, coyote	+

America. Some countries have eradicated brucellosis, including the UK, much of northern Europe, Australia, New Zealand and Canada.

In their natural hosts, *Brucella* spp. tend to cause chronic infections that are mild or asymptomatic. The bacteria localize in the reproductive tissues of ruminants, which are rich in mesoerythritol. Erythritol stimulates the multiplication of *Brucella* spp. This accounts for the main symptoms of brucellosis in animals — sterility or abortion. Erythritol is not present in human tissue. *Brucella* spp. are shed in large numbers in the products of conception, in urine and in milk, and when the animals are slaughtered. Humans are infected either by direct contact with infected animals or animal products or indirectly by ingesting infected milk or dairy produce.

In endemic areas the majority of cases occur in dairymen, herdsmen, abattoir workers, butchers and veterinary surgeons. Children may become infected in rural areas of developing countries if they live in close proximity with domestic animals. The general public generally acquires the infection through the ingestion of unpasteurized milk and milk products such as fresh soft cheese. Case-to-case transmission in humans is very rare. Self-inoculation with live *Brucella* vaccine is a recognized risk among veterinary surgeons. Laboratory workers are at risk of acquiring brucellosis through the inhalation of aerosols.[15] This has occurred when handling as yet unidentified Gram-negative coccobacilli without adequate safety precautions.

Brucella melitensis is responsible for the majority of human infections and is primarily food-borne. The primary hosts for *B. melitensis* are sheep and goats. *Brucella abortus* and *B. suis* infections are generally sporadic and occur in people who work with cattle or pigs respectively.[16] *Brucella canis* infections are the least common in humans and are generally laboratory-acquired.

PATHOGENICITY

Brucella spp. are facultative intracellular parasites, surviving and multiplying within cells of the reticuloendothelial system. The organisms enter the body by inhalation, ingestion or after penetration of intack skin, abrasions or the conjunctival mucosa. The major virulence determinant is the LPS of smooth strains (S-LPS). Organisms possessing S-LPS are more resistant to killing by normal serum. Soon after entry into the body, the bacteria are ingested by polymorphonuclear and mononuclear phagocytes. Virulent *Brucella* spp. can survive and multiply within these cells by releasing AMP and guanine monophosphate (GMP), which inhibit the bactericidal myeloperoxidase-peroxide-halide system of the phagocytes. Other factors that contribute toward the intracellular survival of *Brucella* spp. are the production of copper-zinc superoxide dismutase, which prevents oxidative destruction, S-LPS and stress-induced proteins that promote survival within macrophages. [17] [18]

After ingestion by phagocytes, the organisms proliferate in the local lymph nodes. The infection spreads hematogenously to tissues rich in elements of the reticuloendothelial system, including the liver, bone marrow, lymph nodes and spleen. Organisms may also localize in other tissues, including joints, the central nervous system, the heart and the kidneys.

In humans, *Brucella* spp. infection results in the formation of minute granulomata consisting of epithelioid cells, polymorphonuclear leukocytes, lymphocytes and some giant cells. In *B. melitensis* infections the granulomata are very small but there is often marked toxemia. *Brucella suis* is often accompanied by chronic abscess formation in joints and the spleen.

Endotoxin and hypersensitivity to *Brucella* antigens may cause some of the symptoms of brucellosis, including fever and weight loss. Antibodies against the *Brucella* LPS appear within a few days of the onset of the acute phase of the disease and are important in preventing re-infection. However, cell-mediated immunity, particularly the production of activated mononuclear phagocytes, is more important in promoting recovery.

Macrophages process *Brucella* antigens and present them to T cells, which excrete lymphokines, thus inactivating the bactericidal mechanisms of macrophages. The T-cell-derived lymphokines are also responsible for attracting cells to the foci of infection, resulting in the formation of granulomata. At the same time as the development of cell-mediated immunity, delayed-type hypersensitivity to numerous protein antigens can be demonstrated.

PREVENTION

The ideal method of prevention of human brucellosis is to eliminate the disease from domestic livestock. This has been achieved in several countries. An eradication campaign first focuses on mass vaccination of susceptible animals to reduce the incidence of brucellosis in domestic animals. *Brucella abortus* strain 19 vaccine is used for cattle and *B. melitensis* strain Rev-1 vaccine is used for sheep and goats. In the second phase of the campaign, infected animals are detected, using skin tests for sheep and serologic tests on milk or blood samples for cattle. Any infected animals must be compulsorily slaughtered, with financial compensation for their owners. The movement of animals must also be carefully controlled. All these measures require a program of effective education to ensure the co-operation of all those working

with susceptible animals.

Where eradication has not been achieved, people who are occupationally exposed should minimize the risk of infection by wearing protective clothing, gloves, goggles and masks. These measures are particularly important when handling animals that have recently given birth or aborted.

In the past, live, attenuated animal vaccines have been given to workers at high risk of contracting brucellosis. However, these vaccines may produce infection in humans and therefore are far from ideal. Recent work on pure mutants of *B. melitensis* has given promising results in animals but clinical trials in humans have not been undertaken. *Brucella* spp. are killed after heating at 140°F (60°C) for 10 minutes. Boiling or pasteurizing milk will therefore eliminate the risk of transmission via dairy products.

Laboratory-acquired infections can be prevented by handling all cultures and material possibly infected with *Brucella* spp. in a containment level 3 laboratory and in a category I or III exhaust protective cabinet.

DIAGNOSTIC MICROBIOLOGY

A definitive diagnosis depends on the isolation of *Brucella* spp. from cultures of blood, bone marrow or tissue taken early in the disease. Bone marrow cultures are reported to give a slightly higher yield than peripheral blood cultures but, since modern blood culture methods can produce positive results in up to 80% of cases, bone

marrow cultures are not generally required or advocated. Biphasic Castaneda bottles are traditionally recommended to reduce the risk of contamination during subculturing. Cultures should be incubated at 98.6°F (37°F) for at least 6 weeks before they are discarded. The modern semiautomated blood culture techniques (e.g. Bactec®, Bact-Alert®) are suitable for the isolation of *Brucella* spp. and are in use in many diagnostic laboratories. The lysis centrifugation method also gives good results. These commercial systems may give positive results in a matter of days rather than weeks, depending on the initial inoculum of organisms in the sample.

Positive cultures should be subcultured onto serum dextrose agar or a similar medium. Selective culture media are not necessary for human blood cultures but may be required for contaminated material. *Brucella* spp. produce small, smooth, translucent colonies after 48 hours of incubation at 98.6°F (37°C) in air plus 5–10% carbon dioxide.[19] The identity of the organisms can be confirmed by agglutination with monospecific antisera and lysis by specific Tbilisi bacteriophage.

Commercial galley-test identification systems may misidentify *Brucella* spp. as *Moraxella phenylpyruvica*, [15] and isolates should be sent to a reference laboratory for further tests to determine the biovar of the strain. This classification is based on the production of hydrogen sulfide and the tolerance of the organism to the bacteriostatic dyes basic fuchsin and thionin.

A PCR for diagnosing brucellosis has been described but awaits standardization and evaluation.[20] Antigen detection is another potential diagnostic tool.

Many serologic tests have been described for brucellosis. Interpretation of results is often difficult since both IgG and IgM antibodies can persist for a long time. A sample of serum should be collected as early as possible in the course of the disease. The serum agglutination test (SAT) using *B. abortus* strain 119 is widely used. False-negative results can occur if serum samples are not diluted beyond 1:320, owing to a prozone phenomenon. False-positive reactions have also been reported owing to cross-reactivity with strains of *Escherichia coli*, *Vibrio cholerae*, *Yersinia enterocolitica* and *Francisella tularensis*. The SAT measures both IgM and IgG. To measure the quantity of specific IgG the serum is treated with 2-mercaptoethanol to inactivate IgM. The SAT will not detect antibodies to *B. canis*. Enzyme-linked immunosorbent assay has the advantage that it can quantify IgM, IgG and IgA antibodies. Immunoglobulin G and IgA antibodies seem to be the best indicators of acute infection. A rise in antibody titer is observed in more than 97% of patients who have acute brucellosis and positive blood cultures. An initial IgM antibody response is followed after 1–2 weeks by a rise in IgG. During recovery the IgG antibody titers slowly decline over a period of months but IgM antibodies may persist at a low level in the serum for several years. Sustained IgG antibody titers or a second rise in IgG antibody levels are seen in chronic infection or relapse. Immunoblotting analysis of *Brucella* cytoplasmic antigens may be a way of differentiating active infection from past infection.[21] [22]

CLINICAL MANIFESTATIONS (see also Chapter 180)

Brucellosis is a systemic infection that can affect any tissue of the body. The protean, vague clinical symptoms are generally not specific for brucellosis.[23] The possibility of brucellosis should be considered in any fever of unknown origin, especially in patients who have occupational exposure or have recently traveled in endemic areas.

In about 50% of cases, the onset is acute following an incubation period of 2–8 weeks. An acute presentation is more commonly seen with *B. melitensis* than with the other species. The patient develops 'flu-like' symptoms of headache, myalgia, anorexia, depression, sweats, weight loss and fever. The fever often shows diurnal variation

Figure 231-3 Clinical manifestations of brucellosis.

and may come and go over a few weeks or months if the patient is untreated. This 'undulant' fever pattern is not invariably seen. On examination the patient may have hepatosplenomegaly and lymphadenopathy. The white cell count is often raised and liver function tests may be abnormal.

Some patients present with focal or localized infections (Fig. 231.3). Almost any organ of the body can be involved. Given this myriad of clinical features the only unequivocal way of diagnosing brucellosis is to isolate the organism from blood or tissue cultures (see above).

With appropriate treatment the majority of patients will recover within a few weeks or months. Relapses of infection are, however, fairly common. In some patients the symptoms persist for 12 months or more. This is called chronic brucellosis, an ill-defined condition in which a definitive diagnosis is often elusive. It is usually due to the persistence of a deep-seated focus of infection in a bone, joint, kidney, liver or spleen. Chronic brucellosis has similar features to the chronic fatigue syndrome. Typically, the patient suffers from malaise, depression and a fever, which comes and goes in 2- or 3-week cycles.

MANAGEMENT

Before the introduction of antibiotics, brucellosis was a chronic, relapsing illness. A number of antimicrobial agents are active against *Brucella* spp. in vitro but they are not always clinically effective. *Brucella* spp. tend to be sequestered intracellularly, so agents that achieve adequate intracellular concentrations should be used. It is also necessary to give a prolonged course of treatment to reduce the rate of relapsing infection (see also Chapter 180).

Treatment with doxycycline and rifampin (rifampicin) for 6 weeks is recommended for treating acute brucellosis in adults. Doxycycline plus streptomycin (or gentamicin) is an alternative and may result in fewer relapses. The combination of a quinolone, such as ofloxacin,

plus rifampin looks promising but awaits adequate clinical trials.[24] Children, in whom tetracyclines are contraindicated, can be treated with a combination of trimethoprim-sulfamethoxazole and an aminoglycoside. *Brucella* endocarditis and meningitis have been successfully treated with long-term courses of a combination of doxycycline, rifampin and trimethoprim-sulfamethoxazole. The majority of cases of *Brucella* endocarditis will also require surgical intervention. In the case of meningitis, treatment should be continued for 6–9 months.

FRANCISELLA SPECIES

NATURE

Francisella spp. are very small, faintly staining, pleomorphic Gramnegative, nonmotile and non-spore-forming coccobacilli. They are strictly aerobic, oxidase-negative and weakly catalase-positive. The organisms are surrounded by a thin, lipid-rich capsule. They attack carbohydrates slowly, producing acid but no gas. *Francisella tularensis* requires cysteine or cystine for growth and grows slowly at 98.6°F (37°C) on suitably enriched media. The G + C content of the DNA is 33–36mol%.

Francisella tularensis causes tularemia in animals and humans. Within the species *F. tularensis* there are several biovars or subspecies, which differ in their virulence and their epidemiology (Table 231.4). *Francisella philomiragia* was previously classified as *Yersinia philomiragia*. It is of low virulence to humans. *Francisella tularensis* biogroup *novicida* causes infections in laboratory animals but is of low virulence for humans.

