The natural history of infections following liver transplantation is influenced by various factors including the use of antimicrobial prophylaxis. Generally, these infections are predicted by the time elapsed following liver transplantation (Fig. 105.1). However, it should be emphasized that the use of antimicrobial prophylaxis, the selective use of immunosuppressive agents and improvements in surgical techniques have modified the epidemiology and clinical presentation of infectious complications following liver transplantation.[8]

First month

Like other solid-organ transplant recipients, the majority of infections during this period are related to the surgical procedure (see Fig. 105.1). Liver transplantation is distinct because the surgical manipulation involves parts of the body with high microbial content. The spillage of gastrointestinal contents during the actual liver transplantation procedure is a common source of abdominal infection. Abdominal abscesses and surgical site infections caused by bacteria

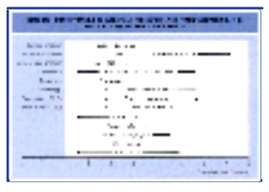

Figure 105-1 Natural history timeline of infections following liver transplantation in the absence of antimicrobial prophylaxis.

(e.g. *Staphylococcus aureus,* coagulase-negative staphylococci, enterococci, Gram-negative bacilli and anaerobic organisms) and fungi (e.g. *Candida albicans*) may disseminate to cause bacteremia and candidemia, respectively. The patients usually manifest with fever and a sepsis syndrome. Erythema, purulence and dehiscence of the surgical wound may be evident, and fluid collections may be demonstrated on radiographic studies. The risk of acquiring these infections is increased among patients who require abdominal re-exploration for any indication (i.e. hepatic artery thrombosis, portal vein thrombosis, biliary leakage or re-transplantation). Consequently, this results in prolonged hospitalization that will further increase predisposition to nosocomial pneumonia, urinary infections, bacteremia and antibiotic-related *Clostridium difficile* diarrhea. Herpes simplex virus reactivation has traditionally been the most common viral infection during the first month following liver transplantation. However, the widespread use of antiviral prophylaxis has significantly decreased the incidence of this viral infection. Among liver transplant recipients, the recurrence of HCV infection may become evident during this period and the degree of HCV replication during this period may be

associated with the recurrence rate and severity of HCV hepatitis and cirrhosis, and ultimately may influence the survival of the liver allograft.[2]

Second to the sixth month

The intense immunosuppression employed during the early months following liver transplantation when hepatic allograft rejection is usually observed and treatment with high-dose corticosteroids or OKT3 monoclonal antibody are administered increases the predisposition to opportunistic infections.

In the absence of antiviral prophylaxis, the ß-herpesviruses (CMV, HHV-6 and HHV-7) reactivate 2–6 weeks following liver transplantation with direct and indirect consequences.[7] However, the widespread use of antiviral prophylaxis has delayed the onset of CMV disease and may have diminished its severity among liver transplant recipients.[9] Several studies in liver transplant patients have suggested potential interactions among the ß-herpesviruses that enhance the severity of CMV disease.[10] Usually accompanied by a viral syndrome of fever and some degree of myelosuppression, organ invasion by CMV following liver transplantation manifests most commonly as CMV hepatitis with elevated serum bilirubin, alkaline phosphatase and transaminases. This is of particular concern because it is usually confused with acute cellular rejection. A liver biopsy is usually required to distinguish between infection, rejection and drug toxicity.

The occurrence of hepatic dysfunction may complicate the use of antimicrobial prophylaxis. Trimethoprim-sulfamethoxazole (cotrimoxazole) may be withheld in these patients and thus predispose them to *P. carinii* pneumonia. Trimethoprim-sulfamethoxazole also protects against bacterial infections such as *Nocardia* spp., which like *Listeria monocytogenes* may present with distinct clinical syndromes (e.g. *Nocardia* spp. brain abscess, *Listeria* spp. bacteremia and meningitis) at any time following liver transplantation, but most commonly during this period.

Invasive aspergillosis, mostly due to *A. fumigatus*, may occur among patients transplanted for fulminant hepatitis and those with epidemiologic exposure and profound immunosuppression.[6] The clinical illness reflects the vasculotrophic nature of *Aspergillus* spp. and causes abscesses in many organs including the liver and the brain. Infection with endemic fungi (e.g. *H. capsulatum*, *C. immitis*) and *Cryptococcus neoformans*, which have been transmitted occasionally through the transplanted liver allograft, may occur during this period.

Beyond the sixth month

Beyond the sixth month, the vast majority of liver transplant recipients have good hepatic allograft function and their level of immunosuppression may have been reduced. These patients are primarily at risk of infections similar to those observed in the non-immunocompromised population.

However, opportunistic infections similar to those observed during the first 6 months following liver transplantation may occur, primarily among patients with poor graft function (i.e. from chronic rejection) who remain on intense immunosuppression. Infection with endemic mycoses due to *H. capsulatum* and *C. immitis*, and the reactivation of varicella-zoster virus commonly occurs during this period. Epstein-Barr virus related post-transplant lymphoproliferative disorder may occur at any time following liver transplantation.

The majority of HCV-infected liver transplant patients demonstrate recurrence of infection with a significantly higher degree of viral replication following liver transplantation.[2] Likewise, HBV infection usually recurs in the absence of antiviral prophylaxis.[3] [4] During this period, an accelerated clinical course of HCV infection may occur among older recipients who have received organs from older donors and those who are receiving high-dose corticosteroids and MMF. [2] Cytomegalovirus infection may also accelerate HCV infection.[2] Among HCV-infected patients, the recurrence of HCV-associated allograft failure is the most common cause of death during the first 5 years following liver transplantation.

It must be re-emphasized that the natural history of infections following liver transplantation has changed and continues to change because of improved surgical techniques, more selective immunosuppression and the widespread use of prophylactic antimicrobial agents. In some cases, as exemplified by CMV infection, the onset of the infection may be delayed and the clinical presentation modified.[9] Thus, physicians must remain alert to the occurrence of opportunistic infections, even during this later period.

DIAGNOSIS

Knowledge of infection risks is essential in the proper implementation of diagnostic surveillance following liver transplantation. Clinical screening with history and physical examination is essential. Surveillance cultures or other sensitive methods such as polymerase chain reaction (PCR) to identify infection before its clinical

manifestation are employed.[11]

Routine surveillance using rectal swab and stool cultures are employed to identify colonization with drug-resistant bacteria (i.e. vancomycin-resistant enterococci) in an effort to interrupt transmission to other 'at risk' patients. In contrast, routine use of bacterial surveillance cultures of biliary drainage after liver transplantation is not recommended. Surveillance cultures for *Candida* spp. and *Aspergillus* spp. infections are not performed routinely, unless there are symptoms.[6] Environmental surveillance should be performed when outbreaks of environmental pathogens such as *Aspergillus* spp. occur.

Screening for CMV infection following liver transplantation is influenced by available diagnostic methods and antiviral drugs.[12] Because of poor sensitivity, virus culture should not be employed to guide pre-emptive therapy. Instead, highly sensitive PCR assays or CMV antigen pp65 detection should guide its implementation.[12] Otherwise, universal prophylaxis should be employed for the prevention of CMV disease, particularly among 'high-risk' individuals.

Surveillance for HBV with measurement of HBV DNA, hepatitis B e antigen and antibody, and hepatitis B surface antigen and antibody should be performed on all HBV-infected patients before and following liver transplantation to document the degree of viral replication (which influences the risk of recurrence) and to monitor effectiveness of viral suppressive therapy. Surveillance for HCV recurrence using molecular methods that measure degree of HCV replication are usually employed.

MANAGEMENT

Prophylaxis

The most important principle in the management of infection following liver transplantation is prevention (Table 105.2).[13] [14] Vaccines against hepatitis A and B viruses should be administered to susceptible liver transplant candidates to decrease the risk of HAV- and HBV-induced fulminant hepatitis following liver transplantation in naive patients.[15]

Oral selective bowel decontamination (consisting of colistin, gentamicin and nystatin) starting during the days immediately before and following transplantation up to the duration of hospitalization is used to apply selective pressure to the intestinal flora (i.e. to decrease colonization with Gram-negative bacilli and fungi, while sparing the anaerobic organisms) and decrease the incidence of bacterial and fungal infections following liver transplantation.[6] Patients

TABLE 105-2 -- Suggested prophylactic strategies in liver transplantation.

SUGGESTED PROPHYLACTIC STRATEGIES IN LIVER TRANSPLANTATION			
Prophylaxis	**Indication**	**Dose and duration**	**Comments**
Cefotaxime	Perioperative prophylaxis	1g q8h iv for 48 hours	Should be adjusted based on resistance patterns
Trimethoprim-sulfamethoxazole	*Pneumocystis carinii*	80 or 160mg of trimethoprim component po q24h	May protect against *Nocardia* spp., *Listeria* spp. and other bacteria
Aciclovir	Herpes simplex virus	200mg po q8h for 28 days	Should be withheld when ganciclovir is used; valaciclovir may be used if available
Ganciclovir	Cytomegalovirus	1g po q8h; duration variable	Used as prophylaxis or pre-emptive therapy; may protect against HHV-6 and HHV-7; valganciclovir may be used if available
Fluconazole	*Candida* spp.	400mg po daily for 28 days	Targeted to patients with complicated and prolonged surgery or profound blood loss
Oral bowel decontamination solution	Gram-negative bacilli and fungi	Variable	Selective pressure favoring anaerobic environment, with goal of decreasing risk of fungal and bacterial infection
Hepatitis B immunoglobulin	Hepatitis B virus	10,000IU/day for first week then every 4 weeks	Maintain serum hepatitis B immunoglobulin level >100IU; may be used in combination with lamivudine; role of other agents such as adefovir not yet defined
Amphotericin B	*Aspergillus* spp.	0.2mg/kg per day	Administered to patients with fulminant hepatic failure

should also receive intravenously administered antibacterial prophylaxis (e.g. cefotaxime) during the perioperative period to decrease surgery-related infections. Prophylaxis against *P. carinii* infection should be used, either trimethoprim-sulfamethoxazole or aerosolized or intravenous pentamidine as alternative regimens.

Antifungal prophylaxis, usually with relatively low-dose amphotericin B is given to patients with fulminant hepatitis.[6] Because of the risk of invasive fungal disease, oral fluconazole may be administered for up to 4 weeks to liver transplant recipients who require re-transplantation or re-operation, and to patients with significantly prolonged surgical time or who had profound blood loss during surgery.[6]

The prevention of HBV recurrence is accomplished with the administration of immunoglobulin with high titers against HBV (HBIg) with or without lamivudine. [4] [16] [17] The dose of HBIg is usually 10,000IU/day for the first week following liver transplantation and at 4-week intervals thereafter, with the goal of achieving serum HBIg levels above 500IU for the first year and over 100IU thereafter. This practice is very effective in reducing HBV recurrence but it is limited by its expense. Lamivudine may decrease HBV replication following liver transplantation and is now routinely employed following liver transplantation despite the lack of rigorous clinical trials showing efficacy. Strategies for decreasing the degree of HBV replication before liver transplantation with HBIg and lamivudine have also been tried. However, their prolonged use before transplantation is strongly discouraged because of the risk of selecting resistant mutants, and thus limiting their use during the post-transplant period. Prolonged use of HBIg is associated with the emergence of surface antigen mutants. Resistance to lamivudine is conferred by the YMDD mutation. Because of the risks of prolonged use and the inherent uncertainty and unpredictability of the timing of liver transplantation, HBIg and lamivudine are usually administered only as post-transplant prophylaxis.

There is currently no optimal strategy for preventing HCV recurrence following liver transplantation. The use of interferon-a and ribavirin has been shown in anecdotal studies to reduce HCV replication following liver transplantation. [18] Because of intolerance to adverse effects and high treatment failure rates, the current practice is not to give anti-HCV therapy unless histologic recurrence is demonstrated. Studies on the efficacy of pegylated interferon-a, which provides more sustained levels of circulating interferon-a, possibly with fewer side-effects, are eagerly anticipated.

Liver transplant recipients who are at risk for CMV infection or who have evidence of CMV infection are given ganciclovir (or valganciclovir) prophylaxis or pre-emptive therapy, respectively.[7] A targeted approach to CMV prevention should be administered to patients with fulminant hepatitis and those receiving OKT3 monoclonal antibody (Chapter 205).

Therapy of established infection

Early diagnosis and administration of specific and effective therapies are key to the optimal management of infections following liver transplantation. The use of antimicrobial therapy should be tailored to the micro-organism involved and should be guided by antimicrobial susceptibility when available.

Reduction of pharmacologic immunosuppression should complement the use of antimicrobial therapy as possible. In addition, drainage of infected fluid collections (e.g. infected hematoma and abdominal abscesses), debridement of surgical site infections and the removal of infected intravascular and urinary catheters are essential components of therapy.

CONCLUSION

Liver transplant recipients have unique characteristics that differentiate them from other transplant patient groups. The complexity of the surgical procedure places the liver transplant patient at higher risk of bacterial and fungal infections. The higher prevalence of infection-related indications for transplantation, such as HCV and HBV infection, among liver transplant recipients presents further challenges. Moreover, the diversity of the indications for liver transplantation requires a tailored and individualized approach to prophylaxis and surveillance.

Chapter 106 - Pancreas Transplant Patients

Luis A Fernandez
Jon S Odorico

INTRODUCTION

Pancreas transplantation is currently a widely accepted modality for the treatment of insulin-dependent diabetes mellitus.[1] While most patients undergo pancreas transplantation in combination with renal transplantation, selected nonuremic patients may also be candidates for pancreas transplantation alone. Although rejection rates have decreased with better immunosuppressive therapy, infections remain a source of major morbidity and are one of the leading causes of death in this population. In contrast to infections after kidney transplantation, much of the infection-related morbidity in the pancreas allograft recipient is related to postsurgical intra-abdominal infections. Common postsurgical infectious complications include urine leak, abscess, infected pseudocyst, infected pancreatic or lymphatic ascites, leakage of pancreatic exocrine secretions or enteric contents, and, rarely, infected pseudoaneurysms.

To handle pancreatic exocrine secretions, drainage into the bladder (bladder drainage, BD) or the small intestine (enteric drainage, ED) are the two most commonly used techniques. Bladder drainage is associated with metabolic acidosis, intravascular volume depletion, reflux pancreatitis and urinary tract complications, including hematuria, urethritis, urethral strictures and urethral disruption, all of which may be compounded by infected urine, and recurrent urinary tract infections (UTIs). On the other hand, ED is associated with significantly fewer urologic and metabolic complications than BD, and ED has therefore become the preferred technique. However, in certain settings, such as solitary pancreas transplantation or severe diabetic enteropathy, BD may still be indicated.

Several factors contribute to the development of intra-abdominal infections after pancreas transplantation, including:

- intense immunosuppressive regimens;
- compromised defenses associated with diabetes;
- postreperfusion pancreatitis with local release of cytokines and digestive enzymes providing a favorable environment for micro-organisms;
- contamination of the operative field by micro-organisms present in the donor duodenum; and
- microbial translocation from the duodenum facilitated by postreperfusion edema, ischemia or rejection.

Infectious complications associated with pancreas transplantation include UTI, anastomotic leaks of the duodenal segment, mycotic aneurysms, infected pancreatic pseudocysts and infected abdominal ascites. In addition, cytomegalovirus may affect the pancreas allograft.

URINARY TRACT INFECTIONS

Urinary tract infections are a common problem in patients with primary BD of the duodenum segment in pancreas transplantation. Bladder-drainage pancreas transplants lead to significantly more UTIs than ED transplants do (63% vs 20% in the first postoperative year).[2] Urinary tract infections can occur either in the early or late post-transplant period, and they are frequently recurrent. The underlying pathophysiology includes impaired integrity of the bladder mucosa, alteration in urinary pH, urinary retention or stasis due to residual diabetic autonomic neuropathy, prolonged catheter drainage, microbial contamination by the contents of the donor duodenum, retained intravesical sutures and bladder stones. Activation of pancreatic enzymes in the bladder together with urinary alkalosis resulting from bicarbonate secretion appears to cause significant impairment of the mucosal defenses.[3]

The presentation of UTI in pancreas transplant recipients does not differ from the presentation in any other immunosuppressed patient. Symptoms of fever, urinary frequency, dysuria and urgency are common, although patients can be asymptomatic. The majority of UTIs are bacterial but fungal infections are also common. The most common bacteria encountered are *Escherichia coli* (27%) and other Gram-negative organisms, such as *Klebsiella* spp., *Proteus* spp. and *Pseudomonas* spp.[4] Gram-positive organisms are present in approximately 20% of cases, primarily in males, and are probably related to the long-term use of indwelling catheters.[4] In BD pancreas transplants, 50–71% of patients developing a first UTI had a recurrence within the first 90 days. However, less than one-third of these recurrent infections were from the same pathogen as that responsible for the previous infection.[4] Occasionally, a simple lower UTI progresses to an upper UTI or pyelonephritis in the renal allograft, a process that may be accelerated by a diabetic neurogenic bladder and vesicoureteral reflux. Frequently, the donor duodenal segment is colonized with *Candida* spp., explaining the prevalence of fungal UTIs.

Most UTIs following pancreas transplantation can be treated successfully with appropriate antibiotics. Non-nephrotoxic antibiotics that concentrate in the urine, such as the fluoroquinolones, are first-line agents. Fungal UTIs can occasionally be successfully treated with fluconazole or amphotericin bladder irrigations; however, recurrence is common and systemic amphotericin B has been the mainstay of therapy. The role of newer potent antifungals is undefined. Recurrent UTIs merit further investigation, including cystoscopy to exclude lower urinary tract pathologies such as bladder calculi, foreign bodies or suture granulomata at the duodenum-bladder anastomosis, or a fungus ball (see also Chapter 96a). In the absence of lower tract abnormalities, the upper tracts is examined by retrograde pyelography and computerized tomography (CT) scans of the transplanted and native urinary systems. Recurrent, problematic, resistant infections in BD pancreas transplant recipients or those causing renal allograft dysfunction are generally considered indications for conversion to ED.[5]

Multiple recurrent UTIs are associated with poorer long-term renal transplant outcomes.[6] [7] Patients with chronic rejection have more UTIs per year, and an earlier onset of chronic rejection correlated with a higher incidence of UTI.[6] However, the pathophysiology uniting UTI with chronic rejection remains unclear. Potential mechanisms include direct injury, mediated by inflammatory cytokines and chemokines, or enhanced alloreactivity, stimulated by inflammation.

TABLE 106-1 -- Leaks in 747 consecutive simultaneous pancreas and kidney transplants at the University of Wisconsin from October 1983 to July 2000.

LEAKS IN 747 CONSECUTIVE SIMULTANEOUS PANCREAS AND KIDNEY TRANSPLANTS			
	Bladder drainage (n=446)	**Enteric drainage (n=301)**	***p* value**
Patients with leak (n)	84	19	0.0001
Patients with leak by 60 days	5.30%	5.50%	
Patients with leak by 1 year	16.1%	6.6%	
Patients with leak by 5 years	20.5%	6.6%	
Patients with leak by 10 years	22.9%	6.6%	
Graft salvage rate after leak	83/84 (98.8%)	6/19 (31.6%)	0.001
Candida-associated infection	15/84 (17.8%)	7/19 (38%)	0.01

Anastomotic duodenal segment leak: enteric drainage versus bladder drainage

Leakage of pancreatic exocrine secretions from the transplant results in severe life-threatening intra-abdominal infection requiring prompt surgical intervention. With greater experience and better immunosuppression, this surgical complication has become less common. A retrospective study at our center compared the incidence of pancreatic enzyme leaks with BD with the incidence with ED. In patients with ED of the duodenum segment the leak rate was 6.3% whereas in BD patients it was 18.8% (p=0.0001; Table 106.1). Most ED leaks occurred within the first 30 days after transplantation. In contrast, leaks in BD transplants may occur months to years after transplantation, suggesting different etiologies between the two groups. In both groups, early post-transplant leaks are largely technical, either related to ischemia of the duodenal segment or dehiscence of the anastomotic suture line. On the other hand, the precise etiology of late leaks in BD transplants is rarely identified and is probably multifactorial. Whereas early leaks are more commonly at the anastomotic suture lines, late leaks may occur anywhere in the duodenal segment and are possibly related to immunologic rejection, chronic distention, cytomegalovirus (CMV) disease or chronic urine irritation.

In addition to differing in their time of presentation, anastomotic duodenal segment leaks in ED and BD pancreas allografts differ in presenting signs and symptoms. Leaks in BD pancreatic transplants present with rapid-onset lower abdominal pain, fever and occasionally hematuria, reflecting sudden spillage of urine into the peritoneal cavity. A sentinel episode of gross hematuria is not uncommon. Concomitant elevation of serum creatinine and serum amylase are classic laboratory findings that usually improve steadily after insertion of an indwelling urinary catheter. In contrast, leaks in ED pancreatic transplants generally cause abdominal pain, fever and hyperamylasemia. An elevated serum creatinine is not part of the usual symptom complex, unless sepsis is severe.

In patients with BD transplants, the diagnosis is made by either a ^{99m} technetium (^{99m}Tc) voiding cystourethrogram (VCUG) or a CT cystogram. A ^{99m} Tc VCUG is performed by administering labeled diethylene-triamine-penta-acetic acid through an indwelling urinary catheter. Persistent radioisotope in the peritoneal cavity on delayed images indicates a leak (Fig. 106.1). In ED transplants the CT scan detects a fluid collection surrounding the pancreas allograft, frequently in proximity to the duodenal segment (see Fig. 106.1). The presence of air or contrast material in the fluid collection is the *sine qua non* for enteric leak. However, the absence of these findings does not exclude a leak and does not prove that the fluid collection is not infected. Determination of sterility depends on sampling the fluid, usually by percutaneous aspiration or laparoscopy. The presence of fluid that is rich in amylase and bilirubin

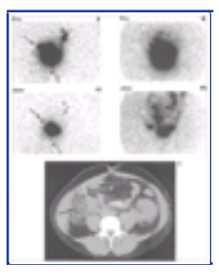

Figure 106-1 ^{99m} Technetium voiding cystourethrograms. (a) Filling and voiding phases of normal ^{99m} Tc DTPA VCUG. The large arrow represents the duodenal segment of the bladder-drained pancreas transplant. The small arrow represents retrograde flow of radioisotope into the pelvis of the transplanted kidney. (b) Abnormal ^{99m} Tc VCUG. Persistence of radioisotope in the peritoneal cavity is consistent with bladder leak (multiple white arrow heads). Although sensitive for diagnosing urine leak, a radioisotope VCUG does not localize the site of leak. A follow-up contrast VCUG may provide localization, if necessary. (c) Abdominal CT scan demonstrating an enteric leak. The pancreas (white arrow) and a peripancreatic fluid collection (black arrow) are seen. Air and contrast material in the fluid collection are diagnostic of an enteric leak. The absence of these findings, however, does not rule out the possibility of a leak.

confirms the diagnosis of enteric content leak. Polymicrobial infections with enteric organisms are common and indicate an enteric leak until proven otherwise. On the other hand, if amylase content is high and bilirubin content is low, then pancreatic parenchymal

injury causing leak of exocrine secretions is likely. This diagnosis is further supported if the fluid is sterile or contains only Gram-positive organisms.

Small leaks in BD transplants can occasionally be treated by Foley catheterization alone for 4–6 weeks. However, if symptoms do not resolve completely or if they recur after removal of the Foley catheter, patients may require surgical conversion to enteric drainage.[5] Leaks in ED transplants usually require urgent surgical intervention. In our experience, the most common organisms associated with leaks in ED transplants are *Candida* spp., including *Candida glabrata* or *Candida albicans* (38%), and vancomycin-resistant enterococci (14%). The mainstays of surgical treatment are debridement of devitalized tissue, tension-free re-closure of the duodenal segment, placement of continuous suction drains in conjunction with the use of appropriate antibiotics and construction of a Roux-en-Y intestinal diversion if this was not performed at the time of transplantation. However, despite these measures, the rate of re-leakage or failure to control sepsis is rather high even in experienced centers. These complications may ultimately necessitate pancreatectomy in a significant number of patients.

The impact of duodenal segment leaks and associated intra-bdominal infections on renal and pancreas allograft survival is significant. These infections and their antimicrobial treatment commonly contribute to renal allograft dysfunction. Furthermore, in the current immunosuppressive era, leak is a major cause of graft loss since ED transplants that develop a leak may require graft pancreatectomy.

INFECTED FALSE ANEURYSM OF THE ARTERIAL GRAFT

Mycotic aneurysms that occur in immunocompetent patients are often thought to be from septic emboli of cardiac origin. In contrast, the origin of mycotic aneurysms after pancreas transplantation is thought to be due to local infection around the iliac Y graft interacting with tissue digestion by activated pancreatic enzymes. A locally invasive infection promoted by enzymatic tissue digestion leads to disruption of the arterial anastomosis culminating in massive bleeding. *Candida* infection is commonly seen in these patients; however, other organisms, such as *Staphylococcus aureus*, *E. coli*, *Enterococcus faecalis*, *Pseudomonas aeruginosa* and *Enterobacter* spp., can also be present individually or in mixed infections. Reduced cell-mediated immunity in transplant recipients, enzymatic digestion of tissues, and adhesiveness and invasion of *C. albicans*[8] may contribute to this infectious complication.

Patients with infected false aneurysms present in the immediate postoperative period with hypotension associated with intrabdominal bleeding and hemorrhagic shock. In some cases, gastrointestinal bleeding may also be present. A sentinel episode of mild intra-abdominal or gastrointestinal bleeding frequently presages a more life-threatening event. It is also occasionally preceded by a significant peripancreatic infection.

An infected false aneurysm of the transplanted pancreas is difficult to diagnose. In stable patients with peripancreatic infection and a sentinel bleeding episode, urgent iliac arteriography should be performed (Fig. 106.2). If unstable, an emergency laparotomy may be life saving. Ultrasound, CT scanning and magnetic resonance imaging are useful adjunctive tools to evaluate peripancreatic infection or bleeding, but only in the stable patient. They may show a dilated vessel in the region of the pancreatic arterial supply. Computerized tomographic angiography or conventional angiography is usually necessary however to confirm the diagnosis (see Fig. 106.2). Samples of the aneurysm wall and contents should be cultured for aerobic and anaerobic bacteria and fungi.

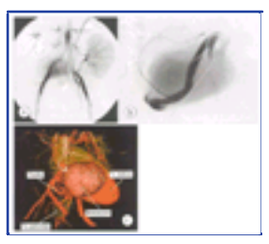

Figure 106-2 Infected false aneurysm of a pancreas transplant. (a), (b) Arteriogram of an infected false aneurysm originating from the ligated superior mesenteric artery stump of the pancreas transplant. (c) Triphasic CT reconstruction (90° rotation) demonstrating the feeding vessels of the false aneurysm in relation to the pancreas transplant.

Extent of active infection in the iliac artery or Y graft artery wall is difficult to determine at the time of surgery, and minimal intervention at the initial surgery is usually doomed to failure. Aggressive management is necessary in order to prevent death. Five general principles apply to the operative management of infected aneurysms:[9]

- control of hemorrhage;
- confirmation of the diagnosis by obtaining tissue specimens for culture;
- operative control of sepsis, including resection of the aneurysm and wide debridement of the infected tissue;
- prolonged antibiotic or antifungal therapy; and
- arterial reconstruction through uninfected tissue planes.

Therefore, the recommended procedure for an infected Y graft is complete excision of the donor and recipient iliac arteries, and transplant pancreatectomy followed by surgical bypass of the recipient common iliac artery in order to restore limb blood flow.[10] The conduit of choice is a blood-type compatible cadaver iliac graft from another donor or autogenous vein. Alternatively, an extra-anatomic femoral-femoral or axillary-femoral bypass with polytetrafluoroethylene is used. The identification of *Candida* spp. in the peripheral blood or blood clot removed from the Y graft indicates systemic fungal involvement. Broad-spectrum antibiotic and antifungal therapy should be initiated immediately until organism-specific antibiotic therapy can be instituted.

INFECTED PANCREATIC PSEUDOCYST

Pancreatic pseudocyst is rare after pancreas transplantation. It is defined as a peripancreatic inflammatory fluid collection rich in pancreatic enzymes but devoid of enteric contents that is localized by a nonepithelial fibrous wall. Patients typically present with nonspecific abdominal complaints including generalized malaise and weakness, nausea, abdominal pain, fevers and weight loss; associated elevations of serum amylase and lipase are common. In cases of BD, malodor of the urine and a UTI may co-exist. A CT scan should be

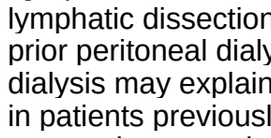

Figure 106-3 Pancreatic pseudocyst. (a) A CT scan demonstrating a pseudocyst of a pancreas transplant in the left pelvis (arrow). (b) Percutaneous drainage of a pancreas transplant pseudocyst. Injection of radiographic contrast material (black arrow) demonstrates the pancreatic duct (arrowhead) in communication with the pancreatic pseudocyst.

obtained. Pseudocyst formation in the pancreas transplant is thought to be similar in origin to that of the native pancreas — namely, inflammatory pancreatitis. Pancreatitis of the pancreas transplant is most commonly related to reflux and neurogenic bladder, alcohol or duct strictures. Biliary stone disease, while commonly contributing to native pancreatitis, is almost nonexistent in the transplant setting.

Loculated fluid encompassing the transplanted pancreas on CT scan suggests pancreatic pseudocyst (Fig. 106.3). A well-developed capsule of the pancreatic pseudocyst can sometimes be observed, as can a dilated pancreatic duct. Aspiration of the fluid collection is necessary to evaluate the presence of organisms as well as to determine the nature of the fluid. The absence of bilirubin and the presence of amylase in the aspirate is the *sine qua non* in the diagnosis of pancreatic pseudocyst.

Management mimics that for pseudocyst of the native pancreas. If the pancreatic pseudocyst is infected, external drainage and antibiotic therapy are key. Sterile pseudocysts that are smaller than 6cm in diameter in relatively asymptomatic patients can be managed expectantly. Persistent infection of the pancreatic pseudocyst can require prolonged antibiotic therapy (up to 6–8 weeks) and percutaneous drainage (Fig 106.3 and Fig 106.4). Persistent high amylase drainage despite conservative measures suggests a possible communication with the pancreatic duct. To confirm this, a fistulogram through the percutaneous drainage catheter is indicated. If a communication with the pancreatic duct is identified and the infection has been treated, a definitive internal drainage procedure is indicated. Internal drainage of a pancreas transplant pseudocyst is optimally achieved via a Roux-en-Y cysto-enterostomy.[11] In BD cases, the pancreatic pseudocyst may alternatively be drained into the bladder by performing a pseudocyst-vesicostomy through a combined transurethral and transabdominal approach. [12] The long-term outcome from these procedures should be excellent.

INFECTED ABDOMINAL ASCITES

Lymphatic ascites after pancreas and kidney transplantation in uremic patients occurs in up to 15–20% of cases. This complication is attributed to the extensive lymphatic dissection necessary for surgical exposure during the operative procedure. It is exacerbated by a poorly absorptive peritoneal membrane if there has been prior peritoneal dialysis complicated by peritonitis. In addition, impaired peritoneal macrophage function and accumulation of peritoneal effluent following peritoneal dialysis may explain the high incidence of deep wound infections in this population.[13] In a comparison study at our institution, the rate of postoperative fluid collections in patients previously on peritoneal dialysis was significantly greater than the rate in patients who had not previously received peritoneal dialysis (24% vs 13%, $p<0.01$; personal communication, Y. Becker). In many instances, fluid collections were associated with Gram-positive or Gram-negative bacterial or fungal contamination and required antibiotic and antifungal therapy. Peritoneal dialysis patients have a greater incidence of intrabdominal fluid collections infected with micro-organisms that colonize human skin.[14]

The initial diagnosis of ascites is based on physical examination. Abdominal radiographs will demonstrate a paucity of air or ground-glass appearance. Computerized tomography scanning or ultrasound confirms the diagnosis. The ascites fluid should be sampled for bacteria and fungi as well as to evaluate cell count, amylase, total protein and chylomicra. Elevated pancreatic enzymes and total protein are characteristic of pancreatic ascites.

Treatment of ascites is based on the use of therapeutic paracentesis, placement of a soft, small-caliber intraperitoneal, indwelling drainage catheter or judicious use of diuretic therapy, or both (see Fig. 106.4). For pancreatic ascites, cessation of oral feedings with the use of hyperalimentation and parenteral octreotide is usual. For infected ascites, percutaneous drainage and appropriate antibiotics usually result in complete resolution and excellent long-term outcomes. Polymicrobial or fungal infection suggests possible leak of enteric contents. Investigation for this entity should include injection of the percutaneous drain with contrast, a CT scan with oral contrast, or enteroclysis.

CYTOMEGALOVIRUS INFECTION OF THE PANCREAS ALLOGRAFT

Cytomegalovirus continues to be the most common viral pathogen affecting organ transplant recipients. The 1-year rate of CMV disease is 13–17% in prophylaxis-treated simultaneous pancreas-kidney transplant recipients.[15] [16] As in bone marrow and other solid organ transplants, the relative risk of CMV infection in pancreas transplantation varies according to the CMV antibody status of donor and recipient. Nearly 80% of cases of CMV occur in recipients in the high-risk donor-positive-recipient-negative cohort.[15] Symptomatic CMV infection and CMV disease increases the risk for subsequent renal graft rejection (relative risk, 2.11; $p=0.0032$) and non-CMV infections (relative risk, 2.22; $p=0.0011$). [16] Despite the high frequency of systemic CMV infection, CMV infection of the pancreas allograft is uncommon.[17]

The clinical presentation of CMV infection of the pancreas allograft is characterized by abdominal pain and fever, associated with elevation of serum amylase and lipase, and leukopenia. Distinguishing CMV allograft pancreatitis from acute rejection on clinical grounds alone is difficult.[17] Evaluation of allograft histology is essential in this setting. Cytomegalovirus pancreatitis demonstrates multifocal, predominantly acinar mononuclear inflammatory infiltrates associated with characteristic cytopathic changes. Marked cellular enlargement, intranuclear acidophilic inclusions with surrounding halos, and granular basophilic cytoplasmic inclusions are characteristic findings. Immunohistochemistry may be a useful adjunctive test in equivocal cases.[17]

Current CMV prophylaxis is based on the use of oral valganciclovir or intravenous ganciclovir for the first 10 days or while being treated with polyclonal antibody therapy. Doses are adjusted according to creatinine clearance. Long-term post-transplant prophylaxis (for 12 weeks) may be tailored to CMV antibody donor-recipient status, using valganciclovir or ganciclovir for high-risk patients, and aciclovir for those patients that have a low risk of CMV infection.

Treatment of tissue-invasive CMV disease, including allograft pancreatitis, includes lowering immunosuppression and using maximum antiviral treatment with either intravenous ganciclovir or oral

Figure 106-4 Algorithm for evaluating enterically drained pancreas transplant patients with abdominal pain.

valganciclovir. Persistent or recurrent cases may merit the addition of CMV immune globulin (starting dose of 100mg/kg intravenously every other day for 3 days, then 100mg/kg intravenously weekly as indicated.

In spite of adequate prophylaxis, CMV remains a problem following pancreas transplantation. Newer, more effective anti-CMV medications may help clinicians to achieve further reduction in symptomatic CMV infection and disease.

Chapter 107 - Intestinal Transplant Patients

Klara M Posfay-Barbe
Marian G Michaels
Michael DL Green

INTRODUCTION

Experimental models of intestinal transplantation in dogs were pioneered in the late 1950s; however, clinical trials in humans were initially unsuccessful because of graft rejection, sepsis and/or technical failure.[1] The availability of tacrolimus in 1989 facilitated better control of rejection and allowed intestinal transplantation to become feasible clinically.[2] [3] With more than 10 years of clinical experience, intestinal transplantation is now performed routinely by a select group of major transplant centers, although both the procedure and postoperative care remain complex.

EPIDEMIOLOGY

Intestinal transplantation is performed as treatment for intestinal failure, defined as a loss of function manifest by an inability to maintain a normal state of fluid and electrolyte balance, nutrition, growth and development. Intestinal failure may be present on the basis of congenital (e.g. intestinal atresia) or mechanical (e.g. pseudo-obstruction syndrome) problems or as a sequelae of an intestinal calamity (e.g. short gut syndrome following necrotizing enterocolitis or volvulus). While total parenteral nutrition (TPN) is available for patients experiencing intestinal failure, its use is associated with significant risks, including venous access complications, recurrent episodes of catheter-associated bloodstream infections and TPN-induced cholestatic liver disease.

Intestinal transplantation can be performed as an isolated procedure, concomitant with a liver allograft, or as a multivisceral (usually including stomach, duodenum, pancreas, liver and the small intestine) transplant procedure. The choice of procedure is individualized based on the underlying diagnosis associated with intestinal failure and the status of liver function in the presence of chronic TPN. Patient and graft survival vary according to which transplant procedure a patient receives; the best patient and graft survival are associated with isolated intestinal transplantation and the worst outcome is observed in recipients of multivisceral transplantation. Currently, 5-year survival for isolated intestinal transplantation, liver-intestine and multivisceral transplantation are 50%, 50% and 30% respectively. Without intestinal transplantation, the 2-year survival rate for patients with intestinal failure is approximately 40%,[4] depending on age and the presence or absence of liver disease. Given these poor results and the improved outcome of intestinal transplantation under tacrolimus-based immunosuppression regimens, this procedure has become a viable option for patients with intestinal failure. The optimal timing for performance of this procedure is unclear because the clinical course and life expectancy of patients with intestinal failure is variable.

Recipients of intestinal transplantation are on average younger than recipients of other types of organ transplantation; 66% of intestinal transplantation recipients are less than 20 years old and 50% are less than 5 years.[1] The young age of these patients reflects the relatively high prevalence of intestinal failure in children due to congenital malformations or intestinal calamity during infancy.

PATHOGENESIS AND PATHOLOGY

Patients undergoing intestinal transplantation are at high risk of developing infectious complications. Although the young age of many of the recipients of intestinal transplants may account for an increased risk of infection, this population's higher risk of infection is probably explained by the exposure of the transplanted organ to enteric bacteria colonizing the intestine, including the allograft. Unique among intestinal transplant recipients is the relationship that has been observed between the presence of rejection of the intestinal allograft and the development of bloodstream infection.[5] This relationship may be explained in part by the development of breaks in the protective barrier of the intestinal mucosa, which can be associated with rejection of the intestinal allograft. The overall incidence of rejection of the intestinal allograft is extremely high (90%); an average patient experiences between one and five episodes per graft.[6] Accordingly, the high rejection rate is one of the major factors accounting for the high frequency of bloodstream infections seen in intestinal transplant recipients.

Patients with rejection of the allograft can present with clinical signs and symptoms (including fever, abdominal pain or distension, nausea, vomiting and an increase in stomal output) that may be suggestive of infection. Because the presentation of intestinal rejection can mimic infection, it is critical to obtain endoscopic biopsy specimens to confirm the diagnosis. Empiric antibiotics (piperacillin-tazobactam or a third-generation cephalosporin with ampicillin, for example) should be considered in patients with severe rejection of the intestinal allograft until blood cultures are found to be negative.

Bloodstream infections are also associated with the presence of Epstein-Barr virus (EBV)-associated post-transplant lymphoproliferative disease (PTLD) of the intestine in this patient population. This association is probably due in part to breaks in the protective barrier of the intestinal mucosa. Infections in intestinal transplant recipients can also be attributed to technical complications. An example of this might include an anastomotic leak resulting in bacterial peritonitis. The intense immunosuppression required by intestinal transplant recipients also puts these patients at high risk for opportunistic pathogens, including cytomegalovirus (CMV), EBV and *Pneumocystis carinii*, typically seen after organ transplantation. Finally, intestinal transplantation patients frequently require prolonged use of central venous catheters after transplantation, placing them at risk for line-associated bloodstream infections as long as the lines remain in place.

TIMING AND PATTERN OF INFECTIOUS COMPLICATIONS

In general, the timing of infectious complications after intestinal transplantation follows the classical pattern described for solid-organ transplantation (Table 107.1). However, some differences in the classic timetable of infection are seen and are probably related to prolonged and intense immunosuppression (see Table 107.1).

TABLE 107-1 -- Timing of infection in intestinal transplant patients.[§]

TIMING OF INFECTION IN INTESTINAL TRANSPLANT PATIENTS	
Type of infection	**Frequency of infection (%)**
Early (0–30 days after transplantation)	
Surgical site:	
• Intra-abdominal	10
• Superficial and deep wound	20–30
Catheter-associated infection:	
• Bloodstream[§]	25
• Urinary tract	10
Ventilator-associated pneumonia	10

Rejection-associated bacteremia	5–10
Intermediate (1–6 months)	
Catheter-associated infection:

Rejection associated bacteremia	10–15
CMV§	20–50*
EBV-PTLD§	10–33†
• Associated with bacteremia§	5
Late (more than 6 months)	
Catheter-associated infection:	
• Bloodstream§	5–10
Rejection associated bacteremia	10–15
CMV§	<10
EBV-PTLD§	<5
• Associated with bacteremia§	<5
Community-acquired infection	Varies‡

§ *Adapted from Fishman and Rubin.*[7]
§Indicates difference from solid-organ transplant recipients.
* Incidence higher in adult intestinal transplant recipients.
† Incidence higher in pediatric intestinal transplant recipients.
‡ Varies with age and community exposure.

The most important difference is that bloodstream infections occur at a higher rate and continue to occur for a prolonged (if not indefinite) period compared with other organ transplant recipients. A second difference is that intestinal transplant recipients appear to be at higher risk than other transplant recipients for morbidity and mortality from viral infections (Table 107.2), especially CMV and

TABLE 107-2 -- Laboratory evaluation of viral infections following intestinal transplantation.

LABORATORY EVALUATION OF VIRAL INFECTIONS FOLLOWING INTESTINAL TRANSPLANTATION			
Organism	**Frequency (%)**	**Diagnostic test**	**Follow-up**
HBV	<1	HBV serologies, HBV PCR, histology	HBV PCR, liver function tests
HCV	<1	HCV serologies	HCV viral load, liver function tests
RSV	Adults: <1	Antigen detection and culture in NP aspirate	None
	Children: 1–5		
Parainfluenza	Adults: <1	NP aspirate for antigen	None
Adenovirus	30–50	Viral culture, histology	None
Enterovirus	Adults: <1	Viral culture	None
	Children: 1–5		
Influenza	1–5	NP aspirate for antigen detection and culture	
HSV	1–5	Culture, Tzanck smear	Chronic aciclovir prophylaxis
CMV	>5	Culture, pp65 antigen, histology	Monitor pp65 antigen or quantitative CMV-PCR
EBV	>5	EBV PCR, histology, serology	Monitor EBV PCR, imaging studies
HBV, hepatitis B virus; HCV, hepatitis C virus; HSV, herpes simplex virus; NP, nasopharyngeal; RSV, respiratory syncytial virus.			

EBV disease. Cytomegalovirus may present much later in intestinal transplantation patients than in other organ recipients and they can develop chronic or recurrent CMV disease (particularly of their graft). Intestinal transplant recipients have an extremely high incidence of EBV disease and PTLD. In contrast to other organ recipients, EBV-PTLD occurs frequently in intestinal transplantation patients even in the face of pre-existing immunity to EBV at the time of transplant.

These differences between intestinal transplant recipients and patients undergoing other types of organ transplantation may be explained in part by the young age of intestinal transplant recipients and the accompanying increased likelihood that they will be seronegative for CMV and EBV at the time of transplant. Thus, they are at risk for developing primary infection, which tends to be more severe. The differences may also be explained by the large amount of lymphoid tissue in the intestinal allograft.

INFECTIOUS SYNDROMES

Bacteremia

Clinical presentation

Bacteremia, typically presenting as fever, alone or in combination with signs of sepsis, occurs most frequently during the first 4 months after transplantation. However, episodes can occur even years after intestinal transplantation. Sepsis has been identified as the major cause of death in more than half of cases reported to the International Intestinal Transplant Registry.[8] The rate of bacteremia in intestinal transplantation patients is much higher (about two episodes per patient)[9] [10] than that reported for patients undergoing other types of organ transplantation (0.14–0.28 episodes per patient for heart, kidney and liver recipients).[11]

The high incidence of bacteremia may be linked to prolonged use of central venous catheters as well as translocation of microbiologic flora from within the lumen of the intestinal allograft. In most studies, the obvious source of bacteremia is not identified[5] but abnormal histologic findings of the allograft (rejection, PTLD or both) are frequently present at the time of bloodstream infection. Enteric organisms (*Enterococcus* spp., *Escherichia coli, Enterobacter* spp., *Klebsiella pneumoniae,* for example) are the most frequently recovered pathogens and are commonly resistant to multiple antibiotic classes. A high correlation has been noted between bacteria

identified in the stool and those recovered from the blood. Bacterial overgrowth (defined as a bacterial count >10^9 cfu/ml of stools) has been postulated to facilitate the development of translocation and has been recognized in nearly 90% of bacteremic episodes in these patients.[12] Bacterial overgrowth may be attributed to surgical manipulation of the transplanted bowel, the absence of the protective ileocecal valve, abnormal gastrointestinal motility, lymphatic disruption, prolonged TPN and the use of antacid medication. In more than half the cases, the overgrowth includes both Gram-positive and Gram-negative bacteria.

Diagnosis

Blood cultures should be obtained from intestinal transplant recipients presenting with fever or other clinical signs suggestive of systemic infection. If enteric pathogens are recovered, endoscopy should be performed to look for underlying causes such as rejection or PTLD.

Treatment

The initial empiric therapy for suspected bacteremia should take into account previous isolates obtained from that patient and their antimicrobial resistance patterns. Final treatment should reflect cultures and antimicrobial susceptibility testing performed at the time of clinical presentation.

Cytomegalovirus

Clinical presentation

Disease from CMV occurs in almost 25% of intestinal transplant recipients and accounts for significant morbidity and mortality despite treatment with ganciclovir. As many as 90% of patients with CMV disease will have involvement of their allograft as well as their native gastrointestinal tract.[13] Similarly to other transplant recipients, CMV-positive donor (D+)/CMV-negative recipient (R-) patients present with disease that is more likely to be invasive and more difficult to treat. Historically, primary CMV disease initially presents in the second month after intestinal transplantation, while reactivation episodes present closer to a year post-transplantation.[13] Recurrent CMV disease occurs frequently (approximately 50%)[13] and should be treated promptly with antiviral agents.

Diagnosis

Cytomegalovirus disease is defined by the presence of symptoms attributable to CMV infection in a patient with a positive culture (or pp65 antigenemia) or histologic evidence of inclusions or positive

TABLE 107-3 -- Prophylactic strategies in small bowel transplantation.

PROPHYLACTIC STRATEGIES IN SMALL BOWEL TRANSPLANTATION			
Indication	**Prophylaxis**	**Dose and duration**	**Comments**
		Adults	
Cytomegalovirus			
Donor +, recipient -	Ganciclovir	5mg/kg iv q12h for 14d. Then 5mg/kg iv q24h for 7–14d if patient remains in hospital; start valganciclovir to complete 90–120d of therapy once there is evidence of good gut function and absorption (adults: 900mg po q24h; children: contact pediatric infectious disease specialist)	Adjust dose for renal function
	CMV-IVIG	150mg/kg within 72h of transplant and at 2, 4, 6 and 8 weeks post-transplant. 100mg/kg at 12 and 16 weeks post-transplant	
Donor ±, recipient +	Ganciclovir	5mg/kg/d iv q12h for 14d	Adjust dose for renal function
Donor -, recipient -	No treatment		
These are the strategies used at the Children's Hospital of Pittsburgh.			

immunofluorescent staining, in the absence of another pathogen to explain these symptoms. Since antigenemia and/or viremia are absent from 50% of proven cases of CMV enteritis, [14] histologic evaluation of biopsy specimens is often required.

Prevention

In general, CMV-seropositive donors should not be used for CMV-seronegative candidates awaiting isolated intestinal transplantation because of the increased risk of mortality and graft loss associated with primary CMV disease. Mismatches are often unavoidable in patients awaiting combined liver-intestine or multivisceral transplantation because the severity of illness makes it impossible to wait for the 'perfect' donor. For these patients, long-term (3–4 months) chemoprophylaxis using ganciclovir (or valganciclovir) as well as CMV intravenous immunoglobulin (IVIG) should be considered (Table 107.3). The potential role for viral load monitoring in combination with pre-emptive ganciclovir therapy has not been formally evaluated in this high risk population. Since CMV enteritis may not be associated with a positive viral load, this strategy is less likely to succeed after intestinal transplantation than after other organ transplant procedures.

Treatment

Cytomegalovirus disease following intestinal transplantation should be managed similarly to that in other organ transplant recipients. Serial measurement of the CMV viral load using the pp65 antigenemia assay or a quantitative CMV polymerase chain reaction (PCR) along with follow-up endoscopic evaluation should guide therapeutic interventions. Use of CMV-IVIG in combination with ganciclovir should be considered for patients with involvement of the gastrointestinal tract (native or allograft) or of the lungs (Table 107.4). The use of ganciclovir has benefited most patients. Children have experienced a better outcome than adults after appropriate anti-CMV treatment, with successful outcomes approaching 90%.[15] The median time to resolution (defined as the absence of inclusions on biopsy) on ganciclovir treatment is approximately 20 days.[13] Immunosuppression should be maintained at baseline levels to avoid rebound rejection after treatment of CMV disease. Recurrence of disease is common, especially in CMV D+/R- patients. Long-term suppression with oral ganciclovir or valganciclovir may be helpful in these patients. Persistence of disease or of elevated CMV viral load despite treatment suggests the presence of ganciclovir resistance. The use of foscarnet or cidofovir should be considered in these cases.

TABLE 107-4 -- Treatment strategies in small bowel transplantation.

TREATMENT STRATEGIES IN SMALL BOWEL TRANSPLANTATION		
Treatment	**Dose and duration**	**Comments**
Cytomegalovirus		
First line therapy		
Ganciclovir	5mg/kg q12h iv for 14–21d	Maintenance therapy 5mg/kg/d iv q24h or consider valganciclovir. Treat until pp65 or CMV PCR reverts to negative. Adjust dose for renal function
CMV IVIG	100mg/kg/dose q48h iv for 3 doses	May repeat every 2 weeks depending on results
Alternative therapy		
Foscarnet	180mg/kg/d divided q8h iv for 14–21d	Maintenance therapy: 90–120mg/kg/d iv
Cidofovir	5mg/kg iv once weekly for 2 weeks	Continuing therapy: 5mg/kg iv once every 2 weeks as clinically needed

Epstein-Barr virus		
Ganciclovir	5mg/kg q12h iv for 14–21d	Adjust for renal function. Clinical efficacy unproven
Aciclovir	500mg/m^2 q8h iv for 14–21d	Adjust for renal function. Clinical efficacy unproven
IVIG	100mg/kg/d q48h iv for 3 doses	May repeat every 2 weeks depending on results. Clinical efficacy unproven.
These are the strategies used at the Children's Hospital of Pittsburgh.		

Epstein-Barr virus

Clinical presentation

Compared with other organ transplant recipients, intestinal transplant recipients appear to be at the highest risk of developing EBV disease. It can present clinically as a febrile syndrome, mononucleosis, PTLD or malignant lymphoma. Non-specific symptoms of fever, weight loss and malaise are common. Lymphadenopathy, bloody diarrhea or ulcerated nodular tumors of the intestinal tract may be present in some cases. Likewise, disseminated disease can occur. Overall, 10% of intestinal transplantation patients develop PTLD but an incidence as high as 40% has been reported in children. [16] The most frequent site of involvement of EBV in intestinal transplant recipients is the intestinal tract. Since EBV frequently involves the allograft, it is important to note that EBV enteritis can be misdiagnosed as rejection. Accordingly, it is recommended that an Epstein-Barr-encoded RNA (EBER) stain be performed on bowel biopsies with presumed rejection to rule out the possibility of EBV infection before treating for rejection.[17] The mortality rate for patients with PTLD has been reported to be as high as 50% after intestinal transplantation; recent experience at our center demonstrates rates of patient and graft survival of approximately 75%.

There are three major differences between PTLD in intestinal transplant recipients and in other solid-organ recipients:

¦ EBV serostatus prior to intestinal transplantation has not been identified as an important risk for the development of PTLD;
¦ EBV-associated PTLD can be concurrent with rejection after intestinal transplantation. In other organ transplant recipients rejection tends to occur only after evidence of regression of the EBV disease; and
¦ as many as 30% of surviving intestinal transplantation patients will experience chronic and/or recurrent episodes of EBV disease, in contrast to a recurrence rate of about 5–10% after transplantation of other organs.[18]

This last difference may be explained by the difficulty in reducing immunosuppressive treatment in the presence of concomitant rejection, limiting the body's ability to generate a cytotoxic T lymphocyte response against EBV.

Diagnosis of Epstein-Barr virus post-transplant lymphoproliferative disease

When PTLD is suspected, computerized tomography of the neck, chest, abdomen and pelvis should be performed to identify occult lesions. Biopsies should be obtained from suspicious lesions and sent for histologic confirmation. The use of immunohistopathologic stains for the presence of EBV (e.g. EBER stain) is necessary to distinguish EBV-infected cells from non-specific lymphocytic infiltrates. Patients with active EBV disease will typically have an elevated EBV viral load in the peripheral blood. However, elevated loads may be present in otherwise asymptomatic individuals.

Prevention of Epstein-Barr virus post-transplant lymphoproliferative disease

The high rates of morbidity and mortality attributed to PTLD have prompted efforts aimed at the prevention or pre-emptive treatment of EBV in intestinal transplant recipients. Serial monitoring of the EBV viral load using quantitative PCR assays has been shown to predict the occurrence of PTLD. This is currently used to guide initiation of pre-emptive therapy at many centers.[19] However, specific target levels of viral load as well as therapeutic pre-emptive treatment regimens vary from center to center and remain to be evaluated in prospective, comparative studies.

Treatment of Epstein-Barr virus post-transplant lymphoproliferative disease

Reduction of immune suppression is the major therapeutic manipulation for transplant recipients with EBV PTLD. Reduction of immunosuppression is felt to allow the body to develop a cytotoxic T lymphocyte response and control the infectious process. Unfortunately, the high rates of rejection observed during attempts at immunomodulation of EBV limit this approach in intestinal transplant recipients. While frequently used, ganciclovir or aciclovir as well as immunoglobulin are probably of only limited benefit for the treatment

of EBV PTLD (see Table 107.4). The use of the new, anti-CD20 monoclonal antibody (rituximab) appears very promising for these patients.

Other pathogens

Like other organ transplant recipients, recipients of intestinal transplants are at risk for infection from a wide variety of pathogens. Infection may develop from nosocomial exposures or once the patient has returned to the ambulatory setting. Infectious pathogens of the intestinal tract that can mimic intestinal rejection include adenovirus, rotavirus, *Clostridium difficile*, herpes simplex virus and nontuberculous mycobacteria.[8] An effort should be made to search for these pathogens by culture, histology and/or immunoassay before treating the patient for rejection. Adenovirus in particular has been recovered at very high rates from intestinal transplant recipients. Interpretation of this finding (asymptomatic shedding versus clinical disease) must be done on a case-by-case basis.

Respiratory viruses (parainfluenza, respiratory syncytial virus, influenza) can be fatal in intestinal transplant recipients.[9] While the relative frequency of acquisition is greater in the intermediate to late time periods after transplantation (after exposure to community-acquired pathogens), occurrence of disease in the early post-transplant period is most dangerous. Additional risks for severe disease with respiratory viruses include age less than 1 year, pre-existing lung disease and exposure to augmented immunosuppression.

Chapter 108 - Vasculitis and Other Immunologically Mediated Diseases

Jonathan Cohen

INTRODUCTION

This chapter is concerned with a diverse group of conditions that have in common the fact that their cause is thought to be related to disordered immune processes and that their treatment involves immunosuppressive therapy. In the past these diseases have been called 'autoimmune', 'autoallergic', 'collagen-vascular' or more frequently 'vasculitis', although as a group I think they are better referred to simply as immunologically mediated diseases (IMDs; Table 108.1). In addition, there is a large group of common disorders (e.g. asthma, eczema or inflammatory bowel disease) in which immunosuppressive therapy may be used, sometimes at high dose. Although not discussed in detail here, patients who have these conditions are at risk from the same type of opportunistic infections as other immunosuppressed patients.

EPIDEMIOLOGY

The importance of IMDs to the infectious diseases practitioner lies in the fact that affected patients frequently have severe multisystem disease and require high-dose immunosuppressive therapy, so the risk of opportunistic infection is high. Furthermore, they differ from other types of immunosuppression in that patients often receive several different modalities of immunosuppression (Table 108.2) and the duration of their treatment is much longer than for patients who have leukemia or cancer, in whom the neutropenic period is nowadays often not much more than 4 weeks (and sometimes much less). Infection is a major cause of morbidity and mortality in patients who have IMD[1] but the incidence of infection in these patients varies considerably depending on the stage of the disease and the intensity of the immunosuppression. In a study of 75 heavily immunosuppressed patients who had a variety of IMDs, we found a rate of 0.74 infections/patient/week.[2] In contrast, a study of 200 outpatients who had systemic lupus erythematosus (SLE), followed for 2 years, found that infections only occurred in a third of cases. Most were single, minor and associated with disease activity.[3]

Whereas organ or bone marrow transplant recipients are a homogeneous population, IMDs are not generally complicated by particular infections, although there are some associations of note. Salmonellosis frequently occurs as a complication of SLE, for instance, although the mechanism is not at all clear.[4] It is difficult to be certain whether the increased incidence of infection in patients who have IMD is attributable to the abnormal immune function of the underlying disease or simply a consequence of the immunosuppressive therapy. Probably both are implicated. As an illustration, Williams and colleagues studied 61 patients who had SLE or the antiphospholipid syndrome and required admission to an intensive care unit (ICU). [5] Infection was the single most common cause of admission, and infection on admission was associated with a significantly increased ICU mortality. However, cyclophosphamide administration, low white cell count and high severity of illness scores were all associated with reduced survival.

PATHOGENESIS AND PATHOLOGY

In some cases, there may be an etiologic association between an infection and the disease itself. A good example of this is the role of the hepatitis viruses in the pathogenesis of cryoglobulinemia, polyarteritis nodosa and other types of systemic vasculitis.[6] [7] Recently, both Epstein-Barr virus and parvovirus B19 have been associated with flares of SLE.[8] [9] There have also been intriguing reports suggesting that Wegener's granulomatosis may be caused by an abnormal response to an unknown infection, and that relapses of Wegener's granulomatosis can be prevented by chronic administration of trimethoprim-sulfamethoxazole. [10]

Although certain types of treatment are associated with particular defects in immune function,[11] patients who have IMD commonly receive combinations of drugs, and this makes predictions very difficult. Certainly, high-dose corticosteroid therapy is complicated by infections such as *Listeria*, herpesviruses and fungi, whereas patients who develop neutropenia as a consequence of cyclophosphamide, for instance, are susceptible to the same kinds of infection as neutropenic bone marrow transplant recipients. Plasma exchange (plasmapheresis) is a form of immunosuppression used particularly in these patients, and this has its own complications, in particular associated with intravenous access.[12] [13] It is generally true that the differential diagnosis of infection in patients who have IMD is considerably wider than in other kinds of immunosuppressed patients (see Clinical features and management, below).

It is not just the longer list of possible infections that makes assessment more difficult in these patients. It is frequently very hard to be sure whether the patient has infection or simply a relapse of the underlying disease. An acute flare-up of SLE involving the central nervous system can be indistinguishable from infective meningitis or encephalitis as a consequence of the immunosuppressive therapy. This leaves the clinician on the horns of an unpleasant dilemma; should the immunosuppression be reduced in order to allow antimicrobial therapy to be more effective, or should it be increased to bring the underlying disease back under control? It is helpful to ask whether the clinical features at this presentation are the same as on previous occasions when the presentation was known to be due to disease activity. Individual patients tend to be consistent in the form of disease they get when it is active.

A further complication is the phenomenon of 'infection provoked relapse'; in patients who have IMD an intercurrent infection can precipitate a relapse of the underlying disease.[14] The infection and the vasculitis need to be treated simultaneously.

PREVENTION

Patients who have IMD, like all immunosuppressed patients, are constantly at risk of a very wide range of infections but it is neither practicable nor desirable to try and prevent all of them. (For a detailed discussion of the approaches to infection prevention in immunocompromised patients see Chapter 100 and Chapter 102 .) Tuberculosis is a particular problem because its presentation may be

TABLE 108-1 -- Immunologically mediated diseases.

IMMUNOLOGICALLY MEDIATED DISEASES
Systemic lupus erythematosus
Polyarteritis nodosa
Wegener's granulomatosis
Lymphomatoid granulomatosis
Bronchocentric granulomatosis
Antiglomerular basement membrane disease (Goodpasture's syndrome)
Mixed essential cryoglobulinemia
Rheumatoid arthritis
Still's disease

Felty's syndrome
Mixed connective tissue disease
Progressive systemic sclerosis/scleroderma
Polymyositis/dermatomyositis
Relapsing polychondritis
Behçet's syndrome
Sjögren's syndrome
Churg-Strauss syndrome
Henoch-Schönlein purpura
Hemolytic-uremic syndrome/thrombotic thrombocytopenic purpura
A list of IMDs in which high-dose immunosuppression is often used and major opportunistic infection is a common problem. The list excludes generally less severe diseases such as asthma; although such patients may occasionally need high-dose immunosuppression, it is much less common.

TABLE 108-2 -- **Immunosuppressive agents and procedures.**

IMMUNOSUPPRESSIVE AGENTS AND PROCEDURES
Corticosteroids
Thiopurines
6-mercaptopurine
Azathioprine
Alkylating agents
Mycophenolate mofetil
Cyclophosphamide
Monoclonal antibodies
Basiliximab
Daclizumab
Rituximab
Infliximab
Etanercept
Adalimumab
Ciclosporin and related drugs
FK506 (tacrolimus)
Sirolimus
Total lymphoid irradiation
Antilymphocyte globulin
Intravenous immunoglobulin
Plasma exchange
Types of immunosuppression typically used in patients who have IMD. It is common for several of these agents to be used in combination

atypical and extrapulmonary disease is common. Patients who are receiving more than 15mg/day of prednisone (prednisolone) for prolonged periods and who have a clinical history or radiologic evidence of past tuberculosis should be given prophylaxis with isoniazid 300mg/day plus pyridoxine 10mg/day.[15] If the risk is less clear, the complications of isoniazid must be considered (see Chapter 202), although my practice is to err on the side of advising prophylaxis.[16]

In my opinion, the routine use of trimethoprim-sulfamethoxazole to prevent *Pneumocystis carinii* pneumonia is not warranted in this population, even if patients are receiving corticosteroids, because of the low incidence of the infection. In marked contrast to patients who have AIDS, relapse of *Pneumocystis* pneumonia is most uncommon in this population and secondary prophylaxis is not indicated.

CLINICAL FEATURES AND MANAGEMENT

Immunologically mediated diseases can represent a very complex challenge to the infectious diseases physician. Factors that must be taken into account in assessing the patient include the nature of the

TABLE 108-3 -- **Causes of fever and pulmonary infiltrates in patients who have immunologically mediated disease.**

CAUSES OF FEVER AND PULMONARY INFILTRATES IN PATIENTS WHO HAVE IMD

Infective	Bacteria	Conventional respiratory pathogens*
		Mycobacteria
		Nocardia[18]
		'Atypical' bacteria (*Mycoplasma* spp., *Coxiella* spp.)
		Legionella spp.
	Fungi	*Aspergillus* spp.[19] *
		Candida spp.
		Cryptococcus neoformans
		Zygomycetes
		Primary systemic fungi (*Histoplasma* spp., *Blastomyces* spp., etc.)
		Other systemic fungi (rarely; e.g., *Sporothrix schenckii*)
		Pneumocystis spp.*
	Parasites	*Strongyloides stercoralis*
		Toxoplasma spp.
	Viruses	Cytomegalovirus*
		Herpes simplex virus
		Varicella-zoster virus
		Respiratory syncytial virus
		Adenovirus
		Influenza and parainfluenza virus
Noninfective		Edema*
		Hemorrhage[20] *
		Infarction
		Emboli
		Tumor
		Radiation
		Chemotherapy
		Vasculitis
		Leukoagglutinin reaction
The list is long but incomplete and, in practice, any organism isolated in pure or predominant culture from a bronchoalveolar lavage or open lung biopsy should be regarded as a pathogen until proved otherwise. Further details about some of the conditions are provided in the references, where indicated		

* Most common causes.

underlying disease and the particular type of immunosuppression used, its duration and its dose (see Chapter 99). Certain clinical syndromes merit particular attention.

Fever and pulmonary infiltrates

The development of fever and new pulmonary infiltrates is one of the most common and most difficult clinical syndromes that occurs in patients who have IMD. The differential diagnosis is extraordinarily wide (Table 108.3) and includes infective and noninfective conditions.[17] Details of specific infections may be found elsewhere in this book; here I consider some general principles that apply to the initial assessment and management of patients who have IMD and who develop fever and pneumonia.

¦ There may be very rapid deterioration, from low-grade fever and cough to severe hypoxia needing mechanical ventilation within 12 hours, particularly if the patient is liable to develop pulmonary hemorrhage.
¦ Radiologic appearances are very non-specific. It is rare to be able to 'guess' the diagnosis just on the basis of the radiograph, with the possible exception of *Pneumocystis* pneumonia.
¦ Multiple infections are common. Even if the physician correctly recognizes the clinical and radiologic features of *Pneumocystis*

pneumonia, the patient may be co-infected with an additional, equally treatable pathogen such as cytomegalovirus (CMV).
¦ Sputum microbiology can be confusing. The presence of *Candida* spp., for instance, may indicate nothing more than colonization of the nasopharynx, whereas important pathogens such as *Aspergillus* spp. or *Pneumocystis* spp. often do not appear in the sputum.

Consideration of the nature of the underlying disease, the type of immunosuppression and epidemiologic features in the history are all helpful in guiding therapy. The single most important factor is gauging the speed of progression of the condition. It cannot be overemphasized that in IMD patients a seemingly trivial community-acquired chest infection can proceed to life-threatening pneumonia and/or pulmonary hemorrhage within a frighteningly short period. Urgent evaluation and investigation is essential. All patients should have simple, basic laboratory investigations performed, including a full blood count, sputum and blood cultures, and measurement of blood gas concentrations and a chest radiograph.

Much has been written about the radiologic features of certain infections. It is perfectly true, for instance, that *Pneumocystis* pneumonia classically produces a bilateral 'ground glass' appearance, but so too does CMV infection and acute pulmonary hemorrhage in a patient who has pulmonary vasculitis. Combining the clinical and radiologic data results in a 'shortlist' of likely diagnoses, but too great a reliance on this is very hazardous. The main value of the chest radiograph is in indicating the extent and rate of progression of the process, not in guessing the pathogen. Empiric antibacterial therapy is usually indicated when the risk of a major opportunistic pathogen is judged to be low. Factors pointing toward this conclusion are:

¦ slow onset/development;
¦ modest immunosuppression (e.g. <10mg prednisone daily);
¦ absence of hypoxia; and
¦ clinical, epidemiologic or microbiologic evidence of a conventional pathogen (e.g. *Streptococcus pneumoniae*).

Pneumocystis pneumonia is said to often have a very characteristic presentation, and some advocate empiric therapy (see Chapter 241). However, this strategy is unwise in patients who have IMD because of the wide differential diagnosis and the possibility of co-infection with other pathogens.

In the majority of patients further specific investigations should be performed. The most useful is a bronchoscopy with a bronchoalveolar lavage. Close liaison with the laboratory is essential to ensure a rapid response and the maximum diagnostic yield. Two other tests deserve mention. Computerized tomography (CT) scans will undoubtedly give additional and sometimes useful information but in my experience are rarely diagnostic. In contrast, pulmonary function tests can be very valuable in this group of patients, in particular measurement of carbon monoxide uptake (the KCO) to detect intrapulmonary hemorrhage.[21]

What if the patient fails to respond to the initial treatment regimen? Infection with more than one organism is not uncommon; for example, in two studies of *Pneumocystis* pneumonia in non-AIDS patients, additional pathogens were found in 35% and 58% of cases.[22] [23] A repeat diagnostic procedure should be considered; the choice usually lies between a second bronchoscopy or an open lung biopsy. There are no published studies that adequately address this question. Comparisons between diagnostic procedures have been made, usually in the setting of solid tumors or hematologic malignancy, but these are not readily extrapolated to second procedures in a different patient population. Although open lung biopsy is more invasive and has a significant morbidity, it should be carefully considered. In a patient who is not responding to first-line therapy, the second procedure will usually be the last chance to make a diagnosis.

When a specific organism is identified the treatment follows conventional guidelines. 'Blind' empiric therapy is rarely advisable because of the wide differential diagnosis.

Acute neurologic problems

A wide differential diagnosis also exists for neurologic problems, and prompt evaluation, investigation and treatment are essential.[24] Knowledge of the nature of the immune deficit can narrow down the list of possibilities. This information can be linked to the clinical presentation to provide useful clues; thus, a patient who has a defect in cellular immunity as a result of high-dose steroid therapy and who develops a subacute meningitis is likely to have *Listeria*, cryptococcal or tuberculous meningitis, whereas in a neutropenic patient *Aspergillus* or a pyogenic bacterial infection is more common.[25] These mental exercises are intellectually challenging but in reality the clinician is faced with a patient in whom even the shortlist of likely causes all demand quite different treatment. Clearly, it is most important to make the diagnosis as quickly as possible.

The initial assessment should include a detailed clinical and epidemiologic history and a careful neurologic examination. Key areas are:

- exposure to family members or others as a potential source;
- relevant foreign travel (not forgetting malaria);
- previous episodes of neurologic manifestations associated with relapse of underlying disease; and
- speed of progression of the disease.

Immediate investigations include a blood film and full blood count, blood and urine cultures and a chest radiograph. If there are new skin lesions they should be biopsied for immediate smear and culture. If a CT scan is available it is invaluable, and a lumbar puncture should be performed provided there are no contraindications.

Meningitis

Meningitis (Table 108.4) can be caused by common bacteria (*S. pneumoniae*, *Neisseria meningitidis*), but in immunosuppressed patients *Listeria monocytogenes* is particularly important. Despite the name, the cerebrospinal fluid (CSF) usually contains neutrophils, not mononuclear cells.

Polymicrobial meningitis (particularly with aerobic Gram-negative bacteria) can be a clue to the presence of hyperinfection with strongyloidiasis, a complication of both corticosteroid therapy and also of infection with human T cell leukemia/lymphoma virus. Enteroviruses are common causes of meningitis in normal hosts; rather curiously, they also occur in patients who have hypogamma-globulinemia. [26] Tuberculosis, cryptococcosis and, much more rarely, *Nocardia* all manifest with a subacute picture and are recognized causes of meningitis in patients who have IMD.

The serum cryptococcal antigen test cannot be used as a surrogate for CSF examination, unlike in AIDS patients in whom the burden of infection is often very high.

Meningitis is rarely caused by relapse of the underlying disease, but it can occasionally be caused by drugs used in its treatment, notably nonsteroidal anti-inflammatory drugs (NSAIDs).[27]

Abscesses

In IMD patients, abscesses are usually nonbacterial (see Table 108.4). The commonest causes of focal neurologic lesions are fungi (especially *Aspergillus* spp.) and *Toxoplasma*. *Nocardia* spp. infections classically cause multiple focal abnormalities but occur less often. Tuberculoma and cryptococcoma are more common in textbooks than in patients. The diagnosis of single or multiple space-occupying lesions in IMD patients is particularly difficult. Neither the radiologic features nor the CSF findings are pathognomonic; it is rare for the causative organism to be identified from the CSF and, with the

TABLE 108-4 -- Causes of neurologic syndromes in patients who have immunologically mediated disease.

CAUSES OF NEUROLOGIC SYNDROMES IN PATIENTS WHO HAVE IMD		
Meningitis	**Abscesses**	**Encephalitis**
Common pyogenic bacteria	Toxoplasmosis	Toxoplasmosis
Mycobacterium tuberculosis	*Aspergillus* spp.	*Listeria* spp.
Listeria monocytogenes	*Mucor* spp.	Measles
Nocardia spp.	Tuberculoma	Progressive multifocal leukoencephalopathy (JC/BK virus)
Cryptococcus spp.	*Nocardia* spp.	Varicella-zoster virus
Candida spp.	Cryptococcoma	Herpes simplex virus
Echoviruses	Pyogenic bacteria and anaerobic bacteria	Cerebral vasculitis
Drugs (e.g. NSAIDs)	Cytomegalovirus	Corticosteroid-induced disease
	Cerebral lymphoma	
High-dose corticosteroids can cause acute neuropsychiatric symptoms		

exception of the cryptococcal latex agglutination test, serologic tests are unhelpful. Particular care is needed in making a presumptive diagnosis of toxoplasmosis. Whereas in other groups of immunosuppressed patients the appearance of multiple enhancing lesions on the CT scan will often be sufficient grounds to commence empiric therapy, in patients who have IMD the differential diagnosis is much wider and if at all possible a tissue diagnosis should be obtained. Furthermore, *Toxoplasma* infection in SLE can mimic lupus cerebritis.[28]

Encephalitis

Encephalitis can be caused by infective and noninfective processes (see Table 108.4). Listeriosis and toxoplasmosis can manifest with an encephalitic picture, as can measles. Cerebral vasculitis (typically in SLE) is a particularly important consideration. It can cause a florid and life-threatening illness that can be extremely difficult to distinguish from an opportunistic infection. Evaluation is complicated by the fact that high-dose corticosteroid therapy can itself cause neuropsychiatric manifestations. It is helpful if the patient is known to have a past history of cerebral vasculitis but sometimes the only course of action is to treat with immunosuppression and antimicrobial agents until the picture becomes clearer.

Two infections merit comment because of their rarity: herpes simplex encephalitis seems to be uncommon, despite the fact that local cutaneous reactivation often occurs; and likewise CMV encephalitis is very unusual in this population.

Gastrointestinal problems

Although immunosuppressed patients are susceptible to a wide range of bacterial, fungal, viral and protozoal infections of the gut,[29] it is largely those that are a feature of high-dose corticosteroid therapy that occur in patients who have IMD. The clinical features of common infections are often modified; herpetic stomatitis can be very severe, for instance (Fig. 108.1). Three infections merit comment.

Extrapulmonary tuberculosis is more common in immunosuppressed patients and even if suspected (e.g. because a patient comes from the Indian subcontinent) can sometimes be hard to prove. The use of polymerase chain reaction to detect mycobacterial DNA in ascitic fluid is becoming available and is invaluable; meanwhile peritoneal biopsy is often the only diagnostic procedure of use. Not infrequently the only option is empiric therapy.

Cytomegalovirus enteritis is perhaps underdiagnosed. It can affect any part of the gut but particularly the colon. Ganciclovir has been very effective. [30]

Strongyloides stercoralis can be present for many years without causing symptoms but after corticosteroid therapy it can cause subacute

Figure 108-1 A large necrotizing lesion caused by herpes simplex type-1 in a patient who has a teratoma. Herpetic stomatitis is common in immunosuppressed patients and is often atypical; any ulcerating lesion in the perioral region should be considered to be herpetic until proved otherwise.

Figure 108-2 Extensive dermatophyte infection in a bone marrow transplant recipient. Many other infections (and graft-versus-host disease) can give a similar appearance but the diagnosis is quickly established by biopsy and microscopy. This condition is limited to the skin but nevertheless requires systemic antifungal therapy.

obstruction, pulmonary infiltrates and polymicrobial bacteremia or meningitis. Ivermectin is the drug of choice but it may need to be given for a longer period than in nonimmunosuppressed patients. Vasculitis (especially in SLE) can cause symptoms and signs indistinguishable from acute infection, including diarrhea, obstruction and perforation. Again, there are no diagnostic tests and management must depend on clinical evaluation and, if necessary, a therapeutic trial.

Skin, soft tissue and joints

Many organisms cause skin disease in immunosuppressed patients and the clinical manifestations are protean (Fig 108.2 and Fig 108.3). [31] In patients receiving plasma exchange, infections of the vascular access sites can be troublesome. Many noninfective causes of skin rash need to be remembered, including cutaneous vasculitis and drug eruptions. Soft tissue infections are unusual except that patients

Figure 108-3 Extensive skin lesions caused by *Mycobacterium chelonae* in a patient who had polyarteritis nodosa. The lesions were palpable but not especially painful.

who have hypogammaglobulinemia are susceptible to enterovirus polymyositis,[32] although myositis is much more likely to be caused by the underlying disease (dermatomyositis, polymyositis or polyarteritis nodosa).

Acute arthritis is always an indication for aspiration to exclude infection; *Staphylococcus aureus* is the most common isolate. Once again, relapse of the underlying disease is an important part of the differential diagnosis.

Chapter 109 - Splenectomy and Splenic Dysfunction

Steven M Opal

INTRODUCTION

The spleen in postnatal life functions primarily as a specialized lymphatic organ. It clears particulate elements from the circulation and promotes a co-ordinated immune response to systemic antigens. The rapidly progressive and highly lethal syndrome of overwhelming postsplenectomy infection (OPSI) attests the critical importance of the spleen to host defense against disseminated infections in the systemic circulation.

EPIDEMIOLOGY

The incidence of fatal postsplenectomy sepsis has been estimated at approximately 1 per 300 patient-years in children and 1 per 800 patient-years in adults.[1] Serious infectious complications may also occur in patients who have splenic hypofunction found in a broad array of systemic disorders (Table 109.1). [2] [3] [4] [5] [6] [7]

Functional asplenia is suggested by the presence of Howell-Jolly bodies (nuclear remnants within red blood cells) and target cells in the peripheral blood smear, and decreased uptake of radioactivity by spleen scan. Splenic hypofunction is more frequent than is commonly appreciated. A recent laboratory based survey [8] analyzed over 100,000 blood smears per year and revealed that 0.5% of patient samples had Howell-Jolly bodies indicative of hyposplenism. This information was unknown to the majority of these patients and their physicians. The most common cause of functional asplenia is sickle-cell disease, which leads to repeated infarction of splenic tissue over the first few years of life. Infants born with congenital asplenia are at particularly high risk of death from systemic infection within the first year of life.[7] [9]

PATHOGENESIS AND PATHOLOGY

Structure-function relationships in the spleen

The spleen is organized to provide an optimal environment for particulate antigen clearance and immunologic surveillance within the systemic circulation. Although the spleen is a small structure that accounts for only 0.25% of body weight, it receives 5% of cardiac output and contains up to 25% of the total lymphocyte population within the body.[10] Blood enters the spleen through central arteries, which branch into penicillary arterioles (Fig. 109.1). These vessels are cuffed with T cells, forming a periarterial lymphocytic sheath. The white pulp of the spleen surrounds arterioles and consists of large populations of T cells with lesser numbers of B cells and natural killer (NK) cells. The marginal zone surrounds the white pulp and principally consists of large concentrations of B cells with lesser numbers of T cells and antigen-presenting cells. Memory cells of the B cell lineage are found primarily within the marginal zones of the spleen. The white pulp and marginal zone bring antigen-presenting cells, particulate antigens, T cells and B cells in close proximity. This microenvironment promotes a co-ordinated immune response to systemic antigens.[1] [2] [11]

The majority of the spleen consists of red pulp and venous sinuses. Before formed elements within the blood can reach the venous sinuses of the spleen, they must negotiate the red pulp with its tightly compact network of endothelial cells and macrophages (the cords of Billroth). This slow filtration process allows for careful immunologic surveillance and removal of damaged cellular elements and foreign particulate matter. The normal architecture of the spleen is depicted in Figure 109.1 .

Immunologic defects and factors predisposing for postsplenectomy sepsis

A number of immunologic defects have been described in the postsplenectomy state (Table 109.2).[1] [11] [12] [13] [14] [15] The work of Hosea and colleagues[16] has demonstrated that the principal immunologic defect associated with the postsplenectomy state is an impairment in clearance of poorly opsonized particulate antigens. Invasive, encapsulated bacterial pathogens possess an outer surface polysaccharide capsule that impedes opsonization by immunoglobulin or complement upon entry to the systemic circulation. The spleen is much more efficient than the liver in removing poorly opsonized bacterial pathogens. Following splenectomy, decreased clearance of these encapsulated organisms results in disseminated intravascular infection and the OPSI syndrome.

Predisposing factors to postsplenectomy infection

Multiple host factors determine the cumulative risk of OPSI. A number of the most important host determinants of infection following surgical or functional asplenia are listed in Table 109.3 . The principal determinant of risk of postsplenectomy sepsis is the age and immunologic experience of the patient before splenectomy.[7] [16] [17] In a recent review of over 12,000 patients who had undergone splenectomy, the incidence of serious postsplenectomy infections was found to be 15.7% in infants, 10.7% in children under the age of 5 years, 4.0% in children under 16 years and 0.9% in adults.[18]

The spleen is particularly important in the primary immunologic response to polysaccharide antigens. These IgM and IgG2 antibody responses are largely T-cell-independent B cell responses that require the spleen for an optimal immune response.[19] This occurs in the marginal zone of the spleen, where B cells are abundant for immunologic surveillance in the systemic circulation. This immune response is attenuated after splenectomy. T-cell-dependent B cell responses to protein antigens and cellular immune responses are reasonably well preserved after splenectomy.[20] [21] [22] The end result is that carbohydrate neoantigens are not recognized and processed efficiently in the postsplenectomy state. This results in delayed clearance of virulent microbial pathogens and their toxins[14] [15] as they first enter the systemic circulation.

If the growth rate of the pathogen exceeds the clearance rate of the host, overwhelming intravascular infection occurs with potentially lethal consequences. In experimental studies, macrophage synthesis of tumor necrosis factor (TNF)-a is upregulated after

TABLE 109-1 -- Conditions associated with functional asplenia.

CONDITIONS ASSOCIATED WITH FUNCTIONAL ASPLENIA	
Atrophic spleen	**Normal-sized or enlarged spleen**
Ulcerative colitis	Hemoglobinopathies other than sickle-cell
Celiac disease	Sarcoidosis
Graft-versus-host disease following bone marrow transplantation	Amyloidosis
Splenic irradiation	Systemic lupus erythematosus, rheumatoid arthritis
Thyrotoxicosis	Epstein-Barr virus infection
Dermatitis herpetiformis	Vasculitides with antineutrophil cytoplasmic antibodies
Idiopathic thrombocythemia	Liver disease — portal hypertension

Sickle-cell disease	AIDS, immunosuppressive agents

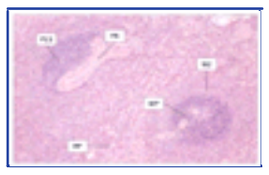

Figure 109-1 Normal splenic architecture in the adult human. PLS, periarterial lymphatic sheath; PA, penicillary arteriole; MZ, marginal zone (B lymphocytes predominate); WP, white pulp (T cells predominate); RP, red pulp (vascular cords and venous sinuses). Hematoxylin and eosin stain.

splenectomy. Enhanced TNF synthesis may increase the risk of systemic activation of the proinflammatory cytokines, and this may contribute to postsplenectomy sepsis. [23] The limited evidence available thus far indicates that patients who have HIV infection tolerate splenectomy reasonably well;[24] nonetheless, severe pneumococcal infections have occurred in splenectomized HIV-positive patients.

PREVENTION OF BABESIOSIS

Individuals living in areas where *Babesia* sp. is endemic should be advised to avoid areas where ticks are common or, if unavoidable, to check daily for the presence of ticks. If the tick is removed within 24 hours it appears to prevent transmission of *Babesia* spp. Babesiosis can be morbidly persistent in splenectomized adults as well as children, and in some cases has required exchange transfusion as well as treatment with clindamycin and quinine. Chills, fever, anemia, leukopenia and thrombocytopenia can all accompany babesiosis. The diagnosis is usually evident if suspected and sought for on the blood smear. Babesiosis can be confused with *Plasmodium falciparum* malaria.

TABLE 109-2 -- Immunologic defects found after splenectomy.

IMMUNOLOGIC DEFECTS FOUND AFTER SPLENECTOMY	
Defect	**Comment**
Decreased clearance of particulate antigens	Hepatic Kupffer cells will partially correct this defect
Diminished clearance of poorly opsonized bacterial antigens	The spleen is the most efficient organ for this purpose
Diminished primary humoral immune response to neoantigens	IgM levels and T-cell-independent antibody responses decrease
Diminished antibody response to polysaccharide antigens	Increased risk from encapsulated bacterial organisms
Decreased tuftsin levels and fibronectin levels	Diminished levels of this tetra peptide and serum protein reduce non-specific attachment and phagocytosis
Quantitative and qualitative defects in the alternative complement pathway	Functional defects in the alternative complement pathway interfere with opsonization

TABLE 109-3 -- Risk factors for postsplenectomy sepsis.

RISK FACTORS FOR POSTSPLENECTOMY SEPSIS	
Risk factors	**Comment**
Patient age	Immunologic experience (vaccines and naturally acquired infections) prior to splenectomy decreases subsequent risk
Absence of spleen at birth	Congenital asplenia results in serious bacterial infections in over 50% of patients in the first year of life
Time interval following splenectomy	Greatest risk of infection is within the first few years following splenectomy
Traumatic versus other indications for splenectomy	Splenosis (splenic implants within the peritoneum) following trauma offers some protection against infection
Immunocompromised states	Patients who have hematologic malignancies and continuing need for immunosuppressive medications have increased risk of postsplenectomy sepsis
Presplenectomy vaccine	Immune responses to polysaccharide antigens are better if administered before splenectomy

PREVENTION OF OVERWHELMING POSTSPLENECTOMY INFECTION

Splenic salvage method

The well recognized risk of OPSI indicates a need to prevent these infections if at all possible. The most direct approach is to minimize the frequency with which splenectomy is performed.[25] Recent evidence suggests that this has leveled off or decreased in North America,[8] [26] perhaps with the recognition of the infectious risks associated with splenectomy. Elective splenectomy for congenital hemolytic disorders should be delayed until after the first 5 years of life if possible (Table 109.4). Surgical repair of splenic hematomas, conservative management of splenic trauma without splenectomy, percutaneous drainage of splenic abscesses and a decreased use of splenic irradiation have led to fewer patients at risk of postsplenectomy infectious syndromes.[27] [28]

TABLE 109-4 -- Preventive measures in postsplenectomy patients.

PREVENTIVE MEASURES IN POSTSPLENECTOMY PATIENTS	
Method	**Comment**
Salvage splenic tissue (splenorrhaphy, autotransplants)	Reasonable, but unproven benefit
Delay elective splenectomy past childhood	Greatest risk of OPSI is in childhood; provide immunizations prior to splenectomy
Immunizations	Pneumococcal, meningococcal and *Haemophilus influenzae* vaccines provide partial protection
Antimicrobial prophylaxis	Indicated in childhood; efficacy in adults uncertain
Early empiric therapy	Unproven but rational approach to rapidly progressive syndrome
Medical alert bracelet	Reminder for patient and health care workers

Partial splenectomy and surgical repair of splenic injury have been used along with autotransplantation of splenic tissue in an attempt to limit the risk of OPSI.[29] [30] Enthusiasm for these splenic salvage maneuvers is tempered by the finding that these methods do not uniformly protect against sepsis in animal models[31] of splenectomy, and case reports exist of overwhelming infections despite these maneuvers. [29] [30] [31] Preservation of residual splenic tissue, if possible, may be preferable to total splenectomy in selected patients. One comparative study by Green and colleagues [32] found two episodes of sepsis in 18 children with splenectomy and no episodes in 16 children who had undergone partial splenectomy. The overall clinical applicability and practical value of splenic salvage techniques remain to be demonstrated in a large patient series.

Immunizations to prevent postsplenectomy sepsis

Immunization with the pneumococcal polysaccharide (PPS) vaccine is safe and offers significant protection in children who have sickle-cell disease. [33] The efficacy of the pneumococcal vaccine is also suggested in other patient groups after splenectomy.[22] [34] [35] To optimize antibody response against T-cell-independent immunogens, it is recommended that the pneumococcal vaccine be administered at least 2 weeks before an elective splenectomy. [16] Nonetheless, adequate antibody responses have been measured after splenectomy in non-immuno-compromised patients.[20] The current recommendations of the Adult Immunization Practices Task Force recommend repeat pneumococcal immunization every 5–6 years from the initial immunization. [36]

The role of newly introduced polysaccharide-protein conjugate pneumococcal vaccine (PCV) in asplenic patients has yet to be fully evaluated in large clinical trials but preliminary results appear promising.[19] [37] The conjugate protein linker allows for the development of T-cell-dependent B cell responses with T helper function amplifying the antibody response. Recent experimental studies[19] have verified that the conjugate vaccine produces peak antibody titers comparable to those in nonsplenectomized animals, albeit at a slower rate of increase. The secondary antibody response to subsequent doses of vaccine are well preserved with the PCV formulation. Attempts to mix unconjugated pneumococcal antigens with the protein conjugated antigens were unsuccessful in boosting antibody titers to nonconjugated pneumococcal antigens. The current PCV has only seven serotypes while the standard PPS vaccine contains 23 serotypes. Further studies are warranted with pneumococcal conjugate vaccines, which will be more efficacious than PPS vaccine.[38]

Haemophilus influenzae type b (Hib) conjugate vaccine is indicated in all children, including those who have functional or surgical asplenia. Immune responses to the conjugate vaccine are well preserved in the absence of splenic function.[38] [39] [40] It is unclear whether the Hib vaccine is useful in adults who have not been vaccinated before splenectomy. The risk-benefit ratio would argue that it is reasonable to immunize children and adults who undergo splenectomy if they have not been previously immunized.[40] The same rationale applies to meningococcal vaccine in children and young adults who undergo splenectomy.[17] [20] [41] The duration of protection and vaccine efficacy against *Haemophilus*, pneumococci and meningococci in the asplenic patient is speculative at the present time. Vaccination is limited by variable antibody responses of uncertain duration and incomplete coverage of important serogroups within *Streptococcus pneumoniae* and *Neisseria meningitidis* (i.e. serogroup B). Vaccine failures are well known in splenectomized patients and therefore additional preventive measures are needed.[19]

The efficacy of bacterial vaccines in the prevention of OPSI has not been adequately tested in large scale, randomized, controlled, clinical trials. The recommendations for these immunizations are largely based upon consensus opinion from expert committees and medical societies. Despite these recommendations, it is clear that the provision of adequate vaccine coverage for the asplenic host is woefully inadequate.[42] A recent survey in the UK found that only 31% of splenectomized patients had received the pneumococcal vaccine. [43] A more concerted effort will be necessary to provide adequate immunizations to these susceptible patients.

Antimicrobial prophylaxis

The efficacy of long-term penicillin prophylaxis to prevent pneumococcal infections has been studied in detail in the pediatric age group. Sufficient clinical evidence now exists to support the recommendation of penicillin prophylaxis in the first 5 years of life in asplenic children.[44] [45] Some authors suggest that prophylaxis be continued indefinitely in immunocompromised patients.[3] [16] [22] Amoxicillin may be preferable to penicillin in that it is better tolerated and has activity against most strains of *H. influenzae*.[8] [42]

The value of penicillin prophylaxis in adults is more controversial. The uncertain benefits of penicillin prophylaxis in the adult must be weighed against the potential risk of acquisition of penicillin-resistant strains of *S. pneumoniae* and infections by other organisms not susceptible to penicillin. [1] [11] [16] [20] I recommend penicillin prophylaxis for 2 years following splenectomy in adult patients at high risk for OPSI (hematologic malignancies, severe liver disease, immunocompromised states). Expectant management with early empiric therapy for symptoms suggestive of OPSI is recommended for non-immunocompromised asplenic adults.

An alternative strategy to continuous prophylaxis is to educate the patient to administer an initial dose of oral amoxicillin at the onset of symptoms compatible with systemic infection. Ideally, patients should have blood cultures taken before empiric antimicrobial therapy; however, this may not be feasible in all patients and treatment should not be delayed if symptoms compatible with OPSI exist.

A medical alert bracelet should be provided to patients following splenectomy. This bracelet serves to remind the patient as well as health care workers that the patient is at risk for OPSI and that urgent management for this potentially devastating syndrome may be life-saving. Patients have developed severe infections up to six decades after splenectomy.[11] [26] The alert bracelet should provide continued awareness of the risk of infection long after surgical removal of the spleen. A summary of preventive measures in the patient who has functional or surgical asplenia is provided in Table 109.4 .

TABLE 109-5 -- Microbial pathogens associated with postsplenectomy infections.

MICROBIAL PATHOGENS ASSOCIATED WITH POSTSPLENECTOMY INFECTIONS	
Micro-organism	**Comment**
Streptococcus pneumoniae	Most common, highly lethal, characteristic presentation
Haemophilus influenzae	Increased risk — especially in childhood
Neisseria meningitidis	Possible increased risk — typical features of primary meningococcemia
Salmonella spp.	Increased risk — especially sickle cell disease
Other streptococci, enterococci	Possible increased risk of infection
Capnocytophaga canimorsus	Gram-negative rod may cause infection following dog bites
Babesia microti	Tick-associated or blood transfusion-associated protozoan parasite; may cause severe infection in asplenic patients
Plasmodium spp.	Sporadic reports of activation of latent malaria and fulminant course with non-*falciparum* malaria species
Anaerobes, Gram-negative enteric organisms, *Pseudomonas*, *Burkholderia*, *Plesiomonas*, *Campylobacter* spp., fungal, parasitic and viral pathogens	Case reports; true association is unclear

CLINICAL FEATURES OF OVERWHELMING POSTSPLENECTOMY INFECTION

A large variety of bacterial, fungal, parasitic and viral pathogens have been reported to cause serious infection in patients who have splenic hypofunction or asplenia.[1] [3] [11] [17] [46] [47] *Streptococcus pneumoniae* continues to account for the majority of bacterial infections associated with OPSI. *Haemophilus influenzae* and *N. meningitidis* contribute approximately 25% of bacterial infections in the post-splenectomy state. The microbiology of systemic infection following splenectomy is provided in Table 109.5 .

The syndrome of overwhelming pneumococcal sepsis after splenectomy is one of the most dramatic and rapidly fatal infections in clinical medicine. Symptoms often begin with a vague sense of general malaise, sore throat, myalgia and gastrointestinal symptoms. Fever and true shaking chills are often seen during the prodromal phase of OPSI. While some patients note lower respiratory tract symptoms or symptoms of meningitis, the primary source of origin of the bacteremic infection is not localized in the majority of patients who have OPSI.

Within 24–48 hours of onset of symptoms patients rapidly deteriorate, with progressive hypotension, diffuse intravascular coagulation, purpuric lesions in the extremities, acute respiratory insufficiency, metabolic acidosis and coma. The rapidly progressive nature of the illness is suggestive of primary meningococcemia. The patient may develop refractory hypotension and die within hours of the onset of symptoms.[1] [14] [16] Long-term sequelae in survivors include gangrene of the extremities, bilateral adrenal hemorrhage, osteomyelitis from vascular insufficiency, endocarditis, meningitis and neurosensory hearing loss.[11] The polysaccharide capsular serotypes 12, 22 and 23 account for the majority of cases of OPSI from *S. pneumoniae*.[16] All three serotypes are found in the current 23 valent pneumococcal

polysaccharide vaccine.[36]

DIAGNOSIS OF OVERWHELMING POSTSPLENECTOMY INFECTION

The diagnosis of OPSI is often readily apparent upon clinical examination. It is important to remember that even a remote history of previous splenectomy should raise suspicion of possible OPSI. Supporting laboratory evidence includes findings compatible with a consumptive coagulopathy, lactic acidosis, hypoxemia and acute renal failure. Children are more likely to have concomitant bacterial pneumonia or meningitis than adults.[1] [11] As a consequence of high-grade bacteremia, micro-organisms can often be identified in the peripheral blood smear (Fig. 109.2). The blood smear should be reviewed for evidence of parasitemia from *Plasmodium* or *Babesia* spp. A Gram stain of the buffy coat may readily reveal organisms as the level of bacteremia may exceed 1 million cfu/ml.

Patients who have concomitant bacterial meningitis may have large numbers of organisms in the cerebrospinal fluid with minimal pleocytosis (Fig. 109.3). Blood cultures, bacterial cultures and results of antigen detection measures in the spinal fluid, sputum and urine will confirm the diagnosis.

MANAGEMENT OF OVERWHELMING POSTSPLENECTOMY INFECTION

This syndrome is a true medical emergency requiring immediate therapeutic administration of antimicrobial agents and intensive care support. High-dose intravenous penicillin has been the standard treatment for post-splenectomy pneumococcal sepsis. Vancomycin and ceftriaxone should be used empirically in areas where penicillin-resistant *S. pneumoniae* is prevalent, or in patients who have received prolonged penicillin prophylaxis. Moreover, broad-spectrum bactericidal antimicrobial agents such as an extended-spectrum cephalosporin or a carbapenem should be used along with an aminoglycoside in those cases in which the suspected micro-organism cannot be identified on Gram strain of the buffy coat or cerebrospinal fluid.

Passive immunotherapy with intravenous immunoglobulin has been shown to be of benefit in experimental models of postsplenectomy sepsis as has granulocyte-macrophage colony-stimulating factor (GM-CSF).[8] [9] The therapeutic efficacy of passive immunotherapy or GM-CSF in human OPSI is worthy of further clinical

investigation. Fluid resuscitation, vasopressor agents, hematologic support, ventilatory support and expert acid-base and electrolyte management are essential to survival in these critically ill patients (see Chapter 56).

The mortality rate for OPSI caused by *S. pneumoniae* has been reported to be between 50% and 70%.[1] [2] [11] [12] [13] [14] [15] [16] With early recognition and treatment combined with skilled supportive care the mortality rate has decreased to as low as 10% in recent series.[26] [48]

During the post-OPSI convalescent period, it may be necessary to surgically debride necrotic tissues irreparably damaged by the prolonged hypotension and intravascular coagulation that often accompany this syndrome. Late complications such as adrenal insufficiency, osteomyelitis and endocarditis should be sought in patients who have persistent fever after an episode of OPSI. Patient education, vaccination and a medical alert bracelet should be offered to survivors to prevent recurrences.

Chapter 110 - Practice Point

Infections in the renal transplant patient

Nina E Tolkoff-Rubin
Robert H Rubin

Renal transplantation has been extraordinarily successful in taking the transplant revolution forward, offering a significant improvement in both quality and quantity of life to recipients. During the evolution of the field there have been extraordinary advances in our understanding of basic and clinical immunology, as well as profound changes in the approaches to immune suppression. However, despite these changes, some aspects have perforce remained the same: the recipient has often been receiving either hemodialysis or peritoneal dialysis before transplantation; the renal allograft is surgically placed through an open abdominal incision; and the therapy required for maintenance of the graft is inherently immunosuppressive and occasionally nephrotoxic. Despite these factors, survival following renal transplantation is over 95% at 1 year and around 90% at 3–5 years. These rates continue to improve, with the improvement for the older recipient showing the greatest change (Briggs, 2001).

The causes of mortality in the renal transplant recipient have changed dramatically over the past several decades. Whereas during the period 1969–82, 40% of deaths were due to infection, in the period 1983–96 only 12% were, with 61% of deaths due to cardiovascular causes (Briggs, 2001). The rate of ischemic heart disease is five times higher in renal transplant recipients than in the general population, no doubt reflecting the myriad cardiovascular influences of underlying renal dysfunction as well as the consequences of transplantation and the drugs and immunologic changes it entails. As overall survival has improved, malignancy has become more common, and it remains a significant risk among long-term survivors. Up to 50% of renal transplant recipients may develop skin cancer of some sort by 20 years post-transplant in high-incidence regions such as Australia; up to 20% of recipients may develop solid organ cancer by 20 years post-transplant (Briggs, 2001). Therefore, management of the transplant patient is increasingly about good medical management, and anticipating other sequelae of long-term immunosuppression.

Renal transplantation has provided the critical workshop for the elucidation of the general principles of solid organ transplantation (see Chapter 102). Because renal transplantation has been practiced for decades and the numbers of recipients is so great in both the developed and the developing world, there is a large repository of data and experience that we can use to inform our understanding of solid organ transplantation in general as well as renal transplantation in particular (Table 110.1).

The factors that make solid organ transplant patients particularly complex and distinguish them from others are the underlying disease and its treatment (e.g. prolonged hemodialysis or peritoneal dialysis with their attendant complications); the surgery to place the allograft; and the dose, intensity and duration of the immunosuppression. This concatenation of events in each patient helps to frame the infectious issues as they arise and leads to the division of care of post-transplant patients into phases: the first month post-transplant, 1–6 months post-transplant and more than 6 months post-transplant. Of course the context in which this occurs is the pre-transplant condition of the patient, adding further disease- and patient-specific components.

The important infectious complications in the first month after renal transplantation are predominantly bacterial and involve the surgical site and the urinary tract. Surgical site infections are similar to those encountered in clean cases in general. Rates of infection in uncomplicated cases are less than 1% and can be further reduced with the use of perioperative antibiotic prophylaxis (e.g. cefazolin). Intraoperative and perioperative complications that necessitate reexploration (e.g. hematoma, anastomotic leak, lymphocele) increase the infection risk several-fold. Bladder catheterization represents a significant risk for bacterial urinary tract infection (UTI). In the absence of prophylaxis with either trimethoprim-sulfamethoxazole (TMP-SMX, co-trimoxazole) or a fluoroquinolone, rates of UTI in the 4 months following transplantation are about 35%, with half of affected patients developing pyelonephritis and 10% developing bacteremia. With prophylaxis, the rate of UTI in uncomplicated transplants is less than 5%. As in the general population, bladder dysfunction (e.g. because of neuropathy) or anatomic anomalies that lead to impaired emptying are important risk factors for UTI. Infections related to vascular access devices or prolonged intubation are also critical risks for bacterial infection in the immediate transplant period.

Viral infections predominate from 1 to 6 months post-transplant. These are related to pre-existing viral infections in the recipient that reactivate in the setting of profound immunosuppression, as well as viral infections transmitted from the donor for which the recipient has no prior or pharmacologically impaired immunity. The herpesviruses, particularly cytomegalovirus (CMV) and Epstein-Barr virus (EBV), receive the major infectious disease focus in this period, because of their involvement in a broad array of infectious disease and malignant presentations. In addition, and distinct from many other viral infections, successful therapeutic and prophylactic therapies and maneuvers exist for several of the herpesviruses. While the roles of these viruses in several clinical syndromes (e.g. fever, pneumonia, hepatitis) are clear, their hypothesized role in precipitating

TABLE 110-1 -- Special considerations in renal transplantation.

SPECIAL CONSIDERATIONS IN RENAL TRANSPLANTATION
Sirolimus may cause a diffuse pneumonitis
Ureteral stenting may predispose to infection
BK virus may mimic graft rejection
Synergistic toxicity of ciclosporin/tacrolimus and macrolides and azoles
Induction of metabolism of ciclosporin and tacrolimus by rifampin, isoniazid and nafcillin, among others

acute or chronic rejection or atherosclerosis is less well proven (Cainelli and Vento, 2002). The diagnosis and treatment of CMV is described in Chapter 112 .

General strategies include prophylaxis, pre-emptive therapy and secondary (post-treatment) prophylaxis. Since transplantation of an organ from a seropositive donor into a seronegative recipient carries a risk of clinical disease of >50%, prophylaxis with either valganciclovir or valaciclovir is indicated. Similarly, prophylaxis of primary EBV infection, varicella-zoster virus (VZV) infection or herpes simplex infection may be appropriate.

Pre-emptive therapy is triggered by a laboratory marker that indicates that clinical disease is likely. For example, CMV viremia suggests that clinical disease is imminent, and the higher the viral load, the greater the probability of symptomatic disease. This requires an infrastructure that can reliably deliver specimens appropriately and in a timely fashion. With many transplant centers serving patients over a wide geographic area, logistics are increasingly important. Although specimens for polymerase chain reaction can be sent by overnight mail, the antigenemia assay is rendered significantly less accurate with such handling. Virologic monitoring is not inexpensive, and when the cost of monitoring is included with the cost of the occasional patient who develops symptomatic CMV disease despite the monitoring effort, the cost saving can be minimal at best (Kusne *et al.*, 1999).

Another form of pre-emptive therapy uses identification of a predictive clinical or epidemiologic characteristic. For example, transplant recipients who are CMV seropositive have a 15–20% risk of clinical disease on standard three-drug immunosuppression; use of induction antilymphocyte antibody in addition leads to a doubling of the risk. If antilymphocyte antibody therapy is used to treat rejection, then 50–65% of CMV seropositive patients will become symptomatic. Ganciclovir (5mg/kg/day intravenously with dosage adjustment for renal function), administered for the duration of the antilymphocyte antibody course, reduces the incidence of clinical disease to about 20%; if 3 months of oral therapy (ganciclovir 2g/day or valganciclovir 900mg/day) is added, the incidence of clinical disease falls to zero.

Secondary prophylaxis is designed to prevent relapsing disease, which may occur during intense immunosuppression, in patients with a high viral load, after premature cessation of treatment doses of ganciclovir, with continuing viremia at ganciclovir cessation, and in the setting of an antigen mismatch between donor and recipient.

Oral valganciclovir prophylaxis for 2–3 months after treatment for clinical disease has been completed with clearance of the viremia may be helpful. Without antiviral agents the incidence of symptomatic herpes simplex disease post-transplant is 30–50%. Therefore, in patients who are not receiving antiviral therapy with ganciclovir, an aciclovir preparation or foscarnet, low-dose oral aciclovir prophylaxis (e.g. 300mg three times per day) is usually given to prevent reactivation disease due to herpes simplex. The primary acquisition of herpes simplex infection is uncommon in the transplant setting.

Development of post-transplant lymphoproliferative disease is correlated with EBV viral load. Cytomegalovirus disease has been shown to increase the incidence of post-transplant lymphoproliferative disease by seven to 10 times, but it is not yet proven whether prevention of CMV will reduce or modify EBV-related events.

Approximately 10% of transplant patients develop dermatomal zoster due to reactivation of VZV, but this rarely progresses to visceral disease. Primary VZV infection, in contrast, is a devastating illness, with dissemination and multiorgan involvement. Because of the high morbidity and mortality associated with primary VZV infection, we advocate pre-transplant VZV serology, with seronegative patients receiving the VZV vaccine and documentation of seroconversion. Seronegative transplant patients who have been exposed to this virus should receive zoster immune globulin immediately. This is about 80% effective in preventing clinical disease but it may not prevent visceral disease. Therefore, after zoster immune globulin, the clinician should remain alert for fever, abdominal pain or organ dysfunction, and initiate high dose aciclovir even without skin lesions. Human herpesvirus-6 can cause pneumonia, encephalitis and fever, and it may synergize with CMV in causing more severe disease. Human herpesvirus-8 has been linked to the pathogenesis of Kaposi's sarcoma.

Infections with BK virus pose a special problem in renal transplantation. Seroprevalence is 100% by age 9–10 years, but it wanes over time. Transplantation of grafts from seropositive donors into either seronegative or seropositive receipients leads to acquisition or reactivation of BK virus. BK virus can cause interstitial nephritis, which is difficult to distinguish from rejection on clinical and laboratory grounds alone; renal biopsy is necessary. Ureteral stenosis can also result from BK virus, also impeding graft function. Treatment for this virus is still quite elusive. Cidofovir has been reported to clear BK viruria in anecdotal series, but its use in renal transplant patients is limited by its own nephrotoxicity (Lin *et al.*, 2001).

There is still no universally accepted approach to vaccination and prophylaxis in the post-transplant patient. Although most centers use TMP-SMX as prophylaxis against *Pneumocystis* and UTI, the issues with regard to other potential pathogens are less clear (Batiuk *et al.*, 2002). There are also important regional differences to consider; for instance, the south-western USA has coccidioidomycosis. The role and value of post-transplant vaccination is also somewhat controversial, with most centers using influenza vaccination, but there is lingering concern about efficacy and the possible triggering of rejection, which limits the use of other vaccines (Batiuk *et al.*, 2002).

Our current approach to the renal transplant recipient is to use perioperative antibiotics; to maintain TMP-SMX prophylaxis against UTI, *Pneumocystis, Listeria, Nocardia*, and possibly toxoplasmosis; to use prophylaxis against CMV in patients at high risk (donor seropositive, recipient seronegative); and to treat all *Aspergillus* infections with antifungal agents (e.g. voriconazole, with careful attention to immunosuppressive levels), regardless of symptoms, because of the risk of invasive disease. Infections are actively sought and aggressively treated, but it must be kept in mind that acute rejection can mimic many of the systemic signs of infection, especially in children.

The spectrum of infectious complications following transplantation is also affected by socioeconomic status, as well as environmental exposures. For instance, 3.4% of Saudi Arabian renal transplant recipients developed *Salmonella* bacteremia. Almost 12% of Indian transplant recipients developed tuberculosis, as opposed to 0.01% of recipients in New York (Tan, 2000). This is especially problematic given the interactions of ciclosporin and rifampin in vivo. The Middle East has high levels of exposure to *Leishmania*, a point to be considered in view of the large number of North Americans and Europeans spending time there who may receive or donate organs in the future.

Chapter 111 - Opportunistic Fungal Infections

Brahm H Segal
Thomas J Walsh

PATIENT POPULATIONS AT RISK FOR OPPORTUNISTIC FUNGAL INFECTIONS

Deficits in host defense that render persons susceptible to fungal infections are complex but can be broadly divided into the following categories:

- neutropenia;
- qualitative deficits in phagocyte function;
- deficits in cell-mediated immunity (CMI); and
- deficits in mucosal immunity.

Humoral immunity is important against *Cryptococcus neoformans* and probably against *Candida* spp. Patients often have multiple defects in immunity predisposing to opportunistic fungal infections (Table 111.1).

PRIMARY IMMUNODEFICIENCIES

Primary immune disorders are far less common than acquired (or iatrogenic) immunodeficiencies. Of the primary phagocytic disorders, patients with chronic granulomatous disease (CGD) are at highest risk for invasive filamentous fungal infections. Chronic granulomatous disease is an inherited disorder of the NADPH oxidase complex in which phagocytes are defective in generating the reactive oxidant superoxide anion and its metabolites, hydrogen peroxide, hydroxyl anion and hypohalous acid. Patients with CGD suffer from recurrent life-threatening bacterial and fungal infections. Aspergillosis is the most important cause of death in CGD.

The hyper-IgE syndrome (HIES; Job's syndrome) is a primary immunodeficiency characterized by eczema first manifesting during infancy, recurrent and severe soft tissue infections, pneumonias and markedly elevated serum IgE levels and several characteristic skeletal and craniofacial manifestations. Mucocutaneous candidiasis is commonly observed. Colonization of cavities (pneumatoceles) by *Aspergillus* spp. may lead to local invasion, abscess formation and hemoptysis.

The spectrum of opportunistic fungal infections in patients with primary T-cell deficiencies is similar to that for patients with AIDS, and includes *Candida* spp., *Pneumocystis carinii, C. neoformans,* dimorphic fungi and more rarely filamentous fungal infections (see Chapter 126).

CANCER

Intrinsic immune deficits in patients with cancer

Although the immune deficits associated with malignancies are overwhelmingly the result of antineoplastic chemotherapy, some intrinsic immune compromise may result from the malignancy itself. Neutropenia may develop independently of chemotherapy in certain patients with cancer. In acute leukemia, virtually the entire marrow may be replaced with malignant cells so that no normal circulating neutrophils exist in the periphery. Similarly, patients with premalignant hematologic disease, such as myelodysplastic syndrome, may have associated bone marrow failure.

Patients with untreated Hodgkin's disease have significant abnormalities in T-cell number and function, which often persist in long-term survivors. These findings may in part explain the predisposition of these patients to development of infections by *C. neoformans, P. carinii* and other opportunistic pathogens. Opportunistic infections occur most frequently in poorly controlled malignancy, when most patients receive corticosteroids, myelotoxic chemotherapy, or both.

Adrenal tumors and ectopic adrenal corticotropic hormone (ACTH)-secreting tumors resulting in high levels of cortisol are associated with defects in cellular immunity resulting in an increased risk of mucosal candidiasis, *P. carinii* infection and invasive aspergillosis.

Neutropenia

The risk of invasive filamentous fungal infection is strongly related to the duration and degree of neutropenia. In patients with aplastic anemia and refractory neutropenia, invasive aspergillosis is a major cause of death. In patients with acute leukemia, Gerson *et al.*[1] showed that aspergillosis was uncommon when neutropenia lasted for less than 14 days. However, after 14 days, the risk of aspergillosis increased in proportion to the duration of neutropenia. Multiple cycles of prolonged neutropenia, such as in the setting of refractory leukemia, further predispose to invasive filamentous fungal infection. Small foci of invasive fungal disease may be clinically and radiographically inapparent during the initial cycles of neutropenia, only to manifest during a later cycle. Concomitant therapy with systemic corticosteroids and other immunosuppresive agents also increases the risk of invasive filamentous fungal infection. Therefore, knowledge about current and prior cycles of chemotherapy is key in risk stratification for opportunistic fungal infections.

Antifungal prophylaxis and empiric antifungal therapy in patients with neutropenic fever unresponsive to standard antibacterial agents have led to a reduction in the morbidity and mortality rate due to candidal infections. However, infections by *Aspergillus* spp. and other filamentous fungi in high-risk patients with hematologic malignancies have become an increasing cause of death.

Lymphopenia

Little attention has been paid to the potential value of the absolute lymphocyte count and lymphocyte subsets in the assessment of infection risk in cancer patients. Among HIV-infected patients, a $CD4^+$ T-cell count less than 200cells/mm^3 is associated with an increased risk of opportunistic infections such *P. carinii* and mucosal candidiasis. Invasive aspergillosis, although relatively uncommon in AIDS, occurs in the setting of advanced HIV infection ($CD4^+$ T-cell count usually <100 cells/mm^3), and in patients with additional co-morbidities such as neutropenia or use of systemic corticosteroids (see Chapter 126).

Fludarabine is a fluorinated lymphotoxic analog of adenine that has been used in a variety of hematologic malignancies, including chronic lymphocytic leukemia, hairy cell leukemia and low-grade lymphoma, primarily affecting $CD4^+$ T cells. The combination of fludarabine and corticosteroids is more immunosuppressive than either agent alone, and results in a uniform depression of $CD4^+$ T cells that may persist for several months after completion of therapy. Patients with

TABLE 111-1 -- Principal risk factors for opportunistic fungal infections in immunocompromised patients.

PRINCIPAL RISK FACTORS FOR OPPORTUNISTIC FUNGAL INFECTIONS IN IMMUNOCOMPROMISED PATIENTS		
Patient population	**Principal risk factors**	**Fungal pathogens**

Hematologic malignancies		
Acute myelogenous leukemia	Neutropenia and mucous membrane toxicity	*Candida* spp. (mucosal and systemic infection), *Aspergillus* spp., other filamentous fungi*, *Trichosporon* spp.
Acute lymphocytic leukemia	Neutropenia, mucous membrane toxicity, T-cell depression (from corticosteroids)	*Candida* spp. (mucosal and systemic infection), *Aspergillus* spp., other filamentous fungi, *Pneumocystis carinii*, *Cryptococcus neoformans,* dimorphic fungi, *Trichosporon* spp.
Chronic lymphocytic leukemia and hairy cell leukemia	T-cell depression (from corticosteroids, fludarabine, other lymphotoxic agents)	*Candida* spp. (usually mucosal), *Pneumocystis carinii*, *Cryptococcus neoformans,* dimorphic fungi, filamentous fungi (less common than in acute leukemia)
Lymphomas	Neutropenia, mucous membrane toxicity and T-cell depression (from corticosteroids, fludarabine)	*Candida* spp. (mucosal and systemic infection), *Aspergillus* spp., other filamentous fungi, *Pneumocystis carinii, Cryptococcus neoformans*, dimorphic fungi
Multiple myeloma	Neutropenia and T-cell depression from corticosteroids	*Candida* spp. (usually mucosal), *Pneumocystis carinii*, *Cryptococcus neoformans,* dimorphic fungi, filamentous fungi (less common than in acute leukemia)
Hematopoietic transplantation		
First month	Neutropenia and mucous membrane toxicity	*Candida* spp. (mucosal and systemic infection), *Aspergillus* spp., other filamentous fungi, *Trichosporon* spp.
1–6 months	T-cell depression (from lack of donor-derived T-cell reconstitution and immunosuppressive agents), phagocyte dysfunction due mainly to corticosteroids, and depressed mucosal immunity due to GVHD	*Candida* spp. (mucosal and systemic infection), *Aspergillus* spp., other filamentous fungi, *Pneumocystis carinii, Cryptococcus neoformans*, dimorphic fungi, *Trichosporon* spp.
> 6 months	Similar to 1–6 months with GVHD requiring corticosteroids	
Solid organ transplantation		
First month	Postoperative infection, most common in liver and pancreatic/small bowel transplantation	*Candida* spp. (wound infection, peritonitis, cholangitis, candidemia)
1–12 months	T-cell and phagocyte dysfunction due to immunosuppressive agents	*Candida* spp. *Pneumocystis carinii*, *Cryptococcus neoformans,* dimorphic fungi, *Aspergillus* spp. (highest frequency in lung transplantation) and other filamentous fungi
>12 months		Similar to 1–12 months with organ rejection treated with intensive immunosuppressive agents
Collagen vascular diseases	T-cell and phagocyte dysfunction due to immunosuppressive agents	*Candida* spp. (mucosal), *Pneumocystis carinii,* dimorphic fungi, *Aspergillus* spp. and other filamentous fungi
Aplastic anemia	Neutropenia	*Aspergillus* spp. and other filamentous fungi
Primary immune disorders		
Chronic granulomatous disease	Defective phagocyte NADPH oxidase	*Aspergillus* spp. and other filamentous fungi
Job's syndrome	Defective phagocyte function	*Candida* spp. (mucosal and cutaneous), *Aspergillus* spp
AIDS and other T-cell deficiencies	Defective T-cell and macrophage function	*Candida* spp. (mucosal and cutaneous), *Pneumocystis carinii, Cryptococcus neoformans,* dimorphic fungi, dermatophyte infection (may be extensive), *Aspergillus* spp. and other filamentous fungi†

*Other filamentous fungi include zygomycetes, *Fusarium* spp., dark-walled molds, *Scedosporium* spp. and *Acremonium* spp.
†Invasive filamentous fungal infections in AIDS often occur in the setting of additional host defense deficits, such as neutropenia and use of corticosteroids.

hematologic malignancies are also being treated with novel monoclonal antibodies that cause a depletion of lymphocyte subsets, and may increase the risk of opportunistic fungal infections.

Mucosal immunity

The mucosal linings in the gastrointestinal, sinopulmonary and genitourinary tracts constitute the first line of host defense against a variety of pathogens. Chemotherapy and radiation therapy cause defects in mucosal immunity at several different levels. The physical protective barrier conferred by the epithelial lining is compromised, thus allowing access to colonizing microflora. Corticosteroids profoundly compromise mucosa-associated lymphoid tissue (MALT) by inducing apoptosis of M-cells and depleting lymphoid follicles of T and B cells.[2]

Mucosal epithelial cells secrete a variety of antimicrobial peptides, including lactoferrin (iron sequestration), lysozyme (hydrolysis of peptidoglycan of Gram-positive bacteria) and phospholipase A2 (cleavage of structural phospholipids of bacteria) and defensins. In patients receiving induction chemotherapy for newly diagnosed acute myelogenous leukemia, the risk of candidemia and hepatosplenic candidiasis is most strongly related to the degree of chemotherapy-induced damage to the intestinal epithelial surface.[3] Molecular studies examining candidemia support the gut as the predominant source of organisms.[4]

Corticosteroids

Corticosteroids have profound effects on the distribution and function of neutrophils, monocytes and lymphocytes (see Chapter 99). They reduce neutrophil adherence to the endothelium, thus inhibiting migration to inflammatory sites, inhibit neutrophil fungicidal activity and cause a monocytopenia that lasts 24 hours.[5] In addition, a number of monocyte functions are impaired, including chemotaxis, bactericidal activity and production of interleukin (IL)-1 and tumor necrosis factor (TNF)-a. Corticosteroids inhibit T-cell activation, leading to reduced proliferative responses and cytokine production, and induce redistribution of lymphocytes out of the circulation, resulting in peripheral lymphocytopenia. In addition to immunosuppression, corticosteroids directly stimulate the growth of *Aspergillus fumigatus* in vitro[6] possibly via sterol binding proteins in the fungus.

HEMATOPOIETIC TRANSPLANTATION

The spectrum of pathogens to which hematopoietic stem cell transplant (HSCT) recipients are most susceptible follows a time line corresponding to the predominant immune defects observed at different periods. In the early stage, neutropenia and mucosal toxicity from the conditioning regimens are the principal host defense defects. Patients are at risk for the same spectrum of fungal pathogens (principally *Candida* spp. and filamentous fungi) that afflict nontransplant patients with hematologic malignancies who have been treated with potent myelotoxic therapy.

Defects in CMI persist for several months, even in uncomplicated allogeneic transplant recipients, thus predisposing these patients to a variety of opportunistic infections. In addition to quantitative T-cell deficiencies, loss of T-cell receptor diversity is observed.[7] By 1 year after transplant, T-cell subsets and responses normalize if graft versus host disease (GVHD) has not occurred.

There is a predominance of invasive filamentous fungal infections in the post-engraftment period in allogeneic BMT/SCT recipients receiving the potent immunosuppressive regimens typically used to treat GVHD. Wald *et al.*[8] conducted a case-control analysis of 158 cases of proven or probable aspergillosis in BMT/SCT recipients. The onset of infection was bimodal, with the first peak occurring before or shortly after engraftment, and the second peak occurring at a mean of

96 days after transplant, commonly in the setting of acute GVHD. In autologous HSCT recipients, aspergillosis occurred most often during neutropenia, and was rare after engraftment. In contrast, aspergillosis was more likely to occur after the first 40 days in allogeneic transplant recipients. Marr *et al.*[9] noted an increase in non-*fumigatus Aspergillus* spp., zygomycetes, *Fusarium* and *Scedosporium* spp. in allogeneic HSCT recipients. Patients requiring multiple transplants were at particular risk for these 'emerging' amphotericin B-resistant pathogens. Aspergillosis also occurs in the post-engraftment period in allogeneic HSCT recipients, with GVHD being the principal risk factor. Cytomegalovirus viremia or disease may also be a risk factor for late-onset aspergillosis.[10]

SOLID ORGAN TRANSPLANTATION

Solid organ transplant (SOT) recipients are at increased risk for fungal infections during two periods. They are at risk for nosocomial candidemia and candidiasis early after transplantation. Reflecting the fact that the bowel is the principal host reservoir of *Candida*, liver recipients are at higher risk for postoperative candidemia and organ candidiasis. Pancreatic transplant recipients are also at high risk for intra-abdominal candidiasis. In renal transplant recipients, candiduria is a risk for an ascending *Candida* pyelonephritis and sepsis, particularly when there is obstruction at the ureteral anastomosis. Fluconazole prophylaxis reduces deep fungal infections and fungal infection-related deaths in liver transplant recipients.[11]

The second period of fungal infection risk is during the depression of immunity induced by agents used to prevent or treat graft rejection. The period of highest risk for opportunistic infections is generally within the first year of transplant. Intensification of immunosuppressive therapy to treat allograft rejection, which may include high-dose corticosteroids and anti-lymphocyte immunoglobulin, significantly increases the risk of opportunistic infections. In this setting, opportunistic fungal infections include candidiasis, *P. carinii, C. neoformans,* dimorphic fungi, *Aspergillus* spp. and other invasive filamentous fungal infections.

Among SOT recipients, lung transplant recipients are at the highest risk of invasive pulmonary aspergillosis. Anastamotic infections occur in approximately 5% of lung transplant recipients, principally due to *Candida* and *Aspergillus* spp. Infection typically responds to appropriate systemic antifungal therapy, and anastomotic dehiscence is uncommon. [12] Colonization of the native lung with *Aspergillus* spp. occurs commonly in end-stage lung disease, and is an important source of post-transplant aspergillosis in single lung transplants. Cytomegalovirus viremia is an additional risk factor for invasive aspergillosis in lung transplant recipients.[13]

Antifungal prophylaxis during the early post-transplant period [14] [15] and pre-emptive therapy in patients with *Aspergillus* airway colonization [16] have shown promising results in uncontrolled studies.

YEAST INFECTIONS

Candidiasis

Oropharyngeal and esophageal candidiasis

Oral mucosal candidiasis, thrush, usually reflects significant T-cell immunodeficiency. The diagnosis of oral candidiasis is usually made visually by identification of white adherent plaques on the palate, buccal mucosa, tongue or gingiva. In patients with cancer, the differential diagnosis includes chemotherapy-induced mucositis, bacterial infections and herpes simplex virus infection. A wet mount or Gram stain showing pseudohyphae establishes the diagnosis. A culture of the oral mucosa that grows *Candida* spp. is not by itself diagnostic because these species commonly colonize the mouth. Therapy for oropharyngeal candidiasis includes local treatments such as nystatin or clotrimazole troches, or fluconazole.

Esophageal candidiasis is a more severe mucosal disease that typically manifests with odynophagia. The differential diagnosis includes esophageal infection by herpes simplex virus, cytomegalovirus principally in allogeneic HSCT recipients, and bacterial infections. Systemic antifungal therapy is required. In fluconazole-resistant *Candida* infections, a second-generation triazole (cross-resistance with fluconazole may occur), amphotericin B preparation or an echinocandin are desirable.

Candidemia

Candida spp. are the fourth most common nosocomial blood culture isolates in the USA.[17] The crude mortality rate varies, but is generally between 30 and 60%. In a European surveillance study of candidemia in cancer patients, the overall 30-day mortality rate was 39%, with an increased mortality rate in older patients, in those with poorly controlled malignancy, and in cases in which *Candida* (*Torulopsis*) *glabrata* was isolated.[18] Bloodstream infection by non-*albicans Candida* spp. was associated with neutropenia in solid tumor and acute leukemia patients and with antifungal prophylaxis in hematology patients. Among hematology patients, additional factors associated with death were allogeneic HSCT, septic shock and lack of antifungal prophylaxis. In a retrospective study of 476 cases

of candidemia at the MD Anderson Cancer Center, the mortality rate was 52%. Neutropenia, a high APACHE score and disseminated candidiasis were associated with poorer outcomes. [19]

The isolation of non-*albicans Candida* spp., which account for approximately 50% of bloodstream isolates, has direct clinical significance. *Candida glabrata* isolates have a broad range of minimum inhibitory concentrations (MICs) to fluconazole, and *Candida krusei* is virtually always resistant. Antifungal susceptibility testing of bloodstream *Candida* isolates is becoming more common and gaining acceptance in clinical practice. Isolates with an intermediate MIC to fluconazole (16–32µg/ml) are referred to as 'susceptible dose-dependent', indicating that therapeutic serum levels are achievable with adequate fluconazole dosing.

Isolation of *Candida* spp. from blood remains unreliable even with modern blood culture isolation systems. Nonculture methods, such as amplification by polymerase chain reaction (PCR), antigen detection and detection of metabolites, are investigational, and may prove useful in complementing culture methods.[20] Molecular studies in the setting of persistent neutropenic fever may eventually guide the clinician in the application of antifungal therapy.[21]

All candidemic patients should receive systemic antifungal therapy. Early catheter removal may reduce the likelihood of late complications by eliminating a potential nidus of ongoing candidemia. Removal of intravenous catheters in candidemic patients reduces the time to blood sterilization in non-neutropenic patients when the catheter was the likely portal of entry.[22] The Infectious Diseases Society of America (IDSA) has advised removal of all intravascular catheters in patients with candidemia, but noted that this recommendation was stronger in non-neutropenic patients in whom the catheter is the most likely primary source of infection.[23] In patients who have received cytotoxic chemotherapy, candidemia is likely to arise from defects in the gut mucosa rather than the catheter. Nucci and Anaissie[24] noted the lack of association between early central venous catheter removal and improved survival, and questioned the routine practice of catheter removal in candidemia. If the catheter is not immediately removed, we advise rotating antifungal infusions through all ports to increase the likelihood of catheter sterilization. All intravenous catheters should be replaced in the setting of clinical instability, lack of resolution of fever within 2–3 days, or persistent candidemia after 1–2 days of appropriate antifungal therapy.

Chronic disseminated candidiasis

Chronic disseminated candidiasis (hepatosplenic candidiasis), typically manifests as a fever that persists after neutrophil recovery. Chronic disseminated candidiasis is a complication of highly mucotoxic chemotherapy regimens, such as those used as induction therapy for acute leukemia. During neutropenia, it is thought that the liver, spleen, kidneys, lungs, skin, bone and other sites become hematogenously seeded by *Candida*, which may go undetected by blood culture. With neutrophil recovery, numerous target lesions in the liver and spleen become apparent by computerized tomography (CT) scan, ultrasonography, or magnetic resonance imaging (MRI; Fig. 111.1). Serial ultrasound examination in patients for whom a high clinical suspicion exists may enhance the likelihood of detecting new or evolving lesions. [25] Liver biopsy is required for definitive diagnosis; but, because the lesions are discrete, a blind percutaneous biopsy may be falsely negative. Open or laporoscopic-guided liver biopsy is recommended if a percutaneous biopsy is not diagnostic.

Chronic disseminated candidiasis is not per se a contraindication for subsequent myelotoxic chemotherapy or hematopoietic transplantation.[26] Patients in whom fever and lesions have resolved with antifungal therapy can undergo further episodes of neutropenia without progression of the fungal infection if antifungal therapy is reinitiated during the neutropenic periods.[26]

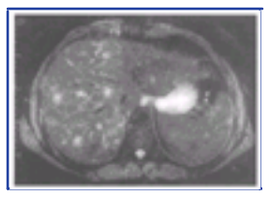

Figure 111-1 A T2-weighted MRI of the liver in a 24-year-old woman being treated for lymphoma who has chronic disseminated (hepatosplenic) candidiasis. The hepatic lesions are central densities surrounded by zones of lower signal intensity which create a 'bull's eye' appearance. Smaller lesions are also visible in the spleen, particularly in the subcapsular region.

Therapy for invasive candidiasis

A large randomized study comparing intravenous fluconazole (400mg/day) with amphotericin B (0.5mg/kg daily) as therapy for candidemia in non-neutropenic patients found the regimens to be equally effective, but fluconazole had less toxicity. [27] Due to the importance of *Candida* isolates with MICs to fluconazole in the susceptible dose-dependent range, a National Institute of Allergy and Infectious Diseases (NIAID) Bacteriology and Mycosis Study Group (BAMSG) trial compared fluconazole (800mg daily) plus amphotericin B (0.7mg/kg daily); (F+A) to fluconazole (800mg daily) plus placebo (F+P) in non-neutropenic patients with candidemia.[28] Despite a worse APACHE II score in the F+P arm at randomization, the survival was similar. The F+A arm had more rapid sterilization of blood, but more renal toxicity.

The echinocandins are a family of cyclic lipopeptides that are noncompetitive inhibitors of (1,3)-ß-D-glucan synthase, an enzyme complex that forms glucan polymers in fungal cell walls. Echinocandins have a broad spectrum of activity against *Candida* and *Aspergillus* spp., with activity against virtually all *Candida* clinical isolates, including those that are resistant to fluconazole or itraconazole. Echinocandins were highly effective in animal models of disseminated candidiasis. Three echinocandins are licensed or in major clinical trials: caspofungin, micafungin (FK463) and anidulafungin (LY303366) (see Chapter 208).

Echinocnadins are effective in mucosal candidiasis. Recently, a phase 3 randomized study comparing caspofungin with conventional amphotericin B in adult patients with invasive candidiasis was completed.[29] The study enrolled 239 patients; 185 met the prespecified criteria for evalution. In the evaluable-patient analysis, a favorable reaponse, defined as improvement or resolution of clinical symptoms and signs attributed to *Candida* infection plus eradication of *Candidan* infection, occurred in 81% of caspofungin recipients and 65% of amphotericin B recipients at the time of discontinuation of intravenous fungal therapy ($p < 0.05$). The modified intent-to-treat analysis showed a trend toward superiority in the caspofungin arm, but this did not reach statistical significnace. Caspofungin recipients had fewer drug-related toxicities. The overall survival and time to sterilization of blood was similar between the two groups. This study supports caspofungin as initial therapy for invasive candidiasis in adults (Table 111.2).

TABLE 111-2 -- **Antifungal agents.** (See also Chapter 208).

ANTIFUNGAL AGENTS	
Antifungal agents	**Comments**
Azoles	
Fluconazole	Acceptable alternative to amphotericin B for candidemia at dose of 400–800mg/day; broad range of MICs to *Candida glabrata* and resistant to *Candida krusei*; prophylaxis in high-risk patients (e.g. acute leukemia during neutropenia, hematopoietic transplantation, liver and pancreatic transplantation); maintenance therapy for cryptococcal meningitis; inactive against filamentous fungi
Itraconazole	Active against *Candida* spp., *Aspergillus* spp., dimorphic fungi, dark-walled molds. Cyclodextrin formulation has increased bioavailability compared with capsules and can be administered parenterally. Itraconazole solution approved for empiric therapy for neutropenic fever
Second-generation azoles	Second-generation antifungal triazoles (voriconazole, posaconazole and ravuconazole) have broad spectrum of activity, including *Candida* spp. (including most, but not all, fluconazole-resistant isolates), *Aspergillus* spp., dimorphic fungi, *Cryptococcus neoformans*, *Trichosporon* spp., *Fusarium* spp., *Pseudallescheria boydii* and dark-walled molds
Voriconazole	New standard of care as initial therapy for invasive aspergillosis; treatment of other filamentous fungi resistant to amphotericin B (*Fusarium* spp., *Pseudallescheria boydii* and dark-walled molds); poor activity against zygomycetes; acceptable alternative to amphotericin B as empiric therapy for neutropenic fever (may be particularly advantageous in relapsed acute leukemia and allogeneic hematopoietic transplantation)
Posaconazole*	Similar spectrum of activity to voriconazole, but active against zygomycetes; growing clinical database from compassionate use protocol for treatment of *Aspergillus* spp. and other refractory filamentous fungi (*Fusarium* spp., *Pseudallescheria boydii* and dark-walled molds); phase III study comparing posaconazole with fluconazole as prophylaxis in allogeneic hematopoietic transplant recipients with GVHD is ongoing
Ravuconazole*	Being evaluated in clinical trials
Polyenes	
Nystatin	Topical agent useful for mucosal candidiasis; parenteral liposomal nystatin is experimental
Amphotericin B deoxycholate (AMB-D)	Broad spectrum of antifungal activity, but with significant infusion-related and nephrotoxicity
Lipid formulations of amphotericin B	Equal to superior efficacy and lower toxicity compared with AMB-D; higher pharmacy acquisition cost
Liposomal amphotericin B (LAMB)	Reduced proven breakthrough fungal infections and less infusion- and nephrotoxicity vs AMB-D as empiric therapy for persistent neutropenic fever; less infusion- and nephrotoxicity vs amphotericin B lipid complex as empiric therapy
Amphotericin B lipid complex (ABLC)	Extensive compassionate use database for patients with refractory invasive fungal infections or intolerance to AMB-D; successfully used in hepatosplenic candidiasis in pediatric patients; high levels in the reticuloendothelial system
Amphotericin B colloidal dispersion	Reduced nephrotoxicity, but more infusion toxicity vs AMB-D as empiric therapy for persistent neutropenic fever
5-flucytosine (5-FC)	Randomized studies support combination of AMB-D and 5-FC for cryptococcal meningitis; pyrimidine analog with dose- and duration-dependent myelotoxicity and gastrointestinal toxicity; monitoring of serum levels and adjustment of dosing for azotemia required
Echinocandins	Class of antifungal peptides that inhibit synthesis of glucan, a fungal cell wall constituent; potently cidal against *Candida* spp., including fluconazole-resistant; fungistatic against *Aspergillus* spp., principally acting at growing hyphal tips; infrequent infusion-related events and not nephrotoxic
Caspofungin	Compassionate use study of patients with refractory invasive aspergillosis or intolerance to licensed antifungal agents showed 41% successful responses (superior to carefully matched historic controls) led to approval for this indication; recent randomized study showed comparable efficacy and less toxicity vs AMB-D for invasive candidiasis
Micafungin*	Phase III study comparing micafungin with fluconazole as prophylaxis in hematopoietic transplant recipients has completed enrollment
Anidulafungin*	

*Non-licensed compounds

Cryptococcus neoformans

Host defense against cryptococcal infection is principally dependent on T-cell immunity. Immunoglobulins directed against capsular epitopes and complement facilitate phagocytosis of the organism, and likely play a role in host defense. The principal portal of entry for C. *neoformans* is by inhalation, with subsequent spread to the

blood and central nervous system (CNS) with development of cryptococcal meningitis.

Although meningitis is the most common presentation of cryptococcal infection, pneumonia, fungemia and cutaneous and visceral dissemination also occur. Additional CNS complications include development of a mass lesion, obstructive hydrocephalus and visual loss. Visual abnormalities may be a consequence of endophthalmitis, a space occupying lesion in the visual pathway, direct invasion of the optic nerve (which may be rapidly progressive), or as a consequence of elevated intracranial pressure. In the pre-AIDS era, patients who died early during therapy were more likely to have rapidly progressive infection, cerebrospinal fluid (CSF) with a high opening pressure, low CSF glucose level, less than 20 leukocytes/µl of CSF, a positive India ink preaparation, culture of cryptococci from extraneural sites, and high titers of crytococcal antigen in serum and CSF.[30]

For AIDS-associated cryptococcal meningitis, the IDSA recommends amphotericin B (0.7–1.0mg/kg daily) plus 5-flucytosine (100mg/kg daily) for the first 2 weeks, followed by lifelong maintenance fluconazole therapy (see Chapter 126).[31] In the absence of recent randomized studies, the same induction regimen is recommended as in non-AIDS

associated cryptococcal meningitis, followed by fluconazole 400mg daily for at least 10 weeks.[31] In neutropenic patients, reduction of the dosage of 5-flucytosine may be considered to avoid delay in myeloid recovery. Interferon-? and passive immunization with monoclonal antibody (mAb 18B7) directed against the cryptococcal capsule[32] are newer therapies being evaluated.

Trichosporon spp.

Trichosporon spp. typically affect profoundly neutropenic patients and those receiving corticosteroid therapy. Acute disseminated trichosporonosis typically manifests with refractory fungemia, funguria, cutaneous lesions, renal failure, pulmonary lesions and chorioretinitis. Disseminated trichosporonosis may yield a false-positive cryptococcal latex antigen test because of cross-reactivity with the polysaccharide capsule of *C. neoformans*. This cross-reactivity may be clinically important because *C. neoformans* typically responds to amphotericin B therapy, while *Trichosporon* spp. are usually resistant.

Blastoschizomyces capitatus (formerly *Trichosporon capitatus*) usually presents as a chronic disseminated infection resembling chronic candidiasis. A CT scan may show lesions suggestive of hepatosplenic candidiasis, but definitive diagnosis requires either a positive culture from blood or biopsy.

INVASIVE FILAMENTOUS FUNGAL INFECTIONS

Aspergillosis

Aspergillus can involve virtually any organ in the immunocompromised host, but sinopulmonary disease is the most common. Alveolar macrophages constitute the first line of host defense against aerosolized conidia. Following germination, neutrophils are the dominant host defense arm against the hyphal stage. Invasive aspergillosis in the neutropenic host may present as fever, sinus pain or congestion, cough, pleuritic chest pain or hemoptysis. Erosion into the wall of a large central blood vessel can lead to massive pulmonary hemorrhage. The radiographic appearance of pulmonary aspergillosis includes bronchopneumonia, lobar consolidation, segmental pneumonia, nodular lesions resembling septic emboli, and cavities. Isolation of any *Aspergillus* sp. from a sputum or bronchoalveolar lavage specimen should be presumed to represent invasive disease in neutropenic patients. [8] [33] *Aspergillus fumigatus* followed by *Aspergillus flavus* are the most common species causing invasive disease. *Aspergillus terreus* is notable for being resistant to amphotericin B; voriconazole may be of value based on in-vitro sensitivity data.[34] See also Chapter 237 .

The CNS is a common target site for hematogenously disseminated aspergillosis. Gastrointestinal aspergillosis usually co-exists with pulmonary disease, but in rare instances it may be the sole organ involved. The manifestations include abdominal pain, gastrointestinal infarction with hemorrhage, perforation and polymicrobial sepsis. Early diagnosis of isolated gastrointestinal aspergillosis followed by resection of the involved bowel and systemic antifungal therapy may be life-saving. Other sites of disseminated aspergillosis include the skin, heart, eye, bone, kidney, liver and thyroid.

Early diagnosis of aspergillosis in profoundly immunocompromised patients remains difficult. Blood cultures are rarely positive; sputum and bronchoalveolar cultures have approximately 50% sensitivity in focal pulmonary lesions; definitive diagnosis often requires an invasive procedure and is usually only made when the disease is advanced. A CT scan of the chest may facilitate early detection by showing peripheral or subpleural nodules that are inapparent on plain chest radiographs (Fig. 111.2). The 'halo sign' is a characteristic chest CT feature of angioinvasion. The hazy alveolar infiltrates appear to correspond to regions of ischemia, and are highly suggestive of invasive aspergillosis. Early recognition followed by intensive antifungal therapy and surgical resection of localized disease was associated with an approved outcome in a retrospective series.[35]

Polymerase chain reaction and antigen-based detection of subclinical aspergillosis are promising tools for early diagnosis. A sensitive double sandwich enzyme-linked immunosorbent assay (ELISA) to detect the fungal cell wall constituent galactomannan has been developed. Maertens *et al.* [36] obtained serial serum galactomannan levels from neutropenic and HSCT patients at high risk for aspergillosis. The positive and negative predictive values for invasive aspergillosis were 87.5 and 98.4%, respectively. All proven cases of invasive aspergillosis, including 23 cases confirmed at autopsy only, had been detected by the ELISA before death, although serial sampling was necessary to maximize detection. Herbrecht *et al.*[37] evaluated the galactomannan antigenemia assay in four groups of patients: neutropenic fever of unknown etio-logy, suspected pulmonary infection, suspected extrapulmonary aspergillosis, and surveillance in HSCT recipients. The positive predictive value varied among the different patient groups reflecting the different frequencies of invasive aspergillosis. The rate was lowest (7.1%) in neutropenic fever. Clinical trials are required to delineate which of these diagnostic methods — or which combination — provides optimal positive and negative predictive value for invasive disease in high-risk patients.

In neutropenic patients and in allogeneic HSCT recipients, locally invasive disease such as sinusitis, primary cutaneous lesions, intravitreal disease, or bone lesions should receive combined surgery and systemic antifungal therapy because of the risk of dissemination.

Patients who recover from an episode of invasive aspergillosis are at risk for relapse during a subsequent course of myelotoxic chemotherapy. A large retrospective analysis on 48 patients with definite or probable aspergillosis who subsequently received bone marrow or stem cell transplantation (77% allogeneic) [38] found that the overall incidence of relapse of *Aspergillus* infection was 29% among patients receiving secondary prophylaxis but 57% among those who did not. Fourteen of 16 (88%) patients with relapse of infection died. Surgical resection does not obviate the need for secondary antifungal prophylaxis during subsequent chemotherapy, given the likelihood of residual foci of persistent inapparent disease.

Antifungal therapy for invasive aspergillosis

Until recently, standard therapy for invasive aspergillosis has been high-dose conventional amphotericin B (1–1.5mg/kg daily). Lipid formulations of amphotericin B may be more effective and certainly have less infusion-related toxicity than conventional amphotericin B, based on noncomparative and compassionate use studies.[39] [40] If a lipid formulation of amphotericin B is used, we suggest a dose of at least 5mg/kg daily. In a dose-escalation study of liposomal amphotericin B in patients with invasive fungal infection, dosing as high as 15mg/kg daily was well-tolerated. [41]

Voriconazole, posaconazole (SCH 56592) and ravuconazole (BMS 207147) are second-generation triazoles that are currently licensed or being evaluated in clinical trials. These agents are active against *Candida* spp. (including most fluconazole-resistant isolates), *Aspergillus* spp., dimorphic fungi, *C. neoformans* and several resistant fungi, including *Scedosporium* spp., dark-walled (dematiaceous) molds, *Trichosporon* spp. and *Fusarium* spp.

Voriconazole has been the most extensively studied of this group. In a noncomparative study of 116 patients with invasive aspergillosis in which voriconazole was given either as initial (52%) or salvage (48%) therapy, a complete or partial response occurred in 48% of patients, with a more favorable prognosis in the group that received voriconazole as initial therapy.[42] When voriconazole was compared with conventional amphotericin B (1.0–1.5mg/kg daily) as initial therapy in an open, randomized study of patients with invasive

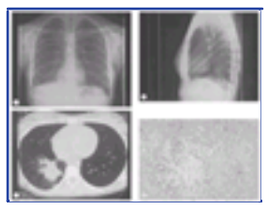

Figure 111-2 Aspergillosis. (a and b) A chest radiograph to evaluate persistent neutropenic fever in a patient with relapsed leukemia showed subtle increased markings in the right lower lung. (c) A chest CT scan obtained the same day showed a significant area of consolidation not apparent on the chest radiograph. Bronchoalveolar lavage grew *Aspergillus fumigatus*. This case illustrates the appropriate use of a chest CT scan in patients with persistent neutropenic fever at high risk for invasive mold infection. (d) Invasive pulmonary aspergillosis in another patient showing necrosis and invasive hyphae (Gomori methenamine silver).

aspergillosis,[43] voriconazole was more effective (53% with complete or partial response vs 32%, respectively) and had improved survival at 12 weeks (71 vs 58%, respectively). Voriconazole had a superior response rate in both neutropenic and non-neutropenic patients. The poorest prognosis was observed in extrapulmonary aspergillosis and in allogeneic HSCT recipients. This study establishes voriconazole as a more effective and less toxic standard of care for therapy of invasive aspergillosis (see Chapter 208).