EPIDEMIOLOGY

Francisella tularensis is distributed throughout the world but the majority of human infections occur in the northern hemisphere between latitudes 30° and 71°. It is well recognized in North America, Scandinavia and Russia. It has not been described in the UK. The organism is found in many species of wild and domestic animals, birds, fish and blood-sucking arthropods.

In the USA the most important reservoirs of *F. tularensis* are rabbits, hares, muskrats and ticks. In Scandinavia and Russia, rodents (such as voles and mice) and mosquitoes are important reservoirs. The modes of transmission to humans include tick or mosquito bites, contact with infected animal tissues, inhalation of an infectious aerosol or ingestion of contaminated meat or water. There is an increased risk of tularemia in certain occupations that bring people into contact with infected material.

There are approximately 200 cases each year reported in the USA, with over 50% occurring in the southern and southern-central states of Missouri, Oklahoma, Arkansas, Texas and Kansas. Most infections occur in males. There are more cases in summer (when there is a greater risk of exposure to biting insects) and in winter when animals are hunted and trapped.[25] [26]

TABLE 231-4 -- ***Francisella*** **species and biogroups.**

FRANCISELLA **SPECIES AND BIOGROUPS**					
Species	**Biogroup**	**Synonyms**	**Virulence in humans**	**Virulence in rabbits**	**Main animal hosts**
Francisella tularensis	*tularensis*	Type A neoarctica	+++	+++	Rabbits, hares, ground squirrels
F. tularensis	*palearctica*	Type B holoarctica	++	+	Rodents, beavers, muskrats
F. tularensis	*novicida*	(formerly *F. novicida*)	+	+	Rodents, rabbits
F. philomiragia		(formerly *Yersinia philomiragia*)	+	?	Muskrats
All the groups listed are found in North America; *Francisella tularensis* biogroup *palearctica* is also found in Asia and Europe.					

PATHOGENICITY

The infectious dose in humans depends on the route of entry. It can be as low as 10–50 organisms when inoculated through the skin or by inhalation. The infecting dose rises to 10^8 when the organisms are ingested. In most cases infection follows an insect bite or contact with infected animal products. Laboratory workers are at high risk through handling infected laboratory animals or cultures of the organism. *Francisella tularensis* is a hazard group 3 pathogen. *Francisella tularensis* biogroup *tularensis* is more virulent to animals and humans than biogroups *palearctica* and *novicida*.

After entry into the body, the organisms spread to the regional lymph nodes, from where they may disseminate via the lymphatic system or bloodstream to involve multiple organs. There is probably a transient bacteremia at this early stage. In affected animals large numbers of bacilli are present in the cells of the liver and the spleen. Focal necrosis occurs in affected tissue and granulomata may develop. The granulomata may sometimes caseate, giving an appearance similar to tuberculosis.

Francisella tularensis is a facultative intracellular parasite and can survive for prolonged periods within macrophages, hepatocytes and endothelial cells. Intracellular survival is associated with a failure of phagosome-lysosome fusion. Recovery from tularemia depends on cell-mediated immunity, which is directed against the protein antigens of the organism. The bacilli are protected from humoral antibodies, which are directed against carbohydrate antigens. [27]

Pathogenic strains of *F. tularensis* possess an antiphagocytic capsule. Loss of the capsule results in decreased virulence. Like other Gram-negative bacilli, *F. tularensis* has endotoxin activity.

PREVENTION

Prevention of tularemia is best achieved by avoiding exposure to the organism. Gloves, masks and goggles should be worn when skinning or eviscerating animals. Animals that look sick should be left intact. Game meat should be thoroughly cooked and fresh water that is possibly contaminated should not be drunk. Ticks should be promptly removed and chemical insect repellants may be used.

A live attenuated vaccine that induces both humoral and cell-mediated immunity is available for high-risk groups such as laboratory staff working on *F. tularensis*.[28] Live attenuated vaccine must the administered by scarification and does not induce complete protection but will reduce the severity of accidental infection. New tularemia vaccines based on individual components of *F. tularensis* are currently being developed and are attracting considerable interest, since *F. tularensis* is a potential biologic weapon.[29]

DIAGNOSTIC MICROBIOLOGY

Isolation of *F. tularensis* from clinical material is potentially hazardous and it is imperative that the laboratory is notified if tularemia is suspected so that appropriate containment precautions can be

taken. *Francisella tularensis* is a category 3 pathogen and should only be knowingly handled in a containment level 3 facility and in a class I or class III exhaust protective cabinet by trained and experienced staff.

The detection of *F. tularensis* in a Gram-stained smear of aspirates or other samples is rarely successful. Direct immunofluorescence of tissue smears is more sensitive and specific. A PCR method has been described that can be applied to blood samples. However, this does not appear to be any more sensitive than culture.

The organism requires cysteine or cystine for growth. Specialized media such as cysteine-glucose-blood agar have been devised, but *F. tularensis* will grow on some media that are routinely used for other organisms. Chocolate blood agar is often supplemented with cysteine (e.g. Iso VitaleX) and will then support the growth of *F.*

tularensis. Similarly, *F. tularensis* will grow on buffered charcoal yeast extract agar (BCYE), which is normally used to isolate *Legionella* spp. Occasionally, strains of *F. tularensis* will grow on ordinary laboratory media. It is therefore imperative to warn the laboratory if tularemia is suspected to ensure that proper containment precautions are taken when processing the specimens.

Cultures should be incubated at 98.6°F (37°F) with additional carbon dioxide in the atmosphere of incubation. *Francisella tularensis* grows slowly, taking 3–5 days to produce visible colonies, and cultures should be incubated for 3 weeks before being discarded as negative. The addition of penicillin to the medium will suppress the overgrowth of contaminants.

Colonies of *F. tularensis* are blue-gray, round, smooth and somewhat mucoid. They are a-hemolytic on blood-containing media. A slide agglutination method using commercial antiserum or a fluorescent antibody technique can be used to confirm the identity of the organism. Biochemical tests are of little value. Further subspeciation should only be undertaken in a reference laboratory.

However, most cases of tularemia are diagnosed serologically. An agglutination test using killed *F. tularensis* antigen is generally used. A

Figure 231-4 Clinical types of tularemia.

4-fold rise in antibody titer or a single titer of more than 1:160 is considered diagnostic. Immunoglobulin G and IgM antibodies can persist for months or years and it may be very difficult to distinguish past from current infection. Infections with *Brucella* spp., *F. novicida* and *F. philomiragia* can give rise to antibodies that cross-react with *F. tularensis*. An ELISA test has been described.

CLINICAL MANIFESTATIONS

The clinical manifestations of *F. tularensis* infection depend on the portal of entry, the virulence of the infecting organism and the immune status of the individual host. After 3–5 days of incubation the patient develops an abrupt onset of flu-like symptoms — fever, chills, malaise, anorexia and tiredness. The cases are classified clinically into six types, based on the site of the infection and the presence of skin lesions and lymphadenopathy. This division is somewhat artificial because there is considerable overlap between the types (Fig. 231.4) (see Chapter 177).[30]

The most common presentation is ulceroglandular tularemia, which accounts for 70–85% of cases. The patient has a painful red papular skin lesion at the site of entry of the organism, which proceeds to ulcerate with regional lymphadenopathy. There is an accompanying systemic illness with fever, headache, sweating and myalgia. In oculoglandular tularemia (1–2% of cases) the organisms are inoculated via the conjunctival route, resulting in a severe conjunctivitis and regional lymphadenopathy. Oropharyngeal tularemia (2–4%) occurs when the primary invasion is via the oropharynx. There is a severe exudative pharyngitis and regional lymphadenopathy.

In some cases there is regional lymphadenopathy and no local skin lesion. This glandular form of tularemia occurs in 5–10% of cases. Other cases present with a systemic illness but no local skin lesions or lymphadenopathy. This typhoidal form of tularemia accounts for 5–15% of cases. Many of these patients have serious underlying illnesses and the infection may follow an acutely fulminating course. Pneumonic tularemia (5–20% of cases) may follow inhalation of contaminated aerosols or may occur as a complication of bacteremic dissemination of organisms in any of the other groups.

The severity of the infection is highly variable and ranges from a mild afebrile or asymptomatic self-limiting infection to fulminant sepsis. Milder cases are often associated with biogroup *palearctica* infections.

Tularemia may result in chronic debility lasting for several months, with fatigue and suppuration of infected lymph nodes. The overall mortality rate is 1–3% with antimicrobial treatment, but typhoidal tularemia and secondary pneumonic tularemia carry a higher morbidity and mortality.[31]

Francisella tularensis biogroup *novicida* infection results in a milder form of tularemia. *Francisella philomiragia* may cause pneumonia, sepsis and meningitis in patients with underlying conditions, including chronic granulomatous disease, myeloproliferative disorders or near-drowning in salt water.

MANAGEMENT

Streptomycin remains the drug of first choice for treating all forms of tularemia. Gentamicin is an acceptable alternative.[25] Tetracycline and chloramphenicol have been used to treat infections but both are bacteriostatic for *F. tularensis* and there is a high rate of relapse when these agents are used. *Francisella tularensis* produces a ß-lactamase, and ß-lactamase-stable ß-lactams, such as cefotaxime, ceftriaxone and imipenem, may be of use, although they have not been fully evaluated. Other potentially useful but unproven agents include erythromycin and fluoroquinolones such as ciprofloxacin (see Chapter 177).[31]

HAEMOPHILUS SPECIES

NATURE

Haemophilus spp. are small, pleomorphic, nonmotile, nonsporing Gram-negative rods or coccobacilli. They are aerobic and facultatively anaerobic. Growth is often enhanced by the addition of 5–10% carbon dioxide to the incubation atmosphere. The oxidase and catalase reactions vary among the species. *Haemophilus* spp. require one or both of two accessory growth factors (X and V). X factor can be provided by hemin, protoporphyrin IX or other iron-containing porphyrins. X-dependent *Haemophilus* spp. cannot synthesize protoporphyrin from d-aminolevulinic acid, a process involving several enzyme-mediated steps, some or all of which may be defective. V factor is nicotinamide adenine dinucleotide (NAD) or NAD phosphate or certain unidentified precursors of these compounds. It is essential for oxidation-reduction processes.

The differential requirements for X and V factors are important criteria for defining *Haemophilus* spp., which are obligate parasites of humans and animals. There are eight species of *Haemophilus* associated with infections in humans (Table 231.5). *Haemophilus influenzae* is the major human pathogen in the group. Some strains of *H. influenzae* have a polysaccharide capsule, of which there are six distinct antigenic types, designated a–f. The most important is type b, which has a capsule consisting of polyribosyl ribitol phosphate (PRP). *Haemophilus influenzae* type b (Hib) strains are associated with the majority of invasive infections.

Haemophilus influenzae biogroup *aegyptius* (formerly *Haemophilus aegyptius*) is a cause of epidemic conjunctivitis and Brazilian purpuric fever. *Haemophilus ducreyi* is the causative agent of chancroid. *Haemophilus aphrophilus*, *H. paraphrophilus* and *H. parainfluenzae* are occasionally implicated in infective endocarditis and in brain and liver abscesses.

The genus *Haemophilus* is a member of the family Pasteurellaceae, which also encompasses the genera *Pasteurella* and *Actinobacillus*. The G + C content of DNA in *Haemophilus* spp. is 37–44mol%.

EPIDEMIOLOGY

Haemophilus influenzae is an obligate parasite of human mucous membranes; it is not found in any other animal species. It colonizes the throat and nasopharynx, and to a lesser extent the conjunctivae and genital tract. The respiratory tract is colonized by *Haemophilus*

TABLE 231-6 -- Spectrum of infections caused by *Haemophilus influenzae*.