Posaconazole was also an effective and well-tolerated salvage treatment for serious invasive fungal infections in immunocompromised patients.[44] It is currently being evaluated as prophylaxis in allogeneic HSCT recipients with GVHD. This study is important in view of the increasing frequency of invasive filamentous fungal infections in this setting and the poor prognosis they convey.[8]

The echinocandin caspofungin is approved for the treatment of invasive aspergillosis refractory to, and in patients intolerant of, conventional or lipid formulations of amphotericin B or itraconazole. This was based on a compassionate use study of 63 patients with invasive aspergillosis (53 refractory, 10 intolerant) in whom caspofungin led to a successful outcome (complete or partial response) in 41% of cases. This compared favorably with carefully matched historic controls. Echinocandins have not been evaluated as initial therapy for invasive filamentous fungal infections, but there is growing interest in evaluating echinocandins in combination with other classes of antifungal agents.

Zygomycosis

Risk factors for zygomycosis (also termed 'mucormycosis') include diabetic ketoacidosis, protein-calorie malnutrition, iron overload and prolonged neutropenia. Patients receiving potent myelotoxic chemotherapy for leukemia are at risk for locally invasive as well as disseminated disease. Zygomycosis typically manifests as rhinocerebral or pulmonary disease following inhalation of spores. In rhinocerebral disease, fever, facial pain and headache are common. Contiguous extension may lead to orbital involvement with proptosis and extraocular muscle paresis, involvement of the hard palate and spread to the brain. An eschar over the palate is suggestive of zygomycosis, but other filamentous fungi can produce similar findings in highly immunocompromised persons. Occasionally, isolated primary cutaneous disease may follow minor trauma. Injection drug

users may inadvertently inject spores directly into the bloodstream and present with isolated space-occupying lesions of the brain or other organs. Current therapy for zygomycosis involves high-dose amphotericin B (conventional or lipid formulations) plus early and aggressive surgical debridement. Voriconazole has poor activity against the zygomycetes, but posaconazole is active in vitro and merits further study.

Dark-walled molds

Dark-walled molds (pheohyphomycetes, dematiaceous molds) contain melanin in their cell walls which imparts a brown or olive-green pigment in culture. In immunocompromised patients, soft tissue infection, sinusitis, CNS infection, pneumonia, fungemia and disseminated disease are observed. Certain species have a strong predisposition for CNS disease.

Therapy in immunocompromised patients involves surgical excision of localized disease when feasible, and systemic antifungal therapy. Sensitivity to amphotericin B is variable and clinical failures have been reported. Itraconazole has been shown to be effective in infections by dark-walled molds refractory to amphotericin B.[45] Second-generation triazoles are also active against dark-walled molds.

Fusarium spp.

Fusarium spp. are soil saprophytes associated with soft tissue infection, onychomycosis and keratitis in immunocompetent hosts. With the widespread use of intensive antineoplastic therapy and BMT/SCT, more than 150 cases of invasive and disseminated fusariosis have been reported — most within the past 15 years.[46] Colonization of hospital water systems is a potential environmental reservoir.[47] The clinical findings and histologic appearance may be indistinguishable from those of aspergillosis. In the absence of a definitive culture diagnosis, the factors that suggest *Fusarium* spp. rather than *Aspergillus* are the presence of disseminated cutaneous lesions or the isolation of a mold from blood culture.

Boutati and Anaissie[46] made important observations about invasive and disseminated fusariosis in a retrospective review of 43 cases occurring in patients with hematologic malignancies. Most cases of disseminated fusariosis were diagnosed during neutropenia. Resolution of infection was only seen in patients who recovered from myelosuppression, and a high risk of relapse of infection was associated with subsequent myelosuppression. The skin was identified as an important portal of entry. Initial localized manifestations included onychomycosis, paronychia and cellulitis. Early identification of localized skin disease and surgical debridement may be life-saving. Inhalation of spores is another major portal of entry, leading to fungal sinusitis and pneumonia.

Survival from disseminated fusariosis is critically dependent on resolution of neutropenia. Susceptibility to amphotericin B is variable and itraconazole is inactive. For *Fusarium* spp. MICs to voriconazole range from 1–8µg/mL, which is higher than those for most pathogenic molds. The experience with voriconazole as therapy for fusariosis is limited, but appears to compare favorably with amphotericin.[48] In data presented to the Food and Drug Administration, 9 (43%) of 21 patients with fusariosis had a partial or complete response to voriconazole in a compassionate use protocol. Posaconazole has a similar in-vitro activity to voriconazole, and may be effective based on limited compassionate use data.[44] (Posaconazole is not yet licensed but is available under a compassionate use protocol through the manufacturer Schering-Plough.)

Scedosporium spp.

Scedosporium apiospermum (Pseudallescheria boydii) and *Scedosporium prolificans* are the principal pathogens in the genus *Scedosporium*. In neutropenic patients, *S. apiospermum* infection is virulent, and clinically and histologically resembles aspergillosis. Invasion of blood vessels leading to infarction is common. *Scedosporium apiospermum* causes sinopulmonary disease, endophthalmitis and dissemination to the CNS. The infection can also spread directly from the skin to bone and joint. Establishing a culture diagnosis of *S. apiospermum* is critical because of its frequent resistance to amphotericin B. Voriconazole is highly promising for *S. apiospermum* infections. Seventeen of 27 (63%) patients with *S. apiospermum* infections, in about one-third of whom there was dissemination or involvement of the CNS, responded to voriconazole salvage therapy.[49] Surgical resection of localized lesions is strongly advised. *Scedosporium prolificans* causes a similar spectrum of disease as *S. apiospermum* and is generally resistant to all antifungal agents.

Endemic dimorphic fungi

Endemic dimorphic fungi are so named because of their characteristic geographic distribution. These organisms include *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis* and *Penicillium marneffei*. *Penicillium marneffei* is endemic in South East Asia. These fungi are dimorphic, existing in nature in the mycelial stage, and convert to yeast stage at body temperature (see Chapter 39).

Endemic mycoses in the central USA include histoplasmosis and blastomycosis. In the immunocompetent host, inhalation of *Histoplasma* microconidia is typically asymptomatic, but may manifest with acute fever, pulmonary infiltrates and hypoxia. Immunocompromised patients have a higher risk of disseminated histoplasmosis involving the liver, spleen, lymph nodes, bone marrow, adrenal glands, mucocutaneous tissues, gastrointestinal tract and CNS. The chest radiograph may show a miliary reticulonudular appearance suggestive of tuberculosis. An acute sepsis syndrome with hypotension, disseminated intravascular coagulation, adrenal crisis and meningitis are potential lethal complications.

Rapid diagnosis of histoplasmosis can be made by Giemsa staining of peripheral blood smears or bone marrow aspirates demonstrating characteristic intracellular yeast forms. Lysis centrifugation is the preferred blood culture system. Antigen detection from blood and urine is sensitive and specific in disseminated disease.

Antibody detection may also be useful, but false-negative results may occur in immunocompromised patients. Biopsy specimens may show suggestive intracellular or narrow budding yeasts, which should be confirmed by culture. In patients with disseminated or life-threatening infection, histoplasmosis should be treated with high-dose amphotericin B (1–1.5mg/kg daily) or a lipid formulation. Prolonged therapy with itraconazole may be initiated after stabilization of disease, and should probably be continued for the duration of immunosuppression. Itraconazole is preferred over fluconazole because of the greater likelihood of emergence of resistance during fluconazole therapy leading to treatment failure.[50]

Coccidioides immitis is endemic in southwestern USA. In normal persons, infection is usually asymptomatic or self-limited. In patients with compromised cell mediated immunity, *C. immitis* is likely to be more virulent. Diagnosis is most easily established by serology or demonstration of pathognomonic spherules in sputum or tissue samples. Coccidioidomycosis can involve virtually any organ, but has a particular trophism for bone and the CNS. Therapy for nonmeningeal disseminated or extrapulmonary disease generally involves an azole. Amphotericin B is an alternative in rapidly progressive or severe infections. [51] In a randomized, double-blind study of progressive nonmeningeal coccidioidomycosis, oral itraconazole was associated with a trend toward increased efficacy compared with fluconazole (72 vs 57% response at 12 months, respectively). [52] Fluconazole is advised for meningitis, given its excellent CSF penetration. Some physicians initiate therapy with intracisternal amphotericin B in addition to systemic azole therapy.[51] In view of the potential life-threatening consequences of relapse, lifelong maintenance azole therapy is advised in patients with meningitis who have responded to initial azole therapy.[51] [53]

Pneumocystis carinii

Pneumocystis carinii is more appropriately classified as a fungus than a protozoan based on gene sequence data and cell wall constituents. Defective T-cell immunity is the principal risk factor for *P. carinii* infection (see Chapter 124). Sepkowitz *et al.*[54] reported that corticosteroid use was associated with 204 of 227 (90%) cases of *P. carinii* infection in patients without AIDS at Memorial Sloan-Kettering Cancer Center between 1963 and 1992. The median time that patients received corticosteroids was 2 months, although a minority of patients had received corticosteroids for less than 1 month. Approximately 60% of patients had hematologic malignancies, 25% had solid tumors, 10% were HSCT recipients and 5% were receiving relatively mild immunosuppressive regimens.

The risk of *P. carinii* infection increases with the intensity of the immunosuppressive regimen. In a study of pediatric patients with acute lymphocytic leukemia, the risk of *P. carinii* infection strikingly increased from less than 5 to 22% when cytosine arabinoside (ARA–C) was used.[55] Browne *et al.*[56] reported a 32% rate of *P. carinii* infection (probable plus definite) in patients with non-Hodgkin's lymphoma treated with an intensive regimen consisting of corticosteroids and multiple cytotoxic agents. There were no cases of *P. carinii* infection in patients who did not receive ARA–C and bleomycin. The diagnosis of *P. carinii* infection relies on visualization of the organism microscopically. Immunofluorescent staining using monoclonal antibodies is more sensitive than older staining methods, such as silver staining or Wright-Giemsa. [57]

Trimethoprim-sulfamethoxazole (co-trimoxazole; 15–20mg/kg daily divided into 3–4 doses) is the treatment of choice for *P. carinii* infection. Children with acute lymphoblastic leukemia and allogeneic HSCT recipients are known to be at high risk and should be offered prophylaxis. Adults with acute lymphoblastic leukemia, patients with CNS tumors receiving high-dose corticosteroid therapy and patients receiving combination corticosteroid therapy with either myelotoxic agents or fludarabine are also at high risk for *P. carinii* infection. In patients with collagen vascular disease, the risk of *P. carinii* infection is highest in those receiving concomitant high-dose corticosteroid and cytotoxic therapies, such as those with Wegener's granulomatosis or lupus nephritis. In these patients prophylaxis should be considered.[58]

FUNGAL INFECTIONS BY ANATOMIC SITE

Sinusitis

Invasive fungal sinusitis in immunocompromised patients often has devastating results. Infection by *Aspergillus* spp. is most common in patients with persistent neutropenia (e.g. aplastic anemia) and in BMT/SCT recipients. Zygomycetes are classically associated with rhinocerebral disease, leading to necrosis of the palate, and extension to surrounding structures. Sinusitis by 'emerging' fungal pathogens, including *Fusarium* spp., dark-walled molds and *Scedosporium* spp., are being recognized with increasing frequency. Symptoms and signs suggestive of fungal sinusitis include fever, nasal congestion, headache, maxillary tenderness and periorbital swelling. Sinus endoscopy may show necrotic material or ulceration. Hyphal invasion into blood vessels leads to tissue infarction and hemorrhage. Mental status changes or focal neurologic findings may indicate involvement of the brain.

Therapy for invasive fungal sinusitis often requires a combined medical and surgical approach. Initial therapy should include either high-dose lipid formulation of amphotericin B (=5mg/kg daily) or a second-generation triazole (voriconazole has poor activity against zygomycetes, posaconazole is active). When feasible, involved tissue should be surgically resected because medical therapy alone is unlikely to contain infection, especially in the setting of neutropenia or severe immunosuppression. Systemic antifungal therapy should be continued even if all necrotic tissue is fully debrided, given the likelihood of inapparent local and disseminated disease. The most important predictor of a successful outcome is usually resolution of neutropenia. Re-initiation of antifungal therapy during subsequent periods of neutropenia is important.[59]

Pneumonia

Aspergillus is the most common cause of fungal pneumonia in persistently neutropenic patients. Less common fungal pathogens include zygomycetes, *Trichosporon*, *Fusarium* and dark-walled molds. Isolation of *Candida* spp. from respiratory samples most likely represents upper airway colonization. *Candida* pneumonia occurs in unusual cases as a focal infiltrate or a miliary pattern reflecting hematogenous dissemination; biopsy is required to diagnose pulmonary candidiasis definitively.[23] *Aspergillus* spp. and other filamentous fungi are typically angioinvasive and may cause pulmonary hemorrhage, infarction, pleuritic chest pain or direct invasion of chest wall structures.

Bronchoalveolar lavage is relatively insensitive for diagnosing aspergillosis, detecting it in only approximately 50% of cases.[60] Percutaneous biopsy may increase the diagnostic yield, but in thrombocytopenic patients the risk of bleeding may be unacceptably high. Open lung biopsy allows for easier visualization and control of bleeding and therefore is the definitive diagnostic method in immunocompromised patients with pulmonary lesions. False-negative results occur in approximately 5% of open lung biopsies due to sampling error in the case of patchy lesions.

Central nervous system fungal infections

The CNS is the most common target organ for hematogenously disseminated aspergillosis. Manifestations of CNS aspergillosis include focal seizures, hemiparesis, cranial nerve palsies and hemorrhagic infarcts due to vascular invasion. Pulmonary infiltrates and focal neurologic deficits in an immunocompromised patient were significantly more predictive of CNS aspergillosis than CNS candidiasis or cryptococcosis in a multivariate discriminate analysis of autopsy-proven fungal CNS infections.[61] *Scedosporium* spp. and certain dark-walled molds also have a predilection for CNS infection.

Aspergillus brain abscesses are typically multiple, hypodense and non-enhancing with little mass effect. Computerized tomography scans with contrast initially may reveal no focal lesions, but later may demonstrate focal ring-enhancement or hemorrhagic changes. Magnetic resonance imaging may improve early detection. Biopsy of these CNS lesions shows vascular invasion and infarction similar to that seen in lung biopsy specimens.

Central nervous system aspergillosis has been almost universally fatal in highly immunocompromised persons. Voriconazole led to complete or partial response in three of 19 (16%) patients with CNS aspergillosis,[42] which compares favorably with the dismal historic experience using other antifungal agents.

Skin lesions and soft tissue infections

In the profoundly immunocompromised patient, skin lesions often arise and may be due to several different etiologies. The characteristic skin lesions of disseminated candidiasis are discrete raised erythematous papules, measuring about 0.5–1cm in diameter. The lesions are usually not tender. Concurrent myalgias raise the possibility of *Candida* myositis. The yeast is cultured from skin lesions in about half the cases, and blood cultures are typically positive. Biopsy and fungal staining of cutaneous lesions can provide an immediate diagnosis, prompting the early addition of antifungal therapy.

Trichosporon beigelii skin lesions cause 30% of disseminated fungal infections in some series, and are characterized by nontender erythematous nodules that may necrose. Histologically, budding

yeasts are present in the dermis, as distinct from *Candida* spp., which produce pseudohyphae. Disseminated *C. neoformans* presents as painless lesions that may appear as papules, pustules, plaques, ulcers, subcutaneous masses, or cellulitis. The discrete papular form may resemble molluscum contagiosum.

Localized cutaneous infection by dimorphic fungi may follow traumatic inoculation. The appearance of disseminated cutaneous infection varies, and is most commonly observed in patients with depressed cellular immunity. Disseminated cutaneous histoplasmosis typically presents with a papular or nodular rash and oral mucosal ulcerative lesions (*Histoplasma duboisii*, the agent of 'African histoplasmosis', typically produces large nodular and ulcerative cutaneous lesions). Large keratotic ulcers and subcutaneous draining abscesses may be observed in disseminated coccidioidomycosis. Erythema nodosum, a panniculitis presenting as tender, raised, red-to-violaceous lesions, typically over the extremities, may be a manifestation of histoplasmosis or coccidioidomycosis. *Penicillium marneffeii* causes disseminated infection resembling histoplasmosis in highly immunocompromised hosts.

Cutaneous infection by filamentous fungi may be primary or may represent systemic infection. Primary cutaneous infection with molds can occur in immunocompetent patients by traumatic inoculation. However, angioinvasion, infarction, extension to the soft tissue and dissemination occur only in the setting of profound immunosuppression. Localized cutaneous aspergillosis can be caused by intravenous arm boards. Surgical resection may be necessary, and has an excellent prognosis. In the neutropenic patient, the likelihood of subclinical systemic infection is high, and therefore systemic antifungal therapy is warranted. Hematogenously disseminated filamentous fungal infection may resemble ecthyma gangrenosum, but histologically hyphal elements are seen associated with angioinvasion and infarction.

EMPIRIC ANTIFUNGAL THERAPY FOR PERSISTENT FEVER IN NEUTROPENIA

The rationale for empiric antifungal therapy for persistent fever during neutropenia is that despite meticulous clinical examination and collection of cultures, our techniques are not sufficiently sensitive for early detection of fungal infections. Before the standard implementation of empiric antifungal therapy, there was a correlation between prolonged fever during neutropenia and death in patients with cancer; fungal infection was frequently found at autopsy. Two randomized prospective studies showed that empiric amphotericin B therapy was associated with a trend toward fewer serious fungal infections.[62] [63]

Because fungal infections are uncommonly encountered in the first 7 days of fever during neutropenia, empiric antifungal therapy is typically begun between days 4 and 7 of neutropenic fever. Empiric antifungal therapy should be continued for the duration of neutropenia. In a large, randomized study of patients with neutropenic fever unresponsive to standard antibacterial agents, liposomal amphotericin B (LAMB) was associated with fewer proven breakthrough fungal infections and less infusion-related and renal toxicity than conventional deoxycholate amphotericin B. [64]

Intravenous followed by oral itraconazole solution (this cyclodextrin formulation has much better bioavailability) was as effective as but less toxic than conventional amphotericin B as empiric therapy for fever during neutropenia,[65] leading to the approval of itraconazole solution for this indication. Previous use of prophylactic fluconazole was similar in both groups, an important consideration given the potential for cross-resistance of fungal pathogens to different classes of azoles. Fluconazole has been used successfully as empiric therapy for neutropenic fever.[66] However, given its lack of activity against filamentous fungi, fluconazole is more suitable as prophylaxis during neutropenia, rather than as empiric therapy in patients at high risk for invasive filamentous fungal infection (e.g. those with acute leukemia, allogeneic HSCT).

Echinocandins and second-generation triazoles are attractive candidates for antifungal prophylaxis and empiric therapy for fever during neutropenia. Voriconazole was compared with LAMB in a nonblinded, randomized study of empiric antifungal therapy in patients with persistent fever during neutropenia unresponsive to antibacterials. [67] The overall success rates were 26% with voriconazole and 31% with LAMB, but empiric voriconazole was associated with fewer breakthrough fungal infections (1.9 vs 5.0%). The greatest protective benefit occurred in high-risk patients, such as those with relapsed acute leukemia and allogeneic HSCT. Voriconazole caused fewer infusion-related and nephrotoxicities, but more transient visual changes and visual hallucinations. However, because of the absence of proof of 'non-inferiority' of voriconazole compared to LAMB, it was not approved by the US Food and Drug Administration for empiric therapy. Comparison of caspofungin with LAMB as empiric antifungal therapy has recently been completed.

Liposomal amphotericin B, the cyclodextrin formulation of itraconazole, and voriconazole are highly acceptable agents for empiric antifungal therapy. The selection of an empiric antifungal agent should be tailored to the individual patient and should broadly consider the risk of breakthrough fungal infection, toxicity and a pharmacoeconomic analysis, and not solely hospital or pharmacy acquisition costs.

ANTIFUNGAL PROPHYLAXIS DURING CHEMOTHERAPY-INDUCED NEUTROPENIA

In HSCT recipients, two double-blinded, placebo-controlled trials have shown that prophylactic fluconazole controlled yeast colonization and reduced the rate of mucosal candidiasis and invasive *Candida* infections.[68] [69] A reduction in mortality rate was noted in the study by Slavin *et al.*,[69] in which most of the patients were allograft recipients. Fluconazole use conferred significant long-term improvement in survival, possibly by reducing *Candida* antigen-induced gut GVHD.[70] Fluconazole is associated with colonization by azole-resistant *Candida* strains, which may be less intrinsically virulent than azole-sensitive *C. albicans*, based on their low rates of candidemia, invasive candidiasis and attributable death. [71]

Fluconazole prophylaxis has produced mixed results in patients with leukemia receiving chemotherapy. In one randomized study, fluconazole prophylaxis was associated with a reduction in skin and mucosal infection and a delay in empiric use of amphotericin B, but made no significant difference in invasive candidiasis or mortality rate compared to placebo.[72] In another study, fluconazole prophylaxis reduced fungal colonization, invasive infection and fungal infection-related mortality rate in chemotherapy patients with leukemia and in autologous transplant recipients.[73] The benefit of fluconazole prophylaxis was greatest in autologous transplant recipients who were not receiving colony growth factor support and in patients receiving mucotoxic regimens (cytarabine plus anthracyclines) — a finding that is consistent with the bowel being a principal portal of entry for *Candida* bloodstream infections. The emergence of resistant *Candida* spp. and the lack of activity against filamentous fungi remain major concerns for prophylactic use of fluconazole.

The erratic bioavailability of the capsular form of itraconazole mitigates its use in highly immunocompromised neutropenic patients. The cyclodextrin formulation of itraconazole allows for increased oral bioavailability, and the intravenous formulation allows for achievement of therapeutic levels within 3 days. The oral cyclodextrin formulation of itraconazole is, in general, safe and effective as prophylaxis during prolonged neutropenia as long as adequate

serum levels are maintained. A meta-analysis has shown that prophylaxis with itraconazole solution was effective in preventing invasive fungal infections in neutropenic patients and reduced the mortality rate due to fungal infections.[74]

IMMUNE AUGMENTATION

Colony growth factors

Normal myelopoiesis requires the establishment of myeloid stem cells. Under the influence of stem cell factor (SCF), IL-3 and granulocyte-macrophage colony stimulating factor (GM-CSF), this gives rise to the colony forming unit granulocyte-macrophage (CFU-GM). Granulocyte colony stimulating factor (G-CSF) acts at a later stage in concert with other growth factors to specifically drive granulopoiesis. Prophylactic G-CSF has been evaluated in several prospective, randomized studies. The most consistent benefit has been a reduction in the neutropenic period. In some studies of patients receiving therapy for acute myelogenous leukemia, the acceleration of myeloid recovery was associated with a reduction in the duration of fever, use of antibiotics and hospitalization.

In one study, GM-CSF was only administered to patients who had a hypocellular or remission marrow on day 10 of induction chemotherapy.[75] Patients who achieved complete remission received the same study drug (GM-CSF or placebo) during consolidation chemotherapy. The median time to neutrophil recovery was significantly reduced in the GM-CSF group as was the frequency of fatal fungal infections and early infection-related deaths. There was a trend toward increased complete remission in the GM-CSF group. Most important, the 6-month mortality rate was significantly reduced in the GM-CSF arm. So far, this is the only study that has shown a survival advantage attributed to a colony stimulating factor. This study formed the basis for US Food and Drug Administration approval of GM-CSF for patients with acute myelogenous leukemia. Other randomized studies of prophylactic GM-CSF have not shown a protective benefit against fungal infections or impact on survival.

In addition to accelerating myelopoiesis, colony stimulating factors augment phagocyte function. G-CSF, GM-CSF and macrophage colony stimulating factor (M-CSF)

increase the fungicidal activity of phagocytes in vitro against *Candida* and *Aspergillus* spp. M-CSF increases phagocytosis, chemotaxis and secondary cytokine production in monocytes and macrophages.[76] GM-CSF stimulates various neutrophil effector functions and prolongs neutrophil survival in vitro, increases antibody-dependent cytotoxicity of eosinophils, accelerates the proliferation of the monocyte-macrophage system, and is a potent activator of monocytes and macrophages.[76] Thus GM-CSF may have a theoretic advantage against pathogens such as *Candida* and *Aspergillus* spp., in which host defense is dependent on both neutrophil and macrophage function.

Granulocyte transfusions

The impetus to re-evaluate granulocyte transfusion therapy stems from improvements made in the methods to mobilize large number of cells from donors and the feasibility of using non-human leukocyte antigen (HLA) matched community donors.[77] Recombinant G-CSF with or without corticosteroids is now routinely administered to donors approximately 12 hours before apheresis to increase granulocyte yield.

Successful outcomes using granulocyte transfusions have been described in patients with life-threatening fungal infections in small series and in case reports. In one non-randomized retrospective series, no benefit of granulocyte transfusions was noted in neutropenic BMT recipients with invasive mold infection.[78] A phase I/II trial using G-CSF-mobilized granulocyte transfusions in refractory fungal infections in neutropenic patients with hematologic malignancies reported favorable responses in 11 of 15 patients.[79] Peters *et al.*[80] evaluated granulocyte transfusions (G-CSF or prednisolone mobilized) in 30 patients with neutropenia and life-threatening, refractory infections. Infections cleared in 20 of 30 patients, including five of nine patients with invasive aspergillosis.

Price *et al.*[77] conducted a phase I/II study of granulocyte transfusions from unrelated, non-HLA-matched, community donors mobilized with G-CSF and dexamethasone for the treatment of hematopoietic transplant recipients with severe infections. The mean transfusion yield was 8.2×10^{10} neutrophils, and 17 of 19 patients had a transient restoration of a normal neutrophil count. Chills, fever and oxygen desaturation of 3% or more occurred in 7% of transfusions, but did not limit therapy. Eight of 11 patients with bacterial infections survived. However, none of 8 patients with invasive filamentous fungal infection survived.

We currently reserve granulocyte transfusions for patients with prolonged neutropenia and life-threatening infection refractory to conventional therapy. Filamentous fungi are likely to constitute the majority of such refractory infections. Infusions of amphotericin B should be separated by several hours from granulocyte transfusions to reduce the likelihood of pulmonary toxicity. In some highly alloimmunized patients, transfused granulocytes are rapidly consumed and are likely to have more toxicity than benefit. In cytomegalovirus-seronegative patients who are likely to be candidates for allogeneic HSCT, we suggest that only cytomegalovirus-seronegative granulocyte donors be used. A prospective randomized study is required to rigorously evaluate the benefits versus toxicity of granulocyte transfusions. In patients with impaired cellular immunity, it is crucial that the granulocytes are irradiated to prevent GVHD from the donor lymphocytes carried in the product.

Interferon-?

Interferon-? is a macrophage activating factor that is critical in host defense against intracellular infections such as *Leishmania* and *Mycobacteria* spp. Interferon-? (IFN-?) augments generation of microbicidal reactive oxidants in phagocytes, and is also a potent activator of oxidant-independent mechanisms, including augmentation of TNF-a production, tryptophan metabolism, granule protein synthesis and major histocompatibility complex surface expression. In several experimental fungal infections, host defense was enhanced by use of cytokines to augment CMI.

Prophylactic IFN-? has been shown to reduce the frequency of serious bacterial and fungal infections in patients with CGD, and is the standard of care in these patients.[81]

Chapter 112 - Opportunistic Viral Infections

Pierre Reusser

INTRODUCTION

Patients who have had bone marrow or peripheral blood stem cell transplantation (SCT) and recipients of solid organ transplants are at increased risk for severe viral diseases, particularly during the period of marked immunosuppression early after transplantation. DNA viruses are generally a more common cause of infection than RNA viruses, which is related to their propensity to establish long-term latency after primary infection and to reactivate during subsequent periods of immunodeficiency.

During the past two decades, considerable progress has been achieved in the management of diseases due to several herpesviruses, including herpes simplex virus types 1 (HSV-1) and 2 (HSV-2), varicella-zoster virus (VZV), and cytomegalovirus (CMV) in immunocompromised hosts, and promising treatment approaches have emerged for influenza A and B viruses. Advances were made possible primarily because of the introduction of rapid and sensitive diagnostic techniques, such as shell-vial cultures, antigen detection assays and the polymerase chain reaction (PCR), which permit the detection and treatment of viral infections at an early stage, and also because of the development of novel antiviral drugs.

HERPES SIMPLEX VIRUS INFECTION

EPIDEMIOLOGY

HSV-1 and HSV-2 are distributed worldwide and the seroprevalence in adults reaches approximately 80–95% for HSV-1 and 20–25% for HSV-2. Seropositivity is correlated with increasing age and lower socio-economic status. Without preventive antiviral drug treatment, HSV reactivation occurs in about 65–80% of seropositive patients receiving induction chemotherapy for acute leukemia or an allogeneic SCT, and is observed in one-third of HSV-seropositive kidney graft recipients. [1] [2]

PATHOGENESIS

Herpesviruses establish latency following primary infection. The mechanisms by which latent infection occurs remain to be elucidated. Latent HSV resides in the neuronal cells of sensory nerve ganglia and may reactivate and replicate upon external stimuli and during periods of immunosuppression.[3] HSV then spreads centrifugally via peripheral sensory nerves to the epithelial surface where it causes confined vesicular lesions. The vast majority of HSV infection and disease in adult cancer patients and organ transplant recipients is due to reactivation of latent virus rather than primary infection.[1] [4] HSV-specific cell-mediated immunity appears crucial in containing HSV infection.[1]

PREVENTION

Prevention of HSV disease in seropositive immunodeficient patients is primarily aimed at suppressing viral reactivation by the use of antiviral agents. An efficient prophylaxis of HSV disease was made possible by the introduction of aciclovir, valaciclovir and famciclovir into clinical use.[3] [5] Early studies of aciclovir prophylaxis among HSV-seropositive patients after allogeneic SCT or on chemotherapy for acute leukemia demonstrated a significant reduction of culture-proven HSV disease from about 70% with placebo to 0% with aciclovir.[1] A more recent placebo-controlled trial of valaciclovir for prevention of cytomegalovirus (CMV) disease in renal transplant recipients documented a significantly decreased risk of clinical HSV disease in both seronegative patients (hazard ratio 0.33) and seropositive patients (hazard ratio 0.16).[2] Recommended regimens for antiviral drug prophylaxis of HSV infection in immunocompromised hosts are summarized in Table 112.1 . While the prophylactic use of aciclovir is not justified in seronegative patients, it is recommended for HSV-seropositive patients receiving chemotherapy for hematologic malignancy or undergoing SCT.[6] [7] Furthermore, HSV-seronegative SCT recipients should be advised of behaviors that reduce the risk of HSV transmission by avoiding contact with potentially infectious secretions, such as saliva and cervical secretions.[7] Low-dose aciclovir has protective effects against HSV hepatitis in liver and kidney transplant recipients and is a recommended prophylactic regimen (Table 112.1).[4]

CLINICAL FEATURES AND DIAGNOSIS

HSV infection in immunocompromised hosts is usually associated with localized mucocutaneous disease which develops in the orofacial region in 85–90% of cases and the genital area in 10–15%.[1] [4] The diagnosis of mucocutaneous HSV lesions can often be made on clinical grounds and may be confirmed by virus cultures or PCR. Virus culture is the standard method for detection of HSV in clinical specimens and usually yields results within 48 hours of inoculation. Moreover, virus culture permits typing of isolates and testing for antiviral drug resistance. Antigen detection is more rapid, but the sensitivity of this assay diminishes with advanced stages of HSV lesions. The PCR is a highly sensitive and specific method for detection of HSV infection and has proved particularly useful in the diagnosis of HSV encephalitis.[3] In cancer patients with severe mucositis following chemotherapy or irradiation, the diagnosis of oropharyngeal HSV disease can be difficult and the identification of virus by culturing or PCR detection may be necessary (Fig. 112.1).[1] [6] In general, serological results are not helpful in confirming the diagnosis of active HSV infection in immunodeficient hosts but allow identification of those patients who might benefit from antiviral drug prophylaxis.

Immunosuppressed patients are at risk of developing disseminated mucocutaneous or visceral HSV infection which is associated with an increased morbidity and mortality.[1] [4] A frequent visceral manifestation of HSV infection in immunocompromised cancer patients is esophageal disease. In prospective endoscopic studies among patients with malignancy who had upper gastrointestinal symptoms, esophagitis associated with HSV was documented in about 10% of

TABLE 112-1 -- Antiviral drug prophylaxis and therapy of HSV infection and disease.[3] [5] [6]

ANTIVIRAL DRUG PROPHYLAXIS AND THERAPY OF HSV INFECTION AND DISEASE			
Indication	**Drug**	**Dose and route**	**Duration**
Prophylaxis			
HSV-seropositive patients	Aciclovir	250mg/m^2 or 5mg/kg every 12h iv	For the period of the most severe immunosuppression (usually 2–3 months)
		or	
		200–400mg 3 times daily to 800mg twice daily po	
	Valaciclovir	500–1000mg twice daily po	
	Famciclovir	500mg twice daily po	
Therapy			
Mucocutaneous or esophageal HSV disease	Aciclovir	250mg/m^2 or 5mg/kg every 8h iv	7–10 days
		or	
		200–400mg 5 times daily po	
	Valaciclovir	500–1000mg twice daily po	7 days
	Famciclovir	500mg twice daily or 250mg 3 times daily po	7 days
HSV encephalitis, pneumonia	Aciclovir	10–15mg/kg every 8h iv	14–21 days

cases.[1] Dysphagia and retrosternal pain with abrupt onset are the most common complaints and patients may also experience otherwise unexplained nausea and vomiting. The specific diagnosis of HSV esophagitis requires both virologic and histologic evidence of HSV infection. For endoscopic biopsy of suspected lesions in thrombocytopenic patients, a minimum platelet count of 50 × 10^9 /l is recommended. Infrequent but life-threatening presentations of HSV disease in immunodeficient hosts include hepatitis, pneumonia, encephalitis and disseminated infection.[1] [4] [6]

MANAGEMENT

Intravenous aciclovir is the therapy of choice for severe mucocutaneous or visceral HSV disease in immunocompromised hosts.[4] [5] [6] Intravenous aciclovir therapy administered for mucocutaneous HSV disease in various immunosuppressed patients significantly shortens the duration of virus shedding and lesion pain, and induces more rapid lesion healing. Oral aciclovir is also documented to be effective therapy of mucocutaneous HSV disease in allogeneic SCT recipients.

The newer antiviral compounds valaciclovir and famciclovir share a high oral bio-availability that is up to five-fold higher than that of

Figure 112-2 Aciclovir-resistant perineal ulcerative HSV lesions after allogeneic SCT.

oral aciclovir, allowing less frequent dosing during therapy of HSV disease. Both agents may be considered as therapeutic alternatives for less serious forms of HSV disease in immunodeficient hosts.[3] [5] Data on the therapy of life-threatening conditions, such as HSV pneumonia and HSV encephalitis in immunosuppressed patients, are limited but outcome may be more favorable with early initiation of high-dose intravenous aciclovir.[3] Table 112.1 lists recommended regimens for antiviral therapy of HSV disease in immunocompromised hosts.

With the introduction of antiviral drug treatment of HSV infection, the emergence of resistant HSV isolates that cause disease unresponsive to therapy has been reported with increasing frequency.[8] In a large retrospective cohort study, the rate of drug-resistant HSV infection among 148 immunodeficient patients previously exposed to aciclovir was 5% (14% after SCT, 8% after pancreas transplant, 5% after kidney transplant, 0% after liver or heart transplant, and 0% in nontransplant cancer patients).[9] Patients with aciclovir-resistant mucocutaneous HSV disease present well-demarcated ulcerative lesions that do not improve during treatment (Fig. 112.2). HSV resistance is observed almost exclusively among patients receiving therapeutic regimens, while

Figure 112-3 Mechanisms of HSV and VZV resistance to antiviral drugs. Most cases of HSV and VZV resistance are due to mutations in the gene of the virus-encoded thymidine kinase, which result in a reduced or abrogated conversion of aciclovir to aciclovir monophosphate. This leads to low or absent levels of aciclovir triphosphate, the active metabolite that inhibits the viral DNA polymerase and acts as DNA chain terminator. Viral replication may then occur despite aciclovir therapy. Foscarnet and cidofovir do not require viral thymidine kinase-dependent intracellular activation. Resistance to these two drugs may occur if HSV or VZV resistance is caused by mutations in the viral DNA polymerase gene *(adapted from[8])*.

prophylactic treatment does not appear to increase the risk for resistant virus strains. [8] [9]

The most common mechanism of HSV resistance is altered or deficient activity of the virus-encoded thymidine kinase which results in reduced or abrogated phosphorylation of aciclovir in HSV-infected cells (Fig. 112.3).[8] Less frequently, mutations in the gene encoding for the viral DNA polymerase lead to resistant HSV strains (Fig. 112.3). Aciclovir-resistant HSV isolates were shown to be susceptible to antiviral agents, such as foscarnet, that do not require intracellular activation. [8] Foscarnet was used successfully as alternative systemic therapy in several cases of aciclovir-unresponsive HSV disease in immunocompromised patients, but multiresistant HSV strains may occur when resistance is due to mutations in the viral DNA polymerase gene.[8] [10] In the case of treatment-refractory HSV disease, isolates should be tested for drug resistance. Therapeutic options in the case of drug-resistant HSV disease are shown in Table 112.2 . If aciclovir-unresponsive HSV lesions are accessible, systemic

TABLE 112-2 -- Alternative therapy for drug-resistant herpesvirus disease*

ALTERNATIVE THERAPY FOR DRUG-RESISTANT HERPESVIRUS DISEASE		
Virus	**Resistant to**	**Alternative therapy**
HSV	Aciclovir, valaciclovir, famciclovir	Foscarnet 60mg/kg twice daily or 40mg/kg 3 times daily iv for 7–21 days or until complete healing
		For accessible HSV lesions:
		• topical trifluridine 5% ophthalmic solution every 8h
		• topical cidofovir gel 0.3% or 1% once daily until complete healing
	Foscarnet	Cidofovir 5mg/kg iv once a week for 2 weeks, then once every 2 weeks until complete healing
VZV	Aciclovir, valaciclovir, famciclovir	Foscarnet 60mg/kg 2–3 times daily iv for 7–14 days or until complete healing
CMV	Ganciclovir	Foscarnet 60mg/kg 3 times daily or 90mg/kg twice daily iv for 2 weeks, then 90–120mg/kg once daily iv until complete recovery from CMV disease

* *(adapted from[6])*.

antiviral therapy may be replaced by topical trifluridine solution or cidofovir gel (Table 112.2).[8]

VARICELLA-ZOSTER VIRUS INFECTION

EPIDEMIOLOGY

Varicella (chickenpox)

Primary VZV infection causes varicella (chickenpox) and occurs in over 90% of cases in children under the age of 14 years. Following the introduction of a live attenuated varicella vaccine for persons 12 months of age or older, varicella cases have markedly declined in areas of extended vaccine coverage.[11] Varicella develops in 2–3% of children after allogeneic or autologous SCT for solid tumor or leukemia.[12] [13]

Herpes zoster (shingles)

The most common manifestation of VZV infection in immunocompromised hosts is herpes zoster which is due to reactivation of latent virus. Zoster is particularly frequent in adults with lymphoreticular malignancy or leukemia who have impaired cell-mediated immune responses. The incidence of zoster after SCT ranges from 14% to 32% and is highest in autograft recipients with Hodgkin's disease.[12] [13] [14] Median time to onset of zoster is 5 months after SCT and over 85% of cases occur within the first post-transplant year.[12] During the first 6 months after solid organ transplantation, zoster develops in 5–13% of patients and presents most often as localized dermatomal rash.[4]

PATHOGENESIS

Following primary infection, VZV establishes latency in dorsal root ganglia where it appears to reside in neurons and satellite cells.[15] In contrast to HSV, VZV reactivation yields extensive viral proliferation and cell-to-cell spread, resulting in numerous neurons infected and dermatomal vesicular rash; in this process, the cumulative damage to the ganglion and its neurons is substantial which explains the occurrence of neuralgia. Both humoral and cell-mediated immunity play a role in limiting the infectivity and replication of VZV.[16] Virus-specific cellular immunity appears to be particularly important in controlling

viral reactivation and dissemination.[15] [16] Immunocompromised children who fail to acquire a VZV-specific T-cell response during varicella are at risk for persistent viremia and life-threatening viral dissemination. Conditions leading to a deficient VZV-specific cellular immune response render VZV-seropositive patients susceptible to herpes zoster, which can disseminate and cause serious organ disease during profound immunosuppression.[16]

PREVENTION

Varicella

VZV is highly contagious and immunodeficient hosts susceptible to varicella should be isolated from infectious individuals. A critical issue is that patients with varicella may be contagious up to 2 days before the onset of mucocutaneous eruptions and transmission may occur before isolation precautions are taken. VZV-seronegative immunocompromised patients may benefit from intravenous VZV immune globulin infusions if administered within 96 hours of exposure.[15]

Active immunization with a live-attenuated VZV vaccine is safe and has protective effects in varicella-susceptible children with leukemia in remission or receiving a kidney graft. Seroconversion was documented in 98% of leukemic children after 1–2 doses of vaccine and was associated with a decreased attack rate of varicella after household exposure from 29% among seronegative children to 8%. [17] Vaccinated children and adolescents after renal transplantation developed a specific antibody response that remained detectable in 62% of cases at 1 year, and had a posttransplant incidence of varicella of 12% compared to 45% in unvaccinated patients with no prior history of varicella.[18]

In summary, the use of a live-attenuated VZV vaccine is recommended for immunization of VZV-seronegative leukemic (in remission) or renal transplant children (Table 112.3).

Herpes zoster

VZV vaccines reduce the risk of zoster in immunocompromised patients. Children with leukemia who were given a live-attenuated varicella vaccine had significantly lower rates of subsequent zoster (0.80 cases per 100 person-years) than those who had natural varicella infection (2.46 cases per 100 person-years).[19] Among VZV-seropositive patients who underwent autologous SCT for non-Hodgkin's or Hodgkin's lymphoma, boosting specific immunity by

TABLE 112-3 -- Prevention and therapy of VZV infection and disease.[5] [6]

PREVENTION AND THERAPY OF VZV INFECTION AND DISEASE			
Indication	**Drug**	**Dose and route**	**Other measures/comments**
Prevention			
Varicella	Not recommended		Strict isolation from infectious individuals
			Intravenous VZV immune globulins if within 96h of exposure
			Live-attenuated VZV vaccine in VZV-seronegative leukemic children in remission or before renal transplantation
Zoster	Not recommended		Inactivated VZV vaccine in VZV-seropositive SCT recipients
Therapy			
Varicella	Aciclovir	500mg/m^2 or 10mg/kg every 8h iv for 7–10 days	
Herpes zoster	Aciclovir	As above iv or 800mg 5 times daily po	For moderately immunosuppressed patients without visceral disease (7–10 days of therapy)
	Valaciclovir	1000mg 3 times daily po	
	Famciclovir	500mg 3 times daily po	

an inactivated varicella vaccine significantly decreased the incidence of zoster within the first 12 months after SCT (13% vs 30% in unvaccinated autograft recipients) and is therefore recommended (Table 112.3).[20] After renal transplantation, the rates of zoster were 7% in vaccinated patients compared to 13% in unvaccinated patients with a history of varicella and 38% in the VZV-naive patients who developed posttransplant varicella.[18]

The long-term use of oral aciclovir as another strategy for the prevention of zoster after allogeneic SCT has been assessed in placebo-controlled trials. Aciclovir prophylaxis given for 6 months after allogeneic SCT abrogates VZV reactivation during treatment. However, patients who receive aciclovir develop zoster at the usual rate following discontinuation of prophylaxis and the overall incidence 1 year after SCT was similar in aciclovir and placebo groups.[6] Thus, aciclovir prophylaxis for 6 months after SCT only delays VZV reactivation but does not reduce the overall incidence of zoster. Moreover, a concern regarding long-term aciclovir prophylaxis is the

potential of inducing resistant VZV strains, as observed in patients with AIDS.[8]

Recommended preventive measures for varicella and herpes zoster in immunosuppressed patients are summarized in Table 112.3 .

CLINICAL FEATURES AND DIAGNOSIS

Varicella in immunocompromised hosts is characterized by more numerous mucocutaneous lesions which may be hemorrhagic and which take about three times longer to heal than among individuals without impaired immunity (Fig. 112.4). In children with malignancy, varicella has a high risk of visceral dissemination in the absence of specific therapy. Among 127 children with untreated varicella, VZV pneumonia occurred in 32% of patients with acute leukemia and in 19% of those with other cancers, and was fatal in 7% of cases.[21] Although rare, primary VZV infection in solid organ transplant recipients can lead to hemorrhagic pneumonia, hepatitis, pancreatitis, encephalitis and disseminated intravascular coagulation which may be life threatening.[4] Figure 112.5 shows bilateral VZV pneumonia in a kidney graft recipient with varicella.

Herpes zoster in immunodeficient hosts tends to be more severe and of longer duration than in patients with normal immunity. In a series of 195 SCT recipients with zoster, cutaneous dissemination developed in 23% and visceral involvement in 13%, and the fatality

Figure 112-4 (a,b) **Disseminated cutaneous lesions in a patient with chronic lymphocytic leukemia who developed fatal varicella despite rapid initiation of intravenous aciclovir therapy.** Varicella lesions are numerous and hemorrhagic.

rate was 18%.[12] Risk factors for VZV infection after SCT as identified by multivariate analyses include age 10 years or older, the use of radiation in pretransplant conditioning, allografting, the occurrence of severe acute or chronic graft versus host disease (GVHD), and SCT for chronic myeloid leukemia. [12] [13]

Diagnosis of varicella and herpes zoster is usually made clinically based on history and the typical rash. During primary VZV infection, generalized vesicular lesions at varying stages are present on the skin and may also be seen on the oropharyngeal mucosa. Localized herpes zoster manifests as unilateral dermatomal eruptions (Fig. 112.6). Confirmation of VZV infection can be obtained by direct immunofluorescence detection of virus antigens which is a rapid and sensitive technique.[15] Virus culture can also be used but is positive in only 30–60% of cases.[15] However, isolation of virus by culture permits testing for antiviral susceptibility if drug resistance is suspected.[8] Visceral organ involvement requires documentation of VZV in biopsies by culture, immunohistology or PCR. For VZV pneumonia, identification of VZV in bronchoalveolar lavage

Figure 112-5 Varicella pneumonia in a renal transplant recipient with bilateral lung infiltrates on chest radiography.

Figure 112-6 Herpes zoster in cervical dermatomes in a patient 5 months after allogeneic SCT for leukemia.

fluid may substitute for lung biopsy. PCR can also be used for detection of VZV infection of the central nervous system.[15] Results of serological assays are generally not helpful in diagnosing VZV infection in immunodeficient patients.

MANAGEMENT

A major goal of antiviral treatment of varicella or herpes zoster in immunocompromised hosts is the prevention and therapy of visceral dissemination which is associated with substantial morbidity and mortality.[12] [13] Aciclovir therapy was shown to be safe and to markedly decrease the risk for VZV dissemination and VZV disease-related mortality. [6] Intravenous aciclovir remains the treatment of choice for established varicella and zoster in profoundly immunodeficient patients (Table 112.3).[4] [5] [15] For moderately immunosuppressed patients without evidence of visceral VZV disease, high-dose oral aciclovir, valaciclovir or famciclovir are possible treatment alternatives (Table 112.3).[5] [15] [22]

Most drug-resistant VZV isolates have been recovered from patients with AIDS but have also been documented occasionally in SCT recipients.[8] [23] VZV resistance to aciclovir is due to altered or deficient thymidine kinase function (see Fig. 112.3).[8] Foscarnet does not require intracellular activation by the viral thymidine kinase, and may be used as alternative therapy when aciclovir-resistant VZV infection is suspected (see Table 112.2).[8] [23]

CYTOMEGALOVIRUS INFECTION

EPIDEMIOLOGY

CMV has a worldwide distribution and infects up to 50–70% of the population in industrialized countries. Immunocompromised hosts are at elevated risk of serious CMV disease following primary infection, reinfection or reactivation of latent virus. CMV is a leading infectious cause of morbidity and mortality in patients after SCT and solid organ transplantation, and is an emerging problem in adults with leukemia.[4] [6] [24] In the absence of preventive measures, CMV infection occurs in 60–70% of allogeneic SCT recipients when patient or donor are CMV seropositive, and is documented in about 50–60% of CMV-seropositive autograft recipients.[6] The strongest predictor of CMV infection after allogeneic SCT is pretransplant CMV seropositivity of the patient (fivefold risk increase).[25] Other predisposing factors include the occurrence of acute GVHD, HLA-mismatched transplant, and a positive CMV serology of the graft donor in seronegative patients.[25] The overall incidence of CMV infection after kidney, heart or liver transplantation is in the range of 44–85%, and the vast majority of CMV infections occur during the first 3–4 months after transplant when patients require intensive immunosuppressive regimens for prevention or therapy of graft rejection.[4]

PATHOGENESIS

Following primary infection, CMV remains in the host in a latent state and can reactivate intermittently, particularly during times of deficient cell-mediated immunity.[26] [27] The precise sites and mechanisms of latency remain to be elucidated but vascular endothelial cells, peripheral blood leukocytes, epithelial kidney cells and salivary glands are possible sites of latency or low-level replication. Transplant recipients may harbor latent CMV, but can also acquire the virus from seropositive organ or blood donors. CMV disease after SCT or solid organ transplantation correlates with the systemic viral load, as assessed by CMV antigenemia or quantitative PCR in peripheral blood.[27] [28] [29]

PREVENTION

In CMV-seronegative patients treated for leukemia or receiving an organ transplant from a seronegative donor, prevention of CMV infection is primarily based on avoiding the acquisition of exogenous virus. Primary CMV infection in these patients can efficiently be prevented by the exclusive use of CMV seronegative or leukocyte-depleted blood products.[30] Although this preventive strategy has only been validated in SCT recipients, it is also frequently used after solid organ transplantation.[30]

Passive immunization with intravenous immune globulins for prevention of CMV infection and disease after SCT remains controversial. Conflicting results between studies may be due to differences in the administration schedules, dosages, kinetics or antibody contents of the immune globulins used.[6] In view of the unclear benefit and the important costs of immune globulin infusions, CMV prophylaxis by passive immunization in SCT recipients cannot be advocated without further studies. By contrast, patients after solid organ transplantation may have some benefit from prophylactic immune globulin infusions. Except for CMV-seronegative patients with a seropositive organ donor, CMV immune globulins decrease the rate of severe CMV disease after liver transplantation.[31] In renal transplant recipients, however, CMV-seronegative patients with a seropositive donor who receive CMV immune globulin infusions have a reduced incidence of CMV syndrome (defined as illness having =2 of the features known to be associated with CMV, namely otherwise unexplained fever for =3 days plus pneumonitis without other cause, leukopenia, elevated serum alanine aminotransferase levels or atypical lymphocytosis) and a trend towards lower rates of CMV pneumonia.[32] Thus, the protective efficacy of CMV immune globulins may vary according to the type of solid organ transplantation.

Active immunization with a live-attenuated Towne strain of CMV is safe and decreases the severity but not the incidence of CMV disease among donor-seropositive/recipient-seronegative renal transplants.[4] Further immunization studies are being carried out with CMV subunit vaccines.

Antiviral drugs are used for suppression of CMV reactivation in CMV-seropositive patients or in organs transplanted from seropositive donors, and play an important role in the prevention of CMV disease. Valaciclovir, ganciclovir, valganciclovir, foscarnet and cidofovir are currently available systemic antiviral drugs for the management of CMV infection and disease, and will be discussed in more detail in the section on Management, below. Preventive measures for CMV infection and disease after allogeneic SCT are listed in Table 112.4 .

CLINICAL FEATURES AND DIAGNOSIS

The manifestations of CMV infection in immunodeficient hosts range from asymptomatic virus excretion to serious organ disease. In the past, various definitions of CMV infection and disease have been used, which renders the comparison of published data difficult. An effort was made to standardize the definitions of CMV infection and CMV disease in immunocompromised hosts at two international consensus conferences (Table 112.5). [33] [34]

Diagnosis of *CMV infection* is based on detection of CMV in clinical specimens by conventional tissue culture or rapid culture with confirmation by specific monoclonal antibodies, or by detection of the lower matrix pp65 CMV antigen in peripheral blood leukocytes (Fig. 112.7). Positive PCR is valid if the technique used was shown to correlate with CMV detection by culture methods. One exception is the demonstration of CMV by PCR in cerebrospinal fluid which is reliable, whereas virus cultures are insensitive. Histopathology, immunochemistry and in situ hybridization in biopsy materials are commonly used, but the sensitivity and specificity of these techniques are not well documented and need further clarification. Serological approaches are considered less reliable in immunocompromised patients, and are not recommended for the definition of CMV infection. Diagnosis of *CMV disease* requires documentation of CMV in tissue specimens or in bronchoalveolar fluid when CMV pneumonia is suspected, and detection of CMV must be associated with clinical symptoms and signs compatible with CMV organ disease.

The most severe manifestation of CMV disease after SCT is CMV pneumonia. Patients with CMV pneumonia usually present with fever, nonproductive cough, tachypnea, rales and uni- or bilateral interstitial lung infiltrates on chest X-rays (Fig. 112.8). Without pre-emptive therapy, CMV pneumonia develops in one-third of allograft recipients with active infection, and is fatal in 85% of cases if untreated.[25] [35] CMV pneumonia is less frequent after autologous SCT, but outcome is as serious as in allograft recipients.[36] CMV

TABLE 112-4 -- Prevention and therapy of CMV infection and disease after allogeneic SCT. [6] [38] [45]

PREVENTION AND THERAPY OF CMV INFECTION AND DISEASE AFTER ALLOGENEIC SCT			
Indication	**Drug**	**Dose and route**	**Other measures/comments**
Prevention			
Donor and patient CMV seronegative			CMV seronegative or leukocyte-depleted blood products
Donor and/or patient CMV positive	Ganciclovir	5mg/kg every 12h iv for 5 days, then once daily	From engraftment until day 100 after SCT
Pre-emptive therapy			
Positive CMV antigenemia or PCR in peripheral blood specimen	Ganciclovir	5mg/kg every 12h iv for 14 days, then 6mg/kg once daily iv for 5 days per week	Discontinuation of treatment after 14 days (or later) if CMV surveillance test negative
	Foscarnet	60 mg/kg every 12h iv for for 14 days, then 90mg/kg once daily iv for 5 days per week	Discontinuation of treatment after 14 days (or later) if CMV surveillance test negative
Therapy			

CMV pneumonia	Ganciclovir	5mg/kg every 12h iv for 14 days, then 5–6mg/kg once daily iv for additional 30 days or until complete recovery	
	plus		
	Intravenous immune globulins	500mg/kg every other day for 2 weeks, then 500mg/kg twice per week for additional 4 weeks	
Other CMV disease	Ganciclovir	As for CMV pneumonia	Ganciclovir alone probably adequate

TABLE 112-5 -- Definitions of CMV infection and CMV disease.[33] [34]

DEFINITIONS OF CMV INFECTION AND CMV DISEASE
CMV infection
Accepted diagnostic methods:
• conventional tissue culture
• shell-vial culture
• antigenemia (detection of pp65 lower-matrix protein in leukocytes)
• PCR in cerebrospinal fluid or in other specimens if PCR shown to correlate with culture results
Probably adequate diagnostic methods:
• histopathology
• immunochemistry
• *in-situ* hybridization
Inadequate for diagnosis of active infection:
• serological assays
CMV disease
• Documentation of CMV in tissue specimens or, in the case of CMV pneumonia, in bronchoalveolar lavage fluid
• Associated symptoms and signs of CMV organ disease

gastrointestinal disease may occur after SCT, whereas other organ diseases, such as CMV retinitis, are rare.[25] Detection of CMV in peripheral blood by culture, antigenemia or PCR is a major predictor for CMV disease. [25] [37] [38] Moreover, absence of a CMV-specific cytotoxic T-cell response in the first 3 months after allogeneic SCT is associated with a high risk for CMV pneumonia.[39]

Adults with leukemia who receive conventional chemotherapy are also at risk for CMV pneumonia. In a series of 2136 leukemic patient, 2.9% developed CMV pneumonia which was fatal in 57% of cases (case-fatality rate of 62% with antiviral therapy vs 50% without treatment).[24]

Without prophylaxis, CMV causes significant morbidity in all types of solid organ transplantation. Symptomatic CMV disease occurs in 10–65% of patients during the first 4 post-transplant months.[2] [27] [29] [40] [41] As in SCT recipients, CMV disease after solid

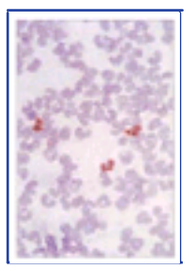

Figure 112-7 Positive CMV antigenemia assay. Three peripheral blood leukocytes containing the pp65 CMV antigen show positive immunoperoxidase staining.

organ transplantation has a propensity to develop in the lungs and in the gastrointestinal tract. Patients, however, have an additional susceptibility for CMV infection in the transplanted organ.[40] The lowest rates of CMV infection and disease are observed when patient and organ donor are both CMV seronegative. CMV-seropositive patients and seronegative patients with a seropositive organ donor show similar rates of CMV infection in most series, but primary CMV disease is generally more frequent and more severe than disease due to reactivation or reinfection. [2] [40] [41] Patients who require OKT3 or antilymphocyte globulins for therapy of graft rejection carry an additional risk for severe CMV disease.[42] Mortality from CMV disease in solid organ transplant recipients is primarily related to serious pneumonia with respiratory failure or to disseminated disease.

MANAGEMENT

Established CMV pneumonia in SCT recipients is a life-threatening condition which is generally treated by a combination of intravenous

Figure 112-8 CMV pneumonia in an allogeneic SCT recipient with diffuse bilateral interstitial lung infiltrates on chest radiography.

ganciclovir and high-dose intravenous immune globulin infusions. However, the survival rate averages only about 57% early after completion of therapy, and ranges from 22–40% 6 months later.[6] CMV pneumonia was recently reported to also respond to cidofovir therapy in 56% of allograft recipients.[43] Nonleukemic deaths in patients who initially survive CMV pneumonia are often due to Gram-negative sepsis and invasive fungal infections which occur at a higher rate than among patients who never developed CMV pneumonia.[6] Because outcome of CMV pneumonia remains severe despite best available therapy, major emphasis must be placed on the prevention of CMV disease after SCT.

Following solid organ transplantation, single-agent therapy with intravenous ganciclovir is most widely used for therapy of CMV disease, and outcome appears to be favorable in most cases, independent of the site of CMV disease or the type of organ transplant.[4] In a series of various solid organ transplant recipients with tissue-invasive CMV disease, ganciclovir therapy resulted in resolution of symptoms and signs in 89% of patients, and no deaths were directly attributable to CMV disease.[44]

For CMV-seropositive transplant recipients or seronegative patients with a seropositive organ donor, two main strategies are currently available for prevention of CMV disease. Antiviral drug *prophylaxis* is aimed at suppressing CMV reactivation, and is given to all patients irrespective of the results of virologic monitoring.[2] [41] [45] [46] Alternatively, *pre-emptive therapy* consists of initiating antiviral drug treatment only when active CMV infection is demonstrated to prevent the development of CMV disease.[37] [38] [47] Thus, with pre-emptive therapy, the use of potentially toxic antiviral drugs is restricted to patients at the highest risk for CMV disease.

Following allogeneic SCT, intravenous ganciclovir prophylaxis reduces the rates of CMV disease, but has no impact on survival when compared to placebo.[45] [46] The

lack of survival advantage with ganciclovir prophylaxis may be related to a higher number of deaths from nonviral infections and to incomplete protection from fatal CMV pneumonia after SCT. By contrast, pre-emptive ganciclovir therapy based on positive CMV cultures substantially decreases the incidence of CMV disease, and is associated with significantly better survival than in controls receiving placebo. [47] A disadvantage of culture-based pre-emptive therapy, however, is that over 10% of patients screened are diagnosed with CMV disease without prior positive CMV cultures or with cultures becoming positive coincident with the onset of disease.[47] Newer diagnostic techniques, such as the CMV antigenemia assay or the PCR in peripheral blood specimens, are more sensitive and more rapid than viral cultures and permit the detection of CMV infection at an early stage when the systemic viral load is still low.[37] [38] In a trial comparing CMV PCR monitoring in blood specimens with virus cultures for initiation of pre-emptive ganciclovir therapy after SCT, CMV infection was detected a median of 17 days earlier by PCR, which resulted in significantly lower incidence of CMV disease and superior patient survival.[37] The introduction of antigenemia assays and PCR for detection of CMV in blood has thus greatly enhanced the efficacy of the pre-emptive therapy approach to the prevention of CMV disease.

Because of the important hematotoxicity observed with ganciclovir use after SCT, alternative drug treatment has been investigated. Prophylactic and pre-emptive intravenous foscarnet can safely be given after SCT and pre-emptive therapy with foscarnet shows similar efficacy as ganciclovir, but is associated with a lower rate of severe neutropenia and of patients who require discontinuation of antiviral therapy due to hematotoxicity.[38] Preliminary retrospective data on pre-emptive cidofovir treatment of CMV infection after allogeneic SCT are promising, but await confirmation by prospective trials.[43] Among allograft recipients who are able to take oral medication, oral valganciclovir might become an alternative to current intravenous treatment regimens if shown to be efficacious and safe.[48]

With the introduction of antiviral drug prophylaxis and pre-emptive therapy against CMV during the first 100 days after SCT, the occurrence of late CMV disease (beyond day 100 post transplant) has become an increasingly recognized problem. Late CMV disease after allogeneic SCT is now observed in 5–10% of patients and is associated with T-cell depletion, chronic GVHD, high viral load in plasma and prolonged (>4 weeks) prior antiviral drug treatment against CMV.[49] [50]

Following solid organ transplantation, the need for antiviral CMV prophylaxis is less clear than after SCT, since CMV disease appears to respond to ganciclovir therapy in most cases, and CMV-related mortality has become virtually nonexistent.[44] Nevertheless, morbidity due to CMV infection and disease after solid organ transplantation is significant in the absence of preventive measures, and may have an important impact on costs. CMV drug prophylaxis may furthermore have beneficial effects on organ outcomes, including rejection.[2] Prophylactic use of aciclovir, valaciclovir or ganciclovir decreases the incidence of CMV disease in various solid organ transplant settings.[2] [4] [41] As a result of its high oral bioavailability, valganciclovir may play a role in the future in replacing both intravenous and oral ganciclovir prophylaxis after solid organ transplantation.[48] [51]

Pre-emptive short-course antiviral treatment of CMV infection reduces drug exposure and is advocated as an alternative to prophylaxis after solid organ transplantation.[4] As observed in SCT recipients, patients after solid organ transplantation may develop CMV disease coincident with or without previous viral excretion. Pre-emptive antiviral treatment based on surveillance cultures might miss a substantial fraction of patients who will develop CMV disease and virologic surveillance by CMV antigenemia or PCR is therefore preferable.

Another concept in solid organ transplant recipients is the prophylactic use of antiviral drugs against CMV only during periods of more intensive immunosuppression irrespective of the results of viral monitoring. A significantly reduced rate of CMV disease was demonstrable among renal transplant recipients who received ganciclovir during antilymphocyte antibody therapy.[52]

Figure 112-9 Mechanisms of CMV resistance to antiviral drugs. Most cases of CMV resistance are due to mutations in the viral UL97 gene encoding for the phosphotransferase, which result in a reduced or abrogated conversion of ganciclovir to ganciclovir monophosphate. This leads to low or absent levels of ganciclovir triphosphate, the active metabolite that inhibits the viral DNA polymerase. Viral replication may then occur despite ganciclovir therapy. Foscarnet and cidofovir do not require viral phosphotransferase-dependent intracellular activation. Resistance to these two drugs may occur if CMV resistance is caused by mutations in the viral DNA polymerase gene *(adapted from[9]).*

CMV resistance to antiviral drugs is an increasing clinical problem in patients with AIDS and after solid organ transplantation and has infrequently been reported in SCT recipients.[8] [53] [54] Most CMV strains are resistant to ganciclovir, but CMV isolates may also be resistant to foscarnet or cidofovir.[53] [55] Drug resistance can be due to mutations in the UL97 phosphotransferase gene of CMV, to mutations in the UL54 gene encoding the viral DNA polymerase, or to both (Fig. 112.9).[55] Cases of ganciclovir-resistant CMV disease due to UL97 gene mutations generally improve or recover completely with intravenous foscarnet treatment (see Table 112.2).[8] Foscarnet, however, is not an alternative to ganciclovir when resistance is caused by mutation in the viral DNA polymerase gene (Table 112.2). Patients carrying multidrug-resistant CMV strains have been reported.[53] [55] The introduction of more rapid and efficient techniques for detection of resistant CMV isolates should allow us to better establish the incidence and clinical importance of CMV resistance in immunocompromised hosts, and alternative treatment options need to be developed and validated for (multi)drug-resistant CMV disease.

OTHER HERPESVIRUSES

EPSTEIN-BARR VIRUS INFECTION

Epstein-Barr virus (EBV) infection occurs in more than 90% of the normal population, and immunocompromised patients are predominantly at risk for disease due to EBV reactivation.[56] While EBV infection may cause fever, sore throat and malaise, EBV-induced posttransplantation lymphoproliferative disease (PTLD) can develop as a serious complication in solid organ transplant recipients and after allogeneic T cell-depleted SCT.[4] [56] [57] The incidence of PTLD varies with the organ transplanted and ranges from 1% for renal to 14% for small bowel transplant recipients, and is virtually always fatal in the absence of therapeutic measures.[4] [56] The clinical manifestations of EBV-associated PTLD may include fever, tonsillitis, lymphadenopathy, hepatosplenomegaly and symptoms and signs from other affected organs.

The pathogenesis of PTLD involves EBV-induced B-cell stimulation and transformation that occurs particularly after OKT3 or antilymphocyte globulin therapy, followed by cyclosporin treatment for suppression of graft rejection.[4] Insufficient immune control of EBV replication appears to be an important initial step in the pathogenesis of PTLD. EBV-related tumors tend to progress from polyclonal to monoclonal phenotypes, but can also present mixed phenotypes.[56]

Aciclovir, ganciclovir and foscarnet have inhibitory activity against EBV *in vitro* and antiviral drug therapy may contribute to improved outcome in early stages of EBV-induced B-cell transformation. In fully established monoclonal PTLD, antiviral agents are inefficient and marked reduction or complete withdrawal of immunosuppression is recommended, but outcome remains poor.[4] [56] A more promising approach to prevention and treatment of EBV-associated PTLD in transplant recipients is the restoration of specific T-cell immunity by infusion of donor-derived leukocytes or EBV-specific cytotoxic T-cell lines.[57] [58]

HUMAN HERPESVIRUS 6 AND 7 INFECTION

Primary infection of human herpesvirus 6 (HHV-6) causes roseola (exanthema subitum) in early childhood and human herpesvirus 7 (HHV-7) is also possibly involved in this syndrome. The seroprevalence of both HHV-6 and HHV-7 in healthy adults exceeds 80%. HHV-6 infection occurs in 38–60% of patients after autologous or allogeneic SCT and in 31–55% of solid organ transplant recipients and is most commonly detectable within 4 weeks of transplantation.[59] [60] The virus has two variants, A and B, and transplant recipients appear to be infected by variant B in most cases. Following SCT, HHV-6 infection is correlated with the severity of acute GVHD and risk factors for symptomatic HHV-6 infection include the use of a bone marrow graft, HHV-6 reactivation before engraftment and the presence of HHV-6 DNA in plasma.[60] HHV-6 infection in transplant recipients has been associated with bone marrow suppression, interstitial pneumonia and encephalitis, but the causative role of HHV-6 for these disease manifestations seems only established for encephalitis.[59] [61]

The clinical role of HHV-7 in immunocompromised hosts is less well defined. HHV-7 appears to be a co-factor in the development of CMV disease in renal and liver transplant recipients and may contribute to graft rejection.[62] [63]

The antiviral agents ganciclovir and foscarnet show inhibitory activity against HHV-6 *in vitro*, whereas aciclovir is less effective.[59] [64] Clinical data on the efficacy of antiviral drugs against HHV-6 are limited and no controlled therapeutic trials in immunodeficient hosts

have been reported to date. In the opinion of experts, intravenous ganciclovir or foscarnet therapy may be used for HHV-6 disease if active infection is documented by cell culture, shell-vial assay, PCR or immunohistochemistry.[59] [61] Because of a lack of data, no recommendations can be made regarding the clinical use of antiviral agents against HHV-7 at this time.

HUMAN HERPESVIRUS 8 INFECTION

Human herpesvirus 8 (HHV-8) is the causative agent of Kaposi's sarcoma and other rare disorders, including primary effusion B-cell lymphoma and multicentric Castleman's disease. The seroprevalence of HHV-8 among healthy adults varies by geographic location. It was reported to be 5% among US blood donors and up to 10% in the general US population, but is higher in areas with endemic forms of Kaposi's sarcoma, such as Mediterranean countries and Africa.[65] Following organ transplantation, the risk for HHV-8 infection due to primary acquisition of virus, reinfection or reactivation is increased. Transplant patients may acquire HHV-8 from the allograft, blood products, caregivers or from family members.[65] [66] Cutaneous or visceral Kaposi's sarcomas develop with a reported incidence of 0.5–5% in solid organ transplant recipients.[65] [66] The antiviral agents ganciclovir, foscarnet and cidofovir show inhibitory activity against HHV-8 *in vitro*, but data on their therapeutic efficacy in transplant recipients with HHV-8 infection are limited and nonconclusive.[64] [67]

OTHER VIRAL INFECTIONS

ADENOVIRUS INFECTION

Adenovirus infection is ubiquitous and the virus is usually acquired during early childhood. Like herpesviruses, adenovirus has the propensity to establish latency following primary infection, and to reactivate during immunosuppression. Over 40 serotypes of adenovirus have been identified. Adenovirus infection is observed in 5–21% of patients after allogeneic SCT and in 7–19% of solid organ transplant recipients.[4] [68] [69] Up to one-third of immunodeficient patients with active adenovirus infection develop disease, including hemorrhagic cystitis, gastroenteritis, colitis, hepatitis, pneumonia, encephalitis or disseminated organ disease.[4] [68] [69] [70] [71] [72] Risk factors for adenovirus disease that were identified in SCT recipients are the isolation of the virus from two or more sites and the occurrence of moderate to severe GVHD.[68] [69] After SCT, mortality related to adenovirus disease was reported to be between 50% and 54%.[68] [69]

There is currently no antiviral agent with proven efficacy for the therapy of adenovirus disease in immunocompromised hosts. Intravenous ribavirin and cidofovir were used therapeutically with mixed results in small series and single cases. In one report, intravenous ribavirin was given to five immunodeficient children, of whom three had pneumonia and two had hemorrhagic cystitis caused by adenovirus; one patient with pneumonia and one with cystitis had complete clinical recovery and viral clearance, whereas outcome was fatal in the other three.[72] Cidofovir therapy was administered to seven children after allogeneic unrelated SCT who had developed adenovirus disease; clinical improvement and clearance of virus were observed in five patients, but one child died from disseminated adenovirus disease and another from invasive aspergillosis.[71]

In the future, outcome of adenovirus disease might be improved by the introduction of diagnostic techniques predictive for severe adenovirus infection, such as the PCR in serum, which permits early initiation of antiviral drug treatment. [70]

COMMUNITY RESPIRATORY VIRUS INFECTIONS

Respiratory syncytial virus (RSV), influenza viruses, parainfluenza viruses, rhinoviruses, coronaviruses and some serotypes of adenovirus cause respiratory infections, the clinical importance of which is increasingly recognized in immunocompromised hosts.[73] [74] [75] [76] Characteristics of community respiratory virus infections include seasonal outbreaks, acquisition in the community or in the hospital, rapid transmission from person to person with the respiratory tract as portal of entry, and a short incubation period. In a prospective study of adult SCT recipients hospitalized with acute respiratory disease, respiratory viruses were isolated by culture from 67 (31%) of 217 patients; 49% of these infections were due to RSV, 18% each to influenza viruses and to picornaviruses, 9% to parainfluenza viruses, and 6% were caused by adenovirus.[75] Of 87 prospectively studied leukemic adults with acute respiratory illness, nine (10%) had culture-proven RSV infection that was complicated by pneumonia in six, with a mortality rate of 83%.[74] Fatal respiratory failure was reported to occur in one-third of patients after SCT who developed parainfluenza virus infection involving the lower respiratory tract.[73] Community respiratory viruses also contribute to significant morbidity and possibly graft rejection after solid organ transplantation. Lung transplant recipients are at particularly high risk for serious infections due to these viruses.[76]

Thus, community respiratory viruses are responsible for important morbidity and mortality among immunocompromised hosts who develop acute respiratory disease, and RSV appears to be the most common cause of infection.

Immunocompromised patients with respiratory virus infection usually present with fever, coryza, cough, shortness of breath and wheezing, and may have radiographic sinus opacification or pulmonary infiltrates.[76] However, the clinical and radiological features are nonspecific and definite diagnosis requires documentation of virus by culture, antigen detection or PCR in bronchoalveolar lavage fluid or open lung biopsy specimens.

Although rapid detection assays are available for most community respiratory viruses, the therapeutic options remain limited. For therapy of RSV infection, ribavirin delivered by aerosol or administered intravenously is used, but is generally ineffective in patients with established RSV pneumonia and respiratory failure. Nevertheless, ribavirin might be beneficial if given early in the course of pneumonia or if administered pre-emptively when only the upper respiratory tract is involved.[74] [77] The combination of aerosolized ribavirin plus intravenous immune globulins containing high titers of RSV antibody could yield better results, and is being studied in immunosuppressed patients with RSV infection.[77]

For therapy of influenza, the recently introduced neuraminidase inhibitors zanamivir and oseltamivir have potent activity against both influenza A and B viruses, and are generally well tolerated. By contrast, the clinical effectiveness of amantadine and rimantadine is limited to influenza A virus infection, and these drugs are associated with gastrointestinal and neurological adverse events and with the rapid emergence of virus resistance, which limits their usefulness. The therapeutic efficacy of antiviral agents against influenza has been established in otherwise healthy individuals. Whether their prophylactic or therapeutic use is beneficial in severely immunocompromised hosts remains to be demonstrated.[6]

Picornaviruses may cause potentially life-threatening respiratory disease in immunocompromised patients. Pleconaril, a novel broad-spectrum antipicornaviral compound, has become available for clinical use. Following oral intake, pleconaril achieves serum concentrations superior to those required to inhibit 90% of clinical enterovirus and

TABLE 112-6 -- Infection control precautions for the prevention of nosocomial respiratory virus infections among immunocompromised patients at a cancer center*

INFECTION CONTROL PRECAUTIONS FOR THE PREVENTION OF NOSOCOMIAL RESPIRATORY VIRUS INFECTIONS
• Screening symptomatic patients by using rapid diagnostic tests for respiratory viruses
• If tests positive, cohorting of patients and initiation of therapy with aerosolized ribavirin
• Contact isolation of infected patients (gloves and gowns)
• Droplet precautions by wearing masks
• Personnel should wear masks and gloves if in close contact (<1m) with SCT recipients during the season of community outbreaks
• Strict enforcement of handwashing between patient visits
• Prohibiting symptomatic personnel from working on patient wards
• Screening visitors for upper respiratory symptoms
• Prohibiting children <12 years old from visiting patients
• Educational program for personnel

* *(adapted from[80])*.

rhinovirus isolates. Preliminary results of oral pleconaril therapy for acute picornaviral respiratory illness among both immunocompetent and immunocompromised patients are encouraging.[78] [79]

Because of the limited therapeutic possibilities, emphasis must be placed on the prevention of respiratory virus infections in immunocompromised hosts. Strict enforcement of infection control measures is of paramount importance to reduce the transmission of respiratory viruses by nosocomial spread or by acquisition from infected visitors of the community. Table 112.6 lists infection control precautions introduced at a cancer center, which resulted in significantly reduced rates of

nosocomial respiratory virus infection. [80] The mainstay of influenza prophylaxis remains active immunization with influenza virus vaccine, which should be offered to both patients at risk and hospital staff before the influenza season.[80] Other vaccines are under development and may help to further reduce the morbidity caused by community respiratory viruses in the future.

POLYOMAVIRUS INFECTIONS

The human polyomaviruses BK and JC are widespread, and their seroprevalence among adults ranges from 60% to 80%. Both viruses may establish a latent infection. BK virus is frequently reactivated and excreted in the urine of transplant recipients. [81] BK virus infection in these patients is often asymptomatic, but can cause ureteric stenosis, hemorrhagic cystitis and severe renal graft dysfunction.[4] [81] [82] Renal transplant recipients at risk for BK virus-related nephropathy may be identified by urinary shedding of 'decoy cells' (cells with viral inclusions) or by positive PCR in plasma specimens.[82] JC virus is the etiologic agent for progressive multifocal leukoencephalopathy (PML) and is occasionally isolated from urinary specimens in SCT and renal transplant recipients, but PML is very rare in these patients.[81] [83] To date, there is no antiviral therapy proven effective for diseases due to BK or JC virus in immunodeficient hosts, and treatment remains largely supportive. Recent data, however, suggest some activity of cidofovir in the treatment of PML among patients with AIDS, an observation that merits further investigation.[84]

OTHER VIRUSES

Several viruses that may cause diseases in SCT and solid organ transplant recipients are discussed in more detail elsewhere. Human papillomavirus infection is associated with anal warts and nonmelanoma skin cancers after renal transplantation (see Chapter 77). [85] [86] Hepatitis B and C viruses can complicate the posttransplant course in infected patients (see Chapter 214). Measles are best prevented by active immunization, but cases of serious disease have re-emerged among transplant recipients in areas with reduced vaccine coverage (see Chapter 212).

Chapter 113 - Opportunistic Parasitic Infections

Jose G Montoya

TOXOPLASMA GONDII

GENERAL CONSIDERATIONS

Toxoplasma gondii is an obligate intracellular parasite that exists in nature in three forms: the oocyst (which releases sporozoites), the tissue cyst (which contains and may release bradyzoites) and the tachyzoite.

Oocysts are formed in the small intestine of members of the cat family and are excreted in their feces for periods varying from 7 to 21 days. Tachyzoites are crescent shaped and measure 4–8µm long and 2–4µm wide (Fig. 113.1). The presence of tachyzoites in human fluids or tissues is the hallmark of acute infection. Encystation and formation of tissue cysts usually occur following cell entry and replication of the tachyzoite form. The tissue cyst is formed within a host cell and may vary in size from those which contain only a few organisms (bradyzoites) to =200µm in size that contain several thousand bradyzoites (Fig. 113.2). The brain and eye as well as cardiac, skeletal and smooth muscles appear to be the most common sites for chronic latent infection. Because of this persistence in tissues, demonstration of cysts in histological sections does not necessarily imply that the infection was recently acquired or reactivated.

The term *T. gondii* infection is best reserved to describe the parasite's primary subclinical infection or its asymptomatic persistence in tissues (chronic or latent infection) and toxoplasmosis should be used to describe the parasite's clinical manifestations or pathological disease in its incidental hosts.[1]

Toxoplasmosis is primarily a disease of individuals with immature or severely impaired T cell-mediated immunity. *T. gondii* can have devastating consequences in the offspring of women who acquire their primary infection during or shortly before pregnancy; the premature or underdeveloped immune system of the fetus is the most likely reason for this potentially tragic outcome. In children and adults, toxoplasmosis most often occurs in those with defects in T cell-mediated immunity, such as hematological malignancies, bone marrow and solid organ transplants or AIDS. Biopsy-proven toxoplasmic myocarditis and polymyositis in the setting of acute toxoplasmosis have been reported in patients on corticosteroids. [2] In immunosuppressed patients, toxoplasmosis is characterized by protean and often subtle clinical manibestations with a high attributable mortality in untreated cases.

In organ transplant recipients, the disease may result from newly acquired infection, reactivation of a previous (latent) infection or infection via the allograft. Reactivation of latent infection is the most common mechanism by which *T. gondii* causes toxoplasmosis in patients with AIDS and bone marrow transplants, whereas the cause is infection via the donated organ in patients with heart and heart-lung transplants. Both mechanisms, reactivation of chronic infection and infection via the allograft, have been described in patients with kidney and liver transplants.

In the majority of otherwise healthy individuals, primary or chronic (latent) infection with *T. gondii* is asymptomatic; following the acute infection, a small percentage will suffer chorioretinitis, lymphadenitis, myocarditis or polymyositis.

TRANSMISSION AND EPIDEMIOLOGY

Toxoplasma gondii is transmitted primarily via the oral route and the definitive hosts are members of the cat family. Infection in humans most commonly occurs through ingestion of raw or undercooked meat that contains cysts, through water or food contaminated with oocysts or congenitally through transplacental transmission following infection during gestation.

Cat ownership should not be used as an epidemiological hint to establish whether the patient is at risk of acquiring infection with the parasite. Transmission of oocysts (shed by the small intestine of recently infected cats) occurs without knowledge of the patient and may be unrelated to direct exposure to a cat (e.g. transmission by contaminated vegetables or water). On the other hand, patients with an indoor cat that is fed only cooked food are not at risk of acquiring the infection from that cat. Serological investigation of a specific cat to determine whether it is a potential source of the infection should be discouraged. Seropositivity in a cat does not predict shedding of oocysts.

In humans, the incidence of *T. gondii* antibodies increases with increasing age. However, seropositivity tends to be lower in cold regions, in hot and arid areas and at high elevations. In general, the incidence of the infection varies with the population group and geographic locale.

In many areas of the world, such as in El Salvador and France, the prevalence of seropositivity is as high as 75% by the fourth decade of life. The overall age-adjusted seroprevalence of *T. gondii* infection in the United States has been reported to be 22.5%.[3] Age-adjusted seroprevalence was higher in the north eastern United States (29.2%) than in the south (22.8%), midwest (20.5%) or west (17.5%) ($p<0.05$). [3]

The incidence of toxoplasmosis in HIV-infected individuals is directly correlated with four factors: *T. gondii* seroprevalence among the general non HIV-infected population, the degree of immunosuppression estimated by the CD4 count, the use of active antiretroviral therapy, and the institution of effective prophylactic regimens against reactivation of the infection. It has been estimated that 30–50% of HIV and toxoplasma-seropositive individuals whose CD4 count is below 100 cells/mm^3 will ultimately develop toxoplasmic encephalitis (TE) if anti-*T. gondii* prophylaxis or antiretroviral therapy is not instituted.

CLINICAL FEATURES

In contrast to the relatively benign clinical course of toxoplasmosis in the vast majority of immunocompetent individuals, it is potentially life threatening in both AIDS and other immunocompromised patients.

The brain is the most commonly affected organ. The clinical presentation of TE varies from a gradual and subacute process evolving

Figure 113-1 Giemsa-stained smear of bronchoalveolar lavage from a bone marrow transplant patient with disseminated toxoplasmosis. Tachyzoite form is demonstrated (arrows).

over weeks to an acute confusional state, with or without focal neurologic defects, evolving over days. Clinical manifestations include mental status abnormalities, focal

motor deficits, sensory aberrances, seizures, cranial nerve disturbances, cerebellar signs, meningismus, movement disorders and neuropsychiatric findings. The most common focal neurologic findings are abnormalities of speech and hemiparesis.

Constitutional symptoms and signs, such as fever and malaise, may vary and may be the only initial clinical manifestations of disseminated toxoplasmosis. A high index of suspicion for toxoplasmosis should always be entertained in patients at high risk for the disease (i.e. bone marrow transplant patients with chronic toxoplasma infection or a toxoplasma-seronegative heart transplant patient who receives a heart from a seropositive donor).

Seizures, cerebral hemorrhage and diffuse TE can occur acutely and progress rapidly to death. Spinal cord toxoplasmosis in patients with organ transplants can present with motor or sensory disturbances of single or multiple extremities, or bladder or bowel dysfunction. Cervical and thoracic myelopathy and conus medullaris syndromes have also been reported.[4]

Toxoplasmosis in immunocompromised patients can also present as chorioretinitis, pneumonitis or multiorgan involvement, presenting with acute respiratory failure and hemodynamic abnormalities similar to septic shock.

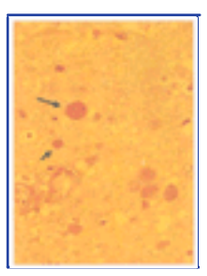

Figure 113-2 Hematoxylin-eosin stain of the cyst form of *T. gondii* in brain (arrows).

SPECIFIC SETTINGS OF IMMUNOSUPPRESSION

AIDS

The majority of AIDS patients with toxoplasmosis have evidence of prior *T. gondii* infection (as demonstrated by positive *T. gondii*-specific IgG in approximately 97% of patients with TE), a CD4 count less than 100 cells/mm^3 and are not taking appropriate toxoplasma-specific prophylaxis (for additional information see Chapter 127).

Clinical manifestations of toxoplasmosis in AIDS patients commonly reflect involvement of the brain (i.e. TE), the lung (pneumonitis) and the eye (chorioretinitis). TE is the most common presentation of toxoplasmosis in AIDS patients. Spinal cord involvement by *T. gondii* in AIDS patients manifests as motor or sensory disturbances of single or multiple limbs, bladder and/or bowel dysfunctions and local pain. Patients may present with a clinical syndrome resembling a spinal cord tumor.

Bone marrow transplantation

Toxoplasmosis mostly occurs by reactivation of latent disease within the first 6 months after marrow transplant. Infection develops in patients who are seropositive for *T. gondii* pretransplant, have received an allogeneic marrow and have severe graft versus host disease (GVHD). [5] [6]

The incidence of toxoplasmosis in bone marrow transplants has been estimated at 0.31 cases per 100 allogeneic transplants.[6] The occurrence of the disease in autologous marrow recipients is extremely rare. The median time of clinical presentation is usually day 60 post transplant; the attributable mortality has been estimated

at =40%. In autopsies of bone marrow transplant recipients, *T. gondii* tachyzoites have been found in brain, heart, lungs, liver, duodenum, bladder, lymph nodes and bone marrow.

Heart and heart-lung transplantation

In heart or heart-lung transplant recipients, toxoplasmosis usually occurs when a seronegative recipient (R-) receives a transplant from a seropositive donor (D+). Seropositive recipients frequently develop IgM and IgG antibody titer rises after transplantation without evidence of clinical disease.[7] [8] In the heart transplant recipient, toxoplasmosis may simulate organ rejection. In such cases, toxoplasmosis has been established by endomyocardial biopsy. In a recent study of infectious complications among 620 consecutive heart transplant patients at Stanford University Medical Center in California, serological testing for toxoplasma was available for 582 donors and 607 recipients, of whom 6% and 16.1% had *T. gondii*-specific IgG antibodies, respectively.[9] The higher incidence of previous *T. gondii* infection observed among recipients (16%) versus that among donors (6%) reflects the increasing seroprevalence with age.

Results of serological testing for toxoplasma were available for 575 D/R pairs; of these, 454 (79%) were D-/R-, 84 (14.6%) D-/R+, 32 (5.6%) D+/R- and five (0.8%) D+/R+. Of the 32 D+/R- patients, 16 received trimethoprim-sulfamethoxazole (TMP-SMX) and/or pyrimethamine prophylaxis and none developed toxoplasmosis; however, four (25%) of the 16 D+/R- patients who did not take either TMP-SMX or pyrimethamine developed toxoplasmosis, and all died of the infection. None of the 98 patients who were seropositive for *T. gondii* preoperatively developed clinical evidence of reactivation of the infection.[9] In this study, the highest mortality attributable to an infectious complication was observed among patients with toxoplasmosis and those with disseminated aspergillosis.

Kidney and liver transplantation

Toxoplasmosis in kidney transplant patients is more likely to occur as a result of primary infection in the setting of a toxoplasma-seropositive donor (D+) and a seronegative recipient (R-); it has also been described in D+/R+ and D-/R+ pairs.[10] Most affected patients develop clinically evident toxoplasmosis by 3 months post transplantation, with fever, neurological disturbances and pneumonia as the main clinical features.

Toxoplasmosis in liver transplant patients is more frequently reported as a result of reactivation of chronic infection[11] but it can also occur in the setting of primary infection in D+/R- pairs.[12] Toxoplasmosis usually develops within 3 months of the transplant. Fever, pneumonia and multiorgan failure are common.

DIAGNOSIS

The diagnosis of *T. gondii* infection or toxoplasmosis may be established by serological tests, polymerase chain reaction (PCR) in body fluids or tissues, histological methods (i.e. immunoperoxidase stain) or isolation of the parasite from body fluids or tissues.[13]

Because reactivation of the chronic infection is the most common cause of toxoplasmosis in patients with malignancies, recipients of organ transplants (particularly bone marrow and liver) or AIDS, initial assessment of these patients should routinely include *T. gondii* IgG antibodies. Those with a positive result are at risk of reactivation of the infection; those with a negative result should be instructed on how they can prevent becoming infected.

It should be kept in mind that in patients with heart and heart-lung transplants (and less frequently in patients with kidney, liver and liver-pancreas transplants), toxoplasmosis is most to likely occur in the previously seronegative patient who receives an allograft from a seropositive donor. Consequently, it is recommended that all candidates for solid transplantation and their potential donors be screened for *T. gondii*-specific IgG prior to transplantation. This strategy allows to identify those patients at risk of developing life-threatening disease, initiate appropriate prophylaxis and to prompt diagnostic tests and empiric treatment should the patient develop a syndrome consistent with the possibility of toxoplasmosis.

When reactivation of *T. gondii* infection is suspected in immunocompromised patients chronically infected with the parasite (those with documented positive *T. gondii*-specific IgG antibody prior to the immunosuppressive state), additional serological testing adds very little or may be misleading.[7] [8] In these patients, apparent reactivation (a rising IgG and IgM titer) may be present in the absence of clinically apparent infection. In addition, serological test results consistent with chronic infection may be seen in the presence of active toxoplasmosis. [8] [14] Thus, for immunocompromised patients in whom toxoplasmosis is suspected, additional diagnostic methods to attempt to establish the diagnosis are strongly recommended. These methods include PCR for the amplification of *T. gondii* DNA in blood or body fluids suspected of being infected (i.e. bronchoalveolar lavage fluid, cerebrospinal fluid, etc.), isolation of the parasite from blood or body fluids, and histological examination

of available tissues with *T. gondii*-specific stains such as immunoperoxidase (e.g. endomyocardial biopsy in heart transplant patients).

When clinical manifestations suggest involvement of the CNS and/or spinal cord, neuroimaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI) are mandatory. Neuroimaging studies should be considered even without focal deficits on examination. Empiric anti-*T. gondii* therapy for patients with multiple ring-enhancing brain lesions (usually established by MRI), positive IgG antibody titers against *T. gondii* and advanced immunodeficiency is accepted practice (Fig. 113.3). Clinical and radiologic response to specific anti-*T. gondii* therapy is supportive of the diagnosis of CNS toxoplasmosis.

Brain biopsy should be considered in immunocompromised patients with presumed CNS toxoplasmosis if there is a single lesion on MRI, a negative IgG antibody test, inadequate clinical response to an optimal treatment regimen or in those who received and adhered to an effective prophylactic regimen against *T. gondii* (e.g. TMP-SMX).[15] If *T. gondii* serological and radiological studies do not support empiric treatment or are inconclusive, and if brain biopsy is not feasible, a lumbar puncture should be considered for PCR on the CSF. CSF can also be sent for isolation studies, although *T. gondii* has uncommonly been isolated from CSF in these patients. PCR examination of the CSF can also be used for detection of

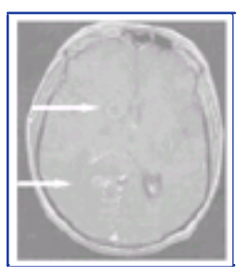

Figure 113-3 Magnetic resonance imaging of the brain in an autologous bone marrow transplant patient with toxoplasmic encephalitis (TE). Enhancing lesions are shown (arrows).

Epstein-Barr virus (EBV), JC virus or cytomegalovirus (CMV) DNA in patients in whom primary CNS lymphoma, progressive multifocal leukoencephalopathy (PML) or CMV ventriculitis, respectively, are included in the differential diagnosis.

TREATMENT

Monotherapy should not be used in the treatment of immunosuppressed patients with toxoplasmosis. The 'gold' standard' regimen for the treatment of toxoplasmosis is the combination of pyrimethamine (200mg loading dose followed by 50–75mg qd), sulfadiazine (2.0–4.0g loading dose initially followed by 1–1.5g q6h) and folinic (not folic) acid (10–50mg qd). Clindamycin (600mg q6h, up to 1200mg q6h) can be used instead of sulfadiazine in patients intolerant of sulfonamides. Duration of treatment should be 4–6 weeks after resolution of all signs and symptoms (often for several months or longer). Recently, TMP-SMX (at 10–15mg/kg/d of the trimethoprim component divided in four doses) has been found to be equivalent to pyrimethamine/sulfadiazine in patients with AIDS.[16]

Atovaquone has potent *in vitro* and *in vivo* activity against both cyst and tachyzoite forms in murine models of TE.[17] [18] In its tablet form, atovaquone has been used as a single agent for primary and maintenance therapy of TE in AIDS patients, with overall discouraging results. The bio-availability of atovaquone is highly dependent on formulation and diet.[19] An international, noncomparative study of atovaquone (as a more bio-available oral suspension) with either pyrimethamine or sulfadiazine for treatment of acute TE found that the atovaquone combination regimens were effective (=75% response rate), safe and had a frequency of adverse events leading to treatment discontinuation (28%) similar to standard treatment regimens (16–33%).[20] [21]

Atovaquone+pyrimethamine may be considered as an alternative treatment for patients intolerant of sulfonamides, and atovaquone+sulfadiazine for patients intolerant of pyrimethamine. The efficacy of atovaquone-based therapies has not been evaluated prospectively.

The roles of clarithromycin, azithromycin or dapsone in TE have not been well established. If used, they should always be combined with other drugs, preferably including pyrimethamine.

After treatment of the acute phase (primary or induction treatment) in patients with AIDS, maintenance treatment (secondary prophylaxis) should be instituted. This is usually accomplished with the same regimen used in the acute phase but at half doses. Currently, maintenance therapy is recommended to be continued for life or until the patient's CD4 count has been >200 cells/mm^3 and HIV PCR peripheral blood viral load nondetectable for at least 6 months. Other immunocompromised patients may require maintenance treatment for as long as their immunosuppressive regimens significantly affect their cell-mediated immunity, as is the case with bone marrow transplant patients.

PREVENTION

Prevention is most important in seronegative immunodeficient patients, and is most readily accomplished through education (Table 113.1).

The *T. gondii*-specific IgG test result should be documented in the medical records of all patients undergoing potent suppression of cell-mediated immunity. In addition, the toxoplasma IgG status of all organ donors should be documented.

In seronegative recipients of a heart, heart-lung, lung, liver or kidney from a seropositive donor, primary prophylaxis (pyrimethamine 25mg po qd for 6 weeks post transplantation) should be considered for patients not taking TMP/SMX for PCP prophylaxis. These

TABLE 113-1 -- Measures to prevent primary *T. gondii* infection in immunosuppressed patients.

MEASURES TO PREVENT PRIMARY *T. GONDII* INFECTION IN IMMUNOSUPPRESSED PATIENTS
Avoid contact with consumer goods potentially contaminated with cat feces, particularly cat litter and gardening.
Disinfect cat litter box with near boiling water for 5 minutes prior to handling.
Cook meat to 66°C or 'well done' or that is not pink in the middle (meat that is smoked or cured in brine may be infectious).
Wash hands thoroughly after contact with raw meat.
Kitchen surfaces and utensils that have come in contact with raw meat should be washed.
Avoid mucous membrane contact when handling raw meat.
Avoid ingestion of dried meat.
Wash fruits and vegetables prior to consumption.
Refrain from skinning animals.

patients now routinely receive TMP-SMX for PCP prophylaxis, and this regimen appears to be sufficient to also prevent toxoplasmosis. Prophylactic daily doses of TMP-SMX (one single-strength tablet a day) are probably sufficient to prevent toxoplasmosis and most likely do not require the addition of pyrimethamine.

Primary prophylaxis against *T. gondii* in AIDS patients at high risk for TE is effective. Potent antiretroviral therapy also has a profound impact in decreasing the incidence of TE in these patients. Primary prophylaxis is recommended for patients who are *T. gondii* seropositive whose lowest $CD4^+$ count has been below 100/mm^3 regardless of the HIV RNA viral load. Once the CD4 count increases above 200/mm^3 , primary prophylaxis can be discontinued particularly in patients with non-detectable or low HIV RNA viral load for at least 6 months. TMP-SMX (daily), dapsone (50mg/day) plus pyrimethamine (50mg/week), atovaquone (750mg qid) and fansidar have been reported to be effective regimens to prevent TE.

STRONGYLOIDES

GENERAL CONSIDERATIONS

Strongyloidiasis is caused by two species of the intestinal nematode Strongyloides, *Strongyloides stercoralis* and *S. fuelleborni. Strongyloides fuelleborni* has rarely been reported to cause infection in humans. *Strongyloides stercoralis* infects as many as 100–200 million people in 70 countries with defects in T cell-mediated immunity, (AIDS, hematological malignancies, bone marrow transplants and those taking relatively high doses of corticosteroids). The overall seroprevalence of *Strongyloides stercoralis* in the United States is between 0.4% and 4.0%.[22]

The unique ability of this nematode to replicate in the small intestine of humans permits cycles of autoinfection, leading to chronic asymptomatic disease that can last undetected for decades.

LIFE CYCLE

Strongyloides stercoralis exists in nature in two forms: filariform infective larvae and rhabditiform. The filariform larvae (infective stage) penetrate unbroken skin of humans that has been exposed to contaminated soil. The larvae pass through the circulation to reach the lungs, enter the airways and are swallowed into the gastrointestinal tract. At the small intestine they mature into adult egg-laying females. Female parasites produce eggs that hatch in the

intestine and the rhabditiform larvae are passed out in the feces. To complete the cycle in the soil, rhabditiform larvae develop into free-living nonparasitic adults (both females and males) and produce eggs that ultimately produce and develop into the rhabditiform stage (see Chapter 246). The rhabditiform larvae transform into the filariform infective larvae. In humans, the autoinfection cycle occurs when the intestinal rhabditiform larvae transform directly into the filariform infective larvae without leaving the gut or perianal areas. This cycle can be sustained in humans for decades after leaving endemic areas and explains the high parasite burden seen in the hyperinfection syndrome.

CLINICAL FEATURES

The vast majority of individuals infected with *S. stercoralis* are asymptomatic. A small minority of patients develop gastrointestinal, pulmonary and dermatological manifestations. Gastrointestinal symptoms of strongyloidiasis include nausea, anorexia, diarrhea, abdominal discomfort and abdominal bloating. Cutaneous manifestations include migratory, serpiginous, urticarial skin lesions on the buttocks, groin and trunk.

Pulmonary strongyloidiasis usually occurs in the setting of the hyperinfection syndrome with disseminated disease. Symptoms include cough, wheezing, sputum production, dyspnea, hemoptysis, tachypnea and pleuritic pain. Hyperinfection usually occurs in patients with chronic asymptomatic strongyloidiasis who become immunocompromised. It is usually a complication of impaired cell-mediated immunity and is seen in organ-transplant recipients, patients with lymphomas or patients receiving high-dose corticosteroids. It is characterized by intestinal obstruction/respiratory tract involvement, meningitis, skin rash or Gram-negative bacteremia. The high rate of Gram-negative bacteremia is attributed to the attachment of bacteria to the surface of the parasite as the latter penetrates the small intestine. A high parasite load is usually observed in tissues (particularly the lungs). It has been suggested that chronic intestinal infection and antigen stimulation may predispose to the development of small bowel lymphoma.

DIAGNOSIS

The diagnosis of the hyperinfection syndrome in immunosuppressed patients requires a high index of suspicion. Disseminated strongyloidiasis should be considered in potently immunosuppressed patients who have been in endemic areas who present with unexplained respiratory and gastrointestinal symptoms.

Finding the motile rhabditiform larvae in stool or duodenal aspirate establishes the diagnosis. Larvae can be found in respiratory secretions, cerebrospinal fluid, urine and ascites of patients with the hyperinfection syndrome. Eosinophilia is usually present in immunocompetent patients, but may be absent in the immunocompromised host. Most infected individuals have *S. stercoralis*-specific IgG. Serology and eosinophilia decrease after therapy and may be useful markers of treatment success.[23]

TREATMENT

Thiabendazole (25mg/kg bid) or ivermectin (200µg/kg/d) are the drugs of choice for the treatment of strongyloidiasis. For the hyperinfection syndrome, prolonged and repeated courses of therapy may be required.

AMEBAE OR RHIZOPODS

GENERAL CONSIDERATIONS

The majority of the amebae or rhizopods are free living and dwell in standing fresh water. Three genera, *Acanthamoeba* spp., *Balamuthia* spp. and *Naegleria* spp., have been reported to cause disease in humans. In normals *Naegleria fowleri* can cause life-threatening meningoencephalitis and *Acanthamoeba* spp. and *Balamuthia* spp. can cause keratitis associated with contact lenses. The latter species can cause subacute or chronic meningoencephalitis and disseminated disease in immunocompromised patients.

Several other genera of amebae, including *Entamoeba, Endolimax* and *Iodamoeba*, are obligate parasites of the human intestinal tract that are transmitted via the fecal-oral route and cannot survive as free-living organisms. Intestinal and extraintestinal amebiasis (mostly caused by *Entamoeba histolytica*) is quite common among homosexual men with or without HIV infection.

CLINICAL FEATURES

Human infections with *Naegleria fowleri* are rare. It enters through the nose and travels to the brain and spinal cord during swimming under water or diving. Infection is most common during dry, hot, summer months, when the ambient temperature is above 80°F and the water is warm. Fever, headache, stiff neck, nausea, vomiting, ataxia, seizures, mental status changes and hallucinations are common manifestations. *Naegleria fowleri* infection of the central nervous system is also called primary amebic meningoencephalitis (PAM) and usually results in death within 7–10 days.

Acanthamoeba spp. are found worldwide, most commonly in the soil and dust, in fresh-water lakes, rivers and hot springs and in hot tubs. *Acanthamoeba* may also be found in brackish and sea water. Heating, venting and air conditioner units (HVAC), humidifiers, dialysis units and contact lens equipment also support growth. Several species of *Acanthamoeba* have been found to infect humans: *A. culbertsoni, A. polyphaga, A. castellanii, A. healyi, (A. astronyxis), A. hatchetti, A. rhysodes* and possibly others. *Acanthamoeba* enter through a cut or wound or through the nostrils and reach the lungs and central nervous system. In immunocompromised patients, *Acanthamoeba* spp. can cause disseminated disease or chronic granulomatous amebic encephalitis (GAE).

Disseminated acanthamebiasis with widespread extracerebral disease is characterized by widespread cutaneous nodules with surrounding erythema which ulcerate with indurated borders. It is extremely rare and occurs mostly in AIDS patients or organ transplant recipients.

GAE is a subacute to chronic disease that results in death within one week to several months of the initial symptoms. It is characterized by weeks to months of headache, mental status changes, cranial nerve involvement, increased intracranial pressure and single or multiple space intracranial lesions. *Acanthamoeba* spp. as well as *Balamuthia* spp. (particularly *Balamuthia mandrillaris*) have been described as etiologic agents.

Entamoeba histolytica in humans usually causes diarrhea and cramping abdominal pain with or without dysentery. Extraintestinal manifestations include liver abscess which can rupture through the diaphragm into the lung or pericardium.

DIAGNOSIS

Demonstration of amebic trophozoites and cysts in tissues or growth in culture is diagnostic.[24] Skin and brain biopsy specimens are useful for culture and for histological examination (hematoxylin and eosin, Gomori's methenamine silver, periodic acid-Schiff stains). Immunohistological techniques such as indirect immunofluorescence assay or electron microscopy may be necessary to identify *Acanthamoeba* spp. or *Balamuthia mandrillaris* in tissue sections. Cerebrospinal fluid resembles the picture of aseptic meningitis with lymphocytic pleiocytosis, a normal to slightly low glucose and elevated protein. Serological tests can be helpful in patients with suspected GAE.

Diagnosis of *Entamoeba histolytica* relies upon the identification of the organism in stool. Extraintestinal amebiasis is more difficult to diagnose as the parasite is not usually visualized in liver aspirates. *Entamoeba histolytica*-specific serological tests can be helpful.

TREATMENT

The prognosis of disease caused by free-living amebae in humans is dismal and usually associated with a 100% attributable mortality. For *Naegleria fowleri* primary amebic meningoencephalitis, intravenous amphotericin B at 1mg/kg/d and intrathecal amphotericin B into the lateral ventricle is recommended. There are no standardized regimens for GAE. For *Acanthamoeba* spp. infections there are anecdotal reports on the use of pentamidine, itraconazole or ketoconazole, TMP-SMX and rifampin in different combinations. For *Balamuthia mandrillaris* infections, pentamidine, clarithromycin, fluconazole, sulfadiazine and flucytosine have been used.

The drug of choice for the treatment of diseases caused by *Entamoeba histolytica* continues to be metronidazole. Metronidazole treatment (500–750mg orally three times daily) should be followed by either paromomycin (500mg orally three times daily for 7 days) or iodoquinol (650mg orally three times daily for 20 days) to prevent relapses from intestinal cyst forms.

For cryptosporidiosis, microsporidiosis, isosporiasis and leishmaniasis see Chapter 127 .

Chapter 114 - Practice Point

Infection prophylaxis for patients with common variable immunodeficiency

Jos WM van der Meer
Bart-Jan Kullberg

Definition of the problem

The immunocompromised host is characterized by a state of immunodefiency, which affects the defense against micro-organisms and hence increases the susceptibility to infections. The type of immunodeficiency critically determines which kinds of infection may ensue, as is pointed out in Chapter 97 . Passive and active immunization are classic and effective methods of reinforcing host defense against pathogenic micro-organisms, not only in the normal host but also in the immunocompromised host. In the immunocompromised host, the nature of the host defense defect has a decisive influence on the success of active immunization; if the capacity to mount a specific and protective antibody response is defective (as in primary agammaglobulinemia), certain immunizations become futile. A similar situation is present when the protection conferred by the vaccine is dependent on T-cell defense and specific cellular immunity is of poor quality. An additional problem in the immunocompromised host is the risk of vaccines containing live (attenuated) micro-organisms. The host defense defect may be such that serious infection ensues. In this chapter these problems are discussed in practical terms. In addition, passive immunization (i.e. the administration of immunoglobulin preparations) is discussed in detail.

Typical case

A 48-year-old woman with a 12-year history of recurrent purulent infections of the respiratory tract and paranasal sinuses, caused by *S. pneumoniae* and *Haemophilus influenzae*, was diagnosed 7 years ago as suffering from common variable immunodeficiency. The serum concentrations of all immunoglobulin classes were extremely low. Immunoglobulin A was not detectable and therefore, the patient's blood was tested for antibodies against IgA. Her T cell subsets and function tests (lymphocyte transformation tests) were normal. Because of the presence of circulating anti-IgA, substitution was started with slow subcutaneous standard immunoglobulin 16% according to the protocol given in Table 114.1 . During this period of substitution the anti-IgA titer became negative.

After 3 months of weekly subcutaneous injections of immunoglobulin, she was transferred to substitution therapy with intravenous immunoglobulin (IvIg) preparations. From the start of the substitution therapy, her clinical condition was much improved. With a 4-weekly dose of 600mg/kg IvIg, IgG concentrations above 6g/l were attained. Her pulmonary function was stable. Occasionally, she still suffered from purulent sinusitis, which readily responded to amoxicillin therapy.

Two years ago she had a period of diarrhea. Stool examinations did not show *Giardia lamblia*, but cultures yielded *Campylobacter jejuni*. Despite a course of erythromycin, stool cultures remained positive for this pathogen. There were no episodes of fever.

Recently, she asked her physician which vaccinations she needs for a 3-week holiday in Tunisia, and what she should do about her immunoglobulin substitution therapy.

Management options

Active immunization issues

This patient with defective humoral immunity presents with a series of problems regarding active and passive immunization.

The first problem is the advice on vaccination for her travel. It is necessary to discuss with the patient whether traveling to Tunisia, a country with a high risk of infection with enteric pathogens even for healthy tourists, is a sensible thing to do for a hypogammaglobulinemic patient. It should be kept in mind that, despite adequate immunoglobulin substitution, mucosal immunity usually remains severely impaired in these patients, owing to the deficiency of mucosal immunoglobulins, especially secretory IgA. This could be assessed by measuring IgA in saliva or tears. The persistence of *C. jejuni* in her stools also points to impaired mucosal immunity, since persistence of this pathogen beyond 4 months does not occur in the normal host. Intravenous immunoglobulin substitution delivers only IgG and no other immunoglobulin classes; no measurable immunoglobulin substitution will be found at mucosal sites.

An additional concern is that many patients with common variable immunodeficiency suffer from hypochlorhydria because of abnormal function of the gastric antrum, and this enhances the susceptibility to enteric pathogens.

If the patient persists in her plan to go to Tunisia, the question arises as to which protective measures should be taken. A healthy traveler would receive the following advice:

¦ booster injection of diphtheria and tetanus toxoid and (in many countries) oral poliomyelitis vaccine (OPV), if there has been complete vaccination in the past and the last booster has been 10 years ago; in some countries, such as The Netherlands, OPV is not used at all, and inactivated poliomyelitis vaccine (IPV) is given instead;

¦ protection against hepatitis A if the history for this infection is negative (such protection may be given by administration of immunoglobulin 16% intramuscularly or, preferably, by hepatitis A vaccination); and
¦ protection against typhoid fever, which can be provided either by the oral vaccine containing live attenuated *Salmonella* Ty21a or by the intramuscular inactivated Vi polysaccharide vaccine.

TABLE 114-1 -- Procedure for immunoglobulin substitution in patients with anti-IgA antibodies or a history of serious reactions to intravenous immunoglobulins.

PROCEDURE FOR IMMUNOGLOBULIN SUBSTITUTION IN PATIENTS WITH ANTI-IgA ANTIBODIES OR A HISTORY OF SERIOUS REACTIONS TO INTRAVENOUS IMMUNOGLOBULINS	
Day 1	In the morning, under clinical observation, iv drip with saline; adrenaline (epinephrine) and hydrocortisone prepared for use; insert butterfly needle subcutaneously
	Start subcutaneous injection of IgG 16% at less than 0.5ml/h with infusion pump
	After 2 hours: increase to 1ml/h
	Stop after 4 hours
Day 2	Same conditions
	Start subcutaneous IgG 16% at a rate of 1ml/h
	Increase at 1ml/h to 3ml/h
	Infuse for 4 hours (total 9ml)

Day 3	3ml/h to total of 20ml
Day 7	3ml/h to total of 20ml

TABLE 114-2 -- Vaccines that are contraindicated in the immunocompromised host.

VACCINES THAT ARE CONTRAINDICATED IN THE IMMUNOCOMPROMISED HOST	
Vaccine	**Complication**
Oral poliomyelitis vaccine	Paralytic poliomyelitis
Measles*	Fever and rash
Mumps*	Parotitis, meningoencephalitis
Rubella*	Arthritis
Yellow fever vaccine	Encephalitis
Smallpox	Generalized vaccinia
Typhoid	Systemic response (?)
Bacille Calmette-Guérin	Local and disseminated infections
The designation of 'immunocompromised host' includes patients with cellular immunodeficiency disorders, agammaglobulinemia or hypogammaglobulinemia, HIV infection, leukaemia, lymphoma or immunosuppressive therapy	

* In HIV-infected children who are not severely immunocompromised measles-mumps-rubella is a recommended vaccine

In this immunodeficient patient, the advice would be very different. There are a series of considerations that are important if vaccination of a compromised host is considered.

First, live vaccines must be avoided in immunocompromised patients because infections with the vaccine strains may ensue. This holds for patients with hypogammaglobulinemia as well as for those with cellular immunodeficiency. Of the vaccines mentioned, OPV and oral *Salmonella* Ty21a are contraindicated. Inactivated poliomyelitis vaccine and the *Salmonella* Vi polysaccharide vaccine are safe. The live vaccines that are contraindicated in the immunocompromised host are listed in Table 114.2 .

Second, is it to be expected that the patient is able to mount a protective immune response to the vaccine? It is remarkable that we know very little about the relative contribution of antibodies and of cellular immunity (specific T cells) in the protective immune response. For most vaccines listed above, it is generally assumed that protection is conferred by the specific antibodies that develop after vaccination. An exception is probably the oral typhoid vaccine, which also elicits a cellular immune response that may contribute to protection (Table 114.3).

Third, assuming that the antibodies against the vaccine antigens are needed for protection, it is most likely that the IvIg substitution provides adequate concentrations antibodies against diphtheria, tetanus, poliomyelitis and hepatitis A. Antibodies against *Salmonella typhi* are not present in sufficient amounts in the IvIg preparations that are available.

Prevention of infection by enteric pathogens is important in this patient. Thus, thorough information on how to prevent alimentary infection in a country such as Tunisia should be provided to the patient, although it is known that there is generally poor compliance with such guidelines. In addition, it is good clinical practice to provide such an immunocompromised patient with a suitable antibiotic (e.g. levofloxacin) to be taken when fever or diarrhea occurs.

As noted above, responses to vaccines may differ according to the host defense defect (Table 114.4). For example, if the patient had systemic lupus erythematosus, rather than hypogammaglobulinemia, and was on low-dose prednisone and azathioprine, the situation would be different. A good boosting response to diphtheria and tetanus toxoid, as well as to IPV, would be expected, since neither the immune suppression nor the underlying disease would seriously hamper the B-cell response. Oral poliomyelitis vaccine would be considered dangerous, and the same holds for the live *Salmonella* vaccine. The *Salmonella* Vi polysaccharide vaccine would be safe and — since it is a T-cell-independent vaccine — would be as effective as in healthy volunteers. In Table 114.2 , the currently available vaccines are listed with regard to their effectiveness and safety in patients with different types of immune defects. The reader should realize that the data in the literature dealing with effectiveness and safety of vaccination in patients with various types of immunodeficiency are rather limited. Therefore, the data in Table 114.2 are not very robust but have often been obtained by prudent extrapolation.

Frequently asked questions address the effectiveness of vaccination in patients with diabetes mellitus, liver cirrhosis, end-stage renal disease, in patients on hemodialysis and in elderly patients. Generally, these patients are mildly immunocompromised and may have suboptimal antibody responses. In diabetic patients, there is no real concern about the response to influenza vaccine. In hemodialyzed patients, the response to hepatitis B vaccine is less than in a healthy population. Attempts have been made to augment the antibody response with concomitant administration of an adjuvant (such as monophosphoryl lipid A) or a cytokine (interleukin-2, interferon-?, granulocyte-macrophage colony stimulating factor) with variable success. In the elderly, the response to a vaccine such as influenza vaccine appears to be dependent on the scores attained in the activities of daily life (ADL) assessment — a high score correlates with a high immune response. It has been shown that stimulating physical activity in elderly patients leads to higher antibody titers.

Immunoglobulin substitution and passive immunization

Immunoglobulin substitution is the cornerstone of the treatment of patients with agammaglobulinemia or hypogammaglobulinemia. Nowadays, almost all patients who need such substitution receive the immunoglobulins by the intravenous route. The commercially available preparations are generally safe, although the quality in terms of antibody profiles and titers, functional capacity of the IgG molecules

(especially the Fc part) and the side-effects differs. Most information about these differences have been obtained in vitro; a direct comparison of different preparations in vivo has not been performed.

There is a clear dose response for these preparations. Higher dosages (i.e. dosages of >600mg IgG/kg every 4 weeks) result in less infectious morbidity, and such higher dosages lead, in the long term, to better preservation of pulmonary function. The dosage regimen should be individualized to obtain optimal substitution; there is not a fixed trough level of IgG that is aimed at.

Because of the relatively long half-life of the infused IgG (most often 2–3 weeks), adequate substitution can be obtained with an interval of 3–4 weeks between infusions. Some patients, especially those with exudative enteropathy, need more frequent infusions, because of a shorter half-life of the IgG. With regard to the question of the present patient, we would aim at giving her IvIg shortly before the planned holiday.

It should be realized that IvIg preparations, although they contain mainly IgG and only trace amounts of the other immunoglobulin classes, are by no means pure preparations. They contain a variety of plasma proteins (e.g. prokallikrein, cytokines), which have biologic effects in the recipient. Recent studies have shown that IvIg infusion leads to a series of changes in the concentrations of inflammatory and anti-inflammatory molecules (e.g. adhesion molecules, cytokines inhibitors such as IL-1ra) and in the functional state of white blood cells. Further research is needed to establish whether such changes are benefical in terms of host defence and to what extent they are responsible for side-effects.

Serious side-effects may occur in patients with antibodies against IgA and sometimes other immunoglobulin classes. In particular, patients with common variable immunodeficiency that was preceded by complete IgA deficiency may have developed antibodies against IgA, which is a neoantigen for these patients. When these patients receive IvIg, they may respond with an anaphylactoid reaction, owing to traces of IgA in the IvIg preparations. During such a reaction, high concentrations of tumor necrosis factor may be found in the patient's blood. It is good clinical practice to assess the presence of anti-IgA in the blood before IvIg is given for the first time.

Patients with anti-IgA as well as those who have experienced side-effects to IvIg not due to anti-immunoglobulins can safely be given 16% immunoglobulin by slow subcutaneous infusion. In Table 114.3 , an example of a treatment protocol is given.

A special problem in the patient presented above is the persisting *C. jejuni* in her stools. This is not a rare occurrence in patients with agammaglobulinemia, and such carrier states may be complicated by recurrent febrile episodes caused by transient bouts of *C. jejuni* bacteremia. Occasionally, such episodes of bacteremia are accompanied by erysipelas-like skin lesions or even metastatic infection. In these patients, there is a bactericidal defect of the serum toward *C. jejuni*,

The designation of 'immunocompromised host' includes patients with cellular immunodeficiency disorders, agammaglobulinemia or hypogammaglobulinemia, HIV infection, leukaemia, lymphoma, or immunosuppressive therapy I, indicated or commonly recommended for this condition. Note: specific recommendations or restrictions apply in some patient groups. Data indicate general principles and may not apply for individual patients; CI, contraindicated; S, standard indication as in normal hosts; NE, not effective; ?, unknown; OPV, oral poliomyelitis vaccine; IPV, inactivated poliomyelitis vaccine preferable; HiB, *Haemophilus influenzae* type b; MMR, mumps-measles-rubella; BCG, bacille Calmette-Guérin; conj, conjugated; ID, immunodeficiency; BMT, bone marrow transplant

and this defect is due to a deficiency of IgM, which should mediate the killing by complement. If antimicrobial treatment against *C. jejuni* fails, then IgM-containing immunoglobulin preparations or plasma infusions should be added to restore the serum bactericidal effect.

Special measures are also necessary in the rare agammaglobulinemic or hypogammaglobulinemic patients who suffer from persistent echovirus encephalitis and dermatomyositis-like syndrome and in those with disseminated refractory *Ureaplasma urealyticum* infection. In patients with persistent echovirus encephalitis, extremely high dosages of immunoglobulin preparations (preferably selected for high neutralization titers against the causative virus) are necessary for successful treatment. In patients with refractory *U. urealyticum* infection, specific antibodies have been raised by immunization of goats to obtain plasma for treatment of such patients.

So far, there are only a few examples of commercially available high-titer specific immunoglobulin preparations. Some of these have been developed for prevention or treatment in immunocompromised hosts. Immunoglobulin preparations with high antibody titers against cytomegalovirus (CMV) have been developed to prevent and treat CMV infections in bone marrow and organ transplant recipients. These preparations are used either alone or in combination with ganciclovir. Clinical trials in renal transplant recipients have demonstrated reductions not only in CMV-associated syndromes but also in secondary fungal and parasitic infections. In addition, increases in graft survival have been noted. Similar observations have been made in recipients of orthotopic liver transplant and probably apply to other transplant patients as well. The efficacy of these preparations in the prevention and treatment of CMV disease in bone marrow transplant recipients is much less clear.

Anti-respiratory syncytial virus (RSV) immunoglobulin has been recommended for prevention of RSV infection in patients at high risk, such as infants with chronic pulmonary disease. Alternatively, palivizumab, a humanized monoclonal antibody against the RSV F glycoprotein, is also effective in preventing RSV infection in high-risk patients. The use of either Anti-RSV immunoglobulin or palivizumab for the treatment of established RSV infection is controversial, and studies have failed to show beneficial effects of either drug.

Conclusion

It is clear from the above that the knowledge of active and passive immunization for the prevention of infections in immunocompromised patients is limited. With respect to active vaccination, we lack data on protective cellular and humoral mechanisms, on clinical efficacy and on risks to the patient. Although much knowledge has been assembled on immunoglobulin substitution in patients with primary antibody deficiency syndromes, it is less clear what should be done with secondary antibody deficiencies (such as occur in chronic lymphatic leukemia and myeloma). The nature and the effects of the nonimmunoglobulin components of the various IvIg preparations have not been studied sufficiently. With regard to specific antibody preparations, there are great opportunities to develop new preparations for the prevention of a variety of infections that occur in compromised hosts.

Chapter 115 - Epidemiology of HIV Infection

Michel Caraël
Bernhard Schwartländer
Peter Piot

INTRODUCTION

This chapter describes the distribution and transmission patterns of HIV infection. Although the biology and modes of transmission are broadly the same in the developing and industrialized world, there are some striking differences in the epidemiology, which are due to a variety of behavioral factors and socio-economic conditions. Furthermore, the AIDS problem is overwhelmingly concentrated in developing countries, where more than 90% of all people infected with HIV live.

In less than 15 years HIV has reached the level of a pandemic and AIDS has been reported in over 190 countries.[1] It is also increasingly clear that the HIV pandemic consists of several separate epidemics, each with its own distinct characteristics. On a world scale, the epidemic has evolved predominantly into a heterosexually transmitted disease in the developing world and, increasingly, of underprivileged and marginalized populations in the industrialized world.

FREQUENCY OF HIV INFECTION AND AIDS AND DEFINITION

Shortly after the first reports of AIDS in the USA in 1981 among homosexual men and injecting drug users, it became obvious that the disease was also present in Haitians living in North America and in Africans seen in Belgium for medical care at the end of 1983.[2] [3] Subsequently, surveys in Haiti and in central Africa confirmed the occurrence of several epidemic foci of HIV in these areas.[4] [5] [6] [7]

The identification of another variant of the virus, labeled HIV-2, among West African populations and then in other African countries with a Portuguese colonial history increased further the heterogeneity of what quickly emerged as a global pandemic. The routes of transmission and risk factors of HIV-2 and HIV-1 are similar, but it has become increasingly clear that the pathogenic effect of HIV-2 is lower than that of HIV-1.[8] In the rest of this chapter, HIV refers to HIV-1.

Although there are no doubts that the HIV epidemic has spread well beyond the most pessimistic predictions, its exact magnitude is difficult to assess. This is due to the largely silent nature of this infection and to limited surveillance in many countries. In addition, diagnostic facilities for HIV infection and its associated opportunistic diseases are still limited in many clinical settings. Another longstanding obstacle has been the absence of a simple definition for AIDS. Indeed, the early definition of AIDS of the Centers for Disease Control and Prevention required expanded laboratory diagnostic capabilities. The World Health Organization (WHO) has adopted a simplified definition of AIDS in adults (1985 Bangui definition), based on the recognition of at least two major clinical signs in combination with at least one minor sign. This is straightforward to use and allows identification of AIDS cases without the need to perform expensive tests. In early 1994, taking into account better access to laboratory diagnostic methods, a positive serologic test for HIV-1 and/or HIV-2 and a broader spectrum of clinical manifestations of HIV such as tuberculosis and pneumonia were added to this definition.[9]

GLOBAL CASES: REPORTS AND ESTIMATIONS

By the end of 2001, over 2.7 million cumulative AIDS cases had been reported to the WHO. However, because of under-reporting, underdiagnosis and delays in reporting, the joint United Nations Program on HIV/AIDS (UNAIDS) and WHO estimated that a total of more than 22 million cumulative AIDS cases in adults and children may have occurred worldwide. The developing world as a whole accounted for well over 80% of all AIDS cases. According to UNAIDS nearly 2.7 million cases are pediatric AIDS cases resulting from mother-to-child HIV transmission. During 2001 alone, HIV infection and AIDS-associated illnesses killed an estimated 3 million people, including 580,000 children; this represents 25% of all deaths since the start of this global epidemic, illustrating that on, a worldwide scale, mortality from HIV infection is accelerating, notwithstanding declining mortality from HIV infection in most industrialized countries.

A more complete picture of the extent of the epidemic is given by the number of people infected with HIV (Table 115.1).[1] By conservative estimates, well over 37.2 million adults and a further 2.7 million children under 15 years have been infected with HIV since the start of the pandemic. Figure 115.1 shows the estimated regional distribution of young people aged 15–24 who have HIV infection and AIDS. More than 13 million children under 15 years of age have lost their mothers or both parents as a result of AIDS-related death.

The incidence of HIV infection in the general population is not known but there have been several cohort studies or repeated surveys of the same population in some countries. The highest HIV incidence rates — 10–15% a year — have been found among sex workers and injecting drug users in various cities around the world. Based on HIV infection trends in different parts of the world, the number of new AIDS cases is expected to continue to increase, mostly in Africa, but also in Asia and eastern Europe.

Geographic distribution of HIV infection and AIDS

North America, Europe and Australia

The cumulative total of reported AIDS cases in the USA was nearly 717,000 at the end of 1999 and it was estimated that more than 940,000 adults and children are living with HIV/AIDS. The annual incidence of AIDS and deaths among people living with AIDS declined during 1996, reflecting the beneficial impact of new available therapies. Although this trend continued through 1998, data for 1999 suggest that the number of AIDS cases and deaths might be leveling out.[10] Early in the epidemic, most infections occurred in men who have sex with men, but the incidence in this group leveled off as early as 1985–7. However, HIV prevalence levels of 7–9% are still found among young adult homosexual and bisexual men in major cities such as San Francisco and New York. The largest decline in the proportion of reported AIDS cases in the USA has occurred among homosexual and bisexual men, whereas cases reported to be acquired by heterosexual transmission have increased, with highest rates in women. Each year approximately 7000 women with HIV

TABLE 115-1 -- Global estimates of HIV/AIDS worldwide at end of 2001.

GLOBAL ESTIMATES OF HIV/AIDS WORLDWIDE AT END OF 2001		
Number of people living with HIV/AIDS	Total	40 million
	Adults	37.2 million
	Women	17.6 million
	Children under 15 years	2.7 million
People newly infected with HIV in 2001	Total	5 million
	Adults	4.3 million
	Women	1.8 million
	Children under 15 years	800,000
AIDS deaths in 2001	Total	3 million
	Adults	2.4 million
	Women	1.1 million
	Children under 15 years	580,000

infection give birth, and without prophylactic treatment 1000–2000 of their infants would be infected with HIV. The prevalence of HIV among injecting drug users has been increasing steadily as well, but with large regional differences. Since the late 1980s on the west coast of the USA, about 90% of people who have AIDS are men who have sex with men, whereas on the northeastern coast the majority of newly diagnosed people with AIDS are injecting drug users. Young adults belonging to ethnic minorities (including men who have sex with men) face considerably greater risks of infection that they did 5 years ago. African-Americans, for instance, make up only 12% of the population of the USA but constituted 47% of AIDS cases reported in 2000 (Fig. 115.2).

Canada has a cumulative number of HIV infections estimated to be around 50,000. Women now represent 24% of new HIV infections, as compared with 8.5% in 1995. The estimated number of new infections has been slowly declining and was around 2000 in

Figure 115-1 Young women and men (aged 15–24 years) estimated to be living with HIV/AIDS, 2001. Total at end of 2001, 40 million.

2001. There was, however, concern about recent outbreaks in the injecting drug user community in Vancouver and an incidence of 5 new infections per 100 drug injectors per year in Montreal, one of the highest rates in North America.[11]

By the end of 1999, in western Europe as a whole, AIDS incidence appeared to have decreased and this seems mainly due to a decrease in the incidence of homosexually acquired AIDS and of injecting drug use (Fig. 115.3).[12] However, in Italy, Spain and Portugal, where the majority of the cases are acquired through injecting drug use, the AIDS incidence is still high. As a consequence of this shift, there is a marked increase in the proportion of reported female cases, from 12% in 1986 to 25% in 2000. Following the introduction of highly active antiretroviral therapy (HAART), the number of reports of deaths among AIDS cases also continued to decrease, at an average annual rate of -30% between 1997 and 2000.

In countries of eastern Europe, which are experiencing profound social change, HIV epidemics are much more recent but are increasing exponentially, mainly in relation to drug use. Ukraine recently reported a rise of HIV prevalence among injecting drug users in Nikolayev from 2% to 57% in 1996 within 1 years. Although fewer than 400 HIV infections were recorded between 1987 and 1994, a total of 1500 were recorded in 1995 and close to 40,000 in 2000. The Russian Federation and eastern European countries are experiencing a similar progression, especially among injecting drug users. Furthermore, in the former Soviet Union, syphilis incidence rates doubled in 1995 compared with those in 1994 to reach close to 200/100,000 population, illustrating increased unsafe sexual behavior. A particular problem has resulted from the nosocomial epidemics in children in Romania and the Russian Federation in the late 1980s, which are the cause of HIV infection in over 50% of children who have AIDS in central and eastern Europe today. With an estimated cumulative total of more than 113,000 HIV infections, the Russian Federation and Ukraine have a similar number of HIV infections to western Europe.

Figure 115-2 Percentage of newly reported AIDS cases by race/ethnicity, USA.

In Australia and New Zealand, just as in several countries of northern Europe and some parts of the USA and Canada, the vast majority of HIV infections have been acquired through sexual contacts between men, but the incidence reached a peak in the mid 1980s. Programs involving community members and allowing easy access to sterile injecting equipment and methadone treatment have permitted the prevalence in injecting drug users to remain very low, at around 1% in several major cities. Heterosexual transmission is rare. There is evidence that HIV infection rates have reached a plateau in Australia and are declining in New Zealand.

Sub-Saharan Africa

In the nations of sub-Saharan Africa, prevalence rates in the general population vary from less than 1% to 20% and more. Although the

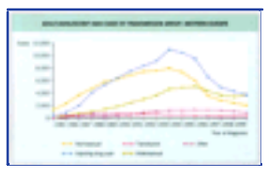

Figure 115-3 Adult/adolescent AIDS cases by transmission group, western Europe.

epidemic was first recognized in central and east Africa, where it remains at high levels, there is also a large epidemic in west Africa within and around the Ivory Coast. According to UNAIDS, at the end of 2000, 28.1 million adults and children had HIV infection in sub-Saharan Africa, of whom 50% were female. Of the 5.1 million estimated HIV-infected children born in the world since the beginning of the pandemic, over 90% have been born in Africa. In some cities in central and southern Africa, approximately 35% of women attending antenatal clinics have HIV.[1]

The prevalence of HIV continues to increase, mainly in the southern part of Africa and in the west. In major urban areas of Botswana, HIV prevalence levels in adults had reached more than 40% by 1997. HIV prevalence in pregnant women in South Africa has also increased dramatically; for example, between 1990 and 1998 HIV

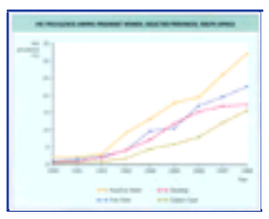

Figure 115-4 HIV prevalence among pregnant women, selected provinces, South Africa.

prevalence in pregnant women increased from 1% to 21% in the Free State, the North Cape, Mpumalanga and the northern and north west states (Fig 115.4).

National and city-based serosurveys carried out at the end of the 1980s have given age- and sex-specific seroprevalence rates that show a similar pattern everywhere, typical of heterosexual and perinatal transmission of HIV from mother to child. Rates usually show a bimodal curve with a first peak prevalence in children under 5 years of age, then very few infections, and a second peak at 20–30 years of age, with very few infections in people over 40. In Kinshasa, Zaire, but also in east Africa, young women under 25 years of age were three to five times more frequently infected with HIV than men of the same age. In contrast, after 35 years of age this ratio reverses and more men than women are infected. An explanation for these differences is probably found in a combination of biologic factors, such as a higher biologic susceptibility to HIV infection and other sexually transmitted diseases (STDs) in young women, and cultural patterns, such as the preference of men for female partners younger than themselves.[13] [14]

HIV-2 is primarily found in West Africa but has also been confirmed in other African countries. The highest prevalence of HIV-2 infection is found in Guinea Bissau, with prevalence rates as high as 9.5% among adults and an annual incidence of 0.9%. In contrast to the increasing spread of HIV-1, the prevalence of HIV-2 has remained rather stable in West Africa. This is probably the result of the higher transmissibility of HIV-1 compared with that of HIV-2.[15]

Asia and the Pacific

It is estimated that about 7.1 million people have HIV infection and AIDS in Asia and the Pacific and 90% of them live in India, Thailand and Myanmar. The spread of HIV in this region became detectable in the second half of the 1980s, at first among injecting drug users in Myanmar and Thailand. The HIV seroprevalence rate among injecting drug users varies substantially; rates of over 60% have been found in China's Yunnan Province, northern Thailand, Manipur state in India, Vietnam and Myanmar. The epidemic has quickly spread out of the injecting drug user and sex worker communities in some major cities of India and into the general population. In Mumbai, in less than 5 years (i.e. by 1996), HIV prevalence had reached 50% among sex workers, 33% in STD patients and 4.3% in pregnant women. Most HIV transmission in Asia and eastern Europe is due to the sharing of infected needles among injecting drug users (Fig. 115.5).

Estimates of the number of adults and children infected with HIV in India are close to 4 million and by the turn of the century there may have been more people in India who had AIDS than in any other country in the world. In most of Asia, heterosexual transmission is now by far the predominant mode of spread.

Surveillance data in China leads to an estimation of more than 1 million people living with HIV. Increasing evidence has emerged of serious epidemics in Henan province in central China, where many tens of thousands of rural villagers have become infected by selling their blood to collecting centers.

In Thailand, the epidemic has been particularly well studied. HIV has spread in overlapping waves through injecting drug users and sex workers, their clients and the female partners of clients. The prevalence among sex workers rose from 3% in 1989 to 30% in 1996 and that among STD clinic attenders rose from nearly zero to 9% over the same period. There is convincing evidence of a fall in risky behaviors following extensive programs to promote condom use in brothels and to discourage men from visiting them.[16] The number of new cases of STDs seen in clinics has fallen and the national prevalence of HIV among young military recruits dropped from 3.6% in 1993 to 2.5% in 1996. There are indications that transmission between spouses is now responsible for more than half of new infections.

An HIV epidemic has recently developed in Papua New Guinea, fueled mainly by heterosexual transmission.

Latin America and the Caribbean

As of the end of 2001, UNAIDS estimated that 1.4 million persons had HIV infection and AIDS in Latin America and the Caribbean, with 30% of all infections occurring in women. Approximately 200,000 adult and pediatric AIDS cases have been reported and more than 70% of these occurred in Brazil, Mexico, Argentina or Honduras.

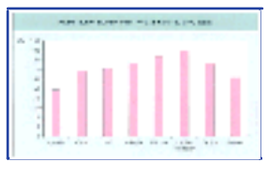

Figure 115-5 Proportion of new HIV infections in injecting drug users.

In the early years of the HIV epidemic in Latin America, over 50% of reported infections were among homosexual and bisexual men; heterosexual transmission contributed another 25%. However, since the mid-1980s, there has been an increase in heterosexual transmission, principally among bisexual men and their female sexual partners, and among sex workers and their clients. In Brazil, for example, the proportion of reported AIDS cases attributable to heterosexual transmission increased from 3% in 1985 to 31% in 1996. In Saõ Paulo, data suggest a different pattern of HIV spread between men and women; whereas HIV prevalence among male STD clinic attenders was stable between 1993 and 1994, rates may have increased more than 5-fold among female STD clinic attenders over the same period. It was estimated in 1999 in Brazil that, in addition to the 30,900 children orphaned as a result of HIV infection and AIDS, more than 100,000 children had mothers who were currently infected with HIV (Fig. 115.6). HIV is also reported to be spreading rapidly among injecting drug users in Brazil and Argentina and presents a growing problem.

Figure 115-6 Impact of the epidemic on children with HIV-infected mothers. *Model of Global Orphan Project, data from Brazil.*

Of the Central American countries, Honduras has been especially broadly affected by heterosexual transmission; nearly 60% of the AIDS cases reported in the subregion are in Honduras. In most of the Caribbean, heterosexual transmission has been the predominant mode of transmission for at least a decade. Prevalence rates among pregnant women have reached 4%, 10% and 6% in the Bahamas, Haiti and Trinidad-Tobago respectively. In contrast, infection rates remain relatively low in Jamaica but have risen in marginalized groups such as crack cocaine users and migrant laborers. In the Dominican Republic, HIV seroprevalence has reached levels of up to 11% among female sex workers, 3–4% among STD patients and 1.4% in pregnant women.

North Africa and the Middle East

By the end of 2001, approximately 440,000 persons in this region had HIV infection and AIDS, with a male:female ratio of 2.5:1. So far, the spread of the virus appears to be limited to homosexual men and injecting drug users in large cities. About 75% of the AIDS cases have been reported from Morocco, Sudan, Saudi Arabia, Tunisia and Djibouti. HIV seroprevalence levels among the general population show seropositivity far less than 1%. Djibouti seems to be the hardest hit country in the region, with prevalence levels of up to 9% in pregnant women. A rise in HIV prevalence among STD patients has recently been noticed in Sudan.

Dynamics of the HIV epidemic

Under circumstances that are not yet fully understood, epidemics may suddenly explode, with rates of infection increasing several-fold within only a few years. For example, estimation of HIV seroprevalence among injecting drug users seeking treatment in Bangkok increased from zero in 1985–6 to 16% in 1988 and 40–60% in 1992. Outside these vulnerable groups, contrasting situations have been found in the general population. Cambodia did not record its first diagnosis of HIV infection until 1991. By 1996, HIV prevalence among pregnant women was approaching 5% but was estimated to have declined to 2.3% at the end of 2000 through the implementation of 100% condom use in brothels.

In sub-Saharan Africa, most new HIV infections are now occurring among young people and particularly among young girls (Fig. 115.7). There is often a doubling of the HIV rate between the 15–19 age group and the 20–24 age group. In these relatively generalized epidemics, more women are infected with HIV than men both in their late teens and in their early 20s. The pattern is consistent

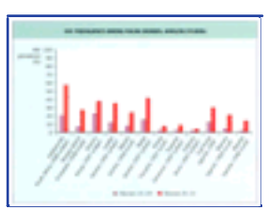

Figure 115-7 HIV prevalence among young women, African studies. Seropositivity among women aged 15–19 years and 20–24 years in selected community surveys in sub-Saharan Africa, 1995–2000.

Figure 115-8 Percentage of adolescents who had their first sexual experience before age 15 years.

regardless of the overall level of HIV prevalence, and regardless of whether the study is conducted in an urban or a rural area. On average, eight times more girls than boys are infected with HIV in their late teens, while among young people in their early 20s three times as many women are infected as men. Sexual behavior patterns and sexual networks are believed to play a critical role as well as an increased biologic susceptibility to HIV/STD associated with early age at first sexual intercourse (Fig 115.8).[17] Another factor influencing the efficiency of the transmission of HIV is the lack of male circumcision and the prevalence of other STDs in a community.

More attention is given now to the role of herpes simplex virus type 2 (HSV-2) as enhancing susceptibility to HIV per sexual act. Figure 115.9 shows the dramatic increase in HSV-2 seropositivity in young girls after a few sexual contacts in a mining town of South Africa.[18] A recent study in Thailand also found that the risk of female-to-male transmission of HIV is about 10 times higher in sex worker-client contact than in a stable sexual relationship, possibly because of the presence of other STDs, such as HSV-2, because of different sexual practices and because of new primary infections associated with a peak in infectiousness.[19] [20]

The possibility should not be excluded that different genetic subtypes of HIV-1 are associated with differences in the efficiency of spread of the virus in a population. Nine subtypes have already been identified in the dominant group M (A–H) and one outlier categorized as O. However, only scarce information exists on their distribution in HIV infected populations (Fig. 115.10).[21] Prospective studies and/or repeated studies in the same populations should allow control

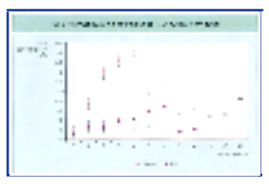

Figure 115-9 HSV-2 among young people in a South African town. Seroprevalence among male and female adolescents aged 15–24 years by number of lifetime sexual partners.

Figure 115-10 Estimated prevalence of HIV-1 *env* subtypes by region, 1998.

for the many confounders before concluding on differences in the transmissibility of HIV subtypes.[22] The recent observation that some sex workers who had been repeatedly exposed to HIV infections remained HIV-antibody-negative raised the hypothesis that some people have a weaker susceptibility to or even immunity against the virus or specific subtypes.[23] It has been suggested that factors such as certain HLA haplotypes and, more recently, polymorphisms of the chemokine receptor gene *CKR5* may explain such resistance but there is still no conclusive evidence.

The hope that the number of new infections is decreasing comes from studies in many countries in the developed world as well as from Thailand,[16] Senegal[24] and Uganda, a country with one of the older epidemics in Africa. A study of recent trends in HIV infection in young pregnant women in urban Uganda showed a 35% decline in HIV prevalence.[25] This may be explained by a variety of factors such as increased death rates among seropositive people, saturation of the most susceptible and decreased infectiousness of people with HIV over time until the occurrence of AIDS. However, a 2-year delay in the average age at first sexual intercourse, a slight reduction in the number of casual partners and a substantially increased use of condoms are the more likely explanations of the HIV decline among youth in Uganda. Figure 115.11 shows HIV prevalence levels over time in selected sites or nationally for Thailand.

MODES OF TRANSMISSION

Sexual transmission

In contrast to the industrialized world, heterosexual intercourse accounts for more than 85% of cases of HIV infection in developing countries. Early epidemiologic studies showed that risk factors associated with HIV infection were unprotected sexual intercourse with multiple partners or an infected partner and the presence of STDs or a history of STDs.[26] [27] [28] [29] [30] More recent studies have highlighted sex differences in patterns of HIV transmission; for many monogamous women the main risk factor for HIV may be the heterosexual and homosexual behavior of their steady partner. Although the probability of HIV transmission associated with unprotected vaginal sexual intercourse is not constant from one contact to another, estimates per episode — based on discordant couples — range from 0.0005 to 0.002 in the absence of co-factors.

A summary of biologic factors influencing the probabilities of HIV transmission from an infected person to a susceptible individual is given in Table 115.2 . The presence of STDs suggests a marked risk of concurrent HIV infection, for at least two reasons:

- the modes of transmission of HIV and other STDs are similar; and
- the role of STD-induced genital ulcers, including genital herpes, chancroid [31] and syphilis, as well as nonulcerative STD, facilitates transmission of HIV.

Studies among prostitutes in Kinshasa and Nairobi found gonorrhea, chlamydial infections and trichomoniasis to be independent risk factors for HIV acquisition, with

relative risks of 2.7–3.5[32] Lack of circumcision in males has been shown in most studies to be associated with the risk of acquiring STDs, especially genital ulcer and HIV.[33] Early diagnosis and treatment of STDs have been shown to reduce the incidence of HIV infection significantly in a controlled trial in Mwanza, Tanzania. In the intervention communities, a 42% decline in the rate of newly acquired HIV infections was observed.[34]

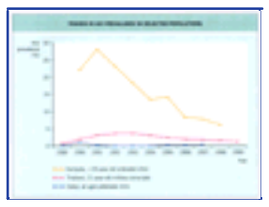

Figure 115-11 Trends in HIV prevalence in selected populations. HIV seroprevalence among pregnant women in Dakar and Kampala and among military conscripts in Thailand, 1989–1999.

TABLE 115-2 -- Biologic factors increasing the probability of sexual transmission of HIV.

BIOLOGIC FACTORS INCREASING THE PROBABILITY OF SEXUAL TRANSMISSION OF HIV	
Confirmed	Acute primary HIV infection
	Advanced clinical stage of HIV
	Sexually transmitted diseases
	Anal intercourse
	Menstruation
	HIV-1 versus HIV-2
Under study	Lack of male circumcision
	Hormonal contraception
	Cervical ectopy
	Genital trauma (use of vaginal products)
	Specific HIV-1 clades

Perinatal transmission

As a result of heterosexual transmission in women, the number of infants born with HIV infection is growing dramatically. Documented rates of transmission of HIV-1 from mother to child vary from 13% to 48%. HIV-2 is apparently very rarely transmitted perinatally. Mechanisms responsible for such variations in transmission rates of HIV are not yet well understood and probably involve multiple factors such as the immunologic status and viral load of the mother, maternal vitamin A deficiency, ingestion by the newborn at the time of delivery of the mother's HIV-infected blood or amniotic fluid, and ingestion of infected breast milk.

Although the virus has been isolated in breast milk, the risk attributable to breast-feeding and the timing of transmission has not yet been fully assessed and varied from 10% to 20% among mothers with HIV infection. A review of studies estimated that the risk of postnatal HIV transmission was about 30% when mothers seroconverted during the period of breast-feeding.[35] [36]

Blood products and contaminated equipment

Because of the rational use of blood, systematic HIV screening of blood donors and avoidance of donors self-reporting at higher risk, the risk of transmitting HIV infection through blood transfusion is estimated to be far less than 1/100,000 units of blood. In many developing countries, however, a significant proportion of blood donations remain unscreened for HIV and an estimated 5–10% of HIV infections may still occur through blood transfusion, with women and children at greater risk because of frequent anemia. Clinical indications for appropriate blood transfusions are often not met. Although the situation of contaminated blood is improving and most countries have national policies to screen blood that is to be used for transfusion, implementation is still not universal.

In many developing countries disposable needles and syringes are often not available and sterilization practices are not always adequate. The use of other skin piercing instruments, for instance for scarification and circumcision, also has some potential for HIV transmission. This results in potentially frequent parenteral exposure to HIV in populations where HIV prevalence is high, including among health care workers.

The probability of HIV infection due to puncture by a contaminated needle may be in the range of that estimated for a single episode of sexual intercourse with an infected partner or for a single episode of intravenous drug use with HIV-contaminated equipment (0.003–0.007). The potential for HIV transmission by unsterilized needles in medical settings is probably weak, but localized outbreaks in the Russian Federation, Romania and Libya among infants and young children have shown that it can occur in special circumstances. In Romania, over 90% of cases have occurred in children living in public institutions as a result of the re-use of contaminated and inadequately sterilized injection equipment or repeated micro-transfusions of contaminated blood from one child to another.

In 2001, it became widely known that, in a number of Chinese provinces but mostly in Henan in central China, paid blood donation had caused HIV infections, with estimates ranging from below 100,000 to several hundreds of thousands. Before 1996, poor rural

farmers had been selling blood and plasma to commercial blood processing companies to supplement their small income. Blood from many donors was collected and mixed. The red blood cells were separated from the pooled plasma and re-injected back into donors to reduce anemia. Infection rates between villages appear to be highly variable but might be more than 50% of the population in some villages. The risky practice of selling plasma to blood products companies has been illegal for several years now and should not be confused with blood donations for medical purposes, which are screened for HIV and other blood-borne diseases.

NATURAL HISTORY

Data from seroincident cohorts in industrialized countries suggest a median adult incubation period of about 10 years,[37] which increased to 10–12 years in the late 1990s with improvements in the use of antiviral therapy and will probably become even longer with the introduction of antiretroviral combination therapy.

Little information is available about the natural history of HIV infection in many developing countries. The literature suggests, nevertheless, that both the incubation and the symptomatic survival period may be shorter than in industrialized countries because of a combination of poor health care, the particularly high burden of other infections and faster progression to severe immunodeficiency. In African studies the reported median times to AIDS are 2–7.5 years. A recent cohort study in Uganda estimated the cumulative progression to AIDS in their incident group — 22% at 5 years — to be similar to that seen in cohorts of homosexual men.[38] Many previous studies have been of sex workers, in whom the disease may progress faster due to HIV infection with more than one HIV strain and/or immune depression linked with repeated infections by STDs. [39]

It has not been convincingly shown that other infections act as cofactors in the development of AIDS, except for tuberculosis. *Pneumocystis carinii* and Kaposi's sarcoma are less frequently associated with AIDS in developing countries than in industrialized countries.

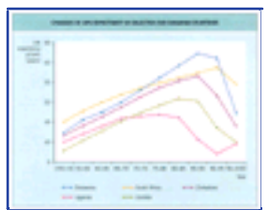

Figure 115-12 Changes in life expectancy in selected sub-Saharan countries. Projected life expectancy at birth, 1950–2000.

An unanticipated consequence of the AIDS epidemic has been a dramatic rise in the incidence of tuberculosis. In sub-Saharan Africa, it is estimated that the annual incidence of tuberculosis is 15 times higher among HIV-positive people than among those who are seronegative.[40] In addition, among people who have HIV infection, tuberculosis is now the most common and deadly opportunistic infection, accounting for 40% of all adult deaths, and it is likely that it increases immunodeficiency. Many countries have seen the number of tuberculosis cases doubling or tripling over the past 5 years. This new situation poses an unprecedented challenge to tuberculosis control programs in much of the developing world.

Demographic and social impact

In cities of western Europe such as Paris and Amsterdam, and in more than 66 cities in the Americas, AIDS was at one time the leading cause of death for young men aged 25–44 years and the third most common cause of death for young women. However, with the increased life-saving effect of antiretroviral therapy, deaths attributed to AIDS are declining rapidly. By 1989, in many cities of Africa, AIDS was the leading cause of death and of years of potential life lost in men over 15 years of age, and the second most important cause, after maternal mortality, among adult women. In a rural area of Uganda, with an HIV prevalence of 8%, 50% of all adult deaths and 89% of deaths in those aged 25–34 years were attributed to HIV.[41] Countries with such high HIV prevalence are showing national increases in adult mortality of the order of 300%. Recent projections suggest that life expectancy in sub-Saharan countries most affected by HIV will have been reduced as much as 15 years by the year 2000 when compared with projections without HIV (Fig. 115.12). [42] The long-term implications of AIDS mortality on the population pyramid for Botswana are illustrated in Figure 115.13 . In the absence of antiretroviral treatment for AIDS patients, it is projected that there will be more adults in their 60s and 70s in 20 years time than there will be adults in their 40s and 50s.

The HIV pandemic kills adults in their most productive years, when they are responsible for the support and care of dependants. It has been estimated that by the end of 2001 over 13 million children

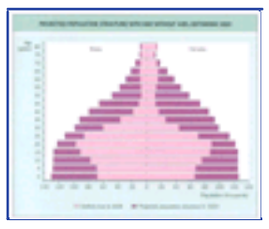

Figure 115-13 Projected population structure with and without AIDS, Botswana, 2020.

had lost their mothers or both parents because of AIDS.[1] Such orphanhood rates may cause traditional child fostering arrangements, which are common in many cultures, to break down.

AIDS has profoundly affected the health systems in industrialized and developing countries alike. In industrialized countries, AIDS has illustrated the need to strengthen some of the weakest components of health services, such as access to appropriate care, counseling and prevention activities and participation of the sick in treatment and medical decision making. In the developing world, HIV vulnerability has been fueled by rapid urbanization, increased migration, conflicts and wars and increased inequalities. In many countries of the developing world, the economic impact of AIDS is felt not only on health care costs but also on skilled labour forces and decreases in gross domestic product, which in turn has a negative impact on many social indicators such as education and health. In cities where HIV prevalence is higher than 10%, hospital wards are overloaded with patients who have AIDS and tuberculosis and require long, repeated hospitalizations, so consuming scarce resources. At the turn of this century, AIDS is posing a threat to economic growth and development in many regions. In June 2001, government and civil society representatives met for a Special Session of the General Assembly of the United Nations to consider an expanded response to HIV/AIDS. This policy forum endorsed the results of a study estimating that, by 2005, that response would require about US$9 billion annually, with half of these resources needed in sub-Saharan Africa. About half of the total amount is required for prevention and the other half is needed for palliative care, treatment and prophylaxis of opportunistic infections, support for orphans and antiretroviral therapy.[43]

Chapter 116 - Prevention of HIV Transmission Through Behavioral and Biological Interventions

Kenneth H Mayer
Steven A Safren

HIV TRANSMISSION DYNAMICS

HIV transmission is a high-consequence but low-probability event with the majority of relevant exposures not resulting in new infections.[1] There are multiple co-factors that may affect HIV transmission, which is why there is a high level of variability in estimates of the relative risk of infection for specific exposures (Table 116.1). [2] [3] HIV may be transmitted as cell-free or cell-associated virus, and different factors may affect expression of virus concentrations in different body fluids (i.e. blood, semen or cervicovaginal secretions).[4] [5] [6] [7] Although lower blood concentrations of HIV are associated with lower rates of HIV transmission, [8] antiretroviral drugs do not necessarily make HIV-infected people noninfectious or incapable of transmitting the virus. In fact, the sexual transmission of multidrug-resistant HIV has been well documented,[9] [10] underscoring the need for providers to promote safer sex among their patients in their care, including those taking antiretroviral therapy.

BIOLOGIC ISSUES RELATED TO HIV TRANSMISSION

HIV is most often transmitted through intimate sexual contact by rapidly binding to cells that are present in the cervical, vaginal, penile, urethral and rectal mucosa.[11] The male foreskin contains abundant cells that can bind HIV; thus, being uncircumcised confers an additional risk for HIV seroconversion[12] [13] (Table 116.2). All the specific mechanisms responsible for the sexual transmission of HIV in humans are not fully understood, since HIV can be found either as cell-free or cell-associated virus in blood and genital secretions and can bind multiple cell types.[4] [14] [15] The cells that can bind HIV in the genital tract include T helper lymphocytes, monocyte/macrophage cells, Langerhans cells and follicular dendritic cells. These last cells may be particularly important because of their mobility, since they can bind HIV on their surface membrane and/or internalize it and migrate via draining lymphatics to distal sites, where propagation in submucosal lymphoid tissue can occur, resulting in subsequent viral dissemination through the bloodstream.

Factors associated with increased HIV infectiousness include sexually transmitted infections[16] and noninfectious factors that can result in genital tract inflammation, recruiting more white blood cells to genital mucosal surfaces.[17] Among the sexually transmitted diseases, ulcerative sexually transmitted diseases such as syphilis, chancroid and genital herpes simplex virus infection afford additional portals of entry through mucosal ulcerations but also recruit inflammatory cells that bind and propagate HIV infection.[18] Inflammatory sexually transmitted diseases, such as gonorrhea, *Chlamydia trachomatis* infection and trichomoniasis have also been associated with increased HIV susceptibility and infectiousness, and may act either by increasing the number of white blood cells in the genital tract or by elaborating cytokines and chemokines that upregulate HIV expression and increase the viral load in the genital tract.[19] [20] Other local genital factors associated with increased inflammation include douching and traumatic sexual intercourse, particularly after sexual assault.[21]

Different tissues in the genital tract have varying levels of susceptibility to being infected with HIV.[7] The vaginal epithelium is stratified and contains fewer cells with co-receptors that can bind HIV.[17] Thus, vaginal mucosa are less likely to become HIV-infected than the endocervix, which has a thinner layer, is highly vascular and contains a much higher concentration of HIV-binding cells. Any physiologic event that results in ectropion (i.e. increased exposure of the endocervix), such as the use of hormonal contraceptives or occult *C. trachomatis* infection, increases susceptibility to HIV.[22] The penile foreskin contains many cells that can readily bind and express HIV, resulting in increased HIV acquisition or transmission in uncircumcised males.[13] The oropharynx contains many fewer cells that can bind HIV, which may partially explain the relative inefficiency of oral exposure to HIV as a means of transmission. [23] Moreover, salivary secretions contain several compounds that have been found to inhibit HIV transmission in vitro, most notably secretory leukocyte protease inhibitor (SLPI).[24] However, rhesus macaques have been readily infected with simian immunodeficiency virus after oral challenge, with evidence of viral replication in tonsillar and adenoidal tissues.[25]

EPIDEMIOLOGIC ISSUES RELATED TO HIV TRANSMISSION

Because of the multiple co-factors that may alter the amount of virus in the blood and genital tract, the calculation of exact risk for infection for each type of HIV exposure is imprecise (see Table 116.1 and Table 116.2). Moreover, much of the data that has been obtained to generate per-contact risks has been based on cohort studies in which individuals recollect their level of risk during preceding time intervals (often every 3–6 months). Some of the participants in these studies may be worried that they have become newly infected or their sexual behavior may have been under the influence of drugs or alcohol, affecting precise recall. Thus, although many people want to have a precise calculation of risk associated with specific practices, it is very difficult to determine with any certainty the precise likelihood of transmission for each specific act. It is important when patients ask questions about the likelihood of risk after an exposure to reassure them that a one-time exposure to HIV is unlikely to result in transmission but that the reason why the epidemic has become so widespread is because of individuals engaging in recurrent risk-taking behavior.

Having noted the limitations of how risk calculations have been obtained, certain key principles have emerged. Direct intravenous exposure to HIV (e.g. blood transfusions) is the most efficient way of transmitting the virus, while percutaneous needle sticks are much less efficient in transmitting HIV.[26] Individuals who share needles who pull back on the syringe and leave substantial blood in the syringe when passing it to their partner are more likely to transmit HIV than in a common health care setting where an occupational needle stick occurs with a solid suture needle.[27] The range of risk for individuals who share intravenous drug paraphernalia ranges from 0.6% to 3% (see Table 116.2). This range overlaps with the level of

TABLE 116-1 -- Estimates of per-contact risk of HIV infection.

ESTIMATES OF PER-CONTACT RISK OF HIV INFECTION	
Type of contact	**Risk**
Needle-sharing	6/1000 to 3/100
Occupational needle stick	1/300
Receptive anal	8/1000 to 3/100
Receptive vaginal	8/1000 to 2/1000
Insertive anal or vaginal	3/10,000 to 1/1000
Receptive oral	Case reports/no denominator

TABLE 116-2 -- Modifiers of the efficiency of HIV transmission.

MODIFIERS OF THE EFFICIENCY OF HIV TRANSMISSION		
Modifier	**Infectiousness**	**Susceptibility**

† Subtype A or C compared with B.

risk for individuals who engage in unprotected receptive anal or vaginal intercourse. [28] One study suggested that, on average, receptive anal intercourse was more than seven times as efficient at transmitting HIV as insertive anal intercourse.[29]

For each type of exposure, many contextual variables may alter the risk of transmission. For example, variations in the prevalence of HIV in different communities may mean that a behavior carrying the same risk has a different likelihood of resulting in infection in two different communities. The amount of virus in the infected source plays a role in determining the risk of becoming HIV-infected after a contact. Co-factors, such as a source with a high plasma viral load[5] [8] [30] or concomitant sexually transmitted infection, can greatly increase the average per contact risk. [31] [32]

In the developed world, the epidemiologic data would suggest that men are more likely to transmit HIV to their female partners. However, in several studies of HIV serodiscordant couples in sub-Saharan Africa, the rates of male-to-female and female-to-male transmission were quite similar.[8] The reasons for the difference in the efficiency of female-to-male transmission in the developing world as compared with the developed world may include the decreased prevalence of male circumcision in the places where these studies were conducted, as well as the high co-prevalence of other sexually transmitted infections. For anal intercourse, the insertive partner is less likely to acquire HIV from an infected receptive partner than vice versa; but there are sufficient cells in the distal male urethra and the foreskin, and such an abundance of HIV-infected cells and mucus secretions containing virus in infected receptive partners, that an insertive partner is still at substantial risk of acquiring HIV from unprotected intercourse.

Figure 116-1 Approaches to preventing HIV transmission.

It is clear that receptive oral intercourse, either fellatio or cunnilingus, is a much less efficient way to acquire HIV, but case reports showing that oral exposure to ejaculate may result in HIV transmission have been well documented. The relative efficiency of oral exposure to HIV is below that of unprotected vaginal intercourse; thus, it may be in the realm of less than 1 per 1000 contacts. However, animal studies have demonstrated that HIV can readily be transmitted orally, since there is lymphoid tissue in the oropharynx that might acquire HIV from genital secretions. In counseling patients who have concerns about the risk of acquiring HIV through oral exposure, it is important to indicate that it is less efficient than unprotected anal or vaginal intercourse but that transmission can still occur. Thus, if an individual wants a zero-risk situation, it is preferable for them to avoid any oral exposure to semen or cervicovaginal secretions from a partner who is known to be HIV-infected or at risk. However, if oral sex is a substitute for unprotected anal or vaginal sex, the patient can be told that this is less risky. Although HIV has been found in very small concentrations in pre-ejaculatory secretions, there are no reliable case reports of HIV transmission through exposure to pre-ejaculate without semen. Thus, it is important to counsel patients that being able to negotiate with their partners about limiting exposure to semen may be a helpful means for 'harm reduction'.

PREVENTION OF HIV TRANSMISSION

HIV transmission may be decreased by biologic or behavioral means (Fig. 116.1). Treating sexually transmitted infections can decrease genital tract HIV load in co-infected patients and can decrease susceptibility in at-risk persons. Antiretroviral therapy can decrease genital as well as plasma viral load but the transmission of multidrug-resistant HIV suggests that these drugs may only have an impact on wider HIV transmission if coupled with programs that encourage safer sexual behavior and optimal drug therapy adherence. Antiretroviral drugs may be used to decrease the likelihood of maternal-child transmission or be used for postexposure prophylaxis. Other experimental approaches, such as microbicides and vaccines, will also be discussed elsewhere. However, for any biologically plausible intervention to work, attention will need to be paid to the behavioral context in which the intervention will be undertaken. For

example, a biologically effective microbicide may fail if the at-risk population refrains from lubricated sex. The following section reviews interventions designed to decrease HIV through sexually transmitted infection treatment and behavioral interventions.

TREATING SEXUALLY TRANSMITTED INFECTIONS

As noted above, there are several different ways that HIV transmission may be minimized; aggressively diagnosing and treating sexually transmitted infections is biologically plausible and cheaper than chronic antiretroviral therapy. There have been several studies conducted in sub-Saharan Africa to test this hypothesis. In a study in the Mwanza district of Uganda, specific syndromic management of sexually transmitted infections in an area where the epidemic was still in its early stages (i.e. 1% of the adult population were infected at the start of the study) resulted in decreasing HIV incidence in communities where the intervention was undertaken. [33] However, in a study in the Rakai district of Tanzania, periodic mass treatment of at-risk adults for sexually transmitted infections did not result in a decrease in HIV incidence.[31] In the latter study, the HIV epidemic was already much more advanced (i.e. 16% of the adult population were infected at the start of the study) and there was a high background rate of concomitant herpes simplex infection, which was not treated in the course of the study.

Thus, the lessons from these studies are that, if one is to decrease HIV spread through treating sexually transmitted diseases, the treatment should be specifically tailored to individual patients, focusing on aggressively diagnosing sexually transmitted diseases that are common in that community. In addition, the benefit of sexually transmitted disease control will be greatest in areas of lower HIV prevalence. In communities where the epidemic is already more widespread, the likelihood of encountering a new partner who is HIV infected may be substantial, so the benefit of modifying a cofactor will be more limited.

HIV SCREENING AS A PREVENTION MODALITY

Other approaches to the prevention of HIV in the developed world are so well established that they seem routine; (i.e. the routine screening of blood). [34] The use of more sensitive antibody screening and careful donor history have resulted in enhanced safety in the blood supply, such that the transmission of HIV via infected blood in the past decade and a half is exceedingly rare. In other parts of the world where the relative cost of blood screening is high, blood supplies may not be as safe.

Another routine practice that results in the prevention of HIV transmission is the guideline that pregnant women be universally offered HIV antibody testing before delivery.[35] Although this guideline is not commonly adhered to, the rate of new perinatally transmitted infections in the USA has decreased dramatically, with fewer than 100 new infections in the past year. The reasons why any perinatal transmission has occurred recently are generally the mother's refusal to be tested because she perceives that she is not at risk or the obstetrician/gynecologist's failure to offer the test, or to spend time with the patient to discuss the reasons for her resistance to being tested. At the present time, because of the great efficacy of antiretroviral medication in decreasing mother-to-child transmission from a rate of 1 in 3 to less

than 1 in 10, routine HIV screening for all pregnant woman is the standard of care.

BEHAVIORAL APPROACHES — OVERVIEW

Despite access to antiretroviral therapy, blood screening and treatment of sexually transmitted infections, the number of new HIV infections in the USA has remained at a plateau of approximately 40,000 new infections per year over most of the past decade. The decision to engage in HIV risk behavior is a complex one that may involve issues related to early life events (such as sexual abuse in childhood), low self-esteem, contextual issues in relationships, concomitant substance use and addiction to specific forms of sexual pleasure. Gender-related power dynamics (e.g. the role of women in many societies) may also limit opportunities to promote safer sex. Thus, no single behavioral approach will invariably lead to an adaptation of consistent safer sexual or drug using practices. Much like dieting, regular exercise and smoking cessation, no single program of HIV risk reduction will work for all at-risk individuals. However, several studies have now indicated that the provision of either individual counseling and/or small group sessions can be helpful in assisting at-risk individuals in moderating their risk.

Good elements of risk reduction programs include the ability of the counselor to approach the patient in a nonjudgmental manner to elicit a realistic assessment of the person's pattern of risk-taking behavior. Given the slow progress in the development of cheap, safe and effective vaccines, microbicides and other biologic approaches to the prevention of HIV transmission, the role of the primary care provider in patient education, discussion of risk-taking behavior, initiation of risk reduction counseling and triage to appropriate prevention services is an essential part of stopping further spread of the epidemic. In the next section, the elements of successful HIV risk reduction interventions are reviewed.

PSYCHOSOCIAL MODELS OF RISK BEHAVIOR UNDERLYING PREVENTION INTERVENTIONS

Knowledge is one aspect of HIV prevention but ongoing risk-taking is a function of many other complex psychosocial variables. The three most common models that have been employed to explain HIV risk-taking are the health belief model, the theory of reasoned action and social cognitive theory (i.e. self-efficacy models). [36] Health beliefs models emphasize the role of perceived benefits and barriers to condom use and perceived severity of and vulnerability to getting HIV.[37] In the theory of reasoned action, health behavior — condom use — is a function of intentions to use condoms and, in turn, intention to use condoms is a function of variables such as attitudes and norms regarding HIV and condom use.[38] Social cognitive models (i.e. self-efficacy) explain condom use as a function of an individual's knowledge about HIV, expectation about the outcomes of using condoms (i.e. pleasure reduction versus disease prevention) and self-efficacy — that the individual will be able to use a condom in different sexual situations.[39] [40] These psychosocial models of HIV prophylactic behavior have been tested both cross-sectionally and longitudinally in a variety of populations and are the basis of many behavioral interventions reviewed below.

Intervention models that address information, motivation and behavioral skills[41] typically take into account models of HIV risk prevention. One is the transtheoretical model of change,[42] which posits that an intervention needs to be adaptable to an individual's current readiness to change. For example, people who are currently at a 'precontemplative' level of readiness to change do not see that their behavior as problematic and do not see a reason to change; someone at a 'contemplative' level may be ambivalent about changing and someone at a 'determination or preparation' level is ready to make a commitment. Additional levels of change include 'action', 'maintenance' and 'relapse prevention', each with different suggested strategies to assist an individual in a counseling situation. Interventions based on the transtheoretical model try to move individuals to a more serious, higher level of readiness to change than where they are initially. Accordingly, an individual at an earlier level may benefit most from information and education, whereas someone

at a mid-level or higher might benefit from more intensive motivational support and skills training.

Many of the randomized controlled trials of interventions reviewed below use aspects of the transtheoretical model of behavioral change, other information-motivation-behavior skills interventions and/or variables relating to self-efficacy, health beliefs and attitudes in the risk-reduction interventions. HIV prevention studies typically collect sexual risk-taking data on HIV-negative individuals but sexually transmitted disease (STD) or HIV incidence may also be used as end points. To address the overarching public health significance of HIV, community randomized designs employ more of a wider-scale approach. These interventions are formulated to develop population-based HIV prevention approaches and compare communities that receive the intervention with another similar community that does not.

OUTCOME OF LARGE SCALE AND HIGH-IMPACT-FOR-HIV PREVENTION STUDIES IN THE USA

Trials primarily involving heterosexual individuals in STD and primary care clinics

Two different randomized controlled trials of HIV prevention interventions have examined the efficacy of risk-reduction counseling approaches in individuals at high risk for HIV infection, by studying heterosexual individuals attending STD or primary care clinics. The first study, the US National Institute of Mental Health's Multisite HIV Prevention Trial (Project Light), recruited 3,706 individuals from 37 inner-city community-based clinics in seven sites across the USA.[43] The three risk groups were:

- men presenting in an STD clinic;
- women presenting in an STD clinic; and
- women presenting in health service organizations.

All participants, at screening, reported engaging in unprotected vaginal or anal sex within 90 days. Approximately one-half were randomized to seven sessions of risk reduction counseling in a group format, and the other half to watch a 1-hour AIDS video followed by a question and answer session. Those in the intervention group reported fewer unprotected sexual acts and were more likely to use condoms consistently over the follow-up period. The intervention group also reported higher overall levels of condom use. With respect to STD infections, there were no overall differences in infection rates between intervention and control group; however, among the men who were recruited from STD clinics, there was a decreased incidence of gonorrhea.

The second large-scale study, Project RESPECT, recruited over 5,787 heterosexual HIV-negative patients who presented for care at STD clinics in across the USA.[44] Participants were randomized to a four-session ('enhanced counseling'), a two-session ('brief counseling') or a noninteractive ('didactic message') condition. The enhanced counseling was based on the theory of reasoned action and social cognitive theory, targeting variables such as self-efficacy, attitudes and perceived norms. At the various sessions, participants would set goals for a next step in risk reduction, and at the final session would interactively come up with a long-term plan. For the brief counseling, participants discussed differences between actual and perceived risk, and also worked on a next step behavioral plan. The didactic message group sought to mimic what is standard of care in most clinics. The counselor would deliver messages (noninteractively) regarding HIV prevention and the meaning of their test result. Those assigned four-session and two-session interactive interventions had fewer new HIV infections at both 6- and 12-month intervals than did those who received the noninteractive counseling. Additionally, self-reported 100% condom use was higher in both interactive counseling groups as compared with the didactic message control.

As HIV risk behavior is a necessary factor for HIV infection, the two studies taken together reveal that HIV risk reduction counseling can both increase condom use and decrease STD infections. They also provide data for the feasibility of adding risk reduction counseling to standard of care in STD and primary care clinics. However, it is not clear whether STD and primary care clinics are routinely implementing these approaches.

Trials including men who have sex with men

Individually randomized controlled trials

One of the earlier individually randomized intervention trials [45] compared an integrated cognitive-behavioral intervention to a waiting list control among 104 gay men in a metropolitan area. The integrated intervention included AIDS risk information as well as cognitive-behavioral self-management training, sexual assertion training and strategies for increasing positive social supports/relationship skills. The intervention was delivered in groups and consisted of 12 sessions. At the post-training assessment, the experimental group had fewer high-risk sexual practices and better behavioral skills for sexual coercive situations than the wait list control.

In a study of African-American men who have sex with men,[46] 318 individuals were randomized, who were recruited from bars, bathhouses, erotic bookstores, organizations for African-American men who have sex with men, street outreach and personal referrals of other participants. The study had three arms; two included cognitive-behavioral self-management training, assertion training and issues related to social identity and support. Of these two arms, one was a single session and the other was three sessions. The third arm was a wait-list control. Those in the triple session arm had strong reductions in risky behavior. Those in the single session

intervention had mild improvements with respect to frequency of unprotected anal intercourse compared with the control group.

To address issues such as attrition and dissemination of interventions, a study in London[47] examined the benefits of a 1-day workshop. Participants had an acute sexually transmitted infection and reported having unprotected anal intercourse at least once over the past year at entry. Both intervention and control participants received 20 minutes of one-to-one counseling about sexual risk behavior and could be referred for clinic-based community counseling services. At 6 and 12 months, the proportions of those who had unprotected intercourse were not different between groups. Also, those in intervention were slightly (borderline statistically significant) more likely to have a new STD.

Some have erroneously concluded, on the basis of this study, that behavioral interventions for HIV prevention do not work. Subsequent criticisms of this conclusion, however, highlight the fact that the intervention was only a one-off workshop, which is unlikely, in general, to have lasting effects.[48] [49] Given the complexity of the ontogeny of risk behavior, more than a single workshop would be necessary for high-risk individuals.

Community randomized controlled trials

One of the first community randomized controlled trials, the Mpowerment Project, studied a peer-outreach program for young gay men (aged 18–29 years), [50] which used a wait-list crossover design. The intervention involved peer outreach (training peers to spread prevention messages and to recruit more individuals to participate), small groups that focused on misperceptions of safer sex, eroticizing safer sex, verbal and nonverbal safer sex strategies, informal outreach and a publicity campaign. To assess outcome, a cohort of 300 individuals from two communities were surveyed. In the intervention community, the proportion of participants who reported unprotected anal intercourse with nonprimary partners decreased, as did the proportion of participants who reported unprotected

anal intercourse with their boyfriends. No significant changes occurred in the comparison community.

Another large-scale community randomized trial[51] involved delivering the intervention through opinion leaders (popular individuals) from the gay community in four US states. Each state randomly had both an intervention city and comparison city. In the intervention city, popular gay men were trained to spread behavior-change messages (to change norms), and in the comparison city pamphlets were placed at gay bars. The team identified 'popular' men with the assistance of bartenders in intervention city bars. The bartenders would observe their customers and record the names of individuals who were greeted most often, greeted others and seemed well-liked. Participants then completed surveys in the bars. Across all states, 1126 men completed baseline surveys and 1010 completed follow-up surveys. At 1-year follow-up, those in the intervention cities reported a significantly greater reduction in the frequency of unprotected anal sex during the previous 2 months and a significantly greater increase in condom use for anal sex compared with comparison cities. Consistent with this finding, more condoms were taken from bars in the intervention cities than in the comparison cities.

The idea of using community opinion leaders to promote HIV prevention among heterosexuals is currently being studied in five international sites — India, Russia, Zimbabwe, China and Peru. The community randomized trials among men who have sex with men validate the utility of providing HIV prevention, on a larger scale, to communities of men who have sex with men. From a public health perspective, raising awareness and changing norms regarding HIV prophylactic behavior can influence transmission rates on the community level. Although recruiting opinion leaders and/or providing an integrated prevention program involving peers, groups, workshops and outreach can be a complex undertaking, these two studies show that such efforts can be useful approaches to curtailing HIV risk-taking, which, in turn, would curtail HIV transmission.

Prevention trials for women

Individually randomized controlled trials

Several large-scale multisite studies have investigated risk reduction counseling among low-income and/or minority women. Kelly *et al.*[52] randomized 197 high-risk women from an urban primary health clinic to a cognitive-behavioral risk reduction intervention or comparison. The intervention consisted of five sessions, including skills training in condom use, sexual assertiveness, problem-solving risk, trigger self-management and peer support for change efforts. The comparison condition received three sessions covering health topics not specifically related to AIDS. Three months later, the intervention group evidenced better sexual communication and negotiation skills (assessed by role play and self-report) and less unprotected sexual intercourse. The comparison group had no changes on these measures.

A second study of HIV risk-reduction counseling among women[53] sought to adapt models of behavioral change to social and contextual variables relevant to 128 economically disadvantaged African American women between the ages of 18 and 29 years. Accordingly, the intervention used the theory of gender and power as a guide and was social skills based. It included the following components delivered in five 2-hour long sessions: ethnic and gender pride, risk reduction information, sexual assertiveness and communication training, condom use skills and norms, and cognitive coping skills, including sexual self-control. At the 3-month follow-up, women in the more intensive intervention showed increased consistent condom use, sexual self-control, sexual communication and sexual assertiveness, and partner's adoption of norms supporting consistent condom use than those in the delayed educational control.

A study of 206 pregnant inner city women randomized participants to an AIDS prevention group or one of two controls.[54] The AIDS prevention intervention consisted of four sessions, each delivered in group format, and included videos as well as group activities such as role play or discussions. Sessions also included cognitive rehearsal skills for behaviors such as using a condom during sex, aversive-conditioning segments that involved imagining a scene in which women practiced an unhealthy sexual behavior, and relapse prevention. After the intervention and after 6 month follow-up, the AIDS prevention group had increases in knowledge and safer sex behaviors in comparison with the two control groups.

Because of difficulties with retention and attrition of high-risk and hard-to-reach women in HIV prevention trials, Belcher *et al.* developed and tested the utility of a single session 2-hour one-on-one intervention using motivational interviewing and information-motivation-behavioral skills training.[55] No differences in HIV knowledge resulted but the group that received skills training and motivational interviewing showed higher levels of HIV protective behaviors than the control group, including higher rates of condom use during vaginal intercourse, demonstrating the efficacy of a brief, minimal intervention.

Carey and colleagues conducted two randomized controlled trials of an HIV risk reduction intervention using information, motivation enhancement and skills training intervention for low-income, primarily African-American women.[56] [57] In both studies, the intervention consisted of four 90-minute sessions that included personalized feedback about their HIV knowledge, risk perceptions and sexual behavior. It also included a motivational videotape, decisional balance motivational exercises (pros and cons of risky and safer sex) and the impact of HIV on other life issues. Finally, the intervention group worked on developing personalized plans for future behaviors, skills training and education. Women in the first study who received the intervention reported stronger intentions to practice safe sex and to communicate these intentions to partners, less unprotected intercourse and less substance use near the time of sexual activity; and these gains were maintained at the 3-month follow-up. In the second study, 102 women comprising a new sample were randomized. Overall, the results of the second study were corroborated.

Taken together, the series of randomized controlled trials of HIV prevention counseling for high-risk women demonstrate both the feasibility and the efficacy of such approaches. While many of these approaches are useful, some may be difficult to disseminate. The utility of the single-session intervention provides support for its further replication.[55] This and the others, however, require special training, and most require a significant expenditure of time by both the participants and the counselors. Future study of individually administered interventions should now focus on ways to implement and disseminate interventions in community-based settings.

Community randomized controlled trials

To attempt to address some of the limitations of clinic-based intervention approaches for women, two studies of community randomized trials have been undertaken. The first used nine low-income housing developments[56] and nine demographically matched control developments. The community-level intervention included workshops and community HIV prevention events implemented by popular opinion leaders within each community. The researchers identified opinion leaders by including questions in the baseline survey — asking each participant to name up to five women whom they liked and trusted most. The women in the housing developments (n = 690) were surveyed at baseline and 1 year later. This revealed that women in the intervention communities showed better decreases in unprotected sex (past 2 months) and frequency of unprotected acts.

A second community-based randomized control trial targeted low-income, primarily African-American women in four urban settings.[57] Four communities in

metropolitan areas were selected: two public housing communities, a low-income neighborhood and a group of inner-city neighborhoods. The intervention was specifically based on the transtheoretical model of change, attempting to reach women who would be at different levels of readiness to change. The intervention consisted of distribution of HIV prevention materials, developing a peer network of community organizers and businesses, and delivering prevention messages by outreach specialists, both individually and in groups. The intervention communities evidenced increases in talking with main partners about condoms and trying to get main partners to use condoms.

Prevention interventions specific to injection drug users

A recent review of 42 studies between 1989 and 1999 suggested that the majority found that needle-exchange programs prevent HIV risk behavior and seroconversion among injection drug users.[58]

Most of the other studies of HIV prevention interventions for drug users are observational or quasi-experimental evaluation studies, which show within-participant reductions in HIV risk behavior.[59]

The SAFE study was a randomized controlled trial of 117 HIV-negative injection drug users who had reported that they had used and shared injection drugs in the previous 6 months.[60] The innovative experimental condition was to have injection drug users bring in the members of their drug network whom they had previously listed in an interview. The index participant and his or her drug network members received a manualized intervention delivered by former heroin users who had stayed in contact with active drug users in their community. The intervention consisted of six sessions that involved recognizing personal risk, committing to practicing both individual and group vigilance toward risk reduction, making plans (and discussing previous plans), assertiveness skills and role play of real-life situations that would involve risk (e.g. one member wanting to share without cleaning). The comparison group received counseling and testing. At the 18-month outcome assessment, the experimental group had significantly less needle sharing and less sharing of cookers for the prior 6 months.

Although innovative and useful, this intervention was arguably hard to deliver. Some 22% of potential index participants did not return with members of their drug network and another 36% did bring in at least one other drug network member but did not ever start the sessions.

Other studies and less extensive interventions have revealed mixed results at best. Kwiatkowski and colleagues did not find differences in high-risk behaviors among 3357 injecting drug users, not in treatment, randomized to standard or enhanced interventions.[61] [62] In general, individuals in this study maintained risk behavior and the authors concluded that new and creative ways to target this population were needed. Another similar study of standard and enhanced interventions for out-of-treatment drug users found both interventions to be at least moderately effective in reducing risk but less so than with sexual risk.[63] Gibson and colleagues [64] studied 295 individuals who were in treatment for heroin detoxification. Participants were randomized to counseling or brochures. Although differences between groups did not emerge, self-reported decreases in injection-related and sexual risk behaviors were present in both groups 6 and 12 months later. However, it is notable that, in this study, participants were acutely presenting for treatment of drug abuse and may have been more motivated to change than those not already in treatment.

Among the studies of prevention interventions for injection drug users, methodologies differ and, consequently, so do the results. Sexual behavior, as shown in previous sections, is a difficult and complex behavior to change. When co-morbid with drug dependence or addiction, its complexity grows; intensive multimodal interventions currently show the most utility in this population.

SUMMARY

Behavioral interventions to decrease HIV transmission have been successful in a wide array of settings and with diverse populations. However, in most situations, interventions were needed to sustain behavior change. Moreover, there is limited experience with these interventions in parts of the world where the epidemic is spreading most rapidly and where the social construction of reality (e.g. disempowerment of women, limited health care infrastructure) may limit the effectiveness of programs developed in resource-rich settings. Clearly, additional work is needed to develop culturally specific behavioral interventions, while the development of more effective biologic prevention modalities (i.e. microbicides and vaccines) is underway.

Chapter 117 - Preventing Occupational Infection with HIV in the Health Care Environment

David K Henderson

This chapter addresses strategies designed to prevent the transmission of HIV in the health care setting.

EPIDEMIOLOGY

Occupational risks, including risks for physical injuries, chemical exposures and infectious diseases, have long been prevalent in the health care workplace. The introduction of HIV infection into the health care workplace in the 1980s, however, focused the attention of health care providers, perhaps for the first time, on the issue of occupational risk. Ironically, HIV infection is only one of the blood-borne pathogen-associated risks in the health care setting. Blood-borne pathogens have been identified as occupational risks for health care workers since the epidemiology and routes of transmission of hepatitis B were delineated in the 1960s. For reasons incompletely understood at present, unlike occupational hepatitis B virus infection, occupational HIV infection remains relatively uncommon. Even with broad use of the hepatitis B vaccine, occupational hepatitis B virus infections continue to occur in US health care workers.

By June 2001, the US Public Health Service's Centers for Disease Control and Prevention (CDC) had recorded only 57 instances of documented occupational HIV infections and 138 instances of probable or possible occupational HIV infections among health care workers in the USA.[1] For each of these 57 cases, the health care worker sustained an occupational exposure to HIV, had a baseline serum sample drawn and evaluated by HIV serology and then, during follow-up, developed serologic evidence consistent with HIV infection. Fewer than 50 additional cases of documented occupational infections and approximately 60 instances of 'possible or probable' occupational infections have been reported from outside the USA. For the 138 'possible or probable' occupational infections reported to the CDC, the exposed health care workers either were unaware of the occurrence of an occupational exposure, did not report the exposure and/or did not have baseline serologic studies performed to document that they were not infected prior to the occupational exposure.

A comparison of the demographics of the 'possible/probable' and definite occupational infection cases reveals substantial differences. When one compares the demographics of these categories of infection with those of all health care workers in the USA, the likelihood that some of the 'possible/probable' cases have occurred as a result of community exposures seems quite high.[2]

A number of both general and specific factors, taken together, determine an individual practitioner's risk for occupational infection with HIV. First, the prevalence of HIV infection among the population of patients served is a major determinant of the overall risk. Second, the type of practice in which the provider engages (e.g. medical, emergency room, surgical) is associated with varying levels of risk for occupational exposure to blood-borne pathogens. Third, the types and frequencies of procedures performed in the practice, as well as the conditions under which the procedures are performed (i.e. emergent versus elective), also contribute to the risk equation. The extent to which the practitioner adheres to recommended infection control procedures and practices is also likely to be a determinant of risk for exposure and infection. Finally, the individual practitioner's technique and attention to detail are also likely contributors to the risk.

Several specific factors contribute to the risk for occupational HIV infection in the health care workplace. Table 117.1 and Table 117.2 list factors that have been demonstrated[3] or suggested in the literature to contribute to the risk for occupational infection with HIV.

Many of the reported cases share several features in common. Most are transcutaneous exposures and the majority of these are injection needlestick injuries. All of the clinical cases have occurred following exposure to blood or grossly blood-stained bodily fluids from HIV-infected patients. As yet, no cases have been documented following a needlestick injury with a solid surgical needle.

To attempt to identify specific factors associated with risk for occupational HIV infection, public health authorities from the USA, France and the UK conducted a retrospective case-control study, matching the known anecdotal case reports of occupational HIV infections with 'controls' from the public health surveillance studies of occupational exposures in each of these countries.[3] This study identified five specific risk factors for occupational infection; these five factors and the level of statistical significance assigned to each in the study are listed in Table 117.2 . The first four of these factors very likely relate directly to the inoculum effect. That an inoculum effect is present in this setting is supported by several pieces of information:

- transfusion of a unit of blood from an HIV-infected donor is associated with virtually 100% risk for infection;[4]
- the depth of a percutaneous exposure is an independent risk factor for occupational HIV infection;[3]
- the presence of visible blood on the device producing the injury was independently associated with risk for infection;[3]
- instruments that had been placed in source-patients' vascular channels were more likely to result in occupational infection;[3] and
- the fact that all of the needlestick exposures to blood have been caused by hollow-bore needles (i.e. injection, as compared with suturing needles).

Both in the CDC study, as well as in the majority of the anecdotal case reports, the source-patients for the exposures resulting in occupational HIV infections had advanced HIV disease. This finding is likely to be a surrogate marker for either the level of circulating viremia, the level of circulating 'free' virus, or both. Finally, most occupational infections have followed parenteral (as compared with mucosal or cutaneous) occupational exposures. These latter routes of exposure are associated with lower risks for occupational infection.

Percutaneous exposure

Several longitudinal studies have attempted to determine the magnitude of risk associated with different types of occupational exposures (summarized by Ippolito *et al.*[5] and Henderson[6] . Combining

TABLE 117-1 -- Factors contributing to the risk for occupational HIV infection.

FACTORS CONTRIBUTING TO THE RISK FOR OCCUPATIONAL HIV INFECTION
Exposure factors
1. Route of exposure (e.g. percutaneous,* mucous membrane, cutaneous)
2. Inoculum size
• Size of the device producing injury
• For needlestick exposures, type of needle (i.e. hollow-bore* vs solid)
• Extent of contamination (e.g. visible blood on device,† whether or not device had been placed in an artery or vein†)
• 'Depth/severity' of exposure* †
• Type of contamination (e.g. blood,* pleural fluid, etc.)
Source/'donor' factors
1. Extent of viremia (e.g. by polymerase chain reaction or branch-chain DNA assay)
2. Stage of illness (as a presumed surrogate for extent of viremia†)
3. Circulating free (as opposed to cell-associated) virus
4. Antiretroviral chemotherapy (presumably reducing level of viremia)

* Features shared by many, if not most, of the occupational infections reported in the literature
† Features identified as significantly associated with risk for occupational infection in the CDC case-control study[3]

the data from the available studies, health care workers have sustained more than 6800 percutaneous exposures to sharp devices contaminated with blood or other

blood-stained body fluids from patients known to be infected with HIV. Twenty-one occupational HIV infections have been documented in these studies, resulting in a risk of transmission per injury of 0.31% (Table 117.3). Thus, one in 324 parenteral exposures in these studies resulted in occupational HIV infection.

Although such a pooled risk estimate provides the best available data concerning the magnitude of risk for occupational HIV infection, this type of analysis has substantial limitations. For example, the longitudinal studies vary somewhat in experimental design and are therefore not directly comparable. Such an analysis implicitly assumes that all parenteral occupational exposures are associated with equal risk, an assumption that does not make intuitive sense and that has apparently been shown to be flawed by the CDC's case-control study cited above.[3] Similarly, all source-patients are also not likely to present the same level of risk for occupational infection, with patients with advanced disease (and high-grade viremia) more likely to transmit than are patients early in the course of HIV infection (see Table 117.2). Because of the large number of factors that influence the risk for occupational infection, these summary data cannot address the risk associated with a specific, discrete exposure in an individual health care worker.

Mucous membrane exposure

Occupational exposures other than parenteral exposures to blood present a lower level of risk for occupational infection. Anecdotal reports document, in rare circumstances, that mucous membrane or cutaneous exposures may produce occupational infections in health care workers.[7] Certain of the longitudinal studies cited above have also addressed occupational risks associated with mucous membrane exposure to blood from HIV-infected patients. To date, with more than 2700 exposures followed prospectively, only one study has reported a seroconversion following a mucous membrane exposure.[8] Thus, as a maximum estimate, (using the 'rule of three' as an approximation for a zero numerator),[9] the pooled risk estimate for infection associated with a mucous membrane exposure is 0.11%

TABLE 117-2 -- Risk factors for occupational HIV infection identified in a retrospective case-control study conducted in the USA, UK and France.[3]

RISK FACTORS FOR OCCUPATIONAL HIV INFECTION IDENTIFIED IN A RETROSPECTIVE CASE-CONTROL STUDY
The risk for occupational HIV infection was increased when:
• the occupational exposure was deep, as compared with superficial (p<0.0001)
• blood was visible on the device causing the occupational exposure (p=0.0014)
• the device causing the exposure had been placed in a source-patient's vein or artery (p=0.0028)
• the source-patient died within 60 days of the exposure (p=0.0011)
• the exposed health care worker did not take zidovudine postexposure chemoprophylaxis (p=0.0026)

TABLE 117-3 -- Occupational risks for HIV infection.

OCCUPATIONAL RISKS FOR HIV INFECTION		
	Percutaneous exposures	**Mucous membrane exposures**
Number of longitudinal studies	27	21
Number of exposures	6807	2768
Number of documented infections	21	0/1*
Infection rate per exposure	0.31%	0–0.11%†

* See text for discussion
† Using the rule of three[9]

per exposure (see Table 117.3). Again, such a pooled risk estimate provides only a framework for considering the risks associated with a discrete exposure.

Occupational exposures other than percutaneous and mucous membrane exposures

Occupational exposures other than percutaneous and mucous membrane exposures are even less likely to result in infection. Prospective studies,[10] [11] which include hundreds of person-years of follow-up, have not identified a single instance of transmission of HIV. Whereas exposures to other fluids are likely to be associated with some occupational risk, this risk is below currently measurable levels.

When one evaluates the occupational exposures that have produced infection, almost all of them result from exposure to blood from HIV-infected patients. Whereas other body fluids may ultimately be shown to represent a risk for occupational infection, the major risk in the health care setting has come from occupational exposures to blood from HIV-infected patients.

PATHOGENESIS

Although the retrospective case-control study of risk factors for occupational HIV infection cited above[3] provided some insight into factors associated with risk for occupational HIV infection, the precise pathogenetic mechanisms of the occupational infection event are, as yet, poorly understood. The major risk for occupational infection is associated with percutaneous injury with a needle or other sharp device that has been used on an HIV-infected patient. The risk is associated primarily with blood exposure. Precisely how the transmission event occurs in the skin, subcutaneous tissue or

underlying muscle remains unclear. Current interest in the pathogenesis of infection by this route focuses on the role of host defense and on the role of the dendritic cell.

The role of host defense in protection against occupational infection is poorly understood. Scientists working at the National Cancer Institute have demonstrated that 75% of health care workers exposed to blood from HIV-infected patients who do not become infected with HIV develop HIV-specific T-helper activity.[12] In a subsequent study these investigators demonstrated that 35% of uninfected health care workers who had sustained occupational exposure to blood from HIV-infected patients studied developed cytotoxic lymphocyte responses to HIV-related envelope antigens. [13] Among health care workers who had sustained occupational exposures to blood from patients who were not infected with HIV, none responded to HIV-associated envelope antigens. Whereas the precise role that cellular immunity plays in host defense against occupational HIV infection remains to be delineated, these data, when combined with results from animal studies, suggest that the role may be an important one. One recent case report also supports a significant role for cellular immunity in the defense against HIV infection.[14] In this case, a health care worker who sustained an HIV needlestick exposure had HIV DNA detected by nucleic acid sequence-based amplification during a course of three-drug antiretroviral postexposure chemoprophylaxis. Despite the detection of proviral DNA, this individual ultimately remained uninfected (as assessed by serial nucleic acid tests and antibody determinations). The health care worker did, however, develop a robust HIV-specific cellular immune response.

INTERVENTIONS DESIGNED TO DECREASE THE RISK FOR OCCUPATIONAL HIV INFECTION

Interventions designed to limit occupational exposures

Several approaches have been used to attempt to decrease risks for occupational exposure to (and therefore occupational infection with) blood-borne pathogens in the health care setting (Table 117.4). Such

TABLE 117-4 -- Prevention strategies for health care workers and institutions to decrease risks for occupational HIV infection.[2]

PREVENTION STRATEGIES FOR HEALTH CARE WORKERS AND INSTITUTIONS TO DECREASE RISKS FOR OCCUPATIONAL HIV INFECTION
1. Use of 'standard precautions' or other isolation procedures designed to place effective barriers between the health care worker and blood or other body fluids.

2. Educating new staff and retraining existing staff regarding occupational risks for blood-borne pathogen infection in the context of other occupational risks present and prevalent in the health care workplace; making certain staff are aware of these risks.
3. Including information about all occupational risks (including those associated with caring for patients who have blood-borne pathogen infections) in biomedical training schools' curricula.
4. Evaluating all procedures associated with occupational risk for exposure to blood-borne pathogens (particularly those presenting risks for transcutaneous exposures), with the intent of modifying the aspects of these procedures associated with risks for occupational exposures.
5. Aggressive use of newly developed engineered controls, including careful evaluation of 'safety devices' for safety, efficacy and cost-effectiveness; implementation of those devices that meet these tests.
6. Development of efficient, readily accessible, user-friendly institutional postexposure management systems, including the option for postexposure antiretroviral chemoprophylaxis for documented occupational HIV exposures.

interventions can be considered as primary prevention. Major categories of intervention include:

- education,
- work practice controls (e.g. adherence to infection control procedures designed to limit risk), and
- engineered controls.

Education and use of infection control procedures

Staff should be routinely informed about all occupational risks. Since the major risk for occupational HIV infection (and for infection with other blood-borne pathogens as well) is by parenteral inoculation, some critics of the use of infection control procedures for managing all patients as if they were potentially infected with blood-borne pathogens (e.g. universal precautions, body substance isolation, standard precautions (discussed below)) have suggested that these precautions will have little impact on the number of occupational infections. However, since these and later guidelines educate staff about the careful handling of needles and sharp objects, recommend against practices associated with a high risk for parenteral exposures (e.g. needle recapping, needle bending or needle clipping) and stress appropriate disposal of needles and other sharp objects,[15] [16] their implementation will probably be associated with a decreased parenteral exposure rate. Two centers have documented a significant decrease in such exposures,[17] [18] one in temporal association with training in, and implementation of, universal precautions. [17] Up to one third of parenteral occupational exposures may be preventable by following guidelines designed to minimize occupational exposures.[19] The use of appropriate barriers may actually reduce occupational risk; the act of piercing a latex glove with a needle covered with blood may reduce the blood inoculum by as much as 50%.[20] Making health care workers aware of the presence of occupational risks may, in itself, result in occupational behavior modification. In a survey of certified nurse-midwives, both knowledge of the routes of transmission of blood-borne pathogens and perception of risk for occupational infection were statistically associated with the appropriate use of precautions. However, risk perception and use of precautions were more closely linked, suggesting that knowledge, in itself, may be insufficient to produce behavior modification.[21]

Employers in the USA are governed by regulations issued by the Occupational Safety and Health Administration of the US Department of Labor in 1991. One regulation mandates that employers follow certain protocols when managing health care workers who have sustained occupational exposures to blood-borne pathogens. [22] This 'final rule' has become the subject of mandatory education for health care workers at every health care institution in the USA.

Work practice controls

In 1987, the CDC issued guidelines for the management of patients infected with blood-borne pathogens that have since provided the underpinnings for all subsequent guidelines in the USA.[15] These 'universal precautions' guidelines set out clearly the principle that health care workers should treat blood and blood-stained body fluids from all patients as potentially infectious, in order to prevent the transmission of blood-borne pathogens (in particular, HIV) from patients to health care workers. More recently, the CDC has issued revised isolation guidelines, called 'standard precautions', which focus on the bidirectional spread of organisms to and from patients and health care providers.[16] All of these sets of guidelines and precautions emphasize:

- that blood and other blood-containing body fluids represent risk to health care workers, and
- that health care workers should use barriers and take precautions to prevent occupational exposures to these materials.

Use of these kinds of precautions in health care settings has resulted in decreased risk for occupational exposure to blood and, presumably, decreased risks for occupational infections with blood-borne pathogens.

Based on self-reports of occupational exposures to blood, Fahey and co-workers at the National Institutes of Health estimated that, in the year prior to training the staff in universal precautions, staff members experienced an average of 36 cutaneous exposures to blood.[23] Eighteen months after the staff were trained in universal precautions, this number decreased to 18. For all categories of employees and information analyzed, exposures to blood were reduced by approximately 50%. These results suggest that changes in behavior occurred between the two surveys, and, although a causal relationship with training cannot be proved, such a relationship can reasonably be inferred.

Compliance with these precautions has been problematic. Gerberding and co-workers identified substantial noncompliance at San Francisco General Hospital. [24] Although Fahey identified substantial improvement in her staff's compliance with universal precautions, the reduction in blood exposures was only 50% (implying that 50% of such exposures continued to occur, despite implementation of these precautions).[23]

Although data regarding procedure-specific adverse exposure rates are limited, certain procedures and devices seem intrinsically associated with increased risk for occupational exposures. To the extent that such modifications are possible, inherently risky procedures should be modified. In some instances, risk modification can be achieved by practitioners modifying the procedure themselves. In other circumstances, new devices or engineering controls (discussed below) may be needed. Some work practice interventions have been shown to reduce the risks for blood exposures. For example, the use of 'double-gloving' in surgery reduced the risk for skin exposure to blood significantly.[25] [26]

Engineered controls

Whereas work practice controls can eliminate a substantial fraction of occupational exposures to blood-borne pathogens, modifying medical devices that, in their current formats, are intrinsically associated with exposure risks can reduce these risks further. Among authorities in the field, Jagger and co-workers detailed the importance of the design of medical devices in the prevention of occupational exposures to blood-borne pathogens.[27] [28]

In the past several years, a number of engineered controls (i.e. presumably 'safer' devices) have been introduced. Of these new safety devices, the following have been identified in at least one published study as being associated with decreased risks for cutaneous and/or percutaneous blood exposures:

- a surgical repair assist device,
- blunt surgical needles,
- surgical finger guards and glove liners,
- phlebotomy equipment,
- needleless intravenous administration systems, and
- modified (e.g. self-capping) intravenous catheters.

Despite their implementation, some exposures will still occur. Development of a process for the systematic, objective evaluation of these devices is crucial to effective risk reduction for all health care institutions.[29]

Interventions designed to decrease the risk for occupational infection once exposure to HIV has occurred

Immediate postexposure management

Despite the emphasis on the prevention of occupational exposures, institutions should also develop strategies for managing occupational exposures effectively. Important constituents of a postexposure management program are listed in Table 117.5 .

Health care workers must be educated about the importance of reporting occupational exposures. Institutional reporting procedures should be simple, straightforward and widely publicized. When an exposure occurs, first aid should be administered and the exposure site should be allowed to bleed freely. The wound should be cleansed and decontaminated as soon as patient safety permits. Wounds should be washed with soap and water and then irrigated with sterile saline, a disinfectant or other suitable solution. Mucosal exposures should be decontaminated by vigorously flushing with water. Eyes should be irrigated with clean water, saline or sterile eye irrigants.

Exposures should be reported promptly. A mechanism to facilitate reporting and provision of follow-up care should be both readily accessible and widely publicized. Reporting systems should offer access to expert consultants. Institutional occupational medical systems must protect the confidentiality of the exposed worker. If confidentiality is not preserved, institutional programs are doomed to failure.

At the time an exposure is reported, occupational medical personnel should draw baseline serologies and chemistries. For documented

TABLE 117-5 -- Components of postexposure management programs for health care workers exposed to HIV.

COMPONENTS OF POSTEXPOSURE MANAGEMENT PROGRAMS FOR HEALTH CARE WORKERS EXPOSED TO HIV
1. Institutions should develop thorough, thoughtful, aggressive, employee educational campaigns concerning the presence of occupational risks in the health care workplace, including the risks for blood-borne pathogen infection; these educational campaigns should emphasize risk prevalence, risk reduction strategies, the importance of reporting adverse occupational exposures and postexposure management protocols.
2. Postexposure management systems must include mechanisms to facilitate both exposure reporting and the provision of follow-up care; these systems should be readily accessible, widely publicized, convenient and user friendly; occupational medicine personnel should be instructed to provide immediate 'first aid' for staff sustaining adverse exposures to blood and body fluids.
3. Institutions should develop a system for categorizing occupational exposures that require differing management strategies and different types of follow-up; protocols should address 'source-unknown' and 'source refuses serologic testing' exposures.
4. Postexposure management protocols should include appropriate serologic testing (mindful of state and local laws regarding consent) of both the source-patient as well as the employee sustaining the occupational exposure.
5. Occupational medicine staff should be thoroughly trained in the counseling of staff sustaining occupational exposures to HIV; all exposed staff should be given appropriate counseling regarding risks for infection and prevention of secondary transmission; all staff should have access to further counseling, if needed; all exposed staff should be given access to experts in the areas of occupational risks and HIV infection.
6. Exposed employees should be counseled to return for appropriate clinical and serologic follow-up and should be instructed to return if signs and/or symptoms of the acute primary HIV infection syndrome should develop.
7. Postexposure management protocols should offer antiretroviral chemoprophylaxis, with appropriate follow-up, for health care workers sustaining occupational exposure to HIV.
8. Counseling should include attention to the known/expected toxicities of the selected regimen. Pre-emptive therapy of these symptoms/side-effects (e.g. prescriptions to treat nausea, diarrhea, etc.) may increase regimen adherence.
9. Postexposure management protocols must, at all costs, maintain the exposed health care worker's medical privacy and confidentiality.

occupational exposures to HIV, follow-up should occur at 6 weeks, 3 months, 6 months and 1 year following exposure. The value of the 1 year follow-up visit remains somewhat controversial; however, some case reports of late seroconversion (i.e. more than 6 months following exposure) have now appeared. More aggressive diagnostic evaluation, such as the use of polymerase chain reaction analysis to detect viral or proviral nucleic acids, is ordered if the health care worker develops symptoms suggestive of acute, primary HIV infection (i.e. the seroconversion illness). Institutions must develop policies regarding the testing of source-patients and employees that are consonant with local and state laws. Occupational medicine staff should counsel the exposed health care worker about the signs and symptoms of the seroconversion illness and should instruct the employee to return for evaluation should any illness consistent with this syndrome occur.

Postexposure chemoprophylaxis with antiretroviral agents

The use of antiretroviral agents as postexposure chemoprophylaxis for occupational exposures was controversial from its inception.[30] Data accumulated over the past 10 years, however, provide a firmer foundation for postexposure chemoprophylaxis programs. Recently, several animal studies of postexposure chemoprophylaxis (most of which use substantially lower viral inocula) have been able to demonstrate efficacy. Another piece of scientific evidence that indirectly supports its use comes from the success of antiretroviral agents administered in pregnancy in reducing maternal-fetal transmission of HIV[31] [32] (see Chapter 135). One of the factors identified in the collaborative retrospective case-control study as significantly associated with an increased risk for occupational HIV infection was 'not taking zidovudine chemoprophylaxis'.[3] In this study, administering zidovudine chemoprophylaxis to exposed health care workers was associated with an approximately 80% reduction in the risk for occupational infection following transcutaneous exposures to HIV.[3]

The US Public Health Service has published guidelines that recommended the use of postexposure antiretroviral chemoprophylaxis in some settings.[33] The current recommendations (summarized in Table 117.6) advocate the use of three agents (zidovudine, lamivudine and one of four additional agents (see Table 117.6)) for the most severe occupational exposures and the use of two of these agents (i.e. zidovudine plus lamivudine) or one of two other alternative two-drug regimens for lesser exposures. If the source-patient for an exposure is (or recently has been) receiving antiretroviral therapy, some authorities have recommended the use of alternative regimens

TABLE 117-6 -- Current US Public Health Service recommendations for chemoprophylaxis of occupational exposures to HIV.[33]

CURRENT US PUBLIC HEALTH SERVICE RECOMMENDATIONS FOR CHEMOPROPHYLAXIS OF OCCUPATIONAL EXPOSURES TO HIV		
HIV exposures with a recognized transmission risk	'Basic regimen'	Zidovudine (ZDV) plus lamivudine (3TC)
	Alternative	Stavudine (D4T) plus lamivudine
	'Basic regimen'	Stavudine plus didanosine (ddI)†
HIV exposures for which the nature of the exposure suggests an elevated transmission risk*	'Basic regimen' plus one of the following agents	Indinavir†
		Nelfinavir
		Abacavir
		Efavirenz†

† Agents not advisable for use in pregnancy and increasingly not recommended in practice
* Elevated risk is associated with 'larger' volume of blood and/or blood containing a high titer of HIV

comprising agents to which the source-patient's virus has not been exposed, tailoring the construction of the regimen in a fashion similar to the planning of 'salvage therapy' for active HIV infection.

This latter point underscores the importance of obtaining expert guidance from individuals knowledgeable about the use of anti-retroviral agents in tailoring a regimen

for a health care worker, especially in circumstances in which the source-patient is known or highly suspected to harbor a resistant virus. Clinicians who are skilled in providing care to HIV-infected patients are perhaps best situated to provide this kind of advice. If you cannot identify a local expert, the US Public Health Service sponsors a postexposure hotline that can provide this expertise (either over the telephone (888-448-4911) or via the World Wide Web at http://pepline.ucsf.edu/pepline). Recently, the use of nevirapine has been contraindicated because of the risk of severe liver toxicity, which can include hepatic failure.[34]

Another special circumstance worthy of additional consideration relates to the administration of postexposure prophylaxis to a health care worker who is (or thinks she may be) pregnant. Because of our extremely limited experience with the use of these agents in uninfected individuals, the risks associated with administering the drugs to pregnant women are essentially undefined. The only relevant clinical experience in humans comes from the administration of the drugs to HIV-infected pregnant women, a circumstance that is not exactly consonant with the postexposure prophylaxis setting. Based on the limited clinical data, as well as several relevant animal studies, general guidelines for this situation have been developed and are summarized in Table 117.7 . [33] [35]

Virtually all of the marketed antiretroviral agents have potential for carcinogenicity, teratogenicity and mutagenicity. Efavirenz has been shown to be teratogenic in cynomolgus monkeys at drug levels similar to those in humans. In addition, administration of the didanosine/stavudine combination in pregnancy has been associated with cases of severe pancreatitis and severe lactic acidosis among

TABLE 117-7 -- General principles for administering antiretroviral chemoprophylaxis to pregnant health care workers.[33] [35]

GENERAL PRINCIPLES FOR ADMINISTERING ANTIRETROVIRAL CHEMOPROPHYLAXIS TO PREGNANT HEALTH CARE WORKERS
1. A pregnant, exposed health care worker is the only person who can decide whether to take chemoprophylaxis, and she must be empowered to make this decision. No one should attempt to make this decision for her.
2. The practitioner providing care to a pregnant, HIV-exposed woman must provide up-to-date and accurate information about what is known (and not known) concerning:
• the magnitude of risk for infection associated with her exposure;
• the efficacy of postexposure prophylaxis;
• the safety of the treatment, including the potential for harm to the health care worker and her fetus; and
• the risk of the fetus becoming infected (and the possible interventions that could be taken to reduce this risk) should the health care worker become infected from the exposure.
3. The practitioner should select a regimen appropriate for the exposure (i.e. pregnancy per se should not dictate the regimen, but consideration should be given to agents for which an experience base exists (e.g. zidovudine and lamivudine)). Some agents/regimens (i.e. those with known toxicities in pregnancy) should be avoided whenever possible (e.g. didanosine plus stavudine; efavirenz, indinavir).
4. Pregnant workers electing to take postexposure chemoprophylaxis must be followed closely for signs of toxicity (both maternal and fetal); pregnancy represents another circumstance in which expert consultative advice is essential.

HIV-infected women, and both maternal and fetal deaths have been recorded.[36] Other issues that may be relevant to the administration of chemoprophylaxis to pregnant health care workers include data from France suggesting a risk for severe mitochondrial toxicity in uninfected infants born to mothers who had taken nucleoside analogues [37] (an experience that has not been detected in the USA) as well as the potential for hepatotoxicity and nephrolithiasis associated with indinavir use.

Despite the encouraging data concerning the use and efficacy of postexposure antiretroviral chemoprophylaxis, legitimate concern remains about the use of these agents in this setting. Antiretrovirals are not trivial agents in terms of potential toxicity. Toxicity data in healthy individuals, especially for the newer agents, are extremely limited; however, it is fair to emphasize that virtually all the studies of antiretroviral chemoprophylaxis for occupational HIV exposures in health care workers have demonstrated substantial side-effects, often limiting completion of the prescribed regimen.[38] Finally, several cases of zidovudine chemoprophylaxis failure (eight of which have direct clinical relevance) have appeared in the literature.

The US Public Health Service last revised its guidelines concerning postexposure prophylaxis in 2001[33] and intends to revise the guidelines whenever new information becomes available concerning the risks or benefits of postexposure chemoprophylaxis. In spite of these considerations, all institutions need to have a policy on postexposure prophylaxis. Offering chemoprophylaxis is seen as 'empowering' by exposed workers. Workers who have had these frightening occupational exposures appreciate the fact that their institutions are willing to offer these drugs.

THE NEED FOR A VACCINE TO PREVENT HIV-1 INFECTION AND AIDS

Identification of HIV-1 as the cause of AIDS led to development of methods to diagnose the infection, quantify the virus in plasma and cells and document the evolution of the disease and treatments. Understanding the mode of transmission has led to some success in prevention, through interventions such as screening of the blood supply, drug treatment for pregnant women and promotion of barrier methods and safe sex. Despite these modest gains, the epidemic has moved with a speed that defies imagination. The hardest-hit countries, in sub-Saharan Africa, have experienced enormous losses, with up to half the young adults infected in some areas and the average lifespan decreased by as much as two decades.[1] The epidemic in Asia threatens to dwarf that in Africa. Meanwhile, in the USA, hard-won gains in education and behavioral prevention seem to be slipping away; infection rates are increasing in certain groups, particularly young gay men and minority women. [2] An effective vaccine is needed more than ever to stop the growth of this epidemic.

PROSPECTS FOR SUCCESS

HIV-1 is a formidable challenge for vaccine prevention programs, from the standpoint of science, development and eventual utilization of a safe and effective vaccine. Its immune evasion mechanisms include molecular tricks to avoid neutralization by antibody, down-regulation of immune functions, direct destruction of the CD4 T cells

TABLE 118-1 -- Evidence that an HIV-1 vaccine is possible.

EVIDENCE THAT AN HIV-1 VACCINE IS POSSIBLE			
Setting	**Type of evidence**	**Conclusion**	**Strength of evidence***
Human epidemiology	Studies of adults repeatedly exposed to HIV-1 by sex or injections and infants exposed during birth or nursing	Infection occurs infrequently after exposure; risk depends on quantity of virus	+++
	T-cell responses reported in some exposed but uninfected persons	T-cell responses are induced by exposure to HIV-1 (abortive infection?)	+
Natural history of HIV-1 infection in humans (and related viruses in animal models)	Virus concentration in blood is very high during acute infection, then drops as T-cell responses appear	T-cell responses induced by infection partially control viral replication, usually for years	+++
	Virus concentration in blood increases late in infection when T-cell levels are very low	T-cell responses control viral replication	+++
	Prompt postexposure drug treatment can prevent or abort infection	A small number of infected cells can be destroyed (by immune mechanisms)	++
Studies of active and passive immunization in animal models	Passive antibody transfer or monoclonal antibody infusion	Antibodies prevent infection (probably by neutralizing the virus)	++
	Vaccination with antigens inducing CD8 T cells or depletion of CD8 T cells in infected animals	T-cell responses limit viral replication after challenge	+++
		T-cell responses slow progression to disease	+++

* Evidence is strong when most or all of several studies lead to the same conclusion; evidence is weaker when there are few or conflicting studies. The evidence has recently been reviewed. [4]

that support both antibody and effector T-cell responses, and a very rapid mutation rate that gives rise to virus strains lacking the antigenic markers (epitopes) to which effective immune responses are directed. Nevertheless, there is evidence that immunity can prevent establishment of infection in exposed persons. The immune responses induced by acute infection clearly establish some control of HIV-1 replication. Vaccine-induced immunity could more frequently prevent or more effectively control virus replication. Limiting virus replication could, in turn, delay disease onset and reduce transmission of HIV-1 to sexual partners, infants or other contacts. Even a modest reduction in the susceptibility to infection or likelihood of transmission could have a significant impact on the HIV-1 pandemic.[3] A reduced replication rate might also diminish the ability of HIV-1 to develop mutations leading to drug resistance or escape from immune responses.

Three types of evidence suggest that vaccines will be effective in preventing HIV-1 infection and/or AIDS (Table 118.1). First, chronic infection with HIV-1 occurs after only a small fraction of all exposures, suggesting that a modest immune defense might be effective. [5] This reasoning is supported by the apparent resistance to infection of some persons who are repeatedly exposed to HIV-1.[6] Cell-mediated immune responses in exposed but uninfected individuals are thought to be induced by autologous infected cells, suggesting that, prior to the establishment of a chronic HIV-1 infection, there may be a brief phase in which the infection can be aborted, perhaps by immune destruction of the infected cells.[7] Second, the natural history of HIV-1 infection shows that, after an initial phase of rapid viral

replication, immune responses may control HIV-1 replication and slow its pathogenic effects for many years.[8] [9] Third, nonhuman primate models (e.g. SIV in macaques or the man-made chimeric SHIV in macaques) show that some vaccines given prior to challenge can prevent infection or slow viral replication and disease progression,[10] [11] [12] [13] an effect dependent at least in part on CD8 effector cells.[14] [15] Likewise, antibodies that are able to neutralize HIV-1 or SHIV can prevent infection in animal models.[16] [17] [18] [19] Immunization that induces mucosal responses is particularly effective against mucosal challenges.[20]

SCIENTIFIC BASIS FOR HIV VACCINE DEVELOPMENT

Immune targets in the HIV infection process

The HIV-1 replication cycle begins with the envelope protein binding to receptors on the host cell surface (CD4, a chemokine receptor molecule, or both) and fusing with the cell membrane, resulting in virus entry and introduction of the viral genetic material into the host cell nucleus. DNA transcribed from viral RNA integrates into the host genome and directs synthesis of viral RNA and proteins, which assemble to form progeny viral particles that bud from the surface of the infected cell. Shortly after infection of a cell, peptides derived from virus proteins (envelope, gag, polymerase and regulatory proteins) are displayed on the surface of the cell, in association with HLA molecules. These can activate T cells and serve as their targets. Some cells, however, can harbor HIV-1 without being 'visible' to T cells. [21] In the first days after infection, HIV-1 and related viruses rapidly spread from the portal of entry, usually at a mucosal surface, to blood, secondary lymphoid organs and lymphoid cells in tissues such as the gut. [22] [23]

Vaccines against other viral diseases may allow asymptomatic infection but prevent disease. Once it is established, HIV-1 infection may not be eradicable. The ideal HIV-1 vaccine will prevent the establishment of infection by inducing antibodies that neutralize HIV-1 virus by binding to envelope protein or by inducing effector T cells that can inhibit virus replication and eliminate the first few cells to become infected. Even if infection is not prevented, priming the immune response could lead to more rapid immune control of virus replication and delayed onset of disease. Immune responses that occur at mucosal sites may play a particularly important role, as most HIV-1 exposure occurs through mucosal routes and the gut lymphoid tissue is an important site for HIV-1 replication regardless of route of infection.[24] As in other viral diseases, it is likely that all components of the immune system will need to work synergistically: the nonadaptive component that offers initial protection and provides the impetus for adaptive responses,[25] [26] antigen-presenting cells of several types, B cells that make antibodies and a multiplicity of T cells, including effectors, that secrete antiviral cytokines and kill virus-infected cells or helpers that simply control the activities of effector T and B cells, and memory cells for each adaptive component will likely be involved in reducing the number of infectious virions, limiting viral replication and eliminating infected cells.[27]

Neutralizing antibodies

Neutralizing antibodies can block the virus from binding to the host cell membrane, thus interfering with envelope-receptor complex formation, and/or with membrane fusion. As a result, the virus cannot enter the cell and replicate.

Neutralizing antibodies are directed against either linear or conformational epitopes (antigenic portions) of the folded viral envelope glycoprotein. Several features of HIV-1 envelope (conformational flexibility, a complex and labile structure, the presence of variable loops and glycosylation of some antigenic regions) contribute to mechanisms by which HIV-1 can avoid inducing neutralizing antibodies or withstand their effects.[28] In addition, after infection, new HIV-1 'escape mutants' emerge that are no longer susceptible to neutralization by the host's antibodies.[29] [30]

Nevertheless, it is clear that neutralizing antibodies can be protective if they are present prior to infection. Neutralization of HIV-1 by passively infused antibodies protects chimpanzees[31] or SCID-hu mice (which lack their own immune system and have a transplanted human system[18] [32]) against infection with HIV-1, and monkeys from infection by the man-made chimeric viruses with the envelope of HIV-1 and other genes derived from the SIV.[19] [33]

When antibodies from individuals chronically infected with HIV-1 are tested for neutralization, the response is often weak. However, broadly cross-reactive neutralizing antibodies can be made by at least some humans; a few human monoclonal antibodies (mAbs) have been developed that efficiently neutralize a range of primary HIV-1 isolates.[34] [35] [36] Unfortunately, no vaccine has been identified that will induce high titers of broadly cross-reactive and durable neutralizing antibodies against strains of HIV-1 recently isolated from human peripheral blood mononuclear cells (PBMCs), often called primary isolates. This standard may be too stringent (it is not necessarily met by all successful vaccines against other viruses); only analysis of the immune responses from one or more efficacious vaccines will resolve the issue. Rational design approaches focusing on structure-function analyses of envelope-antibody binding, further elucidation of the structure of envelope, and library screening for identification of possible immunogens are currently under investigation and may lead to novel strategies for inducing broadly cross-reactive neutralizing antibodies.

Cell-mediated immunity

T cells may protect against HIV-1 infection by killing infected cells (cytotoxic lymphocytes (CTLs)), by producing soluble antiviral substances such as interferon-? or other inflammatory mediators or by 'helping' or amplifying the cytotoxic or antibody responses. T cells bearing the CD8 marker on their surface are effectors (cytotoxic or secrete cytokines), while T cells with CD4 on their surface frequently regulate antibody or cell-mediated responses or may have cytolytic activity. CD8 cells are thought to be most important in controlling virus infections, because they recognize peptides from endogenously produced antigens, such as those found on the surface of virus-infected cells.

T-cell responses are directed against HIV-1 proteins, regardless of their function (structural, enzymatic or regulatory).[37] Thus, T cells have a wider variety of targets and some of the targets are constrained in their genetic variability by the need to preserve functional structures. They can react with a variety of HIV-1 isolates, either because the epitopes are conserved between various strains of HIV-1 or because of immunologic cross-reactivity between similar epitopes.[38] [39] Nevertheless, T-cell epitopes may vary and when the predominant response to retrovirus infection is limited to one or a few specificities, viruses bearing a changed epitope may escape from immune control and cause disease progression.[40] [41] Additionally, due to its high mutation rate, HIV-1 may tend to evolve by losing epitopes to which a specific population responds well,[42] or it might lose epitopes contained in an initially effective vaccine.

Evaluation of vaccine-induced immune responses

Vaccine trials require robust, sensitive and reproducible methods to measure vaccine-induced immune responses. Most of the existing licensed vaccines were developed empirically with little knowledge of what immune responses mediate protection, in an era when only antibody responses could be measured accurately. It is likely that the

TABLE 118-2 -- Characteristics of HIV-1 neutralization assays.

CHARACTERISTICS OF HIV-1 NEUTRALIZATION ASSAYS	
Virus type	Strains adapted to long-term culture in T cells or recently isolated 'primary isolates' or genetically engineered viruses with HIV-1 envelope, some containing a reporter gene
Target cells	PBMCs stimulated with a mitogen to induce cell division, cell lines expressing appropriate cell surface markers (HIV-1 receptor and coreceptor) or genetically engineered cell lines containing a reporter gene
Indicator system	Cell death or cytopathic effect, viral protein production, molecular reporter gene (e.g. green fluorescent protein, luciferase, ß-galactosidase). Some are highly reproducible and capable of high throughput automation
Number of replication cycles	Single or multiple (affects assay duration and variability)

arms of the immune response work synergistically and with the nonadaptive innate immune system. However, the practical reality of vaccine development necessitates selection of one immune response as an indicator of vaccine potency. Manufacturers require highly reproducible and rapid potency assays. This immune response will be used to compare vaccine approaches, to decide which candidate vaccines progress to further testing, and eventually to monitor lot-to-lot consistency in a licensed vaccine or allow modifications in the vaccine without repeating full-scale, placebo-controlled efficacy trials. The ideal assay would be based on protective mechanisms (still unproven) and validated to meet the requirements of good laboratory practices.[43]

Antibody assays

Antibody assays measure binding to viral proteins or neutralization. Binding antibodies are detected by standard enzyme-linked immunosorbent assay (ELISA) colorimetry, Western blot or real-time binding assays.[44] Neutralization, though more difficult to measure, is thought to be more relevant to protection. Antibodies may neutralize HIV by binding to a specific neutralizing epitope[45] or by coating virions and interfering with viral envelope-host cell membrane fusion.[46]

Neutralization measures the reduction of infectivity of cell-free virus particles. Infection of cells by HIV-1 is measured in the presence and absence of serum or other fluids. Neutralizing activity often appears to be very weak, even in the serum of chronically infected individuals. However, the choice of HIV-1 strain(s) used in the neutralization assay will influence the measurements. It appears

TABLE 118-3 -- Characteristics of assays of T-cell responses to HIV-1 antigens.

CHARACTERISTICS OF ASSAYS OF T-CELL RESPONSES TO HIV-1 ANTIGENS

that most antibodies against HIV-1 have a very narrow spectrum of activity while HIV-1 can vary enormously, even within one infected person. Many methods have been developed for assessing neutralizing antibodies (Table 118.2). Conventional neutralizing assays mimic in vivo neutralization of HIV-1, using stimulated PBMCs as targets and measuring cell death[47] [48] [49] or the inhibition of viral protein production.[50] Newer assays may rely on viruses or cell lines that are genetically engineered to contain reporter genes[51] as a surrogate for productive infection, or on flow cytometry[52] to measure infection in individual cells. These assays must take into account the two different types of receptors utilized by HIV-1: CD4 and chemokine receptors. HIV-1 strains adapted to growth in cell lines are often much easier to neutralize than primary isolates. [53]

Assays of cell-mediated immunity

For all assays of cell-mediated immunity (Table 118.3), isolated mononuclear cells or whole-blood specimens are stimulated with antigens that may consist of proteins, peptides or virus-infected cells. The specimen is usually peripheral blood, although T cells can be cloned from secretions or tissue biopsies.[54] T cells are stimulated by peptides associated with HLA molecules on the surface of antigen-presenting cells such as dendritic cells.[55] The classic measurements of responses, killing of virus-infected or peptide-coated target cells (predominantly CD8 cells) and antigen-induced lymphocyte proliferation (CD4), are difficult to apply, especially in resource-poor settings. Assays that measure production of cytokines or chemokines (e.g. IFN-?, IL-2, TNF-a, MIP-1ß) by individual PBMCs in response to antigen or peptide are now widely used (Fig. 118.1). ELIspot enumerates individual cells that secrete particular cytokines, thus revealing the capabilities of the responding cells. Even more informative is intracellular cytokine flow cytometry, which identifies both the cytokine being produced and immune markers on the surface of a cell, such as CD4 or CD8, and molecules indicating activation or propensity to migrate to certain tissues. These assays are simpler, more robust and more informative and they can be validated to meet the requirements of good laboratory practices.[43] Assays on fresh blood, while more technically challenging, are more sensitive and reliable. Artificial fluorescent molecules that mimic antigens and bind to T-cell receptors can also be used (tetramer assay), but this assay is technically much more difficult because of genetic restrictions on T-cell receptor binding to epitopes.[56]

CLINICAL TRIALS

The process

Clinical trials for preventive HIV-1 vaccines are complex. Like all clinical studies, they must comply with ethical principles, applicable laws and good laboratory practices.[43] Volunteers must fully

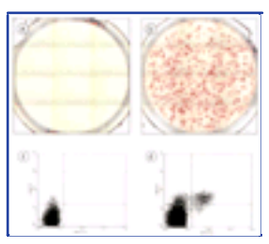

Figure 118-1 Two newer methods for studying responses to HIV vaccines. (a) and (b) are representative negative and positive wells (respectively) from an interferon-? (IFN-?) ELISPOT assay. Mononuclear cells are separated from blood, placed in wells coated with antibody against IFN-?, and stimulated overnight with (b) or without (a) peptides from the antigen of interest. On stimulation, antigen-specific T cells release IFN-?; the captured IFN-? is stained using a second antibody with an enzymatic tag to develop a color change, much like a conventional ELISA test. A colored spot appears for each cell producing IFN-?. The lower panels are representative of the result from a cytokine flow cytometry (CFC) assay. Whole blood from an HIV^+ patient is cultured without (c) or with (d) peptides from the HIV *gag* gene in the presence of an inhibitor of Golgi secretion. Newly synthesized cytokine within the cells, in addition to cell surface markers, are then stained using fluorescently labeled antibodies and analyzed on a fluorescence activated cell sorter (FACS). The cells in (c) and (d) have been labeled for CD3 (general T-cell marker), CD4 (helper class of T cells) and CD69 (activation marker); they are also permeabilized and stained to reveal intracellular IFN-?. The cells staining for CD3 but not CD4 (i.e. CD8 or effector T cells) were selected using automated software. The upper right quadrant indicates which of the CD8 cells are newly activated (CD69 positive) and producing IFN-?.

understand the trial, including the rationale for use of a placebo and the process of randomization.

Risk for HIV-1 infection can be reduced by behavior change. It is critical that volunteers understand the need to protect themselves against HIV-1 infection by standard methods (limiting partners, barriers and avoiding contaminated needles) and that they have the knowledge and means to do so; they need to know that an untested HIV-1 vaccine candidate is not a 'magic bullet'. Trial organizers must educate, counsel and provide protective devices such as condoms or clean needles and syringes to the extent that it is feasible and legally permissible. It is necessary to estimate the incidence of HIV-1 infection in the presence of such interventions in order to determine accurately the sample size for efficacy trials. Research suggests that, in US trials, risk-taking by volunteers has not increased during the trials. [57] This may differ depending on the social circumstances and education of volunteers. Many persons at risk from HIV-1 lack power over their own risks; they may be at risk, for example, through a spouse's risky behavior. These people are the most in need of an effective vaccine.

Certain vaccine candidates may induce antibodies that render a standard diagnostic HIV-1 test positive, even in the absence of HIV-1 infection, and each trial must offer accurate diagnostic testing for trial participants. Stigmatization or discrimination could occur as a result of false-positive testing or, more likely, simply based on trial participation.[58] [59]

Early trials (phase 1) enroll healthy volunteers who are usually not at high risk for HIV-1 infection, as indicated by a screening interview. Risk can change and occasionally such volunteers do encounter HIV-1 in the community and become infected. The clinical course of these infections has been scrutinized and it appears to be no different from acute HIV-1 infection in nonvaccinated individuals, [60] but the number of cases is small. Later stage (phase 2) trials and efficacy trials (phase 3) enroll participants at higher risk of HIV-1 infection, either through sexual contact or injection drug use. Infants at risk of infection through breast-feeding (after initial protection by perinatal drug therapy) are also at risk for infection and early-stage trials have shown that certain vaccine candidates are safe in neonates.[61]

The end points for clinical trials could include prevention of infection or, if infection occurs, modification of viral replication. Slower viral replication would be expected to result in slower disease progression and less risk of transmission to others. Data are insufficient to detect an effect of vaccination on disease progression at this time.[60] Nonhuman primate studies support both possible outcomes and a useful vaccine will likely have both effects.

Progress to date

Several HIV-1 vaccines have recently entered trials or are expected to do so soon.[62] A number of vaccines have been tested and, lacking credible immunogenicity data, abandoned. Table 118.4 shows the status of HIV-1 clinical trials at the time of writing, but the reader is encouraged to seek more current information through websites or newsletters (www.iavi.org/trialsdb; www.vrc.org; www.hvtn.org; http://www.iavi.org/iavireport/; and others).

One vaccine design, bivalent recombinant gp120 (envelope) protein adjuvanted with alum, has entered two phase 3 trials. One efficacy trial which enrolled primarily men who have sex with men, testing a bivalent vaccine in which both components are based on HIV-1 of the B subtype has failed to show overall efficacy in preventing HIV-1 infection (www.vaxgen.com). Post hoc analyses showed the possibility of benefit in certain subgroups, blacks and Asians. However, the numbers were too few to be conclusive and further studies will be needed. A trial in Thailand with an analogous vaccine containing one component derived from B subtype and one derived from E subtype is also underway, enrolling injection drug users. These vaccines induce antibodies that neutralize 'laboratory-adapted' HIV-1 strains but not freshly isolated HIV-1. A novel approach will be required to induce antibodies that can neutralize primary isolates.

A third efficacy trial is planned for Thailand, enrolling heterosexual men and women; this trial will combine a vaccine designed to induce cell-mediated immunity (primarily mediated by CD8 T cells). The vaccine, designed to induce cell-mediated immunity, is recombinant canarypox containing genes that encode HIV-1 envelope,

gag and protease, based on the B and E subtypes. The canarypox is an attenuated form of a virus that infects birds but not mammals. The virus enters mammalian cells, uncoats and releases its genetic material, which then directs the synthesis of endogenous antigens but does not replicate. This induces CD8 T cells that release antiviral substances such as interferon-? and/or kill HIV-infected host cells and CD4 (helper) T cells. In the Thai efficacy trial, the canarypox recombinant will be combined with gp120, in a 'prime-boost' regimen designed to induce both T-cell and antibody responses.[63]

Several novel vaccine candidates are now in clinical trials. Most of these are designed to induce CD8T cells and some may induce antibodies as well. Recently, lipopeptides have been tested in healthy volunteers;[64] these antigens are more effectively presented than the nonlipidated peptide vaccines tested some years ago.[65]

TABLE 118-4 -- Preventive HIV-1 vaccines currently in clinical trials (2003).

PREVENTIVE HIV-1 VACCINES CURRENTLY IN CLINICAL TRIALS (2003)

§ Scheduled for 2003
‡ Peptides without the lipid component have also been tested.
¶ Both recombinant MVA and recombinant adenovirus have been used as a 'boost' subsequent to 'priming' with the corresponding DNA vaccine.

DNA vaccines are directly injected into skin or muscle or applied topically. When taken up by host cells, the plasmids direct the synthesis of vaccine antigens. Early trials with DNA vaccines alone showed limited immunogenicity.[66] Therefore, several groups are studying DNA vaccines as a 'prime' followed by recombinant viral vectors as a boost. This is a different variation of 'prime-boost', in which the initial DNA vaccination is thought to focus the immune response, primarily mediated by T cells, on the products of the HIV-1 genes rather than on the gene products encoded by the virus vector itself,[67] while the recombinant vector induces more effector cells and/or antibodies. DNA priming followed by a recombinant, replication-defective vaccinia boost (MVA) is now being tested in the UK and Kenya[68] and DNA priming followed by a recombinant, replication-defective adenovirus is being tested in the USA.[10] In these trials, the current vaccine constructs are based on the *gag* gene; the groups plan to add new HIV-1 genes to the vaccines.

Which are the most important antigen(s) or gene(s) to include in a recombinant HIV-1 vaccine? The inherent variability of the gene within HIV-1 is likely to be important (clearly, a more conserved gene will be well matched to a larger spectrum of virus strains). For vaccines intended to induce neutralizing antibodies, envelope is the critical gene. However, the selection of the 'best' envelope sequence from among the myriad isolates is difficult. Vaccines could incorporate intact envelope proteins or modified versions that lack some of the features that modify immunogenicity such as variable 'loop' segments and heavy glycosylation.[69] For vaccines designed to induce T cells, the quantity of viral protein made in an infected cell may be important and targeting genes expressed early in infection could lead to destruction of infected cells before they release new virions. Even the optimal number of genes or gene products is debated; a larger number of targets seems desirable but some viral antigens may interfere with responses to others. This debate will be resolved finally by clinical trials.

Newer vaccines, not yet in clinical trials, may utilize different viral or bacterial vaccines as vectors. These vectors each have unique virtues. Some can be grown cheaply, amplifying the HIV-1 genes they carry along with their own. Some can be administered simply, such as bacterial vaccines that are effective when given orally. They may supply the stimulus to the innate immune system that will amplify immunity or deliver the antigen to dendritic cells in lymph nodes or to mucosal lymphoid tissues.

However, vectored vaccines also have real or theoretical drawbacks. For each novel vaccine, safety must be carefully evaluated in phase 1, 2 and 3 trials and then after marketing. They may confer long-lasting immunity; however, if immunity to the vector precludes effective boosting or interferes with the use of a different vaccine

employing the same vector, this may interfere with use on a worldwide, public health scale. Likewise, if naturally occurring immunity to the vector can interfere with immunization, the effects of a vaccine in different populations may be difficult to predict. These issues must be examined during vaccine development.

Older virus vaccines are almost all based on one of two designs: whole inactivated ('killed') or attenuated ('live') versions of the pathogenic virus. These have not been used in prophylactic HIV-1 vaccine trials. Whole killed HIV may be feasible, although inactivating without destroying envelope protein structure and proving that it has been entirely inactivated will be a challenge.[70] In animal studies, live attenuated SIV has proven to be an effective vaccine, but it is unsafe because of occasional reversion.[71] The seemingly insurmountable obstacle for a vaccine based on replication-competent HIV-1 is that there would be no clear way to prove its safety.[72] Such vaccines, however, may prove to be useful in experimental animal models, for understanding immunity to the retroviruses.

HIV-1 VACCINES AS THERAPY

Almost from the beginning of HIV-1 vaccine research, investigators have wondered whether an HIV-1 vaccine could improve the apparently inadequate and waning immune response of infected persons. A large, controlled trial of gp160 protein as a therapeutic vaccine showed clearly that the groups receiving vaccine and placebo had an identical clinical course.[73] Recent trials of whole killed vaccine as a therapy have failed to show convincing benefit. Measures of virus replication and perhaps clinical end points will be required in therapeutic vaccine trials. The best chance for a therapeutic vaccine would appear to be if it is given in the presence of highly

active antiretroviral therapy (HAART), otherwise immune activation of HIV-1-specific CD4 cells could render them more vulnerable to infection and destruction by HIV-1. Trials are now being undertaken to suppress virus with HAART, vaccinate and then interrupt therapy.[74] [75]

If vaccine therapy is successful, it will be encouraging for the field of preventive HIV-1 vaccine research, but not conclusive. If unsuccessful, it may not reflect the potential of that vaccine to prevent HIV-1 infection or AIDS if given prior to infection. After the initial days and weeks of virus replication, more cells may be infected, more genetic variation may have arisen and ineradicable reservoirs may exist in nonreplicating cells or inaccessible anatomic compartments in 'established' HIV-1 infection than the initial encounter with HIV-1.

FUTURE CHALLENGES

Conducting trials of HIV vaccines in the countries most affected by the epidemic is a challenge,[76] albeit one that has been successfully met in Thailand. When one or more HIV-1 vaccines is identified, the task will be just beginning. The next step will be ensuring access for populations where the need is the greatest. Currently, over 60 million people have become infected with HIV-1 and hundreds of millions are at risk. Many of these individuals have little access to medical care, no access to adult vaccinations and live in countries where the per capita expenditure on health care is a few dollars. Often, HIV-1 is ill understood and stigmatized. Diagnostic tests or algorithms may need to be altered. Education will be needed to convey not only the value but the anticipated limitations of the vaccines, so that other preventive strategies will be maintained. The role of community organizations in maintaining this balance will be critical (www.avac.org).

Regulatory approvals in numerous countries will be required. The issues in the USA are complex.[77] Internationally, there are greater challenges. If a vaccine has not been demonstrated to be universally effective against every HIV-1 subtype, the standard paradigm of approval in one or more industrialized countries followed years or even decades later by acceptance in and distribution to developing countries will not apply. Both the governments of countries affected by HIV-1 and the international regulatory and health authorities must plan ahead for the advent of an HIV-1 vaccine to avoid unnecessary delays.

HIV-1 vaccines might induce antibody responses that would completely prevent HIV-1 infection by strains of virus that are sufficiently well matched to the vaccine. Unfortunately, HIV-1 evolves continuously both within an individual (the source of infection) and within human populations. Therefore, a vaccinated person might be protected initially, but later encounter a virus against which he or she is not immune. Multivalent vaccines or repeated immunization with an updated vaccine may be required for continued protection. Thus, eventually, one might imagine licensure not of a specific HIV-1 vaccine but of a method for producing the vaccine and its updated versions, somewhat analogous to the annual updates of influenza vaccine.

The scientific challenges involved in discovery of a safe and effective vaccine against HIV-1, although daunting, are only the prelude. The task of developing and deploying a vaccine against HIV-1 will be enormous (i.e. gaining licensure and scaling up to produce vaccine for worldwide distribution, developing distribution methods and establishing purchase mechanisms will require an unprecedented co-operative effort by governments, international agencies, philanthropic organizations and the private sector).[78] Recent recognition of the importance of controlling HIV-1 for public health, economic and political stability has been encouraging and there has been substantial growth in academic, government, nonprofit and pharmaceutical industry vaccine research, but the fight is not over. Stopping the march of the pandemic will conserve economic and human resources needed to care for those already infected. Ending the HIV-1 epidemic is critical to allow economic development and promote political stability in the developing world and to reduce loss of life and suffering worldwide.

Chapter 119 - Practice Point

Postexposure prophylaxis for nonoccupational HIV exposure

David K Henderson

Introduction

In spite of considerable investment in education and training of the public, community exposures to HIV continue to occur commonly and frequently require clinical intervention. The introduction of postexposure chemoprophylaxis for occupational exposures to HIV in the health care workplace quickly prompted questions about the potential use of these agents for nonoccupational exposures. Several issues related to the administration of postexposure chemoprophylaxis for community exposures are distinctly different from offering these agents for occupational exposures in the health care setting. Since none of the available agents has a specific indication for use in prophylaxis, all antiretroviral chemoprophylaxis (for both occupational and nonoccupational exposures) must be considered 'off-label' use. This Practice Point reviews the immediate management of nonoccupational exposures and discusses the issues that are uniquely relevant to providing chemoprophylaxis for sexual, needle-sharing and other nonoccupational exposures.

Efficacy of postexposure chemoprophylaxis

The recent San Francisco Post Exposure Prophylaxis study demonstrated the feasibility of developing and implementing a postexposure program for managing community/nonoccupational exposures to HIV. Much of what we know about the potential for efficacy of antiretroviral postexposure chemoprophylaxis for sexual or nonoccupational exposures is derived from our experience using these agents in health care workers. Despite differences in the route of exposure (and in other variables likely to influence, at least to some extent, the specific risks for transmission), the results from animal studies, studies of vertical transmission and clinical experience to date with postexposure chemoprophylaxis for occupational exposures would seem to be directly relevant to the use of these agents for chemoprophylaxis for sexual or nonoccupational exposures.

Risk for infection associated with nonoccupational exposures to HIV

The per-exposure risk for HIV infection associated with community exposures varies significantly by the type of exposure. Considering community-based exposures, the risks associated with needle sharing in intravenous drug abuse are perhaps the greatest (Table 119.1). Whereas reasonable estimates of the risks for transmission associated with various sexual encounters have been published, these data clearly represent estimates and the precise risks for infection associated with these exposures are not known (see also Chapter 116). In addition, such estimates are useful only to understand the general risk for events of a certain type, since a variety of additional factors influence the risk associated with a single exposure (e.g. blood exposure, partner's viral burden, presence of reproductive tract infections, viral strain-specific differences in infectivity, cervical ectopy, circumcision and a variety of other factors). With these limitations in mind, estimates for the risk of transmission associated with different kinds of HIV exposures are summarized in Table 119.1 .

Special problems

Chemoprophylaxis following consensual sexual exposure

Perhaps the most common circumstance for which postexposure prophylaxis is sought for community exposures to HIV is consensual sexual exposure. The details surrounding such exposures vary substantially and should be carefully considered before making the decision to initiate postexposure antiretroviral therapy. Circumstances of exposure and commitment to risk reduction/safe sex strategies should be an important determinant of the decision to administer prophylaxis. Several authorities have argued that postexposure prophylaxis is not appropriate for individuals who plan on continuing risk behavior. Conversely, offering postexposure prophylaxis to someone who is committed to risk reduction but had a temporary relapse of higher risk behavior makes implicit sense. From a practical perspective, determining an individual patient's commitment to risk reduction strategies may be extremely difficult, particularly in the context of a single patient-physician encounter. For this reason, most physicians decide to offer treatment unless they are convinced that the individual is not interested in risk reduction. Withholding treatment from someone who is uninterested in risk reduction seems cruel, but may actually be in the individual's best interest (particularly if the availability of postexposure prophylaxis is contributing to the individual's willingness to participate in risk behaviors). Offering repeated courses of prophylaxis may place the patient at increased risk and may be associated with societal risks as well (discussed below).

Rape/sexual abuse

A special set of problems arises with respect to the victims of sexual assault and/or sexual abuse. In most instances, the victim will not be aware of the HIV status of the assailant, and so these exposures represent the equivalent of 'source-unknown' exposures in the health care setting (see Chapter 117). Sexual assault, by its very nature, may be associated with increased risk for HIV transmission due to the increased likelihood of blood exposure, trauma and simultaneous exposure to other sexually transmitted diseases. In fact, several cases of HIV transmission have been directly linked to sexual assaults.

TABLE 119-1 -- Estimated HIV transmission risks associated with selected types of HIV exposures.

ESTIMATED HIV TRANSMISSION RISKS ASSOCIATED WITH SELECTED TYPES OF HIV EXPOSURES	
Route/type of exposure	**Risk for infection mean/range (%)**
Transfusion of contaminated blood	84–100
Intravenous drug use (needle sharing)	0.8
Receptive anal intercourse	0.3–0.8
Insertive anal intercourse	0.04–0.1*
Occupational needlestick exposure	0.28–0.33
Insertive vaginal intercourse	0.03–0.09
Receptive vaginal intercourse	0.005–0.02
Insertive oral intercourse	0.003–0.008*
Receptive oral intercourse	0.006–0.02*

** Estimates drawn from Varghese et al. (2002), Donegan et al. (1990), Henderson et al. (1986); Kaplan and Heimer (1994) and Royce et al. (1997).*

The Centers for Disease Control and Prevention has recommended the use of antiretroviral chemoprophylaxis for rape victims, but has stopped short of recommending

(either for or against) prophylaxis for consensual sexual exposures. The emotional trauma associated with a sexual assault is substantial and is compounded by the possibility of HIV transmission. For this reason, counseling must be an integral part of the postexposure management program. In many centers, follow-up for victims of sexual assault is extremely difficult, often because the victims do not give correct identification information and cannot be located for follow-up. In addition, many such victims do not return for follow-up appointments (even with prompting). Counseling of assault victims is crucial to the postexposure management process; such individuals must be made aware of the importance of follow-up, particularly if they embark on a postexposure prophylaxis regimen. Some authorities have suggested that offering postexposure prophylaxis may improve follow-up adherence.

Prophylaxis in children and adolescents who are the victims of sexual abuse

Children who are victims of sexual abuse may also be at risk for sexually transmitted diseases, including HIV infection. Experience administering antiretrovirals to healthy children is virtually nonexistent and the possibility exists that risks associated with the administration of these agents may be different, and perhaps higher, in children. Nonetheless, for documented sexual abuse exposures in children and adolescents, most authorities would recommend the administration of postexposure prophylaxis.

Parenteral exposures in the community

The most common source of parenteral exposures to HIV in the community setting is needle sharing in the process of intravenous drug use. If an individual shares needles with a partner known to be HIV infected, antiretroviral chemoprophylaxis is definitely indicated. For the more common set of circumstances (i.e. the HIV infection status of the needle-sharing partner is unknown), individualized decisions about postexposure prophylaxis should be made, based on the likelihood of HIV exposure in the community.

An unfortunately common circumstance in emergency rooms is the appearance of a child who has discovered a needle or syringe and has sustained a needlestick exposure. Quantitating the transmission risk in this setting is almost impossible, although some factors may be helpful in deciding whether to administer prophylaxis. Realistically, many such exposures present minimal risk for transmission of HIV; however, exclusion of risk may be almost impossible. The presence of blood in the syringe or on the needle would clearly identify increased risk. Each of these exposures must be assessed epidemiologically for circumstances that might be associated with increased risk and independent decisions must be made about each exposure.

Timing of prophylaxis in relationship to the exposure

Ideally, postexposure prophylaxis with antiretroviral agents should be administered as soon after an exposure as possible. In most of the more recent animal studies, if prophylaxis was begun within 24 hours of exposure the animals were protected. Clearly, delay of treatment is likely to be detrimental. In situations in which the picture of exposure is less than clear (e.g. an exposure to a source whose HIV status is uncertain), I would encourage the individual to initiate prophylaxis (to preserve the option) while the situation is being clarified. A special problem arises with respect to individuals who delay reporting of the exposure. As is the case for health care workers who, for a variety of reasons (e.g. denial, the urgencies of patient care, etc.), delay reporting infections, chemoprophylaxis should still be offered to exposed, susceptible individuals who have sustained community exposures to HIV. The practitioner should explain what is known about the importance of early administration of prophylaxis and should explain that, based on the animal models of retroviral infections, the chance for protection for individuals who delay reporting may be reduced and the risk:benefit ratio of prophylaxis may be altered. In fact, some authorities have recommended that prophylaxis should not be administered if more than 72 hours have elapsed from the time of the exposure. Nonetheless, in my view, withholding treatment in most instances is extremely difficult and I tend to err on the side of offering the treatment, despite a delay in reporting.

Postexposure management approach

As noted above, since an ongoing commitment to risk reduction by the exposed patient is an important determinant of the administration of prophylaxis, a thorough history is essential in the management of such exposures. Since these interactions often take place in a hectic emergency room, obtaining an appropriate history may be a challenge, but is essential to good management. Having trained counselors with experience in this field participate in the management (including history taking) is optimal. Important aspects of the history include (but are not limited to) the following: prior history of having taken courses of prophylaxis, prior history (especially recent history) of risk behaviors, assessment of current commitment to risk reduction, history (especially recent) of other sexually transmitted diseases, specific characteristics of the exposure for which prophylaxis is sought, and as much detailed information about the partner as can be gleaned.

Baseline laboratory studies should be obtained, including serologic testing for HIV infection. The so-called 'rapid' HIV tests are useful in that they are generally quite sensitive, but relatively nonspecific. As a screening test in the absence of risk behavior in the recent past, a negative test is quite useful. A positive test should be confirmed with traditional enzyme-linked immunosorbent assay (ELISA) testing, as well as by an additional confirmatory test, if the ELISA is positive. In addition, baseline chemistries and hematologic studies (in anticipation of prophylaxis administration) and a urinary pregnancy test for women should be undertaken, as well as microbiologic and serologic studies for other sexually transmitted diseases (e.g. gonorrhea, syphilis, chlamydia, hepatitis B and C). Depending on the patient's recent history of risk behavior, consideration should be given to assessing for circulating HIV nucleic acid using polymerase chain reaction (PCR) technology, if readily available. The HIV serologic tests should be repeated at 6 weeks, 3 months and 6 months following the exposure. If prophylaxis is administered, chemistries, including hepatic function studies, and hematologic

---

studies should be conducted bi-weekly. Patients should be instructed to return immediately if they develop any of the signs and symptoms of the acute seroconversion illness or if any of the signs and symptoms of severe drug toxicity develop. Symptoms associated with treatment (e.g. nausea, vomiting, diarrhea, etc.) should be managed aggressively, and perhaps even pre-emptively, with medications addressing these symptoms.

Information about the source of the exposure is extremely useful. If the partner is known and can be tested, determining the partner's HIV antibody status, viral RNA, stage of illness, antiretroviral treatment history and presence of factors that may increase the risk for transmission (e.g. presence of other genitourinary infections, recent menstrual history, etc.) all can be of value. In instances in which the partner cannot be identified, the decision to offer prophylaxis should be based on the practitioner's best epidemiologic assessment of the likelihood of exposure (based on the patient's history, the prevalence of infection in the community, the type of encounter and the time from exposure to presentation), as well as the individual's commitment to risk reduction in the future.

The regimens for postexposure prophylaxis are summarized in Table 119.2 . These recommendations are based on experience with these agents for occupational exposures to HIV in the health care setting. The currently recommended duration of therapy is 4 weeks; however, the choice of 4 weeks is arbitrary and based on limited clinical experience, experience with animal models of retroviral infections and in vitro studies evaluating the prevention of retroviral infection of susceptible tissue culture cells.

No discussion of postexposure management would be complete without underscoring the importance of counseling in this setting. All patients presenting with possible nonoccupational exposures to HIV should be counseled in detail regarding risk behaviors and risk reduction strategies. Counseling should also focus on the specific circumstances of the individual's exposure and should offer constructive suggestions regarding risk reduction.

Managing exposures when the source patient is or might have been taking antiretrovirals

Frequently, a source/partner for an HIV exposure has been taking antiretrovirals as therapy. If the source/partner's HIV infection is not suppressed, the individual may harbor resistant isolates. Prophylaxis should be initiated immediately and then modified if additional information becomes available.

TABLE 119-2 -- Suggested basic and expanded postexposure prophylaxis regimens for chemoprophylaxis after nonoccupational exposures to HIV.‡

SUGGESTED BASIC AND EXPANDED POSTEXPOSURE PROPHYLAXIS REGIMENS FOR CHEMOPROPHYLAXIS AFTER NONOCCUPATIONAL EXPOSURES TO HIV		
HIV exposures with a recognized transmission risk	'Basic regimen'	Zidovudine (ZDV) plus lamivudine (3TC)
	Alternative 'basic regimens'	Stavudine (d4t) plus lamivudine
		d4t plus didanosine (ddl)‡

HIV exposures for which the nature of the exposure suggests an elevated transmission risk*	'Basic regimen' plus one of the following agents	Indinavir‡
		Nelfinavir
		Abacavir
		Efavirenz‡

‡ *Modeled after CDC (2001).*
† Agent(s)/regimens not advisable for use in pregnancy (see text)
* Elevated risk is associated with exposures associated with increased risks for transmission (e.g. sexual assault, trauma, blood exposure, concomitant sexually transmitted disease, source patient with high circulating viral burden, etc.; see text)

Influence on risk behavior — impact on primary prevention strategies and the relationship to societal risks

One significant concern frequently expressed is that the use of anti-retroviral agents for postexposure prophylaxis of nonoccupational exposures may actually increase risk behavior. Individuals may feel that they can take risks that can be abrogated by postexposure treatment and, in so doing, may ironically be putting themselves at increased risk for infection. Several studies have attempted to address this issue but failed to identify evidence that knowledge of the availability of prophylaxis was associated with increased sexual risk behavior. Conversely, the San Francisco prophylaxis study found that 12% of the individuals who participated in the trial returned for a second prophylaxis course within 6 months of the completion of the initial regimen. In spite of the 12% return rate in this study, the authors found that the majority of individuals who enrolled in the program following a sexual exposure to HIV had experienced a temporary lapse in risk reduction behavior that was not related to a consistent pattern of ongoing risk behavior.

Even authorities who are committed to working in this field have raised the concern that the availability of postexposure prophylaxis might undermine public health HIV prevention efforts. To avoid a negative public health impact, a postexposure prophylaxis program should be presented as a secondary prevention intervention, and primary prevention (i.e. avoiding unsafe behaviors, stressing condom use) should be underscored as far more effective, less toxic and less expensive interventions.

Chapter 120 - The Immunopathogenesis of HIV-1 Infection

Pierre-Alexandre Bart
Giuseppe Pantaleo

This chapter examines the immunologic and virologic mechanisms involved in the pathogenesis of HIV-1 infection and the interaction between the virus and the host. The recent availability of highly active antiretroviral combination therapy (HAART) has significantly influenced the natural history of the infection, delaying the progression to overt AIDS and prolonging survival. At the same time, increasing knowledge of the pathogenic mechanisms and of the limitations of HAART has made it clear that eradication of the virus with the available conventional antiviral drugs is not feasible. Recent advances in our understanding of the correlates of protective immunity have drawn attention to the development of immune-based interventions in order to achieve long-term control of HIV-1 disease.

THE NATURAL HISTORY OF HIV INFECTION

The typical course of HIV-1 infection is defined by different phases that generally occur during a period of between 8 and 12 years. Although the pattern and the course of the infection is highly variable among HIV-1-infected patients, three distinct phases can be identified (Fig. 120.1):[1]

- primary HIV-1 infection;
- chronic asymptomatic phase; and
- overt AIDS.

The three phases of the disease

Primary HIV-1 infection

Primary HIV-1 infection is a transient condition, revealed by a symptomatic illness of variable severity in 40–90% of patients, and is invariably accompanied by:

- an initial rapid rise in plasma viremia, often to levels in excess of 1,000,000 RNA copies/ml;
- a decrease in the blood $CD4^+$ T cell; and
- a large increase in the blood $CD8^+$ cell count.

The marked decline of plasma viremia generally coincides with the resolution of the clinical syndrome.[2] The decrease in the viral load correlates with the appearance of the virus-specific immune responses (see below), particularly HIV-1-specific cytotoxic T lymphocytes (CTLs), indicating that virus-specific immune responses certainly play a crucial role in the initial downregulation of virus replication.[3] [4] [5] [6]

The signs and symptoms of primary HIV-1 infection generally appear 2–4 weeks after virus exposure (Fig. 120.1).

The duration of the clinical syndrome ranges between a few days and more than 10 weeks but generally lasts less than 14 days. The clinical presentation of the primary HIV-1 infection may mimic acute mononucleosis (primary Epstein-Barr virus infection; see Chapter 122) as well as many other febrile acute illnesses, emphasizing the non-specific nature of these symptoms and the difficulty of obtaining an accurate early diagnosis.

Because the acute clinical syndrome associated with primary infection is not specific for HIV-1, the diagnosis is based on laboratory tests. In this regard, it is important to underscore the fact that anti-HIV-1 antibodies are usually negative during the acute phase of illness, as well as the Western blot (i.e. the laboratory assay used to confirm the diagnosis of HIV-1 infection), which evaluates the generation of specific antibodies against different HIV-1 proteins. The Western blot is considered to be positive when there are at least three specific bands and/or two bands but with antibody reactivity against HIV-1 *env* and *gag*. Early diagnosis, therefore, relies on a history of exposure, a positive p24 antigen enzyme-linked immunosorbent assay (ELISA) or the detection of plasma viral RNA (almost always more than 50,000 copies/ml of plasma).[2]

The chronic asymptomatic phase

The primary HIV-1 infection is followed by a long phase of clinical latency (median time of 10 years), during which neither signs nor symptoms of illness are present. Relatively stable levels of virus replication and of $CD4^+$ T cell counts for a variable period of time characterize this phase of infection. This 'stability' of measures of disease activity is apparent in the blood only. Virus replication and the accumulation of extracellular virus trapped in the follicular dendritic cell network are particularly active in the lymphoid tissue, where a progressive anatomic and functional deterioration occurs, impairing the ability to maintain effective specific immune responses over time.[7] [8] This is reflected by the rapid increase in the levels of viremia and by a drop in $CD4^+$ T cell counts, which may suddenly speed up the transition from this phase to the advanced stage of the disease.

The advanced stage of HIV-1 disease is marked by low $CD4^+$ T cell counts (below 200 cells/µl) and by the appearance of constitutional symptoms. It may be complicated by the development of AIDS-defining opportunistic infections.[1]

Overt AIDS

Overt AIDS defines the end stage of HIV-1 infection. In the absence of antiretroviral therapy, this phase leads to death in 2–3 years. The risk for death and opportunistic infections significantly increases with $CD4^+$ T cell counts below 50 cells/µl. Fortunately, the recent advent of HAART, including at present as many as 15 antiretroviral drugs administered in different combinations, is significantly decreasing the rate of progression, morbidity and mortality of HIV-1 infection.

Clinical course of the infection

The clinical course of HIV-1 infection is variable. In the majority (60–70%) of HIV-1-infected patients, the median time between infection and development of AIDS, in the absence of therapy, is 10–11 years. These HIV-1-infected persons are defined as typical progressers (Fig. 120.2), and the clinical course of the infection that they generally experience is the one described above.

However, about 10–20% of subjects progress rapidly, developing AIDS in less than 5 years of infection, and they are therefore called rapid progressers (see Fig. 120.2). In these patients, after the primary HIV-1 infection, plasma virus levels are often higher than 10^5 copies of HIV-1 RNA/ml and, in particular, $CD4^+$ T cell counts start to

Figure 120-1 Kinetics of viral load and immune response during the phases of HIV-1 infection. After HIV-1 exposure, initial virus replication and spread occur in the lymphoid organs, and systemic dissemination of HIV-1 is reflected by the peak of plasma viremia. A clinical syndrome of varying severity is associated with this phase of primary HIV-1 infection in up to 70% of HIV-1-infected persons. Downregulation of viremia during the transition from the primary to the early chronic phase coincides with the appearance of HIV-1-specific cytotoxic T cells and with the progressive resolution of the clinical syndrome. The long phase of clinical latency is associated with active virus replication, particularly in the lymphoid tissue. During the clinically latent period, $CD4^+$ T cell counts slowly decrease, as does the HIV-1-specific immune response. When $CD4^+$ T cell counts decrease below H 200 cells/µl (i.e. when overt AIDS occurs), the clinical picture is characterized by severe constitutional symptoms and by the possible development of opportunistic infections and/or neoplasms.

decrease much earlier and more rapidly during the chronic asymptomatic phase, leading to the eventual development of AIDS. Furthermore, both humoral and cell-mediated HIV-1-specific immune responses are either never detected or rapidly lost after the transition from the acute to the chronic phase of infection.

At the other extreme, it is estimated that 5–15% of HIV-1-infected people will remain free of AIDS for more than 15 years; these people are termed slow progressors (see Fig. 120.2). In this situation, $CD4^+$ T cell counts remain stable and they are frequently above 500 cells/µl, and plasma virus levels are usually below 10,000 HIV-1 RNA copies/ml.

Slow progressers include a further subgroup of HIV-1-infected people, so-called long-term nonprogressors (see Fig. 120.2). About 1% of HIV-1-infected subjects probably fall into this category. The definition of long-term nonprogressors should be limited to those who have had a documented infection for at least 8–10 years, are

naive to antiretroviral therapy and have no signs of disease progression (e.g. constant high counts of $CD4^+$ T cells and either low (500–1000 copies of RNA/ml) or very low (<50 copies/ml) plasma virus levels).[1] [9]

This wide variability of the natural course of the disease is evidence of the presence of different driving forces - genetic, immunologic and virologic factors - that determine the evolutionary pattern of HIV-1 infection in the individual patient.[10] It is therefore important, first, to identify the different determinants of the rate of disease progression and, second, to elucidate how these driving forces work together. Furthermore, the potential ability of HAART to restore some determinants of long-term control of the virus must be evaluated in depth. These arguments are discussed in detail below.

The variability of the natural course of HIV-1 infection also underlines the need for markers of disease progression (see below) that may identify as early as possible the patients who are at risk for a more rapid disease progression. This could warrant either the use of different, perhaps more aggressive, therapeutic strategies or the need to monitor these patients more closely, or both.

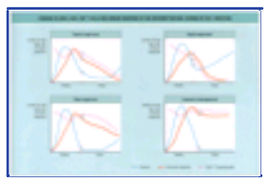

Figure 120-2 Changes in viral load, $CD4^+$ T cells and immune response in the different natural courses of HIV-1 infection. Typical progressors represent 60–70% of the total HIV-1-infected population, rapid progressors represent 10–20%, slow progressors represent 5–15% and long-term nonprogressors represent 1%.

SEQUENCE OF PATHOGENIC EVENTS LEADING TO THE ESTABLISHMENT OF HIV-1 INFECTION

HIV-1 can be transmitted by different routes: by sexual contact, through either genital-genital or genital-oral sex; by blood-blood contamination, via either transfusion of blood and infected blood-derived products or needle sharing among injection-drug users; and by maternal-fetal transmission. The most common route of infection is sexual transmission at the genital mucosa.[11]

Early pathogenic events after entry of HIV-1 into the body

The acute intravaginal infection of rhesus monkeys with the simian immunodeficiency virus (SIV) represents a very useful model for studying the sequence of cellular events that characterize the very early steps of infection after sexual transmission. In this model, tissue dendritic cells (i.e. Langerhans cells that reside in the lamina propria subjacent to the vaginal epithelium) are the first potential target cells of HIV-1 (Fig. 120.3). [12]

The dendritic cells constitute a complex and highly developed system of antigen-presenting cells that are able to prime naive T cells. Their potent antigen-presenting ability is associated with the high expression of major histocompatibility complex (MHC) class I and class II molecules and costimulatory molecules on the cell surface. The ability of dendritic cells to attract and prime naive T cells can be explained by the expression of a type II membrane protein with an external mannose binding, C-type lectin domain, named DC-SIGN.[13] [14] It has been suggested that interaction between DC-SIGN and intracellular adhesion molecule (ICAM)-3 is responsible for the initial contact between dendritic cells and resting T cells, which represents a critical step for the initiation of the T cell immune response. Furthermore, a major contribution to the ability of dendritic cells to initiate T cell immunity is also provided by the fact that dendritic cells express high levels of specific chemokines that target naive rather than memory T cells.[15] Therefore, dendritic cells play a key role, both in priming the initial virus-specific immune response and in serving as a carrier for the transport of HIV-1 to the nearest lymphoid station.

It is important, however, to mention the differences existing between the Langerhans cells (also called 'epidermal' or 'epithelial' dendritic cells) and the 'dermal' or 'subepithelial' dendritic cells.[13] Langerhans cells do not express DC-SIGN and, once they have encountered HIV-1 below the vaginal epithelium, they can either be infected or pick up HIV-1 virions. Epidermal, DC-SIGN-negative dendritic cells are thought to select for the macrophage (M)-tropic viruses that are the most frequently transmitted variants.[16] [17] The M-tropic HIV-1 carried by epidermal dendritic cells can bind to additional subepithelial DC-SIGN-positive dendritic cells. DC-SIGN can capture HIV-1 on the cell surface of dendritic cells without allowing viral entry. [18] It is thought that DC-SIGN-positive dendritic cells play the major role in the delivery of virus to T cells, thus greatly amplifying HIV-1 infection.[17] Subsequently, dendritic cells migrate to the internal iliac lymph nodes, where they target the T cell areas and then present

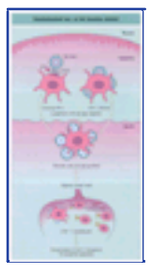

Figure 120-3 Transmission of HIV-1 at the mucosal surface. After entry at the mucosal epithelium, Langerhans cells, also named epidermal dendritic cells, can either be infected by R5 (macrophage (M)-tropic) strains of HIV-1 or pick up HIV-1 virions. Epidermal, DC-SIGN-negative dendritic cells are thought to select for the M-tropic viruses that are the most frequently transmitted variants. The M-tropic HIV-1 carried by epidermal dendritic cells can bind to additional subepithelial DC-SIGN-positive dendritic cells. DC-SIGN can capture HIV-1 on the cell surface of dendritic cells without allowing viral entry. It is thought that DC-SIGN-positive dendritic cells play the major role in the delivery of virus to T cells, thus greatly amplifying HIV-1 infection.

the viral antigens to activated virus-specific T cells. Dendritic cells can support viral replication only in the presence of activated T cells.[15]

Recent advances in our understanding of the mechanisms that modulate the infectivity of HIV-1 can explain why 95% of viruses transmitted are M-tropic. For more than 10 years, it has been known that human CD4 is sufficient for binding HIV-1 gp 120 to cells, but it is sufficient neither for fusion nor for penetration of the viral envelope into the host cell.[19] [20] [21] It is now clear that certain cell-surface receptors for chemokines function as co-receptors by co-operating with the CD4 molecule; moreover, different chemokine receptors, together with CD4, allow entry of HIV-1 strains with distinct cellular tropism. There are two classes of chemokine: CC, if the first two cysteines are adjacent; and CXC, if they are separated by a single amino acid. The CC-chemokine receptor (CCR)5, a seven-transmembrane G-protein-coupled receptor, is the major co-receptor for M-tropic or R4 strains of HIV-1, whereas CXCR4 is the one for T-cell-tropic or X4 strains of HIV-1. Langerhans cells or epithelial dendritic cells express CCR5 but they may not express CXCR4, giving a reason for the preferential transmission of R5 HIV-1 strains.[22]

To this extent, it is worth noting that subepithelial dendritic cells are able to capture the virus through DC-SIGN,[18] a mechanism that is independent of CD4 and co-receptors. However, although both R5 and X4 strains of HIV-1 are carried by dendritic cells to the nearest lymphoid station, only R5 HIV-1 envelopes have the unique ability to mediate an activation signal into $CD4^+$ T cells and to recruit them by chemotaxis.[23] Therefore, the combination of the two events (i.e. the differential expression of co-receptors on the initial target cells and the unique signaling ability of R5 envelopes of HIV-1) may explain why R5 HIV-1 variants are preferentially transmitted, ensuring the rapid recruitment of a large number of activated $CD4^+$ T cells and spread of HIV-1 in the lymphoid organs. It is important to emphasize that rapid recruitment and spreading of target cells (i.e. activated $CD4^+$ T cells) confers to HIV-1 a major advantage because these events occur before the appearance of effective virus-specific immune responses.

Within 2 days after infection, HIV-1 can be detected in the draining lymphoid tissue, and it rapidly disseminates throughout the lymphoid system. Afterwards, HIV-1 enters the bloodstream, where viral replication can be detected in plasma 5 days after infection (see Fig. 120.3). In humans, the time from mucosal infection and initial plasma viremia varies, ranging between 4 days and 11 days according to available estimates. It is of note that the risk of infection is increased by conditions that decrease the function of mucosal barriers, such as lesions caused by the presence of concomitant inflammatory or infectious diseases (e.g. cervicitis, urethritis, genital ulcers).

These same steps of infection can be described in the case of genital-oral HIV-1 transmission, because nasopharyngeal tonsils and adenoid tissue contain many cells of dendritic origin that can support viral replication more efficiently than Langerhans cells.[2]

The role of the lymph nodes in primary HIV-1 infection

The study of virologic events occurring during primary infection with either HIV-1 or SIV emphasizes the key role of lymphoid tissue in the establishment of infection. Longitudinal and cross-sectional analyses of HIV-1 or SIV distribution were performed on lymph node biopsies taken from rhesus monkeys or HIV-1-infected patients. In the SIV model of acute infection, virus can be detected in the lymph node as early as 5 days after infection. At this time, as shown by in-situ hybridization analysis for the detection of HIV-1/SIV RNA, virus is mostly present in the form of numerous individual cells expressing viral RNA, and the highest number of virus-expressing cells is observed 7 days after SIV inoculation. Interestingly, the occurrence of the peak number of virus-expressing cells in the lymph node occurs at the same time as the peak of plasma viremia, or shortly precedes it. The cross-sectional analysis of lymph nodes obtained from HIV-1-infected patients indicates that the kinetics of virus distribution in lymph nodes are consistent with those in the SIV model of acute infection. Altogether, these

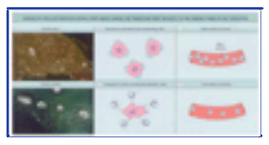

Figure 120-4 Changes in virus distribution within lymph nodes during the transition from the acute to the chronic phase of HIV-1 infection. (a) During the initial weeks of primary HIV-1 infection, the virus is detected in lymphoid tissue as individual virus-expressing cells. This is shown by in-situ hybridization for the detection of HIV-1 RNA (white dots indicate HIV-1 RNA-positive cells). (b) Numerous individual virus-expressing cells seen in the acute phase. (c) Elevated virion levels are found in the circulation in the acute phase. (d) After transition to the chronic phase of the disease, virions trapped in the follicular dendritic cell network become the dominant form of HIV-1, as shown by in-situ hybridization for the detection of HIV-1 RNA (diffuse white areas indicate virus trapped within follicular dendritic cells). (e) Binding of virions on the extracellular surface of follicular dendritic cells in the chronic phase. (f) The number of circulating virions is dramatically reduced in the chronic phase.

findings indicate that the lymph node is the primary anatomic site of infection. [8] [24]

During the transition from primary to chronic infection, a switch from individual virus-expressing cells to virus trapped by the follicular dendritic cell network of lymph node germinal centers occurs (Fig. 120.4). The trapped virus becomes the dominant form of virus present in lymph nodes, and this event is associated with a dramatic decrease in the number of individual cells expressing viral RNA.[8] [24]

At least in part, this is the result of the emergence of virus-specific CTLs that can be detected very early during primary infection and may mediate the elimination of HIV-1-producing cells. Furthermore, the trapping of HIV-1 virions in the follicular dendritic cell network is itself the result of the HIV-1-specific humoral response. In fact, HIV-1 virions are complexed with immunoglobulins and complement, and the binding of these complexes on the extracellular surface of follicular dendritic cells occurs through complement receptors expressed on follicular dendritic cells. In both SIV and HIV-1 infection, the transition from primary to early chronic infection is marked by a decrease of viral RNA in plasma and the resolution of the acute clinical syndrome. Therefore, it is clear that virus-specific immune responses are not only present very early during primary infection but may also significantly affect virus distribution occurring in the early phase of both SIV and HIV-1 infection. [25]

MECHANISMS RESPONSIBLE FOR VIRUS ESCAPE FROM IMMUNE RESPONSE AND ESTABLISHMENT OF CHRONIC INFECTION

Early in primary HIV-1 infection, vigorous virus-specific immune responses can be detected, and they may contribute to both control of the initial peak of virus replication and the reduction in plasma viremia.[3] [4] [5] [6] However, primary HIV-1 infection invariably results in the establishment of chronic disease in the host, inducing a progressive deterioration of the different components of the immune response.

HIV-1-specific immune responses lack the ability to control HIV-1 and to block the progression of the disease. Nevertheless, similar types of immune response are effective against other viruses, such as Epstein-Barr virus and cytomegalovirus (CMV). HIV-1 differs from these other viruses by being able to target very early (during the primary infection) a broad spectrum of effector components of the antiviral immune response and in being able to render these antiviral effector mechanisms ineffective or reshape them into self-defense mechanisms.[26]

Virologic mechanisms of HIV-1 escape from the immune response

HIV-1 possesses the ability to put in motion several mechanisms as the result of the interaction with the host. Some of these virologic mechanisms can be identified:

- formation of a stable pool of latently HIV-1-infected $CD4^+$ T cells containing virus that is capable of replicating;[27] [28] [29] [30] [31]
- the genetic variability of HIV-1;[32] and
- trapping of infectious virions on the surface of follicular dendritic cells. [33]

The rapid formation of a pool of latently HIV-1-infected $CD4^+$ T cells is a key event in the immunopathogenesis of HIV-1 infection for several reasons. First, this event occurs very early and most probably before the appearance of the host's virus-specific immune responses. Second, the pool of latently infected $CD4^+$ T cells contains replication-competent HIV-1 proviral DNA. The proviral DNA can be detected even in compliant HIV-1-infected persons who have been receiving

HAART for a long time (i.e. for more than 2 years); moreover, the virus is wild-type with respect to known drug-induced mutations in the genome. This emphasizes the fact that this pool of cells is a stable reservoir in which HIV-1 remains sheltered from the effects of host immune responses and HAART.[27] [28] [29] [30] [31] Furthermore, it is worth noting that initiation of HAART very early during primary HIV-1 infection does not appear to have a significant impact on the size of this pool of $CD4^+$ T cells. This indicates that this pool is created very rapidly after infection. Third, the decay of this pool of infected $CD4^+$ T lymphocytes is very slow, and the rate of decay is not much influenced by the effective suppression of virus replication obtained by HAART. This clearly represents a major obstacle to the goal of HIV-1 eradication (see below) and long-term control of virus replication.[29] [30] [31]

The high genetic variability of the virus is another efficient mechanism by which it escapes the host immune response.[32] [34] HIV-1 possesses the intrinsic ability to mutate very rapidly. Both during primary and established chronic infection, rapid mutations in the epitopes recognized by HIV-1-specific CTLs may occur. As a consequence, both humoral and cell-mediated virus-specific immune responses quickly lose their ability to control the virus efficiently.

An additional way by which HIV-1 is able to reshape antiviral mechanisms is the trapping of the virus on the surface of follicular dendritic cells in lymphoid tissue germinal centers. As already described, HIV-1 is trapped by the follicular dendritic cell network during the transition from primary to chronic infection and this becomes the dominant form of virus in lymphoid tissue in the chronic phase. Formation of immune complexes and their attachment to the follicular dendritic cell network are physiologic mechanisms that are generally devoted to the clearance of the pathogen and to the generation and maintenance of effective immune responses. In HIV-1 infection, however, these mechanisms lead to the formation of a stable reservoir of infectious virions, representing a continuous source for the infection of $CD4^+$ T cells, and to a chronic inflammatory reaction that ultimately results in the destruction of the lymphoid tissue.[7] [8]

Immunologic mechanisms of HIV-1 escape from the immune response

In addition to the virologic mechanisms described above, through which HIV-1 escapes and reshapes the host immune response, there are some immunologic mechanisms that can be identified:

- deletion of HIV-specific $CD4^+$ T cell clones;[35]
- deletion of HIV-specific cytotoxic $CD8^+$ T cell clones;[36]
- generation of virus escape mutants mediated by CTLs;[26]
- egress of CTLs from lymph nodes;[37]
- impairment of the function of antigen-presenting cells;[26] and
- interference with humoral neutralizing response.[26]

In the majority of HIV-1-infected patients who have established chronic infection, HIV-1-specific $CD4^+$ helper T cell responses cannot be detected, although it is

possible to find evidence of such HIV-1-specific $CD4^+$ T cell responses in long-term nonprogressors.[35] In contrast, HIV-1-specific effector $CD4^+$ T cell responses are consistently detected in patients who have chronic infection.[38] The persistence of the $CD4^+$ helper T cell response may represent one of the determinants of the course of the disease in long-term nonprogressors. In contrast, typical progressors do lose $CD4^+$ helper T cell responses very early in the natural history of the disease (during the primary HIV-1 infection) as a result of direct or indirect virus-induced cytopathology.[35] Furthermore, initiation of HAART during chronic infection and even during early HIV-1 infection is associated with the restoration of the HIV-1-specific $CD4^+$ helper T cell responses only in a subset (about 30–40%) of patients after prolonged treatment.[39] It is, however, possible to preserve HIV-1-specific $CD4^+$ T cell responses if HAART is initiated at the time of the peak of plasma viral RNA (i.e. very early during primary HIV-1-infection).[35]

It is also worth noting that T helper (Th)1 cells preferentially express CCR5 on the membrane surface, suggesting that HIV-1 R5 strains may preferentially and selectively infect Th1 cells during primary HIV infection, when R5 quasispecies predominate. In this regard, recent studies have demonstrated that the initial expansion of HIV-1-specific $CD4^+$ T cells with effector function is aborted during primary infection.[40] In contrast, the expansion of CMV-specific $CD4^+$ T cells in patients who experienced primary HIV-1 and CMV co-infection was not suppressed. These studies indicate a preferential infection of HIV-1-specific $CD4^+$ T cells. Furthermore, they provide evidence that HIV-1-specific $CD4^+$ T cell clones may be rapidly deleted very early during primary HIV-1 infection and that the possibility of rescuing these responses is strictly dependent upon the time of initiation of HAART.[35] [40]

Furthermore, the lack of HIV-1-specific $CD4^+$ helper T cell responses has two other important consequences. First, it can significantly affect the induction and persistence of HIV-1-specific $CD8^+$ CTL responses, because the latter require continuous cognate Th function provided by antigen-specific $CD4^+$ T cells. Therefore, generation and maintenance of vigorous virus-specific responses by CTLs can be compromised over time. Second, it can considerably affect the development of HIV-1-specific antibody responses, because the development of humoral responses is strictly dependent on $CD4^+$ antigen-specific Th cells. [26]

A rapid deletion of certain HIV-1-specific cytotoxic $CD8^+$ T cell clones also occurs during primary HIV-1 infection, in a manner that is analogous to the HIV-1-specific responses mediated by $CD4^+$ helper T cells.[36] These $CD8^+$ T cell clones undergo massive clonal expansion and may be deleted by a mechanism analogous to the clonal exhaustion that is observed in mice during acute lymphocytic choriomeningitis virus infection. This clonal exhaustion of HIV-1-specific $CD8^+$ CTLs causes the early impairment of the virus-specific responses by CTLs. The extent of this phenomenon may determine the varying ability to control virus replication efficiently and therefore it may significantly affect the rate of disease progression. In fact, it is now clear that the appearance of virus-specific responses by CTLs correlates with the decrease in plasma viremia. [6] [41] Furthermore, the higher the relative frequency of HIV-1-specific CTLs, the lower the levels of circulating viral RNA, and higher levels of CTL activity correlate with slower rates of disease progression.[6] [41] [42] However, the clonal exhaustion of virus-specific CTLs does not necessarily result in a complete loss of HIV-1-specific CTL activity, although it does provide additional evidence of how HIV-1 is able to target and impair host immune responses early in the course of the infection.

The detection of CTL-escape variants is common during the course of chronic HIV-1 infection; they may also, however, be found during primary HIV-1 infection. This event provides further evidence of the ability of HIV-1 to reshape some antiviral mechanisms of the immune response into self-defense mechanisms. In fact, although HIV-specific CTLs contribute to the control of both plasma viremia and disease progression,[6] [41] [42] the pressure exerted by CTLs can, at the same time, facilitate the selection of virus mutants that are able to escape the host immune response.[26] [36]

As described above, lymph nodes play a crucial role in the immunopathogenesis of HIV-1 infection. Very high levels of virus replication and spread occur in the lymph nodes during primary infection. Therefore, CTL responses specific for HIV-1 should be predominantly concentrated in the lymphoid tissue in order to achieve the most effective clearance of the virus. However, an early accumulation of HIV-1-specific CTLs in peripheral blood can be observed; CTLs therefore accumulate in a compartment where they cannot efficiently mediate their effector function (i.e. killing of productively HIV-infected cells). Egress of antigen-specific CTLs from lymphoid tissue into the circulation is likely to be a physiologic step that

occurs after the generation of the immune response in order to achieve a wide distribution of antigen-specific effector cells in different anatomic sites. In HIV-1 infection, however, this phenomenon also serves to redirect virus-specific CTLs away from the primary site of virus replication and spread. The observation that the number of HIV-1-expressing cells in lymph nodes does not significantly differ between primary and early chronic infection provides further support for the hypothesis of a defective control of HIV-1 during the early phases of infection.[8]

In addition to $CD4^+$ and $CD8^+$ HIV-1-specific T cells, HIV-1 may interfere with the function of antigen-presenting cells. These cells play a central role in the generation of an effective host immune responses. Cells of the monocyte-macrophage line and dendritic cells can function as specialized antigen-presenting cells and induce both humoral and cell-mediated immune responses. The effect of HIV-1 on these components of the immune system is produced by a quantitative depletion through direct cytopathogenesis or by interference with the formation of MHC-antigenic peptide complexes. To this extent, the expression of MHC class I molecules on antigen-presenting cells can be downregulated by HIV-1 Nef protein, thus affecting both generation of antigen-specific immune responses and recognition of virus-infected target cells by CTLs.[43]

Humoral response against HIV-1 can be detected early during primary HIV-1 infection. This response, however, comprises low-avidity Env-specific IgG that possesses little or no neutralizing activity. Although the reasons for the delay in the appearance of the neutralizing antibody response are poorly understood, such a response is detectable only either after the transition from primary HIV-1 infection to established early chronic HIV-1 infection, or even much later. The virologic and immunologic mechanisms described above significantly affect the global host immune response, within which the $CD4^+$ Th cell function and the interactions between T cells and B cells are profoundly altered. These events may ultimately interfere with circulating titers, avidity maturation and neutralizing activity of HIV-1-specific antibodies.

HOST AND VIROLOGIC FACTORS THAT INFLUENCE THE COURSE OF HIV-1 INFECTION

The events that result in the establishment of chronic HIV-1 infection emphasize the ability of the virus to target the host's antiviral immune response and reshape it into a self-defense mechanism. In this context, the mutual interactions between the virus and the host are major determinants of disease progression. Primary HIV-1 infection is a key phase in the immunopathogenesis of the infection, because all of the events that occur at this stage can determine both the pattern and rate of progression of the disease. In the transition from primary to early chronic HIV-1 infection, levels of plasma viral

TABLE 120-1 -- Host factors and virologic factors in HIV-1 infection.

HOST FACTORS AND VIROLOGIC FACTORS IN HIV-1 INFECTION		
Genetic host factors	**Immunologic host factors**	**Virologic factors**
HLA class I haplotype	Qualitative differences in the primary immune response	Extent of HIV-1 replication
Mutations in chemokine receptor or ligand genes:	Clonal deletion of HIV-1-specific cytotoxic T cells	Viral phenotype (syncytium-inducing or non-syncytium-inducing strains of HIV-1)
Ø32 in CCR5		
m303 in CCR5		
V641 in CCR2b	Persistence of HIV-1-specific $CD4^+$	Trapping of virions in follicular dendritic cell network
G801A in SDF	T cell responses	
Levels of ß-chemokines (RANTES, MIP-1a and MIP-1ß)	Chronic immune activation	Viral latency
		Size of inoculum

RNA tend to reach a virologic set point that is predictive of the rate of disease progression (see below).[44] [45] The virologic set point varies among HIV-1-infected patients and tends to remain stable in the same person during the chronic phase. The virologic set point that a person attains is determined both by the mechanisms involved in the establishment of chronic infection and by host factors that can modulate the course of HIV-1 disease.

Several factors play an important role in modulating both the antiviral host immune response and the susceptibility to HIV-1, and these factors can thus result in a

slower rate of disease progression. These factors are mainly genetic, immunologic and virologic (Table 120.1).[10] [26]

Genetic host factors

Patients infected with HIV-1 who experience a nonprogressive disease are more likely to possess certain HLA class I haplotypes than other members of the general population. Clusters of haplotypes rather than a single haplotype are involved; these haplotypes are more efficient than others at binding peptides that correspond to epitopes recognized by virus-specific CTLs. This suggests that persons who have inherited these clusters of haplotypes could generate HIV-1-specific CTL responses against multiple epitopes, thus resulting in a more efficient antiviral response, as a consequence of their HLA genetic background.[42]

The recent identification and study of the function of several a- and ß-chemokine receptors that can serve as HIV-1 co-receptors have provided evidence of varying chemokine receptor genetic polymorphisms that can influence susceptibility to HIV-1 infection and are associated with different rates of disease progression. Chemokines can be classified into two subfamilies, namely CXC or a-chemokines and CC or ß-chemokines, both of whose receptor molecules are part of the vast and functionally diverse family of seven-transmembrane G protein-coupled receptors. CXCR4, the first identified co-receptor, mediates T-cell-tropic viral fusion and entry (X4 HIV-1 strains), but it does not function as a co-receptor for the macrophage-tropic HIV-1 envelope. The major co-receptor for macrophage-tropic HIV-1 strains is CCR5, and other CC chemokine receptors, such as CCR2b, CCR3 and CCR8, can serve as co-receptors for R5 or dual-tropic (i.e. primary HIV-1 isolates) HIV-1 strains.[46] [47] [48] [49] [50] [51]

Some HIV-1-negative persons, despite being at high risk of exposure, appear to have an innate ability to 'resist' HIV-1 infection. Mapping of the CCR5 structural gene on the human chromosome 3p21 allowed the identification of a 32-base-pair deletion allele (?32CCR5) that encodes a truncated and nonfunctional molecule that fails to reach the cell surface. As a result, cells susceptible to HIV-1 are highly resistant to infection by R5 strains. Available prevalence estimates indicate that between 15% and 20% of Caucasians are heterozygous for the mutation, whereas 1% or fewer are homozygous.[52] The

study of large cohorts of HIV-1-negative persons, including those who have had multiple exposures to HIV-1, and HIV-1-infected patients has provided evidence that the homozygous genotype for the mutation (i.e. ?32CCR5-?32CCR5) confers high resistance to infection by HIV-1,[52] although a few HIV-1-infected patients possess the ?32CCR5-?32CCR5 homozygous genotype. However, the heterozygous genotype (CCR5-?32CCR5) does not prevent HIV-1 from infecting susceptible cells but is significantly associated with a slower rate of disease progression in HIV-1-infected patients and is found more commonly in long-term nonprogressors. [53] In heterozygotes there is a decreased expression of the CCR5 receptor, which can be explained by a transdominant inhibition of wild-type CCR5 receptor function owing to the concomitant intracellular presence of both normal and defective gene products withheld in the endoplasmic reticulum.[54] Another mutation (m303) in the *CCR5* gene prevents the expression of the receptor on the cell surface by introducing a premature stop codon. This mutation, when in *trans* with the ?32CCR5 defective gene, confers resistance because no expression of CCR5 receptor occurs. [55]

Furthermore, other genetic variants do not prevent infection but rather delay the progression of HIV-1 disease. However, their protective effect has not been confirmed in all studies, emphasizing the need to evaluate their role in larger cohorts. These genetic variants include a mutant CCR2b allele (V64I), which encodes a base mutation that replaces valine with isoleucine at position 64 in the transmembrane domain I of the CCR2b receptor;[56] [57] [58] [59] [60] and a guanosine-to-adenosine transition at position 801 (G801A) in the 3' untranslated region of the reference sequence in the gene of the stromal-derived factor (SDF)-1,[61] [62] which is the ligand for CXCR4.

Epidemiologically, the inheritance of the CCR2b mutant is less beneficial than the inheritance of the ?32CCR5 mutant in terms of reducing the risk of progression to AIDS; however, as in the case of CCR5-?32CCR5 heterozygosity, the V64I mutant is more commonly found in long-term nonprogressors.[58] Biologically, it is not clear how the V64I allele could interfere with the co-receptor function, because valine and isoleucine are chemically very similar. It is possible that the V64I allele is in linkage disequilibrium with other mutations,[56] [57] [59] as it has been described with a point mutation in the CCR5 regulatory region.[59]

As far as the SDF-1 G801A mutant allele is concerned, available data are somewhat puzzling. On the one hand, the status of homozygosity for the mutation has been associated with a lower risk of progression to AIDS.[61] A possible explanation for such a protective effect is that the presence of mutant alleles induces a higher than usual release of SDF-1, which inhibits X4 HIV-1 strains. X4 strains tend to emerge during the late phase of the disease and their appearance is generally associated with a more rapid progression. The SDF-1 at high levels could therefore interfere with the spreading of X4 HIV-1 strains, thus reducing the rate of disease progression. Homozygosity for the SDF-1 mutant has been linked to a higher risk of death, although the potential explanation is unclear.[62]

The initial studies that discovered the role of chemokine receptors as HIV-1 co-receptors originated from the observation that chemokines can potently modulate HIV-1 infectivity.[63] The ß-chemokines that are 'regulated upon activation, normal T expressed and secreted' (RANTES) — macrophage inflammatory protein (MIP)-1a and MIP-1ß — have been identified as major HIV-suppressive factors produced by $CD8^+$ T cells in vitro. Furthermore, endogenous levels of RANTES, MIP-1a and MIP-1ß expression in $CD4^+$ T cells were much elevated in some people who remained uninfected despite multiple sexual exposures to HIV-1-infected partners.[64] The binding of one chemokine to its cognate receptor essentially mediates the downregulation of surface chemokine receptor expression. Therefore, in addition to genetic control, chemokine levels themselves may influence infectivity and disease progression. In particular, there is evidence that very high levels of RANTES, MIP-1a and MIP-1ß are detectable in persons bearing the ?32CCR5-?32CCR5 homozygous genotype. [64] Similarly, unusually high levels of ß-chemokines have been found in people with hemophilia who have remained uninfected with HIV-1 despite repeated exposure to contaminated blood products before HIV-1 testing became available.[65] Furthermore, levels of MIP-1ß (which is the only suppressive CCR5-specific chemokine) in those who have overt AIDS can be significantly lower than those in HIV-1-infected patients who have chronic disease; moreover, higher levels of MIP-1ß are associated with a lower risk of disease progression.[66]

These observations suggest that suppressive ß-chemokines may play a role in the control of HIV-1. Production of chemokines by effector $CD4^+$ T cells occurs at the site of virus replication, and the chemokines may protect local target cells and activated effector cells by downregulating CCR5 in an autocrine manner. The varying extents to which these mechanisms are put in motion may explain the varying levels of protection against disease progression.

In summary, host genetic factors do play a role in modulating the course of HIV-1 infection. Furthermore, the potential role of chemokines in affecting infectivity and disease progression may further widen our therapeutic options along with HAART.

Immunologic factors

Importance of HIV-1-specific $CD4^+$ T cells

$CD4^+$ T cells play a fundamental role in the generation of antigen-specific immune responses. Studies performed in mice have clearly demonstrated that stimulation and expansion of antigen-specific $CD4^+$ T cells precedes that of $CD8^+$ T cells during acute virus infection in vivo.[67] Even although $CD4^+$ T cells do not seem to be critical for the generation of the primary virus-specific $CD8^+$ T cell response, the presence of virus-specific $CD4^+$ T cells is required for the maintenance of the $CD8^+$ T cell response over time during the phase of chronic infection.[68] [69]

The progressive depletion of $CD4^+$ T cells is the hallmark of HIV-1 infection.[70] However, even in the early stages of HIV-1 infection when the $CD4^+$ T cell count may still remain in the normal range, certain HIV-1-specific $CD4^+$ T cell functions, such as the ability to proliferate after stimulation with different virus protein, are already absent in the majority (80–90%) of HIV-1-infected patients.[71] [72] The antigen-specific proliferation ability is also known as T helper function. Therefore, the defect of HIV-1-specific $CD4^+$ Th cells occurs very early during HIV-1 infection. Despite the lack of virus-specific $CD4^+$ helper responses, HIV-1-specific $CD4^+$ T cells have been identified even in patients who have progressive disease on the basis of their ability to secrete interferon (IFN)-? following short (6h) stimulation with HIV-1 antigens. [38]

The discordance between the lack of HIV-1-specific CD4 proliferation and the detection of HIV-1-specific IFN-?-secreting $CD4^+$ T cells can be explained by the stimulation of different populations of antigen-specific $CD4^+$ T cells in the two assays. Stimulation of precursors of antigen-specific memory T cells occurs in the 6 days proliferation assay while the short-term (6h) stimulation IFN-? flow cytometry assay probably detects functionally differentiated antigen-specific T cells.