SPECTRUM OF INFECTIONS CAUSED BY *HAEMOPHILUS INFLUENZAE*		
Infections	**Age group affected**	**Strains**
1. Invasive infections:	90% children <4 years old	90% type b
Meningitis	10% older children and adults	10% ncHi
Epiglottitis		1% types e, f
Pneumonia		
Septic arthritis		
Osteomyelitis		
Cellulitis		
Bacteremia		
2. Neonatal and maternal sepsis	Neonates	Over 90% ncHi
	Parturient mothers	
3. Noninvasive respiratory infections, otitis media, sinusitis, conjunctivitis, acute exacerbations of chronic bronchitis	Children and adults	Over 90% ncHi

spp. — mainly *H. parainfluenzae* and noncapsulated strains of *H. influenzae* (ncHi) — in 25–75% of healthy people. Carriage of Hib is found in 3–5% of healthy people. Immunization of infants with conjugate Hib vaccine results in a reduction in the rate of nasopharyngeal colonization by Hib.[32]

Haemophilus influenzae is associated with two types of infection, invasive infections and noninvasive infections (Table 231.6), which have distinctive epidemiologic profiles.[33] The commonest invasive infection caused by *H. influenzae* is meningitis, but epiglottitis, pneumonia, bone and joint infections and cellulitis also occur. These bacteremic infections are usually caused by Hib. Rarely, other capsular serotypes, especially a, e and f, and ncHi, are associated with invasive infections.

Haemophilus influenzae type b meningitis principally affects children aged 2 months to 2 years. Epiglottitis occurs in slightly older children, with the peak incidence being in children aged 2–3 years. Risk factors for invasive disease are mainly socio-economic and include overcrowding, attendance at day care centers, chronic illness and lack of access to good health care facilities.

Invasive Hib infections are distributed worldwide but the incidence varies from country to country with very high incidence rates being found in certain racial groups, for example Apache and Navajo Native

TABLE 231-7 -- **Annual incidence of *Haemophilus influenzae* type b meningitis.**

ANNUAL INCIDENCE OF *HAEMOPHILUS INFLUENZAE* TYPE b MENINGITIS	
Country	**Incidence**
England	25
Finland	26
USA (Texas, North Carolina, Maryland, California)	19–69
Australia (New South Wales, Victoria)	20–25
Hong Kong Chinese	2.7
Gambia	60
Alaskan Inuit	282
Apache Native Americans	254
Australian Aborigines	454
Figures for incidence per 100,000 children under the age of 5 years and are from various countries and ethnic groups prior to the introduction of routine immunization.	

Americans, Alaskan Inuit and Australian Aborigines (Table 231.7).[34] In these racial groups the peak incidence of infection occurs at a younger age. By contrast, a

very low incidence rate has been reported in Hong Kong Chinese. There is seasonal variation, with most cases occurring in the winter months.

The introduction of vaccines effective against Hib in infants has dramatically reduced the incidence of invasive disease in children in countries using this vaccine, and consequently the epidemiology is changing.

The noninvasive infections of the respiratory tract associated with *H. influenzae* include otitis media, sinusitis, acute exacerbations of chronic bronchitis and conjunctivitis. The majority of these infections are caused by ncHi and many occur in adults. There is often an underlying physiologic or anatomic abnormality. These infections have a worldwide distribution and all of them are more common in the winter months.

Haemophilus influenzae biogroup *aegyptius* is associated with an acute form of seasonal conjunctivitis and septicemia (Brazilian purpuric fever) in hot climates; these conditions occur in children.[35]

PATHOGENICITY

Haemophilus influenzae is transmitted by aerosols of respiratory secretions or by direct contact with contaminated material. The primary event is colonization of the nasopharynx. Prior infection with respiratory viruses (e.g. influenza) promotes colonization and subsequent infection by *Haemophilus* spp. The microbial factors that promote colonization include fimbriae, LPS, IgA1 protease and a ciliotoxin.[36] Noninvasive infections of the respiratory tract result

TABLE 231-8 -- Conjugate *Haemophilus influenzae* type b (Hib) vaccines.

CONJUGATE *HAEMOPHILUS INFLUENZAE* TYPE B (Hib) VACCINES

PRP-D	ProHIBit (Connaught)	PRP	Diphtheria toxoid

from contiguous spread of organisms colonizing the respiratory tract. Acute sinusitis, otitis media and acute exacerbations of chronic bronchitis usually follow a viral infection. This predisposes to secondary infection with potentially pathogenic components of the local resident bacterial flora by mechanisms including obstruction to the outflow of respiratory secretions, depression of local immunity and suppression of mucociliary clearance. The majority of these infections are caused by ncHi. Possession of the outer membrane protein P2 is an important virulence factor for ncHi. Immunoglobulin A1 protease and ciliotoxin appear to be important in the pathogenesis of pneumonia.

Invasive infections, notably meningitis and epiglottitis, are mainly caused by Hib and result from invasion of the bloodstream. The pathogenesis of these infections has been elegantly elucidated using an infant rat model.[37] The capsule of type b *H. influenzae* is the single most important determinant of virulence for invasion because it protects the organism from phagocytosis and complement-mediated lysis. The rarity of infections in the first 2 months of life correlates with the presence of maternal antibodies to PRP and the occurrence of infection in early infancy with the absence of antibodies having such specificity. As the mean level of PRP antibodies in the population rises, so Hib infections become less common. It is unclear whether natural antibody production is stimulated by exposure to Hib or to some other organism (e.g. *E. coli* K100) that possesses cross-reacting antigens.

Brazilian purpuric fever is caused by a single clone of *H. influenzae* biogroup *aegyptius*.[35] The LPS phenotype is a critical determinant of virulence for *H. influenzae* biogroup *aegyptius*.

PREVENTION

Vaccination

Conjugate vaccines have now been developed in which the PRP is covalently linked to a protein carrier (Table 231.8).[38] These vaccines produce a lasting anamnestic response, which is not age-related. They can be given effectively to infants as young as 2 months of age and are also effective in high-risk groups of patients who give a poor response to polysaccharide vaccines. The Hib vaccine can be given concurrently with diphtheria-tetanus-pertussis immunization. In the UK, Hib vaccine is thus administered at 2, 3 and 4 months of age. Most countries except the UK and the Republic of Ireland give a booster dose in the second year of life. Countries where Hib vaccine is routinely offered have witnessed a dramatic decline in the occurrence of Hib infections (Fig. 231.5).[39] [40]

Administration of Hib conjugate vaccine has the important additional effect of reducing nasopharyngeal colonization with Hib.[34]

Haemophilus influenzae type b vaccine is recommended after splenectomy, or for patients who have functional asplenia, together with pneumococcal vaccine and meningococcal vaccine.

There is as yet no effective vaccine for ncHi infections.

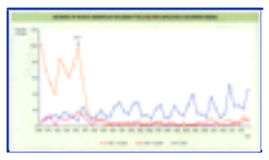

Figure 231-5 Incidence of invasive *Haemophilus influenzae* type b and noncapsulated *H. influenzae* disease. Figures are for the period from October 1990 to June 1997 in England.

Chemoprophylaxis

Oral rifampin for 4 days is recommended for eradicating carriage of *H. influenzae* and has been used to prevent secondary infection in household and nursery contacts. Its efficacy is unproven. Unvaccinated siblings of a case who are more than 4 years old and less than 10 years old should be immunized with Hib conjugate vaccine. Unvaccinated siblings less than 4 years old should be offered both chemoprophylaxis and vaccine. Children less than 4 years of age who have invasive Hib disease should also be offered both vaccine and chemoprophylaxis in order to eliminate nasopharyngeal carriage, because disease sometimes fails to induce immunity in the very young. Widespread use of the vaccine may soon render chemoprophylaxis unnecessary.

DIAGNOSTIC MICROBIOLOGY

Gram-stained smears of cerebrospinal fluid, pus, sputum or aspirates from joints, middle ear or sinuses may provide a rapid diagnosis. *Haemophilus influenzae* tends to stain poorly and dilute carbol fuchsin is a better counterstain than neutral red or safranin.

Rapid tests for Hib capsular antigens, such as latex agglutination or a PCR-based method, can be applied to clinical material. False-positive latex agglutination results have been reported in cere-brospinal fluid samples collected from children who had recently received Hib vaccine.

Specimens should be plated on appropriate culture media as soon as possible. Chocolate agar is the most commonly used medium for culturing *Haemophilus* spp. It can be used without further supplementation for specimens from normally sterile sites. The addition of bacitracin to chocolate agar will assist the recovery of *H. influenzae* from respiratory samples because it will suppress the growth of other respiratory organisms.[41] Good growth can also be obtained on certain transparent

media that contain blood extracts (e.g. Levinthal's agar or Fildes peptic digest agar).

The cultures should be incubated at 98.6°F (37°C) in an aerobic atmosphere enriched with 5–10% carbon dioxide. After 24 hours of incubation, colonies of ncHi are small, circular, smooth and pale gray. Capsulated strains produce somewhat larger, mucoid colonies, which have a characteristic seminal odor. On clear media, such as Levinthal's agar, colonies of capsulated strains exhibit iridescence when viewed obliquely with transmitted light. Type b capsulated strains can also be detected by the presence of precipitin haloes on transparent media containing hyperimmune Hib antiserum.

Confirmation of the identity of colonies depends on demonstrating a requirement for X factor, V factor, or both. This is usually performed as a disk test. The culture is plated onto a nutrient agar that is deficient in both X and V factor, and paper disks containing X factor alone, V factor alone, and both X and V factors are placed on the surface of the agar. After overnight incubation, growth is observed around the disks supplying the required growth factors (Fig. 231.6).

Haemophilus influenzae strains should be typed to determine their capsular serotype. This is normally carried out by slide agglutination using type-specific antisera. This method is prone to misinterpretation, with problems of autoagglutination, cross-reacting antisera and observer error. The definitive method of typing *H. influenzae* is capsular genotyping using a PCR-based method.

CLINICAL MANIFESTATIONS

Invasive infections

Meningitis is the commonest and most serious manifestation of systemic infection with *H. influenzae* (see Table 231.6). It is a disease of infants, principally between the ages of 2 months and 2 years.

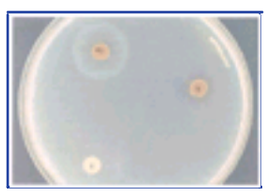

Figure 231-6 Growth factor requirement of *Haemophilus influenzae.* Strain of *H. influenzae* sown on Columbia agar plate. Filter paper disks containing X factor, V factor, and both X and V factors have been placed on the surface of inoculated plate, but colonies of *H. influenzae* grow only around the disk with both X and V factors.

There is often a history of a preceding viral upper respiratory tract infection or otitis media. There are no clinical features that distinguish *Haemophilus* meningitis from other forms of bacterial meningitis. Up to 20% of survivors of *Haemophilus* meningitis have long-term neurologic sequelae — notably sensorineural deafness. *Haemophilus* meningitis can also occur in neonates, [42] older children and adults. In neonates the causative organism is almost invariably ncHi and the presentation can resemble group B streptococcal sepsis. In adults the infection may be secondary to head injury, neurosurgery, chronic sinusitis or mastoiditis. Both ncHi and Hib may be responsible. [43]

Epiglottitis is a life-threatening infection that is almost always caused by Hib. It occurs in slightly older children, aged 2–5 years, with a peak incidence in those aged 2–3 years. Typically there is a rapid onset of sore throat, fever and dyspnea, which may progress to airway obstruction requiring emergency tracheostomy and ventilation. Examination of the larynx is potentially hazardous because it may provoke respiratory obstruction. The diagnosis should be based on the clinical findings confirmed by blood culture results (see also Chapter 31).

Other less common manifestations of invasive *H. influenzae* disease include pneumonia, periorbital cellulitis (which is generally unilateral), septic arthritis and osteomyelitis, or a bacteremia without any obvious focus of infection. *Haemophilus* pneumonia is a major cause of mortality among young children in the developing world.

Noninvasive infections

A variety of local infections, principally in the respiratory tract, may be seen. These include otitis media, sinusitis, conjunctivitis and acute exacerbations of chronic bronchitis (see Chapter 33). Most of these infections are caused by noncapsulated strains of *H. influenzae*. *Haemophilus influenzae* is an important cause of purulent conjunctivitis. This may be sporadic but can occur in outbreaks. Severe conjunctivitis associated with severe sepsis and a high mortality was first described in 1984 in Brazilian children aged 1–4 years. The causative organism is a clone of *H. influenzae* biogroup *aegyptius*, which is indistinguishable in routine laboratory tests from ncHi.

Rarely *H. influenzae* may be associated with other infections, including urinary tract infections, cholecystitis, salpingitis and epididymo-orchitis. Many of these unusual infections are associated with pre-existing damage, including the presence of urinary stones or gallstones.

Haemophilus parainfluenzae, *H. aphrophilus* and *H. paraphrophilus* may be associated with infective endocarditis, meningitis and cerebral abscesses.[44] These species form part of the HACEK group (see below).

Haemophilus segnis is occasionally associated with acute appendicitis.

MANAGEMENT

Cefotaxime, ceftriaxone and related third-generation cephalosporins are the antibiotics of choice for treating *Haemophilus* meningitis. They are bactericidal for *H. influenzae*, achieve high concentrations in the meninges and cerebral tissues, and have proved highly effective in clinical practice.

Chloramphenicol was formerly the treatment of choice. Resistance may be encountered but in most parts of the world this remains uncommon. Ampicillin is also effective but resistance due to a ß-lactamase is now encountered in an unacceptably high percentage of strains.[45] For example, 25% of Hib strains in the UK are ß-lactamase-producing. In view of this, ampicillin should no longer be used as a single agent in *Haemophilus* meningitis in countries where ampicillin resistance is prevalent.

Antibiotic therapy is only one component of the clinical management of meningitis and full supportive care is required to achieve the most favorable outcome. Skilled medical and nursing care is essential in cases of epiglottitis to maintain the patient's airway.

The risk of infection is increased 500-fold for close contacts of a case of invasive Hib disease. Close contacts should be given rifampin chemoprophylaxis and, where appropriate, offered Hib vaccine (see above).

For the treatment of less serious respiratory infections, oral antibiotics including amoxicillin, amoxicillin-clavulanate, tetracycline, erythromycin or newer macrolides such as clarithromycin or azithromycin are all effective. ß-Lactamase-mediated amoxicillin resistance may again be a problem. In the UK, 20% of ncHi isolates are ß-lactamase producers. Occasional strains are resistant to ampicillin by an intrinsic mechanism.

HAEMOPHILUS DUCREYI

EPIDEMIOLOGY

Haemophilus ducreyi is the causative agent of the sexually transmitted disease chancroid, or soft sore.[46] Chancroid is endemic in tropical areas, particularly central and southern Africa, South East Asia, India and the Caribbean. It occurs sporadically in other parts of the world and recently there have been major outbreaks in Canada and the USA. It is more common in nonwhite, uncircumcised males and in low socio-economic groups living in poor hygienic conditions. Infection may be asymptomatic or inapparent in females. Genital ulcers, including chancroid, are associated with increased transmission of HIV.

PATHOGENICITY

Haemophilus ducreyi has not been isolated from nonhuman sources and is sexually transmitted. The organisms gain access via a break in the epithelium and establish infection in a focal area of mucosa or skin in the genital tract. The pathogenesis of chancroid is poorly understood. Potential virulence factors include fimbriae, LPS, cytotoxins and outer membrane protein (OMP).[47] [48]

PREVENTION

The use of condoms dramatically reduces the transmission of *H. ducreyi*. All sexual partners should be identified by contact tracing and treated. Education is vitally important.

DIAGNOSTIC MICROBIOLOGY

Specimens should be collected from the base and margins of ulcers using a saline-moistened swab or by aspirating a bubo. On Gram-stained examination pleomorphic coccobacilli or short rods may be seen. They are more commonly extracellular but may be intracellular. Characteristically they resemble 'shoals of fish'. However, ulcer material is generally contaminated with other bacteria and direct Gram-staining identifies only about 10% of culture-positive cases.

Haemophilus ducreyi is a fastidious organism that grows slowly on chocolate agar. In general a suitable medium contains a growth supplement such as IsoVitaleX and is made selective by the addition of vancomycin. [49] [50]

Cultures should be incubated for up to 5 days at 95–97°F (35–36°C) with added moisture and carbon dioxide.

The appearance of colonies of *H. ducreyi* varies with the medium used. Typically, after 24 hours incubation the colonies are pinpoint, yellow-gray and translucent or semiopaque. Cultures often appear mixed, with a variety of colonial forms. The colonies are very cohesive and can be pushed across the agar surface with an inoculating loop.

Haemophilus ducreyi requires X factor but not V factor for growth. It can be identified using a number of rapid test systems, including API-ZYM, Minitek and RapIDNH.

A variety of noncultural techniques have also been developed for *H. ducreyi* including indirect immunofluorescence, ELISA-based antigen detection and PCR-based methods.[51]

CLINICAL MANIFESTATIONS

After exposure there is an incubation period varying from 1 day to several weeks (average 5–7 days). Initially, tender papules develop on an area of genital skin or mucosa, surrounded by a zone of erythema. After 2–3 days the papules become pustular and then break down to form sharply circumscribed, painful ulcers with ragged, undermined edges. The base of the ulcer bleeds easily when it is scraped. Ulcers may be single or multiple. The ipsilateral regional inguinal lymph nodes become painful and enlarged. If left untreated, nodes may become fluctuant, forming an abscess or bubo. In some cases, buboes may spontaneously rupture, leading to chronic sinus formation (see Chapter 78).

* Requirements on primary isolation; usually lost on subculture.
† Colonies pit the agar.
‡ Pitted colonies.

MANAGEMENT

Most isolates of *H. ducreyi* are susceptible to erythromycin and the newer macrolides azithromycin, clarithromycin and roxithromycin. A 1-week course of oral erythromycin is well established as an effective treatment for chancroid. A single dose of azithromycin[52] or ceftriaxone appears to be effective but there have been reports of treatment failures with ceftriaxone in HIV-positive men in Kenya. Indeed, HIV-positive patients may respond poorly to any treatment for chancroid.

The susceptibility of *H. ducreyi* to antimicrobial agents varies from one geographic area to another.[53] Many strains are ß-lactamase producers and resistance to

tetracycline is common. Trimethoprim-sulfamethoxazole resistance is being increasingly seen, especially in the Far East.

Other agents that show excellent in-vitro activity against *H. ducreyi* include quinolones such as ciprofloxacin, rifampin, spectinomycin and amoxicillin-clavulanate.[54]

Buboes should be drained to prevent sinus formation.

HACEK GROUP

NATURE

The HACEK group of organisms includes *H. parainfluenzae*, *H. aphrophilus*, *H. paraphophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens* and *Kingella kingae*. They are all small, fastidious, pleomorphic Gramnegative bacilli that form part of the normal commensal flora of the oropharynx and are infrequent causes of human infections. They are slow-growing, their growth being enhanced by the use of enriched culture media and an increased carbon dioxide tension. Some biochemical properties that can be used to differentiate the individual species are listed in Table 231.9 .

Cardiobacterium hominis and *E. corrodens* usually require hemin (X factor) and CO_2 on primary isolation and may be misidentified as *Haemophilus* spp.; these requirements are lost on subculture. The colonies of *E. corrodens* have a characteristic 'bleach-like' odor and often 'pit' the surface of the agar. Colonies of *K. kingae* produce slight ß-hemolysis on blood agar.

CLINICAL MANIFESTATIONS

Collectively, the HACEK group of organisms causes 3% of all cases of infective endocarditis[55] and is responsible for a variety of other infections (see Chapter 59).

Actinobacillus actinomycetemcomitans was originally thought to be a secondary pathogen in actinomycotic infections caused by *Actinomyces israelii*. It is now recognized as a cause of periodontal infections, brain and other soft tissue abscesses, osteomyelitis and infective endocarditis.[56]

Cardiobacterium hominis has been implicated in cases of natural and prosthetic valve endocarditis[57] but rarely causes other types of infection.

Eikenella corrodens tends to cause indolent infections, often in association with other organisms. Infections associated with *E. corrodens* include periodontitis, human bite wounds, sinusitis, meningitis, brain abscess, pulmonary infections, pelvic infections, endocarditis, osteomyelitis and septic arthritis.[58] [59] [60] Clenched fist injuries are the most serious human bite wounds and are sustained when the knuckles of the assailant's hand strike the teeth of the adversary.

Kingella spp. (*K. kingae* and *K. denitrificans*) are associated with endocarditis and osteoarticular infections. Since the introduction of routine Hib immunization in the USA, and consequent decline in Hib septic arthritis, *K. kingae* has emerged as a major cause of septic arthritis in children under 2 years of age.[61]

Haemophilus parainfluenzae, *H. aphrophilus* and *H. paraphophilus* may all cause endocarditis. *Haemophilus parainfluenzae* has been reported as a rare cause of the spectrum of infections associated with *H. influenzae*: meningitis, epiglottitis, septic arthritis, osteomyelitis, pneumonia and bacteremia. *Haemophilus aphrophilus* may cause brain abscesses, septic arthritis, osteomyelitis or meningitis. *Haemophilus paraphrophilus* has been implicated in cases of epiglottitis, brain abscess and osteomyelitis.

PREVENTION

Approximately 60% of cases of endocarditis caused by HACEK organisms are associated with poor oral hygiene, bad dentition or recent dental work.[55] Prevention of endocarditis should therefore be based on good dental and oral hygiene in patients at risk of endocarditis.

MANAGEMENT

The treatment of endocarditis caused by HACEK organisms should be based on antimicrobial susceptibility tests, including tests for ß-lactamase activity. Since many of these organisms are slow-growing, such tests can be problematic. Currently, third-generation cephalosporins, including cefotaxime or ceftriaxone, are the drugs of choice for treating endocarditis caused by the HACEK organisms.

Eikenella corrodens is generally susceptible to penicillin, but consideration should be given to the possibility of ß-lactamase-producing aerobic and anaerobic organisms when treating mixed infections, such as human bites.

LEGIONELLA SPECIES

NATURE

Legionella spp. are slender, aerobic, noncapsulated, non-spore-forming Gram-negative rods. In clinical material they often appear as coccobacilli but they tend to form elongated filamentous forms on some culture media. They are motile with polar flagella. *Legionella* spp. stain poorly with Gram stain. Basic fuchsin is a better counterstain for these organisms. They do not attack carbohydrates, and nitrate is not reduced. *Legionella* spp. are nutritionally fastidious and will not grow on ordinary culture media. A suitable medium for their isolation is buffered charcoal yeast extract (BCYE) supplemented with L-cysteine, a-ketoglutarate and ferric ions. The cell wall contains branched-chain fatty acids with high concentrations of ubiquinones, which give characteristic profiles by gas-liquid chromatographic analysis.

TABLE 231-10 -- *Legionella* species associated with disease in humans.

***LEGIONELLA* SPECIES ASSOCIATED WITH DISEASE IN HUMANS**	
Species	**Number of serogroups**

Legionella parisiensis	1
Legionella sainthelensi	2
Legionella tucsonensis	
Legionella wadsworthii	1

There are more than 40 species and 64 subgroups in the genus *Legionella*. More than 15% of human infections are caused by *Legionella pneumophila* serogroup 1, but other serogroups and other species, particularly *Legionella micdadei*, have also been implicated (Table 231.10).

EPIDEMIOLOGY

Legionella spp. are distributed worldwide. They are found in natural bodies of fresh water — streams, rivers, ponds, lakes and thermal pools — in moist soil and mud. They have even been found in the canopy of the rain forest. The organisms are able to survive in moist environments for long periods of time and can withstand temperatures of 32–154°F (0–68°C) and a pH range of 5.0–8.5 They can survive chlorination and can thus enter water supply systems and proliferate in thermal habitats, including air-conditioning cooling towers, hot water systems, shower heads, taps, whirlpool spas and respiratory ventilators. The organisms are found in biofilms on the surfaces of these systems, where they are far less susceptible to the effects of biocides and chlorine. The growth of *Legionella* spp. is aided by co-existing micro-organisms, which provide nutrients, and free-living amebae, in which the *Legionella* spp. can reside and multiply. [62]

The exact incidence of *Legionella* infections is difficult to determine. There is no doubt that exposure to *Legionella* spp. is a fairly frequent event and serologic surveys suggest that asymptomatic infection and seroconversion are common. Large-scale surveys of pneumonia suggest that *Legionella* spp. cause 2–5% of community-acquired pneumonia and up to 30% of nosocomial pneumonia.

Cases may be sporadic or occur as part of an outbreak. The original description of Legionnaires' disease was of an outbreak of a febrile respiratory illness in delegates at an American Legion convention in Philadelphia in 1976. A total of 221 people developed pneumonia and 34 died.[63] Retrospective studies have revealed that the first proven case occurred in 1947 and the first known epidemic was in 1965 in Washington, DC.