The hypothesis above is supported by a series of recent studies that have shed light on memory $CD4^+$ and $CD8^+$ T cells.[73] [74] These studies have shown that different populations of memory T cells can be distinguished upon the expression of different cell surface markers such as CD45RA and the chemokine receptor CCR7. Interestingly, these different populations of memory T cells are at different stages of differentiation and have different functions. Therefore, memory $CD4^+$ T cells with the proliferation function are contained within the precursor cell populations that are at earlier stages of differentiation while

memory T cells at late stages of differentiation acquire effector functions and are able to secrete proinflammatory cytokines such as IFN-? and tumor necrosis factor a. Therefore, in HIV-1 infection there is a selective defect of HIV-1-specific $CD4^+$ helper T cells while HIV-specific $CD4^+$ T cells secreting IFN-? are still present.[35] [38] [75]

How is it possible to explain the persistence of HIV-specific memory $CD4^+$ T cells secreting IFN-? in the absence of the memory cells, (e.g. T helper cells) that function as precursors? The likely explanation is that HIV-1-specific memory $CD4^+$ T cells secreting IFN-? belong to the population of long-lived memory T cells that may persist for several years even in the absence of the replenishment by the precursor cell populations.

$CD4^+$ T cell responses against other viruses such as CMV are detected in most HIV-1-infected patients but they are eventually lost in the advanced stages of disease.[76] In this regard, it is important to underscore the fact that both CMV-specific memory CD4 helper and effector T cell responses are consistently detected. Therefore, the defect of virus-specific memory $CD4^+$ T cells seems to be selective for HIV-1-specific and no for other virus-specific $CD4^+$ helper T cell responses. This suggests that the elimination of HIV-1-specific helper T cells does not occur randomly. It is likely that already at the time of primary HIV-1 infection, when there is massive virus replication and spreading and thus high antigen levels, the pool of precursors of memory HIV-1-specific T cells is rapidly eliminated in the process of responding to the infection.

In addition to the large number of studies in the field of basic immunology and in human virus infections such as CMV and hepatitis C virus,[76] [77] [78] there are also several observations in HIV-1 infection that link the presence of optimal $CD4^+$ T cell responses to lack of progression of HIV-1 disease and better control of virus replication. As mentioned above, a small percentage (1%) of HIV-1-infected patients (i.e. long-term nonprogressors) experience no signs of disease progression, no decline in $CD4^+$ T cell counts and low/absent levels of virus replication, even several (10–15) years after infection. HIV-1-specific $CD4^+$ helper and effector T cell responses are consistently found in long-term nonprogressers. Therefore, it is important to underscore that the detection of HIV-1-specific helper and effector T cell responses represents a constant feature of the effective immune response found in long-term nonprogressors.

Importance of HIV-1-specific $CD8^+$ T cells

There are at least three major lines of evidence for the central role played by CTLs in controlling HIV-1 replication. First, primary HIV-1 infection is associated with a very potent CTL response that generally coincides with the peak in viremia and precedes the neutralizing antibody response.[3] [4] [5] This response is associated with major oligoclonal expansion of HIV-1-specific $CD8^+$ T cells. In some patients a large percentage (up to 40%) of circulating $CD8^+$ T cells are specific for HIV-1.[5] The advent of CTL response is temporally associated with the downregulation of viremia.[4] [5] This observation indicates a role for CTLs, which are mostly contained in the T cell population characterized by the expression of the CD8 surface molecule, in the initial control of virus replication. However, direct demonstration of the important role played by $CD8^+$ CTLs comes from the SIV monkey model of HIV-1 infection. In fact, it has been demonstrated that the depletion of $CD8^+$ cells following infusion with a specific anti-CD8 monoclonal antibody resulted in a failure to control the early peak of viremia in the infected animals.[79] Along the same lines, the depletion of $CD8^+$ CTLs in SIV chronically infected monkeys was associated with transient rises in the viremia levels[80] and loss of immune control occurs following the emergence of virus mutants in vivo that are not recognized by CTLs.[81] [82] [83] [84] [85] [86]

Second, it has been shown that the HLA type may significantly influence the rate of HIV-1 disease progression.[87] In particular, HLA types such as HLA-B27 and HLA-B57 are associated with slow disease progression and HLA-B35 with faster disease progression. Since CTLs recognize virus peptides presented by HLA class I molecules, different HLA types may have different ability to present peptides and thus substantially influence the quality of the immune response elicited.

Third, HIV-1-specific $CD8^+$ T cell responses have been found in virus-exposed uninfected individuals[88] and/or animals.[89] [90] Therefore, the above observations, together with a large quantity of recently accumulated experimental evidence, indicate that $CD8^+$ T cells may potentially play a major role in the control of HIV-1 replication, and the development of a preventive HIV-1 vaccine based on the induction of CD8 CTLs may potentially confer partial and/or complete control of HIV-1 infection.

However, despite all this evidence in support of the fundamental role that $CD8^+$ T cells may exert in the control of HIV-1 replication and disease, this vigorous immune response is not able to eliminate HIV-1 at the time of primary infection and the control of HIV-1 replication after the transition to the chronic phase of infection is only partial. The partially effective control of HIV-1 replication does not fit very well with the magnitude of the HIV-1-specific immune response detected at the time of primary infection and its persistence for several years.[91] Therefore, the observations above indicate that the inability of the HIV-1-specific $CD8^+$ T cell immune response to control virus replication cannot be explained by a defect in the magnitude of the immune response. Even although it has been shown that certain HIV-1-specific $CD8^+$ T cell clones are rapidly deleted during primary infection,[44] this event does not seem to influence significantly the magnitude of the $CD8^+$ T cell response.

These latter observations indicate that the detection of large frequencies of HIV-specific CTLs does not necessarily reflect the effectiveness of the immune response in the control of HIV infection. $CD8^+$ T cells may mediate antiviral activity by the production of soluble factors such as the cytokine IFN-?,[92] [93] [94] the chemokines MIP-1a, MIP-1ß and RANTES,[95] [96] [97] and the partially characterized $CD8^+$ T cell antiviral factor CAF,[98] [99] and/or by lytic mechanisms. HIV-1-specific CTLs are able to produce the above antiviral factors. However, recent studies have strongly suggested that the HIV-1-specific $CD8^+$ T cells present in HIV-1-infected patients may have major abnormalities at both functional and maturational levels. In this regard, it has been shown that HIV-1-specific CTLs have a selective defect in their levels of intracellular perforin that may significantly affect their lytic capacity.[100] Therefore, although HIV-1-specific CTLs have been shown to lyse HIV-1-infected $CD4^+$ T cells following activation in vitro,[101] freshly isolated virus-specific T cells show poor lytic activity.[102] [103]

Furthermore, recent studies have also demonstrated that the pool of memory T cells is composed of several populations of memory $CD8^+$ T cells with different functional capacities and at different stages of maturation. [73] [74] Studies aimed at the functional characterization of the different populations of memory HIV-1-and CMV-specific $CD8^+$ T cells have allowed the development of a lineage differentiation pattern for memory $CD8^+$ T cells and have demonstrated major differences within the composition of the HIV-1- and CMV-specific memory $CD8^+$ T cell pools.[74] The HIV-1-specific memory $CD8^+$ T cell pool is predominantly composed of pre-terminally differentiated $CD8^+$ T cells, as compared with the CMV-specific memory $CD8^+$ T cell pool, which is mostly composed of terminally differentiated $CD8^+$ T cells.[74] The differences in the maturation between HIV-1-specific and CMV-specific $CD8^+$ T cells are probably associated with a different lytic capacity, since CMV-but not HIV-1-specific $CD8^+$ T cells have normal intracellular levels of perforin. [100] More importantly, the different composition in the

pool of memory $CD8^+$ T cells seems to translate into a different efficacy in the control of the two virus infections: effective control of CMV infection versus poor control of HIV-1 infection and progressive disease. Taken together, these observations indicate that the detection of large number of antigen-specific $CD8^+$ T cells by tetramer staining as well as a high frequency of IFN-? secreting cells is not necessarily an indicator of an effective immune response.

Virologic factors

As discussed above, interaction among different host factors helps to determine a certain virologic set point in each HIV-1-infected person after the transition from primary to chronic HIV-1 infection.[44] [45] This set point represents the level of plasma viral RNA that accurately predicts disease progression (i.e. the level of plasma viremia that corresponds to a risk of progression to either AIDS or death). In the past, many predictors have been identified, clinical, biologic and virologic. The $CD4^+$ T cell count is historically the most important and widely used predictor. However, the load of plasma RNA is nowadays the most accurate predictor, especially when used along with the $CD4^+$ T cell count.[45] Therefore, the higher the plasma viral RNA load, the greater the risk of rapid progression to AIDS and death. It is worth noting that the power of association between levels of plasma HIV-1 RNA and risk of progression does not significantly vary if viremia is measured after seroconversion (i.e. knowing the date and duration of HIV-1 infection) or during the established chronic asymptomatic phase (i.e. with no available information about the duration of the infection, as is often the case in clinical settings). [44] Viral load is therefore a very powerful predictor if measured during the chronic asymptomatic phase, once the virologic set point has been reached.

However, the level of plasma viral RNA lacks accuracy and reliability as a predictor if measured during primary HIV-1 infection.[104] In this phase, rapid disease progression is predicted by:

Figure 120-5 Three-phase decay model of virus replication. Viremia below 50 HIV-1 RNA copies/ml plasma does not correspond to complete suppression of virus replication. Residual viremia (5–10 HIV-1 RNA copies/ml plasma) may still be detected 48 weeks after initiation of HAART. However, it is still unclear whether HAART induces complete suppression of virus replication and, if it does, what duration of HAART is needed to achieve this goal.

- a retroviral syndrome lasting more than 14 days;
- the number and the intensity of clinical signs and symptoms;
- central nervous system involvement; and
- viral phenotype.

The viral phenotype is an important virologic factor that can contribute to the rate of disease progression. R5 HIV-1 strains are non-syncytium-inducing strains, whereas X4 HIV-1 strains are syncytium-inducing strains. Syncytium-inducing strains tend to emerge during the late phase of the disease and a shift in viral phenotype from non-syncytium-inducing strains to syncytium-inducing strains heralds disease progression. The viral phenotype of the non-syncytium-inducing strains is associated with prolonged AIDS-free survival and is more commonly found in long-term nonprogressors.[105]

ERADICATION OF HIV-1 INFECTION

An understanding of the immunologic and virologic events that occur during primary HIV-1 infection and that lead to the establishment of the chronic phase has been achieved. Also, the mechanisms that HIV-1 has evolved in order to escape the immune response, have been elucidated. These advances have challenged the most widely accepted theories about the feasibility of HIV eradication.

Decay of HIV-1-infected compartments after highly active antiretroviral combination therapy

The recent development of HAART has permitted the study of the decay of the different HIV-infected compartments after effective suppression of virus replication and, thus, the estimation of the turnover of both virions and cells supporting virus replication. These studies[106] [107] [108] have proposed a two-phase decay model of viral load (Fig. 120.5). By assessing the decay of plasma viral RNA after HAART, it has been estimated that about 10^{10} –10^{11} virions are produced

daily. Two factors determine the decay and the inclination of the slope of plasma viremia after HAART:

- the extent of clearance of virions, and
- the decrease in the number of cells actively producing virus as a result of the inhibition of new rounds of infection.

By means of mathematical models, it has been determined that free virions are eliminated with a half-life of 6 hours, whereas productively infected cells have a half-life of 1.6 days.[107] [108] [109] The combination of these two events explains the first rapid phase of decay of plasma viremia. The nature of this phenomenon is clarified by the mechanisms leading to productive HIV-1 infection. As discussed above, although HIV-1 can target different populations of cells — $CD4^+$ T cells, monocytes and macrophages, dendritic cells and others — virus replication is mostly supported by activated $CD4^+$ T cells with the memory phenotype. The preferential replication in $CD4^+$ T cells can be explained by the physiologic differences and by the differential anatomic distribution of the various cells targeted by HIV. No efficient virus replication can occur without activation of the target cell. Although HIV-1 is able to infect resting $CD4^+$ T cells, proviral DNA is not integrated and thus no active virus replication is achieved. The state of target cell activation is therefore a fundamental requirement for HIV-1 to replicate efficiently.

$CD4^+$ T cell activation may be caused either by antigen-specific stimulation or by the physiologic activation of the small number of cycling $CD4^+$ T cells. About 1% of $CD4^+$ and $CD8^+$ T cells are proliferating at any given time in healthy people. Monocytes, macrophages and dendritic cells turn over at a much lower rate than do T cells, and their activation is probably limited to sites of inflammation. Therefore, the activated pool of proliferating $CD4^+$ T cells can support efficient replication of HIV-1, whereas other cell types, although being susceptible to HIV-1 infection, are probably responsible for a negligible amount of virus production. In addition, cells that continuously recirculate from lymph nodes to the bloodstream are almost exclusively $CD4^+$ T cells. These observations explain not only why $CD4^+$ T cells are responsible for between 98% and 99% of the total virus produced, but also the fact that the use of HAART, which efficiently inhibits the virus so that it cannot complete its replication cycle, causes a rapid and steep decrease in the plasma viral load (first phase of decay).[108] [109]

The first phase of decay of plasma viremia is then followed by a much slower reduction of the levels of HIV-1 RNA in plasma (second phase of decay). Tissue macrophages and long-lived, latently infected T cells could support the residual virus replication, havinga half-life of 1–4 weeks and 0.5–2 weeks, respectively. More likely, HIV-1 virions are released from the deposits trapped in the follicular dendritic cell network in the germinal centers of the lymphoid tissues. In support of this hypothesis, HAART efficiently depletes these deposits over a period of 6–12 months.[110] Consistently, this second phase of decay is flatter and tends to last much longer than the first one.

On the basis of this two-phase decay model, eradication of HIV-1 was hypothesized as being achievable in a relatively short time — between 2 and 3 years.[109] However, this goal could be realized only if a complete suppression of virus replication had been sustained and if there were no pool of long-lived, latently infected cells to serve as a virus reservoir. [27] [28] [29] [30] [31]

The results obtained from HIV-1-infected patients after long-term HAART (2–3 years of treatment) have significantly challenged these theories. In this regard, a pool of latently HIV-1-infected resting memory $CD4^+$ T cells can be detected in HIV-1-infected patients who have adhered to HAART for up to 3 years.[27] [28] [29] [30] [31] This pool possesses a longer half-life than the original estimate of 1–4 weeks and is composed of quiescent memory $CD4^+$ T cells. More importantly, these cells contain replication-competent proviral DNA, and after appropriate activation they are able to support efficient viral replication.

Although the estimated extent of this pool is quantitatively limited, ranging between 50,000 and 5,000,000 resting memory $CD4^+$ T cells for the whole body,[27] [28] [29] [30] [31] this pool of cells has been estimated to have a half-life of 3–6 months,[109] which corresponds approximately to the half-life of uninfected resting memory $CD4^+$ T cells, thus dramatically changing the estimates of the potential time required for HIV-1 eradication.

As mentioned above, this pool probably originates from productively infected cells at the time of the primary HIV-1 infection. It is noteworthy that initiation of HAART as early as 10 days after the onset of symptoms of primary HIV-1 infection does not prevent the generation of this pool, despite the successful control of plasma viremia shortly after initiation of HAART. This emphasizes the rapidity with which viral reservoirs are established after initial infection, and HAART is probably not able to interfere with this immunopathogenic process. It is, therefore, clear that this pool of cells represents a major obstacle in the attempt to eradicate HIV-1 completely in infected people.

The immunopathogenic role of long-lived resting memory $CD4^+$ T cells in HIV-1 infection may reside not only in their function as a reservoir but also in the fact that they may possess the ability to support virus production in vivo, albeit at low levels.[111] Results from several clinical trials show that viral load decreases below detectable levels (i.e. below either 400 copies or 50 copies of HIV-1 RNA/ml plasma) in the majority of HIV-1-infected persons taking HAART for over 6 months. However, the recent availability of more sensitive tests that can detect viremia down to 5 copies of HIV-1 RNA/ml plasma[112] has significantly changed the interpretation of such results, indicating that viral load below 50 copies does not necessarily correspond to complete suppression of viral replication. Between 40% and 60% of patients have levels of viremia that are lower than 50 but higher than 5 HIV-1 RNA copies/ml plasma after 36–48 weeks of HAART. This indicates that the use of ultrasensitive tests measuring plasma viremia allows both detection and quantification of residual virus production.

These observations complicate the situation, in that persistence of very low residual levels of virus replication may be another mechanism through which HIV-1 is able to maintain itself in the host by renewing the pool of cells that can serve as a reservoir. In fact, long-lived infected $CD4^+$ T cells may be responsible for supporting the residual viral replication in vivo. The rapid rebound of plasma viremia to pretherapy levels that occurs within 2–4 weeks of stopping long-term HAART is consistent with this detection of viral persistence. [111]

However, another potential source of residual virus replication may be sanctuaries for the virus — cells and organs where the virus can be sheltered or where HAART does not achieve therapeutic concentrations of drug (Table 120.2). Tissue sanctuaries for the virus include the lymphoid tissue, the mucosa-associated lymphoid

tissue, the genital organs and the central nervous system, where the achievable

TABLE 120-2 -- Tissue and cellular sanctuaries for HIV-1.

TISSUE AND CELLULAR SANCTUARIES FOR HIV-1	
Tissue sanctuaries	**Cellular sanctuaries**
Lymphoid organs	Resting memory $CD4^+$ T cells
Mucosal-associated lymphoid tissue	Macrophages
Central nervous system	Microglial cells
Cerebrospinal fluid	Langerhans cells
Genital organs	

concentration of antiviral drugs, in particular of protease inhibitors, may be suboptimal. These sites may serve both as a potential source of low-level virus replication and as a reservoir of latently HIV-1-infected cells. Latently infected resting $CD4^+$ memory T cells, macrophages, microglial cells, dendritic cells and Langerhans cells may conceivably be cellular sanctuaries for HIV-1.

It appears, then, that cells with a prolonged turnover and a decreased extent of activation, which reduces the susceptibility of HAART, and structures where the bioavailability of antiviral drugs is limited further complicate the issue of HIV-1 eradication.

These observations may indicate the existence of residual virus replication (viremia), whose decay is difficult to evaluate, based on the limited sensitivity of the available laboratory assays.[111] Furthermore, it is difficult to envisage to what extent the population of long-lived latently HIV-infected resting $CD4^+$ T cells may affect the putative time needed to achieve eradication of HIV-1, because no conclusive data are available on the half-life of these cells. However, the time to eradicate HIV-1 has now been set up to 5–10 years, considering a half-life of 4 months for these cells and provided that effective and durable suppression of viral replication is achieved by HAART.

Production of $CD4^+$ T cells after highly active antiretroviral combination therapy

The issue of HIV-1 eradication is also linked to the extent of immune restoration that can be achieved with the prolonged use of HAART. In this context, the study of the kinetics of proliferating $CD4^+$ T cells carried out in both peripheral blood and lymph nodes of HIV-1-infected persons at an early stage of infection has yielded important insights into the extent of HAART-induced restoration of immunity.[113]

Estimates of the production of $CD4^+$ T cells can be obtained by assessing the proportion of cells that are positive for the Ki67 antigen, which is a nuclear antigen associated with proliferation. Using this approach, it is possible to define three phases in the kinetics of production of $CD4^+$ T cells after HAART. Shortly after the initiation of HAART, a rapid increase in peripheral $CD4^+$ T cell counts can be observed, which is not associated with an increase of proliferating $CD4^+$ T cells. The rise in the counts of $CD4^+$ T cells may be associated with a redistribution of T cells from lymphoid compartments, and therefore this first phase may be termed the 'phase of redistribution'. After this phase, there is a progressive and significant increase in the number of proliferating $CD4^+$ T cells. This occurs between 12 and 48 weeks of HAART. During this phase, the 'phase of production', a significant restoration in the $CD4^+$ T cell count occurs. Interestingly, in HIV-1-infected patients who are receiving HAART and who have peripheral $CD4^+$ T cell counts that return to normal levels and remain stable, the phase of production is replaced with a 'plateau phase', as the fraction of proliferating $CD4^+$ T cells tends either to stabilize or to decrease after 36–48 weeks of HAART.

These observations emphasize the fact that the regenerative capacity of $CD4^+$ T cells is present and functional during the early chronic phase of HIV-1 infection. Furthermore, the institution of HAART may play a crucial role in driving the restoration of $CD4^+$ T cells to normal levels.

HIGHLY ACTIVE ANTIRETROVIRAL COMBINATION THERAPY COMBINED WITH IMMUNE-BASED STRATEGIES

There are some important limitations associated with the use of HAART. First, eradication of HIV-1 after HAART cannot be achieved in the originally estimated time (2–3 years) and it probably cannot be eradicated in less than 50–60 years. As discussed above, the T cell reservoir of HIV-1, which is established very early in the natural history of the disease; the residual virus production that persists despite prolonged, effective HAART; and the presence of sanctuaries for the virus constitute major obstacles for the long-term control and eradication of the virus. At the same time, these facts emphasize that simply waiting for the natural extinction of long-lived, latently infected cells may not be a good option because it is unrealistic to maintain HAART over the estimated prolonged period of time needed to achieve HIV-1 eradication.

Second, the questions of when to initiate HAART during established chronic HIV-1 infection and which drugs to use in combination as first-choice therapy are important ones, owing to the observed virologic failure that occurs in about half the HIV-infected persons who take HAART.[114] [115] [116] Virologic failure, however, is more likely in persons who have previously received suboptimal antiviral therapy, such as monotherapy or dual therapy with reverse transcriptase inhibitors; moreover, virologic failure depends on both the clinical stage of HIV-1 disease and the adherence to treatment. On the other hand, the use of HAART in antiviral-therapy-naive asymptomatic HIV-1-infected persons at an early stage of the disease (i.e. when the $CD4^+$ T cell count is 300–400 cells/ml or more) is rarely associated with virologic failure, provided there is good adherence to therapy. Adherence is obviously related to the acceptability of antiviral combination therapy in terms of both daily number and schedule of pills and to drug toxicity. The acceptability of protease inhibitor-sparing regimens[117] is likely to be superior to that of protease inhibitor-containing regimens. However, the long-term virologic and immunologic responses to the former need to be investigated further.

Third, drug toxicity is a fundamental issue. Particular attention has recently been focused on the long-term effects of HAART on metabolism, which include glucose intolerance and altered levels of lipids and fat distribution;[118] however, from an intention-to-treat viewpoint, the benefits that HAART can provide outweigh the drug-toxicity-related risks.

Taken together, these observations emphasize that HAART used alone is unlikely to eradicate HIV-1 infection. However, HAART is undoubtedly the cornerstone of HIV-1 therapy, because it is able to induce effective and durable suppression of virus replication, to block disease progression and to provide some restoration of the immune response despite the presence of residual virus replication. Highly active antiretroviral combination therapy is at present the best available option to prepare the necessary background (i.e. the best achievable control of virus replication and the greatest possible immune restoration) for subsequent immune-based therapies aimed at long-term control or eradication of HIV-1.

There are several possible objectives of immune-based therapies to achieve both the induction of immune-mediated control of HIV-1 and the elimination of cellular sanctuaries for the virus (see Chapter 140).[111] These objectives include:

- the maintenance or enhancement of existing HIV-1-specific immune responses and the restoration or strengthening of nonspecific immune responses; therapies with interleukin-2 may be the best tool for achieving these goals, because they can improve $CD4^+$ helper T cell function and cell-mediated immunity;
- the induction of HIV-1-specific immune responses *de novo*, using therapeutic vaccine strategies with HIV-1-specific antigens; and
- contributing to the clearance of the pool of latently HIV-1-infected cells — strategies aimed at inducing massive activation of memory $CD4^+$ T cells are being developed because activating these cells may reactivate replication of latent HIV-1 and thus cause virus-mediated killing of the target cell, or virus eradication by HAART.

It is, however, worth noting that the accomplishment of these strategies must take into account both the time of initiation of HAART and the stage of the disease, because different immune-based therapies and the type of immune restoration vary according to these factors. Before the introduction of immune-based therapies it is necessary to suppress virus replication efficiently with HAART. Finally, the stage of HIV-1 disease may warrant different rationales of immune-based intervention.[118]

Chapter 121 - Virology of HIV

Chen Liang
Mark A Wainberg

This chapter reviews the life cycle and genetic structure of HIV-1 in the context of understanding how viral and cellular regulatory factors may affect viral replication. Potential as well as current targets of antiviral chemotherapy are discussed. The synthesis of viral proteins and the manner in which viral assembly takes place is also considered.

GENERAL DESCRIPTION OF HIV-1

The virion

The HIV-1 virion forms an icosahedral sphere with projections consisting of the envelope (Env) glycoproteins gp120 and gp41. Gp120 is loosely and noncovalently associated with gp41 and the latter transverses the lipid bilayer. Figure 121.1 is a schematic representation of the mature HIV-1 virion. Under the lipid layer, the matrix (MA) protein (p17) covers the internal surface of the viral coat. The capsid (CA) protein (p24) constitutes the shell of the cone-shaped core, and the nucleocapsid (NC) protein (p7) forms part of a nucleoid structure that also consists of reverse transcriptase (RT), integrase (IN), and two copies of the single-stranded viral genomic RNA.[1]

Genomic organization of HIV-1

The HIV-1 provirus (i.e. the DNA form of the viral nucleic acid) is about 9.5kb in length and contains long terminal repeats (LTRs, 634bp) at each of the 5' and 3' ends.[2] Figure 121.2 is a schematic description of the HIV-1 genome and the known functions of its gene products. The LTRs consist of the U3, R, and U5 regions within which exist *cis*-acting elements essential for viral integration and transcription. RNA synthesis is initiated within the 5'-LTR at the junction between the U3 and R regions. HIV-1 harbors three structural genes (i.e. *gag*, *pol* and *env*) and six regulatory genes (i.e. *vif*, *vpr*, *tat*, *rev*, *vpu* and *nef*). The structural genes code for polyprotein precursors that are involved in virion construction. The open reading frames for the regulatory genes are positioned in the central portion of the genome and flank the *env* gene. The Vpr, Vif as well as Nef proteins are packaged into mature virions.[3] [4] [5]

Gag and Gag-Pol proteins

Pr55Gag and its products

The open reading frame of the *gag* gene (1536 nucleotides) is translated directly into a 55kDa Gag precursor (Pr55Gag; Fig. 121.3). This polyprotein is further cleaved by the viral protease (PR) to yield mature proteins, including MA, CA, NC and p6.[6] Although processing of Pr55 can be detected in the cytoplasm, it is generally believed that this event takes place mainly on the membrane of the host cell or inside the released viral particle. Processing of the precursor is accompanied by morphologic rearrangement of virus particles, and this can be visualized by electron microscopy. Notably, cleavage between p24 and p2 at the late stage of virus morphogenesis allows the formation of the cone-shaped core structure.[7] The final products include:

- p17 — MA protein, which comes from the N terminus of Pr55 and is myristylated at its N terminus;
- p24 — CA protein, which is derived from the central part of Pr55 and forms the cone-shaped core;
- p7 — NC protein, which is highly basic and tightly associated with viral genomic RNA;
- p6, which is part of the core structure; and
- p2 and p1 — spacer peptides, which regulate Pr55 processing.

The MA protein directs the intracellular transport and membrane association of the Gag polyprotein.[8] As part of the preintegration complex, MA is also critical for transporting the complex into the nucleus by virtue of a nuclear localization signal (NLS) at its N-terminus; this process is essential for productive infection of non-dividing cells and may be responsible for recruiting viral envelope proteins to the surface of host cells.[9]

The CA forms the core of the mature virion. It is believed that proteolytic liberation of Pro1 (i.e. the first amino acid in CA) allows the formation of a salt bridge between Pro1 and Asp51, which in turn triggers conformational rearrangement of CA and consequently the formation of the core structure.[10] CA contains a major homology region (MHR) at its C-terminus that plays crucial and yet ill-characterized roles in Gag aggregation. CA recruits the cellular factor cyclophilin A (Cyp A) into virus particles; Cyp A is needed for uncoating after virus entry into the host cells.[11]

NC serves as the interaction domain that mediates Gag-Gag interactions. This protein is highly basic and possesses two copies of zinc finger motifs (CCHC). NC binds to nucleic acid sequences and further modifies their structures to thermostable states; thus, this protein is defined as a nucleic acid chaperone. Multiple functional roles of NC protein have been identified and these are:[12]

- to stimulate reverse transcription;
- to assist in viral genomic RNA packaging; and
- to promote dimerization of viral RNA.

The protein p6 contains the late domain (P(T/S)AP) that is needed for successful budding of virus particles from the plasma membrane. p6 is also responsible for the incorporation of Vpr into virus particles.

Certain drugs have been identified that may antagonize the zinc finger regions of the NC proteins. These compounds may conceivably be tested in future clinical trials.

Pr160 and its products

The open reading frame of the *pol* gene (3045 nucleotides) is translated only as a Gag-Pol fusion protein, Pr160, by a translational frameshift mechanism as ribosomes read full-length genomic HIV-1 transcripts. In mature virions, the *gag* and *pol* gene products are found in a ratio of about 20:1 (see Fig. 121.3).[13] The Pol precursor is cleaved to produce PR (p10), RT (p66/51) and IN (p32).[14]

- PR is responsible for processing the Gag and Gag-Pol precursors — mutations in the catalytic region of PR are lethal to the virus;
- RT is responsible for catalyzing the conversion of viral RNA into DNA (reverse transcription); and
- IN plays a key role in inserting viral DNA into the host cell chromosome.

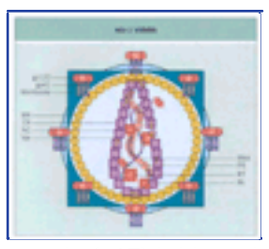

Figure 121-1 HIV-1 virion. The glycoprotein gp120 constitutes the outer envelope of the virus and is noncovalently linked to the transmembrane protein gp41. The matrix protein (p17) bridges the envelope protein with the cone-shaped structure formed by the capsid protein (p24). The viral genomic RNA and processed nucleocapsid (NC; p7) and Pol proteins, reverse transcriptase (RT) and integrase (IN), are located inside the capsid core. PR, protease.

To date, viral RT and PR have been the principal targets of antiviral chemotherapy. Viral IN represents another obvious target for such efforts, and development of drugs that target IN constitutes an important area of research.

Figure 121-2 Genetic organization of HIV-1 and known functions of gene products. The structural genes are *gag, gag-pol* and *env*. Catalytic proteins are encoded by the *pol* gene. Regulatory proteins are translated from fully spliced mRNA. Within the HIV-1 genome, there are additional open reading frames that flank the *env* gene and encode several regulatory proteins including Vif, Vpr, Tat, Rev, Vpu and Nef. LTR, long terminal repeat; PIC, pre-integration complex consisting of viral cDNA, IN, RT, Vpr, MA and NC.

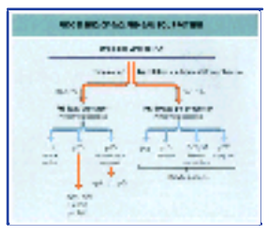

Figure 121-3 Processing of Gag and Gag-Pol proteins. The Gag proteins are initially translated as a 55kDa polyprecursor. Proteolytic processing of Pr55Gag generates several mature products. The catalytic proteins, including reverse transcriptase (RT), integrase (IN) and protease (PR), are first produced as a Gag-Pol precursor (Pr160Gag-Pol) through a translational frameshift mechanism; Pr160Gag-Pol is then cleaved to the smaller enzymatically active subunits.

The *env* gene and its products

The *env* gene is translated into a polyprotein of 160kDa. This precursor protein is folded and further glycosylated in the endoplasmic reticulum (ER) and Golgi apparatus before being transported

to the plasma membrane. A signal peptide (about 30 amino acid residues) at the N terminus of gp160 is removed and a subsequent proteolytic step in the Golgi compartment, mediated by a cellular enzyme, yields the N-terminal gp120 and the C-terminal gp41. [1] Although the external viral protein gp120 plays a key role in interacting with the CD4 receptor and/or co-receptor of susceptible cells,[15] the transmembrane protein gp41 is responsible for anchoring gp120 through noncovalent interactions and mediating the fusion process between viruses and target cells. Peptide inhibitors have been developed that specifically bind to gp41 and thus block virus entry.[16]

HIV-1 regulatory proteins

Tat protein, or viral transactivator

Tat belongs to a novel class of eukaryotic regulatory proteins that exert their effects on transcription through binding to RNA motifs. This protein is primarily located in the nucleus and nucleoli of infected cells and binds to a stem-loop structure, termed TAR (Tat-associated RNA), at the 5' end of nascent RNA (position 1–57). Interaction of Tat and RNA may:

- increase the stability of the RNA polymerase to allow more efficient synthesis of full-length transcripts;
- increase the frequency of RNA initiation; and
- increase the efficiency of translation of TAR-containing RNA.

Tat plays its roles in transcription activation through recruitment of cellular factors to the transcription complex that is assembled along the LTR promoter. Tat directly interacts with cellular factor cyclin T1 and the ternary complex thus assembled, together with TAR RNA, further recruits cyclin-T-dependent kinase (CDK)9, which, in turn, phosphorylates the C-terminal domain (CTD) of RNA polymerase II.[17] Tat can also regulate HIV-1 reverse transcription.[18] [19] In addition, Tat exerts a variety of effects on cell growth and proliferation and is likely to play a significant role in selective depletion of infected cells by triggering apoptosis.

Rev protein (regulator of virion protein expression)

Rev has a profound effect on the fate of primary RNA transcripts within the nucleus. Like Tat, Rev is located primarily in the nucleus and nucleoli of infected cells. The Rev protein binds to a complex stem-loop structure, the Rev-responsive region (RRE), within the HIV-1 *env* gene. The RRE is present in both full-length and singly spliced viral RNAs but is excluded by splicing from multiply spliced viral mRNAs. Consequently, in the absence of Rev, only multiply spliced RNAs, which encode regulatory proteins, are transported into the cytoplasm. In the presence of Rev, both unspliced and singly spliced viral mRNAs (for viral structural and catalytic proteins) are found in the cytoplasm. Rev shuttles between the nucleus and the cytoplasm. This activity is mediated by interactions between its nuclear export signal (NES) or NLS with cellular factors exportin-1 and importin-ß, respectively.[20] Although Rev has been found to be phosphorylated on serine residues, such modification is apparently not required for viral replication. Efforts are ongoing to develop drugs that can antagonize the function of Tat and Rev.

Vif, or the virion infectivity gene

Vif is made from a singly spliced mRNA that accumulates late in infection. Although Vif is dispensable for viral replication in some immortalized cell clones, it is required in peripheral blood mononuclear cells. This suggests that it may play an important role in infected hosts.[21] Vif is associated with viral RNA and may play a role in virus assembly. Because only traces of this protein are found in virions (amounts comparable with those of Pol proteins), its effects are assumed to be indirect.

Vpu protein

Vpu is made from the same singly spliced mRNA as the envelope glycoprotein. At least two functional roles have been identified:

- downmodulation of CD4 by stimulating degradation of CD4 in the ER; and
- enhancement of virion release by a yet to be defined mechanism.

Vpr regulatory protein

Vpr is packaged into mature virus particles through interactions with p6. It appears to be important in assisting the transport of the pre-integration complex from the cytoplasm into the nucleus. Vpr is also able to arrest infected cells at the G2 phase.

Nef protein

Nef is encoded by the extreme 3' end of the viral genome and accumulates even earlier than Tat and Rev in newly infected cells. Recent evidence suggests that Nef is involved in modulating CD4 expression by triggering the rapid endocytosis and lysosomal degradation of this main virus receptor. The Nef protein plays a major role in activation of quiescent T cells and thus facilitates viral replication.[22]

HIV-1 REPLICATION CYCLE

Entry of HIV-1

A schematic description of the HIV-1 life cycle is presented in Figure 121.4 . HIV-1 uses the CD4 receptor (a 58kDa transmembrane protein) to mediate initial attachment to cells through high-affinity interactions between the viral envelope glycoprotein (gp120) and a specific region of the CD4 molecule.[21] On the surface of both immature T cells and mature $CD4^+$ T helper cells, CD4 is present in abundance. It is present at lower concentrations on monocytes, macrophages and antigen-presenting dendritic cells.

A variety of co-receptors have now been identified on lymphocytes and monocytes that promote the entry of HIV-1 into target cells after the initial binding step between CD4 and viral gp120.[15] Two major co-receptors are CCR5 and CXCR4. While cells of monocyte/macrophage origin generally express only the former, many

lymphocyte populations can express both types of co-receptor. These differences in co-receptor expression help to explain why:

- HIV-1 variants may be either lymphocyte-tropic or macrophage-tropic, or both; and
- some viruses may be able to cause lymphocytes to fuse together into giant cells.

Certain host cell membrane proteins may also promote virus entry. One example is a C-type lectin (DC-SIGN) that is highly expressed on dendritic cells and binds to HIV-1 envelope glycoprotein gp120 (see Chapter 120).[23]

Efforts are underway to develop compounds that antagonize the entry of HIV-1 into susceptible cells by interfering with either the CD4 receptor or the various co-receptors on cells of different origins. Cell entry probably occurs by a fusion of viral and cell membranes, mediated by the viral transmembrane protein (gp41). Following fusion, the virion is uncoated by a proteolytic event that is most probably mediated by the virion-encoded protease.

Reverse transcription

After viral entry, the viral RNA is converted into DNA, which is then integrated into host cell chromosomal DNA. Reverse transcription initiates from a cellular $tRNA^{Lys.3}$ that is bound to a viral RNA fragment termed the primer binding site (PBS). This is followed by the first strand transfer, the priming of plus-strand DNA synthesis from the polypurine tract (PPT) and the second-strand transfer. The process of reverse transcription usually occurs within 4–6 hours of infection, takes place mainly in the cytoplasm

Figure 121-4 The HIV-1 life cycle. The diagram shows the various stages involved, including entry, uncoating, reverse transcription, integration, expression of proviral genome, viral assembly and particle release.

and is catalyzed by virion-encoded RT. Reverse transcriptase has at least three enzymatic functions:

- RNA-dependent DNA polymerase activity that copies viral RNA into viral cDNA;
- DNA-dependent DNA polymerase activity that copies (-) strand viral cDNA into (+) strand viral cDNA; and
- ribonuclease H activity (RNase H) that degrades the viral RNA template during synthesis of viral cDNA.

The final products of reverse transcription are double-stranded (ds) DNA molecules that are longer at each end than the viral RNA as a result of duplication of the LTR. It is likely that cellular factors are required for the completion of reverse transcription, as most reverse transcribed products in unstimulated quiescent peripheral blood lymphocytes consist of incomplete viral DNAs.[24] The nature of the host cell factors or cellular activation pathways involved is unknown.

Integration

As stated above, reverse transcription products are mainly generated in the cytoplasm of infected cells. These dsDNAs are then transported into the nucleus of the cell, where viral DNA is integrated into host cell chromosomal DNA. The pre-integration complex of HIV-1 consists of IN, RT, MA, NC, Vpr and reverse-transcribed DNA.

The integration reaction is catalyzed by the virion-encoded IN, which is found in the viral particle. After reverse transcription of genomic viral RNA, IN remains associated with viral DNA as a high-molecular-weight nucleoprotein pre-integration complex. The IN first removes two nucleotides from the 3' end of viral DNA and then cleaves target host DNA. This is followed by insertion of viral DNA into host cell DNA. The 5' gaps flanking the provirus as well as the two nonpaired nucleotides are presumably repaired or removed by a cellular enzyme. The final products (provirus) are flanked by 5-basepair (bp) direct target duplications, which have lost 2bp from each end. Once integrated, viral DNA remains permanently associated with the host genetic material for as long as the cell is alive.

Viral gene expression

HIV-1 exploits the host cell transcription and translation machineries to generate its own gene products. The primary RNA transcripts of the provirus are made by host cell RNA polymerase II. Cellular activation and proliferation signals result in the binding of transcription factors to the LTR and lead to increased rates of initiation of transcription. Tat and Rev are two key virion-encoded proteins that positively regulate viral gene expression and replication, whereas the accessory proteins, including Nef, Vif, Vpu and Vpr, are crucial determinants of HIV virulence. [25] The primary viral RNA transcripts are either transported into the cytoplasm to direct Gag/Gag-Pol synthesis and to serve as genomic RNA for packaging or are spliced to generate around 30 different species of RNAs for the production of additional viral proteins. Host cellular ribosomes translate proviral mRNA into viral proteins in either cap-dependent or cap-independent modes. The cap-independent mechanism involves an internal ribosomal entry site (IRES) present at the 5' end of viral RNA. All viral structural proteins are made as polyproteins. Regulatory proteins are made by translation of spliced mRNA.

Packaging and assembly

Gag proteins are the driving force for virus assembly. Three functional domains have been characterized within Gag; these are the membrane binding domain (M domain), interaction domain (I domain) and late budding domain (L domain). The M domain is located at the N terminus of MA, the I domain involves NC sequences, and the L domain consists of a P(T/S)AP sequence within p6. The Gag proteins play a central role in recruiting both viral proteins and host-cell-derived elements into mature viral particles. Env proteins are recruited into virus particles through interactions between MA and gp41. Two copies of full-length viral RNA are incorporated into each virus particle through interactions of their 5' end RNA sequences with Gag precursors. The replication primer $tRNA^{Lys.3}$ is most probably selected by the viral Gag-Pol protein, together with cellular enzyme $tRNA^{Lys.3}$ synthetase.[26] The L domain recruits a cellular factor, tumor susceptibility gene (TSG)101, to the virus assembly site on the plasma membrane and facilitates the 'pinch-off' of virus particles.[27] Virus budding may require ubiqitination of Gag proteins and cellular factors involved in protein transportation. HIV-1 particles assemble at microdomains of plasma membrane that are enriched in sphingolipids and cholesterol. HIV-1 also recruits other cellular factors, such as Cyp A, Staufen, translation elongation factor 1a and actin, that may assist to assemble infectious virus particles.

THERAPEUTIC CONSIDERATIONS

As stated above, the major targets of anti-HIV chemotherapy have been the viral RT and PR enzymes. The RT of HIV-1 is responsible for copying viral RNA into DNA. However, this enzyme has a high error rate (i.e. about one mutation/virus replication event). This means that mutants are constantly being generated that have the potential for drug resistance, which may be selected under treatment. Drug resistance to HIV will occur when these mutations result in altered forms of the viral RT and PR proteins that can still function yet are no longer efficiently inhibited by antiviral nucleoside and non-nucleoside inhibitors of RT and antagonists of the HIV PR enzyme. Since HIV-1 uses cellular machineries to complete its life cycle, it follows that reasonably conserved cellular components might also be potential targets for development of anti-HIV-1 compounds. The subject of HIV drug resistance is dealt with in detail elsewhere (see Chapter 137).

Chapter 122 - Primary HIV Infection

Bernard Hirschel

INTRODUCTION

Although primary HIV infection (PHI) is a rarely diagnosed, self-limiting disease,[1] it is a topic of considerable interest, since the first encounter of HIV with the immune system sheds light on many aspects of pathogenesis. The severity of PHI predicts progression to immunodeficiency years later; therefore, it is reasonable to hope that treatment of PHI prevents or retards AIDS. From a public health perspective, a diagnosis of PHI is important because such patients are highly infectious;[2] [3] to miss a diagnosis of PHI is to miss an opportunity for prevention.[4]

Experience shows that the diagnosis is not difficult to make; education is the key.

EPIDEMIOLOGY

Primary HIV infection is often asymptomatic but sometimes it presents with spectacular manifestations requiring hospital admission. There is a spectrum between complete absence of symptoms during the time of seroconversion and severe disease; therefore, it is not surprising that opinions vary about the percentage of patients who have symptomatic PHI. A physician's previous experience with PHI and a high index of suspicion greatly increase the number of diagnoses. Retrospective analysis from the US armed forces showed that 33% of patients suffered from an identifiable disease between their last seronegative and first seropositive serum sample. At the other extreme, in Australia,[5] 93% of seroconverting persons reported having been 'sick' compared with 40% of controls; 12% of seroconverting patients were hospitalized.

It is not known what factors determine the severity of PHI. Theoretically, the size of the inoculum, the virulence of the infecting HIV strain (including such factors as cellular tropism and cytopathogenicity), and the patient's immune status could be involved, but evidence as to whether these factors are important is lacking. One case series of transfusion-associated cases found that symptomatic PHI was more frequent among those infected by people who had late-stage disease. There is little evidence that the frequency or severity of PHI differs between transmission categories or between men and women. Symptomatic PHI can occur with HIV-2 infection and in children, although almost all cases have been reported in adults infected with HIV-1. There are theoretic reasons to believe that co-infection with other viruses, particularly from the herpes group, might enhance the proliferation of HIV, and patients who are simultaneously co-infected with cytomegalovirus have had particularly severe symptoms.

Symptoms typically start 2–4 weeks after infection, with extremes of 5 and more than 90 days. The median duration of symptoms is difficult to quantify and is between 12 and 28 days.[6] Moderate and subjective symptoms such as fatigue may persist for months, although almost all patients eventually enter an asymptomatic phase lasting years.

PATHOGENESIS AND PATHOLOGY

Because PHI most often presents as a benign self-limiting disease, pathologic information is only available from easily biopsied tissues.

The skin rash is caused by a dermal perivascular lymphohistiocytic infiltrate around vessels of the superficial dermis; the epidermis is normal. The inflammatory cells are predominantly of the $CD4^+$ phenotype, and may represent a T-cell-mediated reaction to HIV and to the p24 antigen, which can be detected in the Langerhans cells.

Lymph node biopsies reveal abundant HIV, including the envelope proteins gp120 and gp160 in dendritic reticulum cells, as well as in lymphocytes. The structure of the germinal centers is relatively normal and quite unlike the follicular hyperplasia of established HIV-1 infection, but extrafollicular B lymphocytes are reduced in number and the follicles are infiltrated by $CD8^+$ T cells. [7]

Therapy has a pronounced effect on the quantity of HIV detectable in lymph nodes. There is a lag of more than 6 months between disappearance of the virus from plasma and disappearance from lymph nodes. However, even patients who are aviremic for several months while treated for PHI and whose lymph node biopsies are apparently free from HIV relapse after discontinuing medication, emphasizing the role of a virus reservoir such as memory T cells.[8]

CLINICAL FEATURES

During PHI, HIV floods the blood,[9] the central nervous system (CNS)[10] and the lymphatic system, and invades a number of other tissues. Therefore, it is not surprising that PHI is a disease with protean manifestations. Three main presentations have been described.

Cutaneous presentation

This is characterized by a maculopapular rash, 'roseola' and mucosal ulcerations (Fig. 122.1 , Fig. 122.2 , Fig. 122.3 , Fig. 122.4). The rash affects the face, neck and trunk more than the limbs, although the palms and soles may be involved. Individual lesions are usually less than 1cm in diameter and confluence is rare. Case reports have mentioned pustular eruptions, urticaria, erythema multiforme and, during the healing phase of PHI, alopecia and desquamation. Ulceration may occur on the genital and oral mucosa, including the esophagus, where differentiation from herpetic lesions or esophageal candidiasis is difficult.

Presentation resembling infectious mononucleosis

This is characterized by fever, pharyngitis, arthralgia, myalgia and lymphadenopathy. Although the expression 'mononucleosis-like illness' is firmly established, there are many differences from classic infectious mononucleosis, most notably the lack of prominent tonsillar involvement. In a large series (Table 122.1), only 20% of patients had a fever in combination with sore throat and enlarged cervical lymph nodes, whereas 10% did not have fever, sore throat or cervical lymphadenopathy.

Figure 122-1 Maculopapular rash during primary HIV infection.

Figure 122-2 Acneiform lesions during primary HIV infection.

Figure 122-3 Penile ulcer during primary HIV infection.

Figure 122-4 Mucosal ulcerations during primary HIV infection.

Meningoencephalitis

Meningoencephalitis is characterized by photophobia and neck stiffness, headaches and disordered consciousness. The headache is typically retro-orbital and exacerbated by eye movements. Depression and changes in mood are frequent and may reflect underlying encephalitis.

Other symptoms

Table 122.1 shows the frequencies of signs and recorded symptoms in the medical charts of more than 200 patients from Switzerland and Australia. Digestive manifestations have not been well recognized in the past, but they are quite common. In exceptional cases, esophageal candidiasis (an AIDS-defining disease) may occur with a transient decline in $CD4^+$ lymphocyte count.

TABLE 122-1 -- Signs and symptoms of primary HIV infection.

SIGNS AND SYMPTOMS OF PRIMARY HIV INFECTION		
	Symptom/sign	**%**
Reported by more than 50%	Fever	77
	Lethargy/fatigue	66
	Rash	56
	Myalgia	55
	Headache	51
Reported by 20–50%	Pharyngitis	44
	Cervical adenopathy	39
	Arthralgia	31
	Oral ulcer	29
	Pain on swallowing	28
	Axillary adenopathy	24
	Weight loss	24
	Nausea	24
	Diarrhea	23
	Night sweats	22
	Cough	22
	Anorexia	22
Reported by 5–20%	Abdominal pain	19
	Oral candidiasis	17
	Vomiting	12
	Photophobia	12
	Meningitis	12
	Genital ulcer	7
	Tonsillitis	7
	Depression	7
	Dizziness	6
These are the signs and symptoms reported by at least 5% of patients.[1] [2]		

Apart from these major groups of symptoms and signs, many unusual manifestations have been described during PHI, most notably:

- ¦ neurologic syndromes such as radiculopathy, peripheral facial neuropathy and Guillain-Barré syndrome, and severe encephalitis with prolonged coma and seizures; and
- ¦ pulmonary involvement, which may be more frequent in intravenous drug users where PHI can be associated with bacterial pneumonia; severe pneumonitis leading to intubation and *Pneumocystis carinii* pneumonia [11] (with $CD4^+$ lymphocyte counts of less than $100/mm^3$) is exceptional.

Differential diagnosis

Important differential diagnoses are listed in Table 122.2 ; PHI must be distinguished from Epstein-Barr virus infection (infectious mononucleosis) and enterovirus meningitis, and according to the local epidemiologic context, typhoid fever, rickettsial infections and many others.

DIAGNOSIS

Seroconversion (i.e. the appearance of HIV antibodies in the serum) occurs days after the beginning of the symptoms of PHI. Therefore, the usual antibody tests for HIV are not entirely reliable; they are expected to be negative during the first few days of PHI (Fig. 122.5). Assays differ in the duration of this 'seronegative period';

with the currently used sensitive tests it is usually less than 1 week.

The p24 antigen is positive when the antibody test is still negative during PHI, and the same is true of HIV viremia. Whereas both tests can be used to screen for PHI, the p24 antigen test is considerably cheaper.[12] Viremia levels reach extremely high values, often in excess of 10^6 viral genomes/ml[13] and high titers of infectious virus have

TABLE 122-2 -- Important differential diagnoses.

IMPORTANT DIFFERENTIAL DIAGNOSES		
Clinical feature	**Epstein-Barr virus infection**	**HIV infection**
Onset	Gradual	Abrupt
Tonsil involvement	+++	+
Pharyngeal exudate	+++	-
Rash	Rare except in patients treated with antibiotics	Frequent
Jaundice	10%	Never
Diarrhea	Rare	25%
Clinical feature	**Syphilis**	**HIV infection**
Serology	Always positive	At first negative
Chancre: timing	Before roseola	At the same time as rash
Chancre: pain	Painless	Painful
Clinical feature	**Enterovirus meningitis**	**HIV meningitis**
Population	Young adults	Young adults
Diarrhea	Rare	23%
Season	Summer–autumn	None in particular
Duration	<8 days	Often >20 days
Encephalitis	None	Frequent
Skin lesions	Rare	Frequent
Pain on swallowing	None	Frequent

Figure 122-5 Successive Western blots during primary HIV infection. Note that on September 30, 1986, when the patient presented with fever, rash, meningitis and subclinical hepatitis, the screening enzyme-linked immunosorbent assay (ELISA) test for HIV antibodies was negative, while the Western blot showed only a single weak band corresponding to the p24 antigen. CSF, cerebrospinal fluid; ASAT, aspartate transaminase; ALAT, alanine transaminase; H, hepatitis (A or B); ND, not done.

been isolated from many tissues, including seminal fluid, corroborating the epidemiologic evidence that patients who have PHI are highly infectious. Viremia decreases rapidly — at least 100-fold within days after seroconversion — but remains detectable in more than 95% of patients. Steady-state plasma viremia levels predict progression to advanced immunodeficiency and death.[14] Levels tend to remain higher in those who have symptomatic PHI.[15]

The occurrence of HIV infection without the presence of antibodies for many months ('seronegative HIV infection') has caused much controversy, fueled by conflicting results and the extreme sensitivity of the polymerase chain reaction, which makes it vulnerable

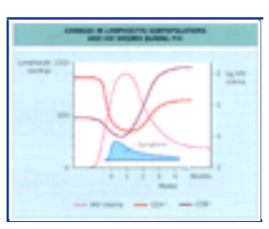

Figure 122-6 Changes in lymphocyte subpopulations and HIV viremia during primary HIV infection.

to contamination and false-positive results. Although patients with chronic seronegative infections may rarely occur, there is no evidence that these individuals are infective, and no patients with symptomatic PHI who have subsequently failed to seroconvert have been described. However, a seronegative patient who is in the process of seroconverting can transmit HIV, for instance by blood transfusion. The results of plasma viremia and p24 antigen tests as well as the clinical history and exposure must guide the interpretation of a negative serologic result.

Like viremia levels, lymphocyte subsets undergo rapid changes during PHI (Fig. 122.6). During the first 5–10 days, lymphopenia characteristically affects both $CD4^+$ and $CD8^+$ lymphocytes, with levels[11] that may be as low as those observed in AIDS. Although

opportunistic infections are rare, in-vitro tests of both B and T cells show immunosuppression. Within another 2–3 weeks there is a lymphocytosis. The $CD8^+$ lymphocyte count expands more than the $CD4^+$ lymphocyte count, leading to a $CD4^+$ /$CD8^+$ lymphocyte ratio of less than 1. This low ratio persists even in patients whose $CD4^+$ lymphocyte count subsequently rises to normal.

Many other laboratory values may be abnormal during PHI, reflecting the acute inflammatory response (e.g. high erythrocyte sedimentation rate, increase in C-reactive protein) and involvement of the bone marrow (thrombocytopenia), the liver (increase in hepatic transaminases) and the CNS (pleocytosis of the cerebrospinal fluid).

MANAGEMENT

Although PHI can be severe and prolonged, it is a self-limiting disease; the symptoms eventually abate and the patient becomes asymptomatic. Years later, immunosuppression may appear and AIDS may develop.

Features of primary HIV infection that may predict the subsequent course toward AIDS

A considerable body of evidence suggests that more severe and more prolonged PHI indicates a more unfavorable course toward AIDS.[16] [17] [18] For instance, in patients who were followed after seroconversion, 58% of those who had had symptomatic PHI had developed AIDS 7 years later compared with 28% of those who had asymptomatic PHI.[17] Another study suggested that the presence of neurologic signs at the time of PHI predicted accelerated immunosuppression,[18] although there was no specific relation to the neurologic signs of AIDS, such as AIDS-related dementia or opportunistic infections of the CNS.

Does treatment of primary HIV infection improve the long-term outcome?

This is a logical question that remains unanswered. Comparative studies between a treated group and an untreated control group face considerable practical obstacles, including the need for a large sample, extremely long follow-up and ethical issues.

Primary HIV infection is a self-limiting disease, usually of only slight or moderate severity. The balance has shifted back and forth between advocates and opponents of treatment.

Arguments in favor are:

- the association of symptomatic PHI with a worse prognosis;
- the limited heterogeneity of the viral population,[19] which should theoretically diminish the probability of emergence of resistance to antiviral drugs;
- the potential impact on infectivity and transmission;[2]
- the generalization of the HIV infection during PHI with invasion of the CNS[10] and lymphoid tissues; and
- the availability of more effective and better tolerated antiviral drugs. [20]

After pilot studies suggested that zidovudine was well tolerated and possibly effective in PHI, a prospective randomized trial in 77 patients compared placebo and zidovudine given for 6 months.[6] An effect on $CD4^+$ lymphocytes and a statistically significant decrease in minor opportunistic infections in patients treated with zidovudine were demonstrated.

Several uncontrolled trials have been conducted in PHI with combinations of antiviral drugs:

- with highly active antiretroviral treatment, including two inhibitors of reverse transcriptase and an inhibitor of the HIV protease, viremia decreases to undetectable levels in practically all compliant patients;[21] [22]
- progression to AIDS is less than in historical control groups;[23]
- the $CD4^+$ /$CD8^+$ lymphocyte ratio normalizes; and
- lymph node biopsies of some of the patients who have persistent suppression of viremia show disappearance of virus, and proviral DNA decays faster than in patients who start treatment during chronic HIV infection.[21] [24]

However, the hope of viral eradication remains unfulfilled, as discussed below.

Opponents of antiviral treatment for primary HIV infection point to the lack of studies showing clinical benefits, the high incidence of side effects, expense and problems with compliance. Some 6 months or so after having started treatment during PHI, patients often have high $CD4^+$ counts and would not otherwise qualify for antiretroviral treatment. Should they stop?

A small case series showed that viral load rebound after stopping was universal. However, even without treatment, viral loads often fell again to levels between 50 and 5000 copies/ml, possibly because of a vigorous immune response triggered by re-exposure to the virus. Many patients have now ceased therapy for more than 1 year and have done well.[25]

The present recommendations are to treat symptomatic primary infection as soon as diagnosed, particularly in patients who have a viral load greater than 100,000 copies/ml and a $CD4^+$ count less than 500 cells/µl. The optimal regimen would include one protease inhibitor (or a non-nucleoside reverse transcriptase inhibitor) and two nucleoside reverse transcriptase inhibitors. In certain communities, genotypic testing for resistance may be indicated because of a high prevalence of primary drug resistance (chapter 137). After a year or so of therapy, a trial of treatment interruption would appear reasonable.

Chapter 123 - Prevention of Opportunistic Infections

Nathan Clumeck
Stéphane de Wit

INTRODUCTION

One of the major clinical advances in the management of patients who have HIV infection has been the implementation in the mid-1980s of antimicrobial prophylaxis for patients with severe immune impairment. Together with the use of antiretroviral drugs, this has led to decreased morbidity and improved survival in patients with AIDS.

Such prophylaxis requires regular measurements of $CD4^+$ lymphocyte counts and compliance on the part of the patient, who must take many pills each day for the rest of his/her life. There are also issues of tolerance, drug interactions, emergence of resistance and cost.

Since the extensive use in Western countries of highly active antiretroviral therapy (HAART), a further marked decrease in the occurrence of AIDS-related opportunistic infections has been noted and the question of continuing or stopping prophylactic regimens has been raised in patients who have $CD4^+$ counts increasing beyond the critical level of 200 lymphocytes/mm^3 .[1] Figure 123.1 summarizes the evolution of the incidence of most opportunistic infections among a cohort of 2000 patients followed at CHU Saint-Pierre hospital in Brussels.

Although prophylactic regimens against most of the opportunistic infections that occur in patients who have HIV infection exist, the decision to use prophylaxis should consider factors such as:

- the incidence and prevalence of specific infections in HIV infected individuals;
- the potential severity of disease in terms of morbidity and mortality;
- the level of immunosuppression at which each disease is likely to occur;
- the feasibility and efficacy of preventive measures, and in particular their impact on quality of life and survival;
- the potential for emergence of organisms resistant to the agents used for prophylaxis;
- the risk of toxicities and drug interactions with antiretrovirals and other drugs used by HIV-infected patients;
- the issue of compliance; and
- the cost-effectiveness of prophylaxis.

INCIDENCE AND PREVALENCE OF OPPORTUNISTIC INFECTIONS

There is a wide geographic variability in the epidemiology of opportunistic infections. The probability of developing a given disease depends on the risk for exposure to potential pathogens, the virulence of the pathogens and the level of immunosuppression of the patient.

In the USA and Northern Europe, *Pneumocystis carinii* pneumonia (PCP), oropharyngeal or esophageal candidiasis, cytomegalovirus disease and infections caused by *Mycobacterium avium* complex (MAC) are common. The incidence of toxoplasmosis and tuberculosis is higher in central and southern Europe and in the developing countries, depending on the prevalence of latent infection in the general population. This geographic heterogenicity has important implications for prophylaxis. In the case of low incidence, prophylactic measures should be targeted to high-risk patients such as those who have a positive antitoxoplasma serology, a positive polymerase chain reaction for cytomegalovirus or a positive cutaneous tuberculin test for tuberculosis. In addition, for tuberculosis, epidemiologic assessment of risk should be used for some high-risk populations (intravenous drug users, migrants from an endemic area).

LEVEL OF IMMUNOSUPPRESSION

Blood $CD4^+$ lymphocyte levels is the best marker for immune status. It has been clearly established that the number of circulating $CD4^+$ lymphocytes is closely correlated with the risk of developing several opportunistic infections (Fig. 123.2). Once the $CD4^+$ lymphocyte count falls below 200 cells/µl, the cumulative risk for developing an AIDS-defining opportunistic infection is 33% by year 1 and 58% by 2 years. Therefore, $CD4^+$ lymphocyte counts remain an important parameter for monitoring patients who have HIV infection because of their predictive value for both opportunistic infections and mortality.

EFFICACY OF PROPHYLACTIC MEASURES AND IMPACT ON SURVIVAL

The survival benefit of prophylaxis for opportunistic infections has been demonstrated in a number of studies, particularly in patients who have severe immunosuppression. In the early 1980s, before the widespread use of antiretroviral therapy, it was demonstrated that trimethoprim-sulfamethoxazole (TMP-SMX) use for prevention of PCP did significantly prolong survival. A similar impact has been shown with MAC prophylaxis with clarithromycin or rifabutin.

It is clear that a prophylactic regimen that prolongs survival should be used in priority to one that does not. In this setting, the use of fluconazole for prophylaxis of systemic mycoses and oral ganciclovir for cytomegalovirus disease have failed to demonstrate a clear survival benefit and are not widely recommended.

EMERGENCE OF DRUG RESISTANCE

The development of resistance to the most commonly used agents is one of the major concerns with the use of long-term antimicrobial prophylaxis in patients who have HIV infection.

Resistance or cross-resistance has become increasingly common with prophylaxis for MAC, fungal infections and PCP. The major consequence is that, when the specific drugs are needed to treat acute infections, resistance hinders their use and alternative less effective or more toxic agents are the only option. [2]

This issue was well illustrated with clarithromycin as prophylaxis for MAC. Despite receiving prophylaxis, 58% of the patients developing MAC had clarithromycin-resistant isolates.[3]

Figure 123-1 Incidence of opportunistic infections among patients who have HIV infection. CHU Saint-Pierre, 1985–2001.

Figure 123-2 Association between opportunistic infections and CD4$^+$ cell count.

Prophylactic treatment of non-life-threatening infections, such as oral thrush with fluconazole, has probably contributed to the emergence and spreading of azole-resistant fungi.

Prophylactic regimens may also lead to the development of cross-resistance against more common pathogens. For example, rifabutin used for MAC prophylaxis may result in the emergence of rifampin-resistant strains of *M. tuberculosis*.[4] Likewise, the widespread use of broad-spectrum antibiotics, such as clarithromycin, azithromycin or TMP-SMX, may lead to the development of resistance among organisms such as pneumococci that were not the primary targets of prophylaxis. An increasing prevalence of *Streptococcus pneumoniae* resistant to TMP-SMX, for example, could decrease the effectiveness of this agent in preventing community-acquired pneumonia in advanced HIV patients and limit therapeutic options for treating common outpatient illnesses such as respiratory, skin and soft tissue infections.[2]

DRUG TOXICITY AND DRUG INTERACTIONS

Drug toxicity can be a major factor limiting the usefulness of widely used agents. The incidence of adverse drug reactions in patients who have HIV infection varies with the type of drug and dosages used, the interactions between drugs and the stage of HIV infection.[5]

HIV-related idiosyncratic factors, organ dysfunction in late stage disease and multiple drug therapy are the primary reasons for the increased risk of drug toxicities in HIV patients.

The issue of drug interactions has become particularly critical in the era of protease inhibitors. However, although the number of potential drug interactions is substantial, few require dosage modifications. Among these, clinicians should be vigilant when using concomitantly prophylaxis and treatment of mycobacterial diseases with rifamycin and macrolides and HIV protease inhibitors.

COMPLIANCE ISSUES

The use of combination therapy for prophylaxis against multiple opportunistic pathogens significantly increases the complexity of treatment of HIV patients. In particular, it may dramatically increase the number of pills that are necessary in combination antiretroviral regimens. Such increasingly complex regimens may lead to patient noncompliance and inability to tolerate other therapeutic regimens, inducing antiretrovirals.

COST-EFFECTIVENESS

To be most cost-effective prophylaxis should be directed at the most common infections in the patient population. However, an expensive prophylactic regimen may be cost-effective if it has a positive impact on quality and duration of life or if it reduces other costs. This is particularly true in severely immunocompromised HIV patients, in whom any intervention, even costly prophylaxis, that significantly reduces the incidence of hospitalization will have a favorable impact on the costs of caring. Studies have shown that prophylaxis for PCP and MAC is cost-effective, whereas prophylaxis for fungal disease and cytomegalovirus is not.[6]

DURATION OF PROPHYLAXIS AGAINST OPPORTUNISTIC INFECTIONS

Since HAART was introduced, it has become clear that prophylaxis against opportunistic infections need not necessarily be life long. As mentioned above, susceptibility to opportunistic infections can accurately be assessed by the CD4$^+$ T cell count.

It is thus logical to stop primary or secondary prophylaxis in patients whose immunity has improved as a consequence of HAART.

Data generated until now support this approach and recommendations concerning the safety of stopping primary or secondary prophylaxis can now be made for many pathogens.

By contrast, no data are available regarding the re-initiation of prophylaxis when the CD4$^+$ lymphocyte count decreases again to levels at which the risk for opportunistic infections exists. In particular, it is unknown whether it is better to use the threshold at which prophylaxis was stopped or the threshold below which initial prophylaxis is recommended.[7]

RECOMMENDATIONS FOR PROPHYLAXIS AGAINST OPPORTUNISTIC INFECTIONS

The US Public Health Services and the Infectious Diseases Society of America have established disease-specific recommendations for the prevention of opportunistic infections in individuals who have HIV infection, which were updated in November 2001. These recommendations include guidelines for preventing exposure to pathogens as well as on specific regimens for preventing initial episodes.[8]

Category I regimens are strongly recommended as standard of care. Category II should be strongly considered in eligible patients. Category III regimens are not routinely recommended but may be considered for use in selected patients (Table 123.1).

Recommendations on prophylactic regimens to prevent recurrence of opportunistic infections have also been updated (Table 123.2).

DISEASE-SPECIFIC CONSIDERATIONS

Pneumocystis carinii

Prophylaxis of PCP has been shown to be highly cost-effective.

A meta-analysis of 35 studies of PCP prophylaxis in 6583 patients showed that TMP-SMX was superior to dapsone or aerosolized pentamidine but there was no statistically significant survival advantage for TMP-SMX versus alternative agents. An advantage of TMP-SMX over alternative drugs is a significant reduction in bacterial infections. Side-effects are sufficiently severe to require discontinuation of the drug in 25–50% of TMP-SMX recipients compared to 25–40% of dapsone recipients and 2–4% of recipients of aerosolized pentamidine. There is good evidence that lower doses of TMP-SMX are better tolerated, and many advocate either the use of the lower dose regimens using one single-strength tablet daily or one double-strength tablet thrice weekly. Patients who have adverse reactions to TMP-SMX usually tolerate dapsone.

Primary and secondary prophylaxis against PCP should be discontinued in patients treated with HAART who show an increase in CD4$^+$ T cells to above 200/mm^3 for at least 3 months. Prophylaxis should be reintroduced if the CD4$^+$ T cell count decreases to less than 200/mm^3 .[9] [10]

Toxoplasma gondii

Toxoplasma seropositive patients who have a CD4$^+$ T cell count below 100/mm^3 or who have had a previous episode of toxoplasmic encephalitis should receive prophylaxis against toxoplasmic encephalitis.

The double-strength tablet daily dose of TMP-SMX is recommended. Alternative regimens in patients who cannot tolerate TMP-SMX include dapsone-pyrimethamine or atovaquone (with or without pyrimethamine). Prophylactic monotherapy with dapsone, clindamycin, pyrimethamine, azithromycin or clarithromycin are not

recommended.

Primary prophylaxis against toxoplasmic encephalitis should be discontinued in patients treated with HAART showing an increase in $CD4^+$ T cells to above 200/mm^3 for at least 3 months. Discontinuation of prophylaxis in patients where $CD4^+$ counts have increased to 100–200 cells/mm^3 has not been carefully evaluated. No firm recommendation can be made regarding discontinuation of secondary prophylaxis, but it appears reasonable to consider discontinuation in patients who have $CD4^+$ T cells above 200/mm^3 for at least 3 months. Prophylaxis should be reintroduced if the $CD4^+$ T cell count decreases to below 100–200/mm^3 .[10] [11]

Mycobacterium tuberculosis

Latent tuberculosis infection should be treated in all patients who have HIV infection and a positive tuberculin skin test, with no evidence of active tuberculosis and no history of treatment for active or latent tuberculosis.

TABLE 123-1 -- Prophylaxis of first episode of opportunistic infections in adults and adolescents with HIV infection.*

PROPHYLAXIS OF FIRST EPISODE OF OPPORTUNISTIC INFECTIONS IN ADULTS AND ADOLESCENTS WITH HIV INFECTION			
Pathogen	**Target population**	**First-choice regimen**	**Alternative regimens**
Category I: recommended as standard of care			
Pneumocystis carinii	$CD4^+$ lymphocyte count <200/mm^3 *and/or* oropharyngeal candidiasis	TMP-SMX 1 DS q24h or 1 SS q24h	Dapsone 100mg q24h or 50mg q12h
			Dapsone 50mg q24h plus pyrimethamine 50mg weekly plus leucovorin 25mg weekly
			Dapsone 200mg weekly plus pyrimethamine 75mg weekly plus leucovorin 25mg weekly
			Aerosolized pentamidine 300mg monthly by nebulizer
			Atovaquone 1500mg q24h
			TMP-SMX 1 DS three times a week
Toxoplasma gondii	$CD4^+$ lymphocyte count <100/mm^3 *and* positive anti-*Toxoplasma* IgG	TMP-SMX 1 DS q24h	TMP-SMX 1 SS q24h
			Dapsone 50mg q24h plus pyrimethamine 50mg weekly plus leucovorin 25mg weekly
			Dapsone 200mg weekly plus pyrimethamine 75mg weekly plus leucovorin 25mg weekly
			Atovaquone 1500mg q24h
Mycobacterium tuberculosis	Positive PPD (5mm) *and/or* previous positive PPD without treatment *and/or* contact with active case (regardless of PPD result)	Isoniazid 300mg q24h plus pyridoxine 50mg q24h for 12 months *or* isoniazid 900mg and pyridoxine 50mg twice weekly with directly observed therapy for 12 months	Rifampin (rifampicin) 600mg q24h for 12 months
			Rifampin 600mg q24h plus pyrazinamide 20mg/kg/day for 2 months
			Rifampin 450–600mg twice weekly plus pyrazinamide 1500–2500mg twice weekly for 2 months
			If isoniazid resistance: rifampin 600mg q24h for 12 months or rifabutin 600mg q24h for 12 months
			If multidrug resistance: choice of drugs depends on susceptibility of isolate from source patient
Mycobacterium avium complex	$CD4^+$ lymphocyte count <50 cells/mm^3	Clarithromycin 500mg q12h *or* azithromycin 1200mg weekly	Rifabutin 300mg q24h or azithromycin 1200mg weekly plus rifabutin 300mg q24h
Varicella-zoster virus (VZV)	Exposure to chickenpox or shingles *and* no history of either or negative serology	Varicella-zoster virus Ig, 5 vials im within 96 hours of exposure (preferably within 48h)	
Category II: generally recommended			
Streptococcus pneumoniae	$CD4^+$ lymphocyte count >200 cells/mm^3	23 valent polysaccharide vaccine 0.5ml im (single dose); repeat in 5 years time	
Hepatitis B virus	All anti-HBV-negative patients	Hepatitis B vaccine 10mg im (three doses)	
Influenza virus	All patients	Inactivated trivalent Influenza vaccine 0.5ml im each year in autumn	Oseltamivir 75mg q24h (influenza A or B)
			Amantadine 100mg q12h
			Rimantadine 100mg q12h (influenza A only)
Hepatitis A virus	All anti-HAV-negative patients at increased risk (illicit drug users, men who have sex with men, hemophiliacs) or with chronic liver disease, including chronic hepatitis B or C	Hepatitis A vaccine (two doses)	
Category III: not recommended for most patients. To be considered in selected patients only			
Cytomegalovirus	$CD4^+$ lymphocyte count < 50 cells/µl *and* positive cytomegalovirus antibodies	Oral ganciclovir 1g q8h	
Bacteria	Neutropenia	G-CSF 5–10µg/kg sc q24h for 2–4 weeks	
		or	
		GM-CSF 250µg/m^2 iv q24h for 2–4 weeks	

Cryptococcus neoformans	CD4$^+$ lymphocyte count <50 cells/mm^3	Fluconazole 100–200mg q24h *or* itraconazole 200mg q24h	
Histoplasmosis	CD4$^+$ lymphocyte count <100 cells/mm^3 *and* residence in endemic area	Itraconazole 200mg q24h	
DS, double strength; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; PPD, purified protein derivatives; SS, single strength; TMP-SMX, trimethoprim-sulfamethoxazole.			

** Adapted from USPHS/IDSA guidelines.*[6]

TABLE 123-2 -- Prophylaxis to prevent recurrence of opportunistic disease in adults and adolescents with HIV infection.*

PROPHYLAXIS TO PREVENT RECURRENCE OF OPPORTUNISTIC DISEASE IN ADULTS AND ADOLESCENTS WITH HIV INFECTION			
Pathogen	**Indication**	**First-choice regimen**	**Alternative regimens**
Category I: Recommended as standard of care			
Pneumocystis carinii	Previous PCP	TMP-SMX 1SS q24h *or* 1 DS q24h	Dapsone 50mg q12h or 100mg q24h
			Dapsone 50mg q24h plus pyrimethamine 50mg weekly *plus* leucovorin 25mg weekly
			Dapsone 200mg *plus* pyrimethamine 75mg *plus* leucovorin 25mg weekly
			Aerosolized pentamidine 300mg monthly by nebulizer
			Atovaquone 1500mg q24h
			TMP-SMX, 1 DS three times weekly
Toxoplasma gondii	Prior toxoplasmic encephalitis	Sulfadiazine 500–1000mg q6h *plus* pyrimethamine 25–50mg q24h *plus* leucovorin 10–25mg po q24h (confers protection against PCP)	Clindamycin 300–450mg q6–8h *plus* pyrimethamine 25–50mg q24h *plus* leucovorin 10–25mg q24h
			Atovaquone 750mg q6–12h *with or without* pyrimethamine 25mg q24h *plus* leucovorin 10mg q24h
Mycobacterium avium complex	Documented disseminated disease	Clarithromycin 500mg q12h *plus* ethambutol 15mg/kg q24h (*with or without* rifabutin 300mg q24h)	Azithromycin 500mg q24h *plus* ethambutol 15mg/kg q24h (*with or without* rifabutin 300mg q24h)
Cytomegalovirus	Previous end-organ disease	Ganciclovir 5–6mg/kg/day iv 5–7 days/week *or* 1000mg orally q8h *or* foscarnet 90–120mg/kg q24h *or* (for retinitis) ganciclovir sustained-release implant every 6–9 months *plus* ganciclovir 1.0–1.5g po q8h	Cidofovir 5mg/kg every 2 weeks (with probenecid)
			Fomivirsen 1 vial (330µg) injected into the vitreous, then repeated every 2–4 weeks
			Valganciclovir 900mg q24h
Cryptococcus neoformans	Documented disease	Fluconazole 200mg q24h	Amphotericin B 0.6–1.0mg/kg weekly
			Itraconazole 200mg q24h
Histoplasma capsulatum	Documented disease	Itraconazole 200mg q12h	Amphotericin B 1.0mg/kg weekly
Coccidioides immitis	Documented disease	Fluconazole 400mg q24h	Amphotericin B 1.0mg/kg weekly
			Itraconazole 200mg q12h
Salmonella spp. (non-*typhi)*	Bacteremia	Ciprofloxacin 500mg q12h for several months	Antibiotic chemoprophylaxis with another active agent
Category II: Recommended only if subsequent episodes are frequent or severe			
Herpes simplex virus	Frequent/severe recurrences	Aciclovir 200mg q8h *or* 400mg q12h *or* Famciclovir 250mg q12h	Valaciclovir 500mg q12h
Candida (oropharyngeal, vaginal or esophageal)	Frequent/severe recurrences	Fluconazole 100–200mg q24h	Itraconazole solution 200mg q24h
DS, double strength; SS, single strength.			

** Adapted from USPHS/IDSA guidelines.*[6]

Regimens include:

- daily or twice weekly isoniazid (plus pyridoxine) for 9 months;
- daily rifampin or rifabutin for 4 months; and
- daily rifampin (or rifabutin) plus pyrazinamide for 2 months (although severe liver injury has been associated with this combination).

In patients whose initial skin test is negative and whose CD4$^+$ T cell count has increased to above 200/mm^3 with HAART, a repeat tuberculin skin test should be considered.[12]

***Mycobacterium avium* complex**

Patients who have a CD4$^+$ T cell count below 50/mm^3 should receive clarithromycin (500mg q12h) or azithromycin (1200mg weekly). Combination with rifabutin is not recommended. Both macrolides confer protection against respiratory bacterial infections. Rifabutin is an alternative in patients who cannot tolerate macrolides.

Primary prophylaxis should be discontinued in patients treated with HAART who show an increase in CD4$^+$ T cells to above 100/mm^3 for at least 3 months and should be reintroduced if the CD4$^+$ T cell count decreases to less than 50–100/mm^3 .[13]

Patients who have disseminated MAC should receive lifelong therapy with clarithromycin (or azithromycin) and ethambutol with or without rifabutin. It is reasonable to consider discontinuation of treatment in patients who have completed a course of at least 12 months of therapy, have no symptoms and show a CD4$^+$ T cell count above 100/mm^3 following HAART for at least 6 months.[14]

Streptococcus pneumoniae

Patients who have a $CD4^+$ T cell count greater than 200/mm^3 should receive a single dose of 23-valent polysaccharide pneumococcal vaccine every 5 years. If the $CD4^+$ T cell count is below 200/mm^3 , vaccination should be considered (with revaccination when the count increases to above 200/mm^3).[15]

Cryptococcosis

Primary prophylaxis should not be used routinely. Patients who have had cryptococcosis should receive lifelong suppressive treatment with fluconazole unless they have a sustained (= 6 months) increase in the $CD4^+$ T cell count following HAART. Suppressive therapy should be reinitiated if the $CD4^+$ T cell count decreases to less than 100–200/mm^3 .[16]

Cytomegalovirus

Patients who have had active cytomegalovirus disease should receive lifelong maintenance therapy with any of the following regimens: parenteral or oral ganciclovir, parenteral foscarnet, combined parenteral ganciclovir and foscarnet, parenteral cidofovir or oral valganciclovir. Administration of ganciclovir via intraocular implant or repetitive intravitreous injections of fomivirsen may be used in patients who have retinitis only, and are generally combined with oral ganciclovir. Repetitive intravitreous injections of ganciclovir, foscarnet and cidofovir have been shown to be effective in uncontrolled case series.[17] [18]

Discontinuation of secondary prophylaxis should be considered in patients who have received HAART and show an increase in $CD4^+$ T cells to above 100–150/mm^3 for at least 6 months. All these patients should continue to undergo regular ophthalmologic examination. Secondary prophylaxis should be restarted when the $CD4^+$ T cell count falls to below 100–150/mm^3 . [19]

Varicella-zoster virus disease

HIV adults who have no history of chickenpox or are seronegative for varicella-zoster virus (VZV) should receive VZV immunoglobulin as soon as possible but within 96 hours after exposure to a patient who has chickenpox or shingles. The efficacy of aciclovir in this setting is unknown.

Chapter 124 - Pneumocystis carinii Pneumonia

Pierre-Marie Girard

EPIDEMIOLOGY

Historically, the occurrence of *Pneumocystis carinii* pneumonia (PCP) in American homosexuals who had no previously known immune deficiency revealed the spread of the AIDS epidemic.[1] Although the implementation of prophylaxis (see Chapter 123) and the advances in effective antiretroviral therapy have markedly decreased its incidence, PCP remains frequent, especially in patients unaware of their HIV seropositivity or who have poor access to the health care system. The use of highly active antiretroviral therapy (HAART) has decreased the incidence of PCP as compared with other pulmonary diseases such as bacterial pneumonia and non-Hodgkin's lymphoma.[2] [3] [4] [5] Development of PCP is mainly due to reactivation of latent infection acquired during childhood or adolescence; however, genetic studies of *P. carinii* isolates suggest that some cases of PCP may be due to recent exposure to environmental strains.[6] In Africa, PCP, initially thought to be a rare complication of AIDS in this area, can actually account for as much as 30% of AIDS-defining diseases.[7] [8]

The best predictor of occurrence of PCP in HIV-infected patients is the $CD4^+$ lymphocyte blood count.[9] A significant risk of PCP exists when the $CD4^+$ lymphocyte count is less than 200/mm^3 or 15–20% of total lymphocytes, and clinical manifestations (e.g. thrush, herpes zoster, unexplained fever, weight loss) or a history of such manifestations are correlated with increased risk, independently of the $CD4^+$ lymphocyte count. Cytotoxic chemotherapies also increase the risk of PCP whatever the $CD4^+$ lymphocyte count. The rate of relapse after a first episode of PCP is high (approximately 60% incidence within 1 year) when neither specific prophylaxis nor HAART is initiated.

PATHOGENESIS AND PATHOLOGY

Development of *P. carinii* is restricted to the lung tissue in more than 95% of cases. The use of aerosolized pentamidine, which has negligible extrapulmonary deposition, explains the occurrence of disseminated infections in bone marrow, spleen, liver, retina and skin.[10]

Pneumocystis carinii pneumonia is characterized by a foamy eosinophilic exudate and the 'honeycomb' appearance of the lung tissue due to mild interstitial pneumonitis with proliferation of type II pneumocytes. *Pneumocystis carinii* cysts are visualized by methenamine-silver nitrate or toluidine blue O stains in the exudate, and trophozoite forms (visualized by Giemsa stains or its derivatives) proliferate and attach to type I pneumocytes. Extensive interstitial fibrosis is the natural process of untreated infections leading to respiratory distress. Mild fibrosis also occurs under treatment.

Other less common pathologic characteristics are seen in people who have AIDS. Diffuse alveolar damage may predominate without alveolar exudate. Cystic and cavitary lesions predominating in upper lobes may also develop. Pneumothorax is a frequent complication resulting from the rupture of cysts. Noncaseating granulomatous inflammation, sometimes with calcification, is occasionally seen.

Animal experiments indicate that $CD4^+$ lymphocytes play a critical role in the host's ability to resist and recover from *P. carinii* infection. In addition, macrophage function may be important for clearance of the micro-organisms and the macrophage mannose receptor seems important for binding and uptake of *P. carinii*. Among cytokines, tumor necrosis factor has been shown to be directly lethal to *P. carinii*.

CLINICAL FEATURES

The most common clinical presentation of PCP in AIDS is a progressive dyspnea with dry cough, fever (often mild) and weight loss. The mean duration of breathlessness is 3–4 weeks at presentation. On examination, fever and tachypnea are common, whereas lung auscultation may be normal or reveal only basal crepitations.

Chest radiography is an important step in the diagnosis procedure of lung diseases in AIDS. The chest radiograph is normal in less than 5% of cases. The most common pattern is a fine bilateral interstitial and then alveolointerstitial infiltrate progressing from the perihilar to the peripheral regions (Fig. 124.1). Without therapy, or even during the first days of treatment, the alveolar interstitial pattern worsens. In advanced cases, progressive consolidation with air bronchograms and complete opacification of the lungs may develop (Fig. 124.2).

Numerous atypical patterns of PCP may occur. They include localized infiltrates, notably of the upper lobes, in patients who fail to respond to aerosolized pentamidine prophylaxis, cavitary lesions, solitary lung nodules, spontaneous pneumothoraces and pleural effusions. Lymphadenopathies causing hilar or mediastinal enlargement are very rare and are usually linked to lymphoma and concomitant infections such as mycobacteriosis.

Parenchymal involvement is well assessed by computerized tomography (CT), which in typical cases exhibits bilateral ground-glass infiltrates that may not have been seen on chest radiography. The

Figure 124-1 Mild *Pneumocystis carinii* pneumonia. There are bilateral micronodular lesions.

Figure 124-2 Severe *Pneumocystis carinii* pneumonia. This shows an extensive alveolar interstitial infiltrate with consolidation of the left lung and upper right lobe. *Courtesy of A Cabié.*

Figure 124-3 Six weeks after treatment of moderate *Pneumocystis carinii* pneumonia. Chest CT shows large, thin-walled bullae of the right lung.

infiltrates can be dense and homogeneous or patchy in both lungs. Parenchymal destruction, from bullae (Fig. 124.3) predominating in the apices to extensive emphysematous changes, may also be seen on CT. Small pulmonary cysts with thin walls throughout the lungs are common.

In extrapulmonary *P. carinii* infections, CT or ultrasonography demonstrates multiple abscess-like lesions varying from several millimeters to a few centimeters in size, mainly in the spleen (Fig. 124.4) and sometimes in the liver. The radiologic abnormalities are not characteristic of *Pneumocystis* infection.

DIFFERENTIAL DIAGNOSIS

A wide spectrum of lung diseases may occur during the course of AIDS, especially in patients who have severe immune deficiency, which is the usual situation for developing PCP.

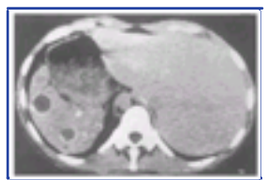

Figure 124-4 Splenic *Pneumocystis carinii* pneumonia. Abdominal CT shows multiple ring-enhancing abscess-like round formations. *Courtesy of C Bazin.*

Kaposi's sarcoma is the most common lung tumor and occurs almost exclusively in homosexual men. Clinical presentation may be a progressive dyspnea and the patient is usually afebrile. Cutaneous and/or palatal Kaposi's sarcoma is frequently diagnosed before lung localization. On chest radiography or CT, nodular lesions and peribronchovascular thickening are more frequent than interstitial abnormalities. In most cases, the macroscopic appearance of the tracheobronchial tract is characteristic. Other considerations include bacterial and fungal pneumonia, and tuberculosis.

Lymphocytic interstitial pneumonia is a rare disease due to lung infiltration by $CD8^+$ lymphocytes and occurs usually in patients who have a $CD4^+$ lymphocyte count above $200/mm^3$.

DIAGNOSIS

Establishing a diagnosis of PCP requires the morphologic demonstration of the micro-organism. Because the sampling procedures that combine both high sensitivity and specificity are invasive (i.e. fiberoptic bronchoscopy with bronchoalveolar lavage, or, less frequently, transbronchial biopsy), the need to make a definite diagnosis before starting anti-*Pneumocystis* therapy is still controversial. Diagnosis on pulmonary samples can be improved by the use of either monoclonal antibodies or polymerase chain reaction (PCR).

Arterial blood gases must be measured to assess the severity of the disease, but have no diagnostic value. Two functional tests that have been thoroughly evaluated — decreased diffusing capacity and increase of alveolar-arterial gradient with exercise — have yielded high sensitivity and low specificity. Increased serum lactate dehydrogenase (LDH) may confirm the lung disease in cases of subtle symptoms or radiologic abnormalities but has no specificity. The level of serum LDH and, more precisely, the slope of its decrease during the first days of treatment have prognostic value. These tests are therefore routinely included in the diagnostic algorithms used by some teams to select patients who will benefit from fiberoptic bronchoscopy. Because of their low specificity their use should not alter the time for bronchoscopy.

No specific biologic marker of *P. carinii* infection exists for individual diagnosis. Antibodies to *P. carinii* are commonly detected in the adult general population and may be less detectable in immunocompromised patients. Attempts to detect *P. carinii* antigens in serum have failed to establish a diagnosis of PCP. Even PCR detection of *P. carinii* genome in blood has been very disappointing. In fact PCR tests are sensitive enough only in the very rare cases of disseminated infection, although they may be useful for detecting *P. carinii* in lung

respiratory samples (bronchoalveolar lavage, induced sputum or possibly saliva). [11]

Identification of *Pneumocystis carinii*

Methods of sampling

Sputum examination is the least invasive procedure for collecting lower respiratory specimens. Because patients who have PCP generally do not have a productive cough, an induced sputum can be obtained after aerosolization of hypertonic saline, ideally under the supervision of a physiotherapist. In routine practice, the sensitivity of the test is approximately 50–60% and is slightly improved by using an immunofluorescence technique for visualization, with monoclonal antibodies directed to the cysts.

Fiberoptic bronchoscopy with bronchoalveolar lavage is the reference routine diagnostic procedure because its sensitivity is more than 95% and its specificity is 100%. When the diagnosis can not be obtained from bronchoalveolar lavage fluid, transbronchial lung biopsy may help, although it is more invasive and is associated with a risk of bleeding and pneumothorax (5–10%). This procedure has a higher sensitivity than bronchoalveolar lavage, especially in patients receiving prophylaxis by aerosolized pentamidine.

Methods of staining

It is recommended that two stains be used to visualize both cysts (methenamine silver or toluidine blue O for the cyst wall, Wright-Giemsa for nuclei) and trophozoites (Wright-Giemsa or Diff-Quik). Immunofluorescent stains are more expensive and are mostly valuable for less-than-optimal samples such as induced sputum, where their sensitivity is superior to conventional stains. The PCR methods are of little benefit on lung samples but can increase the diagnosis rate on induced sputum.

MANAGEMENT

The measurement of arterial gas is used routinely to delineate mild (Pa_{O_2} =70mmHg), moderate (Pa_{O_2} 50–70mmHg) and severe (Pa_{O_2} <50mmHg) PCP. In mild PCP, outpatient management with oral therapy is often possible providing no other disease is present, there is low risk of drug malabsorption and the patient has a good understanding of the management and is aware of the potential side effects of therapy. Hospitalization is required for moderate and severe PCP to ensure careful monitoring of treatment, which will be

TABLE 124-1 -- Factors associated with a poor prognosis of *Pneumocystis carinii* pneumonia.

FACTORS ASSOCIATED WITH A POOR PROGNOSIS OF PCP

At diagnosis	Prolonged history of respiratory symptoms
	Recurrent PCP
	Severe hypoxemia
	Marked radiographic abnormalities
	High plasma LDH level
	High plasma angiotensin-converting enzyme level
	Hypoalbuminemia
	Neutrophilia (>5%) in bronchoalveolar lavage fluid
During the course of the disease	Worsening hypoxemia
	Mechanical ventilation, especially when delayed after initiation of therapy
	Pneumothorax and multiple cavitary lesions or emphysema
	Bacterial co-infection of the respiratory tract
	Persisting high serum levels of LDH

administered intravenously, at least during the first days. Besides blood gas assessment, other factors listed in Table 124.1 are useful prognostic factors that can be taken into account for proposing hospitalization.

Anti-*Pneumocystis* drugs

Therapeutic progress, although quite laborious because of the difficulty encountered with in-vitro cultivation of *P. carinii*, has been made in four main fields:

- the optimal use of old drugs such as pentamidine and trimethoprim-sulfamethoxazole (TMP-SMX) has been defined through numerous trials;
- new combinations of old drugs such as dapsone plus trimethoprim, and clindamycin plus primaquine have been evaluated;
- two innovative compounds, atovaquone and trimetrexate, have been developed and are approved for treatment of PCP; and
- the indications of adjunctive corticosteroids have been carefully defined.

Last, but not least, despite much controversy, the real benefit of mechanical ventilation for a subset of patients has now been established.[12]

Trimethoprim-sulfamethoxazole is the drug of choice for PCP whatever its severity, and no other drug or combination of drugs has demonstrated improved efficacy in control trials. The classic dose of 20mg/kg/day trimethoprim with 100mg/kg/day sulfamethoxazole in three or four divided doses can be reduced to 15mg/kg/day trimethoprim with 80mg/kg/day sulfamethoxazole without loss of efficacy. The unexpectedly high rate of TMP-SMX side effects was noticed early in patients who have AIDS; these include rash, fever, pruritus, digestive disturbances and cytopenia.[13] Most side effects occur after 7–10 days of therapy. More recently, hyperkalemia has been reported. However, many of these side effects, whose mechanisms are still poorly understood, spontaneously resolve and in these cases treatment does not need to be discontinued. Approximately 10–20% of patients will need to be switched to another treatment because of TMP-SMX intolerance. It is possible that adjunctive treatment with corticosteroids decreases the incidence of the cutaneous side effects of TMP-SMX. Monitoring blood concentrations of trimethoprim (concentration maintained below 5–8µg/ml) in order to avoid hematologic toxicity is rarely necessary except in patients who have substantially impaired renal function.

Pentamidine (3–4mg/kg/day intravenously) an aromatic diamidine endowed with antiprotozoal activity, was the first drug successfully used for therapy of PCP in patients who did not have AIDS. Trials conducted in people who have AIDS have confirmed the risk of severe side effects but have not shown activity superior to that of TMP-SMX.[14] The side effects are severe and include hypotension, hypoglycemia, pancreatitis, diabetes, *torsades de pointes* and renal insufficiency. The indications for pentamidine have narrowed with the development of alternative oral combinations for mild PCP in TMP-SMX-intolerant patients and are now restricted to patients who have severe PCP but cannot tolerate or fail to respond to TMP-SMX.

Trimethoprim plus dapsone at 20mg/kg/day and 100mg/day is an oral alternative to TMP-SMX and has appeared to be as effective as TMP-SMX in several trials of mild PCP,[15] [16] although experience is limited. Side effects include rash, methemoglobinemia, hemolytic anemia and neutropenia.

Clindamycin (600–900mg/day) plus primaquine (15–30mg/day) is another oral alternative to TMP-SMX for therapy of mild PCP. These drugs have the advantage of structurally differing from sulfonamide or sulfone compounds, thus limiting the risk of cross-toxicity. This combination is as effective as the previously mentioned combinations in nonsevere PCP[16] but skin rashes, albeit often transient, and digestive complications due to clindamycin occur in 20–25% of patients.

Atovaquone (2250mg/day) is a hydroxynaphthoquinone compound initially developed for its antimalarial activity. Only an oral formulation, which must be taken with food, is available; it has a bioavailability of less than 10%. A new micronized formulation with improved bioavailability has been developed recently and offers better results.[17] Therefore, atovaquone is used as second-line therapy in patients with nonsevere PCP who are or have become intolerant to TMP-SMX and whose digestive absorption is not impaired. Administration of rifampin should be avoided.

Trimetrexate (45mg/m^2 of body surface area) is a lipophilic inhibitor of dihydrofolate reductase that is 1500 times more potent in vitro against *P. carinii* than trimethoprim. However, controlled trials have not shown it to be superior to conventional therapies such as TMP-SMX and intravenous pentamidine.[18] Serious treatment-limiting toxicity was significantly less frequent among patients receiving trimetrexate than TMP-SMX. Trimetrexate is currently used as a second-line therapy for patients requiring intravenous therapy who are refractory or fail to respond to other treatment. It must be administered with leucovorin acid (80mg/m^2 of body surface area) to prevent the development of cytopenia as a severe side effect.

Choice of therapy

The choice of therapy is guided by:

- severity of the disease (see Table 124.1);
- the likelihood of digestive drug absorption; and
- the history of drug intolerance.

The first two criteria will indicate whether an oral regimen is advisable. In case of drug intolerance, it is important to evaluate the severity of past toxicity. In practice, contraindication to reintroduction of TMP-SMX or to the use of a combination with potential cross-intolerance to sulfonamide is based on a history of anaphylaxis or exfoliative dermatitis or other life-threatening toxicity such as severe cytolytic hepatitis. Whenever possible, the first-line therapy is TMP-SMX. For cases of mild PCP and a history of nonsevere TMP-SMX intolerance, one can choose between the use of:

- TMP-SMX;
- dapsone plus trimethoprim; and
- clindamycin plus primaquine or atovaquone.

For cases of mild PCP and a high risk of severe intolerance to TMP-SMX, atovaquone is a reasonable alternative, providing its absorption will not be impaired by digestive malabsorption.

Mutations in *P. carinii* genes expressing genes targeted by current drugs (sulfonamides, sulfones and atovaquone) were reported in the late 1990s. Although several studies have reported an increasing frequency of mutations in the dihydropteroate synthase gene[19] [20] [21] and in cytochrome *b*,[22] the impact of these mutations on clinical outcome remains controversial.

In most cases, respiratory symptoms and oxygenation improve after 5–10 days. Early mild deterioration is not infrequent during the first days of treatment. Duration of

treatment is classically 21 days, although a shorter duration (2 weeks) might be sufficient but has not been adequately evaluated. When TMP-SMX is initiated intravenously, it can be switched to an oral formulation after a few days. There is no need for repeat fibroscopy, and persistence of *P. carinii*, the viability of which is unknown, is common. Secondary prophylaxis is required after treatment of the attack.

Mechanical ventilation should be considered in patients who fail to improve under non-invasive oxygenation methods. The decision is taken according to the patient's wishes and general condition. Anti-*P. carinii* therapy is administered intravenously and TMP-SMX remains the drug of choice, unless there is a history of severe intolerance. In this latter case, pentamidine or trimetrexate with folinic acid rescue are the two alternatives.

In addition to anti-*P. carinii* therapy, corticosteroids are administered as soon as possible in patients who have moderate to severe disease. The use of corticosteroids is recommended in patients whose *P*ao$_2$ is less than 65mmHg for improving oxygenation, reducing the risk of fibrosis, decreasing the need of mechanical ventilation and reducing the case fatality rate. The corticosteroid regimen used is as follows:

- on days 1–5, 40mg oral prednisone (prednisolone) q12h;
- on days 6–10, 40mg oral prednisone/day; and
- on days 11–21, 20mg oral prednisone/day.

When corticosteroid therapy is used one should be aware of possible reactivation of latent co-infections such as mycobacterial and herpes infections.

Management of deterioration on therapy

Patients who deteriorate under therapy need to be carefully evaluated for lung complications related to PCP and associated diseases. The value of changing the initial anti-PCP therapy for another one has not been well demonstrated, but this is common practice. Clindamycin-primaquine (the latter being not available in all countries) could be an attractive regimen in this setting, as suggested by a meta-analysis of 27 clinical trials.[23] Obviously, patients who deteriorate on oral therapy should receive intravenous therapy with either TMP-SMX, pentamidine or trimetrexate. Reasons for the deterioration are various and include:

- severe pulmonary lesions with alveolar and interstitial edema;
- pneumatoceles;
- bullae and cavities that can provoke pneumothorax; and
- emphysema.

In hypoxemic patients, cardiac failure is common and will require appropriate monitoring and treatment.

Associated diseases include bacterial pneumonia (community-acquired or, more frequently, nosocomial), fungal diseases and Kaposi's sarcoma. Repeat bronchoscopy with bronchoalveolar lavage and transbronchial biopsy should therefore be considered. Persistence of *P. carinii* is usual and does not indicate failure of anti-*P. carinii* therapy. In the past 15 years, the case fatality rate of PCP has markedly decreased and is now around 5%. This globally improved prognosis may be due to several factors:

- better awareness of the disease by physicians and patients leading to earlier diagnosis;
- aggressive therapy despite mild toxicity;
- the use of adjunctive corticosteroids; and
- better defined indications of intensive care.

Chapter 125 - Viral Infection

Maurice E Murphy
Bruce Polsky

INTRODUCTION

Viral infections are an important cause of morbidity and mortality in patients who have HIV disease. Over the past two decades, substantial progress has been made in our understanding of the pathogenesis and natural history of viral infections in this patient population. The development of more sensitive diagnostic laboratory techniques and effective therapeutic agents has had a significant impact on the management of these conditions. The introduction of highly active antiretroviral therapy (HAART) for HIV disease has exerted a profound effect on the epidemiology, natural history, clinical manifestations and responses to treatment of opportunistic infections, including viral infections, in HIV-infected patients.[1] With recovery of immune function as a result of effective antiretroviral therapy, the incidence of opportunistic infections has fallen dramatically, chronic and refractory infections are more amenable to treatment, and lifelong treatment is no longer necessary in many instances.

Table 125.1 lists the spectrum of viral infections and associated diseases in HIV-infected people. Most clinically important viral infections in HIV disease are caused by DNA viruses, the majority belonging to the Herpesviridae family. However, improved life expectancy among HIV-infected patients has led to a change in the spectrum of infections influencing morbidity and mortality in this population. Hepatitis B and particularly hepatitis C have emerged as major contributors to morbidity and mortality in HIV-infected patients. This chapter examines the main clinical viral syndromes in HIV disease. The role of viral infections such as human herpes virus-8, Epstein-Barr virus and human papillomavirus in HIV-related neoplastic disorders is discussed elsewhere (see Chapter 130).

CYTOMEGALOVIRUS INFECTIONS

EPIDEMIOLOGY

Serologic evidence of cytomegalovirus (CMV) infection can be detected in approximately 60% of the adult population in the USA. The prevalence of infection is strongly influenced by socioeconomic status and sexual practices; up to 95% of homosexual men are seropositive for CMV.[2]

Before widespread use of HAART, the relative incidence of CMV disease had been increasing and CMV infection was the most common major opportunistic infection associated with AIDS, affecting as many as 45% of patients.[3] Retinitis is the commonest manifestation of CMV infection in patients who have HIV infection or AIDS, accounting for 85% of CMV disease, and is the leading cause of visual loss.[4] Other clinical syndromes include esophagitis, colitis, polyradiculopathy, ventriculoencephalitis, pneumonitis, adrenalitis and pancreatitis.

PATHOGENESIS AND PATHOLOGY

In patients who have AIDS, CMV disease usually results from reactivation of latent infection. Progressive loss of cell-mediated immunity in patients who have advanced HIV disease abrogates the immunologic suppression of CMV replication. Asymptomatic excretion of CMV in urine can be detected in approximately 50% of patients who have advanced HIV disease, and over half of the patients who have CMV viremia go on to develop clinical CMV disease within 8–12 months.[5] [6] Cytomegalovirus end-organ disease usually occurs when the $CD4^+$ lymphocyte count falls below 50 cells/mm^3 .[4] [7]

Cytomegalovirus infects many cell types and tissues. Infection results in tissue necrosis and non-specific inflammation. Microscopically the hallmark of CMV infection is a large (cytomegalic) cell containing a large basophilic intranuclear 'owl's eye' and intracytoplasmic inclusion bodies.

PREVENTION

Patients who have $CD4^+$ lymphocyte counts less than 50/mm^3 should have ophthalmologic screening performed every 3–6 months. Oral ganciclovir is approved for the primary prophylaxis of CMV retinitis in patients who have $CD4^+$ lymphocyte counts below 100/mm^3 . However, this approach is not universal. Results from two randomized controlled trials are conflicting,[8] [9] and the cost benefits of primary CMV prophylaxis are controversial. Newer viral quantitative measures such as quantitative polymerase chain reaction (PCR) and antigenemia assays may identify those patients who would benefit from 'targeted' prophylaxis or 'pre-emptive' therapy even in the absence of end-organ disease.

Patients on HAART experiencing sustained $CD4^+$ lymphocyte counts above 100/mm^3 have a greatly reduced risk of developing CMV disease and evidence suggests that primary and secondary prophylaxis can be discontinued safely in this situation.[1] [10] [11] However, CMV disease can recur after virological and immunological failure of HAART if $CD4^+$ lymphocyte counts fall below 50 cells/mm^3 .

CLINICAL FEATURES AND DIAGNOSIS

Cytomegalovirus retinitis

Cytomegalovirus causes a relentlessly progressive, necrotizing retinitis. Cytomegalovirus retinitis is usually unilateral in the first instance, progressing to affect the contralateral eye if untreated. Patients may be initially asymptomatic but may subsequently experience blurring of vision, floaters and painless progressive visual loss.

Diagnosis of CMV retinitis is made by systematic funduscopic examination by direct or indirect ophthalmoscopy. Characteristically, white, fluffy, or granular lesions with perivascular white exudates associated with retinal hemorrhages are seen (Fig. 125.1).

Cytomegalovirus lesions may be categorized as occurring in three arbitrarily defined anatomic zones. Retinitis located in the immediate vicinity of the macula or optic disc (zone 1) is sight-threatening and should prompt immediate initiation of treatment. Lesions outside the major vascular vessels (zones 2 and 3), commonly referred to as 'peripheral retinitis', are not immediately sight-threatening but will progress if left untreated.

TABLE 125-1 -- Viral infections and clinical syndromes in HIV-infected patients.

VIRAL INFECTIONS AND CLINICAL SYNDROMES IN HIV-INFECTED PATIENTS			
Family	**Subfamily**	**Genus and species**	**Clinical syndromes**

Herpesviridae (DNA)	Alphaherpesvirinae	Herpes simplex 1,2	Orolabial ulceration	
			Anogenital ulceration	
			Herpetic whitlow	
			Encephalitis	
		Varicella-zoster virus	Varicella	
			Herpes zoster	
			Disseminated VZV infection	
			Pneumonitis	
			Encephalitis	
			Hepatitis	
			Retinal necrosis	
	Betaherpesvirinae	Cytomegalovirus	CMV	viremia
				retinitis
				esophagitis
				enterocolitis
				pneumonitis
				encephalitis
				polyradiculopathy
				adrenalitis
		Human herpesvirus 6	Unknown	
			? Retinal disease	
			? Enhanced HIV replication	
	Gammaherpesvirinae	Epstein-Barr virus	Oral hairy leukoplakia	
			Lymphoma, Hodgkin's and non-Hodgkin's disease	
		Human herpesvirus 8	Kaposi's sarcoma	
			Primary effusion lymphoma	
			Multicentric Castleman's disease	
Papovaviridae (DNA)		Papillomavirus	Common and genital warts	
			Squamous intraepithelial neoplasia	
			Cervical carcinoma	
			Anal carcinoma	
		Polyomavirus, JC virus	Progressive multifocal leukoencephalopathy	
Hepadnaviridae (DNA)		Hepatitis B virus	Hepatitis, acute and chronic cirrhosis	
			Liver carcinoma	
Parvoviridae (DNA)		Human parvovirus B19	Aplastic anemia	
Poxviridae (DNA)		Molluscum contagiosum virus	Molluscum contagiosum	
Flaviviridae (RNA)		Hepatitis C virus	Hepatitis, acute and chronic cirrhosis	
			Liver carcinoma	

Gastrointestinal cytomegalovirus disease

The clinical manifestations of CMV infection in the gastrointestinal tract depend largely on the site of infection. In the upper gastrointestinal tract, CMV causes discrete esophageal ulcers, diffuse esophagitis, gastritis, gastric ulcers, duodenal ulcers and enteritis. Esophageal CMV infection usually presents with painful dysphagia. Endoscopic examination frequently reveals inflammation and ulceration, and diagnosis is established by finding characteristic pathologic features on tissue biopsy; it can be confirmed by immunohistochemical or CMV DNA in-situ hybridization techniques. Cytomegalovirus enterocolitis occurs in 5–10% of patients who have AIDS.[12] Lower gastrointestinal CMV disease usually presents with abdominal pain and persistent small-volume diarrhea. Endoscopic examination of the colon reveals plaque-like pseudomembranes, multiple erosions and ulcers, although a mucosa of grossly normal appearance is seen in approximately 10% of patients.

Cytomegalovirus disease of the central nervous system

The two major CMV neurologic syndromes associated with HIV disease are CMV polyradiculopathy and CMV ventriculoencephalitis.[12] [13] Polyradiculopathy is a devastating complication in patients who have advanced AIDS. Approximately 50% of patients have an associated myelitis. It is characterized by lower extremity pain, sensory deficits, weakness that can rapidly progress to flaccid paralysis, and bowel and bladder dysfunction. The most marked pathologic changes in CMV polyradiculomyelitis are found in the cauda equina and lumbosacral roots. In the appropriate clinical setting, findings on magnetic resonance imaging (MRI) of diffuse enhancement of the cauda equina and the surface of the conus strongly support the diagnosis. Cerebrospinal fluid findings include a polymorphonuclear pleocytosis, raised protein concentration and moderately low glucose concentration. Culture of cerebrospinal fluid may be negative

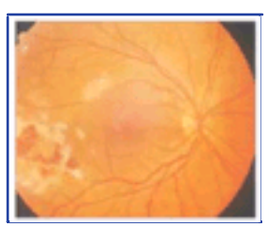

Figure 125-1 Cytomegalovirus retinitis, with characteristic perivascular hemorrhages and exudates.

but CMV antigen assays and PCR for CMV DNA are more sensitive techniques.

Ventriculoencephalitis usually occurs in the setting of a diagnosis of CMV disease elsewhere. Patients present with fever, lethargy and confusion. Characteristic neurologic findings include nystagmus and cranial nerve palsies. Magnetic resonance imaging with gadolinium enhancement may demonstrate periventricular enhancement. Cytomegalovirus DNA can often be detected in cerebrospinal fluid using PCR.

Pulmonary cytomegalovirus disease

There are no particular distinguishing clinical or radiologic features to differentiate CMV pneumonitis from other causes of pneumonitis in HIV disease. Patients present with shortness of breath, dyspnea on exertion and a dry, nonproductive cough. Chest radiographs shows diffuse interstitial infiltrates, and hypoxemia is usually present. Definitive diagnosis of pulmonary CMV disease in patients who have advanced HIV disease is difficult to establish because of a high incidence of asymptomatic CMV shedding — CMV can be isolated in approximately 50% of HIV-infected patients undergoing bronchoscopic examination.[14] However, the true incidence of CMV pneumonitis is less than 10% in patients who have diagnostic bronchoscopy for evaluation of pulmonary infiltrates of unknown origin. [15]

MANAGEMENT

The therapeutic options and strategies for the treatment and prevention of CMV retinitis are outlined in Table 125.2 . Similar treatment strategies are commonly employed in treating other end-organ CMV disease.[16] [17] Treatment options for CMV retinitis include systemic antiviral treatment and maintenance therapy, intraocular implant devices and intraocular injections of antiviral agents. However, the optimal use, combination and timing of each treatment remains to be determined. Important factors to consider include relative efficacies, potential toxicities, the use of concurrent medications and the need for permanent vascular access.

Five antiviral drugs are currently available for the treatment of CMV retinitis:

- ganciclovir, a nucleoside analogue;
- foscarnet, a pyrophosphate analogue;
- cidofovir, a nucleotide analogue;
- valganciclovir, a prodrug of ganciclovir; and
- fomivirsen, an antisense oligonucleotide.

For systemic treatment, each agent is initially given in high doses (induction) for 2–3 weeks, depending on clinical response, followed by lower maintenance doses. In the absence of HAART-mediated immune reconstitution, most patients eventually have reactivation of CMV infection despite long-term suppressive therapy and require further or re-induction therapy.

Ganciclovir, a nucleoside analogue, is phosphorylated in CMV-infected cells by viral-encoded thymidine kinase. In its active form, it inhibits viral DNA replication. It is available as a parenteral and oral preparation.

Intravenous foscarnet is a pyrophosphate analogue that inhibits DNA polymerase without the need for prior phosphorylation. It has a broad spectrum of activity against the herpesviruses.

In 80–90% of patients, intravenous administration of ganciclovir or foscarnet q12h for 14–21 days (induction) initially halts inflammation and retinal necrosis. In the only published trial directly comparing foscarnet with ganciclovir for the treatment of CMV retinitis, efficacy was similar for both agents. [18] However, there was a significant survival benefit for patients treated with foscarnet, probably owing to the intrinsic anti-HIV activity of foscarnet. Combination therapy with ganciclovir and foscarnet has been shown to be synergistic, or at least additive in vitro, and in one trial it was found to be superior to either drug alone for treatment of recurrent CMV retinitis.[19] This may be a useful strategy in patients who have immediately sight-threatening retinitis or repeated episodes of retinitis and in patients not responding to standard therapy. Both ganciclovir and foscarnet require permanent intravenous vascular access, such as a Hickman-Broviac catheter or a Port-a-Cath catheter, for maintenance therapy.

Oral ganciclovir is licensed for maintenance therapy of patients who have CMV retinitis. However, its bioavailability is poor and time to relapse of retinitis is shorter than with intravenous maintenance therapy.[20] It may be particularly useful for patients who do not have extensive or immediately sight-threatening disease and where long-term venous access is not feasible.

Valganciclovir, recently licensed for treating CMV retinitis, is a monovalyl ester oral prodrug that is rapidly hydrolyzed to ganciclovir. The bioavailability of ganciclovir from oral valganciclovir is 60%, with equivalent blood levels to standard systemic ganciclovir, and it is as effective as intravenous ganciclovir for the management of CMV retinitis in patients who have AIDS.[21]

Intravenous cidofovir is a nucleotide analogue of cytosine with potent in-vitro and in-vivo activity against a broad spectrum of herpesviruses including CMV, herpes simplex viruses 1 and 2, varicella-zoster virus and Epstein-Barr virus. [22] Unlike ganciclovir, which requires intracellular activation by viral-encoded enzyme, conversion of cidofovir to cidofovir diphosphate is by host cellular enzymes and therefore is independent of viral replication. The diphosphate form has a long intracellular half-life and a major advantage of cidofovir is the possibility for maintenance therapy to be given as one injection every 2 weeks, thus obviating the need for an indwelling venous catheter. However, renal toxicity is high and cidofovir therapy must be closely monitored.

Because of the toxicity associated with systemic therapy for CMV retinitis, local (intraocular) therapy has been developed. Intravitreal therapy is effective in controlling retinitis and may be particularly useful as salvage therapy in patients who are no longer tolerant of systemic therapy. Intravitreal injections of ganciclovir, foscarnet and cidofovir have been used. Fomivirsen, the first of a new class of highly selective and novel therapeutics, antisense oligonucleotides, has potent anti-CMV activity, and when it is administered intravitreously it is effective for peripheral retinitis and retinitis not controlled by other anti-CMV drugs.[23] [24] Another important approach has been the development of intravitreal devices or implants to deliver ganciclovir continuously over several months.[25] These provide better control of retinitis than systemic therapy and offer significant improvement in the quality of life. Specific complications include bleeding, infection, change in refraction and early retinal detachment. Although implants provide excellent local control of retinitis, the incidence of subsequent contralateral eye disease and systemic disease is high. For this reason, concomitant systemically active treatment (e.g. with oral valganciclovir) is recommended in patients who receive implants.

TABLE 125-2 -- Therapeutic regimens for management of cytomegalovirus retinitis in HIV-infected patients.

THERAPEUTIC REGIMENS FOR MANAGEMENT OF CMV RETINITIS IN HIV-INFECTED PATIENTS			
Drug	**Regimen**	**Adverse effects**	**Comments**
Ganciclovir (iv)	**Induction**	Neutropenia (15–40%)	Median time to progression 47–104 days
	5mg/kg q12h × 14–21d	Thrombocytopenia (5–10%)	Monitor hematology indices
	7.5mg/kg q12h × 14–21d for refractory disease	Anemia (5–10%)	Bone marrow suppression with AZT
	Maintenance	Nausea, vomiting	Administer G-CSF or GM-CSF for neutropenia (ANC <500/mm^3)
	5mg/kg q24h	Confusion, headaches	Drug of choice in patients with baseline renal insufficiency or taking nephrotoxic drugs
	range 5–10mg/kg q24h	Seizures (rare)	Requires indwelling venous catheter
Ganciclovir (po)	**Maintenance**	Nausea, dyspepsia (40–50%)	Median time to progression 29–56 days
	1g q8h	Diarrhea (50–60%)	8–10% bioavailability
		Neutropenia (25%)	? Primary prophylaxis
		Anemia (10%)	Less effective than maintenance iv ganciclovir
		Thrombocytopenia	Rarely used now because valganciclovir available
		Pancreatitis (rare)	

Ganciclovir intraocular implant	4.5mg implanted for 5–8 months	Retinal detachment (12%)	Median time to progression 196–226 days
		Hemorrhage, infection	Contralateral eye disease in 50% and extraocular CMV disease in more than 30% at 6 months
		Endophthalmitis	
Ganciclovir intraocular injections	400µg twice weekly	Hemorrhage, infection	
		Retinal detachment	
Foscarnet (iv)	**Induction**	Renal impairment (20–30%)	Median time to progression 53–93 days
	90mg/kg q12h × 14–21d	Hypocalcemia, hypomagnesemia, hypokalemia, hypophosphatemia (20–30%)	Monitor electrolytes and replete iv or oral hydration reduces adverse effects
	Maintenance	Nausea (25–40%)	Potential survival benefit over ganciclovir
	90–120mg/kg q24h	Confusion, agitation	Active against aciclovir-resistant herpes viruses
		Anemia	Requires indwelling venous catheter
		Genital ulceration	
Foscarnet intraocular injections	2400µg twice weekly	Hemorrhage, infection	
		Retinal detachment	
Cidofovir (iv)	**Induction**	Proteinuria (20%), renal insufficiency	Median time to progression 64–120 days iv hydration pre- and postadministration and pre- and post-probenecid reduces renal toxicity
	5mg/kg weekly × 14d	Fanconi syndrome (25%)	
	Maintenance	Nausea/vomiting	
	3–5mg/kg every 2 weeks	Neutropenia	
Valganciclovir (po)	**Induction**	Diarrhea 19%,	Median time to progression 160 days
	900mg q12h × 21d	Neutropenia 14%	Prodrug of ganciclovir with 60% bioavailability of ganciclovir
	Maintenance		
	900mg q24h		
Fomivirsen intravitreous injections	**Induction**	Anterior chamber inflammation	Median time to progression 71 days
	165µg once weekly × 21d	Increased intra-ocular pressure	Higher dose 330µg effective in relapsed disease or in infections failing to respond to alternative treatments
	Maintenance		
	165µg alternate weeks		

HERPES SIMPLEX VIRUS INFECTIONS

EPIDEMIOLOGY

Severe herpes simplex virus (HSV) infection was one of the initial clinical manifestations heralding the onset of the AIDS epidemic.[26] Herpes simplex virus 1 is normally acquired early in life, whereas HSV-2 is usually acquired through sexual contact, the risk of infection being correlated with the number of sexual partners.[27] [28] The highest prevalence of antibodies to HSV-2 in the USA is among female commercial workers and homosexual males. In HIV-infected people, seroprevalence rates up to 77% for HSV-2 have been reported, reflecting common risk factors for transmission. [29]

PATHOGENESIS AND PATHOLOGY

After initial or primary infection, which may be asymptomatic, HSV has the capacity to establish latent infection in the dorsal root or sensory ganglia. Viral reactivation occurs intermittently and leads to a recurrence of cutaneous or mucosal lesions. Immunosuppressed patients are at greater risk of both recurrent and disseminated HSV infections. Reactivation of HSV occurs frequently in patients who have advanced HIV disease, particularly in those who have low $CD4^+$ lymphocyte counts (<100 cells/mm^3). The histopathologic characteristics of primary or recurrent HSV infection reflect virus-mediated cellular death and associated inflammatory response.

PREVENTION

Frequent or severe recurrent HSV infections can be managed with suppressive oral aciclovir, valaciclovir and famciclovir therapy. The management of recurrent aciclovir-resistant HSV infections is not well established but may require maintenance therapy with foscarnet.

CLINICAL FEATURES AND DIAGNOSIS

The hallmark of herpetic lesions is painful vesicular formation at a mucocutaneous site, progressing rapidly to ulceration with an erythematous base, followed by eventual healing and re-epithelialization. Herpes simplex virus 1 most commonly causes orolabial lesions and HSV-2 generally infects the genital and perianal regions. However, there is considerable overlap in the epidemiology and clinical features of HSV-1 and HSV-2 infections. The clinical manifestations of HSV infections in HIV disease depend on:

- the subtype of HSV;
- the site of infection; and
- the degree of underlying immunosuppression.

As patients become more immunosuppressed, infections are characterized by prolonged viral shedding, more frequent episodes, and severe and persistent clinical disease. [26] [28] Diagnostic techniques available for the diagnosis of HSV infections include cytologic preparations (e.g. the Tzanck test) for multinucleated giant cells, fluorescein-conjugated monoclonal antibodies of scrapings from lesions, cell culture and PCR assays for HSV DNA.

Primary orolabial infection is more frequent in children who have AIDS, who are at risk of severe gingivostomatitis. In adults, orolabial infection is usually due to reactivation of latent infection. Recurrences may increase in frequency and severity as immunosuppression increases. Recurrent genital and perirectal ulcerative lesions are the most common manifestations of HSV infection in patients who have HIV disease and are usually due to reactivation of HSV-2. Lesions may be atypical and severe in patients who have advanced disease (Fig. 125.2). Prolonged new lesion formation, with continued tissue destruction, persistent viral shedding and severe local pain, is common.

Herpes simplex esophagitis may occur in the absence of herpetic lesions in the oropharynx and is difficult to distinguish from CMV esophagitis on clinical and radiologic grounds. Both cause retrosternal pain and dysphagia. Definitive diagnosis requires endoscopy and biopsy. Herpes encephalitis is a rare, life-threatening complication in HIV disease. It usually occurs as a complication of primary or reactivated orolabial HSV infection. Symptoms include headache, personality changes, meningismus, lethargy, confusion, focal neurologic deficits and fits. Computerized tomography (CT) scans or MRI may reveal temporal lobe abnormalities. Cerebrospinal fluid findings are usually non-specific, with a lymphocytosis and elevated protein. Detection of HSV DNA by PCR is highly sensitive and specific for HSV encephalitis.[30]

Figure 125-2 Severe perianal aciclovir-resistant herpes simplex virus 2 infection. (a) Untreated appearance. (b) Healing and re-epithelialization after treatment with foscarnet and institution of HAART.

MANAGEMENT

For over 20 years, aciclovir has been the drug of choice for treating HSV infections. Aciclovir undergoes selective phosphorylation by virus-induced thymidine kinase in HSV-infected cells. Aciclovir monophosphate is further phosphorylated by cellular kinases to the active triphosphate form, which selectively inhibits viral DNA polymerase. Bioavailability of oral aciclovir is approximately 10–20%. The optimum route of administration, dosage and duration of therapy will depend on the site and severity of the HSV infection (Table 125.3).

Valaciclovir and famciclovir are newer, effective and convenient alternatives agents for episodic and suppressive treatment of HSV infection. Oral valaciclovir is rapidly metabolized to aciclovir by the liver achieving a bioavailability of 3–5 times that of oral aciclovir. Famciclovir is a prodrug of penciclovir, an acyclic nucleoside similar to aciclovir but with a significantly longer intracellular half-life.

Infections with HSV that are resistant to aciclovir are increasingly recognized in patients who have advanced HIV disease.[31] Most aciclovir-resistant HSV isolates are deficient in thymidine kinase activity. Persistent ulcerative HSV lesions that fail to respond to aciclovir should alert the physician to the possibility of aciclovir resistance. The degree of immunosuppression and chronicity of mucocutaneous HSV infection are the strongest independent risk factors for the development of resistance in vitro. Foscarnet, which does not require viral-mediated phosphorylation for activity, is the treatment of choice for aciclovir-resistant HSV infections in HIV disease. Topical trifluorothymidine solution and cidofovir gel have also been shown to be effective against aciclovir-resistant HSV infections.

VARICELLA-ZOSTER VIRUS INFECTIONS

EPIDEMIOLOGY

Primary varicella or chickenpox is a common childhood infection. In the USA and Europe, most adults who have HIV disease have previously been infected with varicella-zoster virus (VZV). Among

TABLE 125-3 -- Treatment of herpes simplex virus and varicella-zoster virus infections in HIV-infected patients.

TREATMENT OF HSV AND VZV INFECTIONS IN HIV-INFECTED PATIENTS	
Type of infection	**Treatment**
Mucocutaneous HSV infection	Aciclovir 200–400mg po 5 times/d
	Famciclovir 500mg po q8h
	Valaciclovir 500mg po q12h
	Aciclovir 15–30mg/kg/day iv
Disseminated/visceral HSV infection	Aciclovir 30mg/kg/day iv
Recurrent mucocutaneous HSV infection	Aciclovir 400mg po bid to q6h
	Valaciclovir 500mg po q12h
	Famciclovir 500mg bid po q12h
Aciclovir-resistant HSV infection	Foscarnet 60mg/kg q12h iv
	Topical trifluorothymidine 2% q8h
Primary VZV infection (varicella)	Aciclovir 800mg po 5 times/day
	Aciclovir 10mg/kg/q8h iv
Herpes zoster	Aciclovir 800mg po 5 times/d
	Aciclovir 10mg/kg/q8h iv
	Valaciclovir 500mg po q12h
	Famciclovir 500mg po q8h
Disseminated/visceral VZV infection	Aciclovir 10mg/kg/q8h iv
Aciclovir-resistant VZV infection	Foscarnet 60mg/kg q12h iv
Treatment for HSV and VZV is usually for 5–10 days or until resolution of symptoms.	

HIV-infected children and adults, the manifestations of VZV infections include:

- uncomplicated primary varicella;
- disseminated varicella;
- localized and disseminated herpes zoster; and
- chronic varicella-zoster.

PATHOGENESIS AND PATHOLOGY

Primary VZV infection is usually acquired in susceptible hosts by contact with persons infected with chickenpox, either via the respiratory route or through contact with cutaneous lesions. It can also be acquired by contact with patients who have herpes zoster. Following initial replication, patients become viremic and develop the characteristic vesicular rash of varicella. Crops of new vesicles occur with successive episodes of viremia. Patients who have HIV disease can have prolonged viremia and an extended period of new lesion formation.

During primary infection, VZV enters cutaneous endings of sensory nerves and migrates to reach sensory nerve ganglia, where the virus establishes latency. With the waning of cellular immunity, the virus can reactivate, causing herpes zoster. The vesicular eruption of zoster typically remains confined to one dermatome or to several contiguous dermatomes, corresponding to the distribution of innervation of the affected sensory ganglion.

CLINICAL FEATURES AND DIAGNOSIS

Primary varicella zoster virus infection (Varicella)

The rash of primary VZV infection appears 10–21 days after infection. Lesions progress from small erythematous macules to papules and vesicles that ulcerate, dry and form crusts. A centripetal distribution, successive crops of lesions and lesions at all stages of development are characteristic of varicella. Owing to impaired cellular immunity, HIV-infected patients who have primary VZV are at risk of prolonged new lesion formation and are a higher risk of life-threatening visceral dissemination.

Herpes zoster

Herpes zoster may be the first indication of HIV disease and can occur at any stage of HIV infection. It usually appears as a localized or segmental painful erythematous maculopapular eruption along a single dermatome (Fig. 125.3). Lesions evolve over 1–3 days to form vesicles, pustules and crusts. In HIV-infected patients, zoster lesions may be particularly bullous, hemorrhagic or necrotic. Herpes zoster of the ophthalmic division of the trigeminal nerve can cause anterior uveitis and corneal scarring with visual loss. The diagnosis of herpes zoster is usually clinical but laboratory studies

Figure 125-3 Herpes zoster in the T10 dermatome. *Courtesy of Professor Anthony J Pinching.*

may be required for confirmation. A Tzanck preparation from scrapings of lesions can demonstrate multinucleated giant cells but is not specific for herpes zoster. Fluorescein-conjugated monoclonal antibodies confirm the presence of VZV from scrapings from the base of lesions and their presence is a more rapid and reliable test than virus culture.

Patients infected with HIV are at risk of recurrent episodes of herpes zoster. A less frequent manifestation is persistent localized herpes zoster. These patients typically fail to clear lesions with aciclovir, or lesions recur rapidly after treatment is completed. Occasionally, widespread cutaneous and visceral dissemination may occur.

Visceral dissemination to the lungs, the liver and the central nervous system may cause life-threatening disease. The symptoms, signs and chest radiograph of VZV pneumonitis are non-specific. Encephalitis is a rare complication of VZV infection. Symptoms develop 1–2 weeks after the development of herpes zoster, and include headache and lethargy. Pathologically it is characterized by necrotic and demyelinating lesions, mostly in superficial white matter, the periventricular area and white-gray matter junctions. Cerebrospinal fluid findings may be non-specific, showing a mild mononuclear pleocytosis and elevated protein. Detection of VZV DNA by PCR analysis is diagnostic. Chronic disseminated herpes zoster may present as widespread erythematous ulcerative or hyperkeratotic verrucous lesions, particularly after prolonged treatment with aciclovir. Rapidly progressive herpetic retinal necrosis syndrome is a rare complication that is most often associated with VZV infection. Aggressive antiviral treatment is required to prevent loss of vision.[32]

MANAGEMENT

Primary VZV infection or herpes zoster in HIV-infected patients must be treated with specific antiviral therapy. Higher concentrations of aciclovir are required to inhibit replication of VZV than of HSV (see Table 125.3). Aciclovir significantly reduces pain and shortens the duration of viral shedding, the duration of new lesion formation, the time to crusting of lesions and the time to complete healing. High-dose oral aciclovir, 800mg five times daily, may be used for the treatment of localized herpes zoster in HIV-infected patients who do not require hospitalization. In severe or disseminated VZV infection, high-dose intravenous aciclovir (10mg/kg q8h) is indicated. Famciclovir and valaciclovir are licensed for use in non-immunocompromised patients who have herpes zoster.

Persistent disseminated VZV infection that fails to respond to aciclovir has been described in patients who have advanced HIV disease. In-vitro susceptibility studies have demonstrated isolates that are resistant to aciclovir, usually because of deficient or altered thymidine kinase activity. Intravenous foscarnet is the antiviral drug of choice for infection with aciclovir-resistant VZV.

For HIV infected patients who develop recurrent VZV lesions when aciclovir is discontinued, chronic suppressive aciclovir is indicated.

INFECTION WITH HEPATITIS C VIRUS

EPIDEMIOLOGY

With improved life expectancy among HIV-infected patients as a result of HAART, hepatitis C virus (HCV) infection is emerging as a leading cause of significant morbidity and death in this population. Because of shared risk factors, concomitant HCV and HIV infection is common. A recent study conducted in the USA estimated an overall prevalence of HCV 16% in a nationally distributed HIV cohort, rising to 73% in higher risk populations such as hemophiliacs and injection drug

users.[33] There are six known genotypes of HCV. In a recent study from the USA, type 1 was the most prevalent in co-infected patients and was found in 83%. Chronic HCV infection occurs in about 85% of patients, with cirrhosis and end-stage liver failure eventually developing in approximately 20% of infected individuals in two to three decades.[34] Co-infection with HIV accelerates HCV-related liver disease, and end-stage liver disease morbidity and mortality are greater in co-infected individuals.[35] Conversely, HCV may be independently associated with an increased risk of progression to AIDS and death.[36]

CLINICAL FEATURES AND DIAGNOSIS

Most patients who have acute HCV infection are symptom free, with a minority becoming jaundiced. It is usually with the development of chronic liver disease or extrahepatic manifestations that patients develop symptoms. Virtually all patients who have chronic HCV infection develop histologic features of chronic hepatitis, with as many as 20% progressing to cirrhosis over 20 years. Hepatitis C virus infection is readily diagnosed by enzyme-linked immunosorbent assay (ELISA) with specificity ensured using a recombinant immunoblot assay (RIBA). Signal amplification assays and PCR-based assays allow qualitative and quantitative detection of HCV RNA in plasma. Liver biopsy is an important tool to determine the degree of inflammation and fibrosis.

MANAGEMENT

In recent years significant advances have been made in the management of chronic HCV infection. Treatment is recommended for patients who have elevated alanine aminotransferase (ALT) levels, detectable serum HCV RNA and moderate to severe injury on liver biopsy. Table 125.4 outlines treatment options for HCV.

In 1998, two pivotal studies established the effectiveness of combination therapy with interferon-a-2b (3MU three times weekly) and ribavirin (1000–1200mg daily) for HCV infection in HIV-negative patients.[37] [38] Sustained virologic response rates were observed in 38–43% of patients at 48 weeks with improvement in liver inflammation on histologic examination. Genotypes 2 and 3 show the most favorable responses to treatment. Slow-release a-interferons, covalently bound to polyethylene glycol (PEG), a nontoxic

TABLE 125-4 -- Treatment options for chronic hepatitis B virus and hepatitis C virus infection in non-HIV-infected and HIV-infected patients.

TREATMENT OPTIONS FOR CHRONIC HBV AND HCV INFECTION IN NON-HIV-INFECTED AND HIV-INFECTED PATIENTS		
	Dosing schedule	**Response/comments**
Hepatitis B		
Interferon-a-2b	5MU C q24h or 10MU weekly for 4 months	HBeAg loss/seroconversion in 33%
Lamivudine	100mg po q24h for 1 year	HBeAg loss/seroconversion in 17%
		Prolonged use associated with genotypic-resistant variants
		Licensed for HIV infection at 300mg daily
Adefovir dipoxivil	10mg po q24h	Effective against lamivudine resistant HBV variants
		Mean drop in HBV DNA, -4.77$\log_{10}$, in HIV co-infected patients
Tenofovir	300mg po q24h	Licensed for HIV infection
Hepatitis C		
Interferon-a-2b and ribavirin	Interferon-a-2b 3MU 3 times weekly, ribavirin 1000–1200mg q24h for 6–12 months	SVR in 38–43%
		Higher response rates with genotypes 2 and 3
Pegylated interferon and ribavirin	Ribavirin 800–1200mg q24h; peg-IFN-a-2b (Peg-Intron) 1.5µg/kg or peg-IFN-a-2a (Pegasys) 180µg per week	SVR in 54–56%
		Higher response rates with genotypes 2 and 3
		SVR 44% in HIV/HCV co-infected patients (Pegasys plus ribavirin)
SVR, sustained virologic response.		

polymer, have been developed that allow for more convenient once-weekly injections. Pegylated interferon with ribavirin is now the standard of care in treating chronic HCV infection, with overall sustained virologic response rates of 54–56%.[39] [40]

Data are limited to date on treatment of HIV/HCV co-infected patients. Pegylated interferon-a-2a plus ribavirin has recently been reported to lead to significant treatment responses compared with conventional interferon-a-2a plus ribavirin in HIV/HCV co-infected patients.[41] In co-infected patients, progression of liver disease is associated with a $CD4^+$ lymphocyte count of less than 400cells/mm^3 and patients who have higher $CD4^+$ counts demonstrate greater response rates to HCV treatment.[42] Therefore, in co-infected patients treatment for HCV should be considered before significant decline in immune function occurs or, in those who have low $CD4^+$ counts, antiretroviral therapy should be a priority prior to HCV treatment.

INFECTION WITH HEPATITIS B VIRUS

EPIDEMIOLOGY

Hepatitis B virus (HBV) is a major world health problem and a common cause of cirrhosis and hepatocellular carcinoma. Because of shared risk factors, concomitant HBV and HIV infection is common, particularly in homosexual men. The outcome of acute HBV infection depends on the age of acquisition, the immune status of the host and the rate of replication of the virus. Less than 5% of adult-acquired infection progresses to chronic infection (chronic active hepatitis or asymptomatic carriers). In HIV-infected patients plasma HBV DNA levels are higher than in controls, [43] and recent data suggest that chronic HBV infection increases the risk of liver-related deaths in patients co-infected with HIV.[44]

CLINICAL FEATURES AND DIAGNOSIS

The clinical presentation of acute HBV ranges from subclinical hepatitis (70%) to icteric hepatitis (30%) with rare cases of fulminant hepatitis (0.1–0.5%). Chronic HBV ranges from the asymptomatic carrier through chronic active HBV to cirrhosis and hepatocellular carcinoma.

Serologic markers of HBV infection are well established. The persistence of hepatitis B surface antigen beyond 6 months suggests progression to chronic HBV infection. Hepatitis B e antigen (HBeAg) is a marker of active HBV replication and infectivity and is usually associated with active liver disease. The presence of serum HBV DNA (using signal amplification or PCR-based assays) is sensitive and specific for viral replication and is used to assess patients who have chronic HBV for treatment and to evaluate response.

MANAGEMENT

To date interferon-a, lamivudine and adefovir are the only agents approved for the treatment of chronic HBV (see Table 125.4). Viral clearance (HBeAg loss/seroconversion) occurs in 33% of those treated with interferon-a and 16–18% treated with lamivudine for 1 year. [45] [46] [47] Patients who have lower ALT levels or higher HBV DNA levels and immunosuppressed patients have a poorer response. Lamivudine profoundly suppresses viral replication and with prolonged use achieves an HBeAg seroconversion rate similar to interferon-a. It is also effective in patients not usually responsive to interferon. However, genotypic-resistant mutations emerge after 9–10 months of treatment with a frequency of 50% after 3 years. With both treatments, virologic responses are associated with biochemical and histologic improvement.

Adefovir dipivoxil, an adenine nucleotide analogue, has demonstrated encouraging preliminary results against HBV.[48] Moreover, it is active against lamivudine-resistant strains of HBV. Tenofovir, another nucleotide analogue, which is licensed to treat HIV, is being investigated for treatment of HBV and produces substantial reductions in HBV viral load in co-infected patients. Studies continue to define and refine optimal treatment regimens, and combination therapy studies with approved agents and experimental agents are now in progress.

OTHER VIRAL INFECTIONS

A variety of other viral infections and diseases occur in patients who have HIV disease (see Table 125.1). Those viruses implicated in neoplastic conditions, such as Epstein-Barr virus, human papillomavirus and human herpes virus 8, are discussed in detail in other sections (see Chapter 130). A brief summary of other viral conditions encountered in HIV-infected patients is outlined here.

PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY

Progressive multifocal leukoencephalopathy (PML) is an opportunistic demyelinating infection caused by JC virus. JC virus is a ubiquitous DNA papovavirus and over 70% of adults are seropositive for it. Progressive multifocal leukoencephalopathy occurs in patients who have deficient cell-mediated immunity and is estimated to affect up to 4% of patients who have AIDS.[49] Mortality is high, and average reported survival in AIDS patients is 2–4 months. The symptoms and characteristic radiologic findings of PML are due to virus-induced lysis of oligodendrocytes, resulting in microscopic foci of myelin breakdown that coalesce to produce larger white matter

Figure 125-4 Progressive multifocal leukoencephalopathy. MRI scan showing frontal and occipital white matter lesions. *Courtesy of Dr Jane Anderson.*

lesions (Fig. 125.4). Definitive diagnosis requires tissue from brain biopsy but the identification of JC virus in the cerebrospinal fluid by PCR has a high specificity for active disease.

There is no definitive treatment for PML. Aciclovir, vidarabine and cytarabine have all been used to little effect. Cidofovir is active against polyomaviruses and several case reports have suggested therapeutic benefit in PML using dosing regimens recommended for CMV retinitis.[50] Immune reconstitution following antiretroviral therapy may influence the course of PML in HIV-infected patients, and there are several reports of regression of PML and prolonged survival in patients receiving HAART. Optimal retroviral therapy is now regarded as treatment of choice for PML.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is caused by a double stranded DNA virus, namely molluscum contagiosum virus (MCV). Molecular epidemiology studies have identified at least two major subtypes, MCV-1 and MCV-2. The majority of infections are caused by MCV-1. Cell-mediated immunity is important in the control of molluscum contagiosum and lesions occur in 5–18% of patients. Pathologic features consist of focal areas of hyperplastic and hypertrophied epidermis surrounding a core of keratin and epithelial debris. Ultrastructural studies have demonstrated MCV in all layers of the epidermis.

Lesions appear as small white or pink cutaneous papules. Larger lesions may be umbilicated. In HIV-infected patients, molluscum contagiosum may be extensive, large and disfiguring, and lesions are commonly localized around the head and neck.[51]

Diagnosis is usually made on the basis of the characteristic clinical features. Treatment involves direct disruption of lesions with enucleation, cauterization and cryotherapy. Treatment in HIV-infected patients is less satisfactory owing to the widespread nature of the lesions and the high rate of recurrence. Recalcitrant cases have been reported to respond to topical cidofovir cream 1–2%[52] and topical imiquimod 5% cream, an immune response modifier with antiviral properties. [53] Remission may occur after immune reconstitution with HAART.

Chapter 126 - Fungal Infection

William G Powderly

Fungi are among the most ubiquitous pathogens seen in patients who have HIV disease but are not the most common causes of mortality. Virtually all major fungal pathogens cause disease in patients who have HIV infection.

CANDIDIASIS

EPIDEMIOLOGY

Candidal infection in AIDS is almost exclusively mucosal — systemic invasion is a rare and late event. Oropharyngeal candidiasis occurs in about three-quarters of all those who have HIV infection. In about one-third it tends to be recurrent and becomes progressively more severe with increasing immunodeficiency. Esophageal involvement occurs in 20–40% of all AIDS patients, predominantly in patients who have advanced disease and severe depletion of $CD4^+$ lymphocytes. Vulvovaginal candidiasis occurs in about 30–40% of women who have HIV infection; it appears that HIV infection per se is not an important risk factor for vaginal infection, although it may influence the severity and persistence of disease.

Most candidal disease, especially initial episodes, is associated with infection by *Candida albicans*. Recurrent disease is caused by the same strain of *Candida* in about 50% of cases; the remaining 50% are caused by new strains of *C. albicans* or new species.[1] Other species, notably *Candida glabrata*, *C. dubliniensis* and *C. parapsilosis*, tend to cause infection in patients who have very advanced disease and have had extensive previous exposure to antifungal agents (especially the azoles; see Chapter 237).

PATHOGENESIS AND PATHOLOGY

Most patients are readily colonized with *Canadia* spp., which appears as part of the mouth flora in over 80% of people who have HIV infection. The specific local immunologic defects that predispose to disease are unknown, although it is assumed that some deficiency in T cell immunity is important because disease is clearly more common as the $CD4^+$ lymphocyte count falls. Additional defects in local oral clearance mechanisms (e.g. epithelial barriers, salivary flow, lysozyme and lactoferrin release) have been described in people who have HIV infection and may be relevant to candidiasis. In addition, non-specific factors such as dental hygiene, smoking and the use of antibacterials for prophylaxis may predispose to candidiasis.

CLINICAL FEATURES

Most patients are symptomatic and complain of some oral discomfort. The classic presentation is of creamy-white plaques on an erythematous base — the pseudomembranous form of thrush (Fig. 126.1). Other manifestations include:

- an atrophic form that presents as erythema without plaques (often associated with patchy atrophic glossitis); and
- angular cheilitis, which appears as cracking, fissuring, ulceration or erythema at the corner of the mouth.

Figure 126-1 Pseudomembranous oral candidiasis ('thrush').

Most patients who have vaginal candidiasis present with vaginal itching, burning or pain, and usually complain of a vaginal discharge. Examination of the vaginal cavity usually reveals thrush, identical to that seen in the oropharynx.

Patients who have esophageal candidiasis develop ulcers and erosions of the esophagus and experience odynophagia or dysphagia. The combination of oral candidiasis and esophageal symptoms is both specific and sensitive in predicting esophageal involvement. Patients can be treated empirically with antifungal therapy. Endoscopy is reserved for those patients who fail to respond to evaluate for other diagnoses such as herpetic or cytomegalovirus esophagitis, idiopathic ulceration or resistant candidiasis.[2]

MANAGEMENT

The development of oral candidiasis in an HIV-positive patient should be taken as a sign of progressive immunodeficiency. Patients should have a $CD4^+$ count measured. If they are not currently receiving antiretroviral therapy, it should be initiated. If they are on antiretroviral therapy, it should be reassessed and, if necessary, changed.

A number of options — both local and systemic — are available for the treatment of oral candidiasis (Table 126.1). Initially, most patients respond well clinically to any form of antifungal therapy, although mycologic responses are less common. In general, topical therapy should be used initially and systemic therapy reserved for more difficult problems such as treatment failure or noncompliant patients. Of the local therapies, troches are generally used more effectively by patients than suspensions. Episodes of vulvovaginal candidiasis are also managed readily with topical therapy or short courses of systemic azoles. Esophageal disease requires systemic therapy. Fluconazole 200–400mg q24h orally for 2–3 weeks is probably the therapy of choice; [3] itraconazole 100–200mg q12h orally is also effective.

Relapses are common and at least one-third of patients develop recurrent mucosal candidiasis. One approach to management is to

TABLE 126-1 -- Therapeutic options for oral or esophageal candidiasis.

THERAPEUTIC OPTIONS FOR ORAL OR ESOPHAGEAL CANDIDIASIS		
Agent	**Formulation**	**Dosage**
Nystatin	Oral suspension	400–600 000 units (4–6ml) q6h
	Pastille	1–2 pastilles q6h
Glotrimazole	Troche	10mg (1 troche) 5 times daily
Ketoconazole	Tablet	200mg q24h
		400–600mg q24h (esophageal disease)
Fluconazole	Tablet	50–100mg q24h
		200–400mg q24h (esophageal disease)
	Oral suspension	50–100mg (5–10ml) q24h
Itraconazole	Capsule	200mg q24h
	Oral suspension	100mg (10ml) q12h

Amphotericin B	Oral suspension	500mg (5ml) q6h-q8h
	Lozenge	One q6h
	Intravenous infusion	0.3–0.5 mg/kg q24h
Not all formulations are widely available. Dosage is the usual dose for the typical patient — the average duration of therapy is 7–14 days and individual patients may require higher doses or more prolonged treatment.		

treat each episode as it occurs. However, in many patients, recurrent symptomatic disease may be sufficiently severe to warrant considering chronic suppression. Fluconazole 100–200mg q24h has proved highly successful in suppressing recurrent oropharyngeal disease and preventing esophagitis, and a dose of 100mg per week can prevent vaginal candidiasis. The major risk of this approach is the possibility of developing azole-resistant disease.

Approximately 5–7% of patients who have advanced HIV disease (usually resistant to available antiretroviral therapy) develop candidiasis that is refractory to standard fluconazole therapy. The major risk factors are:

- advanced immunodeficiency ($CD4^+$ lymphocyte counts less than 50 cells/mm^3 and often less than 10 cells/mm^3), and
- extensive previous exposure to fluconazole.[4]

Isolates also tend to be resistant in vitro, with minimum inhibitory concentrations of more than 64mg/ml to fluconazole. The clinical expression of disease is a progressive and symptomatic infection with frequent esophagitis.