Sporadic cases are reported throughout the year, but most cases of epidemic infection occur in the summer and autumn, presumably because warmer weather encourages proliferation of the bacteria in water. The disease tends to occur in the middle-aged and elderly, especially in people who have impaired respiratory and cardiac function, who are heavy smokers or who are immunocompromised. Cases have been documented in children. Person-to-person spread has not been demonstrated. Surgery is a major predisposition in nosocomial infection, with transplant patients at the greatest risk.

Legionella is a good example of an organism that has been present in the environment for a long time but has been brought into close contact with humans as a result of technical developments. Organisms are disseminated via contaminated water droplets from nebulizers and humidifiers and in aerosols from cooling towers, whirlpools and evaporative condensers. Infection arises from inhalation of contaminated aerosols, direct instillation during surgery or possibly by ingestion of contaminated water. Hospital equipment that has been rinsed in tap water prior to use may be a source of infection.

PATHOGENICITY

Legionella spp. residing in water are transmitted to humans via aerosols. Droplet nuclei of less than 5µm will reach the alveoli, where the organisms are ingested by alveolar macrophages. *Legionella* is a facultative intracellular parasite and multiplies freely within the macrophages. The bacteria bind to the alveolar macrophages via complement receptors and are engulfed in phagosomes. Phagolysosome fusion is inhibited by an unknown mechanism that prevents intracellular killing. The bacteria multiply within the phagosomes. Eventually the cell ruptures, releasing bacteria, which are then taken up by other macrophages. This process produces chemotactic substances that attract polymorphonuclear leukocytes and monocytes. The inflammatory response results in a destructive pneumonia.

The virulence factors of *L. pneumophila* have not been fully determined. A 24kDa protein, macrophage infectivity potentiator, appears to be required for virulence. The major outer membrane protein may be important in the uptake of *Legionella* spp. by macrophages. A variety of extracellular enzymes are produced by *Legionella*,

including proteases, esterases and hemolysins, but these have not been shown to be important virulence factors.[64] The virulence of *L. pneumophila* may be enhanced by multiplication in amebae.

PREVENTION

Prevention of legionellosis depends upon identification of the environmental source and reduction of *Legionella* colonization. The most commonly used method of decontamination is periodic superheating and flushing of water supplies. This method is particularly useful for urgent disinfection during an outbreak. Hyperchlorination is no longer recommended because chlorine decomposes in hot water and *Legionella* spp. are relatively chlorine-tolerant. Biocides are relatively ineffective. The most effective method appears to be copper-silver ionization units, which generate metallic ions that disrupt and kill bacterial cells.[65] Despite these costly measures it is often impossible to eliminate *Legionella* spp. from water supplies.[66]

New water systems should be designed to minimize the risk of heavy colonization with *Legionella* spp., avoiding 'dead spaces', stagnation, materials that support the growth of *Legionella* spp. and the build-up of sediment. Regular monitoring for *Legionella* spp. is also advisable, particularly in high-risk areas.

Several putative vaccines have been developed that induce cell-mediated immunity in guinea pigs. These may be an option in the future for highly susceptible patients.

DIAGNOSTIC MICROBIOLOGY

Definitive diagnosis of legionellosis depends on culturing *Legionella* organisms, detecting *Legionella* antigens in body fluids or demonstrating a serologic response to the infection.[67] A PCR method is also available but does not appear to be any more sensitive than culture. A PCR test can be successfully used to identify *Legionella* in water samples.

Legionella spp. can be cultured from sputum, endotracheal aspirates, bronchoalveolar lavages, lung biopsies and pleural fluid. Sputum samples should not be diluted in saline, because this can prove inhibitory to some *Legionella* spp., but in distilled water. Gram-stained smears of the sample will reveal poorly staining Gram-negative rods, which are suggestive of legionellosis. Direct immunofluorescence of the smear using a monoclonal antibody to a major outer membrane protein common to all the serogroups of *L. pneumophila* can give a rapid provisional diagnosis but this test is not as sensitive as culture and will only detect *L. pneumophila*.

Cultures must therefore also be carried out. The sample should be cultured on a specific medium such as BCYE. *Legionella* spp. do not grow on blood agar. It is possible to render BCYE semiselective by the inclusion of antibiotics, but this may prove inhibitory to some strains of *Legionella* spp. It is therefore prudent to culture samples on both BCYE and BCYE supplemented with antibiotics. Contaminated material, such as sputum, can be heated at 122°F (50°C) for 30 minutes to suppress the growth of other less heat-stable organisms prior to inoculating the culture plates. Cultures should be incubated at 98.6°F (37°C) in 2–5% carbon dioxide for up to 14 days. *Legionella* spp. are slow growing, and on primary isolation it may take 3–5 days for colonies to appear. Colonies of *Legionella* spp. have a ground-glass appearance, which may be white, gray, pale blue, or purple-tinged (Fig. 231.7). Often the colonies will fluoresce under ultraviolet light.

Colonies that grow on BCYE but not blood agar, that are catalase-positive and have a characteristic Gram-stain morphology should be regarded as presumptive *Legionella* spp. *Legionella pneumophila* hydrolyzes hippurate, starch and gelatin but in general biochemical tests are not of great help in identifying *Legionella* spp. Serologic typing using direct or indirect fluorescent antibody tests with polyclonal or monoclonal antibodies will confirm the identity of clinical isolates.

Urine samples can be examined for *Legionella* soluble antigen using an ELISA test. This test is specific for *L. pneumophila* serogroup

Figure 231-7 Colonies of *Legionella pneumophila* on BCYE agar, showing the typical ground-glass appearance. *With permission from Harrison TG, Taylor AG (eds). A laboratory manual for Legionella. Chichester: Wiley; 1998.*

1 (which causes 70–80% of human infections) and can give a rapid diagnosis. However, it will not detect infections caused by other *Legionella* spp. The antigen persists in the urine for 1–3 weeks but some patients continue to excrete antigen for months.

Serologic tests can be used to make a diagnosis of legionellosis. The most commonly used technique is an indirect fluorescent antibody test, but other techniques, such as ELISA or a rapid micro-agglutination test, are also available. A 4-fold or greater rise in antibody titer or a single titer of 256 or more indicates *Legionella* infection. It may take weeks or even months for the antibody titer to rise, and antibodies can persist for years, so serology is less useful than culture or antigen detection in the diagnosis of acute cases. Serology is much more useful in epidemiologic studies. The only validated serologic test is for *L. pneumophila* serogroup 1. Cross-reacting antibodies may be found in patients who have *Campylobacter* spp. infection.

CLINICAL MANIFESTATIONS

Asymptomatic *Legionella* infections are relatively common, as demonstrated by seroepidemiologic surveys.

Symptomatic *Legionella* infection can present in two distinct ways: a severe pneumonia — Legionnaires' disease — and an acute influenza-like illness known as Pontiac fever.[68]

Legionnaires' disease

The most common presentation is an acute pneumonia,[69] which accounts for 5% of community-acquired pneumonia and up to 30% of nosocomial pneumonia (see also Chapter 34). After an incubation period of 2–10 days there is an acute onset of fever, malaise, myalgia and headache, followed by a nonproductive cough and dyspnea. Confusion can be a prominent feature, and abdominal pain and diarrhea may also be present. The severity of the illness ranges from a mild infection not requiring hospitalization to life-threatening multilobar *Legionella* pneumonia and respiratory failure. The infection may progress to involve many organs, and renal and hepatic dysfunction are commonly seen. Many of the manifestations are not specific for Legionnaires' disease and may occur in other infective pneumonias. Characteristic features suggestive of *Legionella* spp. are hyponatremia (serum sodium less than 130mmol/ml) and a Gram-stained smear of respiratory secretions showing many polymorphs but few if any visible organisms. Legionnaires' disease should be considered in any pneumonia that has failed to respond to ß-lactam antibiotics.

In previously healthy people, the mortality is approximately 10%, but the mortality rate may be 30–50% in immunocompromised patients or those in whom there is a delay in making the diagnosis.

The chest radiograph characteristically shows patchy interstitial inflammation. Initially this is unilateral and involves the lower lobe. The initial infiltrates progress to areas of consolidation over a few days. Pleural effusions are commonly seen.

Bacteremic dissemination may occur, particularly in immunocompromised patients. Cellulitis, pancreatitis, endocarditis and sinusitis have all been reported.

Cases of wound infection and prosthetic valve endocarditis due to *Legionella* infection have been described. These are generally nosocomial infections.

Pontiac fever

Pontiac fever[68] is an acute, self-limited, flu-like, febrile illness that occurs 1–2 days after exposure. It is thought to represent a hypersensitivity reaction following acute exposure. The illness lasts for 2–5 days and there is no evidence of pneumonia. The chest radiograph is clear. The condition resolves spontaneously. Pontiac fever has a high attack rate, in contrast to Legionnaires' disease, in which only a small proportion of people exposed to the organism develop the disease.

MANAGEMENT

Azithromycin, ciprofloxacin or high-dose erythromycin is the treatment of choice. In the patient who is acutely ill with Legionnaires' disease, azithromycin or a quinolone should be administered together with rifampin (rifampicin), although it should be noted that good comparative clinical trials in this area are lacking.

Cases of Pontiac fever resolve spontaneously without the need for antibiotic therapy.

MORAXELLA SPECIES

NATURE

The genus *Moraxella* is composed of two subgenera, *Moraxella* and *Branhamella*. [70] *Moraxella* (*Moraxella*) spp. are short, oxidase-positive, catalase-positive, DNA-ase-negative Gram-negative coccobacilli that often appear in pairs. They are strictly aerobic and asaccharolytic. The G + C content of DNA is 40–40mol%.

Moraxella (*Moraxella*) *lacunata* is associated with conjunctivitis. *Moraxella* (*Moraxella*) *non-liquefaciens* is a commensal in the upper respiratory tract and may be a secondary invader in respiratory infections. *Moraxella* (*Moraxella*) *osloensis* is a common commensal in the genital tract and may be misidentified as *Neisseria gonorrhoeae*. Unlike *N. gonorrhoeae*, *M. osloensis* grows well on blood agar. *M. osloensis* has been reported in cases of septic arthritis, osteomyelitis and bacteremia. These three organisms will not be further discussed.

Moraxella (*Branhamella*) spp. are Gram-negative diplococci that morphologically and phenotypically resemble *Neisseria* spp. They are aerobic, oxidase-positive, catalase-positive, DNA-ase-positive and asaccharolytic. The G + C content of DNA is 40–45mol%. *Moraxella* (*Branhamella*) *catarrhalis* is now recognized as an important cause of upper and lower respiratory tract infections in children and adults.

EPIDEMIOLOGY

Moraxella (*Branhamella*) *catarrhalis* is exclusively found in humans. The nasopharyngeal carriage rate of *M. catarrhalis* is 1–3% in healthy adults, but up to 75% of infants and young children are colonized with this organism. This remarkable disparity remains unexplained. Nasopharyngeal carriage rates are significantly higher in the autumn and winter months. It also appears that the carriage rate is higher in adults who have chronic lung disease than in healthy adults.

PATHOGENICITY

The majority of *M. catarrhalis* infections result from contiguous spread of organisms colonizing the upper respiratory tract. Little is known of the events that alter the host-pathogen relationship and cause a shift from asymptomatic colonization to infection in the upper or lower respiratory tract.

The virulence factors of *M. catarrhalis* have not been fully elucidated. The majority of strains possess pili or fimbriae, which play a role in adherence to host mucosal cells. The outer membrane lipooligosaccharide (LOS) is probably a virulence factor. Three serotypes of LOS have been identified. Some strains are serum-resistant, by virtue of interference with the formation of the membrane attack complex of complement. There is some evidence that *M. catarrhalis* possesses a polysaccharide capsule. *M. catarrhalis* synthesizes a significant amount of histamine, which results in decreased mucociliary clearing and increased colonization of the respiratory tract. [71]

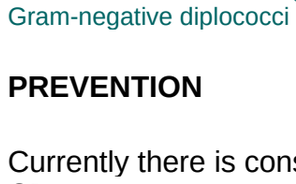

Figure 231-8 Gram-stained smear of sputum containing *Moraxella catarrhalis*. Sample from a patient suffering an acute exacerbation of chronic bronchitis showing Gram-negative diplococci and leukocytes (*Moraxella catarrhalis*).

PREVENTION

Currently there is considerable interest in the development of a vaccine to prevent *M. catarrhalis* infections based on OMPs including UspA, CopB, OMP B1 and OMP CD.

DIAGNOSTIC MICROBIOLOGY

Moraxella catarrhalis grows well on blood agar and chocolate agar, producing small, nonhemolytic, grayish-white colonies that slide across the agar surface, like a hockey puck, when pushed with a bacteriologic loop. It may be difficult to distinguish *M. catarrhalis* from commensal *Neisseria* spp. in respiratory tract specimens, and the use of selective media may be necessary. Gram-stained films reveal Gram-negative diplococci but *M. catarrhalis* often resists destaining and thus may appear to be Gram-positive (Fig. 231.8). The bacteria are oxidase-positive. *M. catarrhalis* is DNA-ase-positive, nitrate-reductase-positive and hydrolyzes tributyrin, tests that differentiate it from the majority of *Neisseria* spp.

A PCR test has been devised that can be applied to clinical material without the need for bacterial culture. This test has been successfully used to detect *M. catarrhalis* in middle ear effusions and appears to be more sensitive than culture.

CLINICAL MANIFESTATIONS

Moraxella catarrhalis is an important cause of otitis media and sinusitis in children, being the third most common cause of these conditions after *Streptococcus pneumoniae* and *H. influenzae*.

In adults *M. catarrhalis* is associated with acute exacerbations of chronic bronchitis, being the third most common isolate after *H. influenzae* and *S. pneumoniae*. *M. catarrhalis* may cause pneumonia, especially in the elderly and is associated with a poor prognosis. Lower respiratory tract infection with *M. catarrhalis* is more common in the winter months.

There have been several reports of nosocomial outbreaks of lower respiratory tract infections due to *M. catarrhalis* in respiratory units.[69]

Moraxella catarrhalis may occasionally cause invasive infections, including bacteremia, meningitis and endocarditis.

MANAGEMENT

Before 1977 no ß-lactamase-positive isolates of *M. catarrhalis* had been reported. By 1980 75% of *M. catarrhalis* isolates in the USA were ß-lactamase-positive and now virtually all strains of *M. catarrhalis* are ß-lactamase-positive. There are two *M. catarrhalis* ß-lactamases, BRO-1 and BRO-2, which are unique to this genus. There is some evidence that, in mixed infections, *M. catarrhalis* ß-lactamases can protect other respiratory pathogens such as *S. pneumoniae* and *H. influenzae* from the action of ß-lactam antibiotics. The ß-lactamases of *M. catarrhalis* are chromosomal and inducible; therefore ampicillin therapy should be avoided.

Many infections due to *M. catarrhalis* can be treated with oral antibiotics, including amoxicillin-clavulanate, trimethoprim, sulfamethoxazole, tetracyclines, (contraindicated in children aged under 7 years), cefaclor, clarithromycin, azithromycin and ciprofloxacin.

PASTEURELLA SPECIES

NATURE

Pasteurella spp. are very small, nonmotile, non-spore-forming Gram-negative bacteria that are coccoid, oval or rod-shaped. They often exhibit bipolar staining. They are aerobic and facultatively anaerobic. Most species are catalase-positive and slowly oxidase-positive. They attack carbohydrates readily, forming acid but no gas. Nitrates are reduced to nitrite. *Pasteurella* spp. will grow on ordinary laboratory media at 98.6°F (37°C). The G + C content of the DNA is 40–45mol%.

The family Pasteurellaceae encompasses the genera *Pasteurella*, *Actinobacillus* and *Haemophilus*. There are 11 species within the genus *Pasteurella*. The species *Pasteurella multocida* is further subdivided into subspecies on the basis of acid production from dulcitol and sorbitol. Most human infections are caused by *P. multocida*.

EPIDEMIOLOGY

Pasteurella spp. are distributed worldwide. They are commensals or parasitic organisms in the upper respiratory tract and gastrointestinal tracts of many domestic and wild animals and birds.

Pasteurella multocida is found in the oropharynx of 50–90% of domestic cats, 50–70% of dogs and 50% of pigs. It is the cause of hemorrhagic sepsis in cattle and water buffalo, pneumonia in pigs and sheep, snuffles in rabbits and fowl, and cholera in chickens, ducks and turkeys. It is generally carried asymptomatically by cats and dogs but may infect bites inflicted on these animals by feline or canine assailants. Humans become infected through contact with infected animals.

Pasteurella multocida can remain viable in soil and water for up to 4 weeks and may survive in animal carcasses for up to 3 months. Most human infections are caused by *P. multocida* subsp. *multocida* and *P. multocida* subsp. *septica*. *Pasteurella canis*, *Pasteurella dagmatis* and *Pasteurella stomatis* have also been associated with human disease (Table 231.11).

PATHOGENICITY

Pasteurella multocida is transmitted to humans by contact with infected animals. The most common source of infection is bites, scratches, or licks from cats or dogs (see Chapter 91).[72] Respiratory tract infections in those handling animals may result from airborne transmission. In a few patients it is not possible to document an animal source of the infection.

TABLE 231-11 -- Species of *Pasteurella* associated with infections in humans.

SPECIES OF *PASTEURELLA* ASSOCIATED WITH INFECTIONS IN HUMANS
Pasteurella multocida subsp. *multocida*
Pasteurella multocida subsp. *septica*
Pasteurella canis
Pasteurella dagmatis
Pasteurella stomatis

Virulence in *P. multocida* is associated with the degree of encapsulation. Strains with large capsules are more resistant to phagocytosis in vivo. There are four capsular types — A, B, D and E — and 11 somatic antigens.

PREVENTION

The only way of effectively preventing *Pasteurella* infections is to avoid contact with domestic or wild animals. Animal bites should be cleaned promptly and devitalized tissue should be debrided. Prophylactic antibiotics may be indicated after cat and dog bites, particularly if the patient is immunocompromised or diabetic or the wound affects the hands or face.

DIAGNOSTIC MICROBIOLOGY

A clinical history of animal bites will, in most instances, alert the laboratory to the possibility of *Pasteurella* spp. Samples should be cultured on blood agar plates at 98.6°F (37°C) for 24 hours. *Pasteurella multocida* grows as small, nonhemolytic colonies. Gramstained films reveal very small Gram-negative coccobacilli. The organisms often show bipolar staining in methylene blue preparations. The identity of the organism can be confirmed by a series of biochemical and serologic tests and serology (Table 231.12). [73]

CLINICAL MANIFESTATIONS

Pasteurella infections in humans usually present as soft tissue infections. The onset is acute, several hours after being bitten or scratched by a domestic or wild animal. Open wounds may be infected by animal licks. The area is erythematous, painful and swollen. In nearly 50% of cases the infection spreads to deeper tissues, leading to tenosynovitis, abscess formation, septic arthritis or osteomyelitis. There may be an accompanying regional lymphadenopathy or lymphangitis. The severity of the infection is often greater than one would suspect on first inspection. Some *Pasteurella* infections present as respiratory infections, which may be chronic. In other cases the patient presents with a bacteremic infection, which may or may not result in a localized focus of infection (Fig. 231.9).[73] [74]

TABLE 231-12 -- Differentiation of *Yersinia* and *Pasteurella* species.

Pasteurella multocida	-	±	+	-	-	+	-	+	-	+

Figure 231-9 Clinical manifestations of *Pasteurella* infection in humans.

Approximately one-third of patients who have bacteremia have underlying cirrhosis.

MANAGEMENT

Animal bites should be carefully cleaned, irrigated and debrided. Penicillin is the treatment of choice for *Pasteurella* infections. Other agents with good activity include ampicillin, amoxicillin-clavulanate, cefuroxime and ciprofloxacin. Many infected animal bites have a polymicrobial etiology and it is prudent to use a regimen that provides good cover against anaerobes and streptococci as well, such as amoxicillin-clavulanate. A strain of *P. multocida* that produced ROB-1 ß-lactamase has been reported.

Prophylactic antibiotics for cat and dog bites are sometimes advocated but their value is not clearly established (see Chapter 91).

YERSINIA SPECIES

NATURE

Yersinia spp. are members of the Enterobacteriaceae. They are short, pleomorphic Gram-negative rods or coccobacilli, which often exhibit

bipolar staining. *Yersinia pestis* is nonmotile. Other species are nonmotile at 98.6°F (37°C) but motile at temperatures less than 86°F (30°C) by means of peritrichous flagella. They are aerobic and facultatively anaerobic, oxidase-negative and catalase-positive. They are nonlactose fermenters. *Yersinia pestis* is urease-negative, and *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* are both urease-positive. *Yersinia* spp. grow on simple laboratory media and are tolerant of bile salts. The optimal temperature for growth is 82–86°F (27.8–;30°C). They do not form spores or capsules, but *Y. pestis* produces a capsule-like envelope. They share antigens with other members of the Enterobacteriaceae.

The genus *Yersinia* contains three important human pathogens associated with zoonotic infections — *Y. pestis* causes plague, and *Y. pseudotuberculosis* and *Y. enterocolitica* give rise to infections known as yersiniosis.

Because these two diseases are very different they are described separately.

PLAGUE

Epidemiology

Yersinia pestis causes plague, an infection that has afflicted humans since biblical times. It was known and feared as 'the Black Death' in the Middle Ages. Over the centuries there have been about 150 recorded epidemics and pandemics of plague. The pandemic of plague that swept across Europe in the 14th century killed about one-third of the total population of continental Europe and England. The 'Great Plague' of 1665 killed more than 100,000 people in London. In the 20th century plague is still found in many parts of the world, including China, Mongolia, South East Asia, India, central and southern Africa, the Middle East, South America and the southwestern states of the USA. Major epidemics or pandemics no longer occur, possibly because of improved standards of hygiene, more effective rodent control and the use of insecticides. Worldwide, approximately 3000 cases of plague were reported in 1994.[75] Males and females are equally affected.

Pathogenicity

Plague is a zoonotic infection. It is transmitted between its natural hosts, wild rodents, by rodent flea bites or by the consumption of infected animal carcasses. The rodents may succumb to plague or become carriers of the organism. This carrier state ensures the endemicity of plague in some parts of the world. *Yersinia pestis* persists in many sylvatic rodent species, including ground squirrels, tree rats, voles and prairie dogs. Urban rats — *Rattus rattus* and *Rattus norvegicus* — are the most important reservoirs of plague for human infections.

Humans are accidentally infected when they are bitten by a plague-carrying rodent flea. Occasionally, humans are infected by handling infected animal tissues. Only rarely, during an epidemic, does person-to-person spread occur. The most efficient vector is the oriental rat flea, *Xenopsylla cheopsis*, but there are over 30 species of rodent fleas capable of transmitting plague. Occasionally, infection may pass from patient to patient via the human flea, *Pulex irritans*. This may have been an important vector in some of the medieval epidemics. During an epizootic there is a build-up of infections in the rodent population and many may die. It is at this time that human infections are more likely to occur, since the rodent fleas turn to humans in search of food (Fig. 231.10).

The flea vector becomes infected by feeding on the blood of a diseased rodent. It ingests *Y. pestis* with the blood meal. The organisms multiply within the stomach of the flea. At temperatures of less than 80°F (26.7°C), *Y. pestis* produces coagulase and a blood clot is formed. This fibrinous clot, which contains viable *Y. pestis*, blocks the proventriculus of the flea. When the hungry flea attempts to feed

Figure 231-10 Transmission of plague.

from another rodent or human, the fresh blood meal, together with thousands of *Y. pestis* bacilli, is regurgitated back into the bite wound. Thus the infection is transmitted to a new host. When the ambient temperature is over 80°F (26.7°C), *Y. pestis* does not produce coagulase and may form fibrinolysin, so a clot does not form and blockage and regurgitation do not occur. Transmission of *Y. pestis* is therefore uncommon during hot, dry seasons.