Therapy for resistant candidal infection is unsatisfactory. Improving immune function (e.g. with antiretroviral therapy) is the best strategy, but options may be limited. Higher doses of fluconazole (up to 800mg) may be effective in patients who have infection caused by organisms with intermediate susceptibility but are usually not effective for truly resistant strains. The cyclodextrin oral suspension formulation of itraconazole has been reported to be effective in about 60% of cases but the benefit is short-lived if some form of chronic maintenance therapy is not given.[5] Many patients require parenteral amphotericin B or caspofungin for symptomatic control.

CRYPTOCOCCOSIS

EPIDEMIOLOGY

Virtually all HIV-associated infection is caused by *Cryptococcus neoformans* var. *neoformans*. The organism is found worldwide as a soil organism. About 5% of patients who have advanced HIV infection in the Western world develop disseminated cryptococcosis; the disease is more prevalent in sub-Saharan Africa and southern Asia. Most cases of infection occur in patients who have very low $CD4^+$ lymphocyte counts (<50,000/ml).

PATHOGENESIS AND PATHOLOGY

It is assumed that transmission occurs via inhalation of the basidiospores or unencapsulated forms, leading to colonization of the airways and subsequent respiratory infection. The absence of an intact cell-mediated response results in ineffective ingestion and killing of the organism, leading to dissemination and an increased cryptococcal burden. The polysaccharide capsule, composed mainly of glucuronoxylomannan, is thought to be the organism's primary virulence factor. It is unclear whether cryptococcal infection in patients who have AIDS represents an acute primary infection or reactivation of previously dormant disease.

CLINICAL FEATURES

Cryptococcosis most commonly presents as a subacute meningitis or meningoencephalitis with fever, malaise and headache.[6] Symptoms are usually present for 2–4 weeks before diagnosis. Classic meningeal symptoms and signs (such as neck stiffness or photophobia) occur in about one-third of patients. Some patients may present with encephalopathic symptoms such as lethargy, altered mentation, personality changes and memory loss. Analysis of the cerebrospinal fluid (CSF) usually shows:

- mildly elevated serum protein;
- normal or slightly low glucose;
- a few lymphocytes; and
- numerous organisms.

Cryptococcal antigen is almost invariably detectable in the CSF at high titer. The CSF opening pressure is elevated in 25% of patients, and this has important prognostic and therapeutic implications.

About one-half of patients have evidence of pulmonary involvement with cough or dyspnea and abnormal chest radiograms. Although most patients who have pneumonic involvement also have disseminated infection, isolated pulmonary involvement may be one of the earliest manifestations of cryptococcal infection. Most patients who have cryptococcal meningitis have positive blood cultures. Skin involvement is common and several types of skin lesion have been described; the most common form is that resembling molluscum contagiosum (Fig. 126.2).

DIAGNOSIS

The latex agglutination test for cryptococcal polysaccharide antigen in the serum is highly sensitive and specific for diagnosing of infection with *C. neoformans,* and a positive serum cryptococcal antigen titer

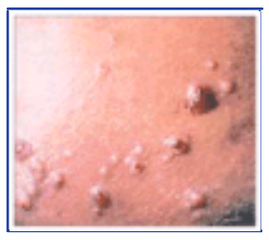

Figure 126-2 Cutaneous cryptococcosis. This lesion is typical of the skin lesions of most endemic mycoses that occur in patients who have AIDS, and such a lesion may therefore also be seen in an AIDS patient who has disseminated histoplasmosis or penicilliosis.

of more than 1:8 is presumptive evidence of cryptococcal infection. The serum cryptococcal antigen can therefore be used as a screening test for the presence of cryptococcal infection in febrile patients who have HIV infection. The finding of a positive cryptococcal antigen titer in this setting is sufficient to warrant antifungal therapy.

MANAGEMENT

An algorithm for the treatment of cryptococcal meningitis is shown in Figure 126.3 . Untreated, cryptococcal meningitis is fatal. Amphotericin B (0.7mg/kg intravenously) given for 2 weeks followed by fluconazole 400mg orally for a further 8 weeks is associated with the best outcome in prospective trials, with a mortality of less than 10% and a mycologic response of approximately 70%.[7] The addition of flucytosine 100mg/kg q24h to the amphotericin B phase does not improve immediate outcome but may decrease the risk of relapse. Initial azole therapy (itraconazole or fluconazole) is associated with a suboptimal 50% response rate. Early results with a combination of fluconazole 400–800mg q24h with flucytosine and the liposomal formulation of amphotericin B suggest that these may be options for patients who are unable to tolerate the usual formulation of amphotericin B.

Clinical deterioration may be due to cerebral edema, which may be diagnosed by a raised opening CSF pressure. Recent studies have linked elevated opening pressures (>200mmH_2 O) with an increased risk of early mortality and/or blindness.[8] The opening pressure of all patients who have cryptococcal meningitis should be measured when a lumbar puncture is performed, and strong consideration should be given to reducing such pressure (by repeated lumbar puncture,

Figure 126-3 Algorithm for the diagnosis and treatment of cryptococcal meningitis.

a lumbar drain or a shunt) if the opening pressure is high (>200mmH_2 O).

Cryptococcal meningitis requires lifelong suppressive therapy, unless there is improvement in immune function. Prospective trials have established the superiority of fluconazole 200mg q24h when compared with placebo, weekly amphotericin B or itraconazole.[9] Prospective trials have also established that fluconazole, in dosages ranging from 400mg per week to 200mg q24h, and itraconazole, 100mg q12h, are very effective in preventing invasive cryptococcal infections, especially in patients who have $CD4^+$ lymphocyte counts below 50–100 cells/mm^3 ,[10] and fluconazole use has probably resulted in the reduced incidence of cryptococcosis as a

complication of AIDS. Because of the relative infrequency of invasive fungal infections, antifungal prophylaxis is not associated with a survival advantage.

All patients who have cryptococcal infection should receive optimal antiretroviral therapy. An immune reconstitution syndrome has been described in some patients who initiate potent antiretroviral therapy after cryptococcal infection. Aseptic meningitis (with a prominent cellular reaction in the CSF) and lymphadenitis have been reported. Chronic suppressive therapy for cryptococcal infection may be discontinued in patients who have had at least 1 year of treatment and who have received successful antiretroviral therapy for at least 6 months. Such patients should have undetectable plasma HIV viral RNA and a rise in $CD4^+$ lymphocyte count to at least 100 cells/mm^3 .

HISTOPLASMOSIS AND PENICILLIOSIS

EPIDEMIOLOGY AND PATHOGENESIS

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum,* which is endemic in the Mississippi and Ohio river valleys of North America as well as certain parts of Central and South America and the Caribbean (Fig. 126.4). Penicilliosis is caused by the dimorphic fungus *Penicillium marneffei*, which is endemic in South East Asia (especially northern Thailand and southern China; Fig. 126.5).

The mycelial form of histoplasmosis is found in the soil and is particularly associated with bird roosts and caves. The environmental niche for *P. marneffei* is unknown, although it is also assumed to be a soil organism. Both fungi cause disseminated infection in 20–30% of patients who have AIDS in endemic areas, as well as sporadic infection among HIV-positive migrants from and visitors to endemic areas.

Infection with both fungi results when spores are inhaled into the lung and these are then converted to the pathogenic yeast form at

Figure 126-4 North American Endemic areas for histoplasmosis and coccidioidomycosis.

Figure 126-5 Endemic area for penicilliosis.

TABLE 126-2 -- Characteristics of histoplasmosis and penicilliosis.

CHARACTERISTICS OF HISTOPLASMOSIS AND PENICILLIOSIS		
Characteristic	**Histoplasmosis**	**Penicilliosis**
Appearance of organism on biopsy	1–5µm round to oval	1–8µm pleomorphic, elongated
Method of duplication	Budding	Fission
Clinical features (% of cases)		
Fever	95	99
Weight loss	90	75
Anemia	70	75
Pulmonary disease	50	50
Lymphadenopathy	20	40–50
Skin lesions	5–10	70
Hepatosplenomegaly	25	50

body temperature. Usually, effective cell-mediated immunity limits acute infection to a mild respiratory illness. Patients who have HIV infection develop disseminated disease due to either reactivation of previously acquired infection or a progressive acute infection.

CLINICAL FEATURES

The characteristic features of histoplasmosis and penicilliosis are shown in Table 126.2 . The most common presentation of both infections is fever and weight loss, which occurs in about 75% of patients.[11] [12] Respiratory symptoms (cough, shortness of breath) occur in about 50% of cases. The chest radiogram is normal in 50% of cases and most of the remaining patients have diffuse nodular infiltrates. Local or generalized lymphadenopathy, hepatosplenomegaly, colonic lesions and skin and oral ulcers also occur. Skin involvement is more common in penicilliosis than histoplasmosis. Involvement of the gastrointestinal tract (usually as ulcers) may present with abdominal pain or gastrointestinal bleeding. Between 5% and 10% of patients have an acute septic-shock-like syndrome that includes hypotension and evidence of disseminated coagulopathy. This presentation carries a very poor prognosis. Laboratory findings may include anemia, neutropenia or thrombocytopenia (because of bone marrow involvement) and elevated hepatic enzymes.

DIAGNOSIS

The diagnosis is usually made by culture or by histopathologic examination of bone marrow aspirate or biopsy, lavage fluid or biopsy material from lung or skin lesions. A peripheral blood smear may show intracellular organisms in white cells in many patients. Blood cultures, especially when collected using the lysis centrifugation system, are positive in over 90% of patients. Anti-*H. capsulatum* antibodies are detected by immunodiffusion or complement fixation in about 70–80% and antigen detection in either urine or serum is an excellent method for diagnosing disseminated histoplasmosis. Serologic tests are not yet useful for diagnosing penicilliosis.

MANAGEMENT

The management of both infections appears to be similar. Patients should receive an initial period of treatment with amphotericin B (for 1–2 weeks) until there is clinical resolution (defervescence and improvement in skin lesions), followed by itraconazole 200mg orally q12h. A small study has suggested that initial treatment with liposomal amphotericin B (4 mg/kg q24h) was superior to amphotericin B deoxycholate for disseminated histoplasmosis suggesting this preparation should be considered for patients who have severe disease.[13] As with the other systemic mycoses, relapse is common and therefore long-term suppressive therapy with itraconazole 200mg q24h is warranted.[14] [15] Itraconazole can probably be used as sole therapy for mild disease.[16] Fluconazole is less effective in histoplasmosis than itraconazole. Itraconazole can also be considered as primary prophylaxis for histoplasmosis in patients residing in endemic areas, especially those with $CD4^+$ lymphocyte counts of less than 100 cells/mm^3 .

As with cryptococcal infection, all patients should receive optimal antiretroviral therapy. Immune reconstitution illness (with abdominal lymphadenopathy) has been described in histoplasmosis. Consideration can be given to stopping secondary prophylaxis in patients who have had immune recovery on potent antiretroviral

treatment.

COCCIDIOIDOMYCOSIS

EPIDEMIOLOGY AND PATHOGENESIS

Coccidioides immitis is a dimorphic fungus found in the soil in the desert around the south-western USA and northern Mexico (see Fig. 126.4), as well as focal areas of Central and South America, and primary infection is restricted to persons living in or visiting those areas (see Chapter 237). Infection follows inhalation of arthrospores, which form endospores and spherules within the lung. Mature spherules release new endospores, which perpetuate infection. Infection tends to occur in situations where soil is disturbed (e.g. construction sites, dry windy conditions), but is usually a self-limiting respiratory illness controlled by cell-mediated immunity. People who have HIV infection develop more severe, disseminated disease. Both

new primary infection and reactivation of previously acquired coccidioidomycosis can occur in patients who have HIV infection. Consequently, both individuals who have had previous coccidioidomycosis and those who have never been infected can develop progressive coccidioidal infections during the course of HIV infection. As with other endemic mycoses, migrants who have HIV infection and visitors to the endemic area are also at risk of infection.

CLINICAL FEATURES

Most patients, especially if their $CD4^+$ lymphocyte count is less than 250 cells/mm^3 , develop pneumonia, presenting with fever, weight loss, night sweats, cough and dyspnea with symptoms lasting from several weeks to several months before diagnosis.[17] Disseminated disease occurs in at least 30%, resulting in generalized lymphadenopathy, skin nodules or ulcers, peritonitis, liver abnormalities, and bone and joint involvement. Meningeal disease, with symptoms of lethargy, fever, headache, nausea, vomiting and/or confusion, occurs in about 10% of patients. Cerebrospinal fluid analysis typically reveals a lymphocytic pleocytosis with a lymphocyte count of more than 50/ml.

DIAGNOSIS

Diagnosis is made by culturing the organism from clinical specimens or by demonstrating the typical spherule on histopathologic examination. As *C. immitis* is a highly contagious organism and can infect laboratory workers handling specimens, the clinical laboratory should be warned of the possibility of positive cultures (see Chapter 90). Blood cultures are positive in a minority of patients. Coccidioidal serology is often positive, but may be negative in up to 25% of patients who have disseminated infection. Patients who present with fever and have positive coccidioidal serology without focal lesions are presumed to have coccidioidal infection.[18]

MANAGEMENT

Amphotericin B, 0.5–1.0mg/kg q24h, is the mainstay of therapy and should be used initially in patients who have diffuse pulmonary or disseminated disease. Some experts advocate combining amphotericin B with fluconazole initially. Fluconazole, 400–800mg q24h orally, may be an alternative for patients who have mild disease. Complete eradication is unlikely and chronic suppressive therapy with either fluconazole 200–400mg q24h or itraconazole 200mg q12h is needed. Successful treatment with itraconazole or fluconazole has been reported in approximately 80% patients who have *C. immitis* meningitis.

There is no evidence that chemoprophylaxis with any of the azole antifungals can prevent coccidioidomycosis. People living in or visiting endemic areas are advised to avoid activities that would increase their exposure to disturbed soil.

ASPERGILLOSIS

EPIDEMIOLOGY

Infection with *Aspergillus* spp. is increasingly seen in patients who have advanced HIV disease. Specific risk factors that have been identified include neutropenia, use of corticosteroids and broad-spectrum antibacterial therapy and previous pneumonia, especially *Pneumocystis carinii* pneumonia. There is also some evidence that aspergillosis may be a direct effect of advanced HIV disease and may occur in the absence of other predisposing factors. Typically, patients have extremely low $CD4^+$ lymphocyte counts and a history of other AIDS-defining opportunistic infections.

CLINICAL FEATURES, DIAGNOSIS AND MANAGEMENT

Two major syndromes predominate:

- respiratory tract disease, and
- central nervous system infection.[19] [20]

Patients often present with cough, shortness of breath and fever. Because aspergilli have a tendency to invade blood vessels and cause infarction, chest pain and hemoptysis are common. Nodular infiltrates, which may be localized or diffuse and commonly cavitate, are seen on chest radiography.

Diagnosis of invasive pulmonary aspergillosis may be difficult. A definitive diagnosis requires a biopsy demonstrating fungal invasion. A presumptive diagnosis of invasive aspergillosis may be made in patients who have pulmonary symptoms and new chest radiographic abnormalities and whose sputum or bronchial secretions grow aspergilli in culture. Additional respiratory syndromes of pulmonary aspergilloma and localized tracheobronchial aspergillosis have been reported occasionally in patients who have AIDS.

Patients who have central nervous system aspergillosis usually present with symptoms and signs of a mass lesion or with features of a stroke due to invasion of blood vessels. Therefore, seizures, hemiparesis and focal abnormalities are common. Computerized tomography or magnetic resonance imaging (MRI) of the head may show single or multiple lesions, usually nonenhancing, with surrounding edema. Bony invasion is common and, because the disease may have spread from involved sinuses, the sinuses may be abnormal. Patients who have fungal sinusitis usually have the classic features of sinusitis (fever, facial pain and swelling, nasal discharge and headache). Often, there is a history of previous sinus infection treated with broad-spectrum antibacterial therapy. As in other sites, aspergilli tend to invade locally. Computerized tomography of the sinuses will usually show bony erosion, and penetration into adjacent tissues such as the brain or orbit can occur.

The prognosis of aspergillosis is poor, in part because of the fungal infection itself and in part because it tends to occur in patients who have advanced AIDS and many other complications of end-stage HIV infection. There is a poorer response to therapy in patients who have AIDS than in other immunocompromised patients.[21] Therefore in most series the median time to death after a diagnosis of aspergillosis is only 2–4 months. Initial therapy should be with amphotericin B (1.0–1.5mg/kg/day of amphotericin B deoxycholate or 5–10mg/kg/day of liposomal amphotericin) or with voriconazole 200mg bid (see Chapter 208). A recent study[22] suggested voriconazole was superior to amphotericin B as initial therapy; however that study did not include many patients with AIDS.

OTHER FUNGAL INFECTIONS

The other endemic mycoses, blastomycosis and paracoccidioidomycosis, have been reported rarely in patients who have AIDS and do not appear to be major opportunists. Typically, there is disseminated disease.

There have also been case reports of disseminated sporotrichosis and localized mucormycosis in patients who have AIDS.

Chapter 127 - Parasitic Infections

Christine Katlama

The use of highly active antiretroviral therapies has profoundly changed the epidemiology of the clinical manifestations of HIV disease. Overall, the incidence of opportunistic infections has decreased by 50–80%; however, toxoplasmosis remains frequent, often revealing AIDS and HIV infection in untreated patients; on the other hand cryptosporidiosis and microsporidiosis, which used to be common in the course of AIDS, are occurring much less frequently in patients with improved immune status because of potent antiretroviral therapy.

TOXOPLASMA GONDII

EPIDEMIOLOGY AND PATHOGENESIS

Toxoplasmosis, caused by *Toxoplasma gondii,* an obligate intracellular protozoan, is a common opportunistic infection in patients with AIDS. It has a prevalence ranging from 10–40% in Europe, the Caribbean area and Africa, to 5–10% in USA. This is due to the different prevalence of *T. gondii* infection in the general population of these areas (e.g. 50–70% in Europe, but 10–40% in the USA).[1] The widespread use of primary prophylaxis that is active against both *Pneumocystis carinii* and *T. gondii* in patients with HIV infection has decreased the incidence of these two most common opportunistic infections. The underlying immune cellular defect in HIV infection is the major cause of the reactivation of latent *T. gondii* infection that has persisted in the central nervous system (CNS) or extraneural tissues after earlier acute infection. Toxoplasmosis usually occurs late in HIV disease, when the $CD4^+$ lymphocyte count is less than $100/mm^3$. By now, given the impact of antiretroviral therapy in western countries and the use of systematic toxoplasmosis and *P. carinii* pneumonia prophylaxis as soon as CD4 cells count are below $200/mm^3$, most of the cases of toxoplasmosis are diagnosed in patients known to have HIV infection but without any medical follow-up (see also Chapter 245).

CLINICAL FEATURES

The CNS is by far the most common site of toxoplasmosis, representing approximately 80% of cases. The next most common site is the retina (5–10%); pneumonitis and myocarditis are less common manifestations.[2] Involvement of other organs, such as the liver and bladder, is usually a histologic or autopsy finding in the context of disseminated disease.

Encephalitis

Toxoplasmic encephalitis (TE) commonly manifests as single or multiple intracerebral abscesses, with focal neurologic signs and constitutional symptoms that progress over a few days or weeks.[3] [4] [5] Fever and headaches are present in 40–70% of cases, neurologic dysfunction including confusion and lethargy in 40% of cases, focal CNS deficits in 50–60% of cases, and seizures in 30–40% of cases, which frequently are the presenting symptom of TE.

The constellation of fever, headaches, mild neurologic deficit or any unexplained neurologic symptoms should suggest the diagnosis of TE (Fig. 127.1), and prompt computerized tomography (CT) scanning or magnetic resonance imaging (MRI) should be undertaken.

Retinitis

Toxoplasmic retinitis represents the third most common opportunistic infection of the retina in AIDS. Symptoms include decreased visual acuity, defects in the visual field, 'floaters' and loss of peripheral vision. Diagnosis relies on funduscopic examination (Fig. 127.2), which typically shows a thick, dense, opaque appearance of retinal lesions with very distinct borders, and an intense vitreal inflammation. There is usually little or no hemorrhage, which is the opposite of the situation in retinitis caused by cytomegalovirus.

Pneumonitis

Toxoplasmic pneumonitis occurs generally in a context of disseminated disease and presents as a bilateral interstitial pneumonia.[6] Clinical and radiologic symptoms are non-specific; they include fever, cough, dyspnea and interstitial radiologic abnormalities. Diagnosis is made by finding *T. gondii* cysts in bronchoalveolar fluid.

DIAGNOSIS

Because it occurs in AIDS as a result of reactivation of a latent preexisting infection caused by the immune suppression induced by HIV, a diagnosis of toxoplasmic disease should be suspected in patients with:

- a low $CD4^+$ lymphocyte count, usually less than $100/mm^3$;
- specific antitoxoplasmal antibodies, indicating past infection; and
- no specific current primary prophylaxis.

In patients with HIV infection and any neurologic symptoms, CNS imaging is the most urgent diagnostic procedure (see Fig. 127.1). Magnetic resonance imaging is more sensitive than CT scanning. Toxoplasmic abscesses are typically contrast-enhancing lesions surrounded by edema; there may be a mass effect, with displacement of the ventricles. Magnetic resonance imaging may also reveal hemorrhages, which are highly suggestive of toxoplasmic necrosis.

Although no neuroradiologic findings can be considered pathognomonic for TE, some findings, such as the presence of multiple lesions, a localization of lesions in the basal ganglia or at the corticomedullary junction, the presence of edema, a mass effect and hemorrhages, may help to distinguish TE from CNS lymphoma, which is the main differential diagnosis.

Antitoxoplasmic therapy leads to a decrease in number and size of the lesions within 10–15 days, and this may confirm the diagnosis. Mild radiologic sequelae with no clinical consequences may persist at the end of therapy. In the absence of any improvement, a cerebral biopsy should be performed to exclude a lymphoma or progressive multifocal leukoencephalopathy.

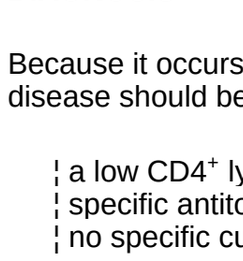

Figure 127-1 Diagnosis and management of cerebral toxoplasmosis in HIV-positive patients.

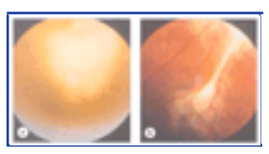

Figure 127-2 Toxoplasmic retinitis. (a) Diagnosis from fundoscopy. (b) Evolution after antitoxoplasma therapy.

The detection of *Toxoplasma* antibodies in patients with HIV infection has no significance other than the assessment of a previous exposure to the parasite, which indicates the potential risk of reactivation in case of severe immunodepression.

In most of cases of encephalitis or retinitis, the diagnosis of toxoplasmosis is presumptive, made on clinical-radiologic criteria and confirmed by the therapeutic response.

The identification of *T. gondii* in extraneural or extraretinal tissue or body fluid gives a definitive diagnosis of toxoplasmosis if a biopsy is performed. The characteristic

toxoplasmic lesions found on cerebral biopsy are necrotic abscesses surrounded by a prominent inflammatory infiltrate that contains extracellular *T. gondii* tachyzoites, edema, vasculitis and hemorrhages. Isolation of *T. gondii* from blood, cerebrospinal fluid, bronchoalveolar lavage fluid or by using polymerase chain reaction appears to be more frequent in disseminated disease than it is in localized disease.[7]

MANAGEMENT

Appropriate treatment is especially important, both because the response to therapy is the main criterion for diagnosis of TE, and because early initiation of therapy gives the best prognosis. Treatment consists of initial acute therapy over 3–6 weeks followed by lifelong maintenance therapy to prevent further reactivation (Table 127.1). Initiation of antiretroviral therapy should be preferentially delayed 3–4 weeks to avoid overlap in drug toxicities.

Sulfadiazine and pyrimethamine combination

The combination of pyrimethamine 50–75mg/day orally and sulfadiazine 4–6g/day is the first-line acute therapy.[3] [4] [5] These drugs act synergistically by blocking the folic acid pathway of tachyzoites, but have no effect on the cyst forms of the parasite. Folinic acid 25mg/day orally should be given as well to prevent hematotoxicity

Clinical improvement occurs within 5–10 days; the diagnosis of TE is confirmed by a decrease in both neuroradiologic and clinical abnormalities (Fig. 127.3). The duration of therapy is 3–6 weeks.

Fever and rash are the most common adverse events of pyrimethamine-sulfadiazine that may lead to discontinuation of therapy; they occur in 20–25% of cases. Other side-effects include hematotoxicity, crystalluria and transaminase elevation.

In the maintenance phase the recommended therapy is pyrimethamine 25mg/day orally plus sulfadiazine 2g/day orally lifelong or until a CD4 cell count of more than 200/mm^3 for more than 3 months is reached in cases of antiretroviral therapy. This combination is also effective as primary prophylaxis for *P. carinii* pneumonia.

Pyrimethamine plus clindamycin

The combination of pyrimethamine 50mg/day orally and clindamycin 2.4g/day orally or intravenously as acute therapy, followed by pyrimethamine 25mg/day orally plus clindamycin 1.2g/day orally as maintenance therapy[3] [4] is considered as second-line therapy for use in cases of intolerance to sulfadiazine, because it has a higher relapse rate (15%) than pyrimethamine-sulfadiazine (3%) in maintenance therapy.[4] [5] [6] Side-effects include rash (30%) and diarrhea (20%), and there is a risk of pseudomembranous colitis induced by clindamycin.

Atovaquone

Atovaquone 750mg q6h orally, a hydroxynaphthoquinone that is a potent in-vitro inhibitor of *T. gondii* and *P. carinii,*[8] [9] [10] may be used in acute or maintenance therapy for patients who are intolerant to the standard therapies mentioned above.[11] Although there have been no comparative controlled studies, the few available data suggest that atovaquone is less effective than standard therapies, with a 25% relapse rate that might be due to wide variations in plasma concentrations of the drug between patients and within the same patient. It is recommended that atovaquone should be combined with pyrimethamine.[10]

Macrolides

Clarithromycin 2g/day orally and azithromycin 500mg/day orally have been given in combination with pyrimethamine in small, open, noncomparative pilot studies. They have been found to have an efficacy rate of 50–70%.[11] However, these drugs are not considered to be major antitoxoplasma drugs.

PREVENTION

In patients with HIV infection who have negative toxoplasma serology, prevention measures to avoid contamination should be recommended (e.g. avoiding contacts with raw meat, cooking meat properly, washing vegetables). Control serology should be performed on a regular basis to warn that contamination might have occurred.

TABLE 127-1 -- Therapeutic management of toxoplasmosis.

THERAPEUTIC MANAGEMENT OF TOXOPLASMOSIS			
	Acute initial therapy	**Maintenance therapy**	**Notes**
First-choice treatment	Pyrimethamine 50mg/day plus sulfadiazine 4g/day po	Pyrimethamine 25mg/day plus sulfadiazine 2g/day po	Highest efficacy; also effective as prophylaxis for *P. carinii* pneumonia
Second-choice treatment	Pyrimethamine 50mg/day plus clindamycin 2.4g/day po or iv	Pyrimethamine 25mg/day plus clindamycin 1.2g/day po	Relapse rate is 25%; prophylaxis for *P. carinii* pneumonia should be added
Alternative treatment	Atovaquone 750mg q6h po	Atovaquone 750mg q6h po	Relapse rate is 25%; also effective as prophylaxis for *P. carinii* pneumonia
	Pyrimethamine-clarithromycin		

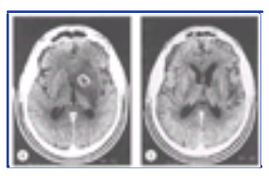

Figure 127-3 Toxoplasmic encephalitis. (a) CT scan at diagnosis. (b) Evolution of the disease after 42 days of treatment with pyrimethamine-sulfadiazine.

Primary prophylaxis is indicated in patients at high risk of infection with *T. gondii*. High-risk patients are defined as those who have a CD4$^+$ lymphocyte count of less than 200 cells/mm^3 and positive antitoxoplasmal serology.[12] The use of drugs having activity against both *P. carinii* and *T. gondii* should be a priority.

Trimethoprim-sulfamethoxazole

Trimethoprim-sulfamethoxazole (co-trimoxazole) is effective in preventing both pneumocystosis and toxoplasmosis.[13] [14] The most commonly used regimens are trimethoprim 160mg and sulfamethoxazole 800mg every day orally or every second day, or trimethoprim 80mg and sulfamethoxazole 400mg every day. Main side-effects are rash and fever (in 5–20% of cases); toxicity appears to be dose-related. The superiority of trimethoprim-sulfamethoxazole over other prophylaxis for both pneumocystosis and toxoplasmosis justifies desensitization procedures in patients with moderate intolerance to these compounds; desensitization has a 50–60% success rate.

Dapsone-pyrimethamine

Recommended regimens are dapsone 50mg/day plus pyrimethamine 50mg per week.[15] A weekly regimen with dapsone 200mg orally plus pyrimethamine 75mg orally showed similar results.[16] However, side-effects are frequent, occurring in 25–70% of patients; rash, hematotoxicity and digestive intolerance are the most common. In clinical practice, dapsone-pyrimethamine offers almost no advantages over trimethoprim-sulfamethoxazole, and cross-intolerance between these two combinations is frequent.

Pyrimethamine

In cases of sulfadiazine intolerance, pyrimethamine alone 50mg three times per week orally may be used as primary prophylaxis in combination with folinic acid 25mg three times per week.[17] Pentamidine aerosol should be added, because pyrimethamine does not provide effective prophylaxis against *P. carinii* pneumonia.

Discontinuation of prophylactic regimen

Several observational and two randomized studies[18] [19] have shown that primary and secondary prophylaxis can be discontinued with minimal risk of developing TE in patients who have responded to highly active antiretroviral therapy (HAART) with an increase in $CD4^+$ T cells for at least 3 months. In case of changes in the immune state following failure or discontinuation of antiretroviral therapy that may lead to a decrease in CD4 cells, prophylaxis should be reintroduced if the $CD4^+$ T cell count decreases to less than 200 cells.

CRYPTOSPORIDIOSIS

EPIDEMIOLOGY

Cryptosporidiosis is a worldwide protozoan infection that is more prevalent in poorly developed countries. Cryptosporodiosis may affect patients with acute disease but more frequently patients with an immune deficit.[20] The prevalence of this infection in the context of HIV disease in Europe was 1–2% and in North America 3–4% before HAART, but the rate has fallen considerably given the generalized use of combined potent antiretroviral drugs in the year 2000; in Asia, Africa, and Central and South America it is 15–10%.[21] [22] Human cryptosporidiosis is generally caused by *Cryptosporidium parvum,* which is transmitted primarily by the fecal-oral route through person to person transmission or indirectly; outbreaks from municipal water, person to person transmission and animal to person transmission have been described. Healthy carriers of oocysts may play a major role in transmission.

CLINICAL FEATURES AND DIAGNOSIS

Diarrhea is the main clinical symptom, ranging in severity from mild diarrhea to cholera-like, watery diarrhea. Abdominal cramps, nausea, vomiting and anorexia usually accompany the diarrhea when it is moderate or severe. Fever is uncommon and may be due to other concurrent infections. The severity of the disease is more pronounced in patients with $CD4^+$ lymphocyte counts of less than 50/mm^3 . Cryptosporidiosis may involve the gallbladder, the biliary tract, the pancreatic ducts (leading to cholecystitis and pancreatitis), the bronchi and the lungs.

Diagnosis is based on the identification of the parasite in feces, in tissue specimens or in other fluids such as in bronchoalveolar lavage, using a modified acid-fast stain such as the Ziehl-Neelsen stain. Other techniques include Giemsa stain, fluorescent auramine-rhodamine, Sheather's sucrase flotation and indirect immunofluorescence.[22] Occasionally, cryptosporidiosis oocysts are associated with other pathogens, including *Entamoeba, Microsporidia* and *Giardia* spp. and cytomegalovirus.

MANAGEMENT AND PREVENTION

Treatment of cryptosporidiosis is essentially symptomatic. Efforts to find useful therapies have been impeded by the absence of an in-vitro model and the lack of a universally accepted animal model, and there is currently no agent that can reliably eradicate the organism. Among the various pharmaceutical agents that have been used, paromomycin,[23] azithromycin and nitazoxanide[24] have shown some efficacy in non-HIV related cryptosporidiasis. However, because the course of cryptosporidial disease depends mainly on immune status, the best option for therapy and prevention against chronic cryptosporidiosis is the restoration of immune function that has been observed as a consequence of potent antiretroviral therapy. Most of the devastating symptoms of cryptosporidiosis are observed in patients with severe immunosuppression and no antiviral therapy; initiation of antiretroviral therapy is the best option for treating cryptosporidiasis. This underlines clearly the role of the immune deficiency in the symptomatic disease. In the absence of specific effective treatment, the following preventive measures should be considered in patients whose $CD4^+$ lymphocyte count is less than 200/mm^3 :

- drinking boiled water or water filtered through a 1µm filter (bottled water may be an option);
- avoiding the consumption of raw fruits or vegetables that have been washed in unfiltered water; and
- avoiding contact with the feces of animals, or the wearing of gloves if such exposure cannot be avoided.

MICROSPORIDIOSIS

MICROBIOLOGY AND EPIDEMIOLOGY

Microsporidiosis is mainly seen in immunocompromised patients. [25] It is caused by an obligate intracellular protozoan parasite. Five genera have been reported in humans — *Enterocytozoon, Encephalitozoon* and *Septata* spp. are the most frequent; *Pleistophora* and *Nosema* spp. are uncommon. The source of human infection is unknown; contamination is thought to occur through ingestion of spores.

CLINICAL FEATURES AND DIAGNOSIS

The intestine is by far the most common site of microsporidiosis in patients with HIV infection, and 90% of cases are caused by *Enterocytozoon bieneusi*. Diarrhea of variable intensity between patients is the most frequent symptom; it may be accompanied by abdominal pain and cramps and nausea. Other localized forms of the disease include cholangitis and cholecystitis.[26] *Septata intestinalis* may cause a similar gastrointestinal syndrome or cholangitis, and it sometimes spreads to the urinary tract, when the organism may be be detectable in the urine.[27] *Nosema corneum* and *Encephalitozoon hellem* have been reported in corneal infection or keratoconjunctivitis.

Microsporidia can be identified in fluids (e.g. feces, urine, sinus mucus and bronchoalveolar lavage) using specific staining procedures such as modified trichrome, calcofluor or uvitex, and in tissue biopsies (e.g. intestinal and sinus biopsies) using staining procedures such as Giemsa, trichrome, periodic acid-Schiff or toluidine blue. Electron microscopy remains the reference diagnostic procedure that allows identification of the species of the organisms that are found (see Chapter 243).

MANAGEMENT

In a placebo controlled study, fumagillin (200mg q8h), an antiparasitic drug used in veterinary medicine, has been shown to be effective in clearing *E. bieneusi* in patients with HIV infection and chronic diarrhea related to this opportunistic infection. Bone marrow toxicity, mainly thrombocytopenia, is the principal side-effect of fumagillin.[28]

ISOSPORIASIS

Isosporiasis is a rare intestinal infection caused by *Isospora belli*. It is seen in immunocompetent patients in endemic areas — Central and South America, South East Asia and Africa — and in immunocompromised patients. Humans are the only known reservoir for *I. belli*. [29] The main route of transmission is thought to be oral absorption of food or water contaminated by *I. belli* oocysts. *Isospora belli* infection has been reported in less than 0.5% of AIDS patients in the USA, and in 15% of AIDS patients in Haiti and Africa. The generalized use of trimethoprim-sulfamethoxazole as prophylaxis against *P. carinii* pneumonia has lead to a large decrease in the prevalence of this infection in HIV-positive patients. Isosporiasis usually manifests in patients with HIV infection as chronic diarrhea that leads to malabsorption syndrome and weight loss.

Diagnosis is made by identification of *I. belli* cysts in specimens of stool; several stool samples must be examined (see Chapter 243).

Specific therapy of *I. belli* is trimethoprim-sulfamethoxazole (trimethoprim 160mg q12h, sulfamethoxazole 800mg q8h, for 10 days).[29] Long-term prophylaxis with trimethoprim-sulfamethoxazole (one double-strength tablet (trimethoprim 160mg and sulfamethoxazole 800mg) three times per week) is required to prevent relapse. Pyrimethamine (50–75mg/day) may be used in patients intolerant to sulfonamides.

LEISHMANIASIS

Visceral leishmaniasis (VL) in the course of HIV infection is mainly seen in southern Europe (Spain, Italy and the south of France) and south America (Venezuela and Brazil). It is estimated that 25–70% of adult VL cases in these areas are related to HIV infection and that 1.5–9% of AIDS patients develop newly acquired or reactivated VL. The majority of cases are due to *Leishmania infantum*. Visceral leishmaniasis usually occurs in late-stage HIV infection (when the $CD4^+$ lymphocyte count is less than $200/mm^3$), and it may be observed several years after the patient has left an endemic area.

The clinical manifestations are those of classic VL, with fever in 90% of cases. Other manifestations may include hepatomegaly and splenomegaly; digestive, pulmonary, or cutaneous disorders may be the only symptoms of VL. Biologic abnormalities include leukopenia and anemia, which may be at least partly due to the HIV infection.

Diagnosis relies on the identification of *Leishmania* spp. in a bone marrow aspirate; this test has a sensitivity of 95% for a first episode and 65% for relapses. Blood smears reveal the parasite in 50% of cases; this increases to 70% after culture of white blood cells. Serology has only limited diagnostic value, with only 35–50% positivity.

Acute therapy consists of meglumine antimoniate (20mg/kg body weight per day) for 28 days; this leads to a positive response in 80–90% of cases. Alternative drugs are pentamidine (4mg/kg/day on alternate days) for 4–12 weeks or amphotericin B (0.5–1mg/kg/day on alternate days) for 4–8 weeks.

The relapse rate is high (50% of cases relapse), justifying the need for long-term maintenance therapy. Different regimens have been suggested; pentavalent antimonials (850mg antimonials per month), pentamidine (2mg/kg every 2 weeks), or amphotericin B (1mg/kg every 2–4 weeks). In the absence of any comparative controlled trials, the best maintenance treatment remains uncertain.

Chapter 128 - Bacterial Infections in HIV Disease

Janine R Maenza
Richard E Chaisson

Parasitic, fungal, mycobacterial and viral diseases are often viewed as the central opportunistic infections in HIV disease, because together they form the majority of AIDS-defining conditions. Bacterial infections as a group, however, are actually the most common complication of HIV disease. Patients with HIV infection are at greater risk for infections caused by common bacterial pathogens (e.g. *Streptococcus pneumoniae, Haemophilus influenzae, Salmonella* spp.) than are HIV-seronegative persons. The relevance of bacterial infections was demonstrated by the addition, in 1993, of recurrent bacterial pneumonia to the Centers for Disease Control and Prevention definition of AIDS indicator conditions.[1] This chapter reviews the underlying immunologic changes that lead to the occurrence of bacterial infections in HIV-infected patients, the epidemiology of these infections and the clinical manifestations and management of these conditions, in the developed world.

EPIDEMIOLOGY

The epidemiology of bacterial infections as complications of HIV infection has been most carefully studied for bacterial pneumonia. The increased risk of bacterial pneumonia in HIV-infected injection drug users was demonstrated in a study that found the annual risk of community-acquired pneumonia was 9.7% in HIV-infected injection drug users without AIDS, compared with 2.1% in HIV-negative injection drug users and only 0.3% in the general population.[2] In another, prospective, study of over 4000 former injection drug users the incidence of community-acquired pneumonia was again markedly higher among HIV-infected patients (90.5/1000 person-years) than among HIV-negative persons (14.2/1000 person-years; Fig. 128.1).[3]

Other studies have examined the risk of bacterial pneumonia in populations that include other exposure categories as well as injection drug use. The epidemiology of bacterial pneumonia was described in the Pulmonary Complications of HIV Infection Study.[4] In this longitudinal study, the majority of participants were homosexual or bisexual men. Again, the rate of bacterial pneumonia was significantly higher in HIV-infected patients than in HIV-negative controls (5.5/100 person-years compared with 0.9/100 person-years). [4] Tobacco smoking was also found to be associated with a significantly increased risk of bacterial pneumonia in both HIV-infected and -uninfected patients.[4]

The introduction of highly active antiretroviral therapy (HAART) in the late 1990s has influenced the incidence of HIV-associated bacterial infections. There appears to have been a decline in the incidence of community-acquired and nosocomial bacterial pneumonia after potent antiretrovirals became widely used.[5] In contrast, the proportion of hospitalizations due to bacterial infections has increased as rates of *Pneumocystis carinii* and other more opportunistic infections have declined.[6] [7] Nevertheless, the increased rate of bacterial pneumonia in HIV-infected patients without AIDS, in comparison to HIV-negative persons, serves to emphasize that pyogenic bacterial infections may occur when immunity is relatively intact owing to the virulence of these organisms compared with other more opportunistic pathogens. Epidemiologic studies of other bacterial infections (e.g. bacteremia and infections caused by enteric pathogens) confirm the generally higher incidence of pyogenic infections in HIV-infected patients than in HIV-negative patients. Discussion of the increased frequency of specific diseases and the risk factors for disease development are found within the specific clinical sections of this chapter.

PATHOGENESIS AND PATHOLOGY

There are a variety of immunologic defects in HIV infection that may predispose patients to acquire bacterial infections. Among these immunologic abnormalities are deficits of mucosal immunity, cell-mediated immunity, humoral immunity and the complement system (Table 128.1). [8]

Defects of mucosal (or local) immunity are ascribed to decreased levels of IgA_2 at mucosal surfaces. It is postulated that this abnormality may increase the risk of invasive bacterial infections with *S. pneumoniae* and *Salmonella* spp. in particular. [8] [9]

A reduction in the $CD4^+$ lymphocyte count and a reversal of the CD4:CD8 ratio in HIV infection is implicated as a predisposing factor for bacterial infections in several ways. $CD4^+$ lymphocytes may also be involved in cell-mediated immunity as mediators of antibody-dependent and antibody-independent killing of enteric bacterial pathogens by mononuclear cells.[10] Changes in regulatory effects secondary to decreased levels of interleukin-2 and interferon-? production are also likely to contribute to an immunologic deficit. [11] In addition, abnormalities of $CD8^+$ lymphocyte activity may occur, leading to decreased cytotoxic function.[11]

Defects in humoral immunity are also present in HIV infection — although patients with HIV infection often have a polyclonal IgG gammopathy, the function of these antibodies is frequently abnormal and levels of specific IgG subclasses (e.g. IgG_2) may be low.[12] There is also evidence that some patients who have HIV infection have low levels of specific complement components or abnormalities of complement activation, or both. [13] [14] Deficits in hepatic and splenic clearance of opsonized organisms may occur. Children in particular are at an increased risk of developing infections caused by encapsulated bacteria (e.g. *S. pneumoniae, H. influenzae*), probably because of a lack of protective antibody in the absence of previous exposure to these organisms.

Neutropenia is a common complication of advanced HIV infection itself, as well as being a toxicity of many medications used in the management of HIV-infected patients. Neutropenia (absolute neutrophil count <1000 cells/mm^3) is an independent risk factor for the development of bacterial infections in patients with advanced HIV disease, and the risk rises as the absolute neutrophil count falls. [15] Low CD4 counts have also been shown to increase the risk of infection during neutropenia.[16] It should be noted, however, that infection rates in patients with HIV infection are substantially lower than in patients with neutropenia related to cancer chemotherapy. This may be because the nadir in the absolute neutrophil count in patients with HIV infection is usually higher than that seen in cancer patients.

TABLE 128-1 -- Factors associated with bacterial infections in HIV-infected patients.

FACTORS ASSOCIATED WITH BACTERIAL INFECTIONS IN HIV-INFECTED PATIENTS
Defects of mucosal immunity
Decreased levels of IgA_2 at mucosal surfaces
T-lymphocyte defects
Loss of $CD4^+$ lymphocytes
Impaired cytotoxic T-lymphocyte function
Decreased production of interleukin-2 and interferon-?
Defects of humoral immunity
Polyclonal gammopathy
Functional abnormalities of antibodies
Decreased levels of IgG subclasses
Granulocyte defects
HIV-related neutropenia
Drug-induced neutropenia
Complement defects
Low complement levels

Abnormal complement activation

PREVENTION

Prevention of bacterial infections may take several forms:

- avoidance of exposure,
- prophylactic antibiotics,
- vaccination,
- passive immunotherapy,
- the use of growth factors, and
- the use of HAART.

Avoidance of exposure

Measures involved in the avoidance of exposure range from avoiding the use of unsanitary water that may be associated with the transmission of enteric pathogens to the strict hygienic techniques recommended for patients with indwelling intravenous catheters. Patients should also avoid undercooked eggs and poultry and unpasteurized milk.[17]

Prophylactic antibiotics

The use of prophylactic antibiotics to prevent other opportunistic infections may have the added benefit of decreasing a patient's risk of bacterial infection. Trimethoprim-sulfamethoxazole (co-trimoxazole), a first-line agent for prophylaxis for *P. carinii*, may decrease the risk of bacterial infections as well. Studies have shown that its use is associated with a decrease in the number of confirmed episodes of bacterial pneumonia,[4] as well as bacterial infections in general.[18] Other studies, however, have failed to show a specific protective effect against pneumococcal infection;[19] this may be associated with selection of pneumococcal strains with decreased susceptibility to this agent. [20] In addition, trimethoprim-sulfamethoxazole has also been shown to be associated with a decline in the susceptibility of *S. pneumoniae* to penicillin.[21] The use of macrolide antibiotics (clarithromycin, azithromycin) as prophylaxis against the development of *Mycobacterium avium* infection has also been shown to be associated with a decreased risk of pyogenic bacterial infections. [22] [23] [24]

Thus, antibacterials being used for prophylaxis of *P. carinii*, toxoplasmosis of *M. avium* may decrease the risk of bacterial infections. Nevertheless, because of the risk of the development of resistance, antibiotics have not been recommended solely to prevent bacterial infections. Recent data from two placebo-controlled trials in Cote d'Ivoire suggest, however, that trimethoprim-sulmethoxazole prophylaxis may provide a health or survival benefit in developing countries where more costly therapies are not available. [25] [26]

Vaccination

Both the pneumococcal vaccine and the *H. influenzae* type b (Hib) vaccine have been evaluated in HIV-infected patients. Antibody responses to the 23-valent pneumococcal vaccine have been shown to be more effective in patients with higher $CD4^+$ lymphocyte counts (Fig. 128.2).[20] [27] There is also clinical evidence from observational studies indicating increased effectiveness when the vaccine is used earlier in the course of HIV infection (when the $CD4^+$ lymphocyte

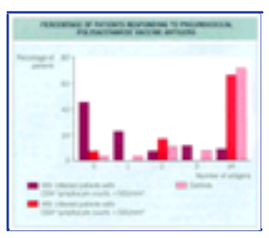

Figure 128-2 Percentage of patients responding to pneumococcal polysaccharide vaccine antigens. *Adapted from Rodriquez-Barradas et al.*[20]

count is greater than 200/mm^3).[19] In a placebo-controlled trial of pneumococcal vaccine in HIV-infected adults in Uganda, however, recipients of the 23-valent vaccine had a marginally higher rate of invasive pneumococcal infections and a significantly higher rate of all forms of pneumonia. [28] A clear rationale for why pneumococcal vaccination should increase the risk of disease is not apparent. Despite the findings of the Ugandan trial, the pneumococcal vaccine is currently recommended in the USA as a preventive measure for all patients with HIV infection and $CD4^+$ lymphocyte counts under 200/mm^3 , the vaccine is optional given the poor antibody and clinical response. Re-vaccination after 6 years is also recommended for patients with HIV infection, but a recent trial suggests that the risk of reactogenicity is considerable and the immunologic benefits may be limited.[29]

Vaccination against Hib has similarly been shown to elicit a better antibody response when used earlier in the course of disease.[30] The Hib polysaccharide vaccine is currently recommended for all children (regardless of HIV status).[31] The benefit of this vaccine in HIV-infected adults is less clear; although the incidence of *H. influenzae* is clearly increased in HIV-infected patients, the low absolute incidence of Hib infection mitigates against the routine use of the vaccine.[32]

Passive immunotherapy

Passive immunotherapy with high-dose intravenous immunoglobulin is often used to prevent recurrent bacterial infections in HIV-infected children. [33] [34] One controlled trial has shown that such therapy may be effective in HIV-infected adults as well; a reduction in the frequency of serious bacterial infections and hospitalizations in patients who were treated with intravenous immunoglobulin every 21 days was demonstrated. [35]

Use of growth factors

Measures to prevent or correct neutropenia must be tailored to the underlying cause of the cytopenia (e.g. treatment of infection causing bone marrow suppression, elimination of myelopsuppressive drugs). As an adjunct to these measures, when elimination of the underlying cause is not possible, or when there is no specific discernible cause of neutropenia, the use of granulocyte colony stimulating factor (G-CSF) should be considered. The use of G-CSF in patients with an absolute neutrophil count less than 1000/mm^3 is associated with a decline in bacterial infections, decreased duration of hospitalizations and improved survival.[36] [37] [38]

Use of highly active antiretroviral therapy

As noted above, HAART has been strongly associated with a decreased incidence of bacterial infections, particularly bacterial respiratory tract infections, in patients with HIV infection. The use of HAART is generally governed by guidelines from professional and governmental groups and is based on the potency and tolerability of specific regimens, the relative risk of disease progression based on clinical status and surrogate markers, and the long-term toxicities of treatment (see Chapter 139).

CLINICAL MANIFESTATIONS AND TREATMENT

The most common clinical manifestations of bacterial infection in HIV-infected patients are skin infections, respiratory infections, sinusitis, enterocolitis and bacteremia.

Skin infections

Bacterial skin infections in HIV-infected patients may vary from impetigo to folliculitis to cutaneous abscesses; cutaneous abscesses are often associated with injection drug use as well. Recurrences

Figure 128-3 Typical appearance of bacillary angiomatosis. *Courtesy of Ciro Martins, MD.*

may be more frequent than in the HIV-negative population, but physical findings and responsible organisms (*Staphylcoccus aureus* and *Streptococcus* spp.) are similar. Treatment involves agents with good coverage of Gram-positive organisms, such as cephalexin or dicloxacillin.

Bacillary angiomatosis is a distinct skin infection that is specifically associated with HIV disease. The condition is caused either by *Bartonella henselae*, the organism that is also responsible for catscratch disease, or by *Bartonella quintana*. The clinical appearance is of very erythematous subcutaneous nodules that may occasionally resemble Kaposi's sarcoma (Fig. 128.3). Lymphadenopathy may be associated with these skin findings. Much less frequently, *B. henselae* has been identified as the cause of more deeply seated infections, including endocarditis, osteomyelitis and hepatic lesions (peliosis hepatis).[39] Diagnosis of the skin infection may be based on the characteristic appearance, but biopsy may be carried out to rule out other causes, and it is necessary to diagnose solid organ involvement. Histology shows vascular proliferation and mixed inflammatory cells. Warthin- Starry staining reveals the organism. Treatment is with a macrolide (erythromycin orally 250–500mg q6h) or a tetracycline (doxycycline orally 100mg q12h) for 1–2 months for skin disease, and longer for other sites of infection.

Sinusitis

Both acute and chronic sinusitis are common complications of HIV infection. Symptoms may include headache, fever, congestion and cough. However, many patients present with only headache or cough and without more typical symptoms of bacterial sinusitis (Table 128.2).

In one study, the organisms most commonly isolated as the cause of sinusitis were viridans streptococci, *S. pneumoniae* and *Pseudomonas aeruginosa*.[40] Other organisms that may be responsible include *H. influenzae*, other *Haemophilus* spp. and *Moraxella catarrhalis*.

The diagnosis is often made clinically, although sinus radiographs or computerized tomography (CT) scanning may be useful in demonstrating mucosal thickening, air-fluid levels or sinus opacification. Sinus CT is more sensitive for these findings than plain films.[40]

Treatment should include a decongestant in addition to antimicrobial therapy. The choice of antimicrobial is often made on empiric grounds with first-line options including amoxicillin-clavulanate, clindamycin, cefuroxime, clarithromycin or azithromycin. In patients who do not respond to such therapy, consideration should be given to sinus aspiration or the addition of antipseudomonal agents (see Chapter 32 and Chapter 229). In patients with $CD4^+$ lymphocyte counts less than 200/mm^3 , response to antibiotic treatment for acute sinusitis is often incomplete, leading to chronic sinusitis.[40]

TABLE 128-2 -- Signs and symptoms of sinusitis in HIV-infected patients.*

PRESENTING CLINICAL FEATURES OF SINUSITIS IN HIV-INFECTED PATIENTS		
		Percentage of patients
Symptoms	Fever	93
	Headache	89
	Nasal congestion	79
	Postnasal drainage	54
	Facial pain	36
	Watery discharge	21
	Purulent discharge	14
	Fever, headache	14
	Fever, headache, congestion	68
	Fever, headache, facial pain, discharge	14
Signs	Fever — temperature over 100.4°F (38°C)	79
	Facial tenderness	50
	Nasal discharge	31
	Facial swelling	21

** These data relate to 72 HIV-infected patients as reported by Godofsky et al.[40]*

Pneumonia

As described above, bacterial pneumonia is more common in patients with HIV infection than in HIV-seronegative comparison groups. The introduction of potent antiretroviral therapy, which has caused a decline in more opportunistic infections, has also led to bacterial pneumonia (and other bacterial infections) being responsible for proportionately more hospitalizations of HIV-infected patients. [6] [7] Risk factors for the development of bacterial pneumonia have been investigated in observational studies and include lower $CD4^+$ lymphocyte counts,[3] [4] [41] injection drug use,[4] cigarette smoking[4] and illicit drug use.[41] In addition, risk factors for pneumococcal infection specifically include any previous history of pneumonia, low serum albumin and a lack of receipt of the pneumococcal vaccination when the patient had a $CD4^+$ lymphocyte count greater than 200/mm^3 .[19] The specific amount of risk associated with declining immunity has been described; a rate of bacterial pneumonia of 2.3/100 person-years in patients with $CD4^+$ lymphocyte counts over 500/mm^3 was found.[4] This rate increased to 6.8/100 person-years in those with $CD4^+$ lymphocyte counts between 200 and 500/mm^3 , and 10.8/100 person-years in those with $CD4^+$ lymphocyte counts less than 200/mm^3 (Fig. 128.4).[4]

The clinical presentation of bacterial pneumonia in HIV-infected patients is indistinguishable from that in HIV-negative patients. The history usually reveals an acute onset of symptoms, including fever, productive cough, dyspnea and pleuritic chest pain. Physical examination commonly shows localized pulmonary findings, and laboratory evaluation may show leukocytosis and hypoxemia. Typical chest radiograph findings are of focal infiltrates, although diffuse disease may be seen. Sputum Gram stain will show multiple polymorphonuclear leukocytes, and sputum cultures are usually positive. These findings differ from the classic presentation of *P. carinii* pneumonia, the most common nonbacterial cause of pneumonia in HIV-infected patients, in which the presentation is more often subacute with a nonproductive cough, a paucity of physical findings and diffuse interstitial infiltrates on chest radiograph. Nevertheless, there are frequently cases in which induced sputum examination or bronchoscopy with bronchoalveolar lavage are necessary to obtain a microbiologic diagnosis.

The pathogens most commonly responsible for bacterial pneumonia are *S. pneumoniae, H. influenzae* and *Haemophilus* spp. other than

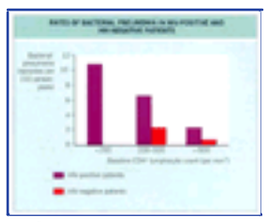

Figure 128-4 Rates of bacterial pneumonia in in HIV-positive and HIV-negative patients. The rates are shown by baseline $CD4^+$ lymphocyte count. *Data from Hirschtick et al.*[4]

H. influenzae.[42] Other organisms that may cause disease include *M. catarrhalis, Klebsiella pneumoniae* and *Staphylococcus aureus*. Empiric therapy usually includes a second- or third-generation cephalosporin. If there is a lack of clinical response, other bacteria that may not respond to such treatment must be considered as possible causes (e.g. *Chlamydia pneumoniae*,[3] *Nocardia* spp.[43] and *Legionella* spp.[44]). In addition, unlike HIV-negative patients, in whom *P. aeruginosa* is usually responsible for only nosocomial infections, in HIV-infected patients *Pseudomonas* pneumonia frequently occurs as a community-acquired infection.[45] [46] There are also data that suggest a shift in bacterial pathogens since the introduction of HAART. A decline in *P. aeruginosa* infections has been reported, and seems to be associated with both generally higher CD4 lymphocyte counts and a reduction in the use of trimethoprim-sulfamethoxazole prophylaxis.[47]

An unusual organism responsible for bacterial pneumonia in HIV-infected patients is *Rhodococcus equii*. This bacterium is a Gram-positive rod usually associated with infections of domestic animals.[48] In HIV-infected patients, the clinical presentation is often subacute and characterized by fever, cough, pleuritic chest pain, fatigue and weight loss.[49] Chest radiographs often show cavitating lesions.[48] [50] [51] Blood cultures may be more sensitive for diagnosis than sputum cultures — 83% sensitivity compared with 33% in one study.[51] Treatment is usually with vancomycin (intravenously 1g q12h) but ciprofloxacin (orally 750mg q12h) or imipenem (intravenously 500mg q6h) may also be used and duration of therapy is 2–4 weeks.

Bacteremia in the setting of pneumonia occurs more commonly in HIV-infected than in HIV-negative patients — increased rates of bacteremia with pneumococcal and *H. influenzae* pneumonia have been documented (Fig. 128.5). [52] [53] [54] [55] Bacteremia may also occur with other pathogens responsible for pulmonary infections (e.g. *P. aeruginosa*). Mortality rates from bacterial pneumonia may also be higher in HIV-infected patients, but there are conflicting data on this topic.[56] [57] [58] [59]

Enterocolitis

Many etiologic agents may cause diarrhea in HIV-infected patients. Among the bacterial pathogens commonly encountered are non-typhoidal *Salmonella* spp., *Shigella flexneri, Campylobacter jejuni* and *Clostridium difficile. Shigella* and *Campylobacter* infections manifest similarly — patients note severe diarrhea (which may be bloody) associated with abdominal cramping, nausea and fever.

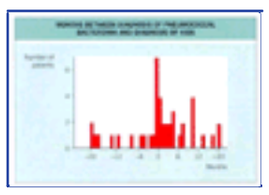

Figure 128-5 Months between diagnosis of pneumococcal bacteremia and diagnosis of AIDS. The data relate to 37 patients as reported by Redd *et al.*[53]

Diagnosis is by stool culture. These infections may both be treated with oral quinolones (see Chapter 43).

Nontyphoidal *Salmonella* spp. infections may present either with or without diarrhea and other symptoms of colitis. In patients without gastrointestinal symptoms, the infection may manifest solely as fever without any localizing findings. The occurrence of *Salmonella* bacteremia is more common in patients with HIV infection than in HIV-seronegative groups.[60] In addition, relapses of bacteremia are common.[61] Unlike the recommendations for patients who are not immunosuppressed, even *Salmonella* infections limited to the gastrointestinal tract should be treated in HIV-infected patients. Treatment is usually with ciprofloxacin (500mg q12h for 2–4 weeks), and suppressive therapy with ciprofloxacin is often used because of the risk of relapse.

Infection due to *C. difficile* also has characteristics in HIV-infected patients that differ from those seen in the HIV-negative population. Clinical symptoms may be more severe in HIV-infected patients, and these patients are more likely to have relapses and chronic symptoms. Antibiotic use and hospitalization are associated with the development of infection, just as they are in HIV-negative patients.[62] [63] *Clostridium difficile* may also occur as a community-acquired infection in HIV-infected patients.[64] Treatment is with oral metronidazole or vancomycin.

Bacteremia

As discussed above, bacteremia may frequently occur as a result of *Salmonella* spp. infections and pneumonia. Bacteremia may also be associated with soft tissue infections and urinary infections. Injection drug use is associated with the development of *S. aureus* bacteremia and endocarditis. In this setting, CD4+ lymphocyte count has been shown to have an inverse correlation with mortality rate.[65] In addition, bacteremia may be a complication of the use of long-term intravenous catheters, which may be needed in the management of HIV-infected patients (e.g. for the intravenous treatment of cytomegalovirus retinitis). In one study of HIV-infected patients admitted with bacteremia, 35% had an infection associated with an intravenous catheter.[66] In this and other studies, the causative organisms most frequently isolated were *S. aureus* and coagulase-negative staphylococci.[66] [67] Line infections caused by Gram-negative organisms are less frequent, but certainly not uncommon — *Escherichia coli, Proteus mirabilis, Serratia marcescens, P. aeruginosa*[46] [67] and other Gram-negative rods have all been isolated as the cause of infections related to an intraveneous catheter. Empiric therapy of line infections while culture results are awaited should therefore involve vancomycin and an aminoglycoside (or vancomycin and a ß-lactam with broad Gram-negative coverage). Removal of the intravenous line may not be necessary in treating *S. aureus* and coagulase-negative staphylococcal infections, but it is usually recommended for Gram-negative bacterial infections. Of interest, however, are data from one study indicating similar recurrence rates whether or not the catheter was removed.[66] As with other infections, the incidence of HIV-associated bacteremia declined after HAART became available. One study has shown that this decline has been associated with a reduction in the use of central venous catheters and in neutropenia.[68]

Chapter 129 - Mycobacterial Infections in HIV-infected Patients

Alex Soriano
José M Gatell

EPIDEMIOLOGY

Mycobacterial infections are common AIDS-defining events in HIV-infected patients. *Mycobacterium tuberculosis* and *Mycobacterium avium* complex (MAC) are the most frequently found infections and have different distributions around the world. *Mycobacterium tuberculosis* has the highest incidence rate in Africa, Asia and southern Europe and MAC in the USA and northern Europe.

HIV infection, because of its immunosuppressive effect, is the most significant risk factor for the development of active tuberculosis.[1] The number of reported cases of tuberculosis increased dramatically during the 1980s and early 1990s and the World Health Organization estimated that, between the onset of the HIV pandemic and mid-1993, more than 5 million persons worldwide had been co-infected by both HIV and *M. tuberculosis*. More than 3.5 million of these are in sub-Saharan Africa (Fig. 129.1).

HIV infection has not only modified the incidence of tuberculosis during the last 15 years but has also altered the clinical presentation, with an increase in extrapulmonary forms of tuberculosis.[3] Furthermore, the mortality rate of tuberculosis before the introduction of new antiretroviral drugs was four to eight times higher in HIV-positive than in HIV-negative patients. [4] Since the introduction of

Figure 129-1 Estimated global distribution of adults co-infected with HIV and *Mycobacterium tuberculosis,* to mid-1993. *From the World Health Organization Tuberculosis Program. Redrawn with permission from Snider et al.*[2]

highly active antiretroviral therapy (HAART) the incidence of opportunistic infections and mortality has dramatically decreased. However, the decrease in the incidence of tuberculosis is less evident (Fig. 129.2) and it is still much higher among HIV-infected patients in all strata of $CD4^+$ lymphocytes than in the general population (Fig. 129.3).

Mycobacterium avium complex is ubiquitous in the environment and has been isolated from a variety of sources around the world, including soil, natural water, municipal water systems, food, house dust and domestic and wild animals. These isolates are thought to be the source of most human infections but there is no evidence of MAC transmission from person to person. In the USA the incidence of MAC disease has been studied prospectively in a number of cohorts; the cumulative probability of disseminated disease due to MAC in subjects who have $CD4^+$ lymphocyte counts below 50 cells/mm^3 is 30%, and 20% in those who have $CD4^+$ lymphocyte counts of 50–100 cells/mm^3 , while in Europe the rates are 20% and 11% respectively.[6] Furthermore, MAC was also infrequently isolated in AIDS patients from Africa. The differences in epidemiologic data between the USA and Europe or Africa have been attributed to a potential cross-immune protection between MAC and *M. tuberculosis* or MAC and bacille Calmette-Guérin (BCG) vaccine, which is much more frequently administered in Europe and Africa.

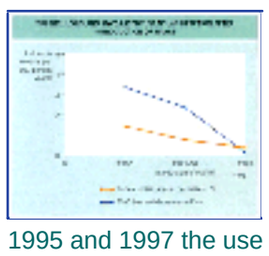

Figure 129-2 Tuberculosis and *Mycobacterium avium* infection after introduction of highly active antiretroviral therapy. Incidence among HIV-positive patients. Between 1995 and 1997 the use of HAART became general practice in Europe. *Redrawn with permission from Kirk et al.*[5]

The use of primary prophylaxis for MAC with clarithromycin, azithromycin or rifabutin and the introduction of HAART are the most likely explanations of the decreased incidence rate of MAC disease[5] (see Fig. 129.2).

PATHOGENESIS

Mycobacterium tuberculosis is acquired via inhalation. In the lung alveoli an immune response is established, mediated by a complex interaction between mononuclear phagocytes and different subsets of T cells. While the former cells act as the main effectors, the latter serve as the predominant inducers of protection. A co-ordinated

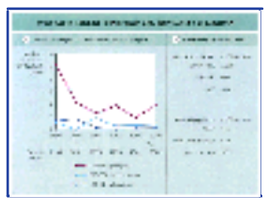

Figure 129-3 Tuberculosis incidence in recipients of highly active antiretroviral therapy, Hospital Clinic of Barcelona. (a) The incidence rate per 100 HIV-infected patients per year, separated into three different groups by $CD4^+$ lymphocyte level. (b) Tuberculosis incidence, 2000, expressed per 100,000 persons per year. It is notable that the incidence of tuberculosis is higher in HIV patients in all $CD4^+$ lymphocyte strata, as compared with the general population.

communication between both cells mediated by different cytokines is essential for optimum protection, especially cytokines such as interferon (INF)-? and tumor necrosis factor (TNF)-a. Such co-ordination' is best achieved in the granulomatous lesion. Frequently, if not always, full eradication of the pathogen is not achieved and the bacilli remain dormant or latent until the host defenses become impaired, as in HIV co-infected patients. This complex immune response is disrupted early in the evolution of HIV infection, which may explain why pulmonary tuberculosis is the first and most common AIDS-defining event in endemic areas. In addition, pulmonary tuberculosis develops in patients who have only mild immunosuppression in contrast to other opportunistic infections (Fig. 129.4).

The histologic patterns of tuberculosis reflect the degree of integrity of the cellular immune response of the patient. Different patterns have been identified and correlate well with the stage of HIV infection. Patients who have relatively intact cellular immunity develop a typical granulomatous response. Epithelioid macrophages and Langhans giant cells are abundant and numbers of acid-fast bacilli (AFB) are low. Patients who have moderate and advanced immunosuppression show a decrease in epithelioid macrophages, Langhans giant cells and $CD4^+$ T cells, which results in poor intracellular killing of mycobacteria. The granulomatous response is absent and there is a large number of AFB surrounded by tissue necrosis. [8]

Mycobacterium avium complex is acquired through inhalation or ingestion and adheres to specific receptors on the epithelial cells that allow the colonization and

invasion of the mucosa. It gains entry to macrophages by opsonic or complement-mediated pathways. Once into the phagosome, MAC inhibits lysosome fusion, allowing their intracellular survival and replication, enhanced by co-infection with HIV.

The immune response against MAC is mediated by $CD4^+$ lymphocytes, cytotoxic lymphocyte responses and local fluxes of the growth-enhancing (i.e. interleukin (IL)-6) and growth-inhibiting cytokines (i.e. INF-?, TNF-a, IL-12). The importance of $CD4^+$ cells is shown by the fact that the increase in $CD4^+$ T cells evoked by HAART considerably reduces the risk of disseminated MAC disease.

Figure 129-4 $CD4^+$ count and opportunistic infection. Figure 129-5 Influence of HIV infection on tuberculosis epidemiology and strategies against spread. HIV^+ , HIV-infected patients; ICH, immunocompetent host; PPD, purified protein derivative; SP, smear-positive.

PREVENTION

The influence of HIV infection in the spread of tuberculosis is shown by the fact that HIV-infected patients who have latent tuberculosis (detected by a positive tuberculin skin test in immunocompetent hosts) have a substantially higher risk of developing active tuberculosis than those who are HIV-negative. Approximately 30–50% of people exposed to *M. tuberculosis* become infected. Immunocompetent people have an effective immune response that allows the successful containment of the infection and only have a 5–10% lifetime risk of developing active tuberculosis later. Conversely, 8% per year of HIV-positive intravenous drug abusers in a methadone program who had a positive tuberculin skin test developed active tuberculosis.[9] Another study demonstrated that 30% of HIV-positive patients who had a positive skin test followed up during 1 year and who did not receive prophylaxis developed active tuberculosis. [10] Therefore, in the HIV era it is very important to promote strategies to prevent the spread of tuberculosis such as investigation of the close contacts of tuberculosis patients, identification and treatment of latent tuberculosis infection, and early diagnosis and adequate therapy of active tuberculosis, including directly observed therapy when necessary (Fig. 129.5).

Vaccination with BCG has demonstrated a high protection rate against serious forms of tuberculosis in children (tuberculous meningitis and disseminated tuberculosis) but its protective efficacy against pulmonary tuberculosis shows enormous variability, ranging from 0% to over 75%. This wide range of protective efficacy is not well understood and, in countries with a low tuberculosis incidence, vaccination is not recommended so as to preserve the tuberculin skin test as a useful tool to diagnose latent tuberculosis infection.

Identification and treatment of latent tuberculosis infection

As $CD4^+$ lymphocyte count decreases, the percentage of patients who have latent infection whose tuberculin skin test is positive decreases. [11] Therefore, screening for latent tuberculosis should be performed as soon as HIV infection is diagnosed. HIV-infected patients who have had contact with persons who have contagious tuberculosis have a higher risk of being infected and of developing active disease; therefore, they must be evaluated for tuberculosis as soon as possible after exposure. For this reason, it is necessary to establish tuberculosis screening initiatives in settings where the prevalence of HIV infection and tuberculosis is high (prisons, drug abuse treatment programs, syringe exchange programs, residences for AIDS patients and homeless shelters). Because of the complexity of problems associated with active tuberculosis in HIV-infected patients, and as a part of the efforts to control and eliminate tuberculosis, all HIV-infected persons identified as latently infected with *M. tuberculosis* should complete a full recommended course of preventive therapy. In certain outpatient and institutional settings, directly observed preventive therapy should be implemented.

The tuberculin skin test with 5TU of purified protein derivative is used to diagnose latent tuberculosis infection. A reaction size of 5mm or more of induration is considered positive in HIV-infected patients. Persons who have less than 5mm but who have a history of exposure to tuberculosis should also be considered to be infected with *M. tuberculosis*. Unfortunately, false-negative tuberculin skin

test (anergy) is common in HIV-infected patients but there is no other test to identify latent tuberculosis infection. In anergic patients a course of preventive therapy with isoniazid does not reduce the incidence of tuberculosis, therefore it is not recommended. However, these patients should be tested with PPD after responding to HAART.[12]

Before starting preventive chemotherapy it is necessary to rule out active tuberculosis via medical history (fever, night sweats, cough, weigh loss or anorexia) and chest radiograph. Those patients who have clinical and/or radiologic abnormalities must collect three consecutive sputum samples for smear and culture to rule out active tuberculosis.

The therapy of choice for latent tuberculosis infection in HIV-infected patients is 9 months of daily isoniazid. It is possible to administer a 9-month regimen of isoniazid twice a week but direct observed therapy is always recommended. Recently it has been reported that 2 months of daily rifampin (rifampicin)—pyrazinamide in a cohort of HIV-infected patients is similar in safety and efficacy to a daily 12-month regimen of isoniazid.[13] However, the Centers for Disease Control and Prevention (CDC) have reported 21 non-HIV patients who developed fatal and severe liver injuries associated with a rifampin-pyrazinamide regimen for a latent tuberculosis infection and they recommend caution, especially in patients concurrently taking other medications associated with liver injury or/and alcoholism. Rifampin-pyrazinamide is not recommended for persons who have underlying liver disease or for those who have had isoniazid-associated liver injury. Therefore, close monitoring of patients receiving a rifampin-pyrazinamide regimen is necessary. Major indications are those patients likely to be infected with an isoniazid-resistant strain of tuberculosis and those who are under control only for brief periods of time (e.g. prisoners serving 2–4 months).

For patients who have pyrazinamide intolerance, a 4- to 6-month regimen of rifampin alone is recommended, although information on its effectiveness is still scarce. In addition, rifampin is contraindicated in HIV-infected patients on protease-inhibitor-containing regimens, except ritonavir, and taking non-nucleoside reverse transcriptase inhibitors, except efavirenz. Rifabutin can be used as an alternative for patients treated with indinavir, nelfinavir, amprenavir and nevirapine, adjusting the doses as described below (see Management).

Preventive treatment for patients who are likely to be infected with isoniazid-rifampin-resistant strains include the use of a combination of at least two antituberculous drugs (e.g. ethambutol, pyrazinamide or levofloxacin). The clinician should always review the drug susceptibility pattern of the *M. tuberculosis* strain isolated from the infecting source before choosing a preventive therapy regimen.

Mycobacterium avium complex prophylaxis

Prophylaxis for MAC is now recommended for all AIDS patients who have $CD4^+$ lymphocyte counts lower than 50 cells/mm^3 . This recommendation is based on the high incidence of MAC bacteremia in this population, the morbidity and mortality associated with disseminated MAC and the efficacy of the available prophylactic agents. In randomized, placebo-controlled trials, 6% of patients receiving clarithromycin 500mg/day developed MAC infection versus 16% of those assigned to receive placebo,[14] representing an estimated 69% reduction in risk for disseminated infection with MAC. In a similar study design using 1200mg of azithromycin once a week,

MAC bacteremia was reduced by 66%. Both regimens have proved to be superior to rifabutin for MAC prophylaxis. [15] It is of note that macrolide resistance has been identified in 29–58% of patients failing clarithromycin prophylaxis and in 16% on an azithromycin regimen. Not even one case of

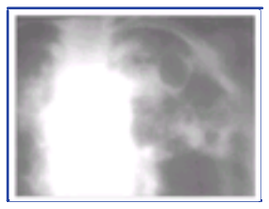

Figure 129-6 Characteristic upper lobe cavity on chest radiograph in an HIV patient who has tuberculosis.

macrolide resistance was reported during rifabutin prophylaxis. Before starting prophylaxis, MAC bacteremia and active tuberculosis should be ruled out.

Discontinuation of MAC prophylaxis is a reasonable option for patients who have a $CD4^+$ T lymphocyte count above 100 cells/mm^3 and low viral load for a sustained period of time[16] (e.g. more than 3–6 months).

CLINICAL FEATURES

Pulmonary manifestations of mycobacterial infections

Pulmonary tuberculosis is often the AIDS-defining event. The most common clinical symptoms are fever, weigh loss, anorexia, asthenia and non-specific cough. The diagnosis may be difficult because of atypical clinical and radiographic findings, especially in those patients who have a low $CD4^+$ lymphocyte count. Upper lobe disease and cavitation (Fig. 129.6) are associated with a high $CD4^+$ lymphocyte count, while miliary patterns and mediastinal and hilar adenopathy are associated with lower $CD4^+$ lymphocyte counts. Presence of adenopathies, pleural effusion and/or cavitation are useful to differentiate tuberculosis from *Pneumocystis carinii* pneumonia. In addition, a normal chest radiograph or diffuse infiltrates mimicking *P. carinii* pneumonia may occur. Acid-fast micro-organisms are found in the sputum smear in 40–67% of patients who have HIV-associated tuberculosis and sputum culture is usually positive in 74–95% of cases. The likelihood that a sputum sample will be smear-positive for AFB decreases with a decreasing $CD4^+$ lymphocyte count and when the chest radiograph is normal.

Pulmonary disease associated with MAC is rare and criteria for diagnosis are not well established. Patients should have a repeatedly positive culture in sputum, an infiltrate on chest radiograph, absence of other lung pathogens and preferably biopsy specimens showing AFB in abnormal lung tissue.

The most frequent nontuberculous mycobacterium isolated from sputum in HIV-infected patients is *Mycobacterium kansasii*. Patients who have *M. kansasii* infection tend to have a low $CD4^+$ lymphocyte count (less than 50 cells/mm^3) and the clinical and radiologic manifestations are not different from tuberculosis. The isolation of *M. kansasii* from sputum is always considered diagnostic of pulmonary disease, since colonization is uncommon.

Figure 129-7 Laterocervical adenopathy in a HIV-infected patient. The needle aspiration demonstrated abundant AFB.

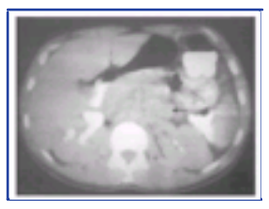

Figure 129-8 Abdominal CT scan of an HIV-infected patient who has tuberculosis. Multiple retroperitoneal lymph nodes (arrow) are typical findings.

Extrapulmonary manifestations of mycobacterial diseases

As the level of immunosuppression increases in HIV-infected patients, tuberculosis involving pulmonary and extrapulmonary locations and mycobacteremia become progressively more frequent. The disseminated disease, defined as having more than one focus or progressive hematogenous disease, has been reported in 38% of cases.[17] These forms show a rapidly and progressive evolution with diffuse pulmonary infiltrates, acute respiratory failure and high mortality rate.

Lymphadenitis is the most common extrapulmonary location (Fig. 129.7). This form is generally multifocal, also invading mediastinal and mesenteric lymph nodes, associated with general major systemic symptoms such as fever or weight loss. Low-density areas in the nodes visualized in computerized tomography (CT) are very characteristic (Fig. 129.8) and the material removed by fine-needle aspiration is usually positive on acid-fast stain (AFS).

Figure 129-9 Chest radiograph of HIV-infected patient who has miliary tuberculosis.

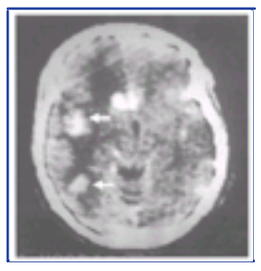

Figure 129-10 Multiple cerebral cortical densities (tuberculomas, arrows) on CT scan of a patient who has tuberculosis of the central nervous system.

Miliary tuberculosis in AIDS can be detected in 10% of pulmonary tuberculosis and in 38% of extrapulmonary tuberculosis cases (Fig. 129.9). The presence of major constitutional symptoms is characteristic. Only 10% of cases have a positive tuberculin skin test and the sputum smear is positive in only 25%, but cultures of other tissues may be positive (e.g. bone marrow, liver or peripheral blood).

The clinical picture of central nervous system tuberculosis is not altered by HIV infection, except for a higher frequency of nodular lesions (tuberculomas), which appear on CT as avascular masses with surrounding edema (Fig. 129.10). Medical therapy without surgery is the preferred approach. Other locations of tuberculosis (pleural, skeletal, genitourinary or gastrointestinal) have a similar clinical presentation to that in immunocompetent patients.

Disseminated MAC disease is characterized by fever, night sweats and weight loss. The gastrointestinal tract is frequently involved and clinical manifestations are nausea, vomiting, watery diarrhea and abdominal pain, which can be severe. At physical examination hepatomegaly, splenomegaly and lymphadenopathy are very common, and elevations of serum alkaline phosphatase, lactate dehydrogenase and anemia are the most frequent laboratory findings. Worsening anemia and an elevated alkaline phosphatase out of proportion to hepatic transaminase elevation should increase suspicion of disseminated MAC. Other unusual manifestations of MAC disease in AIDS patients include cutaneous disease, arthritis, sinusitis, orchitis, peritonitis, chylous ascites, appendicitis, endophthalmitis, choroiditis, pancreatitis, pericarditis and meningitis.[18] Other nontuberculous mycobacterias, including *Mycobacterium genavense, M. intracellulare, M. haemophilum, M. simiae, M. xenopi, M. scrofulaceum, M. marinum* and *M. fortuitum*, have also been described as a cause of disseminated infection in HIV-infected patients.

Paradoxic reactions

Paradoxic reactions during antimycobacterial therapy have been described in up to 36% of patients who began HAART early during antimycobacterial treatment.[19] In contrast, only 7% of patients who received antimycobacterial therapy but not antiretroviral therapy had paradoxic reactions. These reactions appear after clinical improvement and are characterized by fever, worsening chest infiltrates on radiograph and peripheral, mediastinal or abdominal regrowth of lymphadenopathy. However, these manifestations are not associated with changes in *M. tuberculosis* bacteriology (e.g. no change from negative to positive culture and smear) and patients generally feel well and have no signs of toxicity. These reactions are accompanied by a substantial reduction in the HIV burden and a marked increase in reactivity on tuberculin skin testing, which suggest that they are caused by inflammation from a stronger immune response to *M. tuberculosis* or MAC after antiretroviral therapy. In general, paradoxic reactions are self-limited in 10–40 days; however, some reactions are severe and may require a short course of treatment with corticosteroids.

DIAGNOSIS

The physician should always keep in mind the possibility of mycobacterial infection in HIV-positive patients and most especially in those AIDS patients who have fever of unknown origin, any kind of infiltrates on chest radiograph, multifocal lymphadenopathies and subacute lymphocytic meningitis.

The tuberculin skin test has a high proportion of false negatives in patients who have fewer than 400 cells/mm^3 $CD4^+$ lymphocytes/l. Therefore, a rapid diagnosis of tuberculosis in AIDS patients is based on AFS of sputum (instead of normal chest radiograph), urine, bone marrow, lymph node and other samples (e.g. ascites or cerebrospinal fluid). However, AFS is positive in only 50–75% of cases. In addition, a bronchoscopy in AIDS patients yields a rapid diagnosis (based on smears and histologic features) in only one-third of cases.[20] Therefore, it is necessary to start empiric antimycobacterial therapy in patients who have suspected and/or are at risk of tuberculosis even where AFS is negative until the definitive result of the Löwenstein culture is obtained (which requires from 15 days up to 2 months). New tests for rapid identification of *M. tuberculosis* complex based on polymerase chain reaction (PCR) have sensitivity and specificity higher than 95%. Polymerase chain reaction is not necessary in HIV-infected patients who have a positive AFS in whom the clinical suspicion of tuberculosis is high. However, when the AFS is positive and the suspicion of tuberculosis is intermediate or low, a positive PCR is useful to rule out other nontuberculous mycobacterias such as MAC or *M. kansasii* and it allows the use of therapy against tuberculosis only. Positive PCR when AFS is negative avoids invasive procedures (e.g. fiberoptic bronchoscopy) and allows an early diagnosis of tuberculosis. The PCR is also useful in epidemiologic investigations, especially since one study performed in San Francisco demonstrated that patients who have smear-negative and culture-positive tuberculosis were responsible for about 17% of tuberculosis transmission.[21] Restriction fragment length polymorphism (RFLP) analysis of *M. tuberculosis* isolates allows the identification of specific strains. This test has demonstrated that recent infection appears with a similar frequency to reactivation of infections acquired in the past[22] and that exogenous re-infection occurs after curative treatment, especially in areas with a high incidence of the disease.[23] Analysis using RFLP can also be helpful to determine cross-contamination in the laboratory.

The diagnosis of disseminated disease caused by MAC requires the isolation of the organism from a sterile site. A single blood culture has a high diagnostic yield, which is 90–95% sensitive. Currently there are a variety of culture systems that are useful. Liquid media is superior to conventional culture on Löwenstein-Jensen agar slants. In the Bactec radiometric system, the blood taken from a patient is inoculated into culture media containing radiolabeled substrate that is metabolized in the presence of mycobacteria to carbon dioxide and detected by radiorespirometric methods. A growth signal can usually be detected within 8–14 days. Once sufficient growth is achieved, the diagnosis of MAC can be made in few hours with the use of DNA probes. The diagnosis can also be made by identification of MAC from other sterile sites such as bone marrow, liver or lymph node biopsy.

Although colonization can occur in AIDS patients, the isolation of MAC in respiratory or gastrointestinal tract in those patients who have $CD4^+$ lymphocyte counts below 50 cells/mm^3 represents a high risk for the development of MAC bacteremia.[24] In this case prophylaxis or treatment should be considered.

MANAGEMENT

Treatment of drug-susceptible

Mycobacterium tuberculosis

Isoniazid is the most potent bactericidal drug and kills more than 90% of bacilli within 7 days by acting on the metabolically active ones. It is also quite effective at preventing the emergence of drug resistance. Rifampin and rifabutin are also good bactericidal drugs with a potent sterilizing activity and the ability to prevent drug resistance. Both drugs are active against dividing bacilli and those that remain inactive for long periods of time but have intermittent periods of active metabolism. Pyrazinamide is particularly effective at killing intracellular bacilli inside macrophages in an acid environment. Ethambutol and streptomycin are less potent drugs but are effective at preventing emergence of resistance to rifampin and isoniazid. A fourth drug (such as ethambutol or streptomycin) is necessary when the rate of isoniazid resistance in the community is known to be higher than 4%. These drugs can be withdrawn once test results indicate *M. tuberculosis* susceptibility to isoniazid and rifampin.

There is a debate on how long patients who have HIV disease with tuberculosis should be treated.[25] Current CDC and American Thoracic Society guidelines recommend a 6-month treatment regimen but suggest prolonged therapy (9 months or 4 months after culture conversion) for patients who have a delayed clinical and bacteriologic response to antituberculosis therapy. Therefore, sputum evaluation 2 months after initiation of treatment (induction phase) should be performed among persons infected with HIV.

The standard 6- or 9-month regimens based on rifampin or rifabutin and 9- or 12-month regimen without rifamycins are summarized in

TABLE 129-1 -- Treatment regimens for HIV-related tuberculosis.

TREATMENT REGIMENS FOR HIV-RELATED TUBERCULOSIS				
	Induction phase		**Continuation phase**	
	Drugs	**Interval and duration***	**Drugs**	**Interval and duration***
6–9† months rifamycin-based therapy	Isoniazid, rifampin or rifabutin, pyrazinamide, ethambutol‡	Daily for 2 months, or daily for 2 weeks and then twice a week for 6 weeks	Isoniazid, rifampin or rifabutin	Daily or twice a week for 4–7 months
Rifamycin free therapies				
12-month regimen	Isoniazid, pyrazinamide, ethambutol, streptomycin	Daily for 2 months, or daily for 2 weeks and then 2–3 times a week for 6 weeks	Isoniazid, ethambutol	Daily or 2–3 times a week for 10 months
9-month regimen§	Isoniazid, pyrazinamide, ethambutol, streptomycin	Daily for 2 months, or daily for 2 weeks and then 2–3 times a week for 6 weeks	Isoniazid, pyrazinamide, streptomycin	Daily or 2–3 times a week for 7 months

* All intermittent therapies should be directly observed.
† Duration of therapy should be prolonged for patients who have delayed response to therapy (see text).
‡ Ethambutol should be stopped if *Mycobacterium tuberculosis* is susceptible to isoniazid and rifampin.
§ We do not recommend this regimen, since a prolonged course of streptomycin is related to severe adverse events such as tubular necrosis and renal failure, deafness due to cochlear toxicity and

vertigo due to damage to vestibular organs.

Table 129.1 . The selection of a regimen in HIV-infected patients depends on consideration of a number of factors including:

- the high rate of adverse reactions to antituberculosis drugs;
- the drug interactions between antituberculosis and antiviral drugs; and
- the susceptibility pattern of the strain.

Adverse reactions to many drugs occur at high frequency among persons who have HIV infection. Several studies have compared HIV-infected and HIV-uninfected patients and have shown 20–40% adverse reactions in HIV-infected patients in comparison with 3–5% in persons not infected with HIV.[3] [26] The majority of adverse reactions occurred within the first 2 months after starting therapy. Rifampin adverse reactions are the most frequently observed. Generally, rifampin-free regimens are preferable, although there have been reports of successful desensitization to rifampin in HIV-uninfected persons.[27]

Drug interactions between antituberculosis drugs and antiretrovirals occur as a result of induction and inhibition of metabolic pathways. Rifamycins (rifampin and rifabutin) are potent inducers of isoenzyme CYP3A4 of the cytochrome P450 enzyme system and they lead to a reduction of the area under the curve (AUC) of those drugs metabolized by CYP3A4, such as protease inhibitors and non-nucleoside reverse transcriptase inhibitors[28] (interactions are summarized in Table 129.2). Nucleoside reverse transcriptase inhibitors are not metabolized via CYP3A4, but rifampin decreases the AUC of zidovudine by 30%. The clinical relevance of this change is unclear. Rifabutin does not alter the pharmacokinetics of nucleoside reverse transcriptase inhibitors.

Rifampin has the most potent CYP3A4 enzyme-inducing effect, with a resultant 80% decrease in the AUC of all protease inhibitors, with the exception of ritonavir, which is decreased by 35%. Therefore, the combination of rifampin with protease inhibitors is contraindicated (with the possible exception of ritonavir).

To overcome the problems associated with rifampin, the use of rifabutin has been recommended because of its lower enzyme-inducing effect. Rifabutin decreases the AUCs of indinavir and nelfinavir by 30%, amprenavir by 15% and lopinavir/ritonavir by 0%. When indinavir and rifabutin are co-administered, it is recommended that the dose of indinavir be increased to 1g q8h. Furthermore, protease inhibitors are inhibitors of CYP3A4, which can induce an increase in the plasma levels of rifabutin and thus increase its toxicity (leukopenia, uveitis and arthralgia). Therefore, it is necessary to reduce the doses of rifabutin (standard dose is 300mg q24h) to 150mg q24h when it is co-administered with indinavir, nelfinavir and amprenavir and to 150mg twice or three times weekly when administered with lopinavir/ritonavir (since ritonavir is the most potent inhibitor of CYP3A4). Rifabutin reduces the AUC of saquinavir by approximately 45%; therefore, this combination is contraindicated. Rifampin can be combined with ritonavir (at usual doses); however, the utility of this approach is limited because of the poor tolerability of full-dose ritonavir. It may be possible also to use rifampin with ritonavir 400mg and saquinavir 400mg q12h, although this combination has only been evaluated in a few patients.[29]

As in the case of protease inhibitors, rifampin induces a decrease in the AUCs of nevirapine, delavirdine and efavirenz by 37%, 96% and 25% respectively. Thus, co-administration of rifampin with delavirdine is contraindicated. It may be possible to use rifampin with nevirapine, but clinical experience is scarce. Pharmacokinetic studies have shown that levels of efavirenz at a dose of 800mg q24h plus rifampin are equal to 600mg efavirenz q24h without rifampin.[30] Rifabutin can be used with nevirapine without dosage adjustment. Data on the interaction between rifabutin 300mg and efavirenz 600mg showed no significant effect on the pharmacokinetics of efavirenz but a decrease in the AUC of rifabutin of about 30%. Therefore, it may be necessary to increase the dose of rifabutin to 450–600mg q24h without changing the dosage of efavirenz.

Taking into account this information, the most important priority for physicians managing tuberculosis in the HIV-positive patient is to treat tuberculosis, even more so in smear-positive cases. There are two well defined clinical situations: a patient who is naive to antiretroviral therapy and a patient who is already on therapy. In the former, HAART can be delayed in order to improve adherence to antituberculosis treatment and to avoid toxicity and paradoxic reactions. After 2 months of antituberculosis therapy, the recommendation for antiretroviral therapy should be determined on the basis of clinical factors, $CD4^+$ lymphocyte count, HIV viral load and patient commitment to therapy.

However, it is well known that the use of antiretroviral therapy leads to significant reductions in viral load, AIDS-defining illness and mortality, especially in those patients who have advanced HIV infection ($CD4^+$ <100 cells/mm^3). In such patients, delaying HAART is not warranted and it is recommended that HAART be

TABLE 129-2 -- Drug interactions with rifamycin.

DRUG INTERACTIONS WITH RIFAMYCIN						
Antiviral drug (AVD)	**Rifampin (RIF)**			**Rifabutin (RBT)**		
	RIF's effect on AVD	**AVD's effect on RIF**	**Comments**	**RBT's effect on AVD**	**AVD's effect on RBT**	**Comments**
Saquinavir	80% decrease	No data	Contraindicated	45% decrease	No data	Contraindicated
Ritonavir	35% decrease	Unchanged	No dosage adjustments required; not recommended*	No data	293% increase	Not recommended†
Indinavir	89% decrease	No data	Contraindicated	34% decrease	173% increase	The dose of indinavir should be increased to 1g q8h and RBT should be decreased to 150mg daily
Nelfinavir	82% decrease	No data	Contraindicated	32% decrease	200% increase	No dosage adjustments required; RBT should be decreased to 150mg daily
Amprenavir	81% decrease	Unchanged	Contraindicated	15% decrease	200% increase	The dose of RBT should be decreased to 150mg daily
Lopinavir/ritonavir	75% decrease	No data	Contraindicated	Unchanged	290% increase	Not recommended†
Nevirapine	37–68% decrease	Unchanged	No data	16% decrease	Unchanged	No dosage adjustments required
Delavirdine	96% decrease	Unchanged	Contraindicated	80% decrease	342% increase	Contraindicated
Efavirenz	25% decrease	Unchanged	The dose of efavirenz should be increased to 800mg daily	Unchanged	32% decrease	The dose of RBT should be increased to 450–600mg daily
The effects of rifamycin administration with protease inhibitors or non-nucleoside reverse transcriptase inhibitors on the plasma levels of each drug are expressed as a percentage change in the AUC of the concomitant treatment relative to the level for a single drug treatment.						

* Ritonavir is not well tolerated and could hinder the adherence to antituberculosis treatment.
† The association is possible using 150mg 2–3 times/week, however, it is not recommended due to the high risk of RBT toxicity (uveitis, leukopenia and arthralgia).

started early, at the same time as tuberculosis therapy.[31] The antiretroviral therapy we recommended is the combination of efavirenz plus two nucleoside reverse transcriptase inhibitors or, alternatively, three nucleoside reverse transcriptase inhibitors (including abacavir). Both regimens are simple, well tolerated and allow the use of a rifamycin-based regimen for tuberculosis therapy. The alternative therapy is the use of nelfinavir or indinavir plus two nucleoside reverse transcriptase inhibitors and the substitution of rifampin by rifabutin. Rifampin induction of the CYP3A system can persist for up to 2 weeks. Therefore, rifampin should be substituted by rifabutin for 2 weeks before antiretroviral therapy is initiated, with the required dosage adjustment (Fig. 129.11).

Patients already on treatment with a protease inhibitor regimen (indinavir, nelfinavir, amprenavir or lopinavir/ritonavir) and good $CD4^+$ and viral load response who develop tuberculosis could be treated with a rifabutin-based regimen. If the protease inhibitor is saquinavir, this should be switched to an alternative protease inhibitor. Rifampin therapy is possible if the protease inhibitor is ritonavir. In the case of non-nucleoside reverse transcriptase inhibitor regimens, rifampin or rifabutin could be used with efavirenz and nevirapine with appropriate dosage adjustment, while delavirdine should be changed to efavirenz or nevirapine. In all situations it is also possible to switch therapy to a nucleoside reverse transcriptase inhibitor regimen while tuberculosis treatment is ongoing. Non-rifamycin-containing regimens are only recommended for patients who have serious adverse effects with rifamycins or who are infected with a rifamycin-resistant isolate.

Treatment of drug-resistant tuberculosis

Resistance to isoniazid alone is the most common pattern of drug resistance. If the minimum inhibitory concentration (MIC) for isoniazid is more than 1mg/L, the association of rifampin (or rifabutin), pyrazinamide and ethambutol or streptomycin for the first 2 months followed by rifampin plus ethambutol for 10 months is the regimen recommended. It is possible to include isoniazid, when the MIC for isoniazid is more than 0.1mg/L but less than 1mg/L. Monoresistance to rifampin is more common in HIV-infected patients than in immunocompetent persons.[32] It is associated with nonadherence to therapy, the use of rifabutin as prophylaxis against MAC and the presence of diarrhea. The treatment regimen should consist of an initial 2-month phase of isoniazid, pyrazinamide and ethambutol or streptomycin and a second phase of isoniazid and ethambutol for 10 months. It is possible to reduce the duration of therapy using streptomycin associated with isoniazid and pyrazinamide for 9 months, but the toxicity and route of streptomycin administration makes this regimen less appropriate. For the treatment of multidrug-resistant tuberculosis (resistant to both isoniazid and rifampin), the regimen should include four or five drugs to which the organism is susceptible (aminoglycosides, fluoroquinolones, ethionamide, cycloserine, PAS, thiacetazone or clofazimine) for at least 18–24 months.[33]

Figure 129-11 Management strategies for patients who have HIV infection and tuberculosis. EFV, efavirenz; NRTI, nucleoside reverse transcriptase inhibitor; RBT, rifabutin; RIF, rifampin.

Therapy for *Mycobacterium avium* complex

Treatment regimens should include a macrolide (clarithromycin or azithromycin) plus ethambutol.[34] The addition of rifabutin should be considered, since triple therapy has been associated with a reduction in relapses and in the emergence of resistant strains.[35] Aminoglycosides and quinolones may be useful in macrolide-resistant cases. In the era of HAART, it is important to note that the association of clarithromycin and efavirenz is contraindicated since the AUC of clarithromycin is decreased by about 40%. In addition, ritonavir and lopinavir induce an increase of 100% in the AUC of clarithromycin; therefore, when creatinine clearance is less than 60ml/min, it is necessary to reduce the dose of clarithromycin by 50%.

In general, as with other opportunistic infections, therapy for disseminated MAC is for life. However, in situations where $CD4^+$ T cell counts increase to more than 100×10^6 cells/l after 6–12 months of HAART, patients are at low risk of recurrence of MAC and the treatment can be stopped. Although the number of patients who have been evaluated is small, there is increasing confidence that it is possible to discontinue maintenance therapy[36] in such patients.

Treatment of other nontuberculous mycobacterias

Mycobacterium kansasii is the second most frequent cause of pulmonary and disseminated nontuberculous mycobacterial disease. The treatment consists of a daily regimen of rifampin (or rifabutin), isoniazid and ethambutol for 12–18 months. Therapy of other nontuberculous mycobacterias is briefly described. *Mycobacterium genavense* and *M. haemophilum* are resistant to isoniazid, pyrazinamide and ethambutol. *Mycobacterium genavense* may be treated with a regimen similar to MAC and *M. haemophilum* with a combination of rifampin plus another active antituberculosis drug (ciprofloxacin, doxycycline, clarithromycin or amikacin). *Mycobacterium simiae* and *M. xenopi* are susceptible to isoniazid, rifampin, ethambutol and should be treated for 12 months. *Mycobacterium scrofulaceum* therapy requires surgery and isoniazid plus rifampin for 24 months with amikacin for 2–3 months. *Mycobacterium marinum* is resistant to isoniazid and pyrazinamide. Minocycline or clarithromycin or rifampin plus ethambutol for 3 months are possible therapies. *Mycobacterium fortuitum* therapy consists of amikacin plus cefoxitin plus ciprofloxacin for 1 month followed by quinolone plus clarithromycin for 3–6 months.

Chapter 130 - Neoplastic Disease

Umberto Tirelli
Emanuela Vaccher

INTRODUCTION

Infection with human immunodeficiency virus (HIV) is associated with an increased risk of developing cancers, particularly Kaposi's sarcoma (KS) and non-Hodgkin's lymphoma (NHL). The risk of KS and NHL is increased respectively 1000- and 100-fold among HIV-infected patients compared with the general population. [1] [2]

The widespread use of highly active antiretroviral therapy (HAART) has radically changed the clinical spectrum of HIV infection in industrialized countries since the mid-1990s. Incidence rates of opportunistic infections (OIs), KS, primary central nervous system lymphoma (PCNSL) and recently systemic NHL have significantly decreased in the HAART era.[3] [4] [5] [6] Kaposi's sarcoma, PCNSL, systemic intermediate/high-grade B-cell NHL and invasive cervical cancer have been designated as AIDS-defining illnesses, but other malignancies have been reported to be associated with HIV infection. These include Hodgkin's disease and high-grade anal epithelial lesions.[1] [2] [3] [7] Possible excesses of other types of cancer, such as nonmelanomatous skin cancer, lung and testicular carcinoma and myeloma, need to be confirmed.[1] [2] [3]

This chapter focuses on the epidemiology, pathology, clinical features and treatment of the two most common malignant tumors in HIV-infected patients: KS and NHL.

KAPOSI'S SARCOMA

EPIDEMIOLOGY

The epidemiology of KS among HIV-infected individuals has dramatically changed during the second decade of the AIDS epidemic. Kaposi's sarcoma incidence rates started to decline in the late 1980s and then more remarkably with the introduction of HAART in the mid-1990s.[1] [2] [3] [4] In a meta-analysis of data on 47,936 HIV-seropositive individuals from North America, Europe and Australia, the KS rate ratio for 1997–99 vs 1992–96 was 0.3.[3] The risk of KS among male homosexuals is greater than 100,000-fold that of persons with other HIV risk behaviors.[1]

In 1994, Chang *et al* discovered a new herpes virus, called KS-associated herpes virus or human herpes virus 8 (HHV-8), and subsequent studies showed that this was an essential causative agent for all forms of KS.[8] HHV-8 transmission correlates with a history of sexually transmitted diseases and number of male sexual partners. Co-infection with both HHV-8 and HIV increases the risk of developing KS as much as 10,000-fold as compared with HHV-8 infection alone. The 10-year probability of developing KS after co-infection with both HHV-8 and HIV approaches 50%.[8] [9]

PATHOLOGY AND PATHOGENESIS

Kaposi's sarcoma is an angioproliferative disease characterized by angiogenesis, endothelial spindle cell growth (KS cells), inflammatory cell infiltration and edema. The histological cell of origin of KS spindle cells remains uncertain, but is probably a mesenchymal progenitor cell of either endothelial or monocyte-macrophage lineage.

Kaposi's sarcoma lesions arise from a contest of immune dysregulation characterized by $CD8^+$ T-cell activation and production of Th1 type cytokines (i.e. interferon-?), interleukin (IL)-1ß, IL-6 and tumor necrosis factor-a) and angiogenic factors (i.e. basic fibroblastic growth factor and vascular endothelial growth factor), that induces a generalized activation of endothelial cells leading to adhesion and tissue extravasation of lymphomonocytes, spindle cell formation and angiogenesis. These phenomena are triggered or enhanced by HHV-8 infection that, in turn, is reactivated by the same cytokines. Productively infected circulation cells are recruited into 'activated' tissue sites where HHV-8 finds an optimal environment for establishing a persistent latent infection of KS spindle cells. Although early KS is a reactive process of polyclonal nature that can regress, in time it can progress into a true sarcoma. The progression of KS appears to be due to the deregulated expression of oncogenes and oncosuppressor genes and to the long-lasting expression of the HHV-8 latency genes and is promoted by proliferative and angiogenic effects of the HIV Tat protein.[10]

CLINICAL FEATURES

Kaposi's sarcoma ranges from an indolent to an aggressive disease with significant morbidity and mortality. Typically, the disease presents with disseminated skin lesions, often with lymph node and visceral involvement such as the gastrointestinal (GI) tract and lungs. Skin lesions arise as macular or papular eruptions, which progress to nodular plaques or lesions (Fig. 130.1); any area of the skin may be involved. Nodular KS does not usually cause necrosis of overlying skin and rarely invades underlying bone structure.

Lymphedema, particularly of the face, genitalia and lower extremities, may be out of proportion to the cutaneous disease and may be related not just to lymphatic obstruction, but also to the cytokines involved in the pathogenesis of KS. Lymphadenopathic KS primarily affects peripheral lymph nodes, sometimes causing massive nodal enlargement, and it may be present in the absence of mucocutaneous disease.

Oral cavity KS occurs in approximately 35% of patients and is the initial site of disease in about 15%. Intraoral lesions most commonly affect the palate and gingiva and may interfere with nutrition and speech.

Over 50% of patients with skin disease have GI lesions. Any segment of the GI tract may be involved, although the stomach and duodenum are most commonly affected. Gastrointestinal KS is seldom symptomatic, but may cause bowel malabsorption or obstruction and, rarely, bleeding.

Pulmonary involvement is also quite common and may be life threatening. In approximately 20% of cases it may occur in the absence of skin lesions. The symptoms, including shortness of breath, fever, cough, hemoptysis and chest pain, and radiologic appearance of pulmonary KS are indistinguishable from those of the more

Figure 130-1 Kaposi's sarcoma. There are large confluent hyperpigmented patch-stage lesions with lymphedema.

common opportunistic infections. Radiographic findings vary greatly and can include nodular, interstitial and alveolar infiltrates, pleural effusion, hilar and mediastinal adenopathy, and even an isolated pulmonary nodule. The pleural effusions of KS are typically serosanguinous in nature and are associated with KS lesions on the visceral pleura.

DIAGNOSIS

Although a presumptive diagnosis of KS can often be readily made by a trained observer, a skin biopsy can confirm the diagnosis. It is especially important to biopsy lesions that are less typical of KS because other conditions, such as bacillary angiomatosis, may be confused with KS.

Lesions in the GI tract are often recognized easily on endoscopy; however, because the lesions tend to be submucosal, biopsies may not demonstrate KS.

Bronchoscopy is the procedure of choice for pulmonary KS, but gallium-thallium scanning may also be helpful in evaluating an abnormal radiograph. Kaposi's sarcoma is usually thallium avid and gallium negative, whereas infections are usually gallium avid and thallium negative.

The AIDS Clinical Trial Group (ACTG) classification groups patients according to extent of the tumor, immune status and severity of systemic illness (Table 130.1).[11]

MANAGEMENT

Kaposi's sarcoma is a heterogeneous disease and no specific therapy is curative. Therefore, treatment needs to be individualized, based on the patient's overall clinical and immunological status.

Localized KS cutaneous lesions are treated with radiation therapy, laser therapy, cryotherapy, intralesional injections of antineoplastic drugs and alitretinoin topical gel.[12]

Prolongation of time to treatment failure as well as clinical improvement of KS disease by HAART has been reported in the literature,[12] [13] and there are numerous

anecdotal reports of KS regression while on HAART alone. Anti-KS activity of HAART appears to be linked to immuno-reconstitution and to a lesser extent to suppression of HIV replication. Interestingly, a recent study indicates that protease inhibitors are also potent antiangiogenic molecules in *in vitro* and *in vivo* KS models.[14]

Cytotoxic chemotherapy is indicated for patients who do not respond to HAART and for patients with life-threatening or visceral disease. A wide variety of cytotoxic drugs, including vinca alkaloids (vincristine, vinblastine), bleomycin, doxorubicin individually

TABLE 130-1 -- Staging system for HIV-associated Kaposi's sarcoma.[*] [†]

STAGING SYSTEM FOR HIV ASSOCIATED KAPOSI'S SARCOMA		
	Good risk	**Poor risk**
Tumor	Confined to skin and/or lymph nodes and/or minimal oral disease (confined to palate)	Tumor-associated edema or ulceration; extensive oral Kaposi's sarcoma; gastrointestinal Kaposi's sarcoma; Kaposi's sarcoma in visceral organs
Immune system	$CD4^+$ lymphocytes =200/µl	$CD4^+$ lymphocytes <200/µl
Systemic illness	No history of opportunistic infection or thrush; no systemic 'B' symptoms*; Karnofsky performance status	History of opportunistic infection or thrush; systemic 'B' symptoms; Karnofsky performance status <70%; other HIV-related illness

* Systemic 'B' symptoms are fever, night sweats and/or weight loss >10% of normal body weight.
† *Adapted from reference.*[11]

and in combination, have produced tumor regression in 21–59% of patients, with lower rates for monochemotherapy. Randomized trials showed that liposomal anthracyclines are superior to conventional chemotherapy (BV or ABV regimens) in terms of response rate and toxicity profiles.[15] [16] Paclitaxel is the newest systemic chemotherapeutic agent approved for relapsed KS patients. Response rates range between 59% and 71% and the median duration response (10 months) is the longest of any chemotherapy trial reported thus far.[12]

New treatment modalities including al-transretinoic acid and angiostatic agents are currently under investigation.[12]

Corticosteroid therapy induces the development of KS and worsens pre-existing KS lesions.

PROGNOSIS

Prognostic factors for survival are the immune status of the patients (I) and, to a lesser extent, the initial stage (T) of the neoplasm. Median survival of patients with CD4 count =150/µl and early T stage disease (I_0 and T_0 according to the ACTG) is 35 months, while for patients with CD4 <150/µl (I_1) median survival is comparable for early (T_0) and advanced (T_1) T stage disease, being 13 and 12 months respectively. [12]

NON-HODGKIN'S LYMPHOMA

EPIDEMIOLOGY

The incidence of NHL among HIV-infected patients has decreased significantly since the introduction of HAART and the decline has been most pronounced for PCNSL. Systemic NHL incidence decreased less than KS and later than for the other AIDS-defining illnesses. Consequently, lymphoma has become the most common AIDS-associated cancer among patients receiving HAART. Non-Hodgkin's lymphoma constituted 16% and 8% of all AIDS-related diseased diagnosed in 1998, compared with 4% and 6% in 1994, in Western Europe and the United States, respectively.[1] [2] [3] [4] [5] [6]

Risk factors for HIV-related NHL are older age, degree and duration of immunosuppression, no prior HAART use or insufficient immunologic and virologic response to combined antiretroviral therapy.[7] Moreover, the risk of KS as well as NHL is decreased for people with the CCR5 ?32 polymorphism and NHL risk is increased with the stromal cell-derived factor 1 polymorphism. [1]

TABLE 130-2 -- Pathologic features of HIV lymphoproliferative diseases.

PATHOLOGIC FEATURES OF HIV-LYMPHOPROLIFERATIVE DISEASES	
Non-Hodgkin's lymphomas	
Body cavity-based lymphoma	Primary brain (immunoblastic)
Systemic	
Blastic cell lymphomas	Anaplastic' cell lymphomas
• large noncleaved cell (G-WF)	• anaplastic large-cell (CD30/Ki-I$^+$)
• immunoblastic (H-WF) with or without plasma cell differentiation	
• small noncleaved cell (J-WF) with or without plasma cell differentiation	Others (rare types)
• ?extramedullary plasmacytoma	
• blastic cell with 'intermediate' features	
Hodgkin's lymphoma	
Mixed cellularity	Lymphocyte depletion
Multicentric Castleman's disease	
WF, Working Formulation.	

Non-Hodgkin's lymphoma occurs among all population groups at risk for HIV infection, in all age groups and in different countries, with similar epidemiologic and clinicopathologic features.

HIV-related NHL are broadly divisible into three categories according to their anatomical site of origin: systemic NHL, PCNSL and body cavity-based lymphoma or primary effusion lymphoma (PEL). PELs are uncommon, accounting for approximately 3% or less of HIV-NHL. They exhibit a unique constellation of clinical, pathological and molecular characteristics and thus represent a distinct clinicopathological entity.

PATHOLOGY AND PATHOGENESIS

The pathological classification has been redefined at our institution (Table 130.2). The systemic NHLs are histologically heterogeneous, with 80–90% featuring three Working Formulation categories:

- ¦ large cell lymphoma (G group);
- ¦ large cell immunoblastic lymphoma (LCIBL, H group); and
- ¦ small noncleaved cell lymphoma (J group), the equivalent of Burkitt's-type lymphoma (BL).

Cases showing 'intermediate' histologic features may be detected and, in addition, B-cell CD30$^+$ anaplastic large cell lymphoma (ALCL), a heterogeneous group of high-grade lymphomas at the borderline between Hodgkin's disease and NHL, may be found. In contrast with the heterogeneity of systemic NHL, PCNSLs represent a more uniform group and in the vast majority of the cases share LCIBL histologic features. The PELs, typically growing as lymphomatous effusions, have morphologic and immunophenotypic characteristics similar to those of LCIBL or ALCL.

The pathogenesis of HIV-NHL is a multistep process involving factors provided by the host as well as alterations intrinsic to the tumor clone. The molecular pathways of viral infection and lesions of cancer-related genes associated with HIV-NHL vary substantially in different clinicopathological categories of the disease and highlight the marked degree of biological heterogeneity of these lymphomas.

At present, four major molecular pathways can be identified, each of which is associated with peculiar clinical features and restricted to a given NHL histological type. The first pathway associates with BL and is characterized by relatively mild immunodeficiency of the host and multiple genetic lesions of the tumor, including activation of c-*myc*, disruption of p53 and, less frequently, infection by Epstein-Barr virus (EBV). Typically, EBV-infected BL fail to express

Figure 130-2 Non-Hodgkin's lymphoma. Bulky disease in the gingiva.

the viral transforming antigens latent membrane protein 1 (LMP-1) and Epstein-Barr virus nuclear antigen 2 (EBNA-2). Histogenetic studies have shown that BL derives from germinal center (GC) cells, of which the lymphoma closely mimics the phenotype.

Two distinct pathways associate with diffuse large cell lymphoma (DLCL), a type of NHL frequently characterized by a marked disruption of immunofunction. Whereas the majority of DLCL are EBV positive, only a fraction of cases express the viral antigen LMP-1. Expression of LMP-1 and BCL-6 segregate the two pathways associated with HIV-DLCL. On the other hand, LMP-1 positive HIV-DLCL fail to express the BCL-6 protein and display features consistent with immunoblastic-plasmacytoid differentiation, suggesting a derivation from post-GC cells. However, LMP-1 negative DLCL express BCL-6 and display a large noncleaved cell morphology, suggesting an origin from the GC.

Finally, the fourth pathway associates with PEL. This rare lymphoma type consistently harbors infection by HHV-8 and frequently also by EBV. All other genetic lesions commonly detected among HIV-NHL are consistently negative in HIV-PEL. Histogenetic studies have shown that PEL reflects a post-GC stage or differentiation close

to plasma cells.

The identification of the molecular and histogenetic heterogeneity of HIV-NHL is of potential clinical value, because the molecular and histogenetic features of the tumor have been shown to influence the prognosis of several B-cell disorders of immunocompetent hosts.[17]

CLINICAL FEATURES

One of the distinguishing features of NHL is the widespread extent of disease at initial presentation and the frequency of systemic 'B' symptoms, including fever, night sweats and weight loss of more than 10% of the normal body weight. At the time of diagnosis approximately 75% of patients have advanced disease with frequent involvement of extranodal sites, the most common being the central nervous system (CNS), bone marrow, GI tract and liver. Any site of the body, however, may be affected (Fig. 130.2).

Approximately 20–40% of patients have CNS meningeal infiltration at presentation, whereas 65% have brain infiltration at the time of autopsy examination. Leptomeningeal disease, identified during routine lumbar puncture as part of the initial staging evaluation, remains asymptomatic in approximately 20% of patients. Gastrointestinal tract involvement, sometimes at multiple sites, develops in 10–40% of the cases. Bulky disease can be observed in the anorectal region, particularly in homosexual men.

The PCNSL (i.e. intracranial parenchymal lymphoma limited to the CNS) is a manifestation of very advanced HIV disease. Usually the $CD4^+$ lymphocyte count at diagnosis is less than 50/µl. The lymphoma develops as single or multiple lesions in the deep regions of white matter, in the basal ganglia and in the cerebellum. The clinical presentation of PCNSL is not specific and approximately 50% of patients present with lethargy, confusion and personality change, whereas many others lack lateralizing neurologic signs.

The PEL grows exclusively or mainly within pleural, pericardial or peritoneal cavities as lymphomatous effusions, usually in the absence of a contiguous tumor mass. It usually remains strictly localized to the body cavity of origin and only infrequently spreads to local lymph nodes or distant sites.

In the setting of HIV disease, NHL can be difficult to diagnose because of its variable presentation. It can mask many conditions of both HIV disease itself and its associated opportunistic infections. For instance, systemic 'B' symptoms are frequently associated with both advanced HIV infection and opportunistic infections. These symptoms mandate a careful evaluation to exclude other causes, including the presence of *Mycobacterium avium-intracellulare*, cytomegalovirus or tuberculosis infection.

The PCNSL may be radiographically indistinguishable from cerebral toxoplasmosis or other CNS infections. It has been shown that detection of cerebrospinal fluid (CSF) EBV-DNA by polymerase chain reaction (PCR) in HIV-infected patients is reliably associated with PCNSL. By combining CSF EBV-DNA detection by PCR with ^{201} T1 single photon emission computed tomography, the presence of increased uptake and positive EBV-DNA had 100% sensitivity and 100% negative predictive value. Thus in patients with hyperactive lesions and positive EBV-DNA, brain biopsy may be avoided and patients could promptly undergo definitive therapy.[7]

DIAGNOSIS

A diagnosis of NHL should be made by histologic examination of the tissue obtained by incisional or excisional biopsy. It may be possible, however, to make an adequate diagnosis from needle aspiration cytology and this may be required if the patient's clinical condition is critical or deteriorating rapidly.

MANAGEMENT

Optimal therapy for HIV-NHL has not been defined and whether intensive or conservative chemotherapy regimens are indicated in these patients is still a matter of controversy. In fact, poor bone marrow reserve and underlying HIV immunodeficiency challenge the optimal management of systemic NHL. For PCNSL primary therapy consists of whole-brain radiation with intrathecal chemotherapy.

Therapeutic guidelines that should be considered in the management of systemic NHL are:

- first, as with other aggressive lymphomas, the use of combination chemotherapy is essential; and
- second, chemotherapy regimens must include intrathecal chemotherapy, as either a prophylactic or therapeutic modality.

Initially, intensive chemotherapy regimens have been associated with a significant risk of early death due to OIs, suggesting that less intensive treatment strategies should be explored. The use of a low-dose regimen of methotrexate-leucoverin rescue-bleomycin-doxorubicin-cyclophosphamide-vincristine and dexamethasone (m-BACOD) results in a complete response (CR) rate of 46–56%, but median survival is only 15 months for CR patients and 6.5 months for all patients. No significant differences are observed in response rate, response duration or survival when low-dose m-BACOD is randomly compared with standard-dose m-BACOD, in phase III trials. Only 27% of CR patients receiving low-dose therapy and 24% receiving standard-dose therapy survive more than 1 year.[18]

Studies conducted in the pre-HAART era demonstrated that a subset of patients with HIV-NHL is able to tolerate aggressive chemotherapy and appears to do reasonably well in terms of lymphoma-free survival.[7] The use of a continuous infusion of cyclophosphamide-doxorubicin and etoposide (CDE) plus didanosine results in a CR rate of 53% and a median survival of 18 months. However,

TABLE 130-3 -- HIV-associated non-Hodgkin's lymphoma.*

HIV-ASSOCIATED NON-HODGKIN'S LYMPHOMA	
Unfavorable prognostic factors for survival	
Major	$CD4^+$ lymphocyte count <100/µl*
	Previous AIDS diagnosis
	Low performance status
Minor	Bone marrow involvement
	Extranodal disease
	No response to therapy
	'B' symptoms
	Immunoblastic lymphoma
	Age =40 years
	Increased lactate dehydrogenase concentration

* <200/µl in some series.

in the pre-HAART era these encouraging results were associated with a significant and sustained reduction in the CD4 cell count and a twofold increase in the risk of OIs after chemotherapy.[19]

Preliminary studies show that combination therapy with cyclophosphamide-doxorubicin-vincristine and prednisone chemotherapy (CHOP) and HAART is feasible in HIV-NHL patients.[20] [21] Overall response rate as well as duration response and survival may be favorably affected by the use of HAART along with chemotherapy and future trials should be designed to address this issue.

In conclusion, our recommendations are to give standard-dose chemotherapy regimens (like CHOP or CDE) to low- or good-risk category patients and conservative chemotherapy regimens (i.e. single drug or low-dose CHOP-like regimens) to high- or poor-risk patients.

PROGNOSIS

NHL is significantly associated with a worse prognosis than many other complications of AIDS. Nevertheless, some prognostic factors for survival have been identified (Table 130.3). The classic prognostic criteria of the general population (i.e. age, performance status, stage, extranodal involvement) have to be supplemented by host prognostic criteria in the HIV setting, namely low $CD4^+$ lymphocyte count (<100/µl) and a previous AIDS diagnosis, both of which reflect the underlying immunodeficiency. Patients with a low $CD4^+$ lymphocyte count and a previous AIDS diagnosis have a median survival of 3 months, whereas patients without these adverse prognostic features have a median survival of 12 months.[7]

There is some evidence from single institution cohorts that median survival of HIV-NHL patients is improving and is at least three times longer in the HAART than in the pre-HAART era.[5] [6]

HUMAN PAPILLOMAVIRUS AS CAUSATIVE AGENT FOR CERVICAL/ANAL CANCER

An association between HIV infection and human papillomavirus (HPV)-related anogenital neoplasia has recently been recognized. The overall risk of all HPV-associated cancers and their in situ precursor lesions in both women and men is elevated across all HIV exposure risk categories.[1] [2] Risk factors include multiple sexual partners, cigarette smoking and sexually transmitted disease, particularly HPV.

Viral sequences are found in more than 99% of cervical squamous cell carcinomas and in most anal cancers, with HPV type 16 present in 50% and types 18, 31 and 45 in another 30%. High-grade

intraepithelial neoplasia precursor lesions have similarly high rates of the same HPV types. At the molecular level, HPV-associated oncogenesis appears to result from upregulated expression of viral-encoded transforming proteins, including E6 and E7. These proteins interact with and inactivate the products of host cell tumor suppressor genes, including retinoblastoma and p53. This process results in unregulated progression through the cell cycle, insufficient DNA repair and, eventually, transformation to a malignant phenotype.[22]

HIV appears to accelerate the pathogenesis of anogenital cancers at the molecular level although clinical evidence of disease progression is limited. HIV-infected lymphocytes, monocytes and macrophages can be detected in cervical and anal epithelium, and *in vitro* studies suggest the HIV-encoded Tat protein may enhance the expression of HPV E6 and E7 transforming proteins.[23]

The degree of HIV-related immunosuppression appears to be related to the occurrence and the severity of the anogenital neoplasia.

A direct effect of HAART on HPV infections and associated lesions seems unlikely.[23] Screening programs associated with local therapy of early lesions have dramatically reduced the incidence of cervical cancer among HIV-negative women and may have the potential to reduce anal cancer as well. Preventive and therapeutic approaches, i.e. HPV vaccines, need to be urgently evaluated by prospective studies in HIV-infected patients.

Chapter 131 - HIV-associated Wasting and Nutrition

Nicholas IJ Paton
George Griffin

EPIDEMIOLOGY

Before the advent of highly active antiretroviral therapy (HAART), wasting syndrome (defined as loss of more than 10% of body weight together with fever or diarrhea for more than 30 days) was present in about 10% of patients at the time of AIDS diagnosis[1] and occurred in the majority of patients at some stage before death. Although the introduction of HAART has decreased the incidence of opportunistic infections and associated wasting, wasting still remains a common problem in clinical practice.[2]

PATHOGENESIS AND PATHOLOGY

Basal metabolic rate is generally increased at all stages of HIV infection, particularly during opportunistic infections, but this is offset by reductions in physical activity and total energy requirements are therefore normal or reduced. [3] The key etiologic factor in wasting is therefore a reduction in energy intake. The numerous causes include nausea, taste disturbances, dysphagia, early satiety, depression and dementia. Profound anorexia mediated by cytokine release accompanies acute opportunistic infections and results in rapid weight loss (Fig. 131.1).

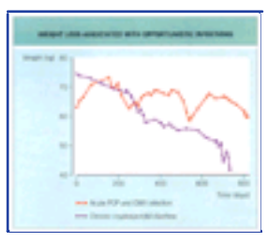

Figure 131-1 Weight loss associated with opportunistic infections. Weight chart of one patient who had episodes of rapid weight loss and partial recovery coinciding with episodes of acute opportunistic infection — *Pneumocystis carinii* pneumonia (PCP) and cytomegalovirus (CMV) — and one patient who had chronic progressive weight loss associated with cryptosporidial diarrhea. Reproduced with permission by the American Journal of Clinical Nutrition © Am L Clin Nutr. American Society for Clinical Nutrition.

Malabsorption is common in AIDS and can be idiopathic (HIV enteropathy) or secondary to gastrointestinal pathogens, especially protozoa. Although malabsorption alone rarely leads to significant weight loss, it may exacerbate the energy intake deficit when combined with other factors. Furthermore, the associated diarrhea may cause a voluntary reduction in food intake in an attempt to minimize symptoms. Chronic gastrointestinal disease often results in a pattern of progressive weight loss (see Fig. 131.1).

HIV infection is accompanied by disturbances in intermediary metabolism, but these are not necessarily of importance in determining the quantity or quality of tissue that is lost. However, hypogonadism is common and may result in preferential lean tissue depletion.

PREVENTION

Patients should be weighed regularly on the same set of scales and the results should be displayed graphically in the medical notes. Assessment at regular intervals by a dietitian is recommended for all patients who have HIV infection. Such reviews should reinforce the need to maintain adequate energy and protein intake to prevent wasting and may correct misconceptions about what constitutes a healthy diet. Regular physical exercise should be encouraged and will assist in maintaining muscle mass.

CLINICAL FEATURES

Clinical assessment of HIV-associated wasting is directed at confirming the diagnosis of malnutrition, estimating severity and also identifying any underlying cause.

Nutritional state can be assessed in several ways. Comparison of body weight with pre-illness weight or ideal weight (determined from standard tables) is the simplest method. A reduction of 10% indicates significant wasting; a loss of over 35% is associated with a grave prognosis. Calculation of body mass index (BMI) can also be used to grade the severity of malnutrition:

$$\text{BMI} = \frac{\text{weight in kg}}{\text{height in m}^2}$$

Severity of malnutrition is graded as follows:

- grade I, <18.5kg/m^2 ;
- grade II, <17kg/m^2 ; and
- grade III, <16kg/m^2 .

Grade III malnutrition is regarded as life-threatening. Measurement of mid-upper-arm circumference or estimation of body cell mass by bioelectrical impedance analysis (BIA) may be more sensitive than body weight or BMI in detecting early malnutrition and provide an additional estimate of severity in advanced wasting. Although single measurements of body weight, BMI, mid-upper-arm circumference and BIA are of some use, serial assessment gives a better indication of nutritional status and the urgency for treatment.

Complications of malnutrition include decubitus ulcers, hypothermia, amenorrhea in women and further propensity to develop

infections. Patients may die from severe wasting alone without other specific complications of HIV disease.[4]

As well as confirming the presence and estimating the severity of wasting, the history and examination should be directed at identifying potential causes. Specific inquiry should be made about anorexia, taste disturbances, dysphagia, odynophagia, nausea, vomiting, abdominal pain, diarrhea and symptoms of depression. Examination may help to distinguish HIV-associated wasting from the lipodystrophy syndrome that occurs as a complication of antiretroviral therapy. Loss of fat from

the face and limbs may initially suggest a diagnosis of HIV-associated wasting, but in the lipodystrophy syndrome muscle mass is preserved and truncal fat mass is usually maintained or increased, so that there is minimal change in overall body weight.

DIAGNOSIS

The purpose of laboratory investigations is to determine the cause of wasting. The choice of tests is influenced by the clinical features but investigations usually include:

- hematology — a full blood count, which may show anemia due to malabsorption;
- biochemistry — low serum albumin accompanies malnutrition and low serum testosterone indicates hypogonadism;
- microbiology — blood should be cultured and at least three stool samples should be assessed;
- virology — serial HIV viral load and $CD4^+$ lymphocyte count estimates may indicate accelerated viral replication;
- radiology — a plain chest radiogram may reveal lymphoma, tuberculosis or subclinical *Pneumocystis carinii* pneumonia, and an abdominal ultrasound may reveal lymphadenopathy (mycobacterial infection or lymphoma), hepatic lesions or abscess; and
- other investigations include an upper gastrointestinal endoscopy with small bowel biopsy or colonoscopy and biopsy.

MANAGEMENT

The aim is to increase lean body mass and so improve quality of life and physical functioning and increase survival. The initial step is to identify and remove any underlying causes for the wasting. Nausea and vomiting should be managed aggressively. Treatment and recovery from acute opportunistic infection is often accompanied by a repletion of body weight (see Fig. 131.1)[5] and lean tissue. Reduction of viral load by effective antiretroviral therapy may sometimes be followed by substantial weight gain, although lean tissue may not be restored fully. For patients who remain malnourished, dietary counseling, nutritional therapies and progressive resistance exercise should be tried in the first instance. Hypogonadal patients should have testosterone replacement. If these steps are unsuccessful, additional pharmacologic therapies may be indicated. Management should be tailored to the individual patient.

NUTRITIONAL THERAPIES AND EXERCISE

High-energy oral nutritional supplements

A valuable increase in total energy intake can be achieved by nutritional supplements, although some patients find them unpalatable or develop 'taste fatigue'.

Nasogastric feeding

Patients who have mechanical difficulties in swallowing or severe anorexia may benefit from feeding through a fine-bore nasogastric tube. This approach has the benefit of allowing nocturnal feeding. Although sometimes well tolerated for short periods of time, a nasogastric tube can be uncomfortable and distressing.

Percutaneous endoscopic gastrotomy tube feeding

Insertion of a percutaneous endoscopic gastrotomy tube is a straightforward procedure performed under local anesthetic. Percutaneous endoscopic gastrotomy feeding can produce dramatic increases in body weight in selected patients who have HIV disease, and serious complications are infrequent. However, pre-existing diarrhea may be exacerbated, and therefore an initial trial of nasogastric feeding is recommended.

Total parenteral nutrition

A controlled trial in malnourished AIDS patients demonstrated that total parenteral nutrition significantly increased body weight and lean tissue when compared with dietary counseling.[6] However, it is a complex and expensive treatment that should only be considered when enteral nutrition has failed. The duration of therapy should be clearly defined at the outset because the decision to stop is often difficult.

Progressive resistance exercise

A supervised training program of progressive resistance exercise can increase lean body mass and may have other health benefits such as increasing high-density lipoprotein (HDL) cholesterol.[7]

PHARMACOLOGIC THERAPIES

Growth hormone

Recombinant human growth hormone at a dose of 0.1mg (0.3 units)/kg q24h increases lean body mass and exercise capacity in patients who have HIV-associated wasting.[8] Although effective, widespread use of growth hormone is limited by its cost. A short course of growth hormone may prevent the loss of lean tissue accompanying opportunistic infection, although further data is needed on this approach and growth hormone should not be used in critically ill HIV patients.[9]

Testosterone

Hypogonadal HIV-positive men may benefit from physiologic testosterone replacement, which can be given by either intramuscular injection (e.g. testosterone enanthate 300mg every 3 weeks)[10] or a cutaneous patch. Supraphysiologic doses of testosterone administered for a few months increase lean body mass in eugonadal men but more safety data is needed before this approach can be advocated for longer term use.[7]

Megestrol acetate

At a dose of 800mg q24h, megestrol increases food intake and body weight in patients who have HIV infection, although the weight gain is predominantly fat.[11] This drug may have a deleterious antianabolic action mediated by decreases in testosterone levels. Although megestrol may be of use for the palliation of anorexia, increases in fat mass alone are unlikely to result in improved survival or physical functioning.

Others

Dronabinol, a synthetic cannabinoid, can stimulate appetite, although sedation and psychotropic symptoms are common. Anabolic steroids that have greater anabolic activity than testosterone are potentially useful in HIV disease, although there is insufficient data from controlled clinical trials to recommend their use and there are concerns over safety (especially in patients who have concomitant hepatic disease). Thalidomide can increase body weight, although drug tolerability (rash and fever) limit its use and treatment is associated with an increase in viral load. [12]

Chapter 132 - Dermatologic Manifestations of HIV Infection

Grace T Kho
Chris Bandel
Clay J Cockerell

INTRODUCTION

The skin is commonly affected in patients who have HIV infection and AIDS. Because it is the organ most readily evaluated by inspection it is essential that the clinicians become proficient in the recognition of skin disorders that herald the presence of HIV disease.[1] The prevalence of cutaneous involvement approaches 100% and in many cases is the motivating force the causes the patient to seek medical care.

To the alert physician, dermatologic manifestations of HIV infection may provide the initial diagnostic clues, not only of the presence of the infection per se but also in some cases the stage of involvement.[2] Early-stage disease (CD4 count 200–500/mm^3) can be associated with seborrheic dermatitis, oral hairy leukoplakia (OHL), Kaposi's Sarcoma (KS), oropharyngeal or recurrent vulvovaginal candidiasis, herpes zoster or recurrent herpes simplex virus (HSV) infection. With a CD4 count of 50–200/mm^3 , bacillary angiomatosis, esophageal candidiasis, disseminated deep fungal infections, molluscum contagiosum, chronic herpetic ulcers and eosinophilic folliculitis become more prominent. With advanced HIV disease (CD4 <50/mm^3), profound immunosuppression may lead to the occurrence of several co-existing infections and neoplasms. In general, skin infections and neoplastic conditions in patients who have AIDS are aggressive and difficult to treat. Early recognition of the different skin diseases will facilitate the use of a pertinent therapeutic approach.

With the introduction of highly active antiretroviral therapy (HAART) in the mid 1990s, changes in the dermatologic manifestations paralleled the stabilization and improvement in CD4 counts.[3] [4] Significant decreases in the incidence of KS, OHL, oral candidiasis, bacterial folliculitis, recurrent HSV and, to a lesser degree, seborrheic dermatitis, psoriasis, drug eruptions, dry skin and pruritus were noted. Conversely, conditions such as warts of all kinds, scabies, photosensitivity and eosinophilic folliculitis did not abate significantly and, in some cases, increased in incidence. Adverse drug reactions improved or worsened with different drugs and individuals. Some entities, such as molluscum contagiosum, became less prevalent in some series and more in others, reflecting varying influences such as immune restoration, altered cytokine patterns and improved lifestyle and increased exposure. As CD4 counts normalize with HAART therapy, many of the skin disorders affecting HIV-infected patients become similar to those seen in immunocompetent patients.

Modifying the influences of HAART therapy is the fact that fewer than 10% of the globally infected individuals have access to the therapy, which remains expensive. Resistant cases are also encountered. Thus, it behoves the clinician to remain knowledgeable about the skin conditions particular to HIV-infected patients. [5]

This chapter describes the most common dermatologic manifestations of HIV infection, including skin changes present early in infection and in advanced disease, such as neoplastic, infectious and noninfectious conditions, hair, nail and oral changes and drug reactions.

EARLY DERMATOLOGIC MANIFESTATIONS OF HIV INFECTION: ACUTE EXANTHEM OF HIV INFECTION

The acute exanthem, which is symptomatic in about 80% of patients, begins 1–5 weeks after exposure to the virus and is associated with prodromal symptoms such as lymphadenopathy, fatigue, fever and night sweats. The skin eruption consists of erythematous, round to oval macules and papules affecting the trunk, chest, back and upper back (Fig. 132.1). The syndrome generally lasts for 4–5 days and resolves with complete recovery. [6] Rarely, a severe form of acute HIV infection can evolve, characterized by recurrent viremia, rapid decline in $CD4^+$ cell numbers and an accelerated disease course. Pneumonitis, esophagitis, meningitis, abdominal pain and melena are the most common systemic manifestations and are often accompanied by urticaria, palatal ulceration, candidiasis and herpesvirus infections. The prognosis for patients who have the severe form of acute HIV infection is poorer than for those who are asymptomatic or have mild symptoms (see Chapter 122).[6]

NON-NEOPLASTIC INFECTIOUS DERMATOLOGIC CONDITIONS

Patients who have HIV infection may present with a broad array of infectious processes, some of which are characteristic of AIDS. Because of immunosuppression these infectious processes may exhibit more aggressive behavior than is usually expected in immunocompetent individuals.

Viral infections

Herpes simplex virus

Infections with HSV types 1 and 2 result in recurrent, severe painful grouped vesicles with an erythematous base localized mainly on the lips, genital and perianal areas. If untreated these lesions may enlarge and become confluent ulcerations that may persist for over 1 month, displaying slow healing and often becoming secondarily infected with bacteria. It is essential to establish the specific diagnosis by means of a biopsy and/or viral cultures. Sometimes, ulceration takes place without well-defined vesicles ever being noted.[7] While the immune system is intact, the course of the disease is similar to that in noninfected individuals. Once immunosuppression sets in, the lesions become persistent. Ulcers can expand and reach large size. Periungual infection is also a manifestation. Culture of tissue can be positive even if a swab is negative. An aggressive therapeutic approach should be used with these patients, as they may be poorly responsive to the standard treatment. Oral aciclovir in doses of up to 400mg five times a day for 10 days should be used. In severe cases hospitalization for administration of high-dose intravenous aciclovir may be required.[8] Foscarnet is recommended in patients in whom aciclovir resistance is suspected (see also Chapter 125).

Figure 132-1 Acute exanthem of HIV infection. There is morbilliform eruption involving the trunk and extremities. The eruption is similar to a morbilliform drug eruption and to other viral exanthemata.

Figure 132-2 Herpes zoster. A painful linear-zosteriform eruption of vesicles on an erythematous base is characteristic of herpes zoster. The eruption may be persistent and

verrucous lesions are not uncommon.

Varicella-zoster virus

The development of recrudescent varicella-zoster virus (VZV) infection in a patient at risk of HIV infection may be a sign of the presence of HIV and should alert the clinician to screen the patient.[9] It usually occurs early in the course of the disease and precedes thrush and hairy leukoplakia by about a year. Varicellazoster virus exists in a dormant state in a dorsal root ganglion that becomes infected during prior varicella infection. With reactivation, the virus progresses downward through the nerve tracts of a solitary dermatome, leading to the characteristic zosteriform distribution of painful tense vesicles of skin (Fig. 132.2). In individuals who have HIV infection, the infection may be recurrent, severe, with more than one dermatome involved, and may run a protracted course associated with residual postherpetic neuralgia and scarring. Disseminated herpes-zoster is not as common but may be more common in HIV-infected individuals. Chronic lesions can be verrucous or ecthymatous. Chickenpox can develop in previously unexposed individuals with HIV infection. The infection can be

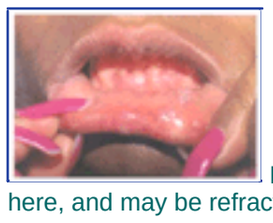

Figure 132-3 Human papillomavirus infection. Human papillomavirus infections are common in HIV-infected patients. They may have unusual features, as demonstrated here, and may be refractory to therapy.

more severe, cause visceral disease and be fatal. Large doses of aciclovir (up to 800mg q4h) are used to treat these patients and often systemic administration is necessary.

Cytomegalovirus

Cytomegalovirus (CMV) is the most common cause of serious opportunistic viral infection in patients who have AIDS.[10] However, cutaneous involvement is rare. In the skin, CMV has different clinical manifestations, including ulcerations, keratotic verrucous lesions and palpable purpuric papules. Because the mucocutaneous lesions caused by CMV do not have specific features, tissue biopsy of the lesions, as well as immunoglobulin titers (IgG and IgM) and viral cultures, are required to define the etiologic cause. The treatment of choice for CMV infection is intravenous ganciclovir. Foscarnet should be used if ganciclovir resistance is suspected.

Epstein-Barr virus

The majority of adults harbor the Epstein-Barr virus (EBV) in the latent phase. With advanced immunodeficiency seen in HIV-infected patients, EBV replication occurs, leading to OHL or EBV-associated large cell lymphoma. Oral hairy leukoplakia manifests as single or multiple white plaques on the lateral margins of the tongue, with a verrucous surface. The presence of oral leukoplakia correlates with moderate to advanced immunodeficiency and has also been correlated with progression from HIV infection to AIDS.[11] Oral hairy leukoplakia responds well to systemically administered aciclovir, although there is prompt recurrence after treatment. Good response to topical application of podophyllin has also been reported.[12] In some patients, OHL may regress with highly active antiviral therapy alone.

Human papillomavirus

Different types of human papillomavirus (HPV) tend to cause different clinical lesions, although there is significant overlap. Infections of the skin and mucous membranes by HPV can cause widespread warts in patients who have AIDS. Types of warts observed include filiform, flat and plantar. Warts can develop in unusual locations, such as on the lips, tongue and oral mucosa (Fig. 132.3). These lesions are often treated with cryotherapy, electrocauterization or topical treatment with caustic agents such as podophyllin. However, the majority of these lesions are resistant to treatment and should be treated repeatedly. In men, HPV affects the penis, urethra, scrotum, perianal, anal and rectal mucosa in the form of condylomata

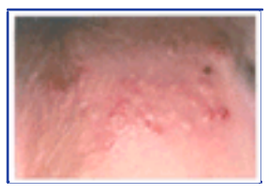

Figure 132-4 Molluscum contagiosum. These lesions are characteristically translucent, waxy papules with central umbilication.

acuminata that are usually recognized as soft sessile lesions with finger-like projections. In women, the spectrum of clinical disease induced by HPV is broad with vulvar, vaginal and cervical condylomata being observed. Other clinical presentations of HPV infection include bowenoid papulosis and epidermodysplasia verruciformis. The former manifests as small, brown, flat-topped papules affecting the perianal and genital areas in both sexes, but is more common in men. The latter consists of a widespread papular eruption of pink-red, flat, wart-like lesions distributed mostly on sun-exposed areas of the skin.[13]

Infection with HPV may cause development of carcinoma, especially in HIV-infected hosts.[14] The most common of these are cervical intraepithelial neoplasia in women and squamous cell carcinoma in men. As with zoster, whenever extensive warts develop in otherwise healthy patients known to be at risk of HIV infection, the patient should be screened for the infection.

Poxvirus

The most common disease caused by poxviruses is molluscum contagiosum, which develops in 10–20% of patients who have AIDS. Molluscum contagiosum is characterized by dome-shaped umbilicated translucent 2–4mm papules that develop in any part of the body but especially the face and genital areas (Fig. 132.4). In AIDS patients these lesions are widespread and may attain immense size.[15] Most patients who have extensive molluscum contagiosum associated with HIV infection have $CD4^+$ counts well below 250 cells/ml. In immunosuppressed patients the diagnosis of molluscum contagiosum should be confirmed by histologic examination in any case that is questionable because this may simulate more serious infections such as cutaneous pneumocystosis, histoplasmosis and *Penicillium marneffei* infection and cryptococcosis. Molluscum contagiosum is treated with cryotherapy, electrodesiccation, curettage or topical application of keratolytic preparations.

Other viral infections

Several viral infections have been reported to develop with increased frequency in patients who have HIV infection. Parvovirus B19, which causes erythema infectiosum, has been reported to produce an exanthem and polyarthralgia in HIV-positive patients. Coxsackie virus and enterovirus may also lead to morbilliform or vesicular eruptions. Measles occur sporadically in nonimmune patients who have AIDS. When associated with encephalitis and pneumonitis, measles can be fatal. Treatment with intravenous ribavirin and gammaglobulin has been used successfully in some patients.

Bacterial infections

Folliculitis

Bacterial folliculitis is common in HIV-infected patients, appearing as widely distributed acneiform papules and pustules. Lesions may be pruritic and become excoriated. Most cases are caused by *Staphylococcus aureus*,[16] but other organisms such as *Staphylococcus epidermidis* and *Pseudomonas aeruginosa* may also cause folliculitis. Bacterial folliculitis in HIV-infected patients is often resistant to standard treatment and prolonged use of systemic antibiotics may be required.[17] Recurrent bacterial folliculitis may serve as a clue to screen a patient for possible HIV infection.

Impetigo, abscesses, cellulitis, lymphadenitis and necrotizing fasciitis

Impetigo, usually caused by *S. aureus*, is seen most commonly on the face, shoulders, axillary and inguinal areas. The infection begins with painful red macules that

become vesicles and pustules and contain purulent fluid; these soon rupture and give rise to the characteristic honey-colored crust. Soft tissue and deep-seated bacterial infections such as cellulitis, abscesses and necrotizing fasciitis may also develop in HIV-infected patients. These manifest as diffuse, red, warm, tender areas in the skin, associated with severe toxemia. Streptococcal axillary lymphadenitis is a diffuse, painful swelling of lymph nodes in the axilla that is usually bilateral. Aggressive antibiotic treatment is recommended for these processes.

Mycobacterial infections

Mycobacteria may produce a wide variety of skin lesions in HIV-infected individuals and infection by these organisms usually signifies severe disseminated systemic infection. Active infection is caused primarily by *Mycobacterium avium-intracellulare* and *M. tuberculosis* and less commonly by *M. kansaii, M. haemophilum, M. genavense, M. marinarum* and *M. leprae*. The infection can manifest as small papules and pustules resembling folliculitis, atopic dermatitis-like eruptions, cutaneous abscesses, lymphadenitis and ulcerations. Culture and tissue biopsy are required for specific diagnosis of the infection. *Mycobacterium haemophilum*, where the only manifestation of infection may be a single or multiple skin lesions, must be cultured at room temperature and with a source of iron in the media.

Bacillary angiomatosis

Bacillary angiomatosis (BA) is a pseudoneoplastic, infectious cutaneous vascular disorder[18] caused by bacteria of the genus *Bartonella*, including *Bartonella quintana* and *Bartonella henselae*.[19] There are a number of clinical manifestations of BA. The earliest and most common lesion appears as discrete pinpoint red-purple papules similar to pyogenic granulomata. These lesions may ulcerate and become crusted (Fig. 132.5). Another variant consists of subcutaneous nodules that may extend into the underlying skeletal muscle and bone. Patients who have BA may have systemic signs and symptoms, including fever, chills, night sweats and weight loss. In advanced cases, the liver and spleen may be involved. Bacillary angiomatosis occurs primarily in the context of the advanced stage of HIV infection, but may occur in patients who have other forms of immunosuppression or in a healthy host. Because the clinical presentation of this infection can easily be confused with pyogenic granuloma, biopsy should be performed. Bacillary angiomatosis responds to treatment with macrolide antibiotics such as erythromycin, clarithromycin and azithromycin or doxycycline. Recurrence is common.