On entering the new host, the bacilli migrate via the lymphatics to the regional lymph nodes. In the flea, *Y. pestis* produces only a small amount of envelope antigen (F-1 antigen). The ingested organisms are readily phagocytosed by polymorphonuclear phagocytes and mononuclear phagocytes. *Yersinia pestis* is a facultative intracellular parasite and resists killing within the mononuclear phagocytes. *Y. pestis* can multiply within these cells, where it elaborates F-1 envelope antigen. If the macrophages are lysed, the re-enveloped organisms are able to resist phagocytosis and can multiply freely in the extracellular environment. The regional lymph nodes become hot, tender and inflamed and undergo hemorrhagic necrosis. This produces the black buboes characteristic of plague. The infection then spills into the bloodstream and may rapidly spread to the liver, lungs and spleen. If the lungs are affected, a severe pneumonia develops and large numbers of plague bacilli are expectorated into the air.[76]

There are a number of putative virulence factors — F-1 antigen consists of a glycoprotein (F-1A) and a carbohydrate-free protein (F-1B). It is antiphagocytic and stimulates protective immunity in mice and humans.

Other important virulence factors are V–W antigens and *Yersinia* outer membrane proteins (YOPs).[77] These protein antigens are produced at 98.6°F (37°C) in the presence of low concentrations of calcium. They appear to be important both for intracellular survival and multiplication and for extracellular survival by virtue of their antiphagocytic activity. The LPS of *Y. pestis* is in part responsible for hemorrhagic necrosis and vascular collapse, but the mechanism is again poorly understood (Table 231.13). Coagulase and fibrinolysin are produced by *Y. pestis*. They aid survival and dissemination within the invertebrate host.

TABLE 231-13 -- Virulence factors of *Yersinia pestis.*

VIRULENCE FACTORS OF *YERSINIA PESTIS*		
Factor	**Composition**	**Pathogenic role**
F-1 antigen 'envelope'	Glycoprotein F^1 A + protein F^1 B	Antiphagocytic

V antigen	Protein	Antiphagocytic
+		
W antigen	Lipoprotein	(Aids intracellular survival)
YOPs	Proteins	Antiphagocytic
LPS	Lipopolysaccharide	Hemorrhagic
		Focal necrosis

Prevention

Prevention depends on effective control of the rodent and flea populations that harbor *Y. pestis*. Fleas can be controlled by the use of insecticides in domestic settings. A variety of measures have been used to control rats in urban environments (e.g. ratproofing houses) and to prevent rats migrating on ships or airplanes. It is, however, virtually impossible to eliminate sylvatic rodents, which remain a reservoir for plague.

A formalin-killed vaccine is effective against bubonic plague but not pneumonic plague. It is recommended for travelers to endemic areas, workers who handle rodents and laboratory staff working with *Y. pestis*. Protection is only short-lived and booster doses are required for those who continue to be exposed to the risk of infection. A subunit vaccine containing recombinant F1 and V antigens is under development and appears to be protective in an animal model.[78]

Diagnostic microbiology

Plague should be suspected in febrile patients exposed to flea bites or rodents in endemic parts of the world. It is important to notify the laboratory if plague is suspected so that appropriate precautions can be taken. There is a considerable risk of laboratory-acquired infection. Material suspected of containing *Y. pestis* must be handled in a containment level 3 laboratory in a category I or III exhaust protective cabinet by experienced, trained personnel. Smears taken from bubo aspirates, blood, sputum or cerebrospinal fluid should be examined using Gram's stain and methylene blue. Gram's stain will reveal Gram-negative pleomorphic coccobacilli with rounded ends. Methylene blue stain will demonstrate bipolar staining. *Yersinia pestis* appear light blue with dark blue polar bodies. Smears can also be examined by direct immunofluorescence.

Material can be cultured on blood agar or MacConkey agar or in broth cultures. Cultures should be incubated at 80°F (26.7°C). Tiny, translucent, nonhemolytic colonies appear on blood agar after 24 hours. After further incubation the colonies enlarge and become opaque. *Yersinia pestis* grows rather poorly in MacConkey agar and the colonies tend to autolyze after 2–3 days. In fluid culture *Y. pestis* tends to form chains.

The identity of presumptive colonies of *Y. pestis* can be confirmed using cultural and biochemical tests. Alternatively, definitive identification can be made by direct immunofluorescence of the organisms. A serologic diagnosis can be made using a passive hemagglutination test using tanned sheep red cells to which F-1 antigen has been adsorbed, or a complement fixation test. A 4-fold or greater rise in titer or a single titer over 1:16 in convalescent serum indicates plague infection. For large-scale seroepidemiologic surveys an ELISA test for antibodies to F-1 antigen can be used.

Strains of *Y. pestis* can be typed using bacteriophage typing.

TABLE 231-14 -- Plague syndromes.

PLAGUE SYNDROMES	
Syndrome	**Clinical features**
Bubonic plague	Fever
	Painful lymph node
	Bubo
Pneumonic plague	Primary following inhalation of *Yersinia pestis* or secondary to bubonic plague
	Fever
	Cough
	Dyspnea
	Hemoptysis
	± bubo
Septicemic plague	Fever
	Shock
	Purpura
	Distal gangrene
	No bubo
Plague meningitis	Secondary to bubonic plague

Clinical manifestations

There are a number of distinct clinical presentations of plague (Table 231.14) (see also Chapter 176).

Bubonic plague

The most common presentation is bubonic plague. Following a flea bite, which is often on the lower extremities, the bacteria proliferate in the regional lymph nodes for 2–8 days. The patient then develops a fever of sudden onset and an intensely painful swelling in a group of lymph nodes. This is the bubo. The most common site for the primary bubo is the groin. From this site the bacteria disseminate throughout the body in a transient bacteremia. Some patients will develop a secondary pneumonia or sepsis. Most patients do not develop skin lesions. Untreated patients may die within 2–4 days of the onset of symptoms.

Pneumonic plague

In some patients who have bubonic plague the infection spreads to the lung via the bloodstream. The patient develops a high fever and cough, chest pain and hemoptysis. Less commonly, pulmonary plague may be the primary event following the inhalation of infected droplet nuclei from patients who have pneumonic disease. Patients who have primary pulmonary plague do not have buboes. Pneumonic plague is highly contagious because large numbers of plague bacilli are expectorated during coughing. This form of plague carries a higher mortality than bubonic plague.

Septicemic plague

In some cases a flea bite is followed by proliferation of *Y. pestis* in the circulation without any localization in lymph nodes and bubo formation. This form is more common in children and is often rapidly fatal.

Other manifestations of plague include a meningitis secondary to inadequately treated bubonic plague. Overall, the mortality of untreated plague is more than 50%.

Management

The treatment of choice remains streptomycin. It is essential to institute therapy as soon as possible because untreated plague runs a rapidly fulminating course. With prompt effective antimicrobial therapy the mortality rate is reduced from over 50% to 6%. Streptomycin resistance has been reported in some parts of the world. Oral tetracycline is an alternative but it is contraindicated in

---

children and during pregnancy. Chloramphenicol may also be used and is the treatment of choice for plague meningitis. All cases of plague should be reported to national health authorities and to the World Health Organization (see Chapter 176).

YERSINIOSIS

Yersiniosis encompasses a wide spectrum of infections caused by *Y. enterocolitica* and *Y. pseudotuberculosis*. The clinical features range from gastroenteritis, enterocolitis, or measenteric adenitis to sepsis.

Epidemiology

Yersinia enterocolitica is harbored in the gastrointestinal tract of a wide range of mammals, including rodents, cattle, sheep, pigs, cats and dogs. Infected animals tend to become chronic carriers and excrete large numbers of bacilli, which can contaminate water and dairy products. Humans are infected by eating inadequately cooked meat (especially pork) or other food contaminated with *Yersinia* spp. Infection may also arise following contact with an infected domestic animal. In the USA, outbreaks associated with dairy products, chocolate and milk have been reported. Rarely, water is the source of the infection. The ability of *Y. enterocolitica* to grow at 39°F (4°C) means that refrigerated meat and meat products can become a potent source of infection. Infections are more common in children than adults. Most cases occur in the autumn and winter. *Yersinia enterocolitica* sepsis has been reported following the transfusion of blood that has been stored for more than 3 weeks at 39°F.

Yersinia enterocolitica is a well-recognized cause of abdominal pain and diarrhea in Scandinavia and northern Europe. It is less commonly seen in the USA. Cases have been reported from other parts of the world. In Europe, infections are generally sporadic and the predominant serotypes are 03 and 09. In the USA, sporadic infections are less common but food-borne outbreaks caused by serotypes 03 and 09 have been described.[79]

Yersinia pseudotuberculosis infection is less commonly seen. The organism is harbored in the gastrointestinal tract of rodents, farm animals and birds. Human infections have been reported from all parts of the world but, as with *Y. enterocolitica*, it is more common in northern Europe than elsewhere. Infection is generally seen in children and affects males more frequently than females. The majority of infections occur in the winter.[80]

Pathogenicity

Yersinia enterocolitica generally gains entry to the body via the gastrointestinal tract. The infecting does is 10^8 –10^9 organisms/ml. Within the ileum the organisms adhere to the mucosa and incite an inflammatory response. They also invade mucosal cells, Peyer's patches and macrophages, where they can survive intracellularly and multiply. This results in a severe diarrhea and abdominal pain mimicking acute appendicitis. There may be necrosis of Peyer's patches, ulcerative ileitis or mesenteric adenitis.

The organisms may disseminate through the body, producing sepsis and splenic and hepatic abscesses. A reactive polyarthritis can occur, particularly in HLA-B27-positive patients.[81]

Yersinia pseudotuberculosis generally gives rise to mesenteric adenitis. Both species produce V–W and YOPs antigens, which are essential for virulence, and an outer membrane protein, invasin, which is involved in adherence to and invasion of cells.

Prevention

Prevention of yersiniosis depends on good animal husbandry and careful slaughtering techniques to minimize contamination of meat with orofecal material. Meat should not be consumed raw and should not be stored at 39°F (4°C) for prolonged periods before consumption. There is no effective vaccine.

Diagnostic microbiology

Material for culture will include stool specimens, blood, lymph nodes and food samples. Specimens should be cultured on blood agar and MacConkey agar at 80°F (26.7C) for 24 hours. Heavily contaminated samples such as feces can be subjected to a cold enrichment technique whereby the sample is inoculated into phosphate-buffered saline and incubated at 39°F (4°C) for 3 weeks or more. The broth is subcultured at weekly intervals on to MacConkey agar or a special selective medium, CIN (cefsulodin, irgasan, novobiocin) agar. *Yersinia pseudotuberculosis* is rarely isolated from feces.

Presumptive colonies of *Yersinia* spp. are identified using a range of physical and biochemical tests (see Table 231.12). The serotype can be determined using slide agglutination tests.

A serologic diagnosis depends on demonstrating a significant rise of serotype-specific antibodies.

Clinical manifestations

A variety of clinical presentations have been documented in yersiniosis (Table 231.15). The commonest form is acute gastroenteritis due to *Y. enterocolitica*. [81] [82] This is often indistinguishable from *Salmonella* or *Campylobacter* gastroenteritis, and the patient complains of abdominal pain, diarrhea and vomiting. The incubation period is probably 3–7 days. The commonest presentation of *Y. pseudotuberculosis* infection is mesenteric adenitis, which can mimic acute appendicitis.

Some patients develop a reactive polyarthritis a few days after the onset of enteritis. This is associated with the presence of HLA-B27. Erythema nodosum occurs in about one-third of patients.

Sepsis is uncommon and is generally associated with a variety of underlying conditions. These include diabetes mellitus, cirrhosis, old age, malignancy, hemachromatosis, multiple blood transfusions and iron overload, particularly when treated with deferoxamine. Patients who have sepsis may develop hepatic or splenic abscesses, endocarditis or meningitis.

The mortality of *Yersinia* sepsis is 50%.

Management

Yersinia enteritis and mesenteric adenitis do not generally require antimicrobial chemotherapy. Sepsis, extraintestinal foci of infection and enteritis in immunocompromised patients should be treated with antimicrobials. *Yersinia enterocolitica* is generally resistant to penicillin, ampicillin and first-generation cephalosporins. Aminoglycosides, quinolones, tetracyclines and third-generation cephalosporins have all been used successfully to treat *Y. enterocolitica* infections. *Yersinia pseudotuberculosis* is usually sensitive to benzylpenicillin and ampicillin.

TABLE 231-15 -- Clinical manifestations of yersiniosis.