Sexually transmitted disease

The accurate diagnosis of sexually transmitted diseases (STDs) is of exceptional importance in individuals at high risk of HIV infection,

Figure 132-5 Bacillary angiomatosis. There are elevated vascular papules of the glabrous skin. When incised, these lesions bleed profusely.

because their presence increases the risk of transmitting and acquiring HIV infection. Studies have demonstrated that, in some populations, the pattern of HIV acquisition parallels that of STD.[20]

Syphilis

A high prevalence of syphilis, active as well as latent, has been found among AIDS patients in the USA.[20] In HIV-infected patients, the primary infection with *Treponema pallidum* does not show major variations. Secondary syphilis may occur in a number of forms in patients who have HIV infection, ranging from the classic papulosquamous form with involvement of palms, soles and mucous membranes to unusual forms such as verrucous plaques, extensive oral ulcerations, keratoderma, deep cutaneous nodules and widespread gummata. The disease may progress faster from secondary to tertiary syphilis in HIV-seropositive patients than in HIV-seronegative individuals. Early central nervous system (CNS) relapse can also be more common in HIV-infected individuals. Syphilis is a strong indicator that an individual may be infected with HIV and all patients should undergo HIV serotesting. Serologic negativity may not rule out secondary syphilis in HIV-infected individuals as true negative serologic studies can be seen with both the FTA-ab and VDRL tests. Skin biopsies and demonstration of spirochetes may be necessary to establish the diagnosis.

Other sexually transmitted diseases

Although granuloma inguinale is a relatively uncommon STD in the USA and other developed countries, HIV-infected patients may develop this disease. In contrast, this condition is extremely common in Africa. It is caused by the Gram-negative rod *Calymmatobacterium granulomatis* and manifests clinically as vegetating lesions on the penis associated with pseudobuboes in the inguinal crease. Culture and skin biopsy for identification of the safety pin-shaped organisms (Donovan bodies) is required to establish the diagnosis. Lymphogranuloma venereum is uncommon in HIV-infected patients, but it manifests as generalized lymphadenopathy with vulvar or penile edema with ulcerations and erosions. Endemic in Africa, chancroid has become more common in the USA during the past few years. The causative organism is the Gram-negative coccobacillus *Haemophilus ducrei*. The disease manifests clinically as nonhealing ulcers in the genital organs and/or legs.[21]

Fungal infections

Candidiasis

Mucosal candidiasis is a very common finding in immunocompromised patients. Since the beginning of the AIDS epidemic a close

Figure 132-6 Cutaneous histoplasmosis. These lesions are characteristically quite nondescript and may simulate other infectious disorders and verrucous neoplastic conditions.

relationship between candidiasis and AIDS has been recognized.[21] The clinical presentation is that of a whitish exudate present on the tongue or buccal mucosa that can easily be scraped away. Candidiasis may involve the esophagus and can disseminate to produce candidal septicemia, brain abscesses and meningitis. Oral candidiasis may be the initial sign of HIV infection in many individuals and has been shown to be a predictor of progression from HIV infection to AIDS. Intertrigo as well as acute and chronic paronychia simulate those seen in non-HIV-infected individuals (see Chapter 126).

Dermatophytosis

Cutaneous dermatophytosis is common in HIV infection and can be extensive and severe. Usually feet, toenails and fingernails are affected. Tinea corporis may manifest as extensive widespread involvement of the trunk and extremities. In any individual with extensive tinea corporis the possibility of underlying HIV infection should be considered.

Systemic fungal infections

The most common opportunistic fungal infections to affect the skin in HIV-seropositive patients are histoplasmosis and cryptococcosis. These occur in patients with advanced HIV disease. Cutaneous involvement may be seen with disseminated disease. Blastomycosis and sporotrichosis have also been observed in HIV-seropositive patients but rarely. Mucocutaneous lesions associated with systemic fungal infections consist of pustules, ulcers, papules and nodules (Fig. 132.6). Less often, the infection manifests as patches, plaques and mucosal ulcerations. Mucocutaneous fungal infections in general may mimic other disorders such as HSV infection, cellulitis or molluscum contagiosum infection. For this reason, when the clinical diagnosis of possible fungal infection is considered, a tissue biopsy of the

lesion should be performed for histologic evaluation and microbiologic cultures (see also Chapter 126). [22]

Parasitic and ectoparasitic infections

HIV-seropositive individuals may present with a wide variety of parasitic and ectoparasitic infections, including scabies, demodicidosis, acanthamebiasis, leishmaniasis and toxoplasmosis. This group of infections manifest either as localized conditions or disseminated disease. The clinical presentation can be unusual and the use of cultures and skin biopsies is essential to render accurate diagnosis. [23]

Scabies

The causative agent of scabies is the mite *Sarcoptes scabei*. Scabies is one of the most frequent conditions encountered in HIV infection and is the most common ectoparasitic infection.[17] The clinical presentation can vary from discrete scattered pruritic papules and slight scale to a widespread papulosquamous eruption that resembles atopic dermatitis. A common clinical presentation is that of hyperkeratotic plaques present on the palms, soles, trunk and extremities. Patients complain of intense pruritus that is worse at night. Contacts are almost always infected.

Demodicidosis

The causative agent of demodicidosis is the mite *Demodex*. Demodicidosis has been reported only sporadically in patients who have AIDS. The clinical presentation is that of a persistent pruritic follicular eruption of the face, trunk and extremities.

Acanthamebiasis

Acanthamebiasis, caused by *Acanthamoeba castellani*, may be seen in AIDS patients and may have a very aggressive course because of immunosuppression. The clinical presentation is that of painful ulcerated nodules located on the trunk and extremities.

Strongyloidiasis

The helminth *Strongyloides stercoralis* can rarely cause skin disease in HIV patients. Clinically, lesions can manifest as urticaria, figurate erythema and livedo reticularis.[5]

Leishmaniasis

The skin lesions resemble those of kala-azar with scaly lichenified depigmented plaques with lichen simplex chronicus. Nonulcerated nodules on the extensor surfaces of the limbs overlying the joints have also been described. Given the prevalence of HIV infection in the Americas, the incidence of leishmaniasis in these patients is surprisingly low.

Pneumocystosis

Pneumocystis carinii may involve the skin, primarily in patients who use aerosolized pentamidine for prophylaxis of *P. carinii* pneumonia. Most common are friable reddish papules or nodules in the ear canal or nares. Small translucent molluscum contagiosum-like papules, bluish cellulitic plaques and deeply seated abscesses have also been observed. [5]

NONINFECTIOUS DERMATOSES

The noninfectious dermatoses associated with HIV infection are numerous and may occur in all stages of the disease. Although none of the disorders reported in this group has been linked directly to an infectious agent, these conditions may be in part caused by an abnormal host response to infectious agents. Noninfectious dermatoses in these patients may have atypical clinical presentations, greater severity and may fail to respond to routine treatment.[24] Because these dermatoses often have atypical presentations in these patients, biopsies and cultures are often required for diagnosis.

Acquired xerosis and ichthyosis

HIV-infected individuals commonly complain of increased dryness of skin. Typically, xerosis is most prominent on the anterior lower legs. In the winter it is more severe and may be associated with inflammation. Patients who have advanced AIDS may present with ichthyosis — dry, thick skin with plate-like scales. The severity of the ichthyosis correlates with the degree of wasting.

Seborrheic dermatitis

This is perhaps the best known dermatosis associated with HIV infection and is seen in up to 85% of all these individuals at some point during the course of the illness.[25] The etiology of seborrheic dermatitis is poorly understood but is thought to be multifactorial. Clinically, the disease is characterized by slightly indurated, diffuse or confluent pinkish-red plaques with yellowish greasy scales and crusting in typical locations, including malar and retro-auricular areas, nasolabial folds, eyebrows and scalp (Fig. 132.7). In severe cases, which are also more common in HIV-infected patients, it extends to the chest, neck and other parts of the body. Seborrheic dermatitis in patients who have HIV infection is often resistant to treatment, which should serve as a clue that a patient might be infected. With HAART therapy, the incidence of refractory cases appears to be diminishing, however.

Psoriasis

This develops in 5% of individuals with HIV infection[26] and may have a number of different manifestations. It may resemble the classic form found in immunocompetent hosts, which consists of reddish plaques with superficial gray to silver scales on the extensor surfaces and nail changes of onycholysis, pitting and subungual hyperkeratosis. Guttate psoriasis may also be seen, with or without classic psoriasis vulgaris. Severe forms may be encountered, such as erythroderma. Treatment of psoriasis in these patients may be difficult, although fortunately it is one of the inflammatory conditions that responds well to therapy, especially with systemic retinoids, either isotretinoin or etretinate. Psoriasis may undergo partial remission in response to zidovudine therapy, although recurrences are common. Other treatments that may be beneficial include topical keratolytic agents, systemic methotrexate and phototherapy.

Eosinophilic folliculitis

Eosinophilic folliculitis (EF), also known as eosinophilic pustular folliculitis, is an inflammatory process of the hair follicles, the etiology of which remains undetermined, although mites, Gram-negative bacteria and fungi have all been implicated as causative. The condition is more common in men and has a peak incidence in the third decade of life. Affected patients may develop marked eosinophilia and elevated levels of IgE. Virtually all patients who have EF have $CD4^+$ counts below 200 cells/mm^3 ; thus, it is an important cutaneous

Figure 132-7 Seborrheic dermatitis. Note the characteristic greasy scale and the erythematous plaques involving the face, especially the nasolabial folds and the eyebrows.

Figure 132-8 Eosinophilic folliculitis. There are follicular papules, many of which have been excoriated, involving the upper trunk and the face. Histologically, numerous eosinophils are present within the follicular ostia.

marker of advanced HIV infection.[27] Clinically, patients develop folliculocentric pruritic urticarial papules measuring 1–4mm in diameter on the upper trunk, face, neck and proximal extremities (Fig. 132.8). There may be coalescence of papules to form plaques and virtually all cases are associated with lichenification secondary to chronic rubbing and scratching. Therapy of EF includes exposure to ultraviolet B and natural sunlight, oral metronidazole, erythromycin and isotretinoin.

Papular dermatitis of AIDS

This is a non-specific chronic papular eruption that has been reported in HIV-seropositive patients.[28] The nosology of this condition has been the subject of debate and many experts consider this to represent a form of eosinophilic folliculitis. Clinically, skin-colored papules are present on the head, neck and upper trunk, many of which may be folliculocentric. The diagnosis is made only by exclusion; thus other eruptions with similar clinical presentation should be excluded, including EF, scabies, papular mucinosis, secondary syphilis, viral exanthem and drug eruption.

Prurigo nodularis

Prurigo nodularis refers to thickened, verrucous papules and nodules and is a reaction pattern of the skin that is associated with a number of pruritic conditions. Patients who have itchy skin chronically rub and scratch, resulting in thickening with formation of typical lesions of prurigo nodularis. Although many different disorders may lead to the condition, in many patients the preceding event has long since resolved and the condition is perpetuated by the so-called itch-scratch cycle. Treatment of the disorder is based on correcting the underlying pruritus by the use of systemic and topical agents to lessen itching, such as topical corticosteroids, topical menthol- and phenol-containing lotions, topical antihistamines and systemic antipruritic agents.

Atopic dermatitis

Atopic dermatitis is seen somewhat more commonly in children who have HIV infection, having been reported in up to 20%.[29] Patients who have atopic dermatitis antedating HIV infection experience increased severity and persistence of their disease. The pathogenesis of atopic dermatitis in these patients has been associated with elevated circulating IgE antibodies to HIV and *S. aureus*. The clinical presentation is similar to that in immunocompetent hosts, with erythematous patches and plaques with fine papulovesicles associated with scaling and crusting.

Granuloma annulare

There have been a number of sporadic case reports of granuloma annulare (GA) in HIV-seropositive patients.[30] A unique feature of GA in these patients is a tendency toward widespread distribution and photoexacerbation. The clinical presentation is that of violaceous, firm papules with annular arrangement distributed on the hands, feet, arms, legs and trunk. In some patients, there may be similarity to KS. The reason for the development of GA in these patients remains unknown.

Leukocytoclastic vasculitis

Patients who have HIV disease may develop leukocytoclastic vasculitis. [31] This condition is a manifestation of immune complex-mediated disease. The clinical presentation progresses through several stages, beginning as urticarial papules or small petechiae. In most cases, characteristic palpable purpuric papules develop. Lesions are distributed on the extremities, although any body site can be affected. In HIV-infected individuals, they are more numerous and more florid than in immunocompetent hosts. The treatment of leukocytoclastic vasculitis consists primarily of identifying the underlying cause and correcting the associated abnormalities. Administration of nonsteroidal anti-inflammatory agents may be beneficial, although colchicine, dapsone or systemic corticosteroids may be required in severe cases.

NEOPLASMS

A number of different neoplastic disorders may develop in these patients as well. Lymphoreticular and vascular neoplasms are commonly observed; however, epithelial, mesenchymal and melanocytic neoplasms have been also described. Among the vascular lesions, KS is the most common neoplasm and is also a hallmark of AIDS. The development of malignant neoplasms is of great significance because they are often sources of morbidity and mortality.[14]

Kaposi's sarcoma

Kaposi's sarcoma is a vascular neoplastic disorder that is divided into classic and epidemic forms. The classic form is an uncommon disorder that was first described in 1827 and is seen mainly in elderly men of Mediterranean origin, black equatorial Africans and patients who have lymphoma or with primary or iatrogenically induced immune deficiencies. The epidemic form of KS is associated with AIDS. This was one of the first indicators of the AIDS epidemic when it was noted in approximately 50% of male homosexual patients in San Francisco.[32] The pathogenesis of the epidemic KS has recently been associated with infection by a human herpesvirus type 8 (KS-associated herpesvirus) (see Chapter 215).[33] Today, of all patients who have HIV infection, 15% develop KS during their clinical course. The clinical presentation may be that of single or multiple skin lesions and there may be mucosal, visceral and/or lymphatic involvement, particularly in the gastrointestinal tract and pulmonary parenchyma. Clinically, KS has three stages, including macule or patch, plaque and nodule (Fig. 132.9). Regressions of KS have been seen in patients treated with antiretroviral combinations including protease inhibitors.

Macule or patch

These lesions are faint pink macules or patches oriented along skin cleavage lines. Initially lesions may be innocuous in appearance and are easily overlooked, being mistaken for bruises, purpura or nevi. The correct recognition of the early lesions can be accomplished by performing biopsies for histopathologic examination.

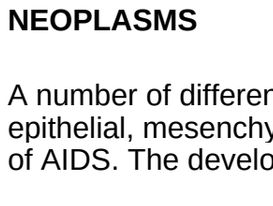

Figure 132-9 Kaposi's sarcoma, plaque stage. There is an erythematous plaque, which is linear in shape, arranged along skin cleavage lines.

Plaque

In time lesions darken and develop into raised firm indurated plaques. The color is purple to brownish because of the presence of abundant blood vessels, extravasated erythrocytes and siderophages. In some cases, lesions may ulcerate.

Nodule

Nodular lesions are dome-shaped, elevated lesions that are usually purple. On palpation they are firm and may be ulcerated. They may simulate bacillary angiomatosis

and pyogenic granulomata.

Treatment

Treatment of uncomplicated KS of the skin is performed for cosmetic purposes. Local destructive measures are generally the most effective. Liquid nitrogen cryotherapy, radiation and intralesional injections of vinblastine sulfate 2–4mg/ml and interferon-a-2b have all been used successfully. Systemic chemotherapy is effective but generally avoided as it further depresses the immune system unless the tumor has disseminated (see also Chapter 130).

Lymphomas and lymphoreticular neoplasms

A number of different lymphoreticular malignancies of both B and T cells may develop in HIV-positive patients. The majority of these are based in the lymph nodes and reticuloendothelial system, although the skin may be involved primarily or secondarily. Most are advanced at the time of diagnosis and are associated with a short medial survival time (see Chapter 130).

Non-Hodgkin's lymphoma with skin manifestations in patients who have AIDS is most commonly of B-lymphocyte origin and mostly high and intermediate grade. Cutaneous T-lymphocyte lymphoma (CTCL), Hodgkin's disease, lymphomatoid granulomatosis and adult T-lymphocyte leukemia/lymphoma also have been reported. The pathogenesis of lymphoreticular neoplasms in these patients is controversial. Chromosomal abnormalities have been encountered and a possible viral etiology has also been suggested.[34] Most cases involve visceral sites and, when the skin is affected, these are usually pink-purple papules or nodules with necrosis. Any site may be involved, including the head, neck, trunk and extremities. Deep-seated soft tissue involvement may expand superficially, forming dome-shaped nodules that often ulcerate. Hodgkin's lymphoma appears similar to non-Hodgkin's lymphoma, either as diffuse nodular lesions or as a panniculitis. CTCL may have the clinical appearance of mycosis fungoides with widespread erythematous scaly lesions distributed usually on the trunk and resembling 'eczema'. Lesions become red- brown ulcerated plaques and tumors during the more advanced stages of the disease.

The diagnosis of lymphoreticular neoplasms should be based on histopathologic examination of tissue biopsies. In many cases the use of gene rearrangement studies, flow cytometry and DNA analysis is necessary to characterize these neoplasms.

Treatment consists of the usual therapy for systemic lymphoma. CTCL may respond to psoralen and ultraviolet A therapy, total body electron beam or topical nitrogen mustard. The prognosis for HIV-positive patients who have lymphoma is poor; survival is in general between 5 and 10 months after diagnosis.

Other cancers

Several reports in the literature have described an increased incidence of intraepithelial and invasive carcinoma of the anus in patients who have AIDS-associated HPV infection. Although there are relatively few case reports, skin cancers may develop more rapidly and behave somewhat more aggressively. Among these malignancies, squamous cell carcinoma and basal cell carcinoma are the most frequently seen. Melanoma has been described, but only a few case reports have been published. There is no information on the incidence of melanomas in HIV patients compared with that in the general population.

Hair and nail changes

A number of abnormalities of hair and nails may be encountered in HIV-positive patients. Chronic inflammatory and noninflammatory alopecia has been observed. Alopecia universalis may also develop and is associated with decreased $CD4^+$ counts.[35] Other hair changes that have been observed include premature graying, thinning and diffuse hair loss. Hypertrichosis has also been associated with HIV infection; however, the cause is unknown. Nail changes, including yellow discoloration, hyperpigmentation, transverse and longitudinal ridging and decreased size or loss of the lunulae, have all been reported. Longitudinal hyperpigmentation is observed in association with treatment with zidovudine.

Oral manifestations

Oral manifestations are common in HIV disease and include novel presentations of previously known opportunistic diseases and some distinctive lesions. [36]

Oral candidiasis usually occurs when the CD4 counts are falling and may be manifest as a pseudomembranous, erythematous, hyperplastic form or as angular cheilitis (see Chapter 126).

Other opportunistic infections such as MAI, histoplasmosis and cryptococcosis may present as palatal masses or ulceration. Herpetic gingivostomatitis is more common in HIV-infected individuals and is painful and slow to heal. Herpes-zoster involving the oral cavity usually shows concurrent skin involvement. Oral HPV lesions are solitary or multiple and can be smooth-surfaced or papillomatous. The HPV types 7, 13 and 32 have been identified in these lesions.

Periodontal disease may occur in clean mouths in HIV-infected patients and present acutely with pain, rapid loss of bone and soft tissue. Response to treatment may be poor and recurrence common. Necrotizing periodontitis and linear gingival erythema are other manifestations.

Recurrent aphthous ulcers are usually idiopathic. They can be as simple as self-limited pinpoint lesions or progressively enlarging destructive lesions. There may be extensive hemorrhage and necrosis. They are frequently recurrent. Pain can be quite severe and esophageal ulceration is well described. Lesions should be cultured

for HSV and a biopsy may be needed to rule out malignancy (e.g. lymphoma) or infection. Smaller ulcers may be treated with a topical corticosteroid preparation. Thalidomide, 200mg/day orally, given for 4 weeks, has been shown to be effective for larger oral and esophageal lesions.[37] It is vital that precautions are taken to avoid exposure to thalidomide during pregnancy.

Oral hairy leukoplakia and intraoral KS may be the first clue to HIV infection. Oral hairy leukoplakia presents unilaterally or bilaterally as a whitish corrugated plaque on the lateral sides of the tongue and is caused by EBV. It is seen in 20% of HIV-infected patients and is a harbinger of progression to AIDS (30% over 3 years). *Candida* is often associated with it. Biopsy shows the characteristic acanthosis, marked parakeratosis and extensive ballooning degeneration of epithelial cells. Intraoral KS may appear alone or be associated with skin or disseminated lesions. It may be flat, raised, solitary or multiple and is red-blue or purple. A biopsy may be required to distinguish it from other vascular or pigmented lesions.

Salivary gland involvement with lymphoepithelial cyst formation can lead to xerostomia and salivary gland enlargement in HIV patients. Labial salivary glands may demonstrate lymphocytic infiltrates similar to Sjögren's syndrome although the infiltrate is composed predominantly of CD8 cells.

Complications of antiretroviral agents

With the advent of more effective antiretroviral agents and the use of HAART therapy, many of the cutaneous manifestations of HIV discussed previously in this chapter occur less frequently. However, a new subset of dermatologic conditions has arisen related to the use of these drugs, namely cutaneous side-effects of antiretroviral agents. Currently there are three classes of medications used for the treatment of HIV: protease inhibitors (PI), nucleoside analogue reverse transcriptase inhibitors (NRTI) and non-nucleoside reverse transcriptase inhibitors (NNRTI).

A wide variety of side-effects occur with the potent antiretroviral therapy. Although each individual drug has its own cutaneous side-effects, therapy has been associated with lipodystrophy (LD). Lipodystrophy consists of the symmetric loss of fat from both the upper and lower extremities as well as the buttocks, causing the muscles and veins to appear more prominent, giving these patients a pseudoathletic appearance. The buccal, parotid and pre-auricular fat pads are also sites of lipoatrophy. Abnormal fat distribution may also be seen in patients with LD. Fat deposits may occur in the abdomen (crix belly), breasts, posterior neck (buffalo hump) and in the supraclavicular area. The concomitant occurrence of peripheral atrophy and abnormal fat deposition has been called the LD syndrome. Striae formation[38] and angiolipomas[39] have been reported in association with the LD syndrome. The simultaneous occurrence of lipoatrophy and fat accumulation is more common than either one occurring alone.[40] These fat abnormalities are often associated with metabolic derangements, including hypertriglyceridemia, hypercholesterolemia, insulin resistance, hyperglycemia and increased C-peptide levels (see also Chapter 139 and Chapter 141). [41] [42] [43]

Incidence of LD has been reported to be from 10% to 80%, but the largest reports put this number around 50%.[44] [45] This number is difficult to establish, in part

because there is no formal definition of LD and it has been measured differently in multiple studies. Signs of LD may begin as early as 2 months but no later than 1 year after initiation of combination therapy. Risk factors for the development of LD include female sex, nonintravenous drug user, increased age and longer duration of exposure to antiretroviral drugs.[46]

Although the LD syndrome has been connected to PI therapy, no known treatment for the LD syndrome exists. Metabolic abnormalities improve somewhat upon cessation of PIs or by switching to a different class of antiretrovirals, but the peripheral atrophy remains although some improvement on switching from thymidine analogues (e.g. stavudine) has been noted.[47] [48] [49]

Specific side-effects are associated with the individual PIs. Fixed drug eruptions have occurred as a result of therapy with saquinavir.[50] Indinavir has been associated with paronychia, most often seen on the great toes. Pyogenic granulomas may also occur in sulci of affected nails. Cessation of indinavir has led to partial or complete reversal of the paronychia over several weeks. Alopecia has also been caused by indinavir, usually on the lower extremities, but hair loss has also been seen in the pubic, axillary and thoracic regions as well as the scalp. Hair regrowth occurs within months of cessation of therapy. Additionally, indinavir has caused cheilitis and dry skin which, along with alopecia and paronychia, are side-effects of retinoid therapy.

Zidovudine, a NRTI, is the oldest drug approved for the treatment of HIV. Two well-known side effects of zidovudine are nail pigmentation and hypertrichosis. Nail pigmentation may occur on several[51] or all nails of the hands and feet.[52] The color of nail pigmentation ranges from yellow-brown to bluish. The discoloration may occur in longitudinal bands or transverse bands or it may affect the entire nail. Transverse bands occur presumably because zidovudine treatment was started and stopped over a short period of time in a patient who would have experienced entire nail pigmentary changes if zidovudine treatment had been prolonged. After cessation of zidovudine therapy, nail growth resumes normal coloration. Nail pigmentation may occur as a result of zidovudine stimulation or toxicity of the melanocytes in the nail matrix.

Hypertrichosis may also be seen with zidovudine. One patient who experienced nail discoloration also noticed increased length of hair on his dorsal forearm and darkening of his public hair.[53] HIV-induced alopecia has resolved in a female treated with zidovudine, then recurred upon cessation of therapy, and later resolved again when zidovudine was restarted.[54] Another patient complained of increased length of eyelashes after beginning treatment with zidovudine; this was the only place on the body affected.[55] A few other rare side-effects have been attributed to zidovudine therapy. An infant born to an HIV-positive mother who was perinatally exposed to zidovudine developed a severe paronychia secondary to *E. coli* and *C. albicans*.[56] The paronychia resolved after treatment with antifungal and antiseptic agents. Torres et al.[57] reported two patients who suffered from leukocytoclastic vasculitis thought to be caused by zidovudine. In both patients, the vasculitis started soon after initiation of zidovudine and resolved with withdrawal of the drug and then recurred when the patients were rechallenged with the drug. Increased sensitivity to mosquito bites has also been linked to zidovudine treatment. Within 3 months of starting zidovudine, three patients reported that following mosquito bites they experienced a heightened reaction to the bites, including immediate pruritic wheals that later developed into indurated areas and subcutaneous nodules lasting from 1 to 4 weeks. None of these patients had ever experienced this type of reaction to a mosquito bite before starting zidovudine therapy.[58]

Dideoxyinosine (DDI), a NRTI, has been reported to cause unusual side-effects in some HIV patients. One case of Ofuji papuloerythroderma, a disease in which the eruption of many confluent erythematous papules causes the appearance of erythroderma, has been reported in association with DDI use.[59] A small vessel vasculitis has been seen with DDI,[60] as has a morbilliform rash[61] (Fig. 132.10) and even the Stevens-Johnson syndrome.[62] Lamivudine, another NRTI, has also been associated with paronychia, mostly of the great toes, but also occasionally seen in fingernails.[63]

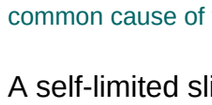

Figure 132-10 Morbilliform drug eruption. There is a diffuse eruption of fine pink macules and papules, which have coalesced, involving the trunk and the extremities. The most common cause of these eruptions is trimethoprim-sulfamethoxazole.

A self-limited slightly pruritic maculopapular eruption has occurred within the first few days of ritonavir (PI) use. The eruption faded within days despite continued use of ritonavir. Hypersensitivity reactions have also been reported with zidovudine and nevirapine. Hypersensitivity with nevirapine is fairly common and may often be prevented by using either a gradually escalating dose or by co-administration of prednisone or an antihistamine during the initial weeks of nevirapine therapy. [64] [65] Despite use of an escalating dose, the Stevens-Johnson reaction has been seen in patients on nevirapine therapy.[66] Abacavir, a NRTI, can cause a severe hypersensitivity reaction which may even be life threatening, especially if treatment is continued despite the reaction or if the patient is rechallenged with abacavir after resolution of the initial reaction.[67]

Acute generalized exanthematous pustulosis was seen in a patient on multiple antiretroviral drug therapy. Although the causative drug cannot be proven with certainty, there was a strong temporal relationship of onset and resolution of the reaction with the use of zidovudine, lamivudine and stavudine.[68]

Chapter 133 - HIV/AIDS-related Problems in Developing Countries

Lisa A Spacek
Thomas C Quinn

INTRODUCTION AND EPIDEMIOLOGY

Since the beginning of the HIV epidemic, approximately 60 million people have been infected.[1] As of December 2001, an estimated 40 million people (37.2 million adults and 2.7 million children) were infected with HIV and 25 million people had died. In 2001 alone, 5 million new HIV infections occurred worldwide. In the developing world, the majority of incident cases occur in young adults. People aged 15–24 years comprise about one-third of those living with HIV/AIDS. In 2001, illnesses associated with HIV/AIDS caused the deaths of approximately 3 million people, including an estimated 580,000 children younger than 15 years. More than 95% of these infections and deaths occurred in developing countries. Accompanying the morbidity and mortality borne by those infected with HIV is the dramatic alteration of the social structure attributable to the HIV epidemic. Because of the premature death of HIV-infected parents, 13 million children have been orphaned. The number of orphaned children is forecast to more than double by 2010.[2]

The contrast between the impact of HIV/AIDS in the developed world and in the developing world is striking. Figure 133.1 illustrates the discrepancy between the annual AIDS deaths in sub-Saharan Africa versus the USA. Whereas AIDS-related mortality is declining in the USA, western Europe and Australia, it is continuing to rise rapidly in sub-Saharan Africa, South East Asia and Latin America.[3] [4] [5] One in 200 adults aged 15–49 years is infected with HIV in the USA and Europe, but 10–40% of pregnant women in some parts of sub-Saharan Africa are infected with HIV. Although antiretroviral therapy is given to pregnant women and their newborn infants in developed countries to prevent transmission, most pregnant women who have HIV infection in developing countries receive little or no antiretroviral therapy, creating an enormous discrepancy in perinatal transmission of HIV in these two regions of the world. In addition, recent surveys have demonstrated that nearly 75% of people with HIV infection are aware of their serostatus in the USA and Europe, whereas 80–90% of infected people in developing countries have never been tested for HIV and remain unaware of their infection.

Since the initial recognition of the AIDS epidemic, much has been done to respond to HIV infection by way of prevention and behavioral modification. Government-supported efforts in Thailand, including HIV and AIDS surveillance systems and programs such as the '100% condom use' campaign for commercial sex, have contributed to decreased rates of HIV and sexually transmitted diseases in military recruits. [6] Similarly, in Cambodia the prevalence of HIV among pregnant women declined by almost a third between 1997 and 2000, to 2.3%. Widespread health education, increased used of condoms and voluntary HIV counseling and testing appear to have lowered the prevalence of HIV infection in some areas of sub-Saharan Africa. In rural Uganda, the most striking decline in HIV prevalence was seen among females aged 20–24. Age-specific prevalence decreased from 20.9% in 1989–90 to 13.8% in 1996–7.

However, in the setting of this mature epidemic, declines in HIV seroprevalence have been seen in the presence of stable and high incidence.[7] Death due to HIV disease, rather than a true decrease in the incidence of HIV infection, appears to have contributed most to the reduced HIV prevalence. Figure 133.2 models the lifetime risk of AIDS death for 15-year-old boys based on current HIV prevalence in adults aged 15–49 years. The upper line, based on current HIV prevalence, is compared with the lower line, which assumes that the risk for new HIV infection at each age decreases by half over the next 15 years. This indicates that, even with successful prevention campaigns, without access to treatment the proportion of young people who will die of AIDS is very high.[8]

Despite ongoing prevention efforts, the overwhelming burden of HIV disease is borne by the developing world. The factors responsible for the discrepancies between the developed and developing world in terms of the diagnosis and care of people with HIV infection and the magnitude of the HIV pandemic are multifactorial. Limited access to care, lack of diagnostic equipment and insufficient money to support either prevention or treatment programs are primarily responsible for the continuing rise in morbidity and mortality associated with HIV infection in developing countries. Underlying high prevalence rates of HIV infection and a combination of high-risk behavior and the widespread prevalence of sexually transmitted diseases act synergistically to propel the epidemic further in many areas of the developing world. Furthermore, the coexistence of other endemic diseases that are widely prevalent in developing countries, such as tuberculosis and gastrointestinal infections, complicate the care of people with HIV infection and pose additional problems for the medical personnel caring for them. This chapter reviews some of these aspects as they relate to the care of people with HIV infection living in developing countries.

CLINICAL FEATURES

The clinical manifestations of HIV infection in developing countries are diverse and reflect the wide variety of other endemic diseases within each region. [9] More than 100 pathogens, including viruses, bacteria, fungi, protozoa, helminths and arthropods, have been identified as having caused opportunistic disease in persons with HIV infection. relatively small number of these pathogens cause a majority of the infections, yet their impact on the health of persons with HIV infection is enormous. Although the reasons for the differences between the spectrum of opportunistic infections observed in developing countries and in developed countries are not completely understood, they are likely to include factors such as the prevalence of pathogens in the environment, social behaviors, ecologic factors that result in exposure to these pathogens, and other undefined factors.

Determining the spectrum of opportunistic infections in a given region requires surveillance systems and diagnostic services that may not be available in many developing countries. For example, opportunistic

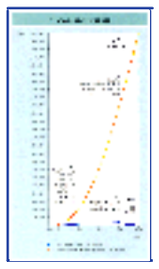

Figure 133-1 Annual AIDS deaths since 1982. Deaths in the USA are contrasted with those in sub-Saharan Africa.

infections that can be diagnosed with reasonable accuracy by physical examination (e.g., oral candidiasis) or by inexpensive laboratory techniques (e.g., Indian ink stain of cerebrospinal fluid for *Cryptococcus neoformans*) may be documented more frequently than opportunistic infections requiring more expensive diagnostic technologies (e.g., *Pneumocystis carinii* pneumonia, disseminated *Mycobacterium avium* complex (MAC) and cytomegalovirus disease). Because most clinical studies that document opportunistic infections are conducted in urban hospitals, those infected outside of urban centers are often not included in disease surveillance efforts. Furthermore, longitudinal cohort studies are costly to maintain in resource-poor settings. Biases in diagnosing and reporting opportunistic infections may be especially important among socially disadvantaged groups with limited access to diagnostic and health care services. Finally, differences in clinical definitions may make comparisons between published reports difficult. For these reasons and for others, much less is known about the frequency of different opportunistic infections in the developing world than in industrialized countries.

Although it is clear that HIV infection has a definite impact on a wide variety of microbial agents in developing countries, less is known about the impact of these diseases on HIV infection. Although it has been shown that HIV disease progresses more rapidly in developing countries, recent studies report similar rates of HIV disease progression when compared with the epidemiology of HIV disease in developed countries prior to the introduction of highly-active antiretroviral therapy (HAART).[10] Data quantifying the median time from seroconversion to AIDS is limited. Early studies suggested that time to AIDS was much shorter in sub-Saharan

Africa and South East Asia. Obstacles included pinpointing the time of seroconversion and reconciling different definitions of AIDS. Similarly, time from seroconversion to AIDS and death has been compared with that seen in the developed world early in the HIV epidemic. In a population-based study in Uganda, the median survival from AIDS to death was 9.3 months but varied according to AIDS-defining illness.[11] Median survival associated with wasting syndrome, Kaposi's sarcoma and esophageal candidiasis was less than 3.5 months, compared with survival longer than 20 months associated with cryptosporidial diarrhea, chronic herpes simplex virus (HSV) infection and extrapulmonary tuberculosis. The median $CD4^+$ lymphocyte count at the time of AIDS onset was 150 cells/mm^3 . Notably, the most common opportunistic infections in resource-poor settings, including tuberculosis and endemic bacterial infections, develop at $CD4^+$ lymphocyte counts higher than 150 cells/mm^3 . Without the benefit of prophylaxis against opportunistic infections and treatment with antiretroviral medications, those infected with HIV will ultimately suffer AIDS-related morbidity and death.

In addition to the clinical spectrum of disease defined by opportunistic infection, co-infection with endemic diseases and resulting immune activation may increase susceptibility to HIV infection. A person whose immune system is activated at the time of exposure to HIV may be more susceptible to infection with HIV. In this regard, the success of an aggressive sexually transmitted disease (STD) treatment program in Tanzania in decreasing the incidence of new HIV infections may be due in part to the removal of immune-activating factors. A similar community-based study conducted in Uganda and designed to evaluate the effect of STD treatment on the development of incident HIV infection found no difference.[12] The lack of a positive effect may be related to the effect of antihelminthic therapy provided to the control group. The eradication of helminths may have had an effect similar to the treatment of STDs. Furthermore, the trial did not treat for genital ulcerative disease due to HSV infection. Future clinical trials will evaluate the effect of treating genital HSV infection on HIV infection and transmission. A recent review outlines the documented associations between chronic immune activation and infections prevalent in the developing world that appear to enhance the pathogenesis of HIV.[13] Thus, both the rate of spread of the HIV epidemic as well as the clinical course in the developing world may be greatly influenced by the underlying state of heightened immune activation that exists in many people in these countries.

Tropical diseases may directly lead to an increased risk of infection with HIV. Treatment of severe anemia induced by malaria has led to HIV infection by transfusion. Female genital schistosomiasis, like other genital inflammatory conditions, may increase the efficiency of HIV transmission. Several drugs used in the treatment and prophylaxis of tropical diseases have an immunosuppressive effect and may thereby influence susceptibility to HIV. Specific interactions between HIV and infectious diseases in developing countries are listed briefly below.

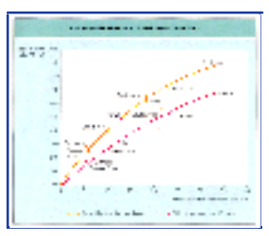

Figure 133-2 Risk of death from AIDS in developing countries. Lifetime risk of AIDS death among 15-year-old boys, assuming unchanged or halved risk of becoming infected with HIV, in selected countries.

Mycobacterial infections

Tuberculosis

Tuberculosis is the most important severe opportunistic infection observed among patients with HIV infection in developing countries because it occurs frequently, is transmissible to both people with HIV infection and uninfected persons, can be readily treated and can be prevented. Globally, tuberculosis is the leading cause of death among people with HIV infection, accounting for a third of deaths due to AIDS. The World Health Organization (WHO) estimates that the number of people infected with the tubercle bacillus is one-third of the world population; throughout the world a new tuberculosis infection occurs every second.[14] The greatest number of tuberculosis infections occur in people living in Asia, sub-Saharan Africa and Latin America, where about half of the adult population is infected. These are the same areas in which HIV continues to increase steadily. The WHO considers HIV as the single most important factor driving the increase in tuberculosis incidence in Africa over the past 10 years.

The increase in tuberculosis attributable to HIV has resulted in increased demand for already overburdened tuberculosis programs. During the initial stages of the HIV epidemic, when incidence rates increased dramatically, tuberculosis rates increased as well. For example, in the early stage of the HIV epidemic in northern Thailand from 1989–90, HIV seroprevalence increased exponentially from 5% to 40% and there was a 5–7% increase in tuberculosis between 1990 and 1992. In developing countries where young adults have high rates of infection with both HIV and tuberculosis, the risk of co-infection is correspondingly high. Worldwide, an estimated 640,000 incident cases of tuberculosis (8%) occur in the setting of HIV infection. Although the largest group of co-infected individuals lives in India, the burden of HIV infection per capita is highest in sub-Saharan Africa, with 32% of tuberculosis cases co-infected with HIV.

Infection with HIV and tuberculosis has become a particular problem in many African countries. A recent review of major causes of HIV-related diseases identified tuberculosis as the most frequently occurring opportunistic infection in hospital and clinic patients in Côte d'Ivoire, South Africa, Kenya and Ethiopia. In the central African countries of Zimbabwe and Malawi, the annual incidence of tuberculosis doubled in the 5 years 1985–90 and 20–44% of AIDS patients developed tuberculosis during the course of their infection. In contrast, only 4% of AIDS patients in the USA have tuberculosis. In a study of tuberculosis treatment in Uganda, a high prevalence (49%) of *Mycobacterium africanum* isolates was identified in patients with HIV infection who had pulmonary tuberculosis. In Uganda, the prevalence of HIV infection among tuberculosis patients was 5.9 times greater than that among patients who had inactive tuberculosis. In Lusaka, Zambia, as many as 37% of hospitalized children who had tuberculosis were infected with HIV, compared with 11% of nontuberculosis controls. Cohort studies have also shown that the risk of developing active tuberculosis among persons infected with *Mycobacterium tuberculosis* is much higher in persons with HIV infection than in HIV-seronegative persons. For someone who is co-infected with HIV and tuberculosis, the annual risk of developing active tuberculosis ranges from 5% to 15%, whereas the lifetime risk among people who have tuberculosis in the absence of HIV infection is only 5–10%.

During the period 1997–9, the estimated number of incident cases of tuberculosis increased from 8.0 million to 8.4 million. If the present trend continues, the WHO estimates an expected 10.2 million new cases by 2005. The progressive increase is largely due to the HIV/AIDS pandemic. In patients dying with HIV disease in Abidjan, Côte d'Ivoire, tuberculosis was present in more than half of those who had AIDS and was responsible for one-third of the deaths. The importance of tuberculosis was demonstrated in an autopsy study among patients dying of pulmonary disease in Abidjan; 40% of the HIV-positive patients died of tuberculosis, compared with only 4% of the HIV-negative patients. In Mexico, disseminated tuberculosis was found at autopsy in 25% of patients who had AIDS; this compares with 6% of patients in the USA and 5% of patients in Italy. This observation is consistent with the higher incidence of pulmonary tuberculosis in Latin America than in the USA, as well as with the

higher incidence of tuberculosis in the USA among foreign-born people and people of Latin American or Asian descent.

A prospective cohort study conducted in South Africa demonstrated that the increased mortality associated with tuberculosis was observed only in patients with a $CD4^+$ lymphocyte count greater than 200 cells/mm^3 and in those without AIDS at baseline.[15] The authors proposed that the immune activation due to tuberculosis increased HIV replication and accelerated HIV disease progression.

Diagnosis, treatment and prophylaxis of tuberculosis is discussed in Chapter 37 . Trials of isoniazid prophylaxis of HIV-positive populations with a positive tuberculin skin test have been conducted in Mexico, Haiti, Kenya, Zambia and Uganda. Meta-analyses of these studies showed a definite reduction in the development of active tuberculosis in the treated group compared with the placebo group during a period of 2–3 years.[16] [17] No significant protection could be demonstrated in the groups with skin test anergy who were included in the same trials. Thus, the benefit of prophylaxis for populations that are already anergic as a result of immunosuppression is more difficult to evaluate because they indicate either no previous exposure to tuberculosis or previous infection with loss of immunologic reactivity. As with many other diseases, the cost of medication needed to carry out effective treatment of tuberculosis is lacking in many developing countries, where the problem is greatest. Furthermore, patient compliance may be a limiting factor in treatment regiments of multiple drugs for periods of several months. Research priorities include the determination of the best method for detection of active tuberculosis in resource-poor settings, and optimum duration of preventive therapy.

In order to prevent active tuberculosis, up to 70% of the world's children are vaccinated with bacillus Calmette-Guérin (BCG). Unfortunately, the efficacy of BCG in HIV-infected populations is unclear. One study found no benefit of vaccination in HIV-seropositive children; another study found a benefit of childhood vaccination in

HIV-seropositive adults and protection from disease caused by *M. tuberculosis*. Recent data suggesting a beneficial effect of early BCG vaccination on mortality from all causes in children not infected with HIV indicate that measures of benefit in HIV-seropositive people need to be broader than mere prevention of tuberculosis. The WHO recommends that BCG should be given to people who have asymptomatic HIV infection in areas with a high risk of tuberculosis infection. In areas where the risk of tuberculosis is minimal, BCG is not recommended, particularly for those who are infected with HIV. Recombinant BCG vector-based vaccines are currently being evaluated in animal models for potential use in vaccination against HIV.

Mycobacterium avium *complex*

Although MAC is very common in advanced HIV infection in the USA and Europe, it has rarely been documented in developing countries. In one study in Uganda, none of 95 blood cultures from severely ill patients who had advanced AIDS were positive for *M. avium*; neither were any of 165 mycobacterial sputum cultures from HIV-seropositive and HIV-seronegative patients at the same hospital. In Côte d'Ivoire, none of 202 blood cultures from HIV-positive adult inpatients were positive from *M. avium*, whereas 4% grew *M. tuberculosis*. Intestinal biopsies from 98 Ugandan, Zairian and Zambian patients who had chronic HIV-related enteropathy yielded histology suggestive of *M. avium* infection in only one case. Similarly, autopsies on 78 HIV-seropositive children in Côte d'Ivoire revealed no evidence of *M. avium* infection. In Kenya and Mexico, *M. avium* has been documented in 6% of patients hospitalized with late-stage HIV disease; in Brazil it has been documented in 18% of 125 hospitalized patients. A recent study conducted in South Africa demonstrated a 10% prevalence of disseminated MAC in 10% of hospitalized patients with a $CD4^+$ lymphocyte count of less than 100 cells/mm^3 .[18]

The reasons for the low frequency of disseminated disease caused by MAC in the developing world are unclear, but there are many possibilities, including less exposure to MAC, exposure to different variants of MAC, differences in host susceptibility, greater acquired immunity to mycobacteria, earlier death from infection with more virulent pathogens, and diagnostic difficulties. There may be greater acquired immunity to mycobacterial disease through BCG vaccine or previous infection with *M. tuberculosis*, but the reported BCG coverage (50%) and purified protein derivative reactivity (82%) in Uganda seem unlikely to explain the lack of any disseminated MAC.

Mycobacterium leprae

To date, there is little evidence that HIV infection has a profound effect on the frequency of *M. leprae* infection (see Chapter 154). Several studies have examined serology for HIV in newly diagnosed leprosy. In one study in Uganda of 189 new cases of leprosy matched for age, sex and district of residence, no significant difference in overall rates of HIV seropositivity was found between the patients who had leprosy (12% HIV seropositive) and the controls (18% HIV seropositive). Interestingly, HIV seropositivity was more frequent among the multibacillary cases than the paucibacillary cases. An association between HIV and leprosy was seen in studies conducted in Zambia and Nigeria. Studies in Kenya and Nigeria both support the hypothesis that HIV infection favors the multibacillary form of leprosy. A different clinical association was noted in Zambian leprosy patients who had active neuritis. The study suggested that HIV-positive patients have poorer recovery of nerve function than controls after treatment with corticosteroids.

Thus, there appears to be no striking evidence that HIV infection has an adverse effect on the course of leprosy. Multibacillary disease could possibly develop under the influence of HIV infection but, because leprosy is chronic and slow in progression, it is difficult to discern the influence of HIV on leprosy directly.

Nonmycobacterial pulmonary infections

Bacterial pneumonia

Investigations of patients with HIV who have pulmonary disease demonstrate that bacterial pneumonia caused by *Streptococcus pneumoniae* and *Haemophilus influenzae* occur as frequently in developing countries as they do in the developed world. In a study in Nairobi, Kenya, 79 episodes of invasive pneumococcal disease were seen in 587 HIV-positive women, whereas there was only one episode in 132 HIV-seronegative women.[19] Serotyping revealed that most recurrent events were related to re-infection. A wide spectrum of HIV-related pneumococcal disease was seen; 56% of cases were pneumonia, 30% were sinusitis and 11% were occult bacteremia. The mean $CD4^+$ lymphocyte count was 302 cells/mm^3 at first presentation and 171 cells/mm^3 for recurrent episodes. In this study *S. pneumoniae* caused more disease at an earlier stage of HIV immunosuppression than did *M. tuberculosis*.

The importance of pneumococcal disease in the host with HIV infection cannot be underestimated. Invasive pneumococcal disease has been shown to cause significant morbidity and mortality. The use of the pneumococcal polysaccharide vaccine to prevent infection in people with HIV infection has been evaluated and generally recommended by the Centers for Disease Control and Prevention. In light of the increased prevalence of antibiotic resistance and ease of administration, this vaccine would appear to be a prudent use of resources. However, studies have shown that the polysaccharide vaccine is not beneficial in individuals with HIV infection in African populations. Conjugate pneumococcal vaccines hold greater promise to reduce the incidence of invasive pneumococcal disease. Evaluations in pediatric population are underway in South Africa and the Gambia.

Pneumocystis carinii *pneumonia*

Several opportunistic infections that are common in developed countries are rarely identified in developing countries. For example, in Abidjan, *P. carinii* pneumonia accounts for only 8% of deaths from HIV-associated pulmonary disease and only 2% of all HIV-associated deaths. A recent report from Zimbabwe demonstrated that even after selecting patients who had abnormal chest radiographs that were consistent with *P. carinii* pneumonia, tuberculosis was still a more frequent diagnosis than *P. carinii* pneumonia.

Although *P. carinii* pneumonia appears to be infrequent in Africa and Asia, it is relatively common in Latin America and Caribbean countries, with rates similar to those documented in the USA. A retrospective case series in a clinic in London, UK, found a significantly higher rate of *P. carinii* pneumonia as a presenting diagnosis in non-Africans (34%) than in Africans (17%). Prevalence rates are also low in Haiti, with a case series incidence of less than 10%. Other reported rates include 7–25% in Thailand, 20–24% in Mexico and 32–45% in Brazil.

The reasons for lower rates of *P. carinii* pneumonia in parts of the developing world are unclear. Possible explanations include less environmental exposure to *P. carinii*, exposure to different strains of *P. carinii*, differences in host susceptibility, earlier deaths in patients in the tropics who have AIDS owing to exposure to more virulent organisms, and diagnostic difficulties. When it does occur, the clinical presentation of *P. carinii* pneumonia in developing countries appears to be similar to that in industrialized countries. Frequent co-infection with tuberculosis may obscure the diagnosis. The diagnosis and treatment of *P. carinii* pneumonia are discussed in Chapter 124 .

Diarrheal disease

In addition to tuberculosis, one of the more common clinical syndromes seen in persons with HIV infection in developing countries is a diarrhea-wasting syndrome frequently referred to as 'slim disease' (Chapter 131). Diarrhea lasting longer than 1 month occurs in up to 50% of patients in Africa who have AIDS, a rate that is more frequent than that observed in persons with HIV infection in industrialized countries. The diarrhea is usually intermittent and not associated with blood or mucus, and it is only rarely secretory in nature. In one-third to two-thirds of patients who have diarrhea in Uganda, Zaire and Zambia, no cause was found despite detailed examinations. In other studies, pathogens (including cryptosporidia, microsporidia, *Shigella* spp., *Salmonella* spp. and *Campylobacter* spp.) have been identified with frequencies of 7–48%.

Other diagnoses are also common among patients who have such profound wasting. In an autopsy study in Côte d'Ivoire, 44% of patients dying with HIV wasting syndrome had disseminated tuberculosis, compared with 25% without the syndrome. A chronic fever syndrome is also frequently associated with tuberculosis and nontyphoid salmonellosis. Often there is very little that can be done for patients who have this syndrome except to provide nutritional support.

Protozoan infections

Toxoplasmosis

Toxoplasma gondii is a common opportunistic infection in both developed and developing countries, and the incidence is proportional to the prevalence of latent infection in the population at risk for HIV. A higher prevalence of cerebral toxoplasmosis has been documented among Latin American patients than in the USA, which is consistent with the higher underlying prevalence of toxoplasmosis in Latin America. Although there is a suggestion that up to 50% of seropositive AIDS patients in

some parts of the world may develop toxoplasmal encephalitis, its frequency in developing countries is unclear because of limited diagnostic capabilities. Autopsy series that have included examination of the brain have suggested disease prevalence rates in late-stage AIDS patients of 15% in Abidjan, 25% in Mexico City and 36% in Kampala. For more detailed information on toxoplasmosis, see Chapter 127 & Chapter 158 .

Visceral leishmaniasis

The overlap of visceral leishmaniasis and AIDS is increasing because of the spread of the AIDS pandemic to rural areas and the spread of visceral leishmaniasis to suburban areas. Consequently, cases of co-infection with *Leishmania* spp. and HIV are becoming more frequent, with important clinical, diagnostic, chemotherapeutic, epidemiologic and economic implications. Co-infection with *Leishmania* spp. and HIV is now considered an 'emerging disease', especially in southern Europe, where 25–75% of adult visceral leishmaniasis cases are related to HIV infection and 1.5–9% of patients who have AIDS suffer from newly acquired or reactivated visceral leishmaniasis. The WHO reviewed 692 retrospective cases that occurred between 1985 and 1996 in southern Europe and eastern Africa.[20] Of the cases of co-infection, 90% were observed in patients with $CD4^+$ lymphocyte counts of less than 200 cells/mm^3 . Bone marrow aspiration was the most frequently used technique for parasitologic diagnosis. In two-thirds of these cases, the diagnosis of HIV was made before that of leishmaniasis.

Multiple visceral locations outside of the reticuloendothelial system are frequent during co-infection; these locations include the blood, skin, gastrointestinal tract, lungs and central nervous system. Because of the high frequency of leishmaniasis in the peripheral blood of these patients, transmission via blood or needles, particularly among injecting drug users, is a major problem.

The *Leishmania* spp. frequently involved in HIV infection are those that cause visceral disease, such as *Leishmania donovani* and *L. infantum* in Asia, southern Europe and Africa, and *L. chagasi* in Latin America. Cutaneous leishmaniasis has a much wider geographic distribution than visceral disease but it is only rarely involved as a complication of HIV infection. Classic visceral leishmaniasis documented in patients with HIV infection is probably caused by reactivation of a latent infection, owing to increasing immunosuppression. In one study, the $CD4^+$ lymphocyte count was less than 200 cells/mm^3 in more than 75% of the patients with HIV infection in whom visceral leishmaniasis was diagnosed, and fewer than 5% of patients had counts of 500 cells/mm^3 or greater.

The clinical presentations of visceral leishmaniasis in HIV are quite similar to that described in HIV-negative patients; clinical features include weight loss, fever, pancytopenia and hepatosplenomegaly. Diagnosis is based on a high index of suspicion in a person who has resided in or traveled to an endemic area, and treatment is similar to that employed in patients without HIV infection who have leishmaniasis (see Chapter 127 and Chapter 172). In Ethiopia, a recent clinical trial evaluated the treatment of visceral leishmaniasis in patients with and without HIV infection. Those co-infected had a greater mortality (33.3% vs 3.6%) and relapse rate (16.7% vs 1.2%). The authors expressed the concern that HIV-positive patients with relapsing visceral leishmaniasis could serve as a reservoir of resistant organisms. Treatment guidelines support the use of two drug combination therapy.

Trypanosomiasis

Trypanosoma cruzi, the cause of Chagas' disease, infects millions of people in Latin America. Reports from Argentina, Brazil and Chile have described clinical and laboratory findings in about two dozen patients co-infected with HIV and *T. cruzi*.[21] These reports suggest that Chagas' disease may result from reactivation of latent *T. cruzi* infection and that clinical manifestations such as meningoencephalitis may be more frequent and more severe in those infected with HIV.

Activation of *T. cruzi* infection by HIV or AIDS usually presents with central nervous system manifestations, but in one review trypanosomes were demonstrated in the blood of five of six cases in whom the examination was done. In one pathologic study of 23 cases, acute myocarditis was frequently noted in those cases that were autopsied, but no information was presented as to whether clinical evidence of myocarditis was present during life.

Malaria

Multiple studies have examined the effect of HIV on the course of malaria, and in general they have found no changes in the severity, incidence or successful treatment of malaria (see Chapter 166). The failure of HIV to affect the course of malaria may be in part due to the complex immune response to malaria, which is not easily perturbed by a predominantly T-cell immunodeficiency. In one study of patients in Burkina Faso, investigators demonstrated a preservation of some components of the malaria-specific immune response in AIDS patients who were co-infected with *Plasmodium falciparum*. Similarly, studies have been unable to demonstrate a significant effect of HIV on malaria or vice versa in children, despite the fact that malarial infection is associated with increased levels of the proinflammatory cytokine tumor necrosis factor a, which would be expected to upregulate HIV replication.

Challenging the apparent lack of a significant interaction are several recent studies conducted in Uganda. A hospital-based case-control study, a rural population-based cohort study and an urban clinic-based cohort study all showed that HIV infection was associated with increased frequency and severity of clinical episodes of malaria parasitemia.[22] [23] [24] The effect increased with declining immunosuppression as indicated by decreasing $CD4^+$ lymphocyte counts. Two recent studies have shown that infant mortality is higher in babies born to mothers who are co-infected with placental malaria and HIV. It was also shown that HIV infection impairs the pregnant woman's ability to control *P. falciparum* infection. Thus, there is an interaction between HIV and malaria at the placenta. In addition, malaria can contribute to the increased spread of HIV, owing to the need for more frequent transfusions to treat the anemia of malaria.

Enteric parasitic infections

Enteric parasitic infections such as isosporiasis and cryptosporidiosis may be reported in as many as 5–10% of patients who have AIDS in the tropics, compared with 0.2% of patients who have AIDS in the USA. Reports have also shown that the risk of isosporiasis among residents of the USA with AIDS is higher among those born in Latin America and Haiti than among those born in the USA. In Zambia, evaluation of persistent diarrhea in patients with AIDS revealed cryptosporidiosis (7%), microsporidiosis (16%), isosporiasis (37%) and no etiology (40%); treatment with albendazole resulted in a complete or partial response in 60% of those shown to have enteric parasitic infection.[25]

Penicillium marneffei

A common fungal pathogen in AIDS patients in South East Asia is *Penicillium marneffei*.[26] It causes the third most common opportunistic infection in HIV disease in northern Thailand, after extrapulmonary tuberculosis and cryptococcal meningitis. *Penicillium marneffei* was first isolated in 1956 and infection was a rare event before the arrival of the AIDS pandemic in South East Asia. Since then hundreds of cases have been diagnosed, mainly in southern China, northern Thailand, Hong Kong, Vietnam, Singapore, Indonesia and Myanmar. The environmental reservoir of *P. marneffei* is unknown, but the organism has been isolated from the organs, feces and burrows of three species of bamboo rat. Exposure to soil appears to be a key factor in transmission.

Disseminated *P. marneffei* infection is characterized by fever, anemia, weight loss and papular skin lesions. Other frequent signs and symptoms include cough, generalized lymphadenopathy, hepatomegaly and diarrhea. The most common cutaneous manifestation is a generalized papular rash with a central umbilication that resembles the lesions of molluscum contagiosum. These are predominantly found on the face, scalp and upper extremities, but occur throughout the body. Chest radiographs are frequently abnormal, with diffused reticulonodular or localized alveolar infiltrates.

The mean duration of illness before presentation is 4 weeks. The incubation period of disseminated disease is unclear and the disease may be a result of reactivation of latent infection as opposed to new infection or re-infection. However, the development of clinically active disease within weeks of exposure in endemic areas, and the reports of children who have vertically transmitted HIV infection developing disease in the first months and years of life demonstrate that primary infection can quickly lead to disseminated disease. Finally, the pronounced seasonal variation in disease incidence implies an important role for exogenous re-infection and the expression of disease with *P. marneffei* in AIDS patients in endemic areas. In addition to endemic areas, travelers from regions where *P. marneffei* is not endemic have become infected with this pathogen while traveling in South East Asia. Diagnosis and treatment are discussed in Chapter 126 and Chapter 237 .

Other opportunistic infections

Other opportunistic infections, which may be similar in all areas of the world, include oral and esophageal candidiasis, cryptococcosis, cytomegalovirus infection and Kaposi's sarcoma. Herpes simplex virus infection, herpes zoster and cerebral toxoplasmosis also appear to be relatively common in most areas where diagnostic equipment is readily available. It should be noted that regional variations in frequencies of these diseases do exist within developing countries. Cryptococcosis

accounted for only 2% of AIDS deaths in Abidjan but is probably more common in central and southern Africa.

Mycobacterial infections apart from tuberculosis, such as *Mycobacterium kansasii*, have been long-standing health problems among miners in South Africa and may now be emerging as HIV-associated infections in those miners with HIV infection.

Endemic Kaposi's sarcoma has a striking geographic distribution, being most common in central Africa. Kaposi's sarcoma associated with HIV is likely to have a similar heterogeneous disease frequency, although the incidence of Kaposi's sarcoma has increased in all countries in which HIV disease occurs. Kaposi's sarcoma has recently been associated with a new human herpes virus, namely HHV-8, although the epidemiology of this virus and its distribution worldwide remains unknown (see Chapter 215).

HIV TESTING

Currently, HIV testing in the developing world is done mostly for purposes of surveillance. This involves very small population samples and is done anonymously. If people have little hope of treatment, they feel little incentive to be tested. In many countries there are no voluntary testing and counseling facilities because of lack of funds. In one study in South Africa, only 2% of people who were HIV-positive knew their status. In Kenya, only one of 63 randomly chosen women who tested HIV-positive was aware of her infection. In addition to cost, the fact that current testing procedures require at least two visits to a testing site further complicates access to testing. In rural South Africa, only 17% of people who asked to be tested came back for their results. Rapid test formats for HIV detection of antibody provide an alternative that has been successful in various countries, but the cost is high and the assay is not readily available in many

locations. In one study of these rapid tests, however, 96% chose to know the result and were informed before leaving the clinic.

Thus, it is apparent that over 90% of people with HIV infection in the developing world do not know their HIV status. At current estimates, this suggests that there are over 27 million people in the world today who have no idea that they are infected. There are important reasons for knowing one's HIV status. The earlier people know they are infected, the greater the opportunity for them to access treatment, some forms of which are not expensive, and to apply pressure on communities and governments for improved access to care. The earlier people are aware of their infection, the better able they are to make informed and responsible decisions about childbearing and avoiding transmission to spouses or partners, and to make plans for family welfare before they become ill or die. Furthermore, the one important benefit of self-knowledge of HIV status is that it helps unmask the invisible epidemic and permits a genuine community response. If people become aware of their infection early on, while they are still relatively healthy, this gives them time and energy to support one another as well as to alert the community to the epidemic.

However, these benefits to individuals, families and communities are realistically achievable only where people feel safe in finding out whether they are infected. Efforts by governments and civil society to combat rejection and discrimination directed at people who have HIV are vital (UNAIDS).

In 1997, WHO issued guidelines for the selection and use of HIV antibody tests applicable for use in developing countries.[27] The three main objectives for HIV antibody testing are:

- screening of blood and blood products;
- unlinked and anonymous testing for the purpose of monitoring prevalence and trends of HIV infection; and
- diagnosis of HIV infection among asymptomatic people and those with clinical signs and symptoms suggestive of HIV infection.

There are three strategies recommended by the WHO. In strategy 1, all serum and plasma is tested with one enzyme-linked immunosorbent assay (ELISA) or rapid assay. Serum that is reactive is considered HIV antibody positive. This strategy can be used for screening blood donors to protect the blood supply but it should not be used for notification of the blood donor unless strategy 2 or 3 is implemented. Strategy 1 can also be used for surveillance when screening anonymous samples.

Strategy 2 includes testing serum by one ELISA or rapid assay and, if it is reactive on the first assay, it is then retested with a second ELISA or rapid assay based on a different antigen preparation or a different test principle. Concordant results after repeat testing will indicate a positive or negative result. If the results of the two assays remain discordant, the specimen is considered indeterminate. Strategy 2 is recommended for surveillance, particularly when testing populations with a low prevalence of HIV. The additional test in strategy 2 compared with strategy 1 is necessary in order not to overestimate the HIV prevalence of such regions. Strategy 2 is also recommended for notification of the blood donor, particularly in developing countries, where strategy 2 is more cost effective than strategy 3.

Strategy 3 is similar to strategy 2, except that it requires a third test if the serum is found to be reactive on the second assay. The three tests in this strategy should be based on different antigen preparations or different test principles. A specimen is considered to be antibody-positive if it is reactive on all three assays. If the serum is discordant on any of the three assays, it is considered to be indeterminate. This strategy is recommended for diagnosis and patient notification.

In the selection of HIV antibody tests for use in strategies 2 and 3, the first test should have the highest sensitivity, whereas the second and third tests should have higher specificity than the first. The number of initial discordant or indeterminate results should not exceed 5%.

An HIV test kit bulk purchase program has been established by the WHO in collaboration with UNAIDS in order to provide national AIDS control programs that use tests giving the most accurate results at the lowest possible cost.

PREVENTION OF HIV INFECTION

Although the epidemic continues to spread throughout the developing world, it is also likely that increased preventive efforts could effectively limit the magnitude of the epidemic. For example, in those countries where the epidemic is still in an expansion phase but is not yet fully visible, the public health response is likely to have a decisive influence on its course. There is every reason to believe that the course of the pandemic could still be altered profoundly by the introduction of HIV prevention strategies that are within the technical reach of all countries. Several successes in slowing the HIV pandemic have provided encouragement and further stimulus for improved programs. Aggressive treatment of STDs coupled with a program of condom distribution has already been shown to be effective in decreasing HIV incidence rates in populations at high risk for HIV in sub-Saharan Africa and Asia. Needle-exchange programs have helped to stabilize and in some cases reduce HIV incidence among intravenous drug users in selected countries. HIV incidence rates can be reduced by an estimated 50% with adequately supported prevention programs. In Asia alone this could mean the prevention of several million AIDS deaths among young adults in their most productive years.

While we await the availability of a vaccine and the effect of therapeutic interventions, a primary prevention strategy must be focused on educational efforts to influence social, cultural and behavioral factors. To control the AIDS epidemic, countries will need not only to promote individual behavior change but also to address the related problems of social disruption associated with mounting unemployment, accelerated urbanization, commercial sex, rapid decline in health services and drug abuse. Fundamental social changes, such as improving the social status of women, will be required if AIDS control efforts are to succeed. In view of the rapid pace of HIV transmission in sub-Saharan Africa and Asia, implementation of these principles of AIDS prevention and care is needed urgently.

Despite the existing economic and logistic restraints of health services in some developing countries, good care for HIV/AIDS patients is possible. The value of symptomatic treatment combined with supportive psychological, pastoral and social services has been well documented in many localities, and establishment of services is a prerequisite for the acceptance of a preventive intervention within any comprehensive control program. Policy makers should invest limited resources in improving the infrastructure of the existing health services to enable them to cope with the increasing number of cases of tuberculosis, pneumonia and other opportunistic infections.

PREVENTION OF OPPORTUNISTIC INFECTIONS

Those opportunistic infections associated with the greatest degree of morbidity and mortality, as well as available preventive and therapeutic options, include tuberculosis and bacteremia due to non-*typhi Salmonella* spp. and *S. pneumoniae*.[28] Tuberculosis and other endemic bacterial infections regularly occur in patients with HIV infection but without profound immunosuppression. Primary preventive therapy against tuberculosis provides an important first line of

defense against the development of disease in earlier stages of HIV infection.

Recent studies have evaluated the role of trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis in reduction of infections other than *P. carinii* pneumonia in patients with HIV infection. A randomized trial conducted in Côte d'Ivoire showed that events leading to hospitalization or death were 43% lower in African adults with early symptomatic HIV disease treated with TMP-SMX rather than with placebo. The beneficial effect was due to activity of TMP-SMX against bacterial infections, malaria and isosporosis. A recent observational study conducted by the Centers for Disease Control illustrated that TMP-SMX prophylaxis during intervals when patients had $CD4^+$ lymphocyte counts of less than 200 cells/mm^3 was associated with significant protection from toxoplasmosis, salmonellosis, infection with *Haemophilus* spp., invasive or any staphylococcal infection, and *P. carinii* pneumonia. In South Africa, TMP-SMX reduced mortality and the incidence of severe HIV-related illness in patients with advanced immunosuppression ($CD4^+$ lymphocyte count <200 cells/mm^3 or total lymphocyte count of 1250 cells/mm^3), despite the low incidence of *P. carinii* pneumonia in this population.[29] Concerns cited as limitations to the use of TMP-SMX include an anticipated increase in antimicrobial resistance in pathogens such as nontyphoidal salmonellas and the pneumococcus. Of additional concern is the potential for cross-resistance between pyrimethamine and trimethoprim, as sulfadoxine-pyrimethamine is one of the most widely used treatments against *P. falciparum*.

HIV TREATMENT IN DEVELOPING COUNTRIES

On April 22nd 2002, the WHO announced the first treatment guidelines for children and adults infected with HIV in the developing world.[30] This action has set the stage for a tremendous increase in access to care; WHO estimated that at least 3 million people needing treatment should have access to medicines by 2005. The treatment guidelines were accompanied by the expansion of the Essential Medicines List to include antiretrovirals in addition to nevirapine and zidovudine, which were previously listed for the prevention of mother-to-child HIV transmission. The WHO report presents a standardization and simplification of HAART. However, the complexity of providing care to millions of people in resource-poor areas extends well beyond access to medications.

In order to ensure the safe and appropriate use of antiretrovirals, resources for evaluating patients prior to the initiation of therapy and monitoring for response to therapy, as well as for the development of potential side effects, must also be available. The WHO recommends initiation of therapy based on clinical staging and $CD4^+$ lymphocyte count or total lymphocyte count.

- WHO stage I includes those individuals with HIV infection who are asymptomatic or manifest persistent generalized lymphadenopathy;
- stage II includes those with weight loss (<10% of body weight), minor mucocutaneous manifestations, herpes zoster and recurrent upper respiratory tract infections;
- stage III includes those with weight loss (>10% body weight), unexplained chronic diarrhea, unexplained prolonged fever, thrush, oral hairy leukoplakia, pulmonary tuberculosis, severe bacterial infections and bedridden for less than 50% of the day during the past month; and
- stage IV includes those with clinical syndromes consistent with AIDS and/or bedridden for more than 50% of the day during the past month.

The guidelines, shown in Table 133.1 , recommend starting HAART in those who have WHO stage IV disease irrespective of $CD4^+$ lymphocyte

TABLE 133-1 -- **World Health Organization recommendations for starting HIV/AIDS therapy.** Recommendations for initiating antiretroviral therapy in adults and adolescents with documented HIV infection.

WHO RECOMMENDATIONS FOR STARTING HIV/AIDS THERAPY.	
If CD4 testing is available	WHO stage IV disease irrespective of $CD4^+$ lymphocyte count
	WHO stage I, II, III with $CD4^+$ lymphocyte counts <200 cells/mm^3
If CD4 testing unavailable	WHO stage IV disease irrespective of total lymphocyte count
	WHO stage II or III disease with a total lymphocyte count <1000–1200 cells/mm^3

count and WHO stage I, II or III with $CD4^+$ lymphocyte count below 200 cells/mm^3 in areas where $CD4^+$ lymphocyte count is available. If $CD4^+$ lymphocyte count is unavailable, HAART is recommended in those with WHO stage II or III with total lymphocyte count below the range of 1000–1200 cells/mm^3 . Assessment of HIV viral load is not considered essential for determining the need for therapy.

In addition to the assessment of immunologic function as indicated by symptoms and lymphocyte count, further testing for the safe and effective use of HAART is divided into four categories listed in Table 133.2 : absolute minimum tests, basic tests, desirable tests and optional tests. Absolute minimum testing includes an HIV antibody test and hemoglobin or hematocrit level. Basic testing adds white blood cell count and differential, liver enzymes, serum creatinine and/or blood urea nitrogen, serum glucose and pregnancy tests for women. Desirable tests include bilirubin, amylase, lipid levels and $CD4^+$ lymphocyte count. Testing for HIV viral load is deemed to be optional.

The guidelines are based on rigorous evaluation conducted almost exclusively in developed countries. A matter for concern is whether guidelines created for the populations of developed nations are adaptable to HIV-infected populations worldwide. Specifics regarding the presence of different HIV subtypes, endemic infections such as tuberculosis, genetic determinants and environmental factors such as nutritional status may introduce factors that alter response to treatment.

Developing nations that have successfully implemented HAART include Brazil, Thailand, Senegal and Uganda. Studies are needed to examine responses to HAART and whether changes to the guidelines would better serve populations in different regions around the world.

TABLE 133-2 -- World Health Organization guidelines for laboratory monitoring of antiretroviral drug use.

WHO GUIDELINES FOR LABORATORY MONITORING OF ANTIRETROVIRAL DRUG USE	
Absolute minimum tests	HIV antibody test
	Hemoglobin or hematocrit
Basic tests	White blood cell count and differential
	Alanine or aspartate aminotransferase
	Creatinine and/or blood urea nitrogen
	Serum glucose
	Pregnancy test for women
Desirable tests	Bilirubin amylase
	Serum lipids
	$CD4^+$ lymphocyte count
Optional test	HIV viral load

With initiation of HAART on a population-wide scale, continuous surveillance of drug-resistant viruses will be needed to inform treatment guidelines. A recent study conducted in Gabon demonstrated resistance to antiretroviral therapy. Of great concern is that antiviral drug resistance due to suboptimal therapies could limit the potency of available treatments. In parallel with promulgation of the guidelines, the WHO, in collaboration with the International AIDS Society, is developing a global HIV drug resistance surveillance network.

Multiple studies conducted in developed nations have proved the tremendous benefit available to people with HIV infection by the initiation of HAART. Consequently, morbidity and mortality due to HIV have declined dramatically. In developed or developing nations, HAART provides the only hope of survival for those with HIV infection who are able to adhere to daily lifelong therapy. Moreover, the availability of HAART can reinforce prevention activities by offering an incentive to seek HIV testing, preventing mother-to-child transmission and decreasing the risk of sexual transmission.

IMPACT OF HIV AND AIDS ON HEALTH CARE SYSTEMS

As the number of people with HIV infection in developing countries continues to increase, HIV/AIDS will continue to make increasing demands on the health care system at all levels. UNAIDS has estimated that, by 2005, US$9.2 billion will be needed per year to support prevention ($4.8 billion) and treatment and support interventions ($4.4 billion).[31] The allocation of funds for prevention versus care and support varies according to region, with 66% and 32% of estimated expenditure needed for care and support in sub-Saharan Africa and Asia respectively. AIDS prevention activities include teacher training and peer education, condom promotion and distribution, treatment of STDs, voluntary testing and counseling, transfusion screening and prevention of mother-to-child HIV transmission. Included in care and support activities are diagnostic testing, palliative care, opportunistic infection treatment, drug costs and monitoring for HAART, as well as orphanage care and living assistance. Mobilization of such tremendous resources will require a considerable commitment from both domestic and donor sources.

Unfortunately, these demands come at a time of great financial vulnerability for health systems and at a stage, particularly in developing countries, when a great deal of work remains to be done to increase primary health care. Primary care is intended to be the interface of contact between communities and the national health care system, bringing health care as close as possible to where people live and work. Diagnosis and treatment to relieve symptoms and to prevent and treat opportunistic infections can ease suffering and prolong the productive lives of people who have HIV, sometimes at a low cost. As the patient's immune system collapses, however, available treatments become increasingly more expensive. An analysis by the World Bank of alternative treatment and care options concludes that community-initiated care provided at home, although often shifting costs from the national taxpayer to the local community, also greatly reduces the cost of care and thereby offers hope of affordability in improving the quality of the last years of life of people who have AIDS.

The epidemic will undoubtedly increase demand for medical care and reduce its supply at a given quality and price. As the number of people who have HIV infection increases, access to medical care will become more difficult and more expensive for everyone, including people not infected with HIV, and total health expenditure per capita will rise. Governments are under pressure to increase their share of health care spending and to provide special subsidies for the treatment of HIV infection. Unfortunately, because of the scarcity of resources and the inability or unwillingness of governments to increase public health spending enough to offset these pressures, either of these policies may exacerbate the impact of the epidemic on the health care sector.

Governments should ensure that patients who have HIV infection benefit from the same access to care as other patients who have comparable illnesses and similar ability to pay. Because of discrimination, people who have HIV are frequently denied treatment or face barriers to care that others do not encounter. Governments should also provide information about the efficacy of treatments for opportunistic illnesses, HIV infection and AIDS; subsidize the treatment of STDs and contagious opportunistic infections; subsidize the screening of the blood supply; and ensure access to health care for the poorest, regardless of HIV infection status.

Chapter 134 - Pediatric HIV Infection

Peter L Havens

EPIDEMIOLOGY

The vast majority of HIV infection in children is perinatally acquired, via transmission from mother to child. HIV in children less commonly occurs from blood transfusion or receipt of blood components (e.g. during treatment of hemophilia or other coagulation disorders). Transmission may also occur by sexual exposure, either sexual abuse in younger children, or consensual sex in older adolescents and young adults.

The first cases of AIDS in children were reported in 1982. The World Health Organization (WHO) estimated that by the end of 2001, for children under 15 years of age, there were 2.7 million children living with HIV/AIDS, 800,000 new infections, and 580,000 child deaths due to HIV/AIDS in that year. Most children with HIV infection live in sub-Saharan Africa, but all regions of the world are affected (Table 134.1).[1] Reported cases of pediatric AIDS make up 1–2% of the total number AIDS cases in developed countries, but 15–20% of the total number in some developing countries. [2] At least 10.4 million children under age 15 years have lost their mother or both parents to AIDS, and this number of orphans is expected to double by 2010.[3]

Because most children who have HIV infection acquire the virus by transmission from their mother, the epidemiology of perinatally acquired HIV infection closely parallels the epidemiology of HIV infection in women (see Chapter 115 and Chapter 135). In most regions of the world, heterosexual transmission is the most common cause of HIV infection in women (see Table 134.1). The greatest growth in numbers of children with HIV infection would be expected in regions where women make up a high percentage of the case total, and where heterosexual exposure is the most common mode of HIV transmission (see Chapter 133).

Half of all new cases of HIV infection are in children and young adults under 25 years of age.[3] Since younger women often have sex with older men, and since transmission from males to females is more likely to result in HIV transmission, HIV infection is more common in female teenagers, with rates in males increasing after the teenage years. HIV infection in adolescents can be associated with heterosexual activity, injection drug use and men having sex with other men (see Chapter 115).

PATHOGENESIS AND PATHOLOGY

In the absence of intervention, the risk of HIV transmission from mother to baby is about 25%, with estimates ranging from 13 to 43% in different regions of the world.[4] While maternal, obstetric, fetal, postnatal and genetic factors may modify perinatal transmission risk (Table 134.2), maternal virus load is critical in determining the risk of perinatal HIV transmission. Maternal-fetal HLA concordance increases perinatal transmission risk,[5] while CCR5 haplotype may be permissive or protective, depending on the specific mutation.[6]

Perinatal transmission of HIV occurs in utero by the virus entering the fetal circulation from maternal blood, by exposure to infected blood or secretions during labor and delivery, or by ingestion of breast milk. Children with HIV infection can be separated into groups of 'rapid progressors' (20–25% of cases) and 'slow progressors' (75–80% of cases), based on the timing of onset of clinical symptoms of HIV disease.[7] Some rapid progressors may have acquired infection in utero, and HIV-1 has been found in villous Hofbauer cells and in fetal tissue in the first trimester of pregnancy. In-utero infection is operationally defined as detection of HIV by culture or identification of HIV genome by polymerase chain reaction (PCR) in infant blood within 48 hours of birth.[8] Peripartum infection, operationally defined in children who were not breast-fed and who have negative HIV culture or tests for HIV DNA or RNA by PCR in the first week of life, followed by positive tests from days 7–90,[8] is associated with slower disease progression. Transmission occurs in utero 26–38% of the time, and in the peripartum period 65–74% of the time.[9] [10] Breast-feeding increases transmission risk by 14–16%.[11]

The immaturity of the neonatal immune response may be responsible for the more rapid progression of HIV infection in children than adults.[12] Neonatal natural killer cells have diminished antibody-mediated recognition and killing of HIV-infected cells. Neonatal T cells have diminished ability to produce cytokines. Responses of cytotoxic T cells ($CD8^+$) to HIV *gag* proteins are detected in a smaller proportion of infants (aged under 6 months) than adults.[13]

Genetic factors also play a role in the rate of disease progression in children. The CCR5?32 allele slows disease progression,[14] and the stromal cell derived factor 1 3'A mutation accelerates the rate of disease progression.[15]

Although the immunodeficiency of T helper ($CD4^+$) cells has great impact on the clinical manifestations of HIV infection in both adults and children, B-cell dysfunction has an important role in the clinical expression of illness in children. Hypergammaglobulinemia may precede $CD4^+$ T cell depletion in children. Many children have deficient antibody responses to vaccination, especially to polysaccharide antigens. B-cell immunodeficiency is frequently manifest in children as recurrent otitis media, sinusitis, or severe bacterial infections with *Streptococcus pneumoniae* or *Haemophilus influenzae* type b. Children also have impaired phagocytic cell oxidative capacity, which may further increase the frequency and severity of pyogenic bacterial infections.

PREVENTION

Treatment of the mother with zidovudine (ZDV) during pregnancy and labor, and treatment of the newborn for the first 6 weeks of life decreases mother to child transmission (MTCT) of HIV from 25 to 8% in the absence of breast-feeding (Table 134.3).[16] Zidovudine treatment begun before 28 weeks of gestation can interrupt in-utero transmission. [17] Other combinations of prepartum and postpartum therapy can reduce MTCT, including shorter courses of ZDV, with or without lamivudine, and a single prepartum and postpartum dose of nevirapine.[18] Treatment of the infant with ZDV within 48 hours after birth may diminish MTCT, but antiretroviral treatment efficacy is clearly better if started during pregnancy. For women being treated

TABLE 134-1 -- HIV/AIDS in children under 15 years of age and factors affecting the increase in HIV/AIDS in children by region, at year end 2001.*

HIV/AIDS IN CHILDREN UNDER 15 YEARS OF AGE AND FACTORS AFFECTING INCREASE IN HIV/AIDS IN CHILDREN BY REGION, AT YEAR END 2001					
Region	**HIV/AIDS in children under 15 years of age**			**Factors affecting Increase in HIV/AIDS in children**	
	Children living with HIV/AIDS at year end, 2001	**Children newly infected with HIV in 2001**	**Deaths from HIV/AIDS in children during 2001**	**% of HIV-infected adults who are women**	**Main modes of transmission for persons with HIV***
Sub-Saharan Africa	2,400,000	700,000	500,000	55	Hetero
North Africa and Middle East	20,000	12,000	6000	40	Hetero, IDU
South and South East Asia	200,000	65,000	40,000	35	Hetero, IDU
East Asia and Pacific	7000	3000	1500	20	IDU, Hetero, MSM

Latin America	40,000	10,000	8000	30	MSM, IDU, Hetero
Caribbean	20,000	6000	5000	50	Hetero, MSM

Total	2,700,000	800,000	580,000	48	

* *Adapted from World Health Organization.*[1]
* Hetero, heterosexual transmission; IDU, transmission through injecting drug use; MSM, sexual transmission among men who have sex with men

with three antiretroviral drugs whose viral load is below limits of quantitation on ultrasensitive assays, perinatal HIV transmission risk is less than 1%.[19] Some practitioners recommend elective cesarean section at 38 weeks be considered to reduce perinatal transmission because cesarean section performed before labor onset and before rupture of membranes reduces HIV transmission risk by 50% in women treated with ZDV alone.[20] Even for women with viral load less than 1000, antiretroviral therapy and elective cesarean delivery (before rupture of membranes and before labor onset) can reduce MTCT.[21] Cesarean delivery is not expected to further reduce the low risk of MTCT for women on triple therapy with undetectable virus load (see also Chapter 135).

Because breast-feeding increases the risk of perinatal transmission of HIV,[11] women with HIV infection should be advised not to breast-feed their infants in countries where safe alternatives to breast-feeding are readily available.[22] In developing countries, the risk of HIV infection from breast-feeding may be lower than the risk of death from other diseases that occur with high frequency in bottle-fed infants, and breast-feeding is still recommended for women in those areas, even those with HIV infection.[23]

Vaginal washes have not been successful in reducing vertical HIV transmission, and peripartum vaginal cleaning is not currently recommended for routine use. Information concerning MTCT of HIV is updated frequently by the WHO and UNAIDS, and is available at http://www.unaids.org/publications/documents/mtct/index.html. Issues of treatment of pregnant women with HIV infection are discussed more fully in Chapter 135 .

CLINICAL FEATURES

The Centers for Disease Control and Prevention (CDC) classification of adolescents[24] and children who have HIV infection (Table 134.4 , Table 134.6 and Table 134.7) [25] outlines clinical manifestations related either directly to HIV infection and the resulting immune response, or those related to the progressive loss of $CD4^+$ T cells and secondary (opportunistic) infections or cancers.

Compared with adults, children have more rapid disease progression, and have a different pattern of primary and secondary HIV-related manifestations (Table 134.5).[26] [27] Symptoms are most common in children under age 4 years, and in those with in-utero transmission, high virus load and rapid disease progression.[28] Growth delay (failure to thrive) and abnormalities of the central nervous system (CNS) with microcephaly and developmental delay are the most important primary manifestations of HIV infection in children. Cardiomyopathy, nephropathy and possibly enteropathy also represent complications primarily related to HIV infection, whereas swollen parotid glands, lymphoid interstitial pneumonitis, hepatomegaly, splenomegaly and lymphadenopathy may result from the immune response to HIV infection. Important opportunistic infections in children with HIV infection include *Pneumocystis carinii* pneumonia (PCP) and recurrent serious bacterial infections with organisms including *S. pneumoniae* and *H. influenzae* type b. Cryptococcosis and toxoplasma infections are much rarer in children than in adults with HIV infection. Cancers most commonly found in children with HIV infection include lymphomas, leiomyomas and Kaposi's sarcoma, but all cancers are much less common in children than in adults with HIV infection.

Because the normal range for the number of $CD4^+$ T cells changes with age, so does the number that defines immunodeficiency, and CD4% is often used (Table 134.6). Classification of children with HIV infection incorporates both clinical and immunologic information (Table 134.7). Before antiretroviral treatment was available, median survival for children with HIV infection in the USA was approximately 8 years (Table 134.8). [29] Survival is lower with lower $CD4^+$ T-cell counts and higher viral loads (Table 134.9).[30] Children diagnosed with symptomatic disease (CDC category B) or those with poor growth in the first 6 months of life, have more rapidly progressive disease and shorter survival.[31]

TABLE 134-2 -- Factors affecting vertical transmission of HIV.

FACTORS AFFECTING VERTICAL TRANSMISSION OF HIV	
Viral factors	• Increased transmission with high virus load
	• Syncytium-inducing phenotype (SI) does not increase transmission risk
	• Non-syncytium-inducing (NSI or macrophage tropic) increases transmission risk
	• HIV-1 is transmitted more readily than HIV-2
Maternal factors	• Advanced disease (low CD4, high CD8 or symptoms of AIDS) increases transmission risk
	• Primary infection is associated with increased transmission
	• Primiparous women may transmit HIV more frequently
	• Maternal Epstein-Barr virus shedding increases transmission risk
	• Maternal antiretroviral therapy reduces perinatal transmission risk
	• Vitamin A deficiency is associated with increased transmission risk
	• Maternal cigarette smoking may increase transmission risk
	• Other infections (condylomata or other sexually transmitted diseases) may increase transmission
	• Combined maternal infection with HIV-1 and HIV-2 may protect against transmission
Obstetric events	• First-born of twins has increased infection risk compared to second-born
	• Rupture of membranes >4 hours increases transmission risk, especially in preterm infants
	• Maternal bleeding during pregnancy increases transmission risk
	• Fetal scalp electrode increases risk of transmission
	• Elective cesarean section reduces perinatal transmission
Fetoplacental factors that increase transmission risk	• Chorioamnionitis
	• Placenta previa
	• Prematurity increases risk of peripartum transmission, but not in-utero transmission

Infant factors	• HLA type and maternal-infant HLA concordance
	• CCR5 chemokine receptor haplotype
	• Fetal immune response (responsiveness of cord blood leukocytes to HIV *env* determinants may be protective)
Postnatal factors important in transmission	• Breast-feeding increases transmission by 14–16% and breast-feeding longer than 15 months multiplies that risk
	• Maternal nipple lesions or mastitis increase transmission risk
	• Maternal seroconversion during breast-feeding increases transmission risk
	• Infant thrush at <6 months of age increases transmission in breast-feeding infants

With the availability of antiretroviral treatment, disease progression has been slowed considerably, with a change in the median age at death from 6 months to 3.6 years in a European study.[28] However, in areas of the world where treatment is not readily available, rapid disease progression and early death remain common. In Malawi, in a cohort of 190 children with perinatally acquired HIV infection, 89% were dead by 3 years, and only 1% were free of symptoms. [32] In South Africa, newborns co-infected with HIV and tuberculosis, syphilis or cytomegalovirus (CMV) had mean age at death of only 3.5 months, and 83% were dead by 9 months.[33]

At birth, infants who have HIV infection are on average 0.28kg lighter and 1.64cm shorter than those without HIV infection[34] born to women with HIV infection. Because both weight and length are affected, children with HIV infection appear symmetrically small, with average body mass index by 18 months of age.[34] Poor growth by 6 months of age is an indicator of rapid disease progression.[31] Growth failure is not usually secondary to neuroendocrine dysfunction, but may be at least partially related to reduced energy intake.

HIV-1 RNA has been found in cerebrospinal fluid of children with HIV infection, and clinical manifestations of this CNS involvement are common, with 9% of patients showing signs of progressive neurologic involvement by 12 months of age,[26] and 21% diagnosed with encephalopathy by 24 months of age.[35] A wide range of manifestations of neurologic involvement is possible, from developmental delay identified only by prospective testing, to profound cognitive deficits and motor disorders, including signs of pyramidal tract dysfunction, movement disorders and ataxia.[36] Some patients have isolated cognitive dysfunction, whereas others have primarily motor abnormalities and many have a mixed pattern of involvement. The clinical course of illness may be static, it may transiently plateau, or it may be progressive. Progression of cognitive and motor delays occurred by 30 months of age in 50% of 114 prospectively evaluated infants with perinatally acquired HIV infection, even in the absence of overt encephalopathy. In children who have HIV infection, small head circumference is common even without encephalopathy,[34] and microcephaly may occur in over half of the children with HIV-associated encephalopathy. Abnormalities on computerized tomography (CT) of the brain were found in 86% of 83 symptomatic children with HIV infection; these abnormalities included ventricular enlargement, cortical and cerebellar atrophy, and cerebral calcifications.[37] Basal ganglia calcifications associated with disruption of the blood-brain barrier and perivascular calcium deposits can be found in children with HIV encephalopathy.

Pulmonary lymphoid hyperplasia (PLH) and lymphoid interstitial pneumonitis (LIP) are focal (PLH) to diffuse (LIP) lymphocytic infiltratitve diseases of the lung. They begin as asymptomatic interstitial nodular pulmonary infiltrates with hilar and mediastinal lymphadenopathy on chest radiograph, and they may progress to an illness characterized by chronic cough and slowly or intermittently progressive hypoxemia associated with clubbing of the digits.

TABLE 134-3 -- Prevention of HIV transmission from pregnant women to their infants.[18]

PREVENTION OF HIV TRANSMISSION FROM PREGNANT WOMEN TO THEIR INFANTS[18]
1. Suggest the use of ZDV, antiretroviral therapy
a. ZDV, following the regimen from ACTG Protocol 076
Pregnant women
During pregnancy: ZDV 200mg/dose q8h or 300mg/dose q12h po, beginning after 14 weeks of gestation and continuing until labor begins
During labor: ZDV iv during labor: 2mg/kg load over 0.5–1 hour followed by 1 mg/kg per hour iv infusion. Add ZDV for infusion to 5% dextrose in water for concentration of =4mg/ml
Before scheduled cesarean section: iv ZDV regimen should be infused at least 3 hours before the cesarean section
Newborn infants
ZDV 2mg/kg/dose po q6h (ZDV 2.6mg/kg/dose po q8h being investigated. Prematures: 1.5mg/kg/dose po q12h 1st 2 weeks, then 2mg/kg/dose po q8h >2 weeks.) Start within 8–12 hours of age. Give 6 weeks of total therapy, if HIV DNA PCR negative. Adjust dose for weight gain as needed. Check hematocrit at 4 weeks. If HIV DNA PCR positive, repeat to confirm and refer to specialist for treatment.
b. Other combinations of prepartum and postpartum therapy can reduce perinatal transmission, including shorter courses of ZDV, with or without lamivudine, and a single prepartum and postpartum dose of nevirapine[18]
2. Avoid procedures that may increase the risk of exposure of the child to maternal blood and secretions (e.g. scalp electrode, scalp pH, etc.)
3. Avoid artificial rupture of membranes unless medically indicated. Rupture of membranes >4 hours increases the risk of MTCT of HIV
4. Cesarean section has been shown to decrease risk of vertical HIV transmission. Cesarean section may be considered if maternal HIV RNA PCR >1000
5. Wash the baby promptly
6. Advise against breast-feeding of the infant, and educate the mother about safe alternatives

PLH-LIP is frequently associated with generalized lymphadenopathy and salivary gland enlargement and, even though it is an AIDS-defining illness, it is associated with prolonged survival compared with survival in other patients with AIDS. Compared to children with PCP, those with PLH-LIP are older (usually over 1 year of age), have less tachypnea and fever, lower lactate dehydrogenase, higher total immunoglobulins and higher titers to Epstein-Barr virus (EBV) antigens.[38] PLH-LIP is pathogenically linked to infection with EBV as well as HIV, and it improves with immune system improvement with antiretroviral therapy. Corticosteroid therapy (e.g. oral prednisone) may be of benefit in selected patients.

Cardiac abnormalities are common. Children with HIV infection have faster heart rate, higher left ventricular mass and lower left ventricular function than uninfected children.[39] HIV genome has been identified in cardiac myocytes and in pericardial fluid in three infants with pericardial effusions and sudden death.[40] Children with rapid disease progression have higher resting heart rate and respiratory rate than other infants with perinatally acquired HIV, and chronic heart disease was found in 53% of 34 children with HIV who died before 5 years of age.[41] Of 81 children with HIV infection evaluated in one study, arrhythmias occurred in 35%, unexpected cardiac arrest in 9%, transient congestive heart failure in 10% and chronic congestive heart failure in 10%.[42] Patients who have encephalopathy may be at highest risk for chronic congestive heart failure and cardiac arrest.[42]

Nephropathy affects 3–40% of children with HIV infection, is more common in blacks, and occurs late in the course of disease. The most common pathologic findings are focal glomerulosclerosis and mesangial hyperplasia associated with lymphohistiocytic tubulointerstitial infiltrates.[43] Although renal disease may be associated with renal failure, it is not usually the cause of death in children with HIV infection.

The occurrence of opportunistic infections in children with HIV infection varies with age and $CD4^+$ T-cell count (Table 134.10).[44] *Pneumocystis carinii* pneumonia in adults occurs late in the course of HIV infection, when T-cell immunodeficiency has progressed enough for this chronic pulmonary colonizer to reactivate and cause acute hypoxemia. In children, PCP occurs at an early age, with peak age of onset at 3–6 months of age.[45] This probably represents primary infection with *P. carinii*, and 20–30% of cases are in children with $CD4^+$ T-cell counts of more than 1500/mm^3 .[46] [47] Compared with the chronic presentation of PLH-LIP in older children, PCP is characterized by acute onset of fever, tachypnea with rib retraction, significant hypoxemia with diminished breath sounds, wheezes and rhonchi.[38] Chest radiograph may be normal but it usually shows bilateral interstitial and alveolar infiltrates. Diagnosis can be made by using special stains to identify cysts or trophozoites in fluid from induced sputum, bronchoalveolar lavage or lung biopsy. Even though treatment with trimethoprim-sulfamethoxazole (co-trimoxazole) is better tolerated in children than adults, the case fatality rate from PCP in infancy is 33%, which is higher than that in adults.

Serious bacterial infections with organisms including *S. pneumoniae* and *H. influenzae* type b are common in children with HIV infection (see Table 134.5 and Table 134.10), and AIDS is defined by two or more episodes of sepsis, pneumonia, meningitis, bone or joint infection, or deep abscess in 2 years.[25] Otitis media, sinusitis and bronchitis are also common manifestations of the B-cell defect that accompanies HIV infection in children, and are caused by the usual childhood respiratory pathogens *S. pneumoniae*, *H. influenzae* and group A streptococci until late stages of immunosuppression, when *Staphylococcus aureus* and *Pseudomonas aeruginosa* may be more common. While intravenous immune globulin (IVIG) has been shown to decrease the number of bacterial infections in selected

TABLE 134-4 -- CDC classification for children (<13 years of age) with HIV infection: diagnostic criteria for clinical categories N, A, B and C.*

CDC CLASSIFICATION FOR CHILDREN (<13 YEARS OF AGE) WITH HIV INFECTION	
Clinical categories	**Diagnostic criteria**
N: Not symptomatic No signs or symptoms of HIV infection or only one of the conditions listed in category A	If <18 months of age two positive results on separate determinations from one or more of the following:
	(a) HIV culture,
	(b) HIV PCR or
	(c) HIV p24 antigen
	If =18 months HIV antibody positive by repeatedly reactive ELISA and confirmatory test (e.g. Western Blot or IFA)
A: Mildly symptomatic Two or more of the conditions listed, but none of the conditions listed in categories B or C	Lymphadenopathy (=0.5cm at more than two sites; bilateral at one site)
	Hepatomegaly
	Splenomegaly
	Dermatitis
	Parotitis
	Recurrent or persistent upper respiratory infection, sinusitis or otitis media
B: Moderately symptomatic Symptoms of HIV infection other than those listed for categories A or C. Examples include but are not limited to those listed	Anemia (<8), neutropenia (<1000) or thrombocytopenia (<100,000) persisting =30 days
	Bacterial meningitis, pneumonia or sepsis (single episode)
	Candidiasis, oropharyngeal thrush, persisting >2 months in children >6 months old
	Cardiomyopathy
	CMV infection, onset before 1 month of age
	Diarrhea, recurrent or chronic
	Hepatitis
	Herpes simplex virus (HSV) stomatitis, recurrent (more than two episodes within 1 year)
	HSV bronchitis, pneumonitis or esophagitis with onset before 1 month of age
	Herpes zoster (shingles) — two episodes or more than one dermatome
	Leiomyosarcoma
	Lymphoid interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia (AIDS defining, report to State)
	Nephropathy
	Nocardiosis
	Persistent fever (lasting >1 month)
	Toxoplasmosis, onset before 1 month of age
	Varicella, disseminated (complicated chickenpox)

C: Severely symptomatic Any condition listed in the 1987 surveillance case definition for AIDS with the exception of LIP	Serious bacterial infection; two in 2 years: sepsis, pneumonia, meningitis, bone or joint infection, abscess of organ or body cavity (excludes otitis media, skin or mucosal abscesses and indwelling catheter infections)
	Candidiasis, (esophageal, tracheal, bronchial, pulmonary)
	Coccidioidomycosis, disseminated or extrapulmonary
	Cryptococcosis, extrapulmonary
	Cryptosporidiosis or isosporiasis >1 month duration
	CMV disease (onset >1 month), other than liver, spleen or lymph nodes
	Encephalopathy: >1 finding for >2 months and no illness that explains:
	(a) failure to attain or loss of milestones or intellectual ability shown by neuropsychologic tests;
	(b) impaired brain growth or acquired microcephaly shown by OFC measurements or brain atrophy on CT scan or MRI (serial imaging needed if <2 years old);
	(c) acquired symmetric motor deficit with at least two of: paresis, pathologic reflexes, ataxia or gait disturbances
	Herpes simplex (ulcer >1 month duration or pneumonia or esophagitis >1 month old)
	Histoplasmosis, disseminated or extrapulmonary
	Kaposi's sarcoma
	Lymphoma, primary, in brain
	Lymphoma, B cell, non-Hodgkin's lymphoma
	Mycobacterium tuberculosis, disseminated or extrapulmonary
	Mycobacterium infection, noncutaneous, extrapulmonary or disseminated (except leprosy)
	Pneumocystis carinii pneumonia
	Progressive multifocal leukoencephalopathy
	Salmonella (nontyphoid) sepsis, recurrent
	Toxoplasmosis of the brain, onset >1 month old
	Wasting syndrome in absence of other illness that explains:
	(a) weight loss >10% of baseline or
	(b) downward crossing of =2 percentile lines on the weight chart in a child =1 year or
	(c) <5th percentile on weight for height on two consecutive measures =30 days apart plus
	(a) chronic diarrhea (=2 loose stools/day for =30 days) or
	(b) documented fever for =30 days, intermittent or constant

CDC CLASSIFICATION FOR CHILDREN (<13 YEARS OF AGE) WITH HIV INFECTION

Immunologic categories	Age of child					
	<12 months		1–5 years		6–12 years	
	Cells/µl	(%)	Cells/µl	(%)	Cells/µl	(%)
1. No suppression	=1500	(=25)	=1000	(=25)	=500	(=25)
2. Moderate suppression	750–1499	(15–24)	500–999	(15–24)	200–499	(15–24)
3. Severe suppression	<750	(<15)	<500	(<15)	<200	(<15)
Immunologic categories based on age-specific $CD4^+$ T-cell counts and percent of total lymphocytes.						

TABLE 134-7 -- Summary of pediatric HIV classification.*

SUMMARY OF PEDIATRIC HIV CLASSIFICATION				
Immunologic categories (see Table 134.6)	Clinical categories			
	N: No signs/symptoms	A: Mild signs/symptoms	B^H : Moderate signs/symptoms	C^H : Severe signs/symptoms
1. No suppression	N1	A1	B1	C1
2. Moderate suppression	N2	A2	B2	C2
3. Severe suppression	N3	A3	B3	C3
Children whose HIV infection status is not confirmed are classified by placing the letter E (for perinatally exposed) before the classification code (e.g. EN1). H, both category C and lymphoid interstitial pneumonitis in category B are reportable to state health departments as AIDS.				

** Adapted from Centers for Disease Control and Prevention.[25]*

pediatric patients with HIV infection,[48] [49] in patients being treated with trimethoprim-sulfamethoxazole (co-trimoxazole) prophylaxis there is no added benefit of IVIG.[50] Children who may benefit from IVIG for prophylaxis of recurrent infections are those with hypogammaglobulinemia or bronchiectasis from recurrent pulmonary infections.

Although HIV is not itself oncogenic, children with HIV infection do have an increased risk of malignancy.[51] Kaposi's sarcoma, although rarer in children than in adults, is found in children with HIV infection.[52] Non-Hodgkin's lymphoma, predominantly of B-cell origin, is the most common malignancy reported in children with HIV infection, and lymphomas of T-cell origin also occur. Many lymphomas are

associated with EBV infection. Smooth muscle tumors, including leiomyomas and leiomyosarcomas, are specifically associated with HIV infection in children,[53] and occur late in the course of illness when the $CD4^+$ T-cell count is low. Epstein-Barr virus genome has been found in the muscle cells of leiomyosarcomas from children with HIV infection, but not in such tumors from persons without HIV infection.[54]

DIAGNOSIS

Because many children with HIV infection remain asymptomatic for long periods of time, the clinical examination is not a sensitive test for the presence of infection. Infection with HIV in adults and children older than 18 months is presumptively diagnosed by using an enzyme-linked immunosorbent assay (ELISA) to screen blood for presence of antibody to HIV. A single positive ELISA is repeated, and if still positive, results are confirmed by Western blot for HIV-specific antibody. [55]

Children born to women with HIV infection passively acquire maternal IgG antibody to HIV, which can make the HIV IgG antibody ELISA reactive for 12–18 months after birth, even in infants not infected with HIV. Therefore, detection of virus or virus products is the preferred means of diagnosis because it can identify infected infants at a younger age.

Culture of HIV is the gold standard for diagnosis of HIV infection in infants under 18 months of age,[56] but DNA PCR is more widely available and has been shown to be equally sensitive. A single positive culture is not diagnostic of HIV infection in infants because 2–7% of children later found to be uninfected may have a positive culture within the first 6 months of life.[57] [58] [59] Therefore, at least two

positive cultures should be obtained to confirm the diagnosis of HIV infection in children.

The PCR for HIV DNA is the most rapid and accurate method for identification of HIV infection in children under 18 months of age.[9] [60] [61] Sensitivity is 38% on the day of birth, 93% by day 14 of life and 96% by day 28.[10] False-positive results are possible, owing to laboratory error,[60] but two positive tests together are 98.5% accurate in identifying infection status, and using three tests performed after 1 month of age achieves 100% accuracy. The first positive HIV DNA PCR after perinatal infection may appear as late at 183 days of life.[10]

Two positive HIV DNA PCR tests are needed to diagnose HIV infection in infants. Two negative PCR tests performed at more than 1 month of age, with one at more than 4 months of age, reasonably exclude HIV infection.[62] Because of the importance of a negative test, PCR testing should include controls to assess DNA sample adequacy. Samples with inadequate DNA should be rejected, and not reported as negative. In the child with two negative HIV DNA PCR tests at more than 1 month of age and 2–4 months of age, ELISA for IgG to HIV should be performed at 18 months to confirm absence of infection (seroreversion). Primers for PCR differ in their ability to identify nucleic acid from non-clade B HIV, and in some settings special testing may be required to identify or exclude such infection (see Chapter 136).[63]

Measurement of HIV p24 antigen in blood is not sensitive enough to be used for early diagnosis of HIV infection in children, even if immune complex dissociated methods are used for sample preparation.

MANAGEMENT

Issues of immediate importance in the care of children born to women with HIV infection are:

- continued intervention to prevent HIV infection if possible (see Table 134.3);
- identification of infected infants; and
- institution of prophylactic therapy for PCP.

Independent of specific HIV-associated problems, certain health-related procedures are necessary for all children with HIV infection. Height and weight are measured at regular intervals and plotted on appropriate growth charts. The head circumference should be measured at least every 3 months until 2 years of age, in conjunction with a careful neurologic assessment. Developmental screening is recommended every 6 months until 24 months of age and yearly thereafter.

Respiratory status should be monitored closely for the possible acute onset of PCP in younger patients or the more insidious onset of PLH-LIP in older children. Symptoms or signs of heart failure should prompt evaluation, including chest radiograph, pediatric cardiology evaluation, electrocardiography and possibly echocardiography. A

TABLE 134-11 -- Immunization of children with HIV infection.*

IMMUNIZATION OF CHILDREN WITH HIV INFECTION

Hepatitis B	Varicella	
Hib-conjugate		
See text for details. DtaP, diphtheria, tetanus and acellular pertussis vaccine.		

** Adapted from Centers for Disease Control and Prevention.[64]*

normal heart size on chest radiograph does not rule out cardiac dysfunction. Chest radiographs are indicated yearly for comparison with later films because of the frequency of pulmonary disease and the often subtle beginnings of PLH-LIP.

Ophthalmologic examinations are recommended annually for children treated with dideoxyinosine (ddI). For children who have CMV infection, more frequent eye examinations may be indicated.

Immunizations

Immunizations follow the schedule for infants and children recommended by the American Academy of Pediatrics (Table 134.11),[64] with the following caveats.

Polio

Enhanced-potency inactivated poliovirus vaccine (eIPV) should be given to infected children and to uninfected children when parents or siblings have HIV infection.

Oral polio vaccine (OPV) should not be used.

Measles, mumps and rubella

In spite of a small risk of immunizing immunosuppressed patients with live vaccine, measles, mumps and rubella vaccine (MMR) should be given because of the high case fatality rate of measles for HIV-infected children. It may be better to give measles vaccine at 12 months to improve the probability of seroconversion. Second dose may be given as soon as 28 days later Measles vaccination of an adult with an extremely low $CD4^+$ T-cell count has resulted in vaccine-associated pneumonitis, and measles vaccine is not recommended for children with CD4% less than 15%. Immunoglobulin prophylaxis is indicated for HIV-infected children exposed to measles, even if they have been previously vaccinated for measles.

Influenza

Influenza vaccine is indicated for children with symptomatic HIV infection, as well as asymptomatic or uninfected children if they are living with family members who have HIV infection and who are ill.

Pneumococcus

Children up to 5 years of age, infected with HIV, are vaccinated with 7-valent conjugate vaccine. After age 5 years, use 23-valent polysaccharide vaccine. For children 10 years of age or under, a single revaccination is recommended 3–5 years after the initial dose. For children over 10 years of age, a single re-vaccination is recommended if 5 or more years has elapsed since the previous dose

Haemophilus influenzae type b

Administration of *H. influenzae* type b (Hib) conjugate vaccine follows standard recommendations for infants and consideration should be given for its administration to newly diagnosed children who are over 60 months of age.

Bacille Calmette-Guérin

Although bacille Calmette-Guérin (BCG) is not recommended for use in the USA,[65] the WHO recommends its use in asymptomatic infants in regions where risk of tuberculosis is high.[66]

Varicella

Vaccination with varicella vaccine is indicated for children with HIV infection in CDC class N1 or A1, with CD4% of at least 25%. Give two doses with a 3-month interval between them.[67] Not addressed by the CDC recommendations is the patient with prior symptoms and prior low $CD4^+$ T-cell count (e.g. C3 in the past), now on triple antiretroviral therapy, asymptomatic, with CD4% over 25%. There are no data to assure the safety or efficacy of varicella vaccine under such circumstances. However, if such patients are clinically stable, with CD4% over 25% for more than 6 months, two-dose vaccination might be considered, with the understanding that safety and efficacy are not assured.

Laboratory monitoring

$CD4^+$ T-cell count and percentage and a full blood cell count with differential are indicated every 3 months to evaluate the integrity of the immune system. Immunoglobulin concentrations are measured once for patients under 6 months of age to identify those patients with hypogammaglobulinemia.

Virus load is measured as the plasma HIV RNA concentration at 3-month intervals to help in the decision to begin or alter antiretroviral therapy. Virus load testing is also performed 4–8 weeks after beginning or changing therapy, to assess the effectiveness of therapy.[68]

Patients with specific clinical problems may require extra laboratory monitoring.

Antiretroviral therapy

Antiretroviral therapy is indicated for children with symptomatic HIV infection, independent of $CD4^+$ T-cell count or virus load, but USA and European guidelines differ on the extent of symptoms that demand treatment (Table 134.12).[68] [69] Since $CD4^+$ T-cell count and virus load are predictive of disease progression and death in children with HIV infection (see Table 134.9) starting antiretrovirals in asymptomatic children with HIV infection may be based on either the $CD4^+$ T-cell count, or on the virus load (see Table 134.12). Before

TABLE 134-12 -- Clinical and immunologic characteristics that prompt initiation of antiretroviral therapy in children with HIV infection.*

CLINICAL AND IMMUNOLOGIC CHARACTERISTICS THAT PROMPT INITIATION OF ANTIRETROVIRAL THERAPY IN CHILDREN WITH HIV INFECTION			
Age group	**Characteristic**	**Treatment recommendations**	
		USA	**Europe**
Infant to 12 months	Any	Recommend for any infant <12 months of age	Consider for any infant <12 months of age
	Symptoms		Always start for CDC category C
	CD4 cell count		Always start for CD4 <20% or rapidly falling CD4
	Virus load		Always start if >1,000,000
Child > 12 months	Symptoms	Recommend for CDC category A, B or C	Always start for CDC category C. Consider for CDC category B. Defer for CDC category N or A
	CD4 cell count	Recommend for CD4 <25% or rapidly falling CD4	Always start for CD4 <15%. Consider for CD4 <20%. Defer for CD4 >20%
	Virus load	Recommend for high or increasing virus load	Consider if >100,000

** Adapted from Centers for Disease Control and Prevention[68] and Sharland et al.[69]*

starting therapy based on the $CD4^+$ T-cell count or virus load, persistent abnormality should be confirmed by repeating at least once, with at least 1 week between tests.

Plasma HIV RNA concentrations early in life are higher than in adults with primary HIV infection, and they decline slowly over an undetermined time period toward the values observed in adults. A 'stable baseline' plasma HIV RNA concentration may not be reached in perinatally infected children until they are 3–6 years of age. Adult guidelines for therapy based on plasma HIV RNA concentration might be applicable to children over 30 months of age, suggesting institution of antiretroviral therapy for children in this age group with plasma HIV RNA of more than 55,000 to 100,000 copies/ml, independent of $CD4^+$ T-cell count.[68] [70]

Some authorities suggest that antiretroviral therapy is indicated in all children with HIV infection who are less than 1 year of age,[68] hoping that early therapy will suppress HIV replication more efficiently by reducing viral quantity and diversity. The potential benefits of this approach are speculative and need to be weighed against

the risks of toxicity of therapy.[69] [71]

Single-agent antiretroviral therapy should not be used in the treatment of children or adolescents with HIV infection (Table 134.13).[71] A combination of three drugs is regarded as optimal therapy, most commonly two nucleoside analog reverse transcriptase inhibitors (NRTIs) plus a protease inhibitor.[68] [69] [70] Most experience in children is with ZDV-3TC or ZDV-ddI plus NFV, or RTV, or LPV-RTV. D4T-3TC, and either d4T or ZDV plus ABC are also reasonable combinations of NRTIs to which a protease inhibitor may be added. An alternative triple combination regimen of two NRTIs plus one non-NRTI (e.g. NVP or EFV) is acceptable. Triple NRTI regimens are possible (e.g. ZDV-3TC-ABC). Regimens of two NRTIs alone may produce initial clinical benefit but do not produce sustained viral suppression. Compared to adults, infants and children have poor absorption and more rapid metabolism of antiretroviral medications, especially non-NRTI and protease inhibitor, and higher doses may be needed for children compared to adults.

ZDV and d4T should not be used together because of antiviral antagonism and diminished clinical effectiveness. ddC should not be combined with ddI, d4T or 3TC because of the potential for overlapping toxicity. IDV should not be used with SQV.

Intolerance of antiretroviral therapy can lead to dosage modification or discontinuation of therapy. Clinical symptoms — including

TABLE 134-13 -- Dosage and administration of antiretrovirals for children.*

DOSAGE AND ADMINISTRATION OF ANTIRETROVIRALS FOR CHILDREN		
Drug name	**Recommended dosage**	**How supplied**
Nucleoside or nucleotide analog reverse transcriptase inhibitors (NRTIs)		
ZDV, zidovudine, azidothymidine, AZT, Retrovir	Premature infants	Syrup: 10mg/ml
	0–2 weeks: 1.5mg/kg/dose q12h po (1.0mg/kg/dose q12h iv)	Capsules: 100mg
	>2 weeks: 2.0mg/kg/dose q8h po (1.5mg/kg/dose q8h iv)	Tablets: 300mg
	Term infants	Combivir: ZDV 300mg plus 3TC 150mg in a single tablet
	0–6 weeks: 2mg/kg/dose q6h po (1.5mg/kg/dose q6h iv), 4mg/kg/dose q12h po (1.5mg/kg/dose q6h iv)	Trizivir: ZDV 300mg + 3TC 150mg + ABC 300mg
	4 weeks–13 years: 120–160mg/m^2 /dose q8h po, 180mg/m^2 /dose q12h po	Injection: 10mg/ml in 20ml vials
	=13 years: 200mg/dose q8h po or 300mg/dose q12h po

	3 months to <13 years: 90–135mg/m^2 /dose q12h po or 240mg/m^2 /dose q24h po	Buffered powder packets: mix with water: 100mg, 167mg, 250mg
	=13 years, <60kg: tablets 125mg q12h po; powder 167mg q12h po; Videx EC 250mg q24h po	Enteric-coated delayed release tabs (Videx EC): 125mg, 200mg, 250mg, 400mg
	=13 years, >60kg: tablets 200mg q12h po, powder 250mg q12h po, Videx EC 400mg q24h po	Pediatric powder for oral solution mixed to final concentration of 10mg/ml
ddC, dideoxycytidine, zalcitabine, HIVID	<13 years: 0.01mg/kg/dose q8h po	Syrup: 0.1mg/ml (investigational)
	=13 years: 0.75mg q8h po	Tablets: 0.375mg, 0.75mg
d4T, stavudine, Zerit	<30kg: 1mg/kg/dose q12h po	Solution: 1mg/ml
	30–60kg: 30mg q12h po	Capsules: 15, 20, 30, 40mg
	>60kg: 40mg q12h po	Mix with apple sauce
3TC, lamivudine, Epivir	<1 month: 2mg/kg/dose q12h po	Oral solution: 10mg/ml
	<37.5kg: 4mg/kg/dose q12h po	Tablets: 150mg
	=37.5kg: 150mg/dose q12h po	Combivir: ZDV 300mg plus 3TC 150mg in a single tablet
		Trizivir: ZDV 300mg + 3TC 150mg + ABC 300mg
Abacavir, 1592U89, Ziagen, ABC	<37.5kg or 16 years: 8mg/kg/dose q12h po	Oral solution: 20mg/ml
	=37.5kg or 16 years: 300mg/dose q12h po	Tablets: 300mg
		Trizivir: ZDV 300mg + 3TC 150mg + ABC 300mg
TDF, tenofovir disoproxil	<13 years: 210mg/m^2 /dose q24h po (investigational)	Tablets: 300mg
	>13 years: 300mg q24h po	
Non-nucleoside analog reverse transcriptase inhibitors (NNRTIs)		
NVP, nevirapine, Viramune	<3 months: 5mg/kg/dose q24h × 2 weeks, then 120mg/m^2 /dose q12h × 2 weeks, then 200mg/m^2 /dose q12h po	Suspension: 10mg/ml
	<1m^2 : 120–200mg/m^2 /dose q12h po	Tablets: 200mg
	=1m^2 : 200mg q12h po (maximum dose)	
	Always start at half dose for 2 weeks, then to full dose if tolerated	
DLV, delavirdine, Rescriptor	<13 years: dosage not established	Tablets: 100mg
	=13 years: 400mg/dose q8h po	
EFV, DMP 266, efavirenz, Sustiva	<2 years: investigational	Capsules: 50, 100, 200, 600mg
	>2 years: 650mg/m^2 /dose q24h po	
	=28kg (0.95m^2) and adults: 600mg/dose q24h po	
Protease Inhibitors (PIs)		
SQV, saquinavir, Invirase (hard gel), Fortovase (soft gel)	<16 years: 50mg/kg/dose q8h po (investigational)	Hard gel capsules: 200mg
	= 16 years: 600mg/dose q8h po with fatty meal (Invirase: poorly absorbed: do not use), 1200mg/dose q8h po with fatty meal (Fortovase)	Soft gel capsules: 200mg
RTV, ritonavir, Norvir	3 months–13 years: 400–450mg/m^2 /dose q12h po	Oral solution: 80mg/ml
	=13 years: 600mg/dose q12h po	Gel caps: 100mg
		Store in original bottle

IDV, indinavir, Crixivan	3–13 years: 500mg/m^2 /dose q8h po	Capsules: 200 and 400mg. Must be stored in original bottle
	=13 years: 800mg q8h po	
NFV, nelfinavir, Viracept	1 month–13 years: 30–50mg/kg/dose q8h po, 55–60mg/kg/dose q12h po (max. 2000mg/dose; investigational)	Powder for oral suspension: 50mg/'level scoop', or 200mg/USA teaspoon (5ml)
	=13 years: 750–1250mg/dose q8h po, 1250mg/dose q12h po (adolescents may need higher dose than adults)	Tablet: 250mg
141W94, APV amprenavir, Agenerase	<3 years: not recommended	Oral solution: 15mg/ml
	3–12 years: 20mg/kg/dose q12h or 15mg/kg/dose q8h po (liquid: 85% bioavailable, so use 22.5mg/kg/dose q12h or 17mg/kg/dose q8h to maximum of 2800mg/day)	Tablets: 50mg, 150mg
	Adults: 1200mg/dose q12h po	
LPV/r, Abbott-378/r, lopinavir/ritonavir, Kaletra	Children: 300/75 (LPV-RTV)mg/m^2 /dose q12h po	Oral solution: 400mg/100mg LPV-RTV per 5ml (80mg/20mg LPV-RTV per ml). Can store at room temp for 2 months
	Adults: 400/100 (LPV-RTV)mg/dose q12h po, 533/133 (LPV-RTV)mg/dose q12h po if given with NVP	Capsules 133.3mg/33.3mg LPV-RTV per capsules
Combination therapy is recommended for treatment, and the preferred regimen is two NRTIs and one PI. Most experience in children is with ZDV/3TC or ZDV/DDI plus NFV or RTV. D4T/DDI, D4T/3TC and ZDV/ABC are also reasonable NRTI combinations to which a PI may be added. An alternative triple combination regimen of two NRTIs plus one NNRTI is acceptable but may be less likely to result in durable suppression of viral load. Regimens of two NRTIs alone may show initial clinical benefit but do not usually show sustained viral suppression. There is wide interperson variation in plasma concentration of antiretrovirals and therapeutic drug monitoring may be helpful to guide dose selection. Do not use monotherapy. Do not use the following combinations: ZDV/D4T; DDC/DDI; DDC/D4T; DDC/3TC; or IDV/SQV. Body surface area (BSA) = ([height (cm) × weight (kg)]/3600^2 .		

** Adapted from Centers for Disease Control and Prevention[68] Sharland et al.,[69] Havens et al.[71] and Centers for Disease Control and Prevention.[72]*

growth delay, new or worsening encephalopathy, or new or recurring opportunistic infections — are markers of progressive HIV disease, and may trigger a change in therapy. Rising plasma HIV RNA, or falling $CD4^+$ T-cell counts, are markers of disease progression that may be used to guide a change in antiretroviral therapy.

Prevention of opportunistic infections

Guidelines for the prevention of opportunistic infections in adults and adolescents who have HIV infection established by the US Public Health Service and the Infectious Diseases Society of America, and endorsed by the American Academy of Pediatrics, have been published. Recommendations in this section follow those guidelines except as noted.

Prophylaxis for PCP is indicated for all children with prior PCP, for all children with a percentage of $CD4^+$ T cells that is less than 15% and for all children with a $CD4^+$ T-cell count less than those indicated in Table 134.14 . Prophylaxis for PCP is indicated for all children born to women with HIV infection, and it should be started at 4–6 weeks of age, regardless of the child's $CD4^+$ T-cell count or HIV infection status.[62] [72] For children in whom HIV infection is reasonably excluded (usually by 4 months of age), PCP prophylaxis can be discontinued.

Children who have HIV infection should continue PCP prophylaxis until at least 12 months of age. Prophylaxis is discontinued at 12 months of age for children with HIV infection whose $CD4^+$ T-cell counts during the first year of life have been over 750/mm^3

TABLE 134-14 -- Normal $CD4^+$ cell counts and $CD4^+$ cell counts at which to initiate prophylaxis for *Pneumocystis carinii* pneumonia and *Mycobacterium avium* complex infections.†

NORMAL $CD4^+$ T CELL COUNTS AND $CD4^+$ T CELL COUNTS AT WHICH TO INITIATE PROPHYLAXIS FOR PCP AND MAC INFECTIONS			
Age	**Normal $CD4^+$ T cell count/mm^3 , median[64]**	**$CD4^+$ T cell count/mm^3 at which to start PCP prophylaxis[55]**	**$CD4^+$ T cell count/mm^3 at which to start MAC prophylaxis[63]**
1–11 months*	>3000	All*	<750
12–23 months	2600	750	<500
24–71 months	1700	500	<75
=6 years	1000	200	<50
Patients with prior PCP should receive prophylaxis. All patients should receive prophylaxis when the CD4% is less than 15%.			

† *Adapted from Centers for Disease Control and Prevention.*[62] [64] [72]
* Even patients for whom the diagnosis of HIV infection has not yet been confirmed should begin PCP prophylaxis at 4–6 weeks of age. For patients in whom HIV infection is reasonably excluded by at least two DNA PCR tests, PCP prophylaxis can be discontinued (usually at 4 months of age)[55]

TABLE 134-15 -- Prophylaxis of *Pneumocystis carinii* pneumonia in children.†

PROPHYLAXIS OF PCP IN CHILDREN		
Drug	**Dose**	**Comment**
Trimethoprim-sulfamethoxazole	150mg/m^2 /day ÷ q12h 3 days/week on consecutive days	Preferred regimen
	150mg/m^2 /day po q24h on consecutive days	More marrow toxicity
	150mg/m^2 /day ÷ q12h 7 days/week	More marrow toxicity
	150mg/m^2 /day ÷ q12h po for 3 days/week alternate days	
Dapsone*	2mg/kg/day, as a single dose (max. 100mg)	Absorption equal at high/low gastric pH
Atovaquone	1–3 months old: 30mg/kg/dose po q24h	
	4–24 months old: 45mg/kg/dose po q24h	
	>24 months old: 30mg/kg/does po q24h	
Pentamidine	300mg monthly by aerosol inhalation via Respirgard II nebulizer	>5 years old
	4mg/kg every 2–4 weeks iv	Of unproven benefit

† *Adapted from Havens et al.*[71]

* Testing for G6PD deficiency is indicated before starting therapy because dapsone may induce hemolysis in G6PD deficient patients

(15%) when regularly measured. Prophylaxis for PCP is continued after 12 months of age for children with HIV infection with any $CD4^+$ T-cell count that was less $750/mm^3$ (15%) during the first 12 months of life. For children between 12 and 24 months old who are not on prophylaxis, begin it if $CD4^+$ T-cell counts are less than $750/mm^3$ (15%). At 24 months, children with HIV infection who have been receiving PCP prophylaxis can discontinue treatment if $CD4^+$ T-cell counts have all been over $500/mm^3$ (15%) when regularly measured every 3 months. Prophylaxis for PCP is continued after 24 months of age for children with HIV infection with any $CD4^+$ T-cell count that was less than $500/mm^3$ (15%) during the first 24 months of life.

For HIV-infected children who are older than 24 months, PCP prophylaxis is begun when the $CD4^+$ T-cell count drops below the critical levels outlined in Table 134.14 . Usual PCP prophylaxis is trimethoprim-sulfamethoxazole $150mg/m^2$ per day (5–7mg/kg per day) divided into two daily doses and given on Monday, Tuesday and Wednesday every week. Alternative regimens are shown in Table 134.15 .

Children and adolescents who have HIV infection and a positive tuberculin skin test (more than 5mm induration) without evidence of active disease, prior antituberculous therapy or prior antituberculous prophylaxis should receive prophylactic isoniazid, 10–15mg/kg (to a maximum of 300mg per dose) once daily for 12 months. Such therapy should also be considered for skin test-negative children who are close contacts of persons with infectious tuberculosis, after active

tuberculous infection has been excluded. Rifampin (rifampicin), 10–20mg/kg (up to a maximum of 600mg per dose) given once daily is reasonable alternative prophylaxis if the strain to which the child was exposed is known to be resistant to isoniazid. [64]

Clarithromycin, 7.5mg/kg (up to a maximum of 500mg per dose) q12h is recommended for prevention of *Mycobacterium avium* complex (MAC) infections in children, based on age and $CD4^+$ T-cell count (see Table 134.14). Alternative regimens include azithromycin, 20mg/kg (up to a maximum of 1200mg per dose) once weekly; azithromycin 5mg/kg (up to a maximum of 250mg per dose) once daily; or rifabutin 5mg/kg (up to a maximum of 300mg per dose) once daily. Blood cultures for mycobacteria should be performed before beginning prophylaxis. Positive blood cultures prompt treatment with at least three drugs (e.g. clarithromycin, ethambutol and rifabutin). At the stage of infection when MAC prophylaxis is considered, patients may be on other medications that may interact with rifabutin. The advantages and disadvantages of beginning therapy should be carefully discussed with families.

Patients who have HIV infection and hypogammaglobulinemia may benefit from infusions of IVIG, 400mg once monthly to prevent serious bacterial infections. Intravenous immunoglobulin for prophylaxis of bacterial infections shows no additional benefit in children without hypogammaglobulinemia who are already receiving concurrent trimethoprim-sulfamethoxazole.

Varicella-zoster immune globulin is given to children who have HIV infection without prior varicella infection if they are exposed to chickenpox or zoster. Varicella-zoster immune globulin is not effective if given more than 96 hours after exposure. Prophylaxis with aciclovir is used for patients with frequently recurring zoster. The exact dose for this indication in children is unclear, but 5mg/kg q12h is a reasonable starting dose, increasing to as high as 10–20mg/kg q6-8h if breakthrough occurs.

Prophylaxis for CMV disease in children is not recommended at this time. Prophylaxis of herpes simplex virus disease and fungal infections in children follow guidelines for adults, with appropriate dose modifications.[64] Other prophylaxis may be indicated for patients with a variety of late complications of HIV infection.[64]

Chapter 135 - Special Problems in Women who have HIV Disease

Beverly E Sha
Constance A Benson

EPIDEMIOLOGY

The number and proportion of women who have HIV-1 infection in the USA have been gradually increasing. Of 41,960 persons reported to the Centers for Disease Control and Prevention (CDC) who had AIDS in 2000, 10,459 (25%) were women.[1] This contrasts with 1985 statistics, when 7% (534/8153) of people reported to the CDC who had AIDS were women. Based on 1999 vital statistics data, HIV-1 infection is the fifth leading cause of death for women aged 25–44 years and the third leading cause of death for African-American and Hispanic women in this age group. The racial distribution of women who had AIDS in 2000 was 62.6% African-American (45.9/100,000), 18.1% white (2.2/100,000) and 17.7% Hispanic (13.8/100,000).

Heterosexual transmission has surpassed injection drug use as the primary route for women acquiring HIV-1 infection in the USA. Geographically, the north-eastern and southern USA have reported the greatest number of cases. Current estimates are that 40,000 new infections occur annually in the USA, of which 30% are in women. Of newly infected women, estimates are that 75% acquired HIV-1 through heterosexual sex and 25% through intravenous drug use.

Worldwide 2001 UNAIDS estimates are that, of the 37.2 million adults living with HIV-1/AIDS, 17.6 million (47%) are women.[2] More than 70% live in sub-Saharan Africa. One in every 100 adults worldwide aged 15–49 years is HIV-1-infected. In sub-Saharan Africa, 8.4% of all adults in this age group are HIV-1 infected. More than 80% of all adults worldwide acquired HIV-1 infection via heterosexual intercourse.

TRANSMISSION

Factors that are important in male-to-female transmission of HIV-1 infection include:

- advanced disease in the infected source partner;
- plasma HIV-1 RNA level (and virus shedding in genital secretions);
- anal receptive intercourse;
- presence of genital ulcers;
- absence of condom use; and
- absence of zidovudine use.[3] [4] [5] [6]

Factors associated with heterosexual female-to-male transmission of HIV-1 infection include:

- advanced disease in the infected source partner;
- plasma HIV-1 RNA level (and virus shedding in genital secretions);
- presence of genital ulcers;
- sexual intercourse during menses; and
- absence of condom use.

In developing countries, observational studies have also suggested an association of non-ulcerative sexually transmitted diseases with increased rates of HIV-1 transmission. For women, *Candida* vaginitis, bacterial vaginosis and use of depot medroxyprogesterone acetate have been associated with an increased incidence of HIV-1 infection. The efficiency of male-to-female transmission of HIV-1 has been estimated to be twice that of female-to-male transmission, although some studies have found equal rates of transmission between the sexes.[4] [5]

CLINICAL FEATURES

Disease manifestations and progression

Overall, there are few differences in the incidence of nongynecologic opportunistic diseases between men and women who have HIV-1 infection, with the exception of a higher incidence of esophageal candidiasis as an AIDS-defining condition and a lower incidence of Kaposi's sarcoma reported among women.[7] It has been postulated that women may have a higher incidence of candidiasis due to vaginal colonization with yeast or hormonal influences, although data supporting these hypotheses are lacking.

Several studies have now demonstrated that women have lower plasma HIV-1 RNA levels than do men after controlling for age, the interval from seroconversion and the $CD4^+$ lymphocyte count.[8] Another study found that this sex difference in plasma HIV-1 RNA levels disappeared 5–6 years after seroconversion. Although women may progress to AIDS with lower viral loads, the time to progression to AIDS appears to be similar for men and women. Similarly, for HIV-1-infected men and women who have adequate access to health care and treatment, survival appears to be equivalent.[9] [10]

Gynecologic manifestations

Infection

Gynecologic disorders are common in women who have HIV-1 infection. [11] Up to 50% of these women develop recurrent *Candida* vaginitis, which often precedes the development of oral or esophageal candidiasis. Several longitudinal cohorts have reported that 14–18% of women who have HIV-1 infection have or develop recurrent genital herpes simplex virus (HSV) infection, which can be more severe or refractory to treatment than among HIV-1-seronegative women.[10]

The relationship between HIV-1 and pelvic inflammatory disease (PID) in women is less clear. Several retrospective studies suggest that women presenting with PID have a high rate of co-infection with HIV-1 and that women who have HIV-1 infection with PID require surgical intervention more frequently because of abscess formation.[12] Prospective studies will be necessary to define this relationship and determine whether there are differences in response to therapy, microbiologic etiology and risk of recurrence or long-term sequelae.

Genital dysplasia

Cervicovaginal dysplasia is common in women who have HIV-1 infection. [11] [13] Abnormal Papanicolaou smears were found in 38.3% of 1713 HIV-1-infected women and 16.2% of 482 women uninfected with HIV-1 but at risk, in the Women's Interagency HIV-1 Study cohort.[13] In multivariate analyses, risk factors for abnormal cytology included HIV-1 infection, low $CD4^+$ lymphocyte counts,

high plasma HIV-1 RNA levels and detection of human papillomavirus (HPV). In follow-up of this cohort, HPV detection, $CD4^+$ lymphocyte count and plasma HIV-1 RNA levels predicted regression.[14] Rates of incidence, progression and regression of abnormal cytology did not differ between the HIV-1-uninfected controls and HIV-1-infected women with $CD4^+$ lymphocyte counts greater than 200 cells/ml and plasma HIV-1 RNA levels below 4,000 copies/ml. In another study, 20% (80/398) of HIV-1-seropositive women compared with 4% (15/357) of HIV-1-seronegative women had cervical intra-epithelial neoplasia (CIN) confirmed by colposcopy.[15] The presence of CIN was found to be independently associated with:

- HPV infection (odds ratio 9.8);
- HIV-1 infection (odds ratio 3.5);
- $CD4^+$ lymphocyte count less than 200/ml (odds ratio 2.7); and
- age greater than 34 years (odds ratio 2.0).

The rate of CIN in women who have HIV-1 infection with fewer than 200 $CD4^+$ lymphocytes/µl was 28% (27/95) compared with 19% (45/236) for those with higher $CD4^+$ lymphocyte counts.

Conflicting data exist regarding whether CIN and invasive cervical cancer have a more aggressive course or a less favorable response to therapy among women who have HIV-1 infection. In one study prior to the availability of highly active antiretroviral therapy (HAART), 62% of 127 women who had HIV-1 infection with CIN developed recurrent CIN within 36 months of treatment compared with 18% of HIV-1-seronegative controls.[16] During the 36-month follow-up period, progression to higher grade dysplasia, including one invasive cancer, occurred in 25% of women who had HIV-1 infection compared with 2% of controls. Recently, HIV-1-infected women in New York were reported to be at higher risk than HIV-1-seronegative women for other HPV-associated malignancies, including vulvar and anal cancers. Highly active antiretroviral therapy that reverses immunosuppression is likely to impact favorably on the rate of HPV detection and prevalence of genital tract and anal dysplasia.

The 2001 Consensus Guidelines for the management of women who have cervical cytologic abnormalities are detailed in Table 135.1 .[17] These guidelines are not specific to women with HIV-1 infection but reflect updated terminology for reporting cervical cytology results, recent availability of HPV DNA testing and further follow-up data on the natural history of atypical squamous cells of undetermined significance/low-grade squamous intraepithelial lesions that were not available for the February 2002 US Public Health Service (USPHS) guidelines for cervical dysplasia screening in women who have HIV-1 infection.[18]

TABLE 135-1 -- Guidelines for cervical dysplasia screening of women infected with HIV-1.*

GUIDELINES FOR CERVICAL DYSPLASIA SCREENING OF WOMEN INFECTED WITH HIV-1	
Initial gynecologic examination with Papanicolaou smear	If normal, repeat in 6 months
	If atypical squamous cells of uncertain significance (ASCUS) proceed to colposcopy
	If atypical glandular cells proceed to colposcopy
	If low grade squamous intraepithelial lesion proceed to colposcopy
	If high grade squamous intraepithelial lesion, proceed to colposcopy
If initial two Papanicolaou smears are normal	Repeat annually as long as smears remain normal

** These are based on the 2001 Consensus Guidelines and the United States Public Health Service Guidelines.[17] [18]*

Because *Candida* vaginitis, genital HSV disease, PID and cervical dysplasia are common in women who have HIV-1 infection, these conditions, along with other common sexually transmitted diseases such as gonorrhea, chlamydial infection and syphilis, should prompt a determination of HIV-1 risk factors and appropriate HIV-1 screening.

Menstrual cycle

The impact of HIV-1 infection on the menstrual cycle remains unknown. There are reports of increased rates of dysmenorrhea, oligomenorrhea, amenorrhea or menorrhagia, but these have been discounted by other studies.[19] Ongoing prospective observational studies of the epidemiology, manifestations and progression of HIV-1 disease in women should address these issues.

PREVENTION

Contraception

Condoms are important for preventing the transmission of HIV-1 and other sexually transmitted diseases. However, alone they may not be adequate to prevent pregnancy. Reported breakage rates for male condoms are less than 2% for vaginal and anal intercourse. An evaluation of the effectiveness of the female condom at preventing pregnancy in 147 women over a 6-month period demonstrated an annual failure rate of 26%. Among 86 women who reported using the condom consistently and correctly, the annual failure rate was still 11%.[20]

Hormonal contraceptives should be considered in addition to condoms for women who have HIV-1 infection, are sexually active and wish to avoid pregnancy. In view of the wide array of potential drugs available for antiretroviral therapy and prevention and treatment of opportunistic infections, the medications of women receiving hormonal agents should be critically reviewed to avoid drug-drug interactions such as:

- those that might lead to a reduction in the efficacy of hormonal agents; and
- those that may reduce the efficacy or increase the toxicity of other drugs in the presence of hormonal agents.

In particular, protease inhibitors and non-nucleoside reverse transcriptase inhibitors (NNRTIs) can affect the levels of hormonal agents. Table 135.2 details these interactions and recommendations for their concomitant use.[21]

Pregnancy

In the USA, in 1993, the rate of HIV-1 infection among women of childbearing age was 1.7 per 1,000 and there were between 1000 and 2000 perinatally infected infants born to 6000–7000 HIV-1-infected women. UNAIDS estimates for 2001 are that, worldwide, 4.3 million children under 15 years of age have died of AIDS; another 2.7 million are currently living with HIV-1/AIDS, of whom 800,000 were infected in 2001.[2]

Perinatal transmission can occur in utero and during labor and delivery, as well as postpartum, primarily through breast-feeding.[22] [23] Excluding postpartum transmission through breast-feeding, data suggest that 80% of maternal-infant transmission occurs late in gestation or during labor and delivery.[24] Several studies have found that breast-feeding may increase the rate of transmission by 7–22% and thus breast-feeding is not recommended when safe alternatives are available. [23] The majority of infections transmitted through breast milk occur during the first few weeks or months of life, suggesting that postpartum maternal and/or infant antiretroviral therapy could further reduce transmission in breast-feeding populations.[25] Risk factors associated with transmission via breast-feeding include level of virus in the breast milk, mastitis, breast abscesses and maternal seroconversion during lactation.

TABLE 135-3 -- Maternal-infant transmission of HIV-1.

MATERNAL-INFANT TRANSMISSION OF HIV-1	
Maternal factors	**Labor and delivery factors**
Advanced maternal HIV disease	Chorioamnionitis
Maternal p24 antigenemia	Prolonged rupture of membranes (>4h)
Low maternal $CD4^+$ lymphocyte counts	Premature delivery before 34 weeks gestation
High maternal plasma HIV-1 RNA levels	Use of fetal scalp electrodes
Acute maternal HIV infection during pregnancy	Non-elective cesarean section delivery
Genital inflammation or maternal sexually transmitted disease at the time of delivery	Lack of antiretroviral therapy
Episiotomy with severe lacerations	
Detectable genital tract HIV-1 RNA near delivery	
Breast-feeding	
Maternal, and labor and delivery factors that increase the risk of transmission.[22] [26]	

A number of maternal and delivery factors appear to influence the risk of transmission and are listed in Table 135.3 .[22] [26] In addition, the rate of maternal-infant transmission has been reported to be increased when maternal virus exhibits rapid or high titer replication in human peripheral blood mononuclear cells, T cell line tropism or resistance to neutralization by maternal serum. Among twin births, the firstborn twin is at greater risk of acquiring HIV-1 infection because of more prolonged exposure to maternal blood and secretions. Interventions currently recommended to reduce transmission include:

- avoidance of invasive monitoring whenever possible;
- avoidance of breast-feeding;
- the use of zidovudine with or without other antiretroviral therapy during pregnancy for the mother and in the peripartum and postpartum period for the infant;
- treatment of sexually transmitted disease or vaginitis; and
- elective cesarean section if plasma HIV-1 RNA level remains above 1,000 copies/ml near term.

Recently the USPHS published revised guidelines on the use of antiretroviral therapy in pregnant women.[27] Since the results of AIDS Clinical Trials Group (ACTG) 076, which demonstrated a 66% reduction in maternal-infant HIV-1 transmission with zidovudine use in the mother (100mg orally 5 times per day initiated at 14–34 weeks gestation), during labor and delivery (2mg/kg intravenous loading dose then 1mg/kg continuous infusion until delivery) and in the baby (2mg/kg orally q6h for the first 6 weeks of life) compared with placebo (7.6% vs 22.6% transmission, respectively), advancements have occurred in our understanding of the pathogenesis of HIV-1 disease and its treatment and management.[28] The precise mechanisms by which zidovudine diminishes maternal-infant transmission of HIV-1 remain unclear but they are probably multifactorial and include decreased maternal plasma HIV-1 RNA levels, resulting in decreased exposure of the fetus to the virus in utero, or of the infant at delivery, or both, thereby preventing infection becoming established in the fetus or infant. Additional analyses have now shown that transmission of HIV-1 occurs at all levels of $CD4^+$ lymphocyte counts and even in some women who have undetectable plasma HIV-1 RNA levels, although overall the risk of transmission is greater in women who have lower $CD4^+$ lymphocyte counts and higher plasma HIV-1 RNA levels, particularly at the time of delivery. [29] Detectable virus in the female genital tract at 38 weeks gestation has also been independently associated with maternal-infant transmission of HIV-1.[30]

It is important to stress that even intervening late in pregnancy can diminish the risk of transmission. Epidemiologic data from New York State showed decreased transmission to the infant when intravenous zidovudine was begun during labor followed by 6 weeks of oral zidovudine for the infant compared with no therapy (10% vs 27% transmission, respectively).[31] A study in Thailand randomized 397 HIV-1-infected pregnant women to receive placebo or zidovudine (300 mg q12h orally from 36 weeks gestation until onset of labor

and 300 mg q3h orally from onset of labor until delivery).[32] There was an 18.9% transmission risk for women receiving placebo compared with a 9.4% transmission risk for women receiving zidovudine. Thus, transmission in this non-breast-feeding cohort was decreased by 50% with the use of a shorter course of zidovudine, oral dosing during labor and no infant treatment compared with a 66% reduction with the more complicated ACTG 076 regimen.

In an African breast-feeding cohort, the PETRA study compared a combination regimen of zidovudine and epivir of four varying durations in the mother and infant: (1) starting at 36 weeks gestation, orally intrapartum and for 1 week postpartum to the woman and infant; (2) starting during labor and for 1 week postpartum to the woman and infant; (3) during labor only to the woman; and (4) placebo.[33] Arms 1 and 2 reduced transmission to the infant by approximately 50% and 38%, respectively, as compared with the placebo arm. Arm 3 provided no reduction in transmission compared with placebo (16% vs 17%, respectively), suggesting that any potential benefit was negated by breast-feeding.

More recently, in Uganda, a two-dose nevirapine regimen was compared with a short-course zidovudine schedule.[34] At the onset of labor, women received either oral nevirapine, 200mg as a single dose, or oral zidovudine, 600mg loading dose followed by 300mg q4h until delivery. Infants

‡ *Data from CDC.* [27]
* Randomized trial showing benefit.
† A, adequate and well controlled studies of pregnant women fail to demonstrate a risk to the fetus during the first trimester and no evidence of risk during later trimesters; B, animal studies fail to demonstrate a risk to the fetus but no adequate studies exist in pregnant women; C, animal studies demonstrate risk or have not been conducted, and safety in human pregnancy has not yet been determined — however, the benefit of the drug may still outweigh the risk; D, positive evidence of human fetal risk exists based on adverse reaction data but benefits may still outweigh the risks.

Infants received matched drug to their mothers, either oral single dose nevirapine 2mg/kg within 72 hours of birth or oral zidovudine 4mg/kg q12h for 7 days. In this breast-feeding population, the risk of HIV-1 transmission at birth was 10.4% in the zidovudine group and 8.2% in the nevirapine group. By 6–8 weeks postpartum, 21.3% of infants had acquired HIV-1 infection in the zidovudine group versus 11.9% in the nevirapine group (p = 0.0027). These data demonstrated that the two-dose nevirapine regimen reduced the risk of maternal-infant transmission by 47% compared with a truncated zidovudine regimen. Follow-up data from this study, however, documented the occurrence of K103N mutations in virus recovered from up to 15% of women who were randomized to nevirapine, a mutation conferring cross-class resistance to NNRTIs.[35] These data may have implications for future treatment of women who received this regimen.

All pregnant women should be offered HIV-1 testing. In general, current recommendations are to approach the treatment of the HIV-1-infected pregnant woman as if she were not pregnant and strive for maximal suppression of viral replication. Nevertheless, knowledge that limited data exist regarding toxicity of the 16 Food and Drug Administration (FDA)-approved antiretroviral agents to the developing fetus and the infant must also be taken into account. Table 135.4 and Table 135.5 summarize the current information known about reverse

transcriptase inhibitors and protease inhibitors with regard to FDA approval status, placental transfer and carcinogenicity data. To date, neither pre-term delivery nor birth defects have been clearly associated with any antiretroviral agent; however, data are limited, particularly for infants exposed to combination therapy. Only efavirenz should be avoided in the first trimester, because of evidence of teratogenicity in rhesus macaques at human doses. A French group reported eight cases of mitochondrial dysfunction among 1754 uninfected infants who received zidovudine or the combination of zidovudine and epivir in utero and/or after birth. Two of these children developed progressive neurologic dysfunction and died. This syndrome has not been detected in over 20,000 children born to HIV-1-infected women in the USA.

On the basis of this information, the USPHS has drafted the following guidelines for the treatment of HIV-1-infected pregnant women.[27]

If the woman has had no prior antiretroviral therapy, treatment should be based on standard indications. However, at a minimum the three-part zidovudine regimen as outlined in ACTG 076 should be administered. In a meta-analysis, antenatal antiretroviral prophylaxis primarily with zidovudine alone was shown to reduce transmission for women who have plasma HIV-1 RNA levels to below 1000 copies/ml at or near delivery compared with no antenatal therapy (1% vs 9.8%, respectively).[36] Many experts feel comfortable substituting zidovudine 300mg q12h orally for the maternal component. Combination therapy is recommended for women who have a plasma HIV-1 RNA level over 1000 copies/ml. Consideration can be given to delaying the initiation of therapy until after 10–12 weeks gestation, which is thought to be the critical time for fetal organogenesis.

If the HIV-1-infected pregnant woman is already on antiretroviral therapy when pregnancy is diagnosed, then therapy should in general be continued, even in the first trimester. If the decision is made to stop therapy during the first trimester owing to concerns about teratogenicity, all drugs should be stopped and then restarted simultaneously in order to minimize the development of resistance.

Zidovudine should be incorporated into the regimen whenever feasible; however, if resistance or intolerance precludes its use, zidovudine should still be administered intravenously intrapartum and to the baby as outlined above. Additionally, zidovudine and stavudine should not be co-administered. Some experts would also recommend zidovudine in combination with other antiretroviral agents for infants born to mothers who have known or suspected zidovudine resistance.

For women receiving standard antenatal antiretroviral therapy, the addition of the two-dose nevirapine regimen did not further reduce transmission rates and, as previously discussed, resulted in the development of mutations conferring resistance to NNRTIs.[37] [38] Thus, for women who do not achieve adequate viral suppression near delivery, cesarean section is recommended and the addition of the two-dose nevirapine regimen is not.

If an HIV-1-infected woman presents in labor and no prior antiretroviral therapy has been given, four antiretroviral treatment options are recommended:

- single-dose nevirapine 200 mg orally to the mother as soon as possible and nevirapine 2mg/kg orally to the infant at 48 hours of life;
- oral zidovudine and epivir to the mother until delivery followed by 1 week of zidovudine and epivir to the infant;
- intrapartum intravenous zidovudine until delivery, and zidovudine to the newborn for 6 weeks; or
- the two-dose nevirapine regimen combined with intrapartum intravenous zidovudine and 6 weeks of zidovudine for the newborn.

Infants born to HIV-1-infected mothers who have received no anti-retroviral therapy during pregnancy or intrapartum should still receive zidovudine for the first 6 weeks of life. Consideration may also be given to treating the infant with additional antiretroviral medications. The mother's therapy should be re-evaluated after delivery in both these situations.

Resistance testing is available to guide antiretroviral therapy choices. The International AIDS Society-USA Panel and Euro-Guidelines Group for HIV-1 Resistance recommend that all pregnant women who have detectable viremia have resistance testing performed prior to initiating or changing antiretroviral therapy. The USPHS recommends resistance testing for HIV-1-infected pregnant women based on standard indications, which include the following settings: acute infection, failing a current regimen, or high likelihood of having resistant virus based on community resistance patterns or known drug resistance in the woman's source partner. While underlying resistance can affect the ability to achieve maximal viral suppression, it is not clear that the presence of mutations increases the likelihood of transmission to the infant. Resistant virus has been transmitted to infants; however, women who have zidovudine resistance mutations have not consistently transmitted infection to their infants at higher rates and, in some cases where transmission has occurred, wild-type virus was transmitted. When less than potent antiretroviral regimens (zidovudine monotherapy or dual nucleoside analogues) are administered to pregnant HIV-1-infected woman because antiretroviral therapy is not indicated for the women herself or the woman chooses to minimize exposure to antiretroviral therapy during pregnancy, development of resistance can occur and can potentially limit future treatment options.

A meta-analysis of 15 prospective cohort studies, conducted in an era when pregnant HIV-1-infected women received no antiretroviral therapy or zidovudine monotherapy, showed that elective cesarean section decreased the risk of maternal-infant transmission of HIV-1 compared with other modes of delivery.[39] For women on zidovudine, transmission was 2% with elective cesarean section and 7.3% with other modes of delivery. Because transmission rates are expected to be below 2% for women on potent antiretroviral therapy with controlled viremia, the American College of Obstetricians and Gynecologists' Committee on Obstetric Practice recommends cesarean section before the onset of labor for women who have plasma HIV-1 RNA levels above 1,000 copies/ml near term. The cesarean section should be performed at 38 weeks gestation without amniocentesis to assess for fetal lung maturity. For a scheduled cesarean section, intravenous zidovudine should be started 3 hours before surgery. Cesarean section has greater morbidity than vaginal delivery but current data suggest that HIV-1 infected women have similar complications to those in uninfected women.

Duration of ruptured membranes is also associated with an increased risk of transmission. For the first 24 hours of membrane rupture, a meta-analysis of the same 15 studies used to assess the benefit of cesarean section showed a 2% increase in transmission for every additional hour of membrane rupture.[40] Cleansing the birth canal with a 0.25% chlorhexidine solution q4h until delivery did not reduce transmission in one study, except when membranes were ruptured more than 4 hours before delivery.[41] Whether or not non-elective cesarean section to shorten the duration of ruptured membranes or labor will further reduce transmission rates is currently unknown.

Safety monitoring guided by the pregnant woman's specific antiretroviral therapy should be performed. Routine hematologic and hepatic enzyme monitoring is recommended for women on zidovudine. Women receiving nucleoside reverse transcriptase inhibitors (NRTIs) should also be assessed for development of lactic acidosis and hepatic steatosis with frequent liver enzyme and electrolyte

---

monitoring in the third trimester. Recently, cases of fatal lactic acidosis have been reported in pregnant women receiving prolonged courses of didanosine and stavudine. When other alternatives are available, this combination should be avoided during pregnancy. Women on protease inhibitors should be monitored for development of hyperglycemia. In general, the $CD4^+$ lymphocyte count and plasma HIV-1 RNA level should be monitored every 3–4 months. A plasma HIV-1 RNA level should be obtained at 34–36 weeks gestation to guide decisions on mode of delivery. A level II ultrasound is recommended to assess the fetus for women on combination antiretroviral therapy.

In the future, ongoing or planned studies will certainly provide more information regarding the use of the newer NRTIs, NNRTIs, nucleotide analogues, protease inhibitors and combination regimens for the treatment of pregnant women and the prevention of transmission to the fetus/infant. Studies are also ongoing to assess the feasibility of rapid HIV-1 testing for women who present in labor with unknown HIV-1 status. In the meantime, HIV-1-infected pregnant women should be referred for participation in clinical trials whenever possible and be reported to the appropriate agencies that collect safety and teratogenicity data. In the USA, the Antiretroviral Pregnancy Registry can be reached at www.APRegistry.com.

In general, pregnant women who have HIV-1 infection should receive prophylaxis for opportunistic infections appropriate for their stage of disease. [18] For *Pneumocystis carinii* pneumonia prophylaxis, some experts recommend avoiding trimethoprim-sulfamethoxazole and dapsone in the first trimester, and trimethoprim-sulfamethoxazole close to term to reduce the risk of kernicterus in the infant. Aerosolized pentamidine can be substituted during these time periods. While rifabutin and the macrolides have not been studied in pregnant women, those at high risk of disseminated *Mycobacterium avium* complex disease may benefit from the use of these medications after the first trimester. Azithromycin is favored owing to its safety profile because clarithromycin is teratogenic in animals. Pregnant women who have a positive purified protein derivative skin test for tuberculosis should also receive isoniazid prophylaxis after the first trimester. Pregnant women should also avoid eating raw or undercooked meat and avoid contact with cat feces to diminish the risk of toxoplasmosis. Good handwashing techniques should be employed for prevention of cytomegalovirus (CMV) disease, particularly in women who are health care workers or who have children in day care settings.[18] For CMV-seronegative women who require blood transfusions, only CMV-seronegative blood products should be used. [18]

Several studies have now demonstrated no adverse effect of pregnancy on the progression of HIV-1 disease for women who have $CD4^+$ lymphocyte counts above 200 cells/µl.[42] Unfortunately, women who have more advanced HIV-1 disease may not tolerate pregnancy as well and may have a higher rate of spontaneous abortion, prematurity, low birth weight infants and other complications of pregnancy.[43]

Chapter 136 - Practice Point

Diagnosis of HIV in newborns

Peter L Havens

In the absence of intervention, children born to women who have HIV infection have about a 25% chance of being infected with HIV. Children born to women who have HIV infection need:

- therapy to prevent HIV infection;
- testing to identify infected infants; and
- institution of therapy to prevent *Pneumocystis carinii* pneumonia (PCP).

Pathogenesis

Perinatal transmission of HIV occurs in utero (about 25–30% of perinatal infections) and in the peripartum period (about 70%). Breast-feeding results in late postnatal HIV transmission in another 14–16% of infants.

Clinical features

Because many children who have HIV infection remain asymptomatic for long periods of time, the clinical examination is not a sensitive test for the presence of infection.

Diagnosis

In adults and children older than 18 months of age, HIV infection is diagnosed using an enzyme-linked immunosorbent assay (ELISA) to screen blood for the presence of antibody to HIV. A single positive ELISA should be repeated, and repeatedly positive tests should be confirmed by Western blot for HIV-specific IgG antibody.

Children born to women who have HIV infection passively acquire maternal IgG antibody to HIV, which can make the HIV IgG antibody ELISA and Western blot reactive for up to 18 months after birth, even in infants not infected with HIV. Therefore, positive tests for IgG antibody to HIV do not confirm the diagnosis of HIV infection in children less than 18 months of age but rather identify infants who are at risk of being infected. However, two or more negative HIV IgG antibody tests (ELISA) performed with an interval of at least 1 month in children over 6 months of age can be used to 'reasonably exclude' HIV infection among children without clinical evidence of HIV disease or previous positive laboratory evidence of HIV infection, such as HIV DNA polymerase chain reaction (PCR) or culture.

Immunoglobulin A does not cross the placenta as readily as IgG, and immunoassays for HIV-specific IgA have been developed to allow serologic diagnosis of children born to women who have HIV infection. Although these assays are 89–100% specific by 1–2 months of age, false-positive tests in the first week of life and low sensitivity as late as 6 months of age limit their usefulness in clinical practice.

Culture of HIV has been considered the gold standard for diagnosis of HIV infection in infants less than 18 months of age. Because up to 7% of children who are later found to be uninfected may have a positive culture within the first 6 months of life, at least two positive cultures are necessary to confirm the diagnosis of HIV infection in infants. Cultures are difficult and costly to perform, they can only be performed in special laboratories and they take a long time to produce a result; therefore, their clinical practicality is limited.

Polymerase chain reaction for HIV DNA is the most rapid and accurate method for identification of HIV infection in children less than 18 months of age. Sensitivity is 38% on the day of birth, 93% by day 14 of life and 96% by day 28. False-positive results are possible from laboratory error but two tests performed on separate samples are 98.5% accurate in identifying infection status and using three tests performed after 1 month of age achieves almost 100% accuracy.

Infants infected with HIV in utero have a positive HIV DNA PCR at birth and are at high risk of rapidly progressive symptomatic HIV infection. Infants infected in the peripartum period have negative HIV DNA PCR in the first few days of life, but in those infants HIV DNA PCR tests may be positive by as early as 2 weeks of age and 96% are positive by 1 month of age. Infants infected by breast-feeding may have negative HIV DNA PCR until after 6 months of age (Table 136.1).

Polymerase chain reaction for HIV RNA may be more sensitive than DNA in very young infants, and two positive HIV RNA PCR tests performed on separately collected blood samples are diagnostic of HIV infection in infants and children. HIV RNA PCR is not routinely recommended for screening at-risk infants because negative HIV RNA PCR testing does not exclude HIV infection. However, for infants infected with non-clade B HIV isolates, HIV RNA PCR using methods developed to include non-clade B RNA sequences may be preferable to standard HIV DNA PCR, which is less sensitive for identifying non-clade B virus.

Measurement of HIV p24 antigen in blood is not sensitive enough to be used for early diagnosis of HIV infection in children, even if immune complex dissociated methods are used for sample preparation. However, repeatedly positive HIV p24 antigen tests are diagnostic of HIV infection.

Management

The details of management of infants born to women who have HIV infection are shown in Table 136.2 .

TABLE 136-1 -- HIV infection and usual pattern of test results in newborns of women who have HIV infection.

HIV INFECTION AND USUAL PATTERN OF TEST RESULTS IN NEWBORNS OF WOMEN WHO HAVE HIV INFECTION							
HIV infection category		**Test**	**Infant's age at time testing performed and usual result of testing**				
			Day of birth	**1 month**	**4 months**	**>6 months**	**18 months**
Not infected	Seroreverter (nontransmitted maternal infection)	ELISA/Western blot	+	+	+	+/-	-
		HIV DNA PCR	-	-	-	-	-

Infection	In utero	ELISA/Western blot	+	+	+	+	+
		HIV DNA PCR	+	+	+	+	+
	Perinatal	ELISA/Western blot	+	+	+	+	+
		HIV DNA PCR	-	±	+	+	+
	Via breast milk	ELISA/Western blot	+	+	+	+	+
		HIV DNA PCR	-	-	±	+	+

TABLE 136-2 -- Laboratory monitoring and treatment of infants born to women who have HIV infection.

LABORATORY MONITORING AND TREATMENT OF INFANTS BORN TO WOMEN WHO HAVE HIV INFECTION		
Age	**Category of intervention**	**Test or treatment indicated**
Newborn	Evaluation	ELISA for antibody to HIV (and Western blot if ELISA is positive); a well documented history of HIV infection in mother can replace ELISA testing in the newborn
		HIV DNA PCR
		Complete blood count with differential, alanine transaminase, bilirubin and glucose if mother taking protease inhibitors during pregancy
	Treatment	Zidovudine for prophylaxis against vertical transmission (see Chapter 134)
		Advise against breast-feeding if safe alternatives are available
4 weeks	Evaluation	HIV DNA PCR
	Treatment	Continue zidovudine; hematocrit (optional; to check for anemia from azidothymidine)
6 weeks	Treatment	Stop zidovudine (assuming the HIV DNA PCR at birth and 4 weeks are negative)
		Begin treatment with trimethoprim-sulfamethoxazole for prophylaxis against Pneumocystis carinii pneumonia
4 months	Evaluation	HIV DNA PCR (if earlier testing negative)
	Treatment	Stop treatment with trimethoprim-sulfamethoxazole if the 4-month HIV DNA PCR returns and is negative, but continue if HIV DNA PCR test is positive
18 months	Evaluation	ELISA for antibody to HIV (Western blot confimation if ELISA positive); if negative, in the presence of previously negative HIV DNA PCR test and absence of symptoms of HIV infection, then the patient is a 'seroreverter', and HIV infection is definitively excluded at the present time; if positive, repeat
HIV culture may be used in place of HIV DNA PCR testing. Any positive culture or HIV DNA PCR is repeated as soon as possible to confirm the diagnosis. Patients diagnosed with HIV infection are treated as outlined in Chapter 134 .		

Prevention of perinatal transmission (see Chapter 135)

One regimen to prevent perinatal transmission of HIV includes 6 weeks of zidovudine therapy in the newborn infant. Breast-feeding increases the risk of perinatal transmission of HIV, so, in areas of the world where safe alternatives to breast-feeding are readily available, women who have HIV infection should be advised not to breast-feed their infants.

Prophylaxis of *Pneumocystis carinii* pneumonia

All children born to women who have HIV infection should be started on PCP prophylaxis at 4–6 weeks of age, regardless of $CD4^+$ T cell count or HIV infection status. The most common drug regimen for prophylaxis is trimethoprim-sulfamethoxazole, trimethoprim 150mg/m^2 /day and sulfamethoxazole 750mg/m^2 /day q12h and given 3 days weekly (see Chapter 134 , Fig. 134.14). For children in whom HIV infection is reasonably excluded, PCP prophylaxis can be discontinued. Prophylaxis against PCP should be continued until at least 12 months of age in children found to be infected with HIV, independent of their $CD4^+$ T cell count.

Follow-up visits

A baseline visit with the primary care provider is recommended. Follow-up visits at 2- to 3-month intervals to primary practitioners are adequate for most children, with timing determined in part by the immunization schedule in infancy. Diagnostic testing for HIV follows the schedule outlined in Table 136.2 . An office visit is not necessary each time laboratory testing is performed.

The uncertainty of an indeterminate infection status is difficult for families. An initial visit or discussion with personnel experienced in the care of children who have or who are at risk for HIV infection can give families an opportunity to learn about the illness and the follow-up

needed. Children who are found to be infected with HIV should follow the care recommendations outlined in Chapter 134 .

Chapter 137 - Diagnostic Tests for HIV Infection and Resistance Assays

Daniel R Kuritzkes

INTRODUCTION

Since the first human immunodeficiency virus (HIV-1) was isolated in 1983 and the first antibody detection tests were marketed in 1985, laboratory tests for the diagnosis and monitoring of HIV infection have evolved constantly. Technologic advances have led to the development of clinical assays that permit the precise quantification of plasma virus levels, detect the presence of key drug resistance mutations or generate recombinant viruses for phenotypic drug resistance testing. Indeed, few areas in medicine have witnessed such rapid and widespread adaptation of molecular biologic tools to everyday patient management.

DIAGNOSTIC TOOLS FOR HIV INFECTION

Serologic assays

Assays have been developed for detection of HIV antibodies in serum, whole blood, saliva, urine and dried blood collected on filter paper.

Enzyme-linked immunosorbent assay

Most laboratories screen for anti-HIV-1 and anti-HIV-2 antibodies by means of an enzyme-linked immunosorbent assay (EIA) based on antigens that consist of viral lysates or recombinant or synthetic proteins corresponding to the immunodominant epitopes from two HIV-1 subtype B variants (LAI and MN strains) and HIV-2 subtype A (ROD strain). These tests are therefore able to detect anti-HIV-1 and anti-HIV-2 antibodies. Current antigen sandwich EIAs have a sensitivity and specificity that approach 100%.[1] In contrast to earlier tests, which detected only IgG antibodies, third-generation HIV EIAs detect all classes of anti-HIV antibodies, considerably shortening the time to diagnosis following acute infection. However, these assays may fail to detect antibodies to the highly divergent HIV-1 subtypes from groups N and O.

Rapid tests

Diagnostic tests based on red cell or particle agglutination as well as dot blot assays have been developed that permit rapid diagnosis of HIV-1 infection. In laboratory comparisons, sensitivity and specificity are similar to those of the EIA, but performance may be somewhat lower in the field.[2] The simplicity and wide operating temperature of these tests make them ideally suited for use in resource-poor settings. Rapid tests are also useful for diagnosis of HIV infection in women during labor and delivery, and to establish the infection status of source patients following an occupational needlestick injury.

Home testing

'Home testing' for HIV infection in fact refers to home collection of a fingerstick blood sample, which is applied to a filter paper, dried and mailed directly to a central laboratory for analysis. Anonymity is preserved by the use of code numbers to identify specimens and their senders. Results and counseling are provided over the telephone. In the USA, fewer than 1% of samples submitted for testing during the first year of availability were positive, suggesting that these tests serve primarily to reassure the worried well.

Western blot

Despite a specificity of >99%, a reactive HIV EIA has a relatively low positive predictive value when applied to populations at low risk for HIV infection. Thus, a confirmatory test is essential to exclude false-positive results. The Western blot (WB) method is currently the most widely used. In a WB, viral proteins are separated by polyacrylamide gel electrophoresis and transferred by blotting onto a nitrocellulose strip. The strips are then reacted with the test serum to determine which, if any, viral proteins are recognized by patient antibodies. Figure 137.1 shows a typical WB positive for HIV-1, with the different reactive proteins. Alternatively, immunoblotting uses recombinant HIV-1 or HIV-2 proteins or synthetic peptides applied as individual strips or spots to a plastic support. Immunoblots are simpler to standardize than Western blots and are more sensitive in cases of recent seroconversion, but are more expensive. Because they use a limited number of synthetic proteins, immunoblots are less likely to detect antibodies to uncommon HIV-1 subtypes.

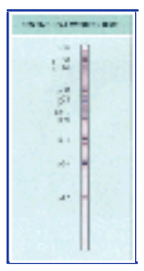

Figure 137-1 Positive HIV-1 Western blot. The binding of the patient's antibodies to viral antigens coated on the strip is revealed by an enzyme-labeled antihuman globulin. gp160, gp120 and gp41 are *env* gene products. p55, p24 and p17 are *gag* gene products. p68, p52 and p34 are *pol* gene products. MW, molecular weight of the viral proteins.

Strain serotyping

Differentiating between HIV-1 and HIV-2

Serologic differentiation is based on the detection of specific antibodies against the HIV-2 transmembrane protein (gp36) by Western blot or immunoblot assay. Monospecific EIAs for HIV-2 also are available for differentiation. Epitope differences between the immunodominant regions of HIV-1 and HIV-2 generally are sufficient for adequate serologic differentiation.

Serotypic differentiation of HIV-1 group M subtypes

The use of peptides corresponding to the V3 loop of the different group M subtypes can identify the infecting subtype with acceptable predictive value relative to genotyping. Alternatively, competitive peptide EIAs can be used. However, phylogenetic analysis of *pol* sequences obtained at the time of genotypic resistance testing (see below) offers a more convenient approach to subtype identification.

HIV isolation

HIV can be isolated from blood, plasma, cerebrospinal fluid (CSF), genital secretions or tissue by co-culture with lymphocytes from a seronegative donor that have

been stimulated with phytohemagglutinin and interleukin-2 before use. Viral replication is revealed by p24 antigen production in the culture supernatant. A positive culture provides direct evidence of HIV-1 infection, but virus culture is rarely necessary to establish a diagnosis. Morever, HIV culture has been supplanted for diagnostic purposes by polymerase chain reaction (PCR)-based assays; its use is limited primarily to specific research applications.

Virus isolation is successful in more than 95% of individuals infected with HIV-1, but sensitivity is lower in patients with higher $CD4^+$ cell counts. For a given $CD4^+$ cell count, the rate of HIV-2 isolation is significantly lower.[3] CD8 T cells that are present in peripheral blood mononuclear cells (PBMCs) exert an antiviral effect and may prevent outgrowth of virus in vitro. Therefore, it is often necessary to remove these cells in vitro in order to recover virus from patients on effective antiretroviral therapy.

Tropism

It has long been known that HIV-1 strains isolated from patients with AIDS can be more virulent in vitro than those isolated from asymptomatic persons. These strains, found in the later stages of immunodepression, are termed 'T lymphotropic' because they are able to multiply in T-lymphocyte lines and induce syncytium formation

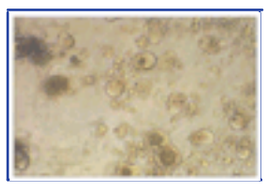

Figure 137-2 Syncytia formed by infection of MT-2 cells with an X4 (syncytium-inducing) isolate of HIV-1.

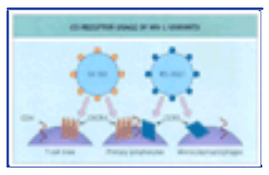

Figure 137-3 Relationship between co-receptor usage and cellular tropism of HIV-1.

in the MT2 cell line (Fig. 137.2). Syncytium-inducing strains are observed in up to 50% of patients in the later stages of infection. Emergence of SI variants is associated with an accelerated decline in $CD4^+$ lymphocyte counts.[4] Nearly all strains isolated during seroconversion usually are non-SI and macrophage tropic and are incapable of multiplying in T-cell lines.

A biologic basis for the switch in tropism associated with the SI phenotype was provided by discovery of the chemokine co-receptors for HIV. CCR5 is expressed by monocytes and primary T cells, but expression of this co-receptor is lost by T-cell lines. Conversely, CXCR4 is expressed by activated T cells and T-cell lines, but not by monocytes. Lymphotropic (SI) strains preferentially use the CXCR4 co-receptor, whereas macrophage-tropic (non-SI) strains use the CCR5 co-receptor (Fig. 137.3). Amino acid differences in certain hypervariable regions of gp120 determine co-receptor specificity. Consequently, SI strains now are referred to as X4 strains (because they use the CXCR4 co-receptor) and non-SI strains as R5 strains (because they use the CCR5 co-receptor). Occasionally duotropic (R5/X4) viruses are isolated. These viruses are able to use both CCR5 and CXCR4 co-receptors and can infect monocytes and $CD4^+$ lymphocytes with similar efficiency. It is thought that R5/X4 viruses represent intermediate forms in the evolution of SI viruses from non-SI strains.

At present, characterizing the co-receptor usage of patient isolates has little clinical utility and tests to distinguish R5 and X4 viruses are not routinely available. However, such knowledge might become important if HIV-1 entry inhibitors that specifically inhibit CCR5 or CXCR4 binding are developed for treatment of HIV-1 infection.

Viral antigen detection

Circulating HIV-1 capsid (p24) antigen can be detected by qualitative or quantitative antigen-capture EIA. High titers of p24 antigen are present during acute infection prior to seroconversion. Subsequently, p24 antigen is complexed with p24-specific antibodies and becomes undetectable in most asymptomatic patients. With advancing disease, p24 antibody titers fall and the antigen once again becomes detectable (a poor prognostic sign). Qualitative assays for p24 antigen are useful in diagnosing HIV-1 infection prior to seroconversion, but quantitative assays have been replaced by more sensitive viral RNA assays. A modified assay that dissociates p24 antigen-antibody complexes by heat treatment may provide an affordable alternative to RNA assays for quantifying plasma viremia in resource-poor countries.[5]

Viral nucleic acid detection

HIV-1 DNA polymerase chain reaction

Presence of integrated proviral HIV-1 DNA can be detected by qualitative PCR. Conserved sequences in *gag* or *pol* are amplified and the PCR product is detected by hybridization using an enzyme- or radiolabeled oligonucleotide probe. Under appropriate conditions, experienced laboratories can achieve a sensitivity and specificity of 100% in detecting subtype B virus.[6] However, sensitivity is lower in individuals with higher $CD4^+$ cell counts due to the lower titer of circulating infected PBMCs, and in patients with nonsubtype B infection. HIV-1 DNA PCR assays are used almost exclusively for early diagnosis of infection in neonates. These tests have limited utility in adults, but occasionally may be useful in resolving cases in which results of serologic tests are ambiguous.

Quantitative HIV-1 RNA assay

The development of sensitive and precise assays for quantifying HIV-1 RNA in plasma led to novel insights into HIV-1 pathogenesis and helped establish complete suppression of detectable virus replication as the appropriate goal of antiretroviral therapy. Use of these assays is now standard in the management of HIV-1-infected patients in the developed world.

Several different assay formats have been developed for HIV-1 RNA quantification. In PCR-based assays (Amplicor HIV-1 Monitor, Roche Molecular Systems), HIV-1 RNA is converted into DNA by reverse transcription followed by PCR amplification of the DNA. The PCR product is detected by hybridization to an enzyme-conjugated probe specific for HIV-1, and quantified by reacting bound probe with a substrate that undergoes a color change, as in an ELISA. The branched DNA assay (Quantiplex HIV-1 RNA, Bayer Nucleic Acid Diagnostics) uses nonenzymatic means to amplify the signal from HIV RNA. In this assay, viral RNA is 'captured' by hybridization to complementary oligonucleotides that are bound to the wells of a microtiter plate. The captured viral RNA target is then hybridized to branched oligonucleotides (hence the name 'branched' DNA assay), which in turn are hybridized to enzyme-conjugated oligonucleotides that can be quantified as above. The NASBA assay (HIV-1 RNA QT, Organon-Teknika) is similar in concept to the RT-PCR assay except that reactions occur at one temperature. A fourth assay, based on DNA hybridization and colorimetric detection (Digene Diagnostics), has been developed, but is not yet widely available.

Performance characteristics of the three commercially available assays are similar (Table 137.1), and studies have demonstrated the excellent correlation between plasma RNA titers in a given plasma sample tested by the three techniques. All three assays have a lower limit of quantification of approximately 50–80 copies/ml. Assay sensitivity can be extended by concentrating plasma virus from

TABLE 137-1 -- Performance characteristics of plasma HIV-1 RNA assays.

PERFORMANCE CHARACTERISTICS OF PLASMA HIV-1 RNA ASSAYS			
	RT-PCR (Roche)	**bDNA (Bayer)**	**NASBA (Organon Teknika)**
Linear range (copies/ml)	$400–8 \times 10^5$	$75–5 \times 10^5$	$80–4 \times 10^7$
Interassay variation (log_{10} SD)	0.12–0.22	0.05–0.17	0.038–0.261
Specimen volume	200µl	2ml	100µl–1ml
Preferred anticoagulant	EDTA/ACD	EDTA	EDTA/ACD/HEP

ACD, acid citrate dextran; EDTA, ethylenediaminetetra-acetic acid; HEP, heparin
The range of the 'ultrasensitive' RT-PCR assay is 50–50,000 copies/ml.

larger sample volumes. Although detection limits of 3–5 copies/ml are achievable by such means, these assays are much less precise at plasma HIV-1 RNA titers below 200 copies/ml.[7] Once infection becomes established, steady-state plasma virus levels are relatively stable, varying by 0.3–0.4 $\log_{10}$ copies/ml over weeks to months. Given these factors, changes of greater than 0.5–0.7 $\log_{10}$ (3- to 5-fold) are likely to reflect significant changes in HIV-1 replication.[8]

Although most strains of HIV-1 that circulate in North America belong to subtype B, more than 10 different subtypes are found around the world. The HIV-1 Monitor 1.0 (RT-PCR) assay is significantly less sensitive for detecting HIV-1 from subtypes A, E and F as compared with the Quantiplex version 3.0 (bDNA) assay.[9] Plasma HIV-1 RNA levels that appear to be lower than expected in a patient with advanced disease can be a clue to infection with a nonsubtype B strain. Incorporation of alternative primer sets in the new version of the HIV-1 Monitor assay (version 1.5) has improved the ability of this assay to detect diverse HIV-1 subtypes.

Drug resistance assays

A variety of assays are available for assessing drug resistance, including:

- genotypic assays, in which nucleotide sequencing of viral genetic material is used to detect the presence or absence of critical drug resistance mutations; and
- phenotypic assays, in which the concentration of drug necessary to inhibit virus replication in vitro is estimated in a drug susceptibility assay.

Each method has potential advantages and disadvantages. An important limitation of both approaches is that they provide a measure of the characteristics of the predominant viral species but do not indicate the presence of minor species that may emerge as resistant variants during subsequent treatment (Table 137.2).

Genotypic tests of HIV-1 drug resistance

Several approaches to genotyping are available, ranging from full-length sequencing of the target gene to point mutation assays, which focus only on a particular mutation of interest. The most commonly used genotypic assays rely on automated DNA sequencing. Using this technique, the nucleotide sequence of some or all of the gene of

TABLE 137-2 -- Comparison of genotypic and phenotypic drug resistance tests for HIV.

COMPARISON OF GENOTYPIC AND PHENOTYPIC DRUG RESISTANCE TESTS FOR HIV		
Type of assay	**Advantages**	**Disadvantages**
Genotypic assays	Rapid turn-around time	Genotype may not correlate with phenotype
	Appearance of resistance mutations may precede change in phenotype	Require expert interpretation
	Widely available	Fail to detect minor species
		Unable to assess mutational interactions
Phenotypic assays	Direct measure of viral drug susceptibility	Cost
		Longer turn-around time
	Assess net effect of mutational interactions and cross-resistance patterns	Fail to detect minor species
		Appropriate cut-offs not defined for all drugs

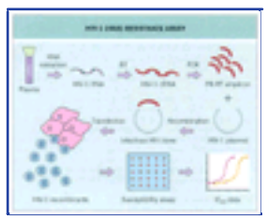

Figure 137-4 HIV-1 drug resistance assay. RT, reverse transcription reaction; cDNA, complementary DNA; PR-RT, protease and reverse transcriptase gene; IC_{50} , 50% inhibitory concentration.

interest (e.g. protease (PR) or reverse transcriptase (RT)) is obtained, then translated into the predicted amino acid sequence in order to determine whether specific mutations are present or absent. Automated sequencing offers the most complete data on viral genotype, but generates more information than is needed for most clinical purposes. For example, HIV-1 RT has 550 amino acids, but mutations at only a small number of these positions are implicated in drug resistance. Therefore, interpretation of the genotype is needed in order to help distinguish which changes are merely polymorphisms and which might be significantly associated with drug resistance.

In most commercially available genotypic tests, viral RNA is extracted from a sample of plasma and reverse transcribed into complementary DNA in the laboratory (Fig. 137.4). The PR- and RT-coding regions of the cDNA are then amplified by PCR, and the nucleotide sequence of the PCR product is determined on an automated DNA sequencer. Some laboratories use specific diagnostic kits that provide standardized reagents needed for the RT-PCR and DNA sequencing steps. Generally, these kits are part of an HIV genotyping system that includes equipment for running the sequencing assays and software for interpreting assay results. The TRUGENE HIV-1 genotyping kit and OpenGene DNA sequencing system and the ViroSeq HIV-1 Genotyping System are approved for clinical use by the US Food and Drug Administration (FDA) in conjunction with the appropriate FDA-cleared interpretation algorithm; approval of the PE/Applied Biosystems HIV-GT kit is pending. Other laboratories employ so-called 'home brew' assays using reagents, primers and interpretive algorithms developed individually by each laboratory.

Other types of genotypic resistance assays, such as the line probe assay (LiPA), differential probe hybridization assays or real-time PCR assays using selective PCR primers, are designed to provide more limited information by testing for the presence or absence of specific mutations at particular codons. These assays are faster than standard genotypic tests and may be more sensitive at detecting minor species. However, because these tests do not generate a comprehensive sequence, information needed to interpret complex genotypes might be missing. Furthermore, the tests must be reconfigured to include important new mutations as they are defined.

The frequency of false-positive and false-negative results is <1% for genotypic assays when assessed using samples that carry predominantly mutant or predominantly wild-type virus populations. However, sensitivity for detecting presence of a mutation is variable when both wild-type and mutant viruses are present as a mixture. In general, mutant species must constitute 10–20% of the population to be detected by standard sequencing methods. Some mutations may go undetected unless they are present as the majority species.

Phenotypic tests of HIV-1 drug resistance

Drug susceptibility tests with HIV-1 usually are performed using a recombinant virus assay, in which the viral genes of interest (e.g. PR and RT) are introduced into a plasmid that carries all of the other viral genes needed for replication in cell culture (see Fig. 137.4).[10] [11] Modification of the assay allows introduction of the integrase (IN) or envelope (ENV) genes in order to determine susceptibility to integrase inhibitors and entry inhibitors, respectively. Using these assays, small differences in susceptibility can be detected (~2- to 4-fold compared with control). Phenotypic assays are more complex and labor intensive than genotypic assays. Automation makes it possible to test many samples simultaneously, and allows for high throughput. However, the cost and complexity of the automation limit availability of these assays to a few reference laboratories.

Viral fitness and replication capacity assays

Accumulation of drug resistance mutations can decrease the replication capacity of the virus. In the absence of drug, resistant variants are significantly less fit than wild-type and are replaced by wild-type virus if antiretroviral therapy is interrupted.[12] Viral fitness can be assessed by growth competition assays, in which the relative replication of two or more viral species is tested in the same culture.[13] Alternatively, viral replication capacity can be measured by a modification of the phenotypic resistance assay. At present, the clinical utility of these assays remains undefined.

Therapeutic drug monitoring

Therapeutic drug monitoring (TDM) is used to maintain plasma levels of a drug within a defined therapeutic range in order to maximize efficacy and minimize toxicity. Plasma concentrations of antiretroviral drugs following administration of a standardized dose show considerable interpatient variation. In theory, TDM of antiretroviral agents could lead to dosage adjustments that would correct for this variation. Although measuring the plasma concentration of most antiretroviral drugs is relatively straightforward, establishing a therapeutic range is more difficult. Consequently, the data needed to guide dosage adjustment for currently available antiretroviral drugs given a particular plasma concentration are lacking. Moreover, in the case of nucleoside RT inhibitors, concentration-response relationships have not been demonstrated consistently. Nevertheless, TDM is likely to prove useful for non-nucleoside RT inhibitors and protease inhibitors, and efforts to generate the information needed to establish clinical utility of TDM are underway.

CLINICAL USE OF HIV DIAGNOSTIC TESTS

Diagnosing acute HIV-1 infection

After exposure to the virus, HIV RNA can be detected from day 12 and p24 antigen from days 14–16 (Fig. 137.5). Detection of HIV-1 p24 antigen has a sensitivity of approximately 90% and a specificity of 100% in the diagnosis of acute infection.[14] HIV-1 RNA assays have a sensitivity of 100% in diagnosing acute infection, but at the cost of lowered specificity (97%). Because of the potential social and legal ramifications of a false-positive HIV-1 test, and the need to perform additional testing to clarify a patient's HIV infection status, some experts prefer p24 antigen assays in this setting. However, false-positive HIV-1 RNA tests usually have titers less than 10,000 copies/ml, whereas HIV-1

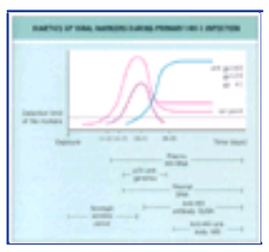

Figure 137-5 Kinetics of viral markers during primary HIV-1 infection. The first positive viral marker is plasma RNA 11–12 days after infection. p24 Antigenemia is detectable on day 14 or 15. The first anti-HIV antibodies are detectable by third-generation ELISAs on days 20–21. (Pink, plasma HIV RNA; purple, p24 antigenemia; blue, anti-HIV antibody).

TABLE 137-3 -- Diagnosis of acute and early HIV infection.

DIAGNOSIS OF ACUTE AND EARLY HIV INFECTION	
EIA negative	• p24 Antigen positive, or
	• Plasma HIV-1 RNA >10,000 copies/ml
EIA positive	• Evolving WB pattern, and/or
	• EIA-negative by 'detuned' assay

RNA levels generally exceed 100,000 copies/ml in primary infection. Thus, plasma HIV-1 RNA testing might be used in selected cases where a history of recent exposure and symptoms consistent with acute HIV-1 infection provide a high index of suspicion (Table 137.3).

The first antibodies are detectable on day 21. However, the kinetics of these markers can vary according to the patient and infecting strain; antibodies against non-B subtypes may be less well recognized early after infection.[15] It is generally agreed that beyond week 6 after infection antibodies are detectable in almost all patients. Reactivity by WB lags behind seroconversion by EIA. Therefore, a positive EIA and negative or evolving WB can provide evidence of recent infection, particularly if antibodies directed against gag proteins are present (Fig. 137.6). A fully reactive WB usually develops within 6 months.[16] Recent seroconverters can also be identified by use of a less sensitive ('detuned') third-generation EIA. Patients infected within 5–6 months prior to testing are reactive on the sensitive EIA but nonreactive on the detuned EIA. A two-step algorithm using a sensitive/less sensitive EIA testing strategy can correctly identify nearly all recent seroconverters.[15]

Diagnosing chronic HIV-1 infection

Testing for HIV antibodies is a two-stage process: samples that test positive by an initial screening assay are retested to exclude clerical

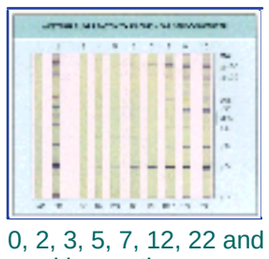

Figure 137-6 Western blot reactivity in one HIV-1 seroconverter. Lanes 1 and 2, negative (NC) and positive controls (PC). Lanes 3–10, serial samples collected on days (D) 0, 2, 3, 5, 7, 12, 22 and 30. Day 0 corresponds to the first collected sample. Anti-p24 was the first antibody detected, rapidly followed by anti-gp160, p55, p40 and gp120. Later, gp41 and p18 are weakly reactive.

or laboratory error and a confirmatory assay is performed on repeatedly reactive sera to verify that the antibodies are directed against HIV antigens. Screening in industrialized countries generally is based on the EIA and in most resource-poor countries on rapid kits. In some countries (France, Switzerland) two different kits must be combined for screening purposes to reduce the risks linked to human error and the possible failure of one test. The possibility of false positivity means that positive screening tests must always be confirmed with highly specific tests.

The WB is the most commonly used confirmatory test, although indirect immunofluorescence assays are used occasionally. Confirmation of a reactive EIA by positive WB establishes the diagnosis of HIV infection. A negative WB suggests a false-positive EIA or acute infection (see above). Criteria for interpretation of HIV-1 WBs have been developed by several groups, but no uniform standard has been adopted (Table 137.4).[17]

TABLE 137-4 -- Criteria for Western blot interpretation.

CRITERIA FOR WB INTERPRETATION	
Organization	**Criteria**
American Red Cross	At least one band from each structural gene product (*gag*, *pol* and *env*)
US Centers for Disease Control and Prevention and Association of State and Territorial Public Health Directors	Reactivity to any two of p24, gp41 or gp120/160
Directors	

Consortium for Retrovirus Serology Standardization	p24 or p31 and one of gp41 or gp120/160
Du Pont	p24 and p31 and gp41 or gp120/160
World Health Organization	Reactivity to two envelope glycoproteins

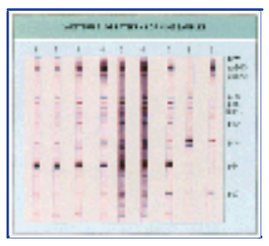

Figure 137-7 Different Western blot patterns of nine samples. Samples 1, 2 and 3 are from recent seroconverters infected by HIV-1 subtype B. Western blot is weakly reactive on gp41 and *pol* products. Patient 4 has a slight decrease in *gag* products by WB. Patients 5 and 6 are fully WB reactive. Patient 7 is a recent seroconverter infected by HIV-1 subtype A. gp120 and gp41 are weakly reactive. Patient 8 is infected with HIV-1 group O. The WB pattern is highly suggestive of infection by a variant, with no *env* reactivity and strong *pol* reactivity. Patient 9 is in the terminal phase of AIDS, with disappearance of *gag* reactivity.

Careful interpretation of the WB can be highly informative (Fig. 137.7).

- A complete pattern (all bands) with reactivity at least as strong as that of the positive control is suggestive of infection dating back more than 6 months.
- Absent or weak reactivity with proteins p68, p52 and p34 (*pol* gene products) is suggestive of recent primary infection (less than 6 months). Follow-up of the kinetics of appearance of these antibodies will confirm recent seroconversion.
- A fall in reactivity to the core proteins p55, p40 and p24 is found in patients infected many years previously.
- Weak reactivity with *env* gene products and strong reactivity with *pol* gene products can point to nonsubtype B infection.

Occasionally, individuals at low risk of infection are identified through screening as having repeatedly positive EIAs and persistent indeterminate WBs. This situation arises most often in patients with rheumatoid arthritis, systemic lupus erythematosuis or polyclonal gammopathy. Such individuals usually are not HIV infected; a negative HIV-1 DNA PCR test can provide additional reassurance.

Diagnosing HIV-1 infection in children

Transplacental passage of IgG leads to a reactive EIA and positive WB that decrease with time. Passively transmitted antibodies disappear by the age of 15 months; their persistence beyond this time is diagnostic of HIV-1 infection in the infant. Serologic screening of the mother should be offered routinely at the outset of all pregnancies. If the mother is HIV negative despite the existence of risk factors, the result should be checked before delivery, as primary infection is possible during pregnancy.

Early diagnosis of mother-to-child transmission (MTCT) is based on the detection of nucleic acids or the virus in several samples. Current guidelines recommend testing infants born to HIV-infected mothers at age 48 hours, 1–2 months and 3–6 months.[18] A positive

TABLE 137-5 -- Epidemiologic risk factors associated with HIV-2 infection.

EPIDEMIOLOGIC RISK FACTORS ASSOCIATED WITH HIV-2 INFECTION
• Sexual contact or needle sharing with HIV-2-infected individual
• Person originating from HIV-2-endemic region
• Receipt of blood transfusion in an HIV-2-endemic region
• Child born of an HIV-2-infected mother

test suggests the possibility of HIV-1 infection, and should be confirmed by a second test as soon as possible. DNA PCR tests are positive in 40% of infected neonates by 48 hours of age and in 93% of infected infants by day 14;[19] virus culture has similar sensitivity and specificity, but is more costly and time consuming. The sensitivity and specificity of RNA tests for diagnosis of HIV-1 infection in neonates have not been defined.

Diagnosing HIV-2 infection

Cross-reactivity of HIV-2 in HIV-1 EIAs ranges from 50% to 93%. [20] In the USA, blood banks use a combination HIV-1/HIV-2 antigen sandwich EIA to screen for HIV infection, but screening for HIV-2 is not routinely performed in other settings. Therefore, an HIV-2-specific EIA should be obtained when the epidemiologic setting suggests the possibility of HIV-2 infection (Table 137.5).

Virus load monitoring

Plasma HIV-1 RNA levels are correlated with disease stage. Patients who have symptomatic HIV infection or AIDS have significantly higher virus loads than do those with asymptomatic infection. The plasma HIV-1 RNA titer is also a powerful predictor of the risk of disease progression and death at all stages of disease. The change in plasma HIV-1 RNA level in response to treatment also provides important clinical information. Analyses from several large clinical trials show a significant correlation between the magnitude of plasma HIV-1 RNA reduction from baseline and the extent of clinical benefit.[21] Conversely, a rise in plasma HIV-1 RNA level suggests failure of a treatment regimen to suppress virus replication.

Analysis of the virologic response to therapy reveals the importance of the nadir achieved in plasma HIV-1 RNA levels as a marker for the duration of virus suppression.[22] Several studies also show that the early response to treatment is predictive of long-term outcome. Substantial increases in the CD4 cell count may be sustained even if plasma viremia remains detectable, so long as virus load remains significantly below the pretreatment baseline.

Samples should be collected in EDTA tubes and plasma separated and stored at -70°C until testing. Although HIV-1 RNA is stable in plasma at room temperature for up to 48 hours, samples should be processed within 6 hours if possible. Because clinical events that lead to immune activation can cause transient increases in virus load, plasma HIV-1 RNA testing should not be performed within 4 weeks of intercurrent infection or vaccination.

Treatment guidelines recommend obtaining two measurements of plasma HIV-1 RNA to determine the baseline or 'set-point' virus load.[23] Virus load testing should be performed immediately prior to initiating treatment and repeated within 2–8 weeks of starting treatment in order to assess the initial response to a regimen. In treatment-naive patients the plasma HIV-1 RNA level should drop by at least 1.0 $\log_{10}$ within 4–8 weeks of starting an initial antiretroviral regimen; by week 16 plasma virus should be undetectable (below 50 copies/ml) in most patients. More than 24 weeks may be required for plasma virus titers to fall below the limit of detection in patients with high pretreatment levels of viremia (above

Figure 137-8 Mutations in HIV-1 reverse transcriptase and protease associated with drug resistance. Wild-type amino acids are shown above the bar, and mutant amino acids are shown below the bar. Numbers indicate amino acid position. Vertical bars indicate cross-resistance. Bold-face indicates major protease inhibitor resistance mutations. 100,000 copies/ml). Declines of 0.5 $\log_{10}$ or more should be expected within 8 weeks following a change in regimen due to treatment failure. Subsequently, plasma HIV-1 RNA levels should be repeated every 3–4 months in order to monitor the success of antiretroviral therapy.

CLINICAL USE OF DRUG RESISTANCE TESTING

Interpreting HIV-1 drug resistance tests

Various systems for interpreting HIV-1 genotypes have been developed. Most interpretations use a 'rules-based' approach in which a group of experts determine which mutations or combination of mutations are associated with resistance to specific drugs, and establish an algorithm for interpreting the genotype (Fig. 137.8). These algorithms are used as the basis of automated computer-generated reports, but require periodic updating as new information becomes available. Alternatively, clinicians may refer to one of a number of online websites that offer genotype interpretation (Table 137.6).

An alternative approach to interpreting genotypic resistance tests is the 'virtual' phenotype. This approach makes use of a large database (>30,000 samples) with paired genotypic and phenotypic data. Viruses with genotypes that are similar to the patient's virus are identified by searching the database and the average IC_{50} of these matching viruses is calculated. This information is then used to estimate the likely phenotype of the patient's virus. The actual and virtual phenotype show excellent correlation for most drugs. The strength of this approach is that it reduces complex genotypic data to simple phenotypic categories based on a rational, data-driven analysis of similar genotypes. However, the virtual phenotype only provides an estimate of the *probable* phenotype of the patient's virus. The confidence placed in the result depends on the number of matches and on picking the right codons to incorporate into the database search. Correlation between actual and virtual phenotype will be weaker for newer drugs or in cases where there are fewer matches due to unusual genotypes.

Interpreting phenotypic resistance tests requires appropriate definition of the 'cut-off' between susceptible and resistant viruses for each drug. Ideally, cut-offs would be defined as the fold-change in susceptibility that corresponds to a reduction in clinical activity of the drug in question. Such data are available only for a few drugs, however, including abacavir, tenofovir and lopinavir. Consequently, definitions of 'susceptible' and 'resistant' for other antiretroviral drugs are based on assay variation and/or population-based susceptibility data for wild-type viruses. Even when based on virologic response data, cut-offs can be misleading, as for most drugs there is a continuous relationship between susceptibility and antiviral activity. Thus, it might be more realistic to consider drugs as having greater or lesser activity against viruses that are more or less susceptible.

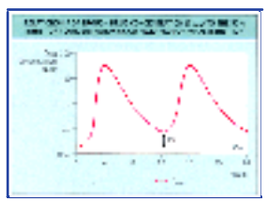

Figure 137-9 Relationship of trough drug concentration (C_{min}) to the 50% inhibitory concentration (IC_{50}) required for viral inhibition. IQ, inhibitory quotient (C_{min} :IC_{50}).

When combined with therapeutic drug monitoring, resistance tests can be interpreted by relating the observed IC_{50} of an isolate to the trough concentration (C_{min} of that drug in a particular patient). The relationship between drug exposure and drug susceptibility can be explored through the inhibitory quotient (IQ), which is the C_{min} :IC_{50} ratio (Fig. 137.9). A high IQ (significantly greater than 1.0) suggests the trough plasma concentration is greater than the amount of drug needed to inhibit the virus in question; a low IQ suggests inadequate drug levels or a highly resistant virus.

Clinical utility of drug resistance testing

Retrospective studies and randomized clinical trials demonstrate the clinical utility of drug resistance testing. A meta-analysis of studies that used either genotype or phenotype to characterize patient viruses found that the risk of virologic failure during salvage therapy was reduced by 30–50% for each drug in the new regimen that was predicted to have activity on the basis of the resistance test performed.[24] These studies also showed that drug resistance remained a significant independent predictor of the likelihood of treatment failure even after controlling for treatment history. Similar results have been obtained with the virtual phenotype.

In randomized clinical trials, virologic response to salvage therapy for patients failing a current treatment regimen generally was superior when therapy was chosen on the basis of genotypic or phenotypic drug resistance testing (Table 137.7). These studies also demonstrated the value of expert advice in selecting a salvage regimen and the necessity of achieving adequate drug levels in plasma. Overall, the benefit of genotyping is clearest in patients failing a first or second regimen, whereas the benefit of phenotyping is most evident in highly treatment-experienced patients. Given the high cost of antiretroviral therapy, using resistance testing to select the best salvage regimen is highly cost-effective.[25]

Recommended uses of drug resistance testing

Most experts recommend use of drug resistance testing to guide the selection of salvage therapy for patients in whom current therapy is failing, and in pregnant women.[26] Resistance testing should also be considered for patients with acute or recent HIV infection. Given the evidence that transmission of drug-resistant HIV-1 is on the rise,[27] testing of all patients prior to initiation of antiretroviral therapy is reasonable where affordable.

TABLE 137-7 -- Randomized trials of HIV-1 drug resistance testing.

RANDOMIZED TRIALS OF HIV-1 DRUG RESISTANCE TESTING			
	Study	**Result**	**Reference**

Genotyping	VIRADAPT	Genotyping superior to SOC	Durant *et al.*[29]
	GART	Genotyping + expert advice superior to SOC	Baxter *et al.*[30]
	ARGENTA	Genotyping superior to SOC in more adherent, less treatment-experienced patients	Cingolani *et al.*[31]
	NARVAL	Genotyping superior to SOC in patients with lower VL, less treatment experience	Maynard *et al.*[32]
	HAVANA	Genotyping and expert each superior to SOC, best in combination	Tural *et al.*[36]
	CERT	No benefit of genotyping	Wegner *et al.*[33]
Phenotyping	VIRA 3001	Phenotyping superior to SOC	Cohen *et al.*[34]
	NARVAL	No benefit of phenotyping	Maynard *et al.*[32]
	CCTG 575	Phenotyping superior to SOC in highly treatment-experienced patients	Haubrich *et al.*[35]
	CERT	Phenotyping superior to SOC in highly treatment-experienced and NNRTI-experienced patients	Wegner *et al.*[33]
SOC, standard of care; VL, virus load; NNRTI, nonnucleoside reverse transcriptase inhibitors			

For treatment-experienced patients, resistance testing will be most informative if samples are obtained while the patient continues on the failing regimen. Once a regimen is stopped, there is the possibility that residual wild-type virus will rapidly overgrow the less fit drug-resistant mutants, giving a potentially misleading test result. To ensure accurate results, testing should be reserved for patients with virus load above 1000 copies/ml. If resistance to a drug is identified, then that drug is likely to have little or no activity and should be avoided, if possible. Similarly, if resistance to a drug has ever been identified, it is safe to assume that resistant virus persists, even if not detected in a current sample. Absence of resistance in the context of treatment failure may be evidence of nonadherence or a pharmacologic barrier to drug activity.

Ultimately, the best choice of therapy for an individual patient should be determined by taking into account all the information available, including history, disease stage, virus load, CD4 count and patient preferences. Although resistance testing is a useful tool, it is not a substitute for sound clinical judgment.

Chapter 138 - Principles of Management in the Developed World

INTRODUCTION

The management of HIV infection continues to evolve as treatments, treatment strategies, laboratory investigations and our understanding of pathogenesis have changed. Not only is viral load testing now available but viral resistance assessments and pharmacokinetic measurements of antiretroviral agents are crossing over from the research laboratory to clinical practice. Improved longevity with better antiretroviral therapy has also been associated with increased incidence, awareness and understanding of various adverse effects of antiretroviral therapy. These include osteoporosis, lactic acidemia, disorders of fat accumulation and fat wasting (lipodystrophy), dyslipidemias, glucose intolerance, hypertension, hepatic toxicity and liver failure.

Traditionally, the $CD4^+$ lymphocyte count has been regarded as the key surrogate marker for prognostic staging and therapeutic monitoring of HIV-infected individuals. Then new molecular techniques became available to detect circulating virion-associated HIV RNA in plasma. The availability of HIV viral load testing led to a major revision of our understanding of the natural history of HIV disease.[1] [2] [3] [4] [5] [6] [7] The notion of a prolonged phase of virologic latency antedating the symptomatic phase of the disease has been replaced by one of continuous viral replication from the time of infection until the terminal phases of the illness. It became clear that an ongoing high viral turnover is directly responsible for the ultimate destruction of the immune system.[3] The rate of $CD4^+$ lymphocyte loss will ultimately be dependent on the balance between viral replication, hence $CD4^+$ lymphocyte destruction, and $CD4^+$ lymphocyte production (see Chapter 130).

Antiretroviral therapy has been shown to decrease AIDS-related death rates, opportunistic infections and hospitalizations.[8] [9] [10] [11] [12] The potency of the immunologic recovery seen with antiretroviral therapy has, in fact, been associated in some patients with recognition of previously subclinical infection and has been coined an 'immune reconstitution syndrome'.[13] [14] Immune reconstitution has also led to an ability to discontinue prophylaxis and even suppressive therapy for opportunistic infection in some settings.[15] [16]

In the past few years an awareness of the need to intervene for HIV with antiretroviral therapies at the correct moment has emerged. Long-term therapy has become associated with various adverse effects as well as incomplete adherence to medications — often leading to the development of drug-resistant strains of virus. Although the 'hit early, hit hard' philosophy has played a role in the management of HIV, current thinking has seen the pendulum swing back to a 'watchful waiting' scenario.[17] [18]

LABORATORY MARKERS OF DISEASE PROGRESSION

Three assays are currently available to quantify plasma HIV-1 viral load. These are commonly referred to as reverse transcriptase polymerase chain reaction (RT-PCR), branched chain DNA and nucleic acid sequence-based amplification. All three assays are generally comparable from a technical standpoint. They are also similar in their reproducibility and physiologic variability. The lower threshold of detection is in the range of 200–500 copies/ml, with the newer RT-PCR assays having a lower limit of detection of 50 copies/ml. The variability of the assays is approximately $0.3\log_{10}$ within the dynamic range of the test. As a result, a $0.5\log_{10}$ change in HIV RNA level is generally regarded as a significant viral load change in the context of antiretroviral therapy. It should be noted that intercurrent events (such as infections) or vaccinations can transiently but substantially increase plasma viral load.[19] [20] [21] [22]

Levels of viral replication appear to be set soon after primary infection.[23] Plasma RNA viral load has been correlated with disease progression and death in a seropositive cohort of untreated gay men using archival samples.[24] Patients were divided into four equal groups (quartiles) based on their viral load levels (Table 138.1). In contrast to the close relationship between baseline viral load and outcome, baseline $CD4^+$ lymphocyte count failed to show a similar gradient among quartiles for the risk of disease progression or death. Furthermore, among the three quartiles with the highest $CD4^+$ lymphocyte count, no differences in these outcomes were observed.

These data also provided conclusive evidence of the independence of viral load from $CD4^+$ lymphocyte counts with regard to prognosis. Among patients who had a $CD4^+$ lymphocyte count of more than $500/mm^3$, there was a significant difference in time to death according to whether the baseline viral load was above or below the median (10,190 copies/ml). The 10-year survival was 70% and 20%, for the low- and high-viral-load groups, respectively; both groups had a median $CD4^+$ lymphocyte count of approximately $780/mm^3$. Similarly, among those who had a baseline $CD4^+$ lymphocyte count below 500/ml, a significantly shorter survival was associated with a baseline HIV RNA greater than the median (17,320 copies/ml), despite similar baseline $CD4^+$ counts within the groups.

Despite the integral role of plasma viral load in HIV management, the $CD4^+$ count continues to be an important and useful test, helping to determine where a patient is on the continuum of HIV disease. In adults, a $CD4^+$ lymphocyte count range of approximately 400–1400 cells/mm^3 is considered normal. Counts below 200 cells/mm^3 are associated with increased risk of opportunistic infection.

TABLE 138-1 -- Relationship between viral load and outcome.*

RELATIONSHIP BETWEEN VIRAL LOAD AND OUTCOME				
Viral load (HIV RNA copies/ml)	**Progression to AIDS at 5 years (%)**	**Median time to AIDS (years)**	**Progression to death at 5 years (%)**	**Median estimated survival (years)**
=4530	8	>10	5	>10
4531–13,020	26	7.7	10	9.5
13,021–36,270	49	5.3	25	7.4
>36,270	62	3.5	49	5.1
These viral load thresholds specifically apply to the study group under the particular circumstances of the study. Caution should be exercised when extrapolating to specific clinical situations. The values obtained will vary depending on assay methodology. Also, samples run on a real-time basis are likely to be higher than those specified here.				

** Adapted from Mellors et al.[24]*

The $CD4^+$ lymphocyte count is usually reported as a fraction (or percentage) and an absolute count. Although the absolute $CD4^+$ lymphocyte count is usually sufficient to guide the clinical management of a given patient, it must be noted that under specific circumstances this may be misleading. For example, patients who have undergone splenectomy typically have a relatively high absolute $CD4^+$ count. In such patients the $CD4^+$ lymphocyte fraction is a more appropriate reflection of their immunologic status. It is therefore advisable to monitor the $CD4^+$ lymphocyte fraction in tandem with the $CD4^+$ count at all times to ensure that these are in general

agreement.

Substantial diurnal variation is shown by $CD4^+$ counts; they are lowest in the morning and highest in the evening. In normal individuals the evening $CD4^+$ lymphocyte count can be nearly double what it is in the morning. Although the normal physiologic variation may be reduced in HIV-infected patients, it is still recommended that specimens for $CD4^+$ counting in HIV-infected patients be collected in the morning. Patients should be advised to avoid alcohol, smoking and exercise before collection of the specimen. Other factors that may affect the count include acute infections such as common viral illnesses, certain pharmaceutical agents such as corticosteroids, vaccinations and stress. The results may also be influenced by differing laboratory methodologies. Short-term fluctuations in $CD4^+$ lymphocyte counts of up to 30% have been shown to occur in HIV-infected individuals who are clinically stable.[5] In addition, correlation between $CD4^+$ lymphocyte count and clinical status can be quite different from one patient to the next. Overall, it is important to monitor the trends in $CD4^+$ counts over time rather than placing too much emphasis on a single reading.[25] [26]

From a practical standpoint it is useful to consider the $CD4^+$ lymphocyte count as indicative of the level of immunosuppression or, better yet, 'the immunologic damage that has already occurred'. On the other hand, the plasma viral load better illustrates disease activity and therefore 'the damage that is about to occur'. The prognostic contribution of viral load determinations at any level of $CD4^+$ lymphocyte count is illustrated in Figure 138.1 . Clinical trials have demonstrated conclusively that a change in plasma HIV-1 RNA viral

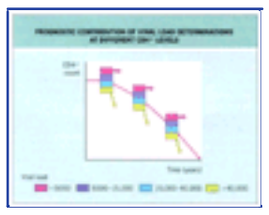

Figure 138-1 Prognostic contribution of viral load determinations at different $CD4^+$ levels. For a given $CD4^+$ lymphocyte count, individuals with high viral load will have a more rapid decline in $CD4^+$ count and therefore a worse clinical prognosis (demonstrated by the downward shift of the survival curve). The viral load is an independent predictor of rapidity of disease progression. A more aggressive virus phenotype — syncytium-inducing versus non-syncytium-inducing — may also adversely affect prognosis, as may viral strains that are resistant to antiretroviral medications.

load is associated with a change in the rate of disease progression.[27] [28] [29] In this context, a treatment-induced 10-fold ($1\log_{10}$) reduction in plasma HIV-1 RNA was associated with a decrease of approximately 50% in the relative risk of death.

On the basis of these data, $CD4^+$ lymphocyte counts and plasma viral load should be measured every 3–4 months in stable HIV-infected adults as part of their routine evaluation. More frequent determinations are warranted under special circumstances, such as when introducing antiretroviral therapy. It should be noted that the use of other surrogate markers such as $ß_2$ -microglobulin, C1q or immune complexes, erythrocyte sedimentation rate and neopterin are no longer recommended in clinical practice.

Advances in the research laboratory are becoming important in the clinical care of patients. Testing for resistance to antiretrovirals can now identify drugs that perhaps should be excluded from a new regimen (see Chapter 137).[30] However, the factors influencing successful therapy are multiple and include the patient's adherence to the regimen and serum or intracellular drug levels, in addition to many others — not only susceptibility testing. Therapeutic drug monitoring of patients receiving nelfinavir-based therapy was recently shown to improve virologic outcomes in a pilot study.[31] Further trials are currently underway aimed to characterize better the optimal use of therapeutic drug monitoring. Until these results are available, therapeutic drug monitoring should be regarded as an experimental tool to be used selectively in special cases, such as patients requiring dose adjustments due to unusual toxicities or those receiving poorly characterized drug combinations.

BASELINE EVALUATION

Baseline evaluation of an infected individual should include a complete history and physical examination. Counseling should be given regularly. Laboratory tests are also very important, particularly before the start of a treatment program. These should include those listed in Table 138.2 .

In terms of blood counts, it is worth noting that anemia, neutropenia and thrombocytopenia are common in patients who have HIV infection. Absolute lymphopenia should raise suspicion of advanced disease. The criterion for the tuberculin skin test is that an induration of 5mm or more in diameter after a 5 tuberculin units purified protein derivative (PPD) test should be regarded as a positive response in an HIV-infected individual; isoniazid prophylaxis

TABLE 138-2 -- Laboratory tests for baseline evaluation of HIV-infected patients.

LABORATORY TESTS FOR BASELINE EVALUATION OF HIV-INFECTED PATIENTS
• Plasma HIV RNA viral load
• $CD4^+$ lymphocyte count, absolute and percentage
• Complete blood count and differential and platelet count
• Liver (aspartate aminotransferase, lactate dehydrogenase, alkaline phosphatase, bilirubin) and renal (blood urea nitrogen, creatinine) profiles
• Creatine phosphokinase, amylase, uric acid and triglycerides
• Hepatitis B, hepatitis C, syphilis, cytomegalovirus (CMV) and toxoplasmosis serologies
• Tuberculin skin test
• Cultures and smears for sexually transmitted diseases, as indicated by the history and physical examination
• Sputum cultures and smears for mycobacteriae, as indicated by history and physical examination
• Chest radiograph
• Urinalysis
• Pregnancy test
• Papanicolaou's smear test (if appropriate)
• Eye fundoscopy if the $CD4^+$ count is <100/ml

should therefore be considered. A negative response in persons who have advanced HIV disease does not rule out infection with *Mycobacterium tuberculosis*, as such individuals may be anergic.[32] [33]

FOLLOW-UP ASSESSMENT

The routine follow-up of a stable asymptomatic HIV-positive patient should include a history and physical examination as well as plasma viral load and $CD4^+$ lymphocyte count every 3–4 months. Counseling should take place at each visit. Patients should also have an opportunity to discuss the most recent trends in management and antiretroviral therapy.

Symptomatic patients and those who have AIDS require active drug therapy and as such they should be seen at least monthly. More frequent and additional laboratory investigations may be warranted for patients presenting with co-morbidities such as viral hepatitis (B or C) or psychiatric illness.

GENERAL APPROACH TO THE SYMPTOMATIC PATIENT

Not every illness in an HIV-infected patient is attributable, or unique, to HIV infection or AIDS. HIV-infected patients, like everyone else, are susceptible to all the usual

illnesses. In fact, as a result of the immune dysfunction that characterizes HIV infection even before the development of overt AIDS, patients typically present with often repeated bouts of common illnesses, such as seborrheic dermatitis, eczema, angular cheilitis, shingles, onychomycosis, sinusitis or community-acquired pneumonia. When signs and symptoms appear, management should be the same as in uninfected individuals.

When $CD4^+$ lymphocyte counts are within the normal range, immune function in adults is almost normal and opportunistic infections are unlikely. The work-up does not usually require any special initiatives. However, it should be noted that some conditions, such as tuberculosis, Kaposi's sarcoma or lymphomas, can occur at any level of $CD4^+$ lymphocyte count. One should have a higher index of suspicion for opportunistic infections as the $CD4^+$ lymphocyte count falls below normal, and particularly once it is below 200 cells/mm^3 or below a $CD4^+$ lymphocyte fraction of 15%.[34]

PROPHYLACTIC TREATMENTS AND VACCINATIONS

Prevention plays a major role in the management of HIV-infected individuals. The following interventions should be considered when a newly diagnosed patient is evaluated.

Tuberculin skin test

A tuberculin skin test should be performed. If there is induration of 5mm or more in diameter, then prophylaxis with isoniazid 5mg/kg daily (maximum 300mg/day) for 12 months should be initiated, along with pyridoxine to reduce the risk of isoniazid toxicity.[32] Prophylaxis may also be indicated in patients at high risk of tuberculosis who have cutaneous anergy or household contact with someone with active tuberculosis, patients who have chest radiograph findings suggestive of previous tuberculosis who do not have a history of adequate treatment, or patients who have not previously received isoniazid prophylaxis or tuberculosis treatment.[32] [33] [34] A positive tuberculin skin test should be interpreted with caution among immigrants, who may have received tuberculosis vaccine during childhood.

Vaccination against common pathogens

While antigen recognition is still intact, it is essential to boost humoral immunity against certain common pathogens. Recommended

TABLE 138-3 -- Vaccination against common travel-related pathogens.

VACCINATION AGAINST COMMON TRAVEL-RELATED PATHOGENS	
Vaccine	**Comments**
	In general, live vaccines should be avoided
Measles	Not recommended for travelers who are severely immunocompromised*
Typhoid	The inactivated parenteral typhoid vaccine should be given instead of the live, attenuated oral vaccine
Yellow fever	Live vaccine of uncertain safety in HIV†
Hepatitis A	A killed vaccine that should be used as for non-HIV-infected travelers‡
Diphtheria-tetanus	A killed vaccine that should be used as for non-HIV-infected travelers
Japanese encephalitis	A killed vaccine that should be used as for non-HIV-infected travelers
Rabies	A killed vaccine that should be used as for non-HIV-infected travelers

* Measles vaccine is recommended for nonimmune travelers. However, measles vaccine is not recommended for travelers who are severely immunocompromised; immune globulin should be considered for measles-susceptible, severely immunosuppressed travelers who are anticipating travel to measles endemic countries.
† Travelers with asymptomatic HIV infection who cannot avoid potential exposure to yellow fever should be offered the choice of vaccination. All travelers should avoid mosquito bites.
‡ In the setting of immunosuppression, these vaccines may not offer complete protection.

vaccines include polyvalent vaccine against *Streptococcus pneumoniae* (Pneumovax) given once, and influenza vaccine given annually in the autumn.[35] [36] The evidence in favor of the latter, however, remains controversial. Tetanus toxoid updates should be offered as necessary, and hepatitis B vaccination should be encouraged for any susceptible patient. Male homosexual HIV-positive men should also receive hepatitis A vaccine. The inactivated polio vaccination should be given to any patient who is traveling. Table 138.3 summarizes additional travel-related vaccine advice. Vaccines against *Haemophilus influenzae* type b and *Neisseria meningitidis* are at present not widely recommended.

Prophylaxis and treatment for opportunistic infections (see Chapter 123)

As shown in Table 138.4 , as HIV disease progresses prophylaxis and treatment of opportunistic infections become increasingly important. Recurrent genital herpes outbreaks may be dealt with using either intermittent treatment or regular suppressive therapy with oral acyclovir, depending on the frequency of the attacks.[37] Mucosal candidiasis may be treated with topical agents or systemic azoles as needed. Systemic azole therapy is usually needed as the immunodeficiency progresses. In some patients intermittent or even continued suppressive therapy with systemic azoles may be warranted to control frequent relapses.

More than 80% of untreated HIV infected individuals will have at least one episode of *Pneumocystis carinii* pneumonia (PCP) during their lifetime. Prophylaxis against PCP is indicated if the $CD4^+$ lymphocyte count is below 200/mm^3 , if the $CD4^+$ lymphocyte fraction is below 15%, if there is a history of recurrent *Candida* infections, or if there are chronic constitutional symptoms such as persistent unexplained fevers and weight loss. All patients should be offered PCP prophylaxis after an episode of PCP (secondary prophylaxis). Prophylaxis against PCP should also be offered to any patient who has had an AIDS-defining illness. The preferred regimen consists of one double-strength tablet of trimethoprim-sulfamethoxazole daily.[37] Alternatively, dapsone 100mg q24h, atovaquone 1500 mg q24h or aerosol pentamidine 300mg once a month can be used. Before starting prophylaxis, patients should be assessed to rule out active pulmonary

TABLE 138-4 -- Prophylaxis and treatment for opportunistic infections.

PROPHYLAXIS AND TREATMENT FOR OPPORTUNISTIC INFECTIONS	
$CD4^+$ lymphocyte count (no/ml)	**Management strategy**
>500	• General counseling (safer sex, nutrition, etc.)
	• History and physical examination every 3–6 months
	• Plasma viral load and $CD4^+$ count every 3–6 months
	• Pneumovax, annual influenza vaccinations
	• Tuberculin skin test and INH prophylaxis if indicated
	• Update diphtheria-pertussis-tetanus (tetanus toxoid for adults) and inactivated polio vaccinations
	• Hepatitis B vaccine if at risk
	• Syphilis serology

<500	• Antiretroviral therapy followed by plasma viral load 1 month later
	• Plasma viral load and $CD4^+$ count every 3–4 months
	• Herpes suppression if frequent recurrences (more than 4–6 outbreaks/year)
	• Relevant history, physical and laboratory investigations at least monthly if symptomatic, diagnosed with AIDS or on antiretroviral therapy
<200	• Start prophylaxis for PCP
<100	• Plasma viral load and $CD4^+$ count every 3–4 months
	• Start prophylaxis for toxoplasmosis if seropositive and not on trimethoprim-sulfamethoxazole
<75	• Consider MAC prophylaxis
<50	• Screening by an ophthalmologist for cytomegalovirus (CMV) retinitis, to be repeated at 3- to 6-monthly intervals; consider CMV prophylaxis

disease. In the context of continued use of highly active antiretroviral therapy (HAART), patients having adequate responses, such as HIV RNA levels below 50 copies/ml and a $CD4^+$ lymphocyte count recovery to 200 cells/mm^3 or more for at least 3 months should be encouraged to discontinue either primary or secondary PCP prophylaxis.[38] [39]

Prophylaxis for toxoplasmosis is indicated for those patients who have positive serum IgG for toxoplasmosis and $CD4^+$ lymphocyte count less than 100/mm^3 . It is worth noting that trimethoprim-sulfamethoxazole, as indicated for PCP prophylaxis, is also effective against toxoplasmosis.[37] As with PCP, prophylaxis may be discontinued for patients who experience HAART-induced immune reconstitution associated with an increase in the $CD4^+$ lymphocyte count to more than 200/mm^3 for at least 3 months. Toxoplasma prophylaxis should be restarted if $CD4^+$ lymphocyte counts fall to less than 100/mm^3 .

There are currently insufficient data for a recommendation regarding the advisability of discontinuing secondary prophylaxis although this is increasingly being done without ill effects once the $CD4^+$ lymphocyte count is above 200/mm^3 for at least 3 months with the use of effective HAART.

As disease progresses, prophylaxis for *Mycobacterium avium* complex (MAC) with intermittent azithromycin or daily clarithromycin may also be considered once the $CD4^+$ lymphocyte count is below 50/mm^3 . MAC prophylaxis can be safely discontinued in patients who have responded to HAART with increased $CD4^+$ counts to more than 100 cells/mm^3 for at least 3 months.[15] Prophylaxis should be restarted if the $CD4^+$ level falls to below 50 cells/mm^3 . Once the $CD4^+$ lymphocyte count is below 100/mm^3 , screening by an ophthalmologist for cytomegalovirus retinitis should be encouraged, and this should be repeated at 3- to 6-monthly intervals thereafter, while the $CD4^+$ count remains below 100/mm^3 .

ANTIRETROVIRAL THERAPY

The objective of antiretroviral therapy use is to prevent disease progression and prolong survival while maintaining quality of life. Long-term nonprogression will be achieved by reducing plasma viral load below 50 copies/ml on a long-term basis. The use of combinations of antiretrovirals with no overlapping toxicity and demonstrated antiviral additive to synergistic effect is recommended to maximize the duration of the antiviral response.[18]

Since 1996, triple drug combination antiretroviral therapy has been shown to decrease morbidity and mortality dramatically in symptomatic and asymptomatic HIV-1 infected individuals.[8] [9] [10] [24] [40] [41] [42] Recommendations for the initiation of therapy have been crafted based on thresholds of $CD4^+$ lymphocyte counts and plasma HIV-1 RNA that reflect the risk for disease progression in natural history and observational studies as well as randomized clinical trials. [30] [43] [44] [45] [46] [47] The optimal time for initiation of therapy, however, has not been defined. Recent work has characterized rates of disease progression to AIDS or death for $CD4^+$ and plasma viral load thresholds in treated patients.[17] [48] [49] [50] In an analysis of a population-based cohort of 1200 HIV-1 infected patients, Hogg *et al.*[17] demonstrated low rates of disease progression to AIDS and death (<3% at 12 months) among patients starting antiretroviral therapy with $CD4^+$ lymphocyte counts of 200 cells/mm^3 or more, independent of HIV-RNA levels. In their study, disease progression to AIDS and death clustered among patients starting therapy with $CD4^+$ lymphocyte counts below 200 cells/mm^3 . From these results, it appears that 200 cells/mm^3 represents a critical $CD4^+$ threshold below which the short-term clinical effectiveness of antiretroviral therapy is at least partially compromised. Currently, it is recommended that all symptomatic individuals, as well as those who have $CD4^+$ lymphocyte counts below 250/mm^3 , be treated with HAART. The risk-benefit ratio associated with earlier intervention (i.e. 250–350 or 350–500/mm^3) remains to be clarified. Patients who have 250–350/mm^3 $CD4^+$ lymphocyte counts should be monitored closely with repeated $CD4^+$ counts, given that rapid declines in $CD4^+$ lymphocytes can occur, particularly among those who have HIV RNA levels of more than 30,000 copies/ml. In such instances, monthly monitoring may be appropriate.

The effectiveness of antiretroviral therapy relies not only on the appropriate time of initiation of treatment but also on the degree to which patients are able to adhere to therapy. Incomplete adherence to antiretroviral treatment has been associated with premature virologic failure.[51] Intermittent adherence increases the risk of having suboptimal drug levels, which in turn may increase the likelihood of drug resistance.[52] [53] Moreover, resistance to one drug is frequently associated with cross-resistance to other members of the same class,[54] [55] thus limiting future treatment options (see Chapter 140). Furthermore, not only has incomplete adherence been associated with premature virologic failure but it has also been linked with increased risk for mortality.[56] Thus, the challenges of effectively treating HIV with antiretrovirals includes attention to both the optimal time for initiation of therapy and the means to maximize adherence.

Prior to initiating antiretroviral therapy, a long-term treatment strategy should be developed considering the possibility of intolerance and treatment failure due to resistance. Consideration must be given to enhancing compliance — with simpler regimens more likely to be effective. The current goal of therapy is to suppress plasma viral load below the level of quantitation of the assay (less than 50 copies/ml) on a long-term basis. If a patient experiences drug toxicity, brief cessation of all medications is recommended. Decreasing dosage or stopping only one medication is not to be encouraged as this will promote the development of resistance. If plasma viral load rebounds despite ongoing therapy, consider noncompliance and resistance as the most likely causes. A confirmed detectable plasma HIV RNA level

TABLE 138-5 -- Antiretroviral medications.

ANTIRETROVIRAL MEDICATIONS			
Drug	**Dosage**	**Comments**	**Cost**
Nucleoside reverse transcriptase inhibitors (NRTIs)			
Zidovudine (AZT)	400–600mg q24h in 2 divided doses	Most common adverse effects: nausea, headache, rash, anemia, leukopenia, elevated liver enzymes, elevated lactic acid and elevated CPK	$$
		Should not be combined with D4T	
Lamivudine (3TC)	150mg bid	Most common adverse effect is neutropenia (rare)	$$
Didanosine (ddI)	35–49kg: 100mg q12h	Main common adverse effects: gastrointestinal intolerance, pancreatitis, gout, reversible peripheral neuropathy	$
	over 50kg: 200mg q12h	Should not be combined with ddC	
	Full daily dose can be given once a day	Should be taken NPO	
DDI-EC	Over 50kg: 400mg q24h		
Zalcitabine (ddC)	0.75mg q8h	Most common adverse effects: reversible peripheral neuropathy, mouth ulcers, pancreatitis	$
		Should not be combined with d4T or ddI	
		Relatively weak risk-benefit ratio limits usefulness	

Stavudine (d4T)	40–60kg: 30mg q12h	Reversible peripheral neuropathy	$$
	Over 60kg: 40mg q12h	Lactic acid elevations (rarely fatal)	
		Should not be combined with AZT	
Tenofovir	300mg q24h	Most common adverse effect: gastrointestinal upset, low phosphate	$$$
Abacavir (ABC)	300mg q12h	Most common adverse effect is a hypersensitivity reaction, which may be characterized by fever, rash, myalgias, arthralgias, malaise. Reaction may be *fatal* if medication is continued or patient is rechallenged	$$$
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)			
Nevirapine (NVP)	200mg q24h for 2 weeks then increase to 200mg q12h	Most common adverse effects: rash, elevated liver enzymes	$$
	Full daily dose can be given once a day		
Delavirdine (DLV)	400mg q8h	Most common adverse effect is rash	$$
Efavirenz (EFV)	600mg q24h (or 300mg q12h)	Most common adverse effects: central nervous system toxicity ('hangover', drowsiness), rash	$$$
Protease inhibitors (PIs)*			
Saquinavir (INV — Invirase®)	Very poor bioavailability unless combined with RTV	Most common adverse effect is elevated liver enzymes	$$$$
	When given with RTV use INV/RTV 400mg/400mg q12h *or* 1000mg/100mg q12h *or* 1600mg/100mg q24h	Better tolerability (i.e. gastrointestinal) and similar PK to FTV when used with RTV boosting	
Saquinavir (FTV — Fortovase®)	1200mg q8h *or* 1000mg/100mg	Most common adverse effect is gastrointestinal toxicity and elevated liver enzymes	$$$$
	q12h *or* 1600mg/100mg q24h	Better bioavailability than INV in the absence of RTV	
Ritonavir (RTV)	600mg q12h	Most common adverse effects: gastrointestinal upset, diarrhea, circumoral paresthesias, elevated liver enzymes, hypertriglyceridemia	$$$$
		Most common use at present is as a PI booster at low doses (i.e. 100mg–400mg q24h)	
Indinavir (IDV)	800mg q8h	Most common adverse effects: elevated liver enzymes, nephrolithiasis, hypertension, ingrown toenails, benign hyperbilirubinemia	$$$$
	Can be given with RTV boosting: IDV 800mg/RTV 100mg q12h		
Lopinavir/ritonavir (LPV/RTV)	3 capsules q12h	Actually two drugs combined in one capsule	$$$$
	Dose should be increased to 4 capsules q12h if used with EFZ or NVP and in the presence of moderately to highly PI-resistant HIV	Most common adverse effects: gastrointestinal upset	
Amprenavir (APV)	1200mg q12h	Most common adverse effects: rash, gastrointestinal upset	$$$$$
	Can be used with RTV at a dose of 600mg APV/100mg RTV q12h		
Nelfinavir (NFV)	750mg q8h	Most common adverse effect is gastrointestinal upset, mostly diarrhea	$$$$

*PIs have multiple drug interactions and may be associated with various metabolic adverse effects such as diabetes mellitus, hyperlipidemias or lipodystrophy (limb and face wasting and accumulation of abnormal fat deposits)

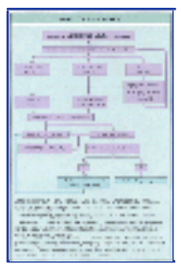

Figure 138-2 Approach to antiretroviral therapy. PI, protease inhibitors.

in an adherent patient indicates virologic failure. At such time the treatment should be re-evaluated and possibly changed to an alternative fully suppressive regimen to avoid development of resistance. Table 138.5 summarizes the currently available antiretroviral agents. For further discussion, refer to Chapter 139 and Chapter 204 . An approach to antiretroviral therapy is suggested in Figure 138.2 .

PRINCIPLES IN CHANGING THERAPY

Currently, drug failure is defined in virologic terms as the occurrence of a confirmed viral load rebound in the absence of other obvious explanation (e.g. treatment interruption, intercurrent illness or immunizations). A change in therapy in this setting will only be carried out after careful evaluation of prior drug exposure, prior response to therapies, prior tolerability and toxicity issues, as well as the results of resistance testing done on a real time basis and on stored samples. It is critically important to understand and correct the determinants of prior treatment failure in any given individual. This must be done before a change in therapy is implemented. Failure to address these issues effectively will invariably compromise the chances of success with the new regimen. Whenever possible, pharmacokinetic issues (past and present) should also be evaluated. Multiple variables are operational when changing regimens in the context of virologic failure in a given clinical case. As such, guidelines cannot replace expert advice in this setting. It is critical, therefore, that the decision of when to change and what to

change to be arrived at under the guidance of an experienced practitioner.

When a decision to change therapy for sustained virologic failure is made, the new regimen should be one with the highest probable effectiveness, as predicted by the patient's complete drug history and the resistance test result, as well as the highest likelihood of tolerability and adherence. New regimens should contain at least two, and if possible three, drugs deemed to be active. The viruses that replicate during treatment failure may not be resistant to all of the drugs in the failing regimen. However, latently infected lymphocytes may harbor archived viruses that are resistant to drugs used in the past but are not detected by routine resistance testing in the plasma. Frequently, shared-resistance mutations conferred by an individual drug lead to cross-resistance among drugs in the same class, complicating the choice of alternative regimens.

With the currently approved non-nucleoside reverse transcriptase inhibitors (NNRTIs), the risk of complete NNRTI-class cross-resistance is high when an NNRTI-containing regimen fails. With protease inhibitors, intraclass cross-resistance is not so predictable. Depending on the pattern of resistance, an alternative protease inhibitor (or a combination of protease inhibitors) can often be selected. With nucleoside reverse transcriptase inhibitors (NRTIs), the extent of class

cross-resistance is greater than anticipated previously, and the level of resistance to alternative drugs (e.g. to stavudine) is more difficult to infer from genotype or phenotype testing results. In rare circumstances, multidrug resistance to NRTIs may develop through a unique pathway of resistance. Alternative regimens must therefore be assessed on a case-by-case basis, based on predicted resistance patterns.

In the absence of virologic or immunologic failure, a regimen may pose problems due to adherence, intolerance or toxicity. Detailed discussion of the management of all possible antiretroviral-related toxicities is beyond the scope of this review. In general, as long as the antiviral potency of the regimen is preserved, exchanging an individual component of the regimen to deal with a toxicity problem is acceptable. The closer the agents are in terms of their potency and resistance profile, the easier and safer the change will be — for instance, replacing stavudine with zidovudine in a patient who has anemia, or zidovudine with stavudine in a patient who has neuropathy. Similarly, replacing nevirapine in a patient who has central nervous system toxicity with epavirenz would be generally safe and effective. Drug substitutions become more complicated as patients present with a history of prior drug exposure and/or failure to multiple regimens. In such cases, changes in therapy should only be performed under the guidance of an experienced physician.

SUMMARY

The overall management of the patient who has HIV infection is dictated by the level of disease activity, as indicated by the plasma viral load and by the degree of immunodeficiency. The latter is best characterized — in the absence of symptoms — by the $CD4^+$ lymphocyte count. As with any chronic disease, the primary care physician is best situated to co-ordinate care in an ongoing fashion in close collaboration with experienced specialists. Because of the multiple complexities associated with the use of currently available antiretroviral therapy regimens, it is best to reserve their use to those with an expertise in this rapidly evolving field. As signs and symptoms of specific diseases appear, referral for special investigation and treatment should be encouraged.

Chapter 139 - Antiviral Therapy

Stefano Vella
Marco Floridia

INTRODUCTION

HIV infection is a chronic disease in which, in the absence of appropriate treatment, high-level viral replication occurs continuously for years, even during the clinically latent phase and in the absence of symptoms and opportunistic infections. Symptoms and opportunistic infections typical of full-blown AIDS usually start occurring 10–12 years after HIV infection. Both viral and cellular turnover show fast kinetics, particularly during primary infection and, later, during the AIDS stage.[1] Viral replication drives the progression of HIV disease and viral load levels are highly predictive of the subsequent risk of disease progression and death.[2] Residual viral replication due to incomplete suppression in the presence of drugs is also responsible for the development of viral resistance to antiretroviral drugs, which further contributes to treatment failure and disease progression.[3] Antiviral treatment should therefore be aimed at obtaining maximal and sustained suppression of HIV replication. Indeed, suppression of HIV replication is associated with a significant delay in the progression to AIDS and increased survival, particularly in previously untreated patients.[4]

Plasma HIV-1 RNA levels and $CD4^+$ lymphocyte counts represent the main tools in the monitoring of antiretroviral treatment.[5] Previously untreated patients are expected to reach undetectable HIV plasma levels in no more than 4–6 months, with a concomitant rise in $CD4^+$ lymphocyte counts. Different drug combinations can produce this effect. It must, however, be stressed that 'undetectable' plasma HIV RNA level does not mean eradication of the virus at other sites (lymphoid tissues, central nervous system, semen). Studies on the effects of therapy in these compartments are ongoing,[6] but eradication of the virus is not considered a realistic goal for the moment.

Even with potent regimens, virologic failure of treatment (i.e. persistently elevated HIV plasma levels in the presence of treatment) is frequent. It may depend on different factors, which include low therapeutic adherence, presence of drug-resistant HIV strains, low drug levels in plasma or tissues and other still undetermined factors. Targeted strategies are being developed in order to improve treatment efficacy, including the development of new drugs with improved formulation and administration schedule, increased potency and reduced toxicity.

The availability of an increasing number of drugs and the rapidly evolving scientific information have made HIV treatment an extremely complex field. Treatment should be supervised by experts, and several national and international guidelines have been developed in order to help in the clinical management of HIV-infected adults and adolescents, pregnant women, infants and children, and uninfected individuals who have occupational exposure to HIV. Proper information for patients and their full involvement in each therapeutic decision are essential elements of a successful response to treatment.

This chapter also addresses the issue of resistance, mostly from the point of view of its clinical implications. Treatment in specific clinical settings such as primary/acute HIV infection and pediatric infection, and the prevention of HIV transmission in the occupational setting are discussed in more detail in Chapter 122 , Chapter 134 and Chapter 117 , respectively. Thus, this chapter focuses mainly on the treatment of established HIV infection. The following text summarizes the antiviral activity, toxicity profiles and clinical efficacy of drugs and combinations of drugs that are already available. Some information on drugs under initial clinical evaluation is also presented.

ANTIRETROVIRAL DRUGS

Until 1987, no drug was available for the treatment of HIV infection. In 1987, zidovudine was widely introduced into clinical practice and zidovudine monotherapy remained the basis of treatment for some years[7] until it became evident that its benefit was limited.[8] Subsequent experience of switching from zidovudine to another nucleoside reverse transcriptase inhibitor or adding a different nucleoside to a prolonged zidovudine regimen was limited in extent.[9] Development of resistance was common with all these drugs and was associated with clinical failure.

Nucleoside monotherapy was finally deemed to be a suboptimal treatment when clinical trials and viral load measurements clearly indicated that two-nucleoside regimens were able to induce a more obvious and prolonged effect on viral load and $CD4^+$ counts, and to delay progression and increase survival.[4] [10] In 1995 available protease inhibitors (PIs), in combination with reverse transcriptase inhibitors, produced a further reduction of HIV replication, often to undetectable levels, and a clinical benefit in intermediate and advanced disease.[11] Non-nucleoside reverse transcriptase inhibitors (NNRTIs), introduced after 1996, have also proved to be highly effective and have become widely used in clinical practice.

It is therefore now clear that the optimal treatment of HIV infection is a potent combination of drugs (termed highly active antiretroviral therapy, HAART), as already established for other important complex diseases such as cancer and tuberculosis. Most of the currently recommended potent regimens are based on a dual nucleoside 'backbone' plus a NNRTI or a PI (with the option of adding low-dose ritonavir to another PI for pharmacoenhancement). Three-nucleoside regimens including abacavir are also increasingly used because these regimens are easy to administer and are dual-class-sparing (i.e. allow deferred use of PIs and NNRTIs).

Many substances are active against HIV in vitro, and almost every step of the HIV replicative cycle is currently being analyzed to identify specific targets of antiviral treatment (Fig. 139.1).

At present, available antiretroviral drugs include six nucleoside reverse transcriptase inhibitors (zidovudine, didanosine, zalcitabine, stavudine, lamivudine and abacavir), one nucleotide reverse transcriptase inhibitor (tenofovir disoproxil fumarate), three NNRTIs (nevirapine, delavirdine and efavirenz) and six HIV PIs (saquinavir, ritonavir, indinavir, nelfinavir, amprenavir and lopinavir; Table 139.1). Their mechanism of action and clinical characteristics are briefly summarized, together with those of some other drugs that are in an advanced phase of evaluation and could enter clinical practice in the next few months or years.

Figure 139-1 Possible sites of intervention in the inhibition of HIV replication.

REVERSE TRANSCRIPTASE INHIBITORS

Reverse transcriptase inhibitors act through at least two mechanisms. First, as 'chain terminators', they block the elongation of the DNA chain through blockage of further nucleosides. This mechanism is characteristic of the nucleoside and nucleotide analogues and depends on the intracellular phosphorylation of the drugs to the corresponding triphosphate. Second, they act by competition/binding of the reverse transcriptase in functionally essential sites; NNRTIs act only through this mechanism and not as 'chain terminators'. Nucleoside analogues have in general good oral bioavailability, are only minimally bound to plasma proteins and are excreted through the kidneys. Because of these metabolic characteristics, they have relatively few interactions with other drugs as compared with PIs. Cerebrospinal fluid (CSF) to plasma ratios may be variable, ranging between 10% and 80%. They are generally active on HIV-1 and HIV-2. Non-nucleoside reverse transcriptase inhibitors are characterized by an HIV-1-restricted antiviral activity and are generally metabolized by the liver; interactions with other drugs with hepatic metabolism may occur. Their binding to plasma protein can also be higher than that with nucleoside analogues, and binding site displacement effects are possible. Data on their

penetration into the central nervous system (CNS) are scarce.

Concerns were recently raised for the occurrence of mitochondrial toxicity due to inhibition of DNA ?-polymerase by nucleoside analogues. Although the clinical correlates of mitochondrial disfunction are poorly defined, a variety of clinical situations have been ascribed to this condition: chronic hyperlactatemia, with possible evolution into potentially fatal lactic acidosis with hepatomegaly and hepatic steatosis (three fatal cases reported in pregnant women receiving didanosine plus stavudine); pancreatitis, neuropathy, myopathy and cardiomyopathy; sporadic cases of severe and potentially fatal neurologic involvement in HIV-negative children exposed in utero to nucleoside analogues; and possibly, some of the features of the lipodystrophy syndrome (see below).[12] At present, lactic acidosis is considered to be the most serious condition associated with treatment with nucleoside analogues.

Zidovudine

Zidovudine (or azidothymidine; AZT) was the first drug approved for the treatment of HIV. It can be used in combination with most of the other antiretroviral drugs, with the exception of stavudine, and is available as dual co-formulation with lamivudine and as triple co-formulation with lamivudine and abacavir. The currently recommended dose is 600mg (200mg q8h or 300mg q12h). If tolerability is compromised by side effects, the dose of zidovudine is often reduced to 100mg q8h. It should be noted that, although currently available data suggest that 100mg q8h can have a favorable effect on surrogate markers, the clinical effectiveness of this dose has not been established. Pediatric dosages are about 180mg/m^2 q6h. Oral availability is approximately 60%. The drug concentrates in the semen, crosses the placenta and has good penetration into the CSF. Drugs inhibiting its glucuroconjugation, such as probenecid, valproic acid, naproxen, indomethacin and oxazepam, should be used with caution; methadone may increase zidovudine concentrations in serum.

The main adverse reactions include anemia, leukopenia, nausea, headache, insomnia and reversible myositis, with raised creatine phosphokinase (CPK) levels. Macrocytosis is a common hallmark of treatment with zidovudine.

Didanosine

Didanosine (ddI) is a nucleoside analogue to be administered in doses adjusted according to body weight: 200mg q12h or 400mg q24h in patients whose body weight is above 60kg, and 125mg q12h or 250mg q24h in patients whose body weight is below 60kg. Recommended dosage in children is on average 200mg/m^2 q24h (as oral solution). Didanosine is rapidly degraded at low pH and must

TABLE 139-1 -- Antiretroviral drugs available for highly active antiretroviral therapy combination regimens.

ANTIRETROVIRAL DRUGS AVAILABLE FOR HAART COMBINATION REGIMENS			
Class	**Drug**		**Dosage**
Nucleoside reverse transcriptase inhibitors	Zidovudine (AZT)	Retrovir®[*] [†]	200mg q8h or 300mg q12h
	Didanosine (ddI)	Videx®	>60kg: 200mg (tablets) or 250mg (powder) q12h, 400mg q24h (tablets or EC capsules)
			<60kg: 125mg (tablets) or 167mg (powder) q12h; 250mg q24h (tablets or EC capsules)
	Zalcitabine (ddC)	Hivid®	0.75mg q8h
	Lamivudine (3TC)	Epivir®[*] [†]	>50kg: 150mg q12h
			<50kg: 2mg/kg q12h
	Stavudine (d4T)	Zerit®	>60kg: 40mg q12h
			<60kg: 30mg q12h
	Abacavir (ABC)	Ziagen®[†]	300mg q12h
Nucleotide reverse transcriptase inhibitors	Tenofovir	Viread®	300mg q24h
Non-nucleoside reverse transcriptase inhibitors	Delavirdine (DLV)	Rescriptor®	400mg q8h
	Nevirapine (NVP)	Viramune®	200mg q24h for 2–4 weeks, then 200mg q12h
	Efavirenz (EFV)	Sustiva®	600mg q24h
Protease inhibitors	Saquinavir (SAQ)	Invirase® (HGC)[‡]	HGC: 400mg q12h, to be used only with ritonavir
		Fortovase® (SGC)[§]	SGC: 1200mg q8h
	Ritonavir (RTV)	Norvir®	300mg q12h, escalate to 600mg q12h in 2 weeks
	Indinavir (IDV)	Crixivan®	800mg q8h
	Nelfinavir (NFV)	Viracept®	750mg q8h or 1250mg q12h
	Amprenavir (APV)	Agenerase®	>50kg: 1200mg q12h
			<50kg: 20mg/kg q12h (max. 2400mg daily total)
	Lopinavir (LPV)	Kaletra®[¶]	400mg lopinavir + 100mg ritonavir q12h

* Also available (300mg AZT+ 150mg 3TC) as Combivir®.
† Also available (300mg AZT+ 150mg 3TC+ 300mg ABV) as Trizivir®.
‡ Hard-gel capsule.
§ Soft-gel capsule.
¶ Only available as Kaletra® (133.3mg lopinavir + 33.3mg ritonavir).

be taken on an empty stomach. The oral bioavailability of didanosine is about 35–40%, and lower penetration than with zidovudine into the CNS has been reported. The metabolism is likely to involve the same pathways as those responsible for the elimination of endogenous purines.

The main adverse effects associated with didanosine therapy include gastrointestinal intolerance, diarrhea, hyperamylasemia, pancreatitis, peripheral neuropathy, hyperuricemia, hypertriglyceridemia and, rarely, rhabdomyolysis and lactic acidosis. Side effects appear to be more frequent in patients who have advanced disease. Concomitant use of pancreotoxic or neurotoxic drugs may increase the risk of pancreatitis and peripheral neuropathy respectively.

Zalcitabine

Zalcitabine (ddC) is a nucleoside analogue generally used in combination with zidovudine. Dosage is 0.75mg q8h for a total of 2.25mg/day. In patients weighing less than 50kg, half dosing is recommended. It has good bioavailability (80%); when administered with food, adsorption is reduced by 14% and time to achieve peak plasma concentrations approximately doubles from 0.8 hours to 1.6 hours.

The main adverse effects associated with zalcitabine therapy include peripheral neuropathy and painful mouth and penile ulcers. Nausea, dysphagia, anorexia, diarrhea, headache and myalgias have also been observed. Less frequently, rash, hyperamylasemia and pancreatitis have occurred in the context of zalcitabine therapy. Because of the common risk of peripheral neuropathy and pancreatitis, concomitant administration of didanosine or stavudine and zalcitabine is not

recommended.

Lamivudine

Lamivudine (3TC), a nucleoside analogue inhibitor of the reverse transcriptase, is to be used in combination with zidovudine or stavudine. The recommended dose is 150mg q12h in adults (2 mg/kg q12h in patients below 50kg) and 8mg/kg/day in children. Because of the

---

increased concentration of lamivudine in patients who have renal impairment, doses must be reduced in the presence of a creatinine clearance below 50ml/min. A dosage of 2mg/kg q12h is recommended in patients whose body weight is below 50kg. Lamivudine can be taken with food and its bioavailability is about 86% in adolescents and adults and 66% in children. Trimethoprim-sulfamethoxazole can increase the concentrations of the drug. Lamivudine can cross the blood-brain barrier, but to a limited extent, with CSF to plasma ratios of 6% in adults and 15% in children.

The main adverse effect associated with lamivudine therapy is reversible neutropenia. This can be exacerbated with zidovudine use and advanced HIV disease. Sporadic cases of pancreatitis and rash have also been reported. In pediatric patients receiving lamivudine, an increased frequency of pancreatitis has been reported, suggesting that particular caution is needed in children who have a previous history or at risk of pancreatitis. The drug has also shown in-vitro activity against hepatitis B virus (see Chapter 125).

Stavudine

The recommended dose of stavudine (d4T) is 40mg q12h (30mg q12h if weight is less than 60kg). The drug should be taken at least 1 hour before meals and has good bioavailability (80%); its terminal half-life is about 1.3 hours (3.5 hours intracellularly). It crosses the blood-brain barrier, although variable CSF to blood ratios have been reported. Elimination seems to occur by excretion in the urine (as unchanged drug) and by elimination through endogenous pathways. Pharmacokinetics in patients who have hepatic impairment are similar to those in patients who have normal hepatic function. Within the cell, zidovudine-5'-monophosphate may inhibit the production of stavudine-5'-monophosphate, suggesting that zidovudine and stavudine may be antagonistic and should therefore not be co-administered in combination.[13] This antagonism has been documented in vivo.

The main adverse effect associated with stavudine therapy is peripheral neuropathy, which is more frequent at higher doses (i.e. 40mg q12h), in advanced disease and in patients who have a previous history of neuropathy. The neuropathy is usually reversible at the cessation of treatment. A mild degree of bone marrow inhibition has also been reported, with moderate macrocytosis. Asymptomatic increases in liver function tests are also possible in about 10% of treated patients, and a small number of cases of pancreatitis have been observed. The risk of asymptomatic hyperlactatemia and lactic acidosis may be greater with stavudine than with other nucleoside analogues, particularly when used in combination with didanosine. Stavudine is also linked to the loss of peripheral fat (lipoatrophy).

Abacavir

Abacavir is the only guanosine analogue among the nucleoside reverse transcriptase inhibitors. After a unique phosphorylation pathway it is converted to carbovir triphosphate and subsequently metabolized by hepatic glycuroconjugation and renal excretion. The recommended dosage is 300mg q12h (with or without food). Central nervous system penetration (0.18 CSF:plasma ratio) and activity on viral load is probably superior to first-generation nucleoside analogues. It is increasingly being used in three-nucleoside combination regimens as a co-formulation with zidovudine and lamivudine. There is some degree of cross-resistance with other nucleoside analogues (didanosine, zalcitabine and lamivudine).

The toxicity profile is characterized, together with relatively nonspecific adverse events (diarrhea, nausea, abdominal pain, asthenia, headache, transaminase and creatinine increases) by a potentially serious hypersensitivity reaction (fever with nausea or vomiting, asthenia or flu-like symptoms, often accompanied by rash), which requires permanent discontinuation of the drug because of the risk of life-threatening reactions associated with drug rechallenge.[14]

Tenofovir

Tenofovir disoproxil fumarate is a prodrug that in vivo is converted to tenofovir, an acyclic nucleoside phosphonate, which represents a nucleotide analogue of adenosine 5'-monophosphate with inhibitory activity against HIV reverse transcriptase. The recommended dosage is 300mg q24h, to be taken with food in order to increase bioavailability. It is mainly excreted through the kidneys and the potential for interactions based on cytochrome P450 enzymes is considered to be low. Resistance profile of tenofovir seems to be unique among nucleoside reverse transcriptase inhibitors, with a limited degree of cross-resistance with other nucleoside analogues that needs to be further defined.

Information on toxicity profile is restricted to short-term side effects, mainly represented by gastrointestinal symptoms, asthenia and headache. Because of its renal metabolism, it is not currently recommended in patients who have low values of creatinine clearance. At present, clinical experience is more limited than with other nucleoside analogues, but preliminary results suggest that three-drug regimens (two nucleoside reverse transcriptase inhibitors plus one NNRTI) that include tenofovir may induce viral load reductions and $CD4^+$ lymphocyte increases comparable to those obtained with other commonly used three-drug regimens.

Nevirapine

Nevirapine (NVP) is the first compound to be approved among HIV NNRTIs. Recommended dosing is 200mg orally once daily for the initial 2 weeks, to be increased to 200mg q12h thereafter. Bioavailability is approximately 65%. Skin rash is the most common adverse event and may occur in up to 30% of nevirapine-treated patients by 24 weeks. In less than 5% of patients rash may be severe and, although rare, Stevens-Johnson syndrome has been described. Headache, diarrhea, nausea, fatigue, drowsiness, fever, chills, and joint and muscle aches are also reported. Hepatotoxicity usually occurs in the first 12 weeks of treatment, is more common in women and may be severe or fatal.

Delavirdine

Delavirdine (DLV) is another approved NNRTI. Recommended dosing is 400mg orally q8h. Adverse effects are headache, skin rash — generally maculopapular — fatigue, gastric intolerance, change in body temperature, increase in liver enzymes, faintness, dizziness or lightheadedness, changes in stools and leg cramps. Delavirdine inhibits cytochrome P450 enzymes, and various drug-drug interactions have been described when it is associated with PIs.

Efavirenz

Efavirenz is a NNRTI that can be administered once daily (600mg at bedtime, with or without food) because of a long plasma half-life. The main adverse effect associated with efavirenz is dizziness. Other CNS symptoms such as abnormal dreams, insomnia, hallucination and euphoria may also occur. Nausea, rash and hypersensitivity reactions have also been reported. Major congenital abnormalities have been observed in monkeys whose mothers were treated with efavirenz during pregnancy. Women on efavirenz treatment must therefore avoid pregnancy.

Like nevirapine, being an inducer of the P450 (CYP) 3A4 cytochrome isozyme, efavirenz can reduce the concentrations of drugs (such as indinavir, saquinavir or lopinavir) that are metabolized by this enzyme. It should not be administered with terfenadine, astemizole, cisapride, midazolam and triazolam because competition for the CYP3A4 isozyme may occur, leading to severe side effects. The resistance profile indicates cross-resistance with other NNRTIs.

PROTEASE INHIBITORS

Protease inhibitors act on the binding to the catalytic site of the HIV aspartic protease. This enzyme is critical in the post-translational processing of the polyprotein products of *gag* and *gag-pol* genes into the functional core proteins and viral enzymes, respectively. Its inhibition leads to the release of immature, noninfectious viral particles. Most of the PIs are compounds that mimic the part of the structure of Gag-Pol protein that is recognized by HIV protease.

Protease inhibitors, as nucleoside analogues, are active on HIV-1 and HIV-2, and have shown antiviral activity in primary human lymphoid and monocytic cell lines and against a variety of viral strains. However, unlike inhibitors of reverse transcriptase, which provide no protection in established in-vitro infection, PIs are active in chronically infected cells. Finally, PIs are active as the administered compound and do not need intracellular phosphorylation. Although these factors may imply a prolonged activity in a wider range of cells, many PIs are significantly bound to plasma proteins, with subsequent reduction in cellular uptake and, thus, intracellular levels. The possibility of achieving elevated blood levels is also affected by the bioavailability of these drugs, which is usually lower than that of reverse transcriptase inhibitors, mostly because of limited absorption and first-pass hepatic metabolism.

Protease inhibitors are generally dependent on the cytochrome P4503A hepatic isozyme for metabolism and can compete with other substrates of this enzyme. When the metabolism of other drugs that are dependent on the same enzyme is inhibited, the blood levels of these drugs can increase dramatically and toxic interactions may occur. This phenomenon has been evaluated for many of the compounds that are frequently used in patients who have HIV disease, and it has been shown that the combination of nucleoside analogues and PIs does not generally lead to untoward effects, although important pharmacokinetic interactions are possible for rifabutin, ketoconazole, rifampin (rifampicin), astemizole, terfenadine, cisapride and other drugs that are dependent on the P4503A hepatic isozyme for metabolism; therefore, attention should be paid before prescribing these drugs together with PIs. However, the concomitant administration of PIs and other drugs with hepatic metabolism may lead to decreased levels of these drugs (see Chapter 141).

Metabolic complications have recently emerged in patients treated with PIs. These include glucose metabolism abnormalities (hyperglycemia or diabetes), hyperlipidemia (mainly hypertriglyceridemia, with or without associated hypercholesterolemia), lipodystrophy or abnormal fat distribution (accumulation in the posterior neck, upper back and central abdomen). The pathogenesis of these abnormalities is still unclear and further studies are needed to define the role played by HIV infection, individual predisposing factors and treatment with specific drugs in the development of these complications.

Available data on the penetration of PIs into the CNS indicate that this is generally low, suggesting that, for optimal clinical use, these drugs should be combined with antiretrovirals that enter the CNS. The rapid development of resistance using reduced doses of PIs indicates that full dosage and adequate compliance should be maintained whenever possible. Protease inhibitors are generally used in combination with reverse transcriptase inhibitors or with another PI, taking advantage of a boosting effect on drug concentrations that occurs when PI are coadministered. The boosting effect, related to inhibitory activity on P450, is most pronounced with ritonavir, which is therefore commonly combined at low dosages (100mg q12h) with other PIs.

Saquinavir

Saquinavir (SQV) was the first PI to be approved in combination with other antiretrovirals for the treatment of HIV infection. A new formulation soft gel with enhanced bioavailability, to be administered at a dosage of 1200mg q8h or at lower dosages with ritonavir q12h, has actually replaced the previous formulation in clinical practice. Saquinavir has a low bioavailability (approximately 4% because of limited absorption and extensive first-pass metabolism). The drug should be taken with food, because drug bioavailability is significantly reduced in the fasting state. The drug is consistently tissue-bound, inactivation is rapid and elimination is predominantly nonrenal.

Diarrhea, abdominal discomfort or pain, headache, nausea, mouth ulcers, dizziness, numbness or tingling in limbs, rash, muscle aches and tiredness have been reported with increased frequency among patients taking saquinavir.

Ritonavir

Ritonavir (RTV) is a PI with potent antiviral activity in vivo. Recommended dosing is 600mg orally q12h. It should be taken with meals if possible. Bioavailability is about 60–70%, with minor differences in the blood levels between the nonfasted and fasted state. Ritonavir is approximately 98–99% plasma-protein-bound. After oral administration, 86% of the given radiolabeled dose was recovered in the feces and less than 4% in the urine. Ritonavir has a marked interference with hepatic metabolic enzymes, mainly represented by inhibition of the cytochrome P450 isoenzyme CYP3A, which can lead to remarkably increased blood levels of other drugs sharing the same metabolic process; these therefore must be avoided in patients receiving ritonavir. It is increasingly, and almost exclusively, used at low dosage as a pharmacokinetic enhancer of other PIs; ritonavir administration (100 or 200mg q12h) significantly increases the plasma levels of other PIs, allowing achievement of therapeutic plasma levels with lower doses and with more convenient schedules (q12h instead of q8h). Significant hepatic impairment is likely to induce a marked decrease in the metabolism and elimination of ritonavir.

The most common clinical side effects are circumoral paresthesias and diarrhea and/or vomiting. Headache, fever, numbness and tingling, muscle weakness and lightheadedness have also been described. Gastrointestinal side effects may be reduced by starting ritonavir alone and then adding the other drugs and gradually increasing ritonavir dosages over 7–10 days. The most frequently reported laboratory abnormalities have been liver enzyme elevations and elevations in blood lipids. Ritonavir should be used with caution among patients at high risk of bleeding, such as hemophiliacs.

Indinavir

Indinavir (IDV) is a PI of similar potency to ritonavir. Recommended dosing is 800mg q8h orally. Indinavir is rapidly absorbed in the fasted state, with a bioavailability of approximately 60%; a decrease in blood levels by approximately 80% is seen when the drug is administered with a high-fat meal, whereas lighter meals have no relevant effect on pharmacokinetics. Binding of indinavir to human plasma proteins is about 60% and metabolism is P450 dependent. After oral administration of a single 400mg dose, over 80% of radioactivity is detected in the feces, with a mean recovery in the urine of 19%; renal clearance studies suggest a secretory component in excretion, which may play a role, together with the observed supersaturation of the urine with indinavir dosages above 600mg, in the formation of indinavir urinary crystals.

Nephrolithiasis and microscopic hematuria can occur in 10–28% of treated patients, and a high fluid intake (at least 2 1/day) is therefore recommended to prevent this complication. Another laboratory side effect that has been frequently associated with indinavir sulfate is hyperbilirubinemia and, at times, jaundice. Other side effects include nausea, vomiting, diarrhea, rash, fatigue and headache.

Nelfinavir

Although introduced later than other PIs, nelfinavir (NFV) is widely used in clinical practice because of its relatively good tolerability/activity ratio. In clinical trials and observational studies, the use of nelfinavir together with nucleoside analogues has resulted in significant and sustained reductions in viral load and in marked increases in $CD4^+$ lymphocyte counts. It can be administered both q12h (1250mg per dose) or q8h (750mg per dose).

The tolerability profile is relatively good compared with other PIs, with diarrhea representing the most commonly observed adverse event and a main cause for drug discontinuation. Other PI-related adverse events may also occur, such as lipid and glucose abnormalities and possible increase in risk of bleeding in patients who have hemophilia. Resistance studies suggest that, if under treatment virus mutates along a specific mutation pathway (D30N), the efficacy of other PIs may be relatively preserved (see Chapter 137).

Lopinavir

Lopinavir is a very potent inhibitor of HIV-1 protease. Its bioavailability is greatly enhanced by coadministration of ritonavir and is therefore co-formulated at a 4:1 ratio with ritonavir (capsules: 133.3mg lopinavir/33.3mg lopinavir; oral solution 80mg lopinavir/20mg ritonavir per ml). Recommended dosage is 400/100mg q12h with food. Data on clinical progression are not yet available. Lopinavir has been used in patients in whom previous treatment has failed and in previously untreated patients. Available data indicate that the drug has high potency on viral load and $CD4^+$ lymphocyte counts, and efficacy both in salvage regimens and in previously untreated patients. Lopinavir is principally metabolized by the liver, and shares many of the drug interactions and contraindications common to other PIs.

The safety profile of the drug is not fully assessed because of the small number of patients as yet studied. The main adverse events observed in clinical trials were diarrhea and other gastrointestinal complaints. Hyperlipidemia is also relatively common. Rash was observed in some children. The high potency characteristics make this drug a potentially important element in the design of particularly potent first-line drug regimens or salvage strategies.

Amprenavir

Amprenavir (APV) is a PI approved for use in both adults and children. It is available both as capsules and as oral solution and can be administered q12h, without restrictions in terms of food timing. Coadministration of ritonavir, as for other PIs, improves amprenavir pharmacokinetic parameters and allows dosage reductions. There are limited data from controlled trials comparing amprenavir and other PIs in terms of efficacy.

The safety profile is also only partially assessed because of the relatively recent introduction of the drug. Preliminary data suggest that amprenavir is relatively well tolerated, with gastrointestinal disturbances and rash representing the main events leading to treatment discontinuation in early trials. Oral/perioral paresthesias have also been observed. The drug is metabolized by the P450 isozyme system and shares some of interactions and contraindications common to other PIs. Amprenavir should be avoided in patients who have sulfonamide allergy. Judging from the evidence of in vitro studies and on preliminary observations in vivo, the drug might also have, as compared with other PIs, a lower impact on metabolic status and on lipodystrophy. The resistance mutation profile is also potentially interesting, suggesting lower potential for cross-resistance with other drugs of this class. These specific tolerability and resistance characteristics, if confirmed by further evaluations, may prove useful in the design of sequential therapeutic strategies against HIV.

NEW INVESTIGATIONAL AGENTS (see also Chapter 204)

A number of novel nucleoside (nucleotide) reverse transcriptase inhibitors (NRTIs), NNRTIs and PIs are currently in development. Desirable characteristics of this new generation of drugs include easier administration schedule, perfected pharmacokinetics, potency, tolerability and the ability to inhibit HIV viruses that are resistant to the existing agents.

TMC125, a new NNRTI, showed high antiviral effect in preliminary studies based on small samples of patients. In treatment-experienced patients failing efavirenz- or nevirapine-containing therapy, TMC125 administered at a dose of 900mg q12h for 7 days decreased the median viral load by approximately 1$\log_{10}$ copies/ml compared with baseline.[15] Diarrhea and headache were the most frequent adverse effects reported by patients taking the drug.

Tipranavir, a new PI, administered together with a small dose of ritonavir in patients who were failing multiple PIs, showed an interesting resistance profile. After more than 1 year of tipranavir/ritonavir treatment, only 2% of the clinical isolates (5/41) exhibited a reduced susceptibility to tipranavir. Moreover, the number of mutations in the protease gene at baseline did not influence the virologic response to tipranavir/ritonavir, and tipranavir/ritonavir treatment did not affect the susceptibility of HIV to other PIs.[16] These data indicate that resistance to tipranavir is uncommon in HIV-positive patients who have failed multiple PI-containing regimens, either at baseline or after 1 year of treatment.

Atanazavir is a new once-daily PI in development that seems to be characterized by a favorable metabolic profile; the drug in antiretroviral-naive individuals had no negative impact on levels of total cholesterol, low-density lipoprotein or triglyceride.

Although current antiretroviral treatment is still based on reverse transcriptase and PIs, inhibitors of the entry/fusion process of HIV into the target cell (T20 and T1249) gave important results in preliminary clinical trials and are likely to join the therapeutic repertoire soon, mainly as components of salvage regimens. In addition, integrase inhibitors are also entering clinical evaluation.

The chemokine receptors CCR5 and CXCR4, which represent co-receptors used by HIV strains in addition to CD4 to enter target cells, are also potentially important therapeutic targets. Antiretroviral agents that inhibit HIV-1 entry by blocking these co-receptors are being developed and some of them recently entered phase I studies.

NEWLY RECOGNIZED ADVERSE EVENTS OBSERVED IN PATIENTS UNDERGOING POTENT ANTIRETROVIRAL THERAPY

In addition to drug-specific adverse events, the long-term use of potent antiretroviral therapy has highlighted a number of adverse events that were previously not recognized. Some of these events appear to be associated with a specific class of drugs, such as mitochondrial toxicity and lactic acidosis with NRTIs or hyperglycemia with PIs; in other cases the association with a single class of drugs is less evident and the pathogenesis of the adverse events is poorly understood (e.g. metabolic disturbances, fat maldistribution, bone abnormalities). All these events may seriously jeopardize adherence and continuation of antiretroviral treatment and therefore represent a major problem in clinical management.

Possible manifestations of NRTI-related mitochondrial toxicity include cardiomyopathy, myopathy, peripheral neuropathy, pancreatitis, proximal renal tubular dysfunction, hepatic steatosis and lactic acidosis. However, it needs to be considered that many effects associated with mitochondrial toxicity are difficult to distinguish from effects associated with HIV infection itself.

Fat distribution changes (also commonly described as lipodystrophy) represent a major event in terms of clinical relevance. This syndrome may present with atrophic changes (peripheral fat loss involving face and limbs), hypertrophic changes (visceral or dorsocervical fat accumulation, breast enlargement) or both. A dysmetabolic profile involving hyperglycemia, hyperlipidemia and hyperinsulinemia is frequently but not always associated with the lipodystrophy syndrome. A common case definition is still lacking, pathogenesis is uncertain and treatment strategies have proved unsatisfactory so far in terms of efficacy. The impact of metabolic changes on incidence of cardiovascular disease is also poorly defined. Although a number of biochemical and vascular abnormalities have been reported, observational studies have yielded conflicting results, with some studies showing association between potent antiretroviral therapy and increased risk of cardiovascular disease and others not indicating an increased number of cardiovascular events following introduction of potent antiretroviral therapy regimens. Bone abnormalities have also been reported, with no clear association with any specific class of antiretroviral drugs; the abnormalities observed include avascular osteonecrosis, osteopenia and osteoporosis, sometimes in association with metabolic changes.

Although lack of a standard case definition complicates characterization, diagnosis and tracking, the morphologic changes have a real and substantial impact on quality of life. Cardiovascular sequelae of dyslipidemia appear to be minimal in the short term but long-term outcome is unknown. So far, management approaches of fat redistribution syndromes and of metabolic toxicities are largely empirical. Only a few of them are based on short-term controlled studies: antiretroviral therapy switches, exercise and diet, anabolic steroids, recombinant human growth hormone (rhGH), testosterone, metformin, thiazolidinediones and plastic surgery for fat redistribution syndromes; lifestyle modification (diet, exercise), use of lipid-lowering agents and switching to non-PI regimens for dyslipidemic syndromes.

HIV RESISTANCE TO ANTIRETROVIRAL DRUGS

Definition and biologic basis of resistance

Emergence of HIV resistance to all classes of antiretroviral drugs used until now has been described. Although other factors may play a role in determining the loss of efficacy of antiretroviral treatment, drug resistance plays a major role in this phenomenon, and great attention is paid to possible strategies to prevent or delay it.

How treatment can affect resistance

Because resistant variants may exist before treatment and evolve under selective pressure, therapy can address viral resistance in three ways:

- by maximizing the suppression of viral replication;
- by using drugs where multiple mutations are required for resistance; and
- by forcing the emergence of variants that result in attenuated replication or decreased virulence (see Chapter 137).

Resistance to nucleoside analogues

HIV variants with decreased susceptibility were first reported in clinical isolates in 1989 for zidovudine, followed by reports of drug-resistance to the other nucleoside analogues and PIs. Advanced disease stage, baseline low $CD4^+$ lymphocyte count and high RNA plasma levels are strongly predictive of the development of resistance. With zidovudine (as with some PIs), resistance appears to be the consequence of a stepwise accumulation of mutations. For other drugs, such as didanosine and zalcitabine, the mechanisms and the molecular correlates of resistance are less clear, although a number of mutations responsible for reduced susceptibility have been identified.

Resistance to zidovudine is the most widely explored in its molecular and clinical aspects. It is related to the ordered emergence of HIV variants with mutations at reverse transcriptase codons 215, 70, 41, 67 and 219, with wild-type strains showing a generally narrow range of IC_{50} –IC_{90} . From a clinical point of view, zidovudine resistance has been shown to predict a more rapid progression of HIV disease, although the clinical significance of resistance to the dideoxynucleosides has not yet been completely defined. High-level resistance to didanosine or zalcitabine has not been reported to date and there is no clear explanation for these findings. Cross-resistance has been reported and multidrug resistance has been observed after combination therapy with nucleoside analogues.

Development of resistance may not necessarily represent an entirely negative event; under treatment with lamivudine, resistance occurs rapidly in vivo, associated with a substitution at codon 184. This codon change may antagonize the effect of zidovudine resistance mediated by the 215 (and 41) mutations, leading to a restored phenotypic sensitivity to zidovudine.[17] This mechanism, however, does not seem to be effective in all cases, with dual zidovudine/lamivudine resistance also observed.

Resistance to non-nucleoside reverse transcriptase inhibitors

Non-nucleoside reverse transcriptase inhibitor use in monotherapy is associated with a rapid development of resistance, which initially suggested a limited usefulness in clinical practice. However, when these drugs were used in triple combination regimens with nucleoside analogues, resistance did not occur in patients who had a sustained viral load suppression to undetectable levels, supporting the concept that resistance occurs as a direct consequence of viral replication. Many NNRTIs have a common pattern of resistance, and this limits sequential use of these drugs because of cross-resistance.

Resistance to protease inhibitors

As for the other classes of antiretrovirals, reduced sensitivity has been reported for all tested PIs, with some strains exhibiting cross-resistance to different PIs after in-vitro or in-vivo drug exposure.[18] The patterns of mutations, however, appear to be more complex than for reverse transcriptase inhibitors, with a higher number of sites involved and higher variability in the temporal patterns and combinations of mutations leading to 'phenotypic' resistance; this suggests that the protease can adapt differently and perhaps more easily than the reverse transcriptase under the genetic pressure induced by drugs. At present, although about 20 codons have been identified as possible mutation sites, several different genetic profiles can be identified and can therefore be employed in designing sequential treatment.

Resistance to entry/fusion inhibitors

Unfortunately, HIV resistance should be expected with any class of drugs used. The increasing clinical use of fusion inhibitors in HIV-infected patients has recently highlighted the occurrence of resistance in some patients receiving the fusion inhibitor enfuvirtide (T-20) in monotherapy.[19]

Clinical implications of drug resistance

Resistance may be a consequence of incomplete viral suppression (in the presence of antiretroviral drugs) and this what usually occurs during the virologic failure of first-line therapy. On the other hand, resistance may be a *cause* of incomplete viral suppression if mutations

pre-exist, which is the case with patients failing second- and third-line regimens.

In all cases, the presence of drug resistance, together with other factors (low antiviral potency of the regimen, poor adherence, pharmacokinetic interactions) may compromise the effectiveness of treatment. Information on resistance status is therefore considered useful both in instituting antiretroviral treatment in previously untreated patients and in managing therapeutic decisions in patients already on antiviral therapy. There is, however, uncertainty about the weight of resistance data in clinical decisions, because available resistance tests are as yet not fully validated and are based on different techniques. In the interpretation of results, absence of resistance (through genotypic or phenotypic testing) does not rule out the possibility of resistant virus in small quantities or in tissue reservoirs. Conversely, evidence of resistance, although indicating a potential reduction in the activity of the drug, should always prompt (before instituting treatment changes) a careful technical interpretation of the resistance test used, longitudinal evaluation of viral load and $CD4^+$ trends over time, an estimate of adherence to treatment and a review of concomitant treatments potentially interfering with drug efficacy. Further studies are needed to define which resistance test(s) will be more adequate in clinical management. Until their validation, changes in HIV RNA levels, together with treatment history, represent the dominant parameters that should guide treatment changes, and the additional information provided by resistance testing should at present be included in a global evaluation of the patient's response to treatment.

HIV TREATMENT STRATEGIES

Principles

The treatment of HIV infection is one of the most rapidly evolving fields in medicine. Advances in basic research, the development of new technologies for the monitoring of therapy, the continuous introduction of new drugs into clinical practice and the relentless dissemination of the results of recent trials contribute to create new expectations and to suggest new strategies for optimal management of the disease. The dynamics of HIV-1 replication in vivo strongly suggest that HIV should definitely be 'hit hard' with potent combinations of antiretroviral drugs to minimize the negative consequences of HIV replication and genetic evolution. Recent data, however, have indicated that replication-competent HIV may survive, even in the presence of highly active treatment, within latently infected cells in the blood or in tissue reservoirs and 'sanctuary sites' inaccessible to treatment in lymphoid tissues, bone marrow and other macrophagerich tissues and organs.

More studies are needed to define the size and distribution of the latent/infected cellular population, the impact of treatment on HIV load in latent reservoirs, and the extent to which immune reconstitution is possible in already immunocompromised patients.

A variety of therapeutic guidelines have been developed to keep clinical practice up to date, as far as possible, with the data emerging from basic and clinical research. The recommendations currently represent an authoritative reference in the field.[20] National guidelines have been published, in the USA[21] and in many other countries.

When to start treatment

Early initiation of therapy with a combination of antiretroviral drugs has been shown to produce more durable clinical benefit than the initiation of therapy in advanced disease. Therapy should be started before the development of symptoms and fall of $CD4^+$ lymphocyte count to low levels, using regimens able to induce and maintain maximal viral suppression and to prevent the emergence of resistant strains. Moreover, because even complete inhibition of viral replication may not be able, in the long term, to prevent the selection of resistance mutants if they exist at a high enough frequency before therapy, treating very early in the course of the infection (i.e. at or immediately before seroconversion), when the virus population is at its most homogenous, may be more beneficial. For these reasons, in the mid-late 1990s, the treatment philosophy for many HIV/AIDS physicians and patients was 'treat early, treat hard'.

However, more recently, the growing appreciation of the difficulties of taking antiretroviral therapy on a long-term basis, the adverse effects of many antiretroviral drugs and regimens, and their negative impact on quality of life has led to a re-evaluation of this early intervention strategy. With 'eradication' not on the horizon, the goal of therapy must now be redirected toward the long-term management of a chronic infection. The decision of when to initiate treatment is now based first on the patient's disease stage, because its clear that a symptomatic patient should always be treated. For an asymptomatic patient, the decision should be driven mainly by the $CD4^+$ lymphocyte count (which is an immediate predictor of progression) and the plasma HIV-1 RNA level (which is an indicator of the level of actual HIV replication and predicts the subsequent rate of loss of $CD4^+$ lymphocytes). Other elements should, however, be factored into the decision to start treatment: the patient's commitment to therapy and a knowledge of the limitations of current regimens.

Therefore, the decision to initiate therapy in asymptomatic patients should be based on prognosis as determined by the $CD4^+$ T cell count and RNA level. Despite the fact that serious complications of HIV infection do not frequently occur when $CD4^+$ lymphocytes are still above 200/mm^3 , a reasonable approach is to start treatment if $CD4^+$ lymphocytes decrease below 300–350/mm^3 and to treat independently of $CD4^+$ if viral load is particularly high (plasma HIV RNA >50,000–100,000 copies/ml). In any case, treatment should be started only when the patient has been educated regarding therapy and is committed to adherence.

A situation that may indicate treatment is primary/acute HIV infection; when viral load is generally remarkably high, the infection disseminates in several reservoirs and the interaction between HIV and the immune system establishes a 'set point' of viremia, which is predictive of the subsequent course of the disease. It now seems clear that this condition can be clinically identified in some patients, allowing a timely intervention that could potentially have positive consequences on the course of the

disease. Whether it is possible to discontinue therapy after a prolonged period of adequate suppression is the subject of ongoing trials (see Chapter 122).

What to start with

With combination therapy representing the key to an effective treatment, achieving a low or undetectable viral load is dependent on the availability of a sufficient number of drugs with as wide a specificity of action as possible, and by a rational design of combination regimens (Table 139.2). An optimal combination regimen should fulfill several requirements, the first of which is a high antiviral potency. Although viral suppression in vitro is indicative of the drug's efficacy, a better estimate is obtained by measuring the effect of the regimen on HIV viral load in vivo. Indeed, some of the new drugs and regimens have recently proved effective in reducing the number of plasma HIV-1 RNA copies by 3$\log_{10}$ from baseline, compared with the mean 0.5–1$\log_{10}$ reduction that is characteristic of most of the first-generation, monotherapy regimens, with a more durable response in terms of $CD4^+$ and HIV RNA (Fig. 139.2). Similarly, and perhaps more importantly, regimens characterized by a substantial proportion of patients achieving durably 'undetectable' viral load should be given priority in clinical practice.

TABLE 139-2 -- Criteria for the selection of combination regimens.

CRITERIA FOR THE SELECTION OF COMBINATION REGIMENS
• High and sustained antiviral activity in vivo (able to induce at least 2$\log_{10}$ reduction in viral load; able to achieve 'undetectable' HIV-1 RNA level in > 70% of patients)
• Simultaneous targeting of multiple viral enzymes
• Wide spectrum cell specificity (e.g. lymphocytes/macrophages, active/resting)
• Wide spectrum tissue activity (lymph nodes, other sanctuary sites, CNS)
• Absence of cross-toxicity patterns
• Induction of 'favorable' mutations (reduced replicative capacity, reversal of resistance, enhanced 'fidelity')
• Absence of cross-resistance (allowing a higher number of subsequent options)
• Favorable pharmacokinetic interactions (e.g. increase in plasma concentrations of one of the drugs used)
• Accessibility, tolerability, compliance and therapeutic index

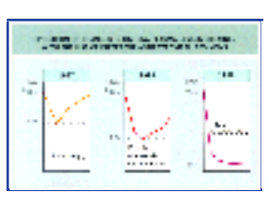

Figure 139-2 Evolution of changes in HIV RNA plasma levels obtained with the use of different antiretroviral regimens.

As for any combination therapy, the drugs selected should also show different toxicity and resistance profiles and be characterized by distinct tissue or cellular specificity to ensure a more generalized viral suppression in the body. Of particular relevance are:

- ¦ penetration into the CNS, because of its possible role in preventing HIV-associated neurologic disease;
- ¦ possible differences in antiviral activity among resting or activated cells, according to specific phosphorylation profiles of nucleoside analogues in different cells;[22] and
- ¦ wide cell and enzyme target profiles — two or more drugs 'convergent' against the same HIV enzyme can reduce the possibility of viral 'escape' of variants with functional mutations, whereas combining reverse transcriptase and PIs may allow activity on acutely and chronically infected cells, adding effectiveness to the regimen.

Another important tool in designing treatment is represented by information on the resistance profile of the drugs, the impact of drug-induced mutations on the replicative characteristics of the virus and sensitivity to other drugs that have been previously used or could be used sequentially. Pharmacokinetics also represent an important aspect in the design of the regimen because an adequate knowledge and rational use of drug interactions allows a simpler administration schedule and an increased potency regimen. Finally, it must always be considered that HIV infection is a long-term disease mostly affecting young people; in this condition, as for other chronic diseases necessitating continuous treatment, tolerability, compliance and accessibility are important factors that must carefully be considered in the design of treatment to ensure compliance and efficacy.

In conclusion, factors determining therapeutic efficacy are certainly linked to the quality of the antiretroviral agents (potent combinations, tolerability, convenient dosing, affordability) but also to the health care provider (who should be accessible in working with patients, give clear instructions and counseling, and use an individualized approach) and to patient commitment and motivation to treatment (conducive lifestyle, family support).

Different combinations of drugs belonging to the three classes have shown similar activity and efficacy in the short to mid term. Considerations in the selection of the most appropriate regimen for the individual patient may include potency; side effect profile; patient's predicted adherence, with potential effect on quality of life and pill burden; the potential for maintenance of future options in terms of drug class sparing and cross-resistance profile; the presence of co-morbid conditions and medications; and, finally, in certain clinical circumstances and geographic areas, the potential for primary acquisition of resistant viral strains.

The most widely used regimens include:

- ¦ PI (± low-dose ritonavir) + two NRTIs (NNRTI-sparing regimen);
- ¦ NNRTI + two NRTIs (PI-sparing regimen); and
- ¦ three NRTIs, including abacavir (PI/NNRTI-sparing regimen).

Other combinations under clinical investigation include a regimen with drugs belonging to all three classes (1–2 PIs + NNRTI + 1–2 NRTIs) and a combination that excludes NRTIs (PI/low-dose ritonavir + NNRTI).

All available regimens have both advantages and disadvantages. For PI-containing regimens the advantages include the solidity of available clinical data, the longest experience, high potency and a relatively high genetic barrier to resistance. Combinations of two PIs are increasingly being used instead of a single PI because they have pharmacokinetic advantages and possibly increase the PI regimen's potency while greatly improving adherence to therapy. Addition of a low dose of ritonavir (100 or 200mg q12h) to saquinavir, indinavir or amprenavir improves the pharmacokinetic profile, reduces pill burden, lowers the dose frequency, lowers the costs and obviates the need for administration of PIs on an empty stomach. A coformulation of lopinavir + ritonavir has recently been introduced. Disadvantages of PI-containing regimens are mainly represented by the high risk of metabolic complications, which, in the long term, may occur in a considerable proportion of patients (>40%).

Advantages of NNRTI-containing regimens, which appears to be equipotent to PI-containing regimens, include very low pill burden and convenience. The main disadvantage, together with some relevant although organ-focused toxicities, is the low genetic barrier to resistance, which limits the use of other members of this class.

Combinations composed only of NRTIs have the advantage of deferring the use of two classes of antiretroviral (the PIs and the NNRTIs). For patients who have high viral loads, more data are needed regarding the efficacy of triple NRTI regimens. The long-term consequences of NRTI additive toxicities are unknown. In addition, most available efficacy data refer to combinations including abacavir, with which serious hypersensitivity reactions may occur in about 5% of patients at institution of therapy.

Specific consideration is necessary for the selection of the most appropriate NRTI backbone combination. As initial treatment often fails, it is likely that a sequence of

NRTIs will be given during the lifetime of an HIV-infected patient. The best NRTI backbone to be used first to give the optimum chance of the second regimen being

successful is currently unknown and is under evaluation in strategic trials. In general we rarely use zalcitabine because of its significant potential for neurotoxicity and the need for q8h administration. Clinical data suggest that stavudine and zidovudine should not be given in combination. There is recent evidence of increased toxicity when stavudine and didanosine were used together and therefore we are less enthusiastic about this combination at the present time. We tend not to recommend abacavir and nevirapine together as initial therapy because there is evidence that the nevirapine rash may complicate the management of suspected abacavir hypersensitivity.

Most of the experience for initial therapy has been accumulated regarding zidovudine plus lamivudine, or stavudine plus lamivudine. Tenofovir plus lamivudine has also been shown in prospective trails to be effective and well tolerated. Zidovudine plus didanosine has been extensively studied in the past but issues of palatability relating to the didanosine formulation precluded widespread use of this combination. More recently, with the availability of an enteric-coated formulation of didanosine, this has been circumvented and the new formulations allow once-daily dosing, which is particularly attractive for certain patients. Despite the limited data available for abacavir in the initial regimen, this agent has worked well, particularly with lamivudine or as part of a zidovudine and lamivudine triple combination. However a recent study comparing zidovudine and lamivudine plus efavirenz to zidovudine and lamivudine plus abacavir suggested the three-nucleoside combination was inferior as initial therapy. Finally, the likelihood of potential toxicities will ultimately help us to decide what is the best backbone NRTI combination for a given patient.

Changing treatment

The success of antiretroviral treatment can be evaluated in different ways. From a laboratory point of view, sustained maximal viral load reduction is certainly proof of the activity of the selected regimen on HIV replication, together with a sustained rise in $CD4^+$ lymphocyte counts. However, we should not lose sight of the need for improved clinical outcome (in terms of opportunistic infections, symptomatic HIV disease and survival) and of the need to preserve the patient's quality of life.

Criteria for changing therapy (Table 139.3) include:

- a suboptimal reduction in plasma viremia after initiation of therapy;
- re-appearance of viremia after suppression to undetectable;
- significant increases in plasma viremia from the nadir of suppression; and
- declining numbers of $CD4^+$ T cells.

To exert a significant effect on the viral 'background' of the patient, changes should therefore be implemented before complete virologic failure, selecting at least two potent drugs not previously used by the patient with appropriate toxicity and resistance profiles. However, because of the lack of many options for changing treatment, one must not prematurely abandon a given regimen. In patients who have very high baseline RNA levels, maximal suppression may not be seen until after 12–24 weeks of potent therapy. Moreover, a careful assessment of adherence must also be made before deciding to switch the patient to a new therapeutic regimen.

Any discussions on salvage strategies requires a definition of treatment failure. For the adherent patient on an initial treatment regimen, confirmed detectable plasma HIV-1 RNA (>50 copies/ml) should be considered evidence of treatment failure. Continued treatment with the same regimen in this situation will eventually lead to development of high-level drug resistance and diminishes the likelihood that salvage regimens will be successful. Thus, for the patient who has clear treatment options, early switching could maximize the chances for therapeutic success of the next treatment regimen and preserve future options.

TABLE 139-3 -- Use of viral load in the management of antiretroviral therapy.

USE OF VIRAL LOAD IN THE MANAGEMENT OF ANTIRETROVIRAL THERAPY	
Parameter	**Recommendation**
Plasma HIV RNA levels that should lead to close monitoring and consideration of starting treatment, regardless of laboratory or clinical status	50,000–100,000 copies/ml or more
Target HIV RNA level after initiation of treatment	Undetectable
Suggested frequency of HIV RNA measurement	At baseline: two measurements, 3–4 weeks apart
	One measurement 4–6 weeks after starting therapy, to confirm antiviral activity of the regimen
	For patients starting at very high baseline RNA levels, maximal suppression may not be seen until 12–24 weeks, when HIV RNA should be remeasured
	Plasma HIV-RNA should thereafter be checked every 3–4 months, in conjunction with CD4 count (shorter intervals in proximity of critical decisions)
Change in HIV RNA suggesting treatment failure	Insufficient viral suppression after 4–6 months of starting treatment Significant viral rebound in patients who had previously undetectable viral load
	Definite trend toward pre-treatment levels in patients who have incomplete viral suppression

The situation differs for patients who are highly treatment experienced and for whom fewer options remain. In such cases, a more conservative approach may be warranted. Usually, virologic escape is followed by immunologic deterioration and eventually clinical evolution. However, the time lag between HIV RNA rebound and clinical failure varies from patient to patient, and it has become clear that $CD4^+$ lymphocyte count may remain high even in the presence of a clear rebound in HIV RNA.

Before making any decisions about changes in antiretroviral treatment, it is important to determine why the current regimen is failing, in order to avoid choosing an inappropriate remedy. In particular, factors such as drug resistance, inadequate drug exposure due to poor adherence, absorption and pharmacokinetics, and persistence of HIV in viral reservoirs all represent major causes of failure that should be investigated in depth before switching to a different regimen.

General criteria for the choice of second-line regimens

Unfortunately, because of the large degree of cross-resistance occurring within all antiretroviral drug classes, the options that actually exist are limited, especially for patients experiencing their second or third failure. In this heavily pre-treated population, both observational and prospective studies have shown quite disappointing results for any investigated salvage regimens.

Different studies have demonstrated that 90–95% adherence to a NRTI/PI regimen is required to achieve/maintain full suppression. In

addition to patient information and training, future opportunities to improve adherence may include once-daily NRTI dosing (didanosine, lamivudine, abacavir), once-daily PI dosing (saquinavir/ritonavir, lopinavir/ritonavir, indinavir/ritonavir), directly observed therapy, simplification after suppression, use of NRTI-class-sparing regimens and phosphokinase manipulation.

The path to be followed in the face of a confirmed treatment failure could be summarized as follows:

- review antiretroviral history;

- assess adherence and tolerability;
- distinguish first, second, multiple failures;
- consider newer agents through expanded access or clinical trials;
- consider phosphokinase enhancement; and
- perform resistance testing to identify susceptible drugs/drug classes.

Use of resistance testing

The most important issue in clinical practice is the relatively high level of cross-resistance among drugs in the same classes. Sequential utility in the case of resistance is almost nonexistent with NNRTIs and only moderate with PIs or NRTIs. The rationale for resistance testing in patient management includes demonstration of the correlation between drug resistance and virologic response to new regimen when prior therapy has failed; the fact that drug resistance is an independent risk factor for poor virologic response after controlling for HIV-1 RNA level, $CD4^+$ lymphocyte count and treatment history; and the fact that virologic failure is not inevitably accompanied by resistance to all drugs in the regimen.

Although representing a major advantage for the management of HIV patients, the routine use of resistance tests in the clinical setting has still to be validated. In general, whereas resistance is generally a good predictor of the probable failure of a drug, sus-ceptibility is no guarantee of success. It is becoming a common belief, therefore, that these assays have their major application in predicting which drugs not to use, rather than which are likely to be successful. Their best current application is therefore in the design of salvage regimens. Indeed, several retrospective and a few prospective studies have shown that, at least in the short term, a higher response rate is likely to occur when a salvage regimen is selected on the basis of genotype/phenotype testing results (see Chapter 137).[23] [24] [25] [26] [27]

Finally, transmission of drug-resistant virus at primary HIV infection is a growing phenomenon. Data from the USA show that the prevalence of high level resistance to NNRTI and PIs has increased in the last year compared with 1996-8. [28] Continuing surveillance is required and many suggest that drug resistance testing should be performed in patients who have primary HIV infection before initiating antiretroviral therapy.

FUTURE PERSPECTIVES

The development of new drugs within existing antiretroviral classes may provide patients with potent agents that have improved tolerability profiles and are more convenient to take than current drugs. However, as has happened in the recent history of antiretroviral therapy, a major impact has been made by the careful evaluation of new treatment strategies.

Treatment simplification strategies are necessary to improve patient adherence and hence outcome. A number of antiretroviral switch regimens have been proposed and/or studied in order to prevent or alleviate antiretroviral-associated toxicities, as well as to improve adherence. There are two main types of switching:

- PI switch regimen (i.e. from a PI-based regimen to a triple NRTI or one NNRTI/two NRTIs regimen); or
- NRTI-sparing switch (i.e. from one PI or NNRTI/two NRTIs regimen to one containing a PI and a NNRTI in order to minimize the risk of mitochondrial toxicity).

Many patients now being treated had marginal indications for therapy based on current guidelines and may be able to remain off therapy for a substantial period of time following a period of full viral suppression and $CD4^+$ gain. Structured or strategic treatment interruption has raised many practical and theoretical questions. This must be seen as a research tool and cannot be recommended apart from in controlled trials.

Despite impressive progress, much work remains to be done. In Western countries, increasing progress in antiretroviral therapy will result from new data obtained in clinical trials, a better knowledge of the pathophysiology of the disease, an increased awareness of the long-term toxicity of drugs and of viral cross-resistance, and the availability of new drugs.

Finally, we cannot forget that, on a global scale, the recent impressive therapeutic gains have only benefited 10% of those infected in the world. In the southern hemisphere the epidemic is reversing decades of development and widening the gap between rich and poor nations.

The dramatic inequalities between rich and poor nations in caring for persons living with HIV/AIDS highlight the moral imperative to develop strategies to increase access to life-saving treatments for the majority of infected people. The impact that AIDS is having on societies and communities makes it not only the most dramatic health emergency of our times but also the major developmental threat to populations and countries in the southern hemisphere. This is why — in addition to humanitarian and ethical reasons — there is an urgent need to start reversing this catastrophe and to bring HIV care and medicines to the developing world.

Although this may be seen as one of the most difficult scientific, social, political and economic challenges of our century, universal access to HIV treatment should be seen as the ultimate goal.

Chapter 140 - Immunobased Therapies

Richard B Pollard
Michelle Onorato

INTRODUCTION

Paralleling the development of more effective and better tolerated antiretroviral therapy for HIV infection has been the growing interest in developing alternative therapeutic approaches. Recent appreciation of the limitations and adverse effects of long-term antiretroviral therapy led to continued exploration of immune-based therapy for HIV infection. Both enhancement of HIV-specific immune responses and stimulation of general immune responses are potential strategies for immune-based therapies of HIV infection that are being developed. Table 140.1 outlines these approaches, which may be of particular value in the treatment of later stage patients, whose high levels of viremia and previous exposure to therapy place them at greatest risk of developing resistance to therapeutic agents and who also have the greatest need for a restoration of normal immune function. However, such interventions must be used with care to avoid compromising the effects of highly active antiretroviral therapy (HAART), which has significant antiviral and immunologic activity.

ENHANCEMENT OF HIV-SPECIFIC IMMUNITY

There are four approaches to the enhancement of HIV-specific response:

- ¦ structured treatment interruption or treatment cycling eventually resulting in viral rebound and rechallenge;
- ¦ administration of HIV-specific therapeutic and prophylactic vaccines (which are discussed in detail in Chapter 118);
- ¦ administration of passive immunotherapy, via either transfer of pooled immunoglobulin from people who have HIV infection or monoclonal antibodies to specific viral epitopes; and
- ¦ passive transfer of specific cell populations in an effort to enhance immune responsiveness to HIV.

A better understanding of host response to HIV infection, both by cellular immune responses and by the antibody response (particularly neutralizing antibody response), has led to refinement of the above strategies. However, enhancement of the HIV-specific immune response does not necessarily lead to improved clearance of the virus.