CLINICAL MANIFESTATIONS OF YERSINIOSIS

Yersinia enterocolitica	***Yersinia pseudotuberculosis***
Gastroenteritis	Mesenteric lymphadenitis
Mesenteric lymphadenitis	Ulcerative ileitis
Ulcerative ileitis	Septicemia
Septicemia	Erythema nodosum
Hepatic or splenic abscesses	
Reactive polyarthritis (HLA-B27)	
Reiter's syndrome	
Erythema nodosum	
Meningitis	
Exudative pharyngitis	
Note that septicemia in *Yersinia enterocolitica* infection is associated with underlying conditions, including diabetes mellitus, cirrhosis, malignancy, hemochromatosis, old age, anemia, iron overload and deferoxamine treatment.

Chapter 232 - Anaerobic Bacteria

Itzhak Brook

INTRODUCTION

Infections caused by anaerobic bacteria are common, and may be serious and life-threatening. Anaerobes are the predominant components of the bacterial flora of normal human skin and mucous membranes,[1] and are therefore a common cause of bacterial infections of endogenous origin. Because of their fastidious nature, these organisms are difficult to isolate from infectious sites and are often overlooked. Delay in appropriate therapy against these organisms often leads to clinical failures. Their isolation requires appropriate methods of collection, transportation and cultivation of specimens.[2] [3] [4] Treatment of anaerobic bacterial infection is complicated by the slow growth of these organisms, which makes diagnosis in the laboratory only possible after several days, by the often polymicrobial nature of the infection and by the growing resistance of anaerobic bacteria to antimicrobial agents.

NATURE

Anaerobic bacteria do not grow on solid media in the presence of room air (10% carbon dioxide and 18% oxygen), whereas facultative anaerobic bacteria grow both in the presence and in the absence of air. Microaerophilic bacteria grow poorly or not at all aerobically, but grow better under 10% carbon dioxide or anaerobically. Anaerobes can be divided into strict anaerobes that are unable to grow in the presence of more than 0.5% oxygen and moderate anaerobes that are capable of growing at between 2 and 8% oxygen.[4] Anaerobes generally do not possess catalase, but some clinical isolates produce superoxide dismutase that can protect them from oxygen.

The clinically important anaerobic bacteria are:

- six genera of Gram-negative rods (*Bacteroides, Prevotella, Porphyromonas, Fusobacterium, Bilophila* and *Sutterella* spp.);
- Gram-positive cocci (primarily *Peptostreptococcus* spp.);
- Gram-positive spore-forming (*Clostridium* spp.) and nonspore-forming bacilli (*Actinomyces, Propionibacterium, Eubacterium, Lactobacillus* and *Bifidobacterium* spp.); and
- Gram-negative cocci (mainly *Veillonella* spp.) (Table 232.1).[4] [5] [6]

The frequency of recovery of anaerobic bacterial strains differs in various infectious sites (Table 232.2). Mixed infections caused by numerous aerobic and anaerobic organisms are observed commonly in clinical situations (Fig. 232.1). [2] [3]

The taxonomy of anaerobic bacteria has changed in recent years because of improved characterization methods using genetic studies.[4] [6] The ability to differentiate between similar strains enables better characterization of type of infection and predicted antimicrobial susceptibility.

The species of anaerobes most frequently isolated from clinical infections are, in decreasing frequency:

- Gram-negative bacilli,
- Gram-positive cocci,
- *Clostridium* spp.,
- *Fusobacterium* spp.,
- Gram-positive bacilli (*Eubacterium, Lactobacillus, Propionibacterium, Actinomyces* and *Bifidobacterium* spp.), and
- Gram-negative cocci (*Veillonella* and *Acidaminococcus* spp.).[2] [3] [4]

Approximately 95% of the anaerobes isolated from clinical infections are members of these genera. The remaining isolates belong to species not yet described, but these usually can be assigned to the appropriate genus on the basis of morphologic characteristics and fermentation products. The frequency of recovery of anaerobic strains differs in various infectious sites.

EPIDEMIOLOGY

Most infections are caused by anaerobes that belong to the normal flora. Only when the situation is out of balance and the local defenses are decreased in capacity, anaerobic infection can then occur. Some anaerobic infections are caused by contamination of

TABLE 232-1 -- Predominant anaerobic bacteria.

PREDOMINANT ANAEROBIC BACTERIA	
Gram-positive cocci	*Peptostreptococcus* spp.: *P. magnus*, *P. asaccharolyticus*, *P. prevotii*, *P. intermedius*, *P. anaerobius*, *P. micros*
	Microaerophilic streptococci (not true anaerobes)
Gram-positive nonspore-forming bacilli	*Propionibacterium* spp.: *P. acnes*, *P. propionicum*, *P. granulosum*
	Eubacterium tentum
	Bifidobacterium spp.: *B. eriksonii*, *B. dentium*
	Actinomyces spp.: *A. israelii*, *A. naestundii*, *A. viscosus*, *A. odontolyticus*, *A. meyerii*
Gram-positive spore-forming bacilli	*Clostridium* spp.: *C. perfringens*, *C. ramosum*, *C. septicum*, *C. novyi*, *C. histolytica*, *C. sporogenes*, *C. difficile*, *C. bifermentans*, *C. butyricum*, *C. innocuum*, *C. sordellii*, *C. botulinum*, *C. tetani*
Gram-negative bacilli	*Bacteroides fragilis* group: *B. fragilis*, *B. thetaiotaomicron*, *B. distasonis*, *B. vulgatus*, *B. ovatus*, *B. uniformis*
	Other *Bacteroides* spp.: *B. gracilis*, *B. ureolyticus*
	Pigmented *Prevotella* spp.: *P. melaninogenica*, *P. intermedia*, *P. denticola*, *P. loescheii*, *P. corporis*, *P. nigrescens*
	Other *Prevotella* spp.: *P. oris*, *P. buccae*, *P. oralis* group (*P. oralis*, *P. buccalis*, *P. veroralis*), *P. bivia*, *P. disiens*
	Porphyromonas spp.: *P. asaccharolytica*, *P. gingivalis*, *P. endodontalis*
	Fusobacterium spp.: *F. nucleatum*, *F. necrophorum*, *F. gonidiaformans*, *F. naviforme*, *F. mortiferum*, *F. varium*

TABLE 232-2 -- Anaerobic bacteria most frequently encountered in specific infection sites.

ANAEROBIC BACTERIA MOST FREQUENTLY ENCOUNTERED IN SPECIFIC INFECTION SITES		
Organism		**Infection site**
Gram-positive cocci	*Peptostreptococcus* spp.	Respiratory tract, intra-abdominal and soft-tissue infections
	Microaerophilic streptococci (not obligate anaerobes)	Sinusitis, brain abscesses
Gram-positive bacilli	Nonspore-forming:	
	Actinomyces spp.	Intracranial abscesses, chronic mastoiditis, aspiration pneumonia, head and neck infections
	Propionibacterium acnes	Shunt infections (cardiac, intracranial), infections associated with foreign body
	Bifidobacterium spp.	Chronic otitis media, cervical lymphadenitis, abdominal infections
	Spore-forming:	
	Clostridium perfringens	Soft-tissue infection, sepsis, food poisoning
	Clostridium septicum	Sepsis, neutropenic enterocolitis
	Clostridium difficile	Colitis, antibiotic-associated diarrheal disease
	Clostridium botulinum	Botulism
	Clostridium tetani	Tetanus
	Clostridium ramosum	Soft-tissue infections
Gram-negative bacilli	*Bacteroides fragilis* group	Intra-abdominal and female genital tract infections, sepsis, neonatal infections
	Pigmented *Prevotella* and *Porphyromonas* spp.	Orofacial infections, aspiration pneumonia, periodontitis
	Prevotella oralis	Orofacial infections
	Prevotella oris-buccae	Orofacial infections, intra-abdominal infections
	Prevotella bivia, Prevotella disiens	Female genital tract infections
	Fusobacterium nucleatum	Orofacial and respiratory tract infections, brain abscesses, bacteremia
	Fusobacterium necrophorum	Aspiration pneumonia, bacteremia

wounds by soil containing anaerobes. Such is the case with some *Clostridium* infections. *Clostridium difficile* enterocolitis can lead to epidemics in the hospital. In geriatric wards and nurseries in particular, these bacteria are transmitted by hands from one patient to another. *Clostridium botulinum* causes food poisoning due to the presence of the toxin produced by *C. botulinum* in food.

Gram-positive spore-forming bacilli

Anaerobic spore-forming bacilli belong to the genus *Clostridium*. Morphologically, the clostridia are highly pleomorphic, ranging from short, thick bacilli to long filamentous forms, and are either ramrod

Figure 232-1 Gram stain of a perirectal abscess caused by polymicrobial aerobic and anaerobic flora.

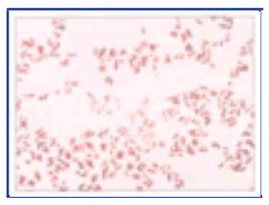

Figure 232-2 Gram stain of *Clostridium perfringens.*

straight or slightly curved. The clostridia found most frequently in clinical infections are *Clostridium perfringens* (Fig. 232.2), *Clostridium septicum, Clostridium ramosum, Clostridium novyi, Clostridium sordellii, Clostridium histolyticum, Clostridium fallax, Clostridium bifermentans* and *Clostridium innocuum*.

Clostridium perfringens, the most commonly recovered *Clostridium* isolate, is an inhabitant of soil and of intestines of humans and animals, and is the most frequently encountered histotoxic *Clostridium* species. This micro-organism, which elaborates a number of necrotizing extracellular toxins,[7] [8] is easily isolated and identified in the clinical laboratory. It can be characterized in direct smears of a purulent exudate by the presence of stout Gram-variable rods of varying length, frequently surrounded by a capsule. *Clostridium perfringens* can cause a devastating illness with a high mortality rate. Bacteremia caused by *Clostridium* spp. is associated with extensive tissue necrosis, hemolytic anemia and renal failure.

Clostridium septicum has often been found to be associated with malignancy. The intestinal tract is thought to be the source of the organism, and most of the isolates are recovered from blood and subcutaneous tissue.

Although *C. botulinum* is usually associated with food poisoning, wound infections caused by this organism are being recognized with increasing frequency. Proteolytic strains of types A and B have been reported from food poisoning and wound infections. Infant botulism occurs with types A, B and F.[7] Disease caused by *C. botulinum* is usually an intoxication produced by ingestion of contaminated food (uncooked meat, poorly processed fish, improperly canned vegetables) containing a highly potent neurotoxin.[8] The polypeptide neurotoxin is relatively heat labile, and food containing this toxin may be rendered innocuous by exposure to 212°F (100°C) for 10 minutes. Infection of a wound with *C. botulinum* occurs rarely and can produce botulism.

Clostridium difficile has been incriminated as the causative agent of antibiotic-associated and spontaneous diarrhea and colitis.[9] *Clostridium tetani* is found in soil and is rarely isolated from human feces. Infections caused by this bacillus are a result of contamination of wounds with soil containing *C. tetani* spores.[8] The spores will

germinate in devitalized tissue and produce the neurotoxin that is responsible for the clinical findings.

Gram-positive, nonspore-forming bacilli

Anaerobic, Gram-positive, nonspore-forming rods comprise part of the microflora of the gingival crevices, the gastrointestinal tract, the vagina and the skin. Several distinct genera are recognized: *Actinomyces, Arcanobacterium, Atopobium, Bifidobacterium, Eubacterium, Lactobacillus, Mobiluncus, Propionibacterium* and *Pseudoramibacter*. The most frequently recovered species are *Propionibacterium, Eubacterium, Bifidobacterium* and *Lactobacillus.*

The *Actinomyces, Arcanobacterium* and *Bifidobacterium* spp. are Gram-positive, pleomorphic, anaerobic to microaerophilic bacilli.

Actinomyces israelii, Actinomyces naeslundii and *Propionibacterium propionicum* are normal inhabitants of the human mouth and throat and are the most frequent

cause of actinomycosis. The organisms have been recovered from intracranial abscesses, chronic mastoiditis, aspiration pneumonia and peritonitis.[3] [5] The lesions of actinomycosis occur most commonly in the tissues of the face, neck, lungs, pleura and ileocecal regions. Bone, pericardial and anorectal lesions are less common, but virtually any tissue may be invaded; even disseminated infection with bacteremia has been described.