TABLE 140-1 -- Strategies of immunobased therapy.

STRATEGIES OF IMMUNOBASED THERAPY	
Enhancement of HIV-specific immunity	Therapeutic vaccine
	Transfer of HIV-specific cell populations
	Transfer of pooted immune sera
	Transfer of monoclonal antibody
General immune enhancement	Inhibition of proinflammatory cytokines
	Administration of immune modulators (i.e. interleukin (IL)-2, IL-12, interferon (IFN)-a)

Therapeutic vaccination

Although early attempts to enhance HIV-specific immunity by immunization with HIV-specific antigens in the era prior to effective antiretroviral therapy did result in enhanced lymphoproliferative response, these apparent immunologic benefits did not lead to improved clinical outcome with respect to disease progression or control of viral replication. Clinical trials of various gp120 vaccines in patients with early and later stage HIV infection did not show an effect on viral replication or rate of CD4 cell decline[1] despite immunologic response to immunization (particularly in the higher CD4 group). Another therapeutic vaccine tested extensively in clinical trials is the gp120 depleted Remune® product, which has been shown to induce LPA responses in several cohorts; although in a large multicenter US trial clinical benefit was not observed.[2] [3] However, the lack of benefit seen in the setting of continued viral replication, prior to treatment with effective antiretroviral therapy, may be due to the already maximal benefit of antigen-driven responses in these subjects and so the role of therapeutic vaccination in stimulating HIV-specific immunity and providing antigenic stimulation may be quite different in the setting of undetectable levels of circulating virus. Several approaches are being explored to induce immune response to envelope, internal coat and accessory protein epitopes; these include recombinant proteins, peptide, naked DNA, viral vectors and prime-boost combinations. In addition to exploring the types of vaccines that will prove effective in therapeutic vaccination, there is great interest in therapeutic vaccination in conjunction with other immune modulators, such as administration of interleukin-2 and the ALVAC vaccine, or vaccination in combination with treatment cycling.

Structured treatment interruption

Structured treatment interruption (STI) was first proposed as a strategy to boost HIV-specific responses capable of controlling viral replication after the report of a patient treated during primary HIV infection with effective antiretroviral therapy who was able to control viral replication for a prolonged period after cycling on and off therapy twice; this patient demonstrated T-cell-mediated immunity without detectable neutralizing antibodies to HIV.[4] Further study of STI in patients treated early in the course of HIV infection showed that, in many patients, control of viremia could be achieved by T- cell-mediated immune response.[5] [6] However, because the success of the autologous immunization during STI depends on a robust immune response, the promise of this strategy in the chronically HIV-infected patient is less clear, given the wider variation in immune response that can be induced in this patient population. The Swiss-Spanish Study is the largest clinical trial of STI in chronically infected patients. Subjects were treated for 2 weeks off followed by 8 weeks on HAART; this was repeated for four cycles, then therapy was interrupted until viral load rebounded to >5000 copies/ml. All but nine of 54 subjects reached this threshold within 12 weeks, including all subjects with baseline viral loads of >100,000 copies/ml, suggesting this approach has limited value in chronic

infection. Also, patients with highest viral loads and lowest CD4 counts at baseline were the most likely to be unable to achieve undetectable levels of viremia after resumption of therapy. The degree of virologic control and duration of suppression in these chronically infected patients seem to depend on the magnitude of cell-mediated responses. Although exposure to circulating virus results in mobilization of HIV-specific T-cell response, suppression is transient as these T-cell populations are eventually exhausted in the face of continued viral replication.[7] [8] [9]

HIV-specific cytotoxic T-lymphocyte responses

The interaction between HIV-1 and the cellular immune response is central to the immunopathogenesis of HIV infection, and delineation of this interaction may lead to interventions that can change the natural history of HIV infection.

Much attention has been focused on understanding the cellular immune response following primary infection as it is responsible in part for a several log drop in viral replication following the initial burst of viremia. Primary infection, with its high levels of viremia, is also the time when the virus begins to develop genetic diversity in

response to selective pressures exerted by the host immune response. This dynamic interaction at the initial phase of HIV infection sets the stage for the natural history of HIV infection.

Several studies have suggested that the cell-mediated immune response, rather than specific neutralizing antibody, is the main mechanism responsible for this initial control of viral replication.

The first piece of evidence is the finding that HIV-specific cytotoxic T lymphocytes (CTLs) can be found just as high levels of viremia begin to abate and before the rise in neutralizing antibody titers, suggesting that the CTL response is responsible for declines in initial viremia.[10] [11] In addition, the HIV-1-specific CTL response is demonstrable as early as 21 days following clinical presentation with primary infection and is directed at diverse epitopes within many of the HIV-1 gene products. [11]

Nonhuman primate models of primary infection with simian immunodeficiency virus (SIV) show a remarkably parallel sequence of events; within 4 weeks of detecting SIV p27 antigen in blood and SIV RNA in the extrafollicular and sinusoidal areas of lymphoid tissue, p27 antigen is cleared. Increased numbers of $CD8^+$ lymphocytes are detected in the periphery and in lymph nodes at the same time as this plasma viremia is declining. Humoral and cellular SIV-specific immune responses can be detected within 2 weeks of initial infection. Therefore, both human and simian data suggest that the remarkable containment of initial viremia is largely due to both humoral and cellular immune responses.[12]

Further study has shown that, although the CTL response during primary infection develops to multiple antigenic determinants, this repertoire is more limited than would be predicted. It is this limitation that perhaps allows the virus, with its genetic diversity, a chance to escape immune surveillance by mutating critical epitopes.[11] [13] Indeed, in a patient with early HIV infection, serial observations revealed an early CTL response aimed at a highly immunodominant epitope in gp160. However, with a mutation resulting in a single amino acid change, an escape mutant emerged that could not be recognized by epitope-specific CTLs. Therefore, the CTL response can exert selective pressure, which drives the emergence of resistant virus, just as is seen with antiretroviral therapy.[14] Implications of this finding include:

- vaccine strategies that result in CTL response to multiple codominant epitopes; and
- the importance of concurrent antiretroviral and immune-based approaches to therapy of HIV infection.

Data from natural history studies as well as study of long-term nonprogressors with HIV-1 infection suggest that the immunopathogenesis of HIV infection is influenced by the quality of the CTL response. For example, CTL activity is preserved in the long-term nonprogressors, which is in stark contrast to vertically infected children, who generally have little CTL response and rapid progression of clinical disease. [14] [15] Furthermore, longitudinal studies of CTL response over time show a steady decline in HIV-1-specific CTL precursor cells, paralleling the decline in the ability of $CD8^+$ lymphocytes to suppress HIV replication with progressive infection.[16]

Transfer of HIV-specific cell populations

Given the importance of cell-mediated immunity both in primary infection and in the asymptomatic nonprogressors, the ex vivo propagation and expansion of lymphocyte populations and reinfusion of expanded cell populations to people who have HIV infection is a potential treatment strategy that is currently being explored. One study examined the ex-vivo expansion of unfractionated lymphocytes from an HIV-negative identical twin and infusion of the expanded cell population to the HIV-infected twin. This appeared to be safe, and to result in increases in $CD4^+$ lymphocyte counts in the twin who had the infection.[17]

Dendritic cells, which are key in developing T-cell-dependent immunity by activating quiescent T cells, including naive T cells, and by inducing CD4 and CD8 killer T cells, are also being explored as an HIV-specific cell population that could help boost CTL response to HIV. Sensitized enriched populations of dendritic cells have been used to enhance CTL response in patients with lymphoma and melanoma, as well as other malignancies, with demonstrated immunologic and some clinical benefit. [18] [19] [20] [21] Clinical trials will employ this strategy comparing CTL responses in patients immunized with ALVAC alone versus those who receive subcutaneous reinfusion of populations of ALVAC-exposed dendritic cells.

Another approach is the adoptive transfer of $CD8^+$ lymphocytes following expansion. Preliminary reports suggest that these reinfused cells have little CTL activity, and that the majority are rapidly cleared from the circulation. The administration of $CD8^+$ lymphocytes expanded ex vivo with interleukin (IL)-2 has been investigated as a potential therapy for Kaposi's sarcoma.[22]

Another strategy under investigation is the administration of HIV-specific autologous CTL cell lines that have been selected in vitro and expanded for reinfusion; the safety and effects on immunologic parameters of this approach are currently under study. The finding that $CD4^+$ lymphocytes can be expanded in vitro in the presence of three antiretroviral drugs holds promise for autologous expanded $CD4^+$ lymphocytes as therapy as well.[23]

The limitations of these approaches are:

- the enormous investment in cell culture facilities;
- careful quality control; and
- the variable half-life of the reinfused cells, necessitating repeated administrations.

Transfer of pooled immune sera

The strategy of transferring pooled antibodies from donors who have HIV infection or of monoclonal antibodies directed against HIV is of interest not only as a potential prophylactic measure to prevent infection in exposed seronegative individuals, but also as an attempt to enhance antiviral activity in the serum of individuals who already have HIV infection. This could occur not only by neutralization of the virus, but perhaps also by enhancement of antibody-dependent cellular cytotoxicity and increased complement-mediated lysis. The long half-life of antibodies makes this approach particularly attractive, as intermittent therapy at bimonthly intervals may be practical. The drawbacks of this approach again relate to the genetic diversity of HIV and the potential for the development of mutants not recognized by the more specific antibody preparations. In addition, the vast amount of circulating viral antigen could potentially lead to the formation of immune complexes, resulting in adverse effects due to their

deposition in various tissues, although to date there have been no reported adverse events after these infusions that can be related to immune complex deposition.

Trials of polyclonal antisera

Two controlled trials evaluating the effect of HIV immune plasma on disease progression in HIV-positive individuals have been published. One reported no benefit;[24] in the second, in which patients received either immune plasma or plasma from negative donors every 2 weeks for 1 year, there was a significant decrease in the number of opportunistic infections in subjects receiving immune sera.[25] Others have reported preliminary results of similar strategies, using pooled hyperimmune plasma or a sterile filtered pooled high-titer anti-HIV plasma preparation (treated with ß-propiolactone to inactivate any HIV that may be present).[26] [27]

The role of hyperimmune anti-HIV intravenous immunoglobulin (IVIG) in preventing perinatal transmission has also been assessed. In a phase 1–2 double-blind controlled study by the pediatric AIDS Clinical Trials Group (ACTG), 28 maternal-infant pairs were randomized to receive either HIV hyperimmune IVIG or placebo (IVIG) beginning at between 20 and 30 weeks of gestation; all of the mothers enrolled were receiving zidovudine. Mothers received infusions every 28 days until delivery; infants received a single infusion within 12 hours of birth. All mothers and infants received zidovudine as per the ACTG 076 protocol. Sustained suppression of immune complex dissociated p24 antigenemia was seen in the treated women, although no change was seen in quantitative HIV RNA. Infants in the treatment group had higher levels of p24 antibody at birth, confirming trans-placental transfer of antibody from the HIV hyperimmune IVIG infusions.[28]

Further studies are necessary before the significance of these results and the potential for specific immunoglobulin as therapy are fully understood.

Various trials have also examined the efficacy of IVIG without specific anti-HIV activity and consistently show no effect on HIV-related virologic or immunologic parameters, although IVIG may have a role in reducing the frequency of bacterial infections.[29]

Transfer of monoclonal antibody

Another approach that has been considered is the administration of specific monoclonal antibodies to various epitopes of HIV. This has been limited by concerns that

the virus would acquire resistance to specific antibodies, although this may be overcome by administering antibody combinations that are directed at more than one neutralizing epitope. Another obstacle to clinical trials of specific monoclonal antibodies is the expense of the large-scale production that would be required.

The first step in developing monoclonal antibodies to be tested in clinical trials is to identify epitopes that will induce antibodies that will result in anti-HIV activity. Most attention to date has focused on antibodies to various surface epitopes of HIV, either to the V3 loop, C4 and gp41 or, in the case of F105 (a monoclonal antibody), directed against the CD4 binding site. Combinations of these antibodies in vitro show at least additive activity and, against some strains of HIV, synergistic activity.

The F105 antibody has been evaluated in a dose-escalating phase 1–2 ACTG trial; half-lives of the antibody were prolonged, but there was no change in HIV titers.[30]

GENERAL IMMUNE ENHANCEMENT

The availability of cytokine inhibitors that could potentially counteract the overproduction of cytokines seen in HIV infection and of general immune stimulators has led to interest in manipulating the immune system as a therapeutic tool.

Theoretically, the general immune stimulation or suppression that may result from these manipulations may hasten the rate of HIV progression, particularly as there is concern that stimulation of certain cell populations may enhance HIV replication. Therefore, active antiretroviral therapy has to be administered concurrently with any of these modulators of the immune system.

Inhibition of proinflammatory cytokines

The cytokine that has been most extensively studied is tumor necrosis factor (TNF)-a because:

- it is produced in large quantities in HIV infection; and
- it upregulates HIV expression in vitro.

Pentoxifylline, thalidomide and corticosteroids have all been studied as potential therapies because they inhibit TNF-a production.

Pentoxifylline

Studies of the use of pentoxifylline in people who have HIV infection have shown a decrease in TNF-a mRNA; however, in a controlled trial of pentoxifylline at the highest tolerable dosages, no significant antiviral effect was detected.[29] It seems that the benefit is seen mainly in patients who have high pretreatment levels of TNF-a. This observation led to the initiation of a placebo-controlled trial of pentoxifylline in people who have HIV infection with active pulmonary tuberculosis in Uganda, because they have very high levels of circulating TNF-a. The patients enrolled in this study had relatively early HIV infection, with a mean $CD4^+$ lymphocyte count of 380/µl, and did not receive other antiretroviral therapy. Patients in the pentoxifylline arm had lower levels of HIV RNA than the control arm and reduced levels of $ß_2$ -microglobulin; however, no difference was observed in the two groups with regard to new AIDS-defining illness or survival. [31] [32] [33] [34]

Thalidomide

Thalidomide is also known to inhibit production of TNF-a and has been shown to inhibit HIV-1 replication in vitro. A placebo-controlled trial has shown benefit in the treatment of HIV-associated oral and esophageal aphthous ulcers. Of note, patients in the thalidomide arm appeared to have increases in HIV-1 RNA, underscoring the importance of concurrent antiretroviral therapy.[35] [36]

Corticosteroids

The observation that corticosteroids appear to benefit patients with HIV-associated nephropathy has led to interest in them for interrupting cytokine activity, but there are insufficient controlled data to evaluate their use.

Ciclosporin

Ciclosporin has been proposed as an immunomodulatory agent with potential activity in HIV infection. A phase 2 trial of ciclosporin versus placebo in patients with early HIV infection ($CD4^+$ lymphocyte count >500/µl) has been completed; although the drug was well tolerated in this population, it had no effect on level of immune activation or CD4 count at the dose studied. However, Pantaleo and others reported a positive effect of a limited course of ciclosporin A when given in conjunction with HAART to patients during primary HIV infection as compared with HAART alone. The group that received ciclosporin showed acute benefit in terms of restoration of normal $CD4^+$ cell number and proportion, which was seen more than a year after the ciclosporin was stopped. It appears that dampening of T-cell activation during primary infection may have lasting immunologic benefit. [37]

Cyclophosphamide

Administration of cytotoxic therapy has been postulated as a way to reduce the cellular reservoir of HIV in chronically infected patients on HAART. A study, ACTG 380, was designed to address

this question: 10 treatment-naive individuals were randomized to receive either antiretroviral therapy alone or escalating doses of cyclophosphamide after they had achieved a viral load of <50 copies/ml. The drug was well tolerated, but no difference was seen between the two groups in terms of peripheral blood or lymphoid HIV DNA levels.[38]

Enhancement of immune response via cytokines and lymphokines: administration of immune modulators

Recent studies of administration of immune modulators have focused mainly on IL-2 and interferon (IFN)-a.

Interferon-a

Low-dose oral IFN-a has been studied with and without concurrent antiretroviral administration; there appears to be little benefit with regard to antiviral activity. Subcutaneous IFN-a in combination with other antiviral agents has also been evaluated. The most positive data regarding IFN-a to date are for its use in the treatment of HIV-associated thrombocytopenia. Patients in two uncontrolled studies showed benefit with regard to platelet levels at low doses of this agent.[39] [40] [41] [42] In general, systemic administration of IFN-a has resulted in unacceptable toxicity and marginal benefit in patients who have HIV infection, limiting its clinical usefulness, although the use of pegylated interferon as an antiviral agent for HIV infection is being tested in clinical trials.

Interleukin-2

Interleukin-2 has emerged as a potentially exciting agent for immune-based therapy of HIV infection. Results of a small trial of intermittent intravenous IL-2 (5-day continuous infusions every 8 weeks) are encouraging. Of patients who had baseline $CD4^+$ lymphocyte counts over 200/µl, 60% showed sustained increases in $CD4^+$ lymphocyte counts following treatment. This increase in $CD4^+$ lymphocyte count was seen over a 14-month follow-up of these patients, although no change was seen in plasma HIV RNA levels or levels of p24 antigenemia. In patients who had a baseline $CD4^+$ lymphocyte count of less than 100/µl, no benefit was seen in terms of $CD4^+$ lymphocyte count. However, the transient rise in viral load reported in preliminary studies of IL-2 use in patients who have later stage HIV infection was not seen in this study, presumably because of concurrent antiretroviral therapy.[43] [44]

A major drawback of this approach is the frequency of continuous intravenous therapy, and so trials of subcutaneous or intermittent intravenous IL-2 are in progress. ACTG 328 is a trial of intravenous IL-2 with HAART versus subcutaneous IL-2 with HAART versus HAART alone. Primary analysis at weeks 60 and 84 showed marked and sustained increases in $CD4^+$ cells counts. Furthermore, significant increases in naive and memory $CD4^+$ cells were seen along with increases in $CD25^+$, $CD28^+$

and CD95^{+} subpopulations in both treatment arms. Assessment of AIDS-defining events suggested a lower incidence of progression to AIDS in the two treatment arms compared with HAART alone. Two other long-term studies (SILCAT and ESPRIT) are underway examining the benefit of IL-2 in patients receiving HAART, but will require several years of follow-up to gather adequate clinical end-point data.

Interleukin-12

Interleukin-12 is currently in phase 1 clinical trials. It is known to increase natural killer lymphocyte and CTL activity in vitro and to be deficient in people who have HIV-1 infection. It is hoped that treatment will stimulate the development of T-helper type 1 lymphocytes, reverting the shift to T-helper type 2 predominance that is seen in HIV infection and may be a detrimental consequence of the host response to HIV-1 infection.[45] In a preliminary study, IL-12 was well tolerated in doses of up to 100ng/kg in patients with <50 CD4 cells/mm^3 , and up to 300ng/kg in a group with higher CD4 counts. Although IL-12 administration resulted in significant dose-related decreases in serum neopterin, no change in LPA response to HIV or *M. avium-intracellulare* was seen; nor was any change in serum IFN-? levels or HIV RNA levels seen. [46]

Granulocyte-macrophage colony-stimulating factor

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is another immune modulator that has been examined for its effect on HIV disease progression. ACTG 5041 was a two-step clinical trial with an initial randomized, placebo-controlled phase, followed by a open label phase, which looked at the effect of GM-CSF on CD4 counts and HIV viral loads in patients with stable, quantifiable viral loads. Initial analysis showed a trend toward higher viral load and higher CD4 counts in the treatment group at 16 weeks.[47]

CONCLUSION

In summary, both pharmacologic and immunologic approaches to new interventions for HIV infection have yielded a number of encouraging agents and potential combinations of agents. The challenge is to sort out which strategies are likely to result in long-term clinical benefit with minimum toxicity in the setting of planning therapy for a chronic disease such as HIV infection. In a rapidly changing environment of new antiretrovirals, the position of immunologic therapy will have to be carefully understood. Major developments in the suppression of HIV with significant improvements in immune function have been reported. However, whether immune function can be restored with antiretroviral therapy alone is unclear at present. It is likely that immune-based therapies will be an important adjuvant to antiretroviral therapy in some patient populations.

Chapter 141 - Practice Points

141.a The role of resistance typing

Peter Reiss
Charles Boucher
Stefano Vella

Introduction

The circulating plasma HIV-1 RNA level reflects the extremely high rate of virus replication that occurs in the lymphoid tissue, with billions of new virions being produced each day throughout all stages of HIV infection, including the period of clinical latency. Within the first year of primary HIV-1 infection, the level at which plasma HIV-1 RNA plateaus is strongly predictive of the rate of progression to HIV-associated disease and death. Furthermore, the degree to which HIV-1 replication can be inhibited by antiretroviral therapy in a sustained fashion, as determined by increasingly sensitive techniques to measure reductions in plasma HIV-1 RNA levels, is an important determinant of the clinical benefit of treatment. Both the nadir plasma HIV-1 RNA level that is reached and the time to reach the nadir determine the sustainability of the virologic response to treatment. Thus, the principal goal of modern-day antiretroviral therapy is to reduce virus replication as much as possible for as long as possible. Unfortunately, one of the factors that jeopardizes the achievement of this goal is the danger that viral drug resistance may develop.

Pathogenesis

The principal targets of currently available antiretroviral agents are the HIV-1 reverse transcriptase and protease enzymes. The viral genes that encode these two enzymes are prone to the development of mutations because the HIV-1 reverse transcriptase is highly error-prone when reverse transcribing viral RNA into proviral DNA, the characteristic step in the viral life cycle during each round of replication of a retrovirus, including HIV-1. Given the extremely high replication rate of HIV-1, mutations in the HIV-1 reverse transcriptase and protease-encoding genes, including those that confer drug resistance, can be expected to be generated on a daily basis and to be present in a patient in a minority of virus subpopulations, even in the absence of antiretroviral drug pressure. Thus, in the absence of sufficient drug pressure, such as the use of any current antiretroviral monotherapy or of insufficiently potent combination therapy, pre-existing drug-resistant viruses eventually show preferential growth that results in treatment failure (Fig. 141a.1). This forms the basis for the current standard of giving treatment with highly active antiretroviral therapy (HAART) using potent combinations of multiple antiretrovirals.

Clinical features

Clinically, a harbinger of the possible emergence of retroviral drug resistance is the repeated demonstration of levels of plasma HIV-1 RNA above the quantification limit of the assay being used, after HIV-1 RNA levels, following the institution of therapy, have become undetectable using the same assay. It is important to realize that this is not necessarily immediately accompanied by a decline in blood $CD4^+$ lymphocyte numbers or by the development of clinical symptoms. It is therefore crucial that patients being treated with HAART are monitored by regular determination of plasma HIV-1 RNA levels, so that the emergence of potential retroviral drug resistance can be noted in a timely manner.

Investigations

Although rebound of plasma HIV-1 RNA during HAART to detectable levels may indicate retroviral drug resistance, other causes for drug failure need to be considered to determine the subsequent approach to treatment in such patients. Certain of the combinations of antiretrovirals currently used for HAART dictate the use of large numbers of pills according to strict administration schedules, with different requirements for each drug in the combination with respect to timing, possibility of co-administration and concomitant consumption of food. Consequently, it is understandable why lack of continuous patient adherence to these often complicated treatment regimens is increasingly becoming apparent as an important determinant of HAART failure. Thus, taking the patient's history with respect to treatment adherence is crucial when evaluating 'drug' failure. Therapeutic drug monitoring by determining plasma levels, particularly of HIV protease and non-nucleoside reverse transcriptase inhibitors (NNRTIs), may yield additional information in judging patient compliance with therapy. Furthermore, such monitoring may identify patients who, despite proper compliance, have insufficient drug exposure because of variation between individuals in pharmacokinetics and/or pharmacodynamics of protease inhibitors or NNRTIs, or because of drug interactions that result from the use of certain concomitant medications.

Poor patient adherence leads to insufficient drug pressure and results in increased virus replication and emergence of virus resistant to those antiretroviral agents that are being continued (see Fig. 141a.1). This is

Figure 141.a-1 A way to explain troughs, mutants and staunch compliance. Relationship between lack of patient adherence to treatment, insufficient drug levels and emergence of resistance. *Adapted with permission from Mascolini M. The drugs we've got ... the drugs we're getting ... beyond blood: a three part look at the Fourth Conference on Retroviruses and Opportunistic Infections. J Int Assoc Physicians AIDS Care 1997;3:30.*

seen most rapidly and is most pronounced for those agents that are particularly vulnerable to resistance development, such as lamivudine and the currently available NNRTIs.

The measurement of retroviral drug resistance of circulating virus can be carried out with both genotypic and phenotypic assays (see also Chapter 137 and Chapter 204). Genotypic assays, which identify the presence of specific mutations in defined gene sequences (e.g. the HIV reverse transcriptase or protease genes), are relatively rapid to perform but only provide an indirect measure of resistance and do not necessarily correlate with phenotypic assays, a problem particularly pronounced for HIV protease inhibitors. Moreover, certain of these assays cannot detect the presence of minority populations of viruses (i.e. those that comprise <20% of total plasma viral RNA), which harbor potentially resistance-conferring mutations. Phenotypic assays, which measure the in-vitro growth capacity of a virus isolate in the presence of increasing concentrations of a drug, are a more direct measure of resistance but are labor-intensive, slower to perform and (like genotypic assays) may be insensitive to minority populations of virus. Finally, it is important to realize that the cut-off for determining phenotypic susceptibility or resistance of a virus to a particular drug should be judged in relation to the concentration of that drug that is achieved in vivo. Resistance to a drug that is present when dosed in its usual manner could be overcome by increasing the dose of the drug as long as increasing drug concentrations are not hampered by loss of tolerability. This demands the availability of drugs with a wider therapeutic margin than is currently the case.

Further standardization and validation of the currently available resistance assays in relation to the drug levels achieved in the patient will become increasingly important to enhance the usefulness of resistance testing in guiding therapeutic choices in individual patients.

Management

Several prospective randomized clinical trials have now demonstrated an improved short-term (6–12 months) virologic outcome for patients who had failed to maintain adequate virus suppression on their current treatment, when treatment was adjusted based on genotyping and/or phenotyping as compared with clinical judgment only.

In addition, these trials have demonstrated that the benefit of resistance testing is enhanced by providing the clinician not just with a result of resistance testing but also with expert advice on how to interpret and use this result. Clearly, given the significant degree of cross-resistance between drugs within each of the three currently available classes of antiretrovirals, the usefulness of resistance testing is hampered by the lack of available alternative agents. This is also reflected in the relatively small degree of improved virologic outcome in the above-mentioned trials. Whether to change therapy and which alternative drugs to use in patients who are failing treatment will always remain a multifactorial decision-making process. This will involve not only the use of resistance testing assisted by expert interpretation and advice but at the same time obtaining a detailed history of prior antiretroviral exposure, knowledge of patterns of cross-resistance, and information concerning patients' adherence and drug level monitoring. The increasing availability of rapid and reliable HIV drug-resistance assays is likely to help not only to guide the choice of therapy in patients who have become resistant to prior treatment, but also to select initial treatment in certain circumstances. Examples of these are the choice of initial treatment in regions that have a high prevalence of primary HIV infection with drug-resistant strains, in infants who have become perinatally infected despite the use of antiretroviral therapy by their mothers, and in the setting of drug prophylaxis following accidental or sexual exposure to HIV from a known source. In patients failing therapy with a history of exposure to multiple prior drugs and drug regimens, the usefulness of resistance testing will to a large extent remain dependent on the development and introduction of novel drugs that do not exhibit cross-resistance to the current armamentarium. (See also Chapter 137 , Chapter 138 and Chapter 204 .)

141.b Drug interactions in HIV and AIDS

Charles W Flexner
Stephen C Piscitelli

Introduction

The recognition and management of pharmacokinetic and pharmacodynamic drug interactions is a major factor in choosing drugs and designing dosage regimens for the HIV-infected patient. Complex, multidrug regimens have become the standard of care and clinicians must be aware of the potential need for dosage alterations with combination therapy. Many of the antiretrovirals in current use can alter concentrations of concomitantly administered drugs or have their own concentrations altered by other agents. These interactions can be detrimental or beneficial to the patient.

Nucleoside reverse transcriptase inhibitors

The nucleoside reverse transcriptase inhibitors (NRTIs) are primarily eliminated by renal mechanisms and thus they are not generally involved in clinically significant pharmacokinetic interactions. These agents can be used with protease inhibitors and non-nucleoside reverse transcriptase inhibitors (NNRTIs) without the need for dosage alterations. Two NRTIs — zidovudine and abacavir — are eliminated in part by hepatic glucuronidation. Inducers of glucuronyl transferase activity could modestly lower plasma concentrations of these agents, although the clinical significance of this is uncertain since the active metabolites are intracellular nucleoside triphosphates.

Nucleoside reverse transcriptase inhibitors may interact pharmacodynamically with agents that have similar side-effect profiles. Increased bone marrow toxicity may be observed when zidovudine is used with other drugs capable of bone marrow suppression, such as ganciclovir and sulfamethoxazole. Didanosine and stavudine are associated with pancreatitis and should be used with caution in those receiving other agents with known pancreatic toxicity, such as pentamidine. Patients receiving combinations of didanosine, stavudine and zalcitabine should be counseled on the signs and symptoms of peripheral neuropathy and pancreatitis. Several NRTIs have been associated with lactic acidosis and should be used cautiously with other agents causing hyperlactatemia, such as metformin. The combination of didanosine and stavudine has been particularly associated with lactic acidosis and should be avoided.

The NRTI tenofovir increases the plasma levels of concomitantly administered didanosine and may increase the toxicity of didanosine if standard doses are used. A dose reduction to didanosine 250mg daily is recommended.

Non-nucleoside reverse transcriptase inhibitors

Nevirapine and efavirenz are moderate inducers of cytochrome P450 (CYP) 3A4. Both agents have been shown to decrease the area under the concentration-time curve (AUC) of amprenavir, indinavir and saquinavir (Table 141b.1). These agents should not be used with saquinavir, unless in combination with ritonavir, because of a large decrease in the saquinavir AUC.

TABLE 141.b-1 -- Consequences of selected cytochrome P450-mediated drug interactions.

CONSEQUENCES OF SELECTED CYP450-MEDIATED DRUG INTERACTIONS		
	Agents affected	**Consequence**
CYP450 inhibitors		
Amprenavir	Amprenavir, benzodiazepines, calcium channel antagonists, indinavir, lopinavir, rifabutin, saquinavir, terfenadine	Increased concentration of co-administered drug and possible increased therapeutic effect or toxicity
Cimetidine		
Clarithromycin		
Delavirdine		
Erythromycin		
Grapefruit juice		
Itraconazole		
Indinavir		
Ketoconazole		
Nelfinavir		
Ritonavir		
CYP450 inducers		
Carbamazepine	Amprenavir, calcium channel antagonists, indinavir, lopinavir, methadone, oral contraceptives, saquinavir	Decreased concentration of co-administered drug and possible decreased therapeutic effect
Efavirenz		
Nelfinavir		
Nevirapine		
Phenobarbital		
Phenytoin		
Rifabutin		
Rifampin (rifampicin)		
Rifapentine		
St John's wort		

Efavirenz affects other drug-metabolizing enzymes and may act as a P450 inhibitor in certain situations. It increases concentrations of ritonavir and nelfinavir by approximately 20% presumably through inhibition of CYP450 pathways. In general, no dosage adjustments are required with these combinations.

Delavirdine is a moderate inhibitor of the CYP 3A4 enzyme and can increase concentrations of saquinavir 5-fold and indinavir 3-fold (see Table 141b.1). Serious

toxicity could occur if delavirdine is used with certain 3A4 substrates, such as the nonsedating antihistamines astemizole and terfenadine (no longer marketed in the USA), cisapride (also no longer marketed), certain benzodiazepines or ergot derivatives (Table 141b.2). Absorption of delavirdine can be affected by changes in gastric pH and its administration should be separated from didanosine, antacids and H_2 -blockers.

Protease inhibitors

The protease inhibitors are metabolized by CYP450, mainly by 3A4, and can inhibit these enzymes. Thus, they possess the same contra-indications as noted above with delavirdine. Ritonavir has the greatest degree of inhibition and is associated with the largest number of observed and potential drug interactions. Amprenavir, indinavir and nelfinavir have a moderate potential to cause interactions and saquinavir has the fewest drug interactions described.

The potent inhibition of CYP 3A4 by ritonavir can be used to optimize the AUC of saquinavir, which previously required ingestion of up to 18 large capsules per day. Concomitant administration with ritonavir results in a 20-fold increase in steady-state saquinavir concentrations, allowing for a dosage reduction of saquinavir to as little as 400mg q12h, while maintaining high blood concentrations. Once-daily combinations of 1600mg saquinavir with 100mg of ritonavir are under investigation. This combination was successful at suppressing HIV replication in clinical trials in protease inhibitor-naive subjects. The combinations of ritonavir with amprenavir, indinavir or lopinavir show similar activity.

In addition to enzyme inhibition, ritonavir and nelfinavir possess moderate enzyme-inducing properties and decrease concentrations of a number of co-administered agents (see Table 141b.2). Ritonavir

TABLE 141.b-2 -- Specific contraindicated drugs with potential for serious drug interactions.

SPECIFIC CONTRAINDICATED DRUGS WITH POTENTIAL FOR SERIOUS DRUG INTERACTIONS		
Agent or drug class	**Interacting drugs**	**Consequence**
Terfenadine, astemizole and cisapride*	CYP450 inhibitors (macrolides, delavirdine, protease inhibitors, azole antifungals)	Decreased metabolism with increased concentrations and potential for cardiac toxicity
Long-acting benzodiazepines (alprazolam, midazolam)	CYP450 inhibitors	Decreased metabolism with potential for oversedation
Ergot derivatives	CYP450 inhibitors	Decreased metabolism with potential for cardiovascular toxicity
Protease inhibitors	CYP450 inducers (efavirenz, rifampin, St John's wort)	Increased metabolism with decreased concentrations and potential for resistance and treatment failure

* Removed from the US market.

and nelfinavir also increase glucuronyl transferase activity. Ethinyl estradiol and progesterone concentrations can be decreased by concomitant administration of these two protease inhibitors, necessitating alternative forms of birth control. Amprenavir appears to be an inducer of drug-metabolizing enzymes in some circumstances.

Combining protease inhibitors with ritonavir can offer additional advantages to patients. For example, indinavir requires three times daily administration on an empty stomach or with a light meal. When administered in combination with ritonavir, it can be dosed twice daily with food and still produce high plasma concentrations.

Certain enzyme-inducing agents can produce profound decreases in the concentrations of protease inhibitors. For example, rifampin (rifampicin) has been shown to decrease the saquinavir AUC by 80% and the indinavir AUC by 65%. The resulting low blood levels have the potential to promote drug resistance and treatment failure, so indinavir and saquinavir should be avoided in patients receiving rifampin. Other potent enzyme inducers, such as phenytoin, phenobarbital and carbamazepine, could produce similar reductions.

Management of drug interactions

A careful review of patient medication profiles is essential to managing drug interactions in the HIV-infected patient. This should include complementary and alternative medicines, since agents such as St John's wort induce CYP 3A4 and can reduce concentrations of indinavir and presumably other protease inhibitors. Clinicians need to have a general understanding of certain 'red flag' drugs that are potent inhibitors and inducers of CYP450 (i.e. ritonavir, efavirenz, etc.). In this era of complex regimens, a table of recommended dosages for each combination of protease inhibitors or NNRTIs should be immediately available.

Patient counseling is critically important when complex antiretroviral regimens are prescribed. Patients must be instructed on how to take their medications with regard to timing and content of meals. In some cases, a written daily calendar of medications and times of administration may be useful to the patient and may improve adherence. Proper separation of dosing of certain drugs (i.e. didanosine and indinavir) must be explained and can also be documented on a daily dosage planner.

The HIV clinician can use a variety of interventions to manage drug interactions. Selection of a drug with fewer interactions should be considered if warranted by the clinical situation. For example, azithromycin is not metabolized by CYP450 and has far fewer drug interactions compared with other macrolides. Also, drugs that can be administered once or twice daily may be useful to lessen food-related interactions or dosage separation problems. Finally, clinicians should be aware of and try to avoid drugs with overlapping toxicities. However such combinations are sometimes unavoidable and patients who receive these agents must be closely monitored for the development of toxicity.

141.c How to manage the hepatitis C virus co-infected HIV patient

Stanislas Pol
Anaïs Vallet-Pichard
Hélène Fontaine
Pascal Lebray
Rodolphe Sobesky

Interactions between HIV and the hepatitis C virus (HCV) were widely studied before the introduction of highly active antiretroviral therapy (HAART). The latter has markedly modified the prognosis of HIV infection, resulting in a significant decrease in morbidity and mortality that may now reveal liver-related complications. Since the improvement in treating HCV infection paralleled the progress in treating HIV, the question is now how to manage HIV-HCV co-infected patients.

Why evaluate HIV-hepatitis C virus co-infection?

Consequences of HIV-hepatitis C virus co-infection

Anti-HCV antibodies are frequently detected in HIV-infected patients, especially in hemophiliacs and intravenous drug users (around 70–90%), and are usually associated with active infection as assessed by detectable HCV viremia. This prevalence may be underestimated in case of delayed seroconversion and seroreversions.

It has recently been suggested that genotype 1b HCV may worsen the natural history of HIV in hemophiliacs and drug users. Moreover, HCV infection (and active intravenous drug use) has been suggested as an important factor in the morbidity and mortality of HIV-1-infected patients. Liver disease associated with HCV is an important cause of morbidity (8.6% of admissions) and mortality (4.8%) in HIV-HCV co-infected patients.

On the other hand, HIV significantly modifies the natural history of HCV infection:

- ¦ by increasing levels of HCV viremia;
- ¦ by significantly increasing the risk of mother-to-child or sexual transmission (from a mean of 6% to 20% and from 0% to 3%, respectively);
- ¦ by increasing (2- to 5-fold) and accelerating the risk of cirrhosis: this translates into a significantly increased yearly progression of the fibrosis score in co-infected subjects depending on the CD4 cell count level (<200 cells/mm^3) and possibly chronic alcohol consumption; and
- ¦ by increasing the risk of fibrosing cholestatic hepatitis, related to direct cytotoxicity of HCV in case of high viremia leading to accumulation of viral proteins in the endoplasmic reticulum and hepatocyte death.

The pathophysiology of HCV-related chronic hepatitis is not fully understood. Immune-mediated mechanisms are mainly involved but a direct cytotoxicity of the high HCV viremia cannot be excluded. Infection with HIV may have a direct cytopathic effect on liver cells or may modify the pattern of cytokine production, leading to production of fibrogenic factors or to decrease in antifibrogenic factors.

Impact of highly active antiretroviral therapy

Late consequences of HCV-related chronic liver disease were probably overshadowed by the extrahepatic causes of deaths, related to severe immune deficiency. Given the increasing frequency of HCV-HIV co-infection, the significant increase of cirrhosis in immunocompromised patients and the significant improvement in survival with therapeutic progress in the field of anti-HIV therapy, the next few years may see the occurrence of symptomatic liver disease leading ultimately to hepatic carcinoma in HIV-HCV co-infected patients, underlining the need for early diagnostic procedures and therapeutic strategies.

Improvement in immunity could be deleterious in case of diseases involving immune-mediated mechanisms, such as chronic viral hepatitis. Antiretroviral therapy restores both CD4 and CD8 cells (directed against specific HCV antigens), which may participate in the pathologic deterioration. Several cases of liver deterioration paralleling immune restoration in HCV-HIV co-infected patients have been reported. Thus, a careful liver follow-up in HCV-HIV co-infected patients on triple combination antiretroviral therapy is required.

Antiretroviral therapy, by improving immune status, could decrease HCV viral load and thus the severity of HCV liver disease if direct viral cytotoxicity is, at least partially, responsible for the histopathologic lesions of chronic hepatitis. However, there is no significant variation in HCV RNA load after 3, 6 or 9 months of triple therapy in HCV-HIV co-infected subjects, as compared with baseline values, suggesting that HAART will not decrease HCV-related liver disease associated with HCV replication.

All antiviral drugs have potential toxicity. Nucleoside reverse transcriptase inhibitors cause rare but severe hepatitis, which is due to a mitochondrial cytopathy with severe microsteatosis and lethal lactic acidosis. Non-nucleoside reverse transcriptase inhibitors are responsible for clinical hepatitis in 2–5% of cases, which are sometimes severe (0.1% of cases) and are associated with signs of hypersensitivity in two-thirds of cases. Drug-related hepatitis in association with protease inhibitors is observed in 2–8.5% of treated patients, with a predilection for patients co-infected with HCV or HBV. In most cases of drug-related hepatitis, liver biochemical abnormalities resolve after discontinuation of the drug and do not relapse after changing of protease inhibitor. The rate of HAART withdrawal in relation to hepatotoxicity is around 2% without significant difference regarding the type of antiretroviral treatment.

Drug-related hepatitis may participate in the deterioration of liver histology, as well as hepatitis of immune function restoration, direct cytotoxicity of HCV and other usual causes of liver damage, including alcohol toxicity (Fig. 141c.1).

Figure 141.c-1 Involvement of putative liver lesions in HIV-HCV co-infection.

Therapeutic implications

Treatment of hepatitis C virus infection in co-infected patients

The increased risk of cirrhosis in HCV-HIV co-infected patients, the histologic deterioration under anti-HIV therapy related to immune restoration, direct viral cytotoxicity or drug toxicity, and the increase in survival of HIV-infected patients underline the need for reliable anti-HCV antiviral therapies. An important issue is to distinguish who among HIV-HCV co-infected patients should receive anti-HCV treatment with the aim of eradicating HCV.

In co-infected patients, interferon alone led to a low rate of viral eradication (around 15%) with significant side-effects but a low impact on the HIV status.

The standard treatment of HCV infection is now the combination of ribavirin and interferon. Ribavirin, a nucleoside analogue, has no clear effect as monotherapy on HCV or HIV and is now currently given in combination with interferon-a in treating hepatitis C in HIV-infected patients. The ribavirin-interferon-a combination results in a 40% rate of HCV eradication in the non-HIV population with a range from 15% to 80% according to the virologic (genotype and quantitative viremia) and pathologic (fibrosis) predictive factors and to the duration of therapy (6 or 12 months). Sustained viral eradication is usually associated with a long-lasting resolution and histologic improvement or normalization.

The results of the ribavirin-interferon combination in HIV co-infected patients have been reported. In-vitro inhibition of the phosphorylation by ribavirin of zidovudine, stavudine and zalcitabine has been reported but it does not seem to clearly modify the efficacy of HAART in vivo. By contrast, in vitro, ribavirin may positively interfere with phosphorylation of didanosine and the combination didanosine, ribavirin and interferon is highly synergistic and increases the side-effects of didanosine, especially lactic acidosis and pancreatitis.

The combination of interferon-a and ribavirin may lead, in naive HCV-HIV co-infected patients, to an overall 25% rate of sustained eradication, with a good tolerance, especially at the immunologic level. This low rate of sustained response is expected since cirrhosis, high pretreatment viremia and high genomic heterogeneity, predictors of poor response, are more frequent in co-infected patients. In summary, we recommend such a combination in HCV-HIV co-infected patients with close monitoring of CD4 and HIV viral load in those with a biopsy-proven fibrotic liver disease (Fig. 141c.2).

Recently, pegylated (long-lasting) interferon-a was shown to be more efficient than the usual interferon-a to obtain viral eradication with a better quality of life. In the non-HIV population, the combination of the pegylated interferon-a (1.0–1.5µg/kg/week subcutaneously) with ribavirin (800–1200mg/day, the recommended dose being >10.6mg/kg/day) for 48 weeks leads to an overall 55% rate of viral eradication, with a benefit mainly observed in patients with poor predictors of sustained response (genotype 1, high quantitative viremia). Preliminary results of studies of pegylated interferon-a plus ribavirin in HIV positive patients suggest it is superior to interferon-a plus ribavirin (see also Chapter 125).

Pragmatic management of hepatitis C virus co-infected patients

Pre-existing biochemical abnormalities do not contraindicate the use of antiretroviral drugs although nevirapine and ritonavir should be used cautiously. In some difficult situations, the measurement of the plasma levels of antiretroviral drugs may be valuable in order to avoid any overdoses that may lead to hepatotoxicity. In HCV-HIV co-infected patients treated with protease inhibitor, a monthly biochemical follow-up is warranted in the first 3 months after introduction of any new antiretroviral drug and then every 3 months in order

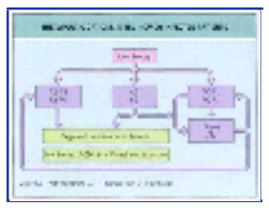

Figure 141.c-2 Therapeutic options in HIV-HCV co-infected patients.

to identify potential drug-related toxicity. An increase in ALT levels (>5-fold the upper normal value, but the rate of increase is more important than the absolute values) should lead to a switch of the protease inhibitor or to the introduction of a non-nucleoside reverse transcriptase inhibitor. Biochemical liver abnormalities occurring with non-nucleoside reverse transcriptase inhibitor should lead to treatment withdrawal, especially if cutaneous signs of hypersensitivity are associated. However, the interpretation of such biochemical liver abnormalities is difficult, raising the question of drug-related hepatitis but also of other toxic causes such as alcohol, cocaine, or metamphetamine.

An unsolved question is the respective place of anti-HCV and anti-HIV therapies. In clinical practice, most HIV patients are referred to the hepatologist while receiving HAART and the question is not relevant. In the future, physicians will have to consider the priority of each treatment according to liver histology and immune status. Given the chance of complete eradication of HCV-associated chronic hepatitis, anti-HCV therapy should be considered a priority and be treated first if the CD4 lymphocyte count is not less than 300 cells/mm^3 . A marked inflammatory activity or fibrosis (A2–A3 or F3–F4) indicates a need for anti-HCV treatment in order to avoid deleterious evolution; in contrast, a low inflammatory activity or fibrosis (A0–A1 or F0–F1) does not necessarily indicate anti-HCV treatment but a liver follow-up by biopsy and biochemical evaluation of fibrosis every 3 years. In intermediate situations (A2–F2), the choice to treat or not to treat should be based mainly on the predictive factors, including genotype and quantitative viremia (see Fig. 141c.2).

In conclusion, physicians should be aware of the potential risk of:

- symptomatic liver disease in HCV-HIV co-infected patients in the era of antiretroviral therapy;
- liver deterioration paralleling immune function restoration;
- lack of impact of active antiretroviral therapy on HCV load; and
- potential drug-related hepatitis that may modify the natural history of HCV-related liver disease.

Liver biopsies should be regularly performed to identify patients with severe liver disease who require early anti-HCV therapy (see Fig. 141c.2) under close monitoring of the immune status.

141.d How to manage hyperlipidemia in the HIV patient

Judith Currier

Typical case

A 45-year-old woman with HIV infection presents to establish primary care. She was diagnosed with HIV during pregnancy 7 years ago. Initially her $CD4^+$ T cell count was 450 cells/mm^3 . She was treated with ZDV monotherapy for 8 months during her pregnancy and stopped all therapy 1 month postpartum. She restarted treatment 2 years ago when her $CD4^+$ T cell count was 225 cells/mm^3 and her HIV RNA is 65,000 copies/ml. She has maintained an undetectable HIV RNA on her current regimen of stavudine, lamivudine and nelfinavir. She has no family history of diabetes or heart disease. She has not had a menstrual period for 3 years. She smokes one pack of cigarettes per day. Her physical examination is normal and her blood pressure is 142/80mmHg. Fasting lipid values include triglycerides of 420mg/dl (4.75mmol/l), total cholesterol 260mg/dl (6.73mmol/l) and HDL cholesterol 28mg/dl (0.73mmol/l). Lipid values prior to starting treatment are not available. Does this patient have a clinically significant dyslipidemia and, if so, what are the options for management?

Dyslipidemia in HIV infection

The dyslipidemia associated with HIV infection may be a consequence of HIV infection per se, a direct effect of the antiretroviral agents used to treat HIV infection or it may be secondary to central adiposity and insulin resistance that can occur during treatment. Currently marketed protease inhibitors (PIs) differ slightly in their ability to cause dyslipidemia, whereas in general non-PI-containing regimens have been found to have less of an effect on lipids. Median increases in total cholesterol of 40–60mg/dl (1.04–1.55mmol/l) and triglyceride increases of 80–100mg/dl (0.90–1.13mmol/l) have been reported in studies examining currently marketed PIs. The magnitude of the effect on lipids may vary for different PI combinations. Patients with untreated advanced HIV infection have been noted to have a pattern of low HDL cholesterol and increased triglycerides.

Estimating cardiovascular risk

The long-term significance of dyslipidemia in HIV-infected individuals is not completely known. The patterns of lipid abnormalities most commonly observed in patients with HIV infection might be expected to result in increased cardiovascular morbidity. In many cases both antiretroviral therapies and HIV infection per se are thought to contribute. Large studies are currently underway to determine the incidence of cardiovascular events and atherosclerosis in HIV-infected individuals and the relative contribution of the identified risk factors. Preliminary recommendations for the management of dyslipidemia in HIV-infected individuals have been developed from existing guidelines applicable to the general population.

The National Cholesterol Education Program (NCEP) guidelines are a reasonable starting point for considering the need for intervention. These guidelines utilize threshold values of LDL cholesterol and consider the following as important risk factors for cardiovascular disease: current cigarette smoking, diabetes, hypertension, family history of coronary heart disease and HDL cholesterol. The first step in evaluating cardiovascular risk is to determine whether two or more risk factors are present. If so, then an estimate of the 10-year cardiovascular risk using the Framingham scoring system is suggested. In our example the patient has several classic risk factors for cardiovascular diseases; she is a smoker with untreated hypertension who is postmenopausal and she also has low HDL cholesterol and elevated total cholesterol. Using Table 141d.1 Table 141d.2 Table 141d.3 Table 141d.4 Table 141d.5 Table 141d.6 Table 141d.7 adapted from the NCEP ATP III guidelines, we can total her points for each of the risk factors to discover that she has a total of 23 points, which correlates with an estimated 10-year cardiovascular risk of over 20%. This is considered a high risk, similar to that of someone with established coronary heart disease.

The reliance on LDL cholesterol complicates the use of NCEP guidelines in the management of patients with HIV infection. When the value for triglycerides exceeds 400mg/dl (4.52mmol/l), calculation of LDL cholesterol from the total cholesterol and HDL is not accurate. Direct measurement of LDL is not available in many settings and hence it may be reasonable to base decisions for intervention on the values of non-HDL cholesterol. The value for non-HDL cholesterol is the total cholesterol minus HDL cholesterol. In our example, the value for non-HDL cholesterol would be 260 - 28 = 232mg/dl (6.0mmol/l). The NCEP ATP III guidelines include goals for non-HDL cholesterol in addition to LDL cholesterol and these are included in Table 141d.8 .

Management

Now that we have established that the patient in this example requires intervention for her dyslipidemia, we can consider the options for management. The first steps would include discussing her diet and lifestyle. The importance of smoking cessation and treatment of her hypertension should be addressed. These modifiable risk factors

should be addressed prior to considering altering her currently successful antiretroviral regimen. Her diet should be reviewed and she should be given information on a low-fat (with reduced saturated fat), low-cholesterol diet. Given her calculated level of cardiovascular risk, additional measures to lower her non-HDL cholesterol are likely to be needed.

The additional measures for management of this patient's dyslipidemia include alteration in her antiretroviral regimen and the use of lipid-lowering agents. There are currently limited data to guide clinicians in this regard. Several studies have suggested a benefit of substituting a non-nucleoside analogue such as nevirapine or efavirenz as a reasonable option for patients who are well suppressed on a PI-containing regimen with dyslipidemia. The nucleoside analogue abacavir can also be substituted for the PI component of the regimen; however, in patients with a history of prior nucleoside analogue monotherapy the substitution of abacavir may be associated with an increased risk of virologic failure due to pre-existing nucleoside resistance mutations. The patient in this example received monotherapy with zidovudine for 8 months during an earlier pregnancy and this may increase her risk of failing an abacavir substitution. In our case, substitution of nelfinavir with nevirapine or efavirenz would be my preference for initial management of her dyslipidemia. If the patient is reluctant to change her therapy, the use of lipid-lowering agents should then be considered if changes in diet are not successful.

There are currently limited data on the efficacy of lipid-lowering therapy in patients with HIV infection. The HMG-CoA reductase inhibitors (statins) are generally the first-line intervention for lipid disorders in the general population. Important drug interactions between the statin agents lovastatin and simvastatin and the PIs have been reported and these agents are not currently recommended. The statin agent least likely to interact with PIs is pravastatin. Drug interactions are unlikely to occur with the use of fibric acid derivatives gemfibrozil and fenofibrate. Preliminary results of clinical trials evaluating the use of either gemfibrozil and statin agents have been reported. In the case above, with elevations in both triglycerides and non-HDL cholesterol, the use of gemfibrozil at a dose of 600mg po twice daily 30 minutes prior to meals in addition to dietary advice would be a reasonable first approach if substituting the nelfinavir with a non-nucleoside were not an option. If there was no response after 3 months consideration should be given to adding a statin agent-pravastatin at a dose of 20mg po qd. Close monitoring for hepatotoxicity and myopathy is warranted when statin and fibrate agents are used concurrently. Again, substituting the PI component of the regimen would be preferable to adding a second lipid-lowering agent.

As the treatment of HIV infection has evolved into the management of a chronic disease more emphasis is being placed on preventing long-term complications from both the disease and the therapies used to treat it. Currently, it is not known whether patients with HIV infection who sustain increases in lipids are at the same risk as would be expected if these lipid changes occurred spontaneously. It is important for clinicians to be aware of these issues and to screen patients for lipid disorders. Attention to modifiable cardiac risk factors such as smoking, diet and level of physical activity is critical and should not be overlooked. In settings where the underlying cardiovascular risk appears to be high, further interventions with lipid-lowering agents or modification of the antiretroviral regimen may be warranted.

141.e Managing the patient with multidrug-resistant HIV

Pablo Tebas

Frequency of the problem

Unfortunately, because of difficulty with adherence to antiretroviral treatment or the sequential use of partially suppressive regimens when therapy was initiated, a very significant proportion of patients with HIV infection develop multidrug-resistant HIV. In a recent survey of the ongoing HIV Costs and Service Utilization Study (HCSUS), approximately 63% of the patients under care had a detectable viral load at the time of the last determination, 78% of those had resistance to at least one drug and more than 50% were resistant to two. These data suggest that more than 100,000 patients in the USA alone (or half of the total number of patients in care) are infected with viruses that are resistant to antiretroviral drugs. HIV disease is like other infectious diseases, such as tuberculosis or malaria, in which the development of resistance is a frequent clinical problem. The problem of drug resistance in HIV is more common among subjects receiving therapy and those who are in care than among patients who have never received treatment.

Primary resistance to HIV therapies is rising alarmingly among new and chronically infected individuals in the developed world. Unfortunately, this problem will also affect the developing world when antiretroviral therapy becomes more widely available. Primary resistance is more frequently seen with nucleoside reverse transcriptase inhibitors, since these are the drugs that have been used for the longest period of time. It is increasing among non-nucleoside reverse transcriptase inhibitors and protease inhibitors. The goal is to prevent this problem by the intelligent use of antiretroviral medications and resistance testing. Despite these efforts, the use of antiretroviral therapy will always be associated with the development of resistance. Clinicians will frequently face patients for whom no therapeutic options are readily available.

Therapeutic options for the patient who has multidrug-resistant HIV

When the number of treatment options is limited, the clinician must select between discontinuing a costly, and potentially ineffective toxic treatment that is increasing the risk of accumulating multiple resistance mutations, or maintaining a partially suppressive regimen in the hope that this approach will delay the appearance of immunologic and clinical failure.

Several considerations are important in this all too frequent situation. First, virologic failure is not equivalent to immunologic and clinical failure. A recent study indicates that the median period of time between virologic and immunologic failure is 36.4 months (3 years). The delay between virologic and immunologic failure seems to be associated with the decreased replicative fitness of viruses that harbor protease-inhibitor-associated resistance mutations. Viruses with multiple mutations are less cytopathic in vitro than wild-type isolates. Second, discontinuing therapy in the patient with multidrug-resistant virus is associated with the overgrowth of wild-type virus after approximately 12 weeks. This switch to wild type as the predominant quasispecies in the patient is associated with a significant decay in the CD4+ T cell count, rapid progression of HIV disease and, in some cases, serious opportunistic infections. Third, there is growing evidence that the rates of clinical progression are low in patients who continue antiretroviral therapy in the presence of virologic failure. These subjects maintain their CD4+ cell numbers, especially if the viral load is maintained below the natural set point of the patient (the HIV RNA load before the initiation of antiretroviral therapy).

Based on the above, most experienced clinicians would maintain a partially suppressive regimen in a patient with limited therapeutic options, especially if the disease is in an advanced stage. The goal of therapy in this situation shifts from complete suppression of viral replication to partial suppression to prevent immunologic and clinical decline.

Many clinicians also maintain lamivudine in these patients because the presence of the M184V mutation (usually associated with the use of lamivudine) may enhance susceptibility to zidovudine, stavudine or tenofovir. These drugs are frequently used individually as part of combination regimens in the patient with multidrug resistance. The presence of this mutation also stabilizes the reverse transcriptase of the virus and makes it less prone to make errors, which are associated with the development of resistance. This effect may be overcome by an accumulation of nucleoside associated mutations (also known as NAMs): M41L, E44D, D67N, K70R, V118I, L210W, T215Y/F and K219Q/E (see Chapter 137 and Chapter 204).

Other authors have suggested the used of multidrug combination regimens (six or more drugs), also called 'mega-HAART regimens', in this situation. Occasionally, significant antiviral activity has been observed; however, these regimens are complicated to use, especially in patients with adherence problems (as is usually the case in patients with multidrug resistance). They are also associated with significant side effects, drug-drug interactions and increased cost. The use of therapeutic drug monitoring (measuring antiretroviral drugs levels, and adjusting dosages accordingly) might be necessary in these cases.

Although some authors have suggested that transient discontinuation of antiretroviral treatment might 'resensitize' the virus and make it susceptible to previously used antiretroviral agents, this phenomenon is probably short-lived because of 'archived' resistance of the integrated HIV in the T cell memory reservoirs. This approach might work better in the patient who has some therapeutic options left, and should always be undertaken with extreme caution because of the high risk of significant clinical deterioration in the patient who has advanced disease.

In the patient with multidrug-resistant HIV, it is also critically important to maintain all prophylactic regimens that the subject should be taking at the recommended CD4+ T cell count thresholds. Thus, it is important to maintain *Pneumocystis carinii, Toxoplasma* and *Mycobacterium avium* complex prophylaxis if indicated. It is probably also a good idea to increase the frequency of the clinical visits to once every month or two, so opportunistic infections can be readily identified and treated.

New drug availability

Before the licensing agencies (e.g. the Food and Drug Administration in the USA) grant full approval, new drugs often become available as part of compassionate use and expanded access programs. The clinician frequently is pressed and tempted to add this 'single' new drug to the regimen that the patient is taking, hoping to obtain at least a partial virologic and clinical benefit in a patient with very limited options. The decision to do this should be based on the clinical situation of the patient and the types of drugs available. For some classes of drugs, such as non-nucleoside reverse transcriptase inhibitors and fusion inhibitors, resistance develops very quickly if those drugs are not used as part of fully suppressive regimens. With other classes of drugs, such as protease inhibitors or nucleoside/nucleotide analogues, resistance takes longer to develop and durable virologic and potentially clinical benefits might be obtained.

For compounds where the threshold for developing resistance is low, it might be reasonable to wait until more drugs become available and a combination regimen with a good chance of response can be developed. For drugs with a higher threshold for resistance, immediate use might be advisable, especially in the patient who is clinically deteriorating. For example, enfuvirtide (also known as T-20) is a peptide fusion inhibitor that binds to the HR-1 domain of gp41. Its use has been associated with significant decreases in viral load when used as monotherapy, and improvements in the viral load response of otherwise optimized rescue regimens. HIV becomes resistant to this drug very quickly if it is not used as part of a fully suppressive antiretroviral regimen. Resistance mutations in the gp41 envelope gene have been identified primarily at positions 36 to 45 of the first heptad repeat (HR1) region. On the other hand, tenofovir, a recently approved nucleotide, was evaluated as an 'intensification' (the addition of a single drug to a failing antiretroviral regimen) in Gilead study 907. The virologic benefits (approximately half a log decrease in HIV viral load) were still present after 48 weeks of treatment.

If the patient is clinically failing antiretroviral therapy or the addition of a single drug is being considered, it is important to maximize the benefits of the background regimen that the patient is taking. Phenotypic resistance testing might have an edge over genotypic or 'virtual phenotype' testing (a genotype test with an automatic interpretation linked to a large database of geno-phenotypes) in this very complicated situation (see Chapter 137). It might better identify which drugs maintain a residual activity in vitro in a patient who has limited therapeutic options. It also might provide a measurement of 'replicative capacity' of the patient's virus.

The use of the replication capacity assay

Replicative fitness is the ability of a species or strain of virus to compete against others in a defined environment; for example, a wild-type virus is more 'fit' than a virus with multidrug resistance in a environment where there is no drug, but the reverse is true in the presence of antiretroviral therapy. To evaluate replicative fitness, it is necessary to conduct very cumbersome assays in which the two different strains to be tested compete against each other. Recently a 'replication capacity assay' has been provided as part of the phenotypic assay (see Chapter 137). In this assay patient-derived HIV reverse transcriptase or protease undergoes a single round of replication. The vector contains a luciferase gene that permits quantitation of replication, which is then compared to the level of replication of a wild-type HIV reference strain. The result is provided as the ratio of the patient strain replication to the wild-type (reference) strain replication. Normally, multidrug-resistant viruses have replication capacity values less than 1. Theoretically, the lower the number the less fit the virus is.

The number of studies using this assay is limited. Changes in the results obtained with this assay predicted the change in viral load when therapy was discontinued in patients with evidence of multidrug resistance. Based on those results and the results of small-cohort studies, some clinicians are using this assay to guide therapy in the patient with multidrug resistance by selecting combination regimens that lower the replication capacity of the predominant quasispecies of the patient. However, clinical validation of the utility of this assay is still lacking. Until then this approach might lead to unnecessary changes of otherwise well-tolerated regimens. Ensuring that the viral load is kept as low as possible, preferably below the natural set point of the patient, might be another approach to handle the patient who has limited therapeutic options.

Section 6 - GEOGRAPHIC AND TRAVEL MEDICINE

Seth F Berkley
Keith PWJ McAdam

Chapter 142 - Geography of Infectious Diseases

Mary E Wilson

INTRODUCTION

Infectious diseases vary by geographic region and population, and they change over time.[1] Increasingly, humans are moving from one region to another, thereby becoming exposed to a variety of potential pathogens and also serving as part of the global dispersal process.[2] Microbes picked up at one time and in one place may manifest in disease far away in time and place. Because many microbes have the capacity of persisting in the human host for months, years or even decades, the relevant time frame for study of exposures becomes a lifetime. Furthermore, microbes also move and change and reach humans via multiple channels.

Caring for patients in today's world requires an understanding of the basic factors that underlie the geography of human diseases and events that cause shifts in the distribution and burden of specific diseases. Current technology contributes to massive population movements and rapid shifts in diseases and their distributions, but it also provides communication channels that can aid clinicians who care for patients with complicated medical problems. This chapter reviews the factors that shape the global distribution of infectious diseases and the forces that are expected to shift distributions in the future. Several examples are used to illustrate the broad range of factors that affect the distribution and expression of infectious diseases.[3]

Many authors have traced the origins and spread of specific infectious diseases through human history. A century and a half ago, John Snow noted that epidemics of cholera followed major routes of commerce and appeared first at seaports when entering a new region.[4] Yersinia pestis, the cause of plague, accompanied trade caravans and moved across oceans with rats on ships. Exploration of the New World by Europeans introduced a range of human pathogens that killed one-third or more of the local populations in some areas of the Americas. The plants and animals introduced as a result of this exploration have also had profound and long-lasting consequences for the ecology and economics of the new environment. [5] The speed, reach and volume of today's travel are unprecedented in human history and offer multiple potential routes to move biologic species around the globe. Pathogens of animals and plants are being transported as well and this can affect global food security.[6] This chapter focuses only on pathogens that directly affect human health and on their sources (Table 142.1). When thinking about geography of human infections, it is useful to consider both the origin of the organism and the conveyor or immediate source for the human (Fig. 142.1).

This chapter addresses three key issues:

- factors influencing geographic distribution: why are some infectious diseases found only in focal geographic regions or in isolated populations?
- factors influencing the burden of disease: why does the impact from widely distributed infections vary markedly from one region or one population to another? and
- factors influencing emergence of disease: what allows or facilitates the introduction, persistence and spread of an infection in a new region and what makes a region or population resistant to the introduction of an infection?

FACTORS INFLUENCING GEOGRAPHIC DISTRIBUTION

In past centuries, lack of interaction with the outside world could allow an infection to remain geographically isolated. Today, most infections that are found only in focal areas have biologic or geoclimatic constraints that prevent them from being introduced into other geographic regions. For example, the fungus *Coccidioides immitis*, which causes coccidioidomycosis, thrives in surface soil in arid and semiarid areas with alkaline soil, hot summers and short, moist winters; it is endemic in parts of south-western USA, Mexico and Central and South America. People become infected when they inhale arthroconidia from soil. An unusual wind storm in 1977 lifted soil from the endemic region and deposited it in northern California, outside the usual endemic region.[7] In general, infection is associated with residence in or travel through the endemic region. However, because the fungus can persist in the human host for years, even decades, after initial infection (which may be mild and unrecognized), disease may be diagnosed far from the endemic regions.

Vectors

Many microbes require a particular arthropod vector or animal host and hence inhabit circumscribed regions and may be unable to survive in other habitats. Malaria is a vector-borne infection that cannot persist in a region without a competent vector. The presence of a competent vector is a necessary but not sufficient condition for human infection. The mosquito must have a source of malarial parasites (gametocytemic human who may be asymptomatic), an appropriate incubation period to allow development of the parasite to a form that is infective via a bite, and access to other humans. Prevailing temperature and humidity must allow the mosquito to survive long enough for the malarial parasite to undergo maturation to reach an infective state for humans. Competent vectors exist in many areas without malaria transmission, because the other conditions are not met. These areas are at risk of the introduction of malaria, as illustrated by several recent examples in the USA and elsewhere.[8] [9]

Malaria was endemic in many parts of the USA into the 20th century (Fig. 142.2), with estimates of more than 600,000 cases in 1914.[9] Even before extensive mosquito control programs were instituted, transmission declined. Demographic factors (population shifts from rural to urban areas), improved housing with screened doors and windows and the availability of treatment were among the factors that may have contributed to this decrease.

The flavivirus dengue is transmitted primarily by the widely distributed mosquito, *Aedes aegypti*, which is well adapted to human habitats. This viral infection has now become a major and growing problem in many tropical and subtropical regions throughout the world (see below).

The distribution of onchocerciasis in Africa is notable for its association with rivers.[10] The reason becomes clear by understanding that the vector of this filarial parasite, the black fly (genus *Simulium*), lays her eggs on vegetation and rocks of rapidly flowing rivers and

TABLE 142-1 -- Origins and conveyors of human pathogens.

ORIGINS AND CONVEYORS OF HUMAN PATHOGENS		
Origin or carrier	**Conveyor or immediate source**	**Examples of disease**
Humans	Humans	HIV, syphilis, hepatitis B
Humans	Humans (air-borne pathogen)	Measles, tuberculosis
Soil	Soil, air-borne	Coccidioidomycosis
Soil	Food	Botulism
Animals	Water	Leptospirosis
Humans	Mosquitoes	Malaria, dengue

Humans or animals (with snails as essential intermediate host)	Water	Schistosomiasis
Humans	Food	Typhoid fever
Animals	Water	Cryptosporidiosis, giardiasis
Some pathogens have multiple potential sources.		

usually inhabits a region within 5–10km on either side of a river. Another name for onchocerciasis, river blindness, describes the epidemiology as well as one consequence of infection.

Some pathogens have a complex cycle of development that requires one or more intermediate hosts. Distribution may remain relatively fixed, even when infected humans travel widely, if other regions do not supply the right combination and geographic proximity of hosts (Fig. 142.3). Although persons with schistosomiasis visit many regions of the world, the parasite cannot be introduced into a new region unless an appropriate snail host is present, excreted eggs (in urine or feces) are released into water where they reach the snail hosts and humans subsequently have contact with the untreated water.[11]

Many hantaviruses exist worldwide with distributions that are still being defined. Each hantavirus seems to have its specific rodent reservoir with which it has evolved. As with many zoonoses, humans are incidental to the survival of the virus in rodents, yet humans can develop severe and sometimes fatal disease if they happen to enter an environment where they are exposed to the virus. Undoubtedly, other rodent-associated viruses and other pathogens (as well as pathogens associated with other animals or insects) with the capacity to infect humans will be identified as humans enter unexplored environments in the future.

Lassa and Ebola viruses are other viruses that have focal distributions, although the reservoir host for Ebola virus has not yet been defined. Because these infections can be spread from person to person, secondary household and nosocomial spread in several instances has amplified what began as an isolated event. Lack of adequate resources in hospitals in many developing regions contributes to the spread of infections within hospitals and to persons receiving outpatient care, such as those receiving injections.

Figure 142-1 Life cycles of some important pathogens.

Cultural practices can lead to unusual infections in isolated areas. Residents of the highlands of Papua New Guinea developed kuru after ingestion (or percutaneous inoculation) of human tissue during the preparation of the tissues of dead relatives.

Thus, the presence of a pathogen in a region may reflect the biologic properties of the organism, its need for a certain physicochemical environment or its dependence on specific arthropods, plants or animals to provide the milieu where it can sustain its lifecycle (Table 142.2). The presence of a pathogen in a region does not necessarily equate with human disease, because mechanisms must exist for the pathogen to reach a susceptible human host for human disease to occur. Sometimes it is only with exploration of new regions or changes in land use that humans place themselves in an environment where they come into contact with microbes that were

Figure 142-2 Areas of the USA thought to be endemic for malaria during the years 1882–1912.

previously unrecognized as human pathogens. Preferences for specific foods, certain preparation techniques or cultural traditions may place one population at a unique risk for infection.

TABLE 142-3 -- Modes of transmission for major global infectious diseases.[*]

MODES OF TRANSMISSION FOR MAJOR GLOBAL INFECTIOUS DISEASES	
Mode of transmission	**% of total**
Person-to-person	65
Food-borne, water-borne or soil-borne	22
Insect-borne	13
Animal-borne	0.3

** The figures are based on an estimated 17.3 million deaths due to infectious diseases in 1995, as reported by the World Health Organization.[12]*

FACTORS INFLUENCING THE BURDEN OF DISEASE

Among the infectious diseases that impose the greatest burden of death globally, most are widely distributed: respiratory tract infections (e.g. influenza, *Streptococcus pneumoniae* and others), diarrheal infections, tuberculosis, measles, AIDS and hepatitis B.[12] Most of these infections are spread from person to person. The World Health Organization estimated that about 65% of infectious diseases deaths globally in 1995 were due to infections transmitted from person to person (Table 142.3).[12]

Burden from these diseases is unevenly distributed across populations and among different countries. Poor sanitation, lack of clean water, crowded living conditions and lack of vaccination contribute to the disproportionate burden from many of these infections in developing regions of the world. In industrialized countries, pockets of high risk persist. Disadvantaged populations have higher rates of tuberculosis, HIV and many other infectious and noninfectious diseases. Rates of reported cases of tuberculosis vary widely by region (Table 142.4).[13] Variation also exists within countries. Figure 142.4 shows the effect of crowded living conditions on rates of tuberculosis in England and Wales in 1992.[14] Among welfare applicants and recipients addicted to drugs or alcohol in New York City, the rate of tuberculosis was 744 per 100,000 person years or more than 70 times the overall rate for the USA. [15] The impact of an infection derives not only from the risk of exposure but also from the access to effective therapy. For example, treatment of a patient with active tuberculosis can cure the individual and eliminate a source of infection for others in the community.

Neonatal tetanus, which was estimated to kill 459,000 persons (mostly neonates) in 1995,[12] is caused by a widely distributed bacterium, but the disease predominates in areas where pregnant women and their infants are not protected by immunization with tetanus toxoid. Diphtheria, controlled in many parts of the world,

resurged in new independent states of the former Soviet Union in the 1990s, a reminder of the tenuous control over many infectious diseases. Populations in other countries also felt the impact as cases related to exposures in the Russian Federation were reported in Poland, Finland, Germany and the USA. Serologic studies in America and Europe suggest that up to 60% of adults may be susceptible to diphtheria.

Travelers to tropical and developing regions of the world can pick up geographically focal, often vector- or animal-associated infections (such as malaria and dengue), but travelers most often acquire infections with a worldwide distribution that are especially common in areas lacking good sanitation. Food- and water-borne infections are common and lead to traveler's diarrhea, which is caused by multiple agents (including *Escherichia coli, Salmonella* spp., *Shigella* spp., *Campylobacter* spp. and others), typhoid fever and hepatitis A. Respiratory tract infections may be acquired from other travelers from all over the globe during the crowding that occurs in travel (e.g. in buses, airplanes, terminals and on cruise ships) as well as from persons in the local environment. Table 142.5 and Table 142.6 note factors that influence the types and abundance of microbes in a community and the probability of exposure to pathogens.

Hepatitis A virus remains a common cause of infection in developing regions of the world although it is not considered a major cause

TABLE 142-5 -- Factors that influence the types and abundance of microbes in a community.

FACTORS THAT INFLUENCE THE TYPES AND ABUNDANCE OF MICROBES IN A COMMUNITY
• Geoclimatic conditions
• Socio-economic conditions
• Public health infrastructure
• Urban versus rural environment
• Density and mobility of population

• Season of the year

TABLE 142-6 -- Factors that influence the probability of exposure to pathogens.

FACTORS THAT INFLUENCE THE PROBABILITY OF EXPOSURE TO PATHOGENS

• Level of sanitation
• Occupational and recreational activities
• Food preparation and preferences
• Sexual activities and other behavior
• Contact with pets and other animals
• Time spent in the area

of morbidity or mortality in those regions where most persons are infected at a young age and become immune for life. The presence and severity of symptoms are related to the age at which a person becomes infected. Infection in young children is typically mild or inapparent. Persons living in areas of high transmission may be unaware of the presence of high levels of transmission, although nonimmune, older people (such as travelers) who enter the environment may develop severe, and occasionally fatal, infection. Some countries with an improving standard of living have noted a paradoxic increase in the incidence of disease from hepatitis A virus as the likelihood of exposure at a young age decreases, shifting upward the age of infection to a time when jaundice and other symptoms are more likely to occur.

Travelers may also contribute to the spread of infectious diseases and influence the global burden of these diseases. *Neisseria meningitidis*, a global pathogen, occurs in seasonal epidemics in parts of Africa: the so-called meningitis belt (Fig. 142.5).[16] Irritation of the throat by the dry, dusty air probably contributes to invasion by colonizing bacteria. Pilgrims carried an epidemic strain of group A *N. meningitidis* from southern Asia to Mecca in 1987. Other pilgrims who became colonized with the epidemic strain introduced it into sub-Saharan Africa, where it caused a wave of epidemics in 1988 and 1989. Using molecular markers, investigators were able to trace the spread of the epidemic clone to several other countries.[17] In 1996 in Africa, major outbreaks of meningococcal meningitis occurred (>185,000 reported cases with a case fatality rate of ~10%) caused by *N. meningitidis* serogroup A, clone III-1.[18] A virulent group C, ET-15 strain of *N. meningitidis* spread in Canada and was associated with an increased case fatality rate and a higher proportion of cases in persons over the age of 5 years.[19] In these examples, the virulence of the microbe and travel and trade acted synergistically to change the epidemiology and burden of disease. In the spring of 2000 serogroup W135 *N. meningitidis* caused an outbreak of infection in pilgrims to the Hajj and subsequently spread to their contacts and others around the world. Studies using serotyping, multilocus sequence typing, multilocus

Figure 142-5 Meningitis belt in Africa.

DNA fingerprints and other techniques found identical W135 isolates in multiple countries. Pilgrims are required to receive a meningococcal vaccine but before this outbreak, pilgrims from many countries received a vaccine that protected against serotype A but not W135. The vaccine reduces risk of disease but does not prevent oropharyngeal carriage of *N. meningitidis*.[20]

FACTORS INFLUENCING EMERGENCE OF DISEASE

Regular, rapid movement of persons from tropical regions to major urban areas throughout the world raises concerns that unusual infections could be introduced into an environment where they could spread to large populations. How likely is this? Microbes are repeatedly carried around the globe, yet endemic regions for many infections remain relatively fixed. Most examples of the appearance of a microbe or disease in a region are not followed by sustained spread.

In order to assess the potential for a pathogen to be introduced into a new population, information is required about the biologic properties of the organism, the region and population being considered and the mechanisms of transmission (see Table 142.1). The key factor that determines whether a pathogen can survive and spread in a new environment is its basic reproductive rate, which is the average number of successful offspring a pathogen can produce. To become established in a new host population, a parasitic species must have a basic reproductive rate that exceeds one offspring per pathogen. [21] The concept is simple but invasion and persistence are affected by a range of biologic, social and environmental factors.

Certain factors restrict the introduction and spread or persistence of infection in a region (Table 142.7); many of these are discussed above. Before measles vaccine was introduced, the epidemiology of measles exhibited marked periodicity in large populations, with peaks typically occurring every 2–3 years.[22] In general, a community size of about 250,000 is necessary to provide a sufficient number of susceptible people to sustain the virus. In small island communities

TABLE 142-7 -- Factors that restrict the introduction and spread of infections.

FACTORS THAT RESTRICT INTRODUCTION AND SPREAD OF INFECTIONS
• Geoclimatic factors that cannot support vector or intermediate host
• Genetics of human population, making it genetically resistant or relatively resistant
• Immunity of human population, making it not susceptible because of past infection with same or related microbe or via vaccination
• Demographic factors (e.g. size and density of population will not support sustained transmission of diseases such as measles)
• Social and behavioral factors (absence of activities such as iv drug use and unprotected sex with multiple partners)
• Food preparation habits and local traditions (e.g. certain dishes not eaten, food always well cooked)
• High-quality housing, sanitation, public health infrastructure
• High standard of living, good nutrition, lack of crowding

(or other isolated populations), outbreaks typically occur only after periodic introductions from outside. Size and density of a population thus influence the epidemiology of some infections. It has been suggested that measles as it has been known in the 20th century could not have established itself much before 3000 BC because before that time human populations had not achieved sufficient size to sustain the virus. Measles could not have persisted in nomadic, hunting communities.

Examples of emerging pathogens

It is instructive to look at examples of infections that have recently undergone major shifts in distribution and to review the key factors that have influenced their geographic spread. They are a reminder of the complexity of the interactions among host, microbe and the environment. A recurring theme is the movement of humans who introduce pathogens into a new region (see also Chapter 4).

Human immunodeficiency virus and other pathogens carried by humans

Organisms that survive primarily or entirely in the human host and are spread from person to person (e.g. by sexual or other close contact or by droplet nuclei) can be

carried to any part of the world. The spread of HIV in the past two decades to all parts of the world is a reminder of the rapid and broad reach of travel networks. Although the infection has also spread via blood and shared needles, it has been the human host engaging in sex and reproduction who has been the origin for the majority of the infections worldwide. Person-to-person spread accounted for the rapid world-wide distribution of SARS (severe acute respiratory syndrome), a coronavirus infection, in the spring of 2003.

Drugs or vaccines injected by reused inadequately sterilized needles and syringes have been and continue to be an important means of spread of blood-borne infections, such as hepatitis C, hepatitis B and HIV, in some parts of the world. [23]

A large outbreak of antibiotic-resistant shigellosis involving more than 50% of the estimated 12,700 persons at a mass gathering in North Carolina, USA, was followed by nationwide dissemination of the organism and outbreaks in at least three other states.[24] Using molecular techniques coupled with epidemiologic data, investigators were able to show the emergence of multiple drug-resistant tuberculosis clones in New York and their dissemination in New York and to at least four other cities in the USA.[25] It is not only the pathogens carried by humans that are relevant. Humans also carry resistance and virulence factors that can be transferred to and exchanged with other microbes.[26]

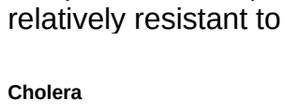

Figure 142-6 Areas reporting dengue fever and areas with a competent vector (2002). Many areas with a competent vector do not report dengue epidemic activity. *Data from the Centers for Disease Control and Prevention.*[16]

Dengue fever

Dengue fever is a mosquito-borne viral infection that has now spread to most tropical and subtropical regions of the world and threatens to continue to increase in incidence and severity. Viremic humans regularly enter regions infested with *Aedes aegypti*, the principal vector of dengue, transporting the virus for new outbreaks. Infection can spread rapidly and outbreaks are sometimes massive, involving >30% of the population. Because four serotypes of dengue virus exist and infection with one serotype does not confer lasting immunity against other serotypes, a person can be infected more than once. The risk of developing severe dengue (e.g. dengue shock syndrome or dengue hemorrhagic fever, DSS or DHF) after repeat infection is 82–103 times greater than after primary infection. [27] In an outbreak in Cuba, 98.5% of cases of DSS or DHF were in persons with a prior dengue infection. The rate of DSS or DHF was 4.2% in persons with prior dengue infection who became infected with a new serotype. [28] Geographic regions where multiple serotypes are circulating have continued to expand, setting the stage for more severe consequences of infection. Factors that have aided the spread of dengue include increasing (and rapid) travel to and from tropical regions; expansion of the regions infested with *Aedes aegypti*; increasing urbanization, especially in tropical areas, which has provided large, dense populations; the use of nonbiodegradeable and other containers that make ideal breeding sites for the mosquito; and lack of support for vector control programs.

Most of the world population growth is occurring in tropical and developing regions. The expectation is that more urban areas in tropical regions will reach the critical population size, perhaps somewhere between 150,000 and 1 million people, to permit sustained transmission of dengue and to increase the risk of the severe forms of infection, dengue hemorrhagic fever and dengue shock syndrome. [29] But travelers are also at risk and the 90 laboratory-diagnosed infections in travelers returning to the USA in 1998 represented a 70% increase from 1997.[30]

It is instructive to ask not only where dengue occurs but also where it does not. Although large dengue epidemics occurred in the USA earlier in this century, only a handful of cases have been acquired in the USA in recent years, despite the presence of epidemic disease in adjacent areas of Mexico and the presence of a competent vector (*Aedes aegypti*) in south-eastern USA (Fig. 142.6).[16] It is possible that the presence of screened dwellings and air conditioning may make an area relatively resistant to the introduction of infection, even if a competent vector infests a region.

Cholera

Cholera is an ancient disease that is continuing to spread and to change. In 1991 it entered Latin America for the first time in more than a century and spread rapidly from Peru to infect persons throughout the region. By 1996, more than 1.4 million cases had been reported to cause more than 10,000 deaths.[31] In 1992, a novel strain of cholera, classified as *Vibrio cholerae* 0139 Bengal, emerged in India and Bangladesh, causing major epidemics in India, Bangladesh and other Asian countries. Travelers carried infections back to Europe, the USA and Japan. This new strain was unusual in that it was the first non-01 strain that could cause epidemics. Persons in cholera-endemic regions who had immunity to the well-known cholera strains were susceptible to this new strain. The already licensed vaccines did not protect against *V. cholerae* 0139.

Cholera illustrates the complex interactions between microbe, environment and host.[32] Epidemics are seasonal in endemic regions. *V. cholerae* lives in close association with marine life, binding to chitin in crustacean shells and colonizing surfaces of algae, phytoplankton, zooplankton and water plants. *V. cholerae* can persist within the aquatic environment for months or years, often in a viable but dormant state, nonculturable by usual techniques. Environmental factors, including temperature, salinity, pH and sea-water nutrients, affect the persistence, abundance and viability of the organisms, and hence have a striking influence on human epidemics.

Under conditions of population crowding, poor sanitation and lack of clean water, cholera can have a devastating impact, as was shown by the massive outbreak of El Tor cholera in Rwandan refugees in Goma, Zaire, which caused 12,000 deaths in July 1994.[33]

The organism can be carried by humans, who sometimes have few or no symptoms, and introduced into new regions. Trade probably also plays a critical role. Ballast water, picked up by boats in multiple locations and discharged at another time and place, carries a wide range of species, including many that have no direct impact on human health.[34] [35] [36] In studies of the ballast and bilge of cargo ships in the USA Gulf of Mexico, researchers were able to identify *V. cholerae* identical to the strains causing epidemic disease in Latin America. [37]

Food-borne disease

The globalization of the food market means pathogens from one region can appear in another; some are common pathogens with a worldwide distribution but others are not. An outbreak of cholera in Maryland, USA, was traced to imported, contaminated commercial frozen coconut milk.[38] Alfalfa sprouts grown from contaminated seed sent to a Dutch shipper caused outbreaks of infections with *Salmonella* spp. on two continents, in at least Arizona and Michigan in the USA and in Finland.[39] Commercial movement of fruits and vegetables redistributes resistance factors along with the microbes. Tracing the source after an infection has been diagnosed can be convoluted and often is not carried out unless disease is severe, lethal or epidemic or involves a highly visible person or population.

Travel and trade are key features in the epidemiology of the infection *Cyclospora*, a cause of gastroenteritis. Recognized for many years in multiple regions of the world, cases were often associated with living in or travel to areas where sanitary facilities were poor. Most of the experience in the USA with the disease was in overseas travelers. In the summer of 1996, a large outbreak occurred in persons who had not traveled. Over a period of a few months, 1465 cases of cyclosporiasis were reported from 20 states. The outbreak was linked to eating raspberries imported from Guatemala.[40] During some seasons of the year up to 70% of selected fruits and vegetables sold in the USA come from developing countries.

Schistosomiasis

Seemingly unrelated events can profoundly alter the epidemiology of infectious diseases in humans. Changes in the way land is used is an important one. In Egypt, prevalence of *Schistosoma mansoni* infection increased from 21.7% in 1985 to 42.1% in 1992 among settlers in a region where recent irrigation projects had reclaimed land from the desert. The irrigation water came from the Nile River or its irrigation dams, which made it likely that snail vectors would be introduced into the new regions. Many settlers to the area were already infected and so contributed to the contamination of the waters because sanitary treatment of human excreta was generally unavailable. New settlers came from other regions and had little or no pre-existing immunity to schistosomiasis, making them especially vulnerable to the

consequences of infection.[41]

In Senegal, extensive agricultural development and the building of two large dams led to the introduction of *Schistosoma mansoni* into the Senegal river basin.[42] The first case was discovered in 1988. Infection spread rapidly and the prevalence of schistosomiasis reached 45–70% by 1990.

Visceral leishmaniasis

In the past, visceral leishmaniasis in Brazil was primarily a rural disease. Recently, however, several cities have reported large outbreaks of visceral leishmaniasis.[43] Reasons for the change in epidemiology include geoclimatic and economic factors (drought, lack of farm land, famine) leading to migration of large numbers of persons, who settle in periurban areas where they live in densely crowded shanties, lacking basic sanitation. The presence of domestic animals, such as dogs, chickens and horses, in and adjacent to human dwellings provides ample sources of blood meals for the sand fly, the vector of leishmaniasis. Outbreaks have occurred in many cities in Brazil, including Teresina, São Luis and Natal. Children and young people have been most affected. Malnutrition also can contribute to the severity of the disease.

Disease-disease interactions can also alter the epidemiology of infections. Visceral leishmaniasis has become an important infection in HIV-infected people in Spain and other areas where the two diseases co-exist.[44] The presence of HIV leads to increased risk of progression of infection; late appearance of disease can occur years to decades after exposure in an endemic region, leading to the appearance of cases of leishmaniasis in regions distant from endemic areas. A common consequence is missed or delayed diagnosis.

Movement of vectors and other species

Movement today involves all forms of life and the movement of nonhuman species can affect infections in humans. *Aedes albopictus* introduced into the USA via used tyres shipped from Asia[45] has since become established in at least 21 contiguous states of the USA and in Hawaii. *Aedes albopictus* can transmit dengue and is a competent laboratory vector of La Crosse, yellow fever and other viruses. It is also hardier than many other mosquito species and therefore may spread widely and be extremely difficult to eradicate. Multiple strains of eastern equine encephalitis virus have been isolated from *Aedes albopictus* in Florida.

An example from the past illustrates the potential consequences of the introduction of a mosquito vector into a new region. In March 1930, an entomologist in Natal, Brazil, came upon *Anopheles gambiae* larvae in a small, wet, grassy field between a railway and a river.[46] He was surprised, because the usual habitat for this mosquito was Africa. Investigation revealed that the probable route of entry into South America was via boats that made mail runs between Dakar in Senegal and Natal in Brazil, covering the 3300km in less than 100 hours. In Dakar the boats were anchored a distance from the shore within easy flight range of *A. gambiae*. In Brazil, over the ensuing years, the mosquito spread along the coastal region and inland. Natal, as an ocean port, terminus of two railway lines and the hub of truck, car and river transportation, was well suited for dissemination of *A. gambiae* into the region. Although malaria already existed in the region, the local mosquitoes were not efficient vectors. *Anopheles gambiae*, in contrast, lived in close proximity to humans, entered houses, sought human blood and was an efficient biter. In 1938 and 1939, devastating outbreaks of malaria killed more than 20,000 persons. In this instance, the simple introduction of a new vector into a region led to severe problems. Fortunately, an intensive (and expensive) eradication campaign was effective.

Current transportation systems regularly carry all forms of life, including potential vectors, along with people and cargo.[47] In an experiment carried out several years ago, mosquitoes, house flies and beetles in special cages were placed in wheel bays of 747 aircraft and carried on flights lasting up to 7 hours. Temperatures were as low as -62°F (-52°C) outside and ranged from 46 to 77°F (8–25°C) in the wheel bays. Survival rates were greater than 99% for the beetles, 84% for the mosquitoes and 93% for the flies. [48] Occasional cases of so-called airport malaria — cases of malaria near airports in temperate regions — attest to the occasional transport and survival of a commuter mosquito long enough to take at least one blood meal in the new environment.[49]

In the USA, transportation of racoons in the late 1970s from Florida to the area between Virginia and West Virginia (in order to stock hunting clubs) unintentionally introduced a rabies virus variant into the animals of the region. From there, the rabies enzootic spread for hundreds of miles, reaching racoons in suburban and densely

Figure 142-7 Worldwide distribution of malaria (2001). *Data from the Centers for Disease Control and Prevention.* [16]

populated regions of the north-east USA. Spill-over of the rabies virus variant into cats, dogs and other animal populations and direct racoon-human interactions have had extremely costly and unpleasant consequences.[50]

GEOGRAPHIC INFLUENCES ON DIFFERENTIAL DIAGNOSIS

Geographic exposures influence how one thinks about probable diagnoses in a given patient. In Mexico, for example, more than 50% of patients with late-onset seizures have CT evidence of the parasitic infection, neurocysticercosis.[51] In Peru, 29% of persons born outside Lima who had onset of seizures after age 20 years had serologic evidence of cysticercosis.[52] In northern Thailand, melioidosis is a common cause of sepsis, accounting for 40% of all deaths from community-acquired sepsis.[53]

In considering the consequences of exposures in other geographic regions, relevant data in assessing the probability of various infections include the duration of visit, activities and living conditions during the stay and the time lapsed since the visit. Among British travelers to West Africa, the relative risk of malaria was 80.3 times higher for persons staying for 6–12 months than among those staying 1 week.[54] In Malawi, the risk of schistosome infection increased directly with duration of stay. Seroprevalence was 11% for those present for 1 year or less, but this increased to 48% among those present for 4 years or longer.[55] In a study of persons with cysticercosis, the average time between acquisition of infection and onset of symptoms was about 7 years.[56]

For malaria, it is necessary to know not only whether infection can be acquired in a specific location but also the types of parasites present and the patterns of resistance to antimalarial agents. As chloroquine resistance has spread, maps now typically highlight the few remaining areas of chloroquine sensitivity. Because the resistance to antimalarial agents is a dynamic process, with levels of resistance generally increasing over time (involving *Plasmodium vivax* in some areas as well as *P. falciparum*), it is essential to base decisions about chemoprophylaxis and treatment on up-to-date information. Figure 142.7 shows the distribution of malaria and resistance patterns globally as of 2001.

Expression of disease may vary depending on age of first exposure, immunologic status of the host, genetic factors and the number and timing of subsequent exposures. Temporary residents of endemic regions have different patterns of response to a number of helminths from those of long-term residents. In cases of loiasis, temporary residents have immunologic hyperresponsiveness, high-grade eosinophilia and severe symptoms that are not seen in long-term residents of the same area.[57] Genetic factors can affect susceptibility to infection or expression of disease. Some persons, for example, are genetically resistant to infection with parvovirus because they lack appropriate receptors on their erythrocytes.[58] Persons lacking Duffy factor cannot be infected with the malarial parasite, *P. vivax*.

CONCLUSION

Knowledge about the geographic distribution of diseases is essential for informed evaluation and care of patients, who increasingly have had exposures in multiple geographic regions. Infectious diseases are dynamic and will continue to change in distribution. Changes in virulence and shifts in resistance patterns will also require ongoing surveillance and communication to health care providers. Multiple factors favor even more rapid change, perhaps in unexpected ways, in the future: rapidity and volume of travel, increasing urbanization (especially in developing regions), the globalization of trade, multiple technologic changes that favor mass processing and broad dispersal and the backdrop of ongoing microbial adaptation and change, which may be hastened by alterations in the physicochemical environment.

Chapter 143 - Pretravel Advice and Immunization

David R Hill

The pretravel care of the international traveler is entirely preventive medicine.[1] The first step in providing this care is to assess the health risk of a particular trip. This is done by determining a traveler's itinerary (not only the country of destination, but also the areas within the country that will be visited) and the types of accommodation. For example, a prolonged research expedition to the shores of Kenya's Lake Victoria will expose the traveler to more health risks than a short business trip to Nairobi. The epidemiology of infectious disease health risks can be found in several publications[2] [3] [4] and Internet sites (See Sources of Information and Keystone *et al* [5]) (Fig. 143.1). The duration of travel is also important. With longer trips there will be a cumulative risk of disease as well as the possibility that the traveler will become increasingly lax in preventive measures such as malaria chemoprophylaxis. [6] Finally, the purpose of the trip needs to be determined.

The next step is to assess the traveler's current health. Although more than 25% of individuals travel with chronic medical conditions, these generally do not interfere with the traveler's plans. Nevertheless, consideration of specific vaccines or prophylactic medications will need to be matched against the traveler's health. Once assessed, the traveler should be given vaccines, medications and preventive advice. Education about illness avoidance may be the most cost-effective measure, but it is difficult to ensure compliance. Finally, each traveler should be informed how to access medical care during travel and on return. With constantly changing epidemiology of disease and patterns of microbial resistance, complexity of travel itineraries and newly released vaccines and preventive medications, most travelers should be cared for in specialized travel clinics that have trained personnel, carry all vaccines and provide accurate preventive advice.[7]

IMMUNIZATIONS

It is helpful to divide immunizations into three categories (Table 143.1):

- recommended as part of routine health maintenance irrespective of international travel;
- may be required for entry into a country; and
- recommended because of risk during travel.

It is imperative that adequate records are kept for immunizations. This includes the type and dose of vaccine, date of administration, manufacturer and lot number, site of administration and administrator's signature. Adverse reactions to vaccines should be reported to the appropriate monitoring agency. Prior to administration of any vaccine patients should undergo informed consent procedures. The use of vaccine information sheets will help to explain to travelers the benefits and risk of each vaccine. These are often available from vaccine manufacturers or can be downloaded from the Centers for Disease Control and Prevention (CDC): www.cdc.gov/nip/publications/vis.

Most vaccines may be administered simultaneously at different sites. Patient tolerance, therefore, usually dictates how many may be given at any one time. A few rules do apply. Live viral vaccines should be either given together or separated by at least 1 month and immunoglobulin should not be given less than 5 months before or less than 2 weeks after measles, mumps or rubella vaccines and 3 weeks after varicella vaccine.[8] Other specific conditions are discussed later. The major travel vaccines, their administration schedule and side effects are listed in Table 143.2 . Full manufacturer's prescribing information should be consulted before administration of each vaccine, as schedules, doses and products often differ between countries.

Immunizations for routine health maintenance

The pretravel visit is an ideal time to update routinely recommended immunizations. In most areas of the world this includes tetanus-diphtheria, pertussis, measles, mumps and rubella, polio, pneumococcal, influenza and, increasingly, hepatitis B vaccines. Many older adults have never been adequately immunized against tetanus and diphtheria or have waning serologic evidence of protection because of failure to receive regular boosters. In the USA this has translated into tetanus cases, most of which occur in adults over the age of 50 years. Diphtheria has occurred in regions where vaccine coverage has declined secondary to population migration or failure of the infrastructure for vaccination. These regions include some countries in Latin America, the Caribbean, Africa, Asia and Eastern Europe. All travelers should have completed a primary series against tetanus-diphtheria and then received boosters on a 10-yearly basis. Because a tetanus-prone wound requires a booster if more than 5 years have elapsed since immunization, some travelers may benefit from vaccination at this interval, particularly if it would be difficult to obtain vaccination overseas.

Although many countries only require a single dose of live measles vaccination in childhood, in 1989 the USA adopted a two-dose policy in response to an increase in measles cases. This means

TABLE 143-1 -- Three categories of immunization.

THREE CATEGORIES OF IMMUNIZATION		
Routine health care	**Required**	**Recommended because of exposure**
Tetanus-diphtheria	Yellow fever	Hepatitis A
Varicella	(Cholera)	Typhoid
Measles (mumps, rubella)		Meningococcal
Haemophilus influenzae type b		Rabies
Polio		Japanese B encephalitis
Pertussis		Tick-borne encephalitis
Influenza		
Pneumococcal		
Hepatitis B		
Note that cholera vaccination is no longer required as a condition of entry to any country.		

TABLE 143-2 -- Immunizations for foreign travel.

IMMUNIZATIONS FOR FOREIGN TRAVEL						
Vaccine	**Type**	**Route**	**Schedule**	**Indications**	**Precautions and contraindications**	**Side-effects**
Toxoids						
Tetanus-diphtheria	Adsorbed toxoids	im	Primary: 3 doses, first 2, 4–8 weeks apart; 3rd dose 6–12 months later	All adults	First trimester of pregnancy	Local reactions
			Booster: every 10 years		Hypersensitivity or neurologic reaction to previous doses	Occasional fever, systemic symptoms
					Severe local reaction	Arthus-like reactions if history of multiple boosters
						Rare: systemic allergy
Inactivated bacterial vaccines						
Cholera	Phenol-killed *Vibrio cholera* (4 × 10^9 /ml)	im, sc or id	Primary: 2 doses 1 week to 1 month apart, =6 days before travel	Oral vaccines preferred	Safety in pregnancy not known	Local reaction of pain, erythema and induration lasting 1–2 days
			Booster: every 6 months	No longer required by individual countries	Previous severe local or systemic reaction	Occasional fever, malaise
				No longer available in USA	No protection against *V. cholerae* 0139	

Cholera	Killed, whole cell *Vibrio cholerae* with recombinant B subunit of cholera toxin	Oral	Primary: 2 doses at 0 and =7 days	No longer required for international travel	Hypersensitivity to previous dose	Mild gastrointestinal side-effects
			Booster: 6 months to 2 years	May give some protection against enterotoxigenic *E. coli* (traveler's diarrhea)		
				Not available in USA		
Streptococcus pneumoniae	Polysaccharide containing 23 serotypes	sc or im	Primary: single dose	=5 years old and at increased risk of pneumococcal disease and its complications	Safety in pregnancy not known	Mild erythema and pain at injection site in c.50%
	7-valent conjugate vaccine available (see text)		Booster: recommended for high-risk patients after 5 years	Healthy adults 65 years or older	Previous pneumococcal vaccination (relative)	Systemic reaction in <1%
						Arthus-like reaction with booster doses
Neisseria meningitidis	Polysaccharide containing serotypes (A, C, Y, W135) (serotype C conjugate vaccine available in some countries)	sc	Primary: 1 dose	Travel to areas with epidemic meningococcal disease	Safety in pregnancy is not known	Infrequent, mild local reactions
			Booster (after 5 years): not officially recommended. May be given after 3–5 years	Asplenia or certain complement deficiency states		
Typhoid	Heat-phenol-inactivated	sc	Primary: 2 doses given =4 weeks apart	Risk of exposure to typhoid fever	Previous severe local or systemic reaction	Frequent local reaction of pain; swelling and induration lasting 1–2 days
	Salmonella typhi (10^9 /ml)		Booster: every 3 years	No longer available in USA	Acetone-killed vaccines should not be given id	Occasional systemic reaction, can be severe
					Pregnancy	
Typhoid	Vi polysaccharide	im	Primary: 1 dose	Risk of exposure to typhoid fever	Safety in pregnancy not known	Local pain and induration in 10–20%
			Booster: every 2 years		Hypersensitivity to vaccine components	Systemic reaction in <5%
Attenuated live bacterial vaccine						
Typhoid	Attenuated Ty21a strain of *Salmonella typhi*	po	Primary: 1 capsule every other day for 4 doses	Risk of exposure to typhoid fever	Safety in pregnancy not known	Infrequent gastrointestinal upset, rash
			Booster: every 5 years		Immunocompromised host	
					Children <6 years	
					Acute febrile or gastrointestinal illness	
					Antibiotics or mefloquine (separate the doses by =24h)	
					Capsules must be refrigerated	
Cholera	Live, attenuated CVD 103-HgR strain of *V. cholerae*	Oral	Primary: single dose	No longer required for international travel	Safety in pregnancy is not known	Mild nausea, cramping and diarrhea in about 2%
			Booster: 6 months	Not available in USA	Immunocompromised host	
					Antibiotics (separate dose by =24h)	
					Complete vaccination at least 1 week before malaria chemoprophylaxis	
Attenuated live virus vaccines						
Measles	Attenuated live virus: monovalent form or combined with rubella (MR) ± mumps (MMR)	sc	Primary: 2 doses, first at 12–15 months, 2nd at 4–12 years of age.	People born after 1956 who have not had documented measles or received 2 doses of live vaccine	Pregnancy	Temperature =39.4°C, 5–21 days after vaccination in 5–15%
			For adults, 2 doses separated by =1 month		Immunocompromised host; can be considered for asymptomatic HIV-infected persons (see text)	Transient rash in 5%
			Booster: none		History of anaphylaxis to eggs or neomycin	Local reaction if previously immunized with killed vaccine (1963–67): 4–55%
					Recent (<5 months) administration lg	
Mumps	Attenuated live viral	sc	Primary: 1 dose (usually given as part of MMR vaccine)	People born after 1956 who have not had documented mumps	Pregnancy	Mild allergic reactions uncommon
			Booster: none		Immunocompromised host	Rare: parotitis
					History of anaphylaxis to eggs or neomycin	
					Recent (<5 months) administration of lg	

Poliomyelitis	Attenuated live virus, trivalent	po	Primary: 3 doses, the first 2 given at a 6–8 week interval, the third 8–12 months later	<18 years old	Immunocompromised host or immunocompromised contacts of recipients	Rare: paralysis
			Booster: 1 oral dose	Boost previously immunized people; complete series in partially immunized adults		Occasional outbreaks
				No longer used for vaccination in USA		
Rubella	Attenuated live virus	sc	Primary: 1 dose (usually given as part of MR or MMR)	All people, particularly women of childbearing age, without documented illness or receipt of live vaccine at =12 months of age	Pregnancy	Post pubertal women: up to 40% have joint pains, transient arthritis, beginning 3–25 days after vaccination, persisting 1–11 days
			Booster: none		Immunocompromised host	Frank arthritis in <2%
					History of anaphylaxis to neomycin	
					Recent (<5 months) administration of Ig	
Varicella	Attenuated live virus	sc	Primary: children of 1–12 years, 1 dose; >12 years, 2 doses at a 4–8 week interval	=12 months old and no history of varicella	Pregnancy	Local pain and induration in 20%
					Immunocompromised host	Fever in 15%
					Potential for rare transmission of vaccine virus to susceptible hosts	Localized or systemic mild varicella rash in 6%
					Recent (<5 months) administration of Ig	
Yellow fever	Attenuated live virus	sc	Primary: 1 dose, 10 days to 10 years before travel	As required by individual countries	Avoid in pregnant women, unless high-risk travel	Mild headache, myalgia, fever, 5–10 days after vaccination in 2–5%
			Booster: every 10 years		Infants <9 months	Rare: immediate hypersensitivity, multiorgan system failure (see text)
					Immunocompromised host	
					Hypersensitivity to eggs	
Inactivated virus vaccines						
Hepatitis A	Inactivated	im	Primary: 2 doses, 2nd dose after 6–24 months provides long-term (=10 years) protection	Travel to developing countries	Safety in pregnancy is not known	Local reaction of pain and tenderness in <20%
			Booster: not currently recommended	Used in routine immunization of children in some regions of USA (see text)		Occasional fever in <5%
				Some travelers may benefit from pre-vaccine hepatitis A testing		
Hepatitis B	Yeast-derived recombinant hepatitis B surface antigen	im	Primary: 3 doses at 0, 1 and 6 months. Can accelerate vaccine schedule (see text)	Health care workers in contact with blood	Pregnancy is not a contraindication in high-risk persons	Mild local reactions in 10–20%
			Booster: not routinely recommended	Residence or sexually active in areas of high endemicity for HBsAg	Hypersensitivity to vaccine components	Occasional fever, headache, fatigue and nausea
				Contact with blood, body fluids, or blood-contaminated medical or dental instruments		
Hepatitis A and B antigens combined	Inactivated virus (A) plus recombinant hepatitis B surface antigen	im	Primary: 3 doses at 0, 1 and 6 months	Travelers at risk for both hepatitis A and B; lower age limit of vaccination varies between countries	Safety in pregnancy is not known	Local reaction in ~35%
			Booster: not currently recommended	Give at least 2 doses of vaccine before departure to protect against hepatitis A	Hypersensitivity to vaccine components	Systemic symptoms of headache and fatigue, similar to single antigen preparations
Poliomyelitis	Killed poliomyelitis virus, trivalent enhanced potency	sc	Primary: 3 doses, first 2 at a 4–8 week interval; 3rd 6–12 months after 2nd	Travel to polio-endemic countries	Safety in pregnancy not known	Mild local reaction
			Booster: 1 lifetime dose		Anaphylactic reactions to streptomycin or neomycin	

Influenza	Inactivated whole and split influenza A and B virus	sc	Annual vaccination with current vaccine	=6 months old and at increased risk of complications from influenza	First trimester of pregnancy is a relative contraindication	Mild local reactions in <33%
				Healthy adults >50 years old	Anaphylaxis to eggs	Occasional systemic reaction of malaise and myalgia: begins 6–12h after vaccination; lasts 1–2 days
				Medical care personnel		Rare: allergic reaction
				Travelers at risk		
Japanese B encephalitis	Inactivated virus	sc	Primary: 3 doses at weekly intervals	Travel to areas of risk with rural exposure or prolonged residence	Pregnancy	Local mild reactions lasting 1–3 days in 20%
			Booster: 1 dose at 3-year intervals		Allergy to mice or rodents	Systemic symptoms of fever, myalgia, headache or GI upset, in 10%
					History of anaphylaxis or urticaria	Severe reactions with urticaria, rash, angioedema, or respiratory distress (0.01–1%)
Rabies	Inactivated virus	im or id	Pre-exposure: 3 doses at days 0, 7, and 21 or 28	Itinerary and activities that place traveler at risk of rabies	Allergy to previous doses	Local reactions in ~30%
			Booster: depends upon risk category and is based upon serologic testing at specified intervals		May be given in pregnancy if indicated	Mild systemic reactions: headache, nausea, aches, dizziness in ~20%
					id route should be completed =30 days before travel	Rare: neurologic illness
					id route should not be used with concurrent chloroquine or mefloquine	Immune-complex reactions with booster doses of human diploid cell vaccine occurring 2–21 days after vaccination, in 6%
					id dosing no longer available in USA	
Tick-borne encephalitis	Inactivated virus	im	Primary: 3 doses at 0, 1 and 9–12 months	Hiking, camping in areas of risk; exercise tick avoidance	Safety in pregnancy is not known	Occasional local reactions of swelling, redness or swollen regional lymph nodes
			Booster: 3 years		Hypersensitivity to previous doses	Infrequent fever, headache
						Rare neuritis
Passive prophylaxis						
Immunoglobulin	Fractionated Ig (primarily IgG)	im	Travel <3 months: 0.02ml/kg	For prevention of hepatitis A	Not to be given less than 2 weeks after (3 weeks for varicella) or 5 months before, measles mumps and rubella, or varicella vaccines	Transient local discomfort
			Travel >3 months: 0.06ml/kg every 4–6 months	Some travelers may benefit from pretravel hepatitis A antibody testing		Rare systemic reaction

Manufacturer's full prescribing information should be consulted because vaccines, doses and schedules may differ among countries. Only major precautions, contraindications and side-effects are listed. Indications are discussed in more detail in the text. Immunocompromised host refers to persons immunocompromised because of immunodeficiency disease, leukemia, lymphoma, generalized malignancy or AIDS, or immunosuppressed from therapy with corticosteroids, alkylating agents, antimetabolites or radiation.

TABLE 143-3 -- Accelerated immunization of children under 2 years of age.

ACCELERATED IMMUNIZATION OF CHILDREN UNDER 2 YEARS OF AGE			
Vaccine	**No. of doses after which protection may be achieved**	**Earliest age at which dose may be given**	**Interval (weeks)**
Diphtheria-tetanus-pertussis	3	6 weeks	=4
Measles	1	6 months	
Polio (oral)	3	6 weeks	=6
Polio (inactivated)	3	6 weeks	=4
Haemophilus influenzae type b	2	6 weeks	=4
Hepatitis B	2	newborn	=4
The data shown are for children who will travel to developing areas and require protection faster than by the routine schedule. Protection conferred by these schedules may not be complete. Children vaccinated with measles at under 12 months of age should be revaccinated at 12–15 months. In polio-endemic countries, the first oral polio dose may be given in the newborn period but three additional doses should be given, the first at 6 weeks of age and then at 4-week intervals.			

that adults born in 1957 and after, a time before which it is assumed that measles infection was universal, should have received two doses of live vaccine. Measles vaccine coverage may be limited in developing countries, particularly those in the African and Eastern Mediterranean regions, so it is important to ensure adequate protection in travelers.[9] It may be helpful in some travelers to perform serologic testing for immunity to measles and rubella.

Pneumococcal and influenza vaccines are routine for healthy, older adults (=65 years), who make up nearly 15% of all travelers. In addition to the older adult, those with chronic illness who would be adversely affected by pneumococcal pneumonia or influenza, such as persons who have HIV or AIDS, diabetes or chronic pulmonary, renal, hepatic or cardiac disease, should be vaccinated. Pneumococcal vaccine should also be administered to those with hemoglobinopathies and

functional or surgical asplenia, and influenza vaccine to health care workers, children up to the age of 18 years on chronic aspirin therapy, pregnant women in their second and third trimesters, and to healthy adults and others if they desire it. Influenza strains included in the vaccine are selected on the basis of worldwide influenza activity during the season preceding vaccine manufacture. The risk of influenza is year round in tropical areas and between April and September in countries in the southern hemisphere. Outbreaks can occur out of season when persons from diverse regions of the world congregate in close quarters, such as on cruise ships.

Routine vaccination of children is important. Children should receive vaccines that are age recommended; however, the schedule may be advanced if a child is traveling before they would have received a scheduled vaccine and the risk during their trip is sufficient (Table 143.3).[3] In the USA vaccines recommended in childhood are measles, mumps and rubella, polio, *Haemophilus influenzae* type b, diphtheria-pertussis-tetanus (DPT), hepatitis B, varicella and pneumococcal. An acellular pertussis vaccine has been incorporated into the DPT vaccine to decrease the risk of febrile reactions from the pertussis component. A 7-valent conjugate vaccine against *Streptococcus pneumoniae* has been introduced for children aged 2–23 months (and in high-risk older children), and in some countries a conjugate *Neisseria meningitidis* type C is administered.[10] Other countries routinely administer BCG vaccine for the prevention of tuberculosis.

Required immunizations

The only vaccine that may be required for international travel is yellow fever vaccine. Yellow fever is prevalent throughout the Amazon basin of South America and sub-Saharan Africa between 15° north and 10° south of the equator. It is one of the diseases that is re-emerging and expanding into new regions and in recent years has caused the deaths of unvaccinated short-term tourists to infected areas.[11] Travelers to rural regions in the endemic zone for yellow fever (areas

TABLE 143-4 -- Mosquito avoidance.

MOSQUITO AVOIDANCE	
Repellents	DEET-containing products (=35%)
	Apply to exposed areas of skin
Protective clothing	Long sleeves and trousers may be impregnated with permethrin-containing sprays or solutions
Screens and netting	May be impregnated with permethrin-containing sprays or solutions
Pyrethroid insecticide sprays and coils	May be sprayed or burned in enclosed areas
For avoidance of *Anopheles* malaria mosquitoes, precautions should be exercised from dusk to dawn. *Aedes* spp. mosquitoes, which transmit dengue and yellow fever, are active in the daytime hours.	

with the appropriate ecology for transmission, but without cases) and to areas actually infected with yellow fever should receive vaccine. Infected areas are listed in the CDC publication *Summary of health information for international travel* which can be accessed on-line at the CDC travel website: www.cdc.gov/ travel/bluesheet.htm. Other countries that have no reported cases of yellow fever and are not in the endemic zone may require vaccination of travelers arriving from yellow fever countries. The specific regulations governing this may be found in the respective CDC and World Health Organization (WHO) publications, *Health information for international travel*[3] and *International travel and health*. *Vaccination requirements and health advice.*[4] Yellow fever vaccination has to be recorded in the International Certificate of Vaccination (see Sources of Information). In addition to vaccine, travelers should protect themselves against the daytime-biting *Aedes* mosquito (Table 143.4).

There have been recent reports of multiorgan system failure in apparently normal hosts following yellow fever vaccine.[12] There was increased risk with advancing age of the vaccine recipient, particularly in those over the age of 75 years. Considering that these cases are rare, there have been no changes made to vaccine recommendations. Health care providers should ensure that vaccine is only administered to persons traveling to infected or endemic areas.[12A]

Cholera vaccine is no longer required for international travel, although some local authorities may act outside international health regulations and request documentation. The removal of cholera vaccination for travelers is likely because of the very low risk of disease in travelers, the variable efficacy of vaccines against cholera and the lack of a clear role of vaccination in the control of cholera in nonepidemic settings.[13] In addition, the only vaccine which was available for US travelers (a whole-cell, inactivated vaccine which was poorly

tolerated and had a limited duration of efficacy) is no longer being produced. Cholera is endemic throughout Latin America, Asia and Africa. *Vibrio cholerae* 01 circulates in all areas and *V. cholerae* 0139 in Asia. More than 85% of cholera cases are reported from Africa.[14]

Two oral vaccines are now available in many countries outside the US.[13] [15] One is live attenuated (Mutachol®, Berna) and the other is inactivated (Dukoral®, SBL Vaccine AB). These vaccines are well tolerated and provide improved protection (60–80% protective efficacy depending upon age of the recipient) compared with the parenteral, inactivated vaccine. They may be considered for individuals, often health care or relief workers, living in a highly endemic area under poor sanitary conditions.

Smallpox vaccine has not been required for international travel since 1982 following the global eradication of smallpox in 1977. There has been renewed interest in smallpox vaccine with concerns about a potential use of smallpox in a bioterrorist attack. New guidelines for the existing vaccinia virus vaccine are being developed.[16]

Immunizations recommended because of risk

The following vaccines are recommended because there is a risk of exposure during travel to particular regions of the world or during travel under certain conditions such as poor sanitation. There are three vaccine-preventable diseases transmitted because of poor food and beverage hygiene: hepatitis A, typhoid fever and polio (for information on cholera see above).

Hepatitis A is the most common vaccine-preventable infection with a risk of 1–10 cases per 1000 travelers (Fig. 143.1), and can be acquired even during 'first-class' trips.[17] [18] For this reason most travelers should receive protection. The first step is counseling about safe food and liquids and then providing either passive protection with immunoglobulin or active protection with one of the inactivated vaccines. Immunoglobulin provides immediate protection with antibodies that are circulating for 2–6 months. Because of its shorter duration of protection and a decreased acceptance by both provider and traveler because it is a blood product, most protection against hepatitis A is now done with inactivated vaccines.

There are several inactivated vaccines marketed throughout the world.[19] Two of the most completely studied are Havrix® (GlaxoSmithKline) and Vaqta® (Merck). These vaccines provide long-term protection with efficacy rates exceeding 90%. On the basis of mathematical models, two doses of vaccine should provide protection for at least 10–20 years. The use of inactivated vaccines in other risk groups such as raw seafood eaters, sewer workers, men who have sex with men, illegal drug users, persons with chronic liver disease and health care workers is being debated. In the USA vaccine is administered as part of routine childhood immunization in regions with high endemic rates of hepatitis A, e.g. the south-west USA.[20]

The first dose of an inactivated hepatitis A vaccine should be administered at least 2 weeks before departure, but for immediate protection immunoglobulin plus vaccine may be given simultaneously in separate sites. However, indirect information suggests that protection begins immediately following immunization with inactivated vaccines.[21] [22] Travelers with a high likelihood of previous hepatitis A infection may benefit from hepatitis A antibody testing to avoid unnecessary vaccination if they are positive. These include those born before 1945, those born and raised in developing countries and those with a history of jaundice.[17] [20]

Protection against both hepatitis A and B may be achieved with the use of a combined antigen vaccine, Twinrix® (GlaxoSmithKline), in a three-dose schedule. Two doses of vaccine should be given before departure to ensure protection against hepatitis A since a lower concentration of antigen is used in this preparation compared with the single antigen hepatitis A vaccines.

Figure 143-1 Estimated monthly incidence of health problems for travelers to tropical areas. *Adapted from reference* [18] .

Hepatitis E is enterically transmitted in the developing world, particularly during periods of high rainfall. In travelers, most cases have originated from India. Pregnant women have a high mortality. Immunoglobulin and the current hepatitis vaccines do not prevent hepatitis E so food and liquid hygiene is the best prevention (see Chapter 214).

Most cases of imported typhoid in the USA have been acquired in Mexico, although travel to the Indian subcontinent represents the highest risk with 1–4 cases per 10,000 travelers.[23] Multidrug-resistant *Salmonella typhi* is also common. There are three vaccines for protection (see Table 143.2) but production of the whole-cell inactivated vaccine was discontinued in the USA in 2000. These

vaccines have similar efficacy rates (60–70%) but they differ widely in method of administration and side-effects.[24] [25] The whole-cell inactivated vaccine may have uncomfortable local and systemic side-effects. Although it is inexpensive, its main place is in providing protection for children aged 6–24 months, an age range when the other vaccines are not effective. The oral, live-attenuated vaccine (Ty21a) is well tolerated, effective in children older than 4 years and provides protection for 5 years. If a traveler is on mefloquine for malaria prophylaxis or taking antibiotics, they should wait at least 24 hours before taking the Ty21a vaccine so that its replication will not be inhibited. A polysaccharide vaccine that uses the Vi antigen of *S. typhi* is given in a single intramuscular dose and is effective for 2–3 years. For persons who cannot take the oral vaccine because of time or compliance issues or for children between the ages of 2 and 4 years, this vaccine may be the one of choice. Conjugate vaccines in development should provide higher levels of protection.[26]

All travelers should have completed a primary series against poliomyelitis. Because the risk of polio during travel is low, a polio booster is not given routinely. Also, efforts at global eradication of polio have dramatically decreased the risk associated with travel to many areas of the world;[27] the western hemisphere was declared polio free in September 1994, the Western Pacific region in October 2000 and the European region in June 2002. The Indian subcontinent and Africa account for most polio cases each year.

At-risk travelers who have completed a primary series of vaccine should receive a one-time adult booster with the enhanced-potency inactivated polio vaccine (eIPV). Production of the oral vaccine was discontinued in the USA in January 2000 to eliminate the rare risk of flaccid paralysis from this vaccine. Those who have never completed a primary series should complete one.

Immunizations recommended because of exposure during certain activities or risk behavior include those against hepatitis B, *Neisseria meningitidis*, rabies, Japanese B encephalitis, tick-borne encephalitis and plague.

In an effort to control hepatitis B infection in the USA, vaccination is now included during routine childhood immunization. Unimmunized health care workers who will reside in endemic regions should receive the hepatitis B vaccine. Protection against both hepatitis A and B is now available in a combination vaccine (see section on hepatitis A). The vaccination schedule for hepatitis B (Engerix® only, GlaxoSmithKline) may be accelerated to 0, 1 and 2 months with a booster at 6–12 months. It can be further accelerated by giving doses at 0, 7 and 21 days; 65% will seroconvert at 28 days.[28]

Meningococcal vaccine is recommended for travelers to areas with high risk of meningococcal disease such as the meningitis belt of sub-Saharan Africa (particularly during the months from December through June).[29] Saudi Arabia requires it for religious pilgrims during the Hajj. Neither the bivalent (A, C) or quadrivalent vaccine (A, C, Y, W135) contains serogroup B, but this serogroup is less frequently a cause of meningitis in endemic regions. A conjugate group C vaccine is being used in some European countries and Canada for protection of children. [10] In the USA it is recommended that first-year university students consider vaccination.

All travelers should be counseled about rabies. In much of the developing world rabies is transmitted through the bite of a dog (see Chapter 153), although other mammals (e.g. bats, cats, foxes) may transmit the virus. Rabies-free countries may be determined by consulting the CDC[3] or going on-line to the Rabnet site of the WHO (oms2.b3e.jussieu.fr/rabnet/). All bites should be thoroughly cleansed with soap and water; postexposure rabies prophylaxis should then be obtained. Regimens may differ throughout the world, but if prophylaxis is administered properly with rabies antiserum (either a human or equine product) plus vaccine, the traveler should be protected.[30] If there is any question as to the potency of vaccine a traveler may have received, they should have serology checked upon return and postexposure treatment initiated while awaiting serologic evidence of protection (see Chapter 219).

Pre-exposure protection against rabies is considered for those traveling to endemic areas for 1 month or more, for persons with high-risk travel over a shorter period or for persons who will have difficulty obtaining safe and effective postexposure rabies biologics. Pre-exposure prophylaxis eliminates the need for rabies immune globulin which can be difficult to obtain in many areas of the world. Most pre-exposure vaccination is now administered intramuscularly to ensure adequate development of immunity.

Japanese B encephalitis is a viral encephalitis in Asia transmitted by the *Culex* spp. mosquito. The complete listing of risk areas and seasons of transmission may be found in *Health information for international travel*.[3] It is recommended that persons receive vaccine if they will have prolonged residence in endemic areas or will engage in high-risk activities such as camping, bicycling or field work. Rural Asia, particularly where rice and pigs are farmed, is the highest risk area; the pigs act as a reservoir for the virus and the rice fields as a breeding ground for the mosquito vector. The vaccine would probably receive wider use but for the serious, rare (approximately 0.1–5 per 1000) hypersensitivity reactions. About 20% of vaccinees have mild local and systemic reactions but serious allergic reactions, including anaphylaxis, urticaria, angio-edema and respiratory distress, have occurred at intervals ranging from minutes to as long as 1 week after vaccination. [31] Reactions can occur after any of the three doses. The traveler should remain in the waiting room for 30 minutes after receipt of vaccine and not travel within 10 days of completing the series in case a reaction occurs during flight or on arrival in the country of destination. Patients who have a history of allergies or urticaria may be at a slightly higher risk of severe reaction, so they should be vaccinated only after careful consideration.

Plague (see Chapter 176) is a rare disease for international travelers. Seven countries have reported cases each year from 1995 through 1999: Madagascar, Tanzania, Peru, USA, China, Mongolia and Vietnam. The vaccine is of uncertain efficacy and is generally not recommended. The rare adult traveler with exceptionally high exposure can take tetracycline or doxycycline chemoprophylaxis and children can take sulfonamides.

Tick-borne encephalitis is a viral meningoencephalitis spread by *Ixodes* ticks throughout forested areas of Eastern and Central Europe, and Siberia in the spring and summer months. Unpasteurized dairy products in endemic areas may also transmit the virus. There are two inactivated vaccines (Encepur®, Chiron, and FSME-Immun®, Baxter AG), but they are not available in the USA and require three doses over a year to achieve full protection, which is not practical or possible for most travelers. Travelers to these areas should exercise precautions against ticks by the use of protective clothing, repellents and insecticides. These measures will help to prevent Lyme disease, which is also transmitted throughout Europe and the USA by the bite of *Ixodes* ticks. Production of a Lyme disease vaccine in the USA was recently discontinued.

Tuberculosis is endemic in many parts of the world. The incidence of infection can be as high as eight cases per 1000 person-months; this rate was seen in PPD-negative health care personnel working in tuberculosis-endemic regions. [32] Most children reared outside the USA have received the BCG vaccine in childhood. BCG vaccine is not advocated for travel except for children who will have unavoidable, close exposure to persons with untreated tuberculosis. [33] Long-term travelers should receive pretravel and post-travel tuberculin (purified protein derivative) skin testing to check for conversion and, therefore, infection. The post-travel skin test should be administered 1 month or more after return.

TABLE 143-5 -- Immunization of the pregnant traveler.*

IMMUNIZATION OF THE PREGNANT TRAVELER

Vaccine		Is the vaccine safe?	Notes
Bacterial	Tetanus-diphtheria	Yes	Should ideally wait until after first trimester of pregnancy
	Pneumococcal	Yes	
	Meningococcal	Yes	Probably safe but has not been studied conclusively
	Typhoid		
	Killed	No	
	Live-attenuated	Not known	Vaccination should generally be avoided
	Vi polysaccharide	Not known	May be given with high-risk exposure; vaccine of choice in pregnancy
	Cholera		
	killed	No	
	oral	Not known	
	BCG	No	
Viral	Poliomyelitis		
	Inactivated	Yes	
	Live-attenuated	Yes	
	Yellow fever	Yes	Should generally be avoided, but may be given with high-risk exposure
	Measles, mumps, rubella	No	
	Influenza	Yes	Should ideally wait until after first trimester of pregnancy
	Rabies	Yes	
	Japanese B encephalitis	Not known	Should generally be avoided, but may be given with high-risk exposure
	Hepatitis B	Yes	
	Hepatitis A		
	Immunoglobulin	Yes	
	Inactivated	Not known	Should generally be avoided, but may be given with high-risk exposure
	Tick-borne encephalitis	Not known	Should generally be avoided, but may be given with high-risk exposure
	Varicella	No	

** Adapted from references [3] and [4] .*

Immunization in special groups

Two major groups of travelers require special consideration before immunization — pregnant women and immunocompromised hosts, particularly those who have HIV or AIDS. For pregnant women, any vaccine should have a clear indication to avoid potential adverse fetal effects (Table 143.5).[3] [4] [34] Although many inactivated vaccines may be given safely, those that have the potential for major systemic side effects, such as whole-cell typhoid vaccine, should be avoided. Measles, mumps and rubella, and the varicella vaccine should not be given, although data have not clearly demonstrated adverse outcomes when women have received rubella vaccine. Although yellow fever vaccine strain virus may be transmitted to the unborn child, this has not been associated with fetal abnormalities.[35] Other vaccines are likely to be safe, but there is insufficient experience to make a clear recommendation.

HIV-infected patients are another group to consider separately (Table 143.6).[36] [37] All travelers should be asked about HIV risk factors before vaccination. Then the safety, immunogenicity and efficacy of the vaccine need to be balanced against the risk of the disease. It is generally agreed that immunogenicity decreases with advanced disease; a $CD4^+$ lymphocyte count of <200–400 cells/ml or <25% by age-specific percentages correlates with decreased immunogenicity. Although it has not been clearly studied, this may also be a cut-off point for an increased risk of adverse consequences of live viral vaccines. If assurance of immunity is needed, then post-vaccination serology should be obtained.

In addition to vaccination, HIV-infected travelers should consider the health risks associated with travel to developing regions. Many enteric infections, such as *Salmonella, Cyclospora* and *Cryptosporidium*, and systemic infections such as leishmaniasis and tuberculosis

TABLE 143-6 -- Immunization in HIV infection.*

IMMUNIZATION IN HIV INFECTION			
Vaccine		**Is the vaccine safe?**	**Notes**
Bacterial	Tetanus-diphtheria	Yes	
	Pneumococcal	Yes	
	Meningococcal	Yes	
	Typhoid		
	Killed	Yes	
	Live-attenuated	Not known	Safety is not known and vaccination should be avoided
	Vi polysaccharide	Yes	
	Cholera		
	Parenteral	Yes	
	Oral, attenuated	No	
	Oral, killed	Not known	
	BCG	No	
	Tick-borne encephalitis	Not known	Safety is not known and vaccination should be avoided

Viral	Poliomyelitis		
	Inactivated	Yes	
	Live-attenuated	No	
	Yellow fever		Probably safe in persons without immunosuppression (e.g. CD4 count =200 cells/mm^3), but has not been conclusively studied
	Measles		Can be given to persons without severe immunosuppression (e.g. CD4 count =200 cells/mm^3)
	Influenza	Yes	
	Rabies	Yes	
	Japanese B encephalitis	Not known	Safety is not known and vaccination should be avoided
	Hepatitis B	Yes	
	Hepatitis A		
	Immunoglobulin	Yes	
	Inactivated	Yes	
	Varicella		Can be considered for children without severe immunosuppression (e.g. CD4% of >25%)

** Data from references [3] and [4] .*

are more prevalent and can be prolonged and difficult to treat in HIV-infected individuals. The ability to access sophisticated medical care may also be an issue.

TRAVELER'S DIARRHEA

Traveler's diarrhea is the most common illness in developing areas of the world and affects 30–50% of travelers.[38] Illness usually begins in the first week after arrival and is typically mild, characterized by three or more loose to watery stools with nausea, abdominal cramping and malaise. Fever is usually less than 101°F (38°C) and vomiting is unusual. In most cases, illness is self-limiting over 3–5 days. Dysentery with tenesmus and bloody stools occurs in less than 10% of patients. Although most individuals can continue with their activities, 20–30% will need to alter plans. Enterotoxigenic *Escherichia coli* accounts for about 50% of the known causes, and *Shigella, Salmonella* and *Campylobacter* spp. for a large proportion of the other bacteria (see Chapter 144). Viruses cause 10–20% of cases and protozoa cause 5–10%. New etiologic agents are being described continually; some of the most recent ones have been *Cryptosporidium* and *Cyclospora* spp. and new types of *E. coli*, such as enteroaggregative types. The incidence of diarrhea does not seem to decline with increasing time of residence in developing areas.

Prevention

A full description of the prevention and treatment of traveler's diarrhea can be found in Chapter 43 . The best prevention is care in the selection of food and liquids. Although most travelers understand the importance of being careful, many still make errors soon after arrival overseas. Foods and liquids that are likely to be contaminated are ground-grown greens and vegetables, incompletely cooked or poorly stored meats and seafood, untreated water and ice cubes, unpasteurized milk products and food from street vendors. Thus, travelers should restrict themselves to commercially prepared or heated beverages, recently and thoroughly cooked meats and greens, and fruits that can be peeled by the traveler. Water may be purified by bringing

it to the boil or by halogenating (iodine or chlorine preparations) and then filtering it with a filter of pore size "1µm.[39] The cysts of *Cryptosporidium* spp. and *Cyclospora* (and eggs of helminths) are likely to be halogen resistant, so water potentially contaminated with these parasites should be filtered or boiled.

Several nonantimicrobial agents have been used to prevent diarrhea. Bismuth subsalicylate is modestly effective either in tablet (2 tablets (252mg/tablet), q6h) or liquid form (2 oz qid), decreasing the incidence of diarrhea by about 65%. It should not be taken by individuals who are allergic to salicylates, who are taking large doses of them for other reasons or are on anticoagulant therapy. It can decrease the absorption of doxycycline. Ingestion of prophylactic *Lactobacillus* spp. does not confer significant protection and antimotility agents such as loperamide and diphenoxylate should not be taken preventively.

Antibiotics are effective for prophylaxis but they may be associated with side effects, contribute to bacterial resistance and are not practical for travelers going for more than 2–3 weeks. There are also many areas of the world that have sulfonamide-resistant and tetracycline-resistant bacteria, making these agents less effective. Therefore, most persons should not be given prophylaxis and it should be reserved for travelers in whom an episode of diarrhea would have extreme consequences.

Treatment

If the traveler becomes ill, prompt treatment should be initiated with hydration (see Chapter 161 for a full discussion of rehydration). Commercial rehydration packets combining electrolytes, sugar and bicarbonate are easy to use and, for small children, are probably safer than home-made preparations. They are widely available throughout the developing world or can be purchased before travel. Infants who are breast-feeding should continue nursing. As diarrhea improves, the diet can be increased by adding bland foods (breads and cereals, potatoes, soups, bananas, fish and chicken) in frequent small meals.

Mild disease may be treated with bismuth subsalicylate. This reduces the number of loose stools by about 50%, but does not begin to work until about 4 hours after taking it. Antimotility agents such as loperamide rapidly decrease cramping and loose stools. They should be avoided if there is blood in the stool or a fever >101.5°F (38.5°C). Because most episodes of diarrhea are self-limiting, symptomatic therapy alone may be sufficient.

A short course of antibiotics will often improve diarrhea within 1 day. Antibiotics combined with loperamide may control symptoms within hours, but there has been variable success with this approach depending upon the etiologic agent. [40] [41] The wide prevalence of sulfonamide and tetracycline resistance in *E. coli, Salmonella, Shigella* and *Campylobacter* spp. has made the fluoroquinolones such as ciprofloxacin, norfloxacin, ofloxacin and levofloxacin the most commonly recommended antibiotics in treatment. In Asia where *Campylobacter* may be resistant to the fluoroquinolones, azithromycin may be used. This agent can also be safely given to children. Antibiotics are prescribed for up to 3 days, but single-dose therapy may be sufficient.[42] Medical care should be sought by persons with dysentery if self-treatment does not result in improvement within 24 hours, or in cases of severe dehydration. Diarrhea that persists after return should be evaluated (see Chapter 144 for a full discussion of persistent diarrhea) for causes ranging from functional bowel disease to infection with *Giardia* or *Cyclospora* spp. to tropical sprue.

MALARIA PREVENTION

Malaria is one of the most important diseases to prevent as it can be fatal. The type of malaria and risk of acquisition vary by destination and reason for travel, but worldwide there are approximately 10,000 cases in returned travelers. Over 80% of cases of the most severe form of malaria, *Plasmodium falciparum*, are acquired by travelers on trips to Africa, where resistance to chloroquine is widespread and transmission may occur in urban and rural areas. Deaths in travelers can almost always be prevented by adherence to mosquito avoidance, compliance with appropriate chemoprophylaxis and prompt recognition of malaria symptoms and consequent initiation of treatment.[43]

Malaria is transmitted by the *Anopheles* mosquito, which is most active during the nighttime hours from dusk to dawn. During these times travelers should wear loose-fitting cotton clothing which covers their arms and legs, apply repellents to exposed areas of skin and sleep in enclosed areas behind screens or under netting (see Table 143.4). The most effective repellents are those that contain *N,N*-diethyl-3-methylbenzamide (DEET).[44] There is no need to exceed a concentration of 20–35%. DEET-containing repellents are safe to use in children and pregnant women, but should be used sparingly to avoid systemic absorption and rare neurologic toxicity. Travelers should not apply repellents to mucous membranes and irritated skin and should wash them off when coming indoors. Residual insecticide preparations (e.g. permethrin-containing compounds) can be applied to clothing and netting to kill insects rather than only repel them. Mosquito coils and sprays containing pyrethroids may be used in enclosed sleeping areas.

Chemoprophylaxis needs to be taken on a regular basis during travel and for a period of time after return that depends on which medications were taken (Table 143.7). Many cases of malaria occur not because of drug resistance but because of poor compliance. Fifty to sixty per cent of short-term travelers will be completely compliant and less than this number of long-term travelers. The choice of a chemoprophylactic regimen should be based on risk of exposure, types of parasites prevalent in the travel destination and health status of the traveler. Up-to-date sources should be consulted before prescribing any antimalarial.[3] [4]

Chloroquine as a single agent is effective only in areas where *P. falciparum* is not present or remains sensitive: Mexico, Central America west and north of the Panama Canal, the Dominican Republic and Haiti, Egypt, most areas of the Middle East and parts of China. Travelers to other risk areas in Africa, Asia and Latin America will need to take mefloquine, a new combination medication called Malarone® (atovaquone/proguanil, GlaxoSmithKline), doxycycline or add proguanil to chloroquine.

In the USA, mefloquine and Malarone® are the drugs of choice for travel to areas with chloroquine-resistant *P. falciparum*. [3] Mefloquine is highly efficacious in preventing malaria but concern has been expressed by both health care providers and travelers as to the drug's potential for side effects. When it is taken in prophylactic doses, minor GI and neuropsychiatric events occur in 5–30% of users.[45] The neuropsychiatric side effects may include sleep disturbance, vivid dreams, mood changes, anxiety, headache and dizziness. Serious adverse events such as psychosis are rare with an occurrence of about one case per 13,000 users.[46]

Contraindications to mefloquine are a known hypersensitivity to the drug, a history of seizures or psychiatric disorder, an underlying cardiac conduction abnormality, but not the use of ß-blockers for blood pressure control. It is likely to be safe in pregnancy, but should be avoided if possible during the first trimester. Some travel health consultants prescribe mefloquine 2–3 weeks before departure to assess patient tolerance and allow a switch to other agents if there is a problem.[4] Seventy per cent of adverse reactions occur during the first three doses. Loading doses of the drug are usually not advocated.

Malarone® is a fixed combination antimalarial containing atovaquone and proguanil.[47] [48] It is available in the US, Canada and

TABLE 143-7 -- Prophylaxis of malaria.*

PROPHYLAXIS OF MALARIA		
Drug	**Adult dose**	**Pediatric dose**
Chloroquine	300mg base (500mg salt) orally, once/week, beginning 1 week before travels, weekly whilst traveling and for 4 weeks after travel	5mg/kg base (8.3mg/kg salt), once per week (not to exceed adult dose)
Mefloquine	250mg salt orally, once/week	<15kg: 5mg of salt/kg/week
		15–19kg: 1/4 tablet/week
		20–30kg: 1/2 tablet/week
		31–45kg: 3/4 tablet/week
		>45kg: 1 tablet/week
Atovaquone/proguanil (A/P) (Malarone®)	250mg A/100mg P	62.5mg A/25mg P
	1 tablet daily, beginning 1–2 days before travel and for 7 days after travel	11–20kg: 1 tablet daily
		21–30kg: 2 tablets daily
		31–40kg: 3 tablets daily
		>40kg: adult dosing
Doxycycline	100mg orally, once/day, beginning 1–2 days before travel and for 4 weeks after travel	>8 years of age: 2mg/kg orally, once/day, not to exceed adult dose
Proguanil	200mg orally, once/day	<2 years: 50mg/day
	Used in combination with chloroquine	2–6 years: 100mg/day
		7–10 years: 150mg/day
		>10 years: 200mg/day
Primaquine	15mg base (26.3mg salt) orally, once/day for 14 days	0.3mg/kg base (0.5mg/kg salt) Orally, once/day for 14 days
	Used to eradicate extraerythrocytic stage	
Full manufacturer's prescribing instructions should be consulted on dosing guidelines as they may vary between countries.		

* *Information from reference[3] .*

many European countries and comes in both adult and pediatric formulations. It is effective in treatment and prophylaxis of all malaria species, although experience with non-falciparum species is limited. It is started the day before exposure to malaria, continued daily and discontinued 7 days after leaving the malarious area. It has causal prophylactic effect (kills developing hepatic-stage parasites but not the hypnoziotes of *P. virax* or *P. ovale*) which allows the shortened period of time post travel. It is ideally targeted for short-term travelers to areas of risk.

Rural, forested, border areas of Thailand with Myanmar (formerly Burma) and Cambodia have multidrug-resistant *P. falciparum* malaria; the few travelers to these areas should take daily doxycycline for prophylaxis. Malarone may also be effective in these areas. Doxycycline is also an alternative medication for those intolerant of mefloquine, although it cannot be given to children under the age of 8 and to pregnant women. Doxycycline should be swallowed with a large volume of liquid to prevent esophageal irritation. It may predispose to vaginal yeast infection and act as a photosensitizer.

The combination of chloroquine plus proguanil has been recommended for areas in which there is chloroquine-resistant *P. falciparum* malaria but only a small risk of acquisition, such as India.[4] It is in these limited risk areas that US and European recommendations differ; the CDC no longer recommends this combination.[3] Health practitioners should consult the appropriate source for their country.

All travelers need to be told that no antimalarial is 100% protective and that they can develop malaria in spite of being compliant with prophylaxis. If they develop a fever or flu-like illness overseas that could be malaria, they should seek medical care. Their evaluation needs to include a blood smear performed by a competent laboratory, because the sensitivity of symptoms or physical findings alone is low. The use of self-administered diagnostic kits (dipstick tests) is controversial as travelers can have difficulty in using and interpreting these tests.[49] If medical care cannot be obtained within 24 hours the traveler can consider self-treatment. The combination drug sulfadoxine/pyrimethamine (Fansidar, three tablets at one time) may be taken in many areas of the world except where there is resistant disease such as in South East Asia.[4] There, quinine alone or with doxycycline or tetracycline can be used. Malarone is another option for standby treatment. Fansidar should not be taken by those with a sulfonamide allergy. Halofantrine has excellent activity against all species of malaria but it should not be used as standby therapy because of potentially fatal cardiac side effects in predisposed individuals.[50]

Travelers who have had prolonged exposure to malaria in areas of *P. vivax* and *P. ovale* activity can consider primaquine to eradicate hepatic-stage parasites. Before taking primaquine a glucose-6-phosphate dehydrogenase (G-6-PD) test should be obtained. Primaquine cannot be given to pregnant women because the G-6-PD status of the fetus cannot be determined. Chloroquine-resistant *P. vivax* has been described primarily from South East Asia (Papua New Guinea and Irian Jaya) with sporadic cases from Myanmar, India and Guyana and Brazil, but is unusual. Primaquine resistance may also occur.

Pregnant women should not travel to malarious areas unless absolutely necessary, because of the added risk of complications of malaria during pregnancy. Chloroquine is safe. Mefloquine can be taken after the first trimester (and may be safe in the first trimester), although the US Food and Drug Administration has not

approved mefloquine use in pregnancy. Doxycycline and primaquine are contraindicated and there is insufficient data on Malarone®.

ENVIRONMENTAL RISK

Travel to the tropics is associated with increased heat and humidity; the traveler will need to take into account the effects these changes may have on their health. These can range from a feeling of malaise

and tiredness to increased loss of salt and water with resultant dehydration. Travelers should maintain hydration, limit exercise and sleep in a cool environment, particularly if they are elderly or have chronic medical problems. Excessive sun exposure should be avoided by wearing loose-fitting cotton clothing to cover exposed skin, wearing hats and using sunscreens with a sun protection factor of at least 15. Water insolubility may extend the life of the sunscreen. If the patient is taking doxycycline for malaria prophylaxis, it is particularly important to limit sun exposure. In addition to protecting the skin against sunburn, it should be kept dry and clean to avoid cellulitis and dermatophyte infection.

Travelers to altitudes above 2500–3000 meters may experience acute mountain sickness (AMS) or the more severe high-altitude pulmonary edema, retinal hemorrhage and cerebral edema.[51] AMS is characterized by headache, nausea, vomiting, insomnia and lassitude and may affect up to 50% of persons. The risk of illness can be lessened by acclimatization: spending a few days at intermediate altitudes of 1500–2200 meters and gradually ascending, sleeping at elevations no more than 300–500 meters higher each night. Acetazolamide, a carbonic anhydrase inhibitor, may be taken to assist acclimatization. It is given at a dose of 125–250mg orally twice daily, starting 2 days before being at altitude and for several days at altitude. It has also been used to treat mild symptoms of AMS. Dexamethasone may be used to treat AMS but in severe illness the safest course is always to descend.[51] Acetazolamide is contraindicated in persons with sulfonamide allergy.

Jet lag is a common problem, particularly when more than five time zones are crossed. It is easier to travel west and lengthen the day than to travel east and shorten the day. In order to help with jet lag, several methods have been proposed. Exposure to bright light after arrival may help. Taking a short to intermediate-acting benzodiazepine or a pyrazolopyrimidine can help travelers to fall asleep and maintain sleep, which decreases the contribution of exhaustion to the effects of time zone adjustment. Melatonin, which is secreted during the night hours, has also been studied.[52] A dose of 5–8mg taken at night for the first few nights may be helpful but the purity and effectiveness of over-the-counter preparations have not been documented and the effectiveness of this approach is controversial.

The risk of deep venous thrombosis (DVT) and pulmonary embolism has received recent attention. DVTs can occur in as many as 5% of persons flying for 10–15 hours and who have cardiovascular risk factors. Some of these will go on to have pulmonary embolism.[53] At-risk travelers should maintain their hydration, exercise at regular intervals and consider wearing below-the-knee support stockings to decrease the risk.

BEHAVIORAL RISK

Although health care providers and travelers tend to focus on infectious and medical illness, the most important contributor to severe morbidity and mortality, particularly in young adults, is accidents and injuries.[18] [54] To prevent assault and theft, travelers should not wear jewellery and ostentatious clothing and they should travel in groups, avoiding high-risk urban areas, particularly at night. The US State Department posts travel advisory and safety information at: http://travel.state.gov/. Motor vehicle safety can be enhanced by riding in vehicles with seat belts, avoiding excessive speed and not driving at night. One should avoid riding in the back of open bed trucks and overcrowded buses. When swimming, travelers should be aware of undercurrents and never dive into unknown waters.

Sexually transmitted diseases, including HIV, gonorrhea, syphilis and chancroid, are prevalent. In some countries in sub-Saharan Africa nearly 50% of sexually active adults may be HIV positive. In parts of Latin America, South East Asia and China, HIV has increased exponentially.[55] Although condoms and spermicides may help to prevent transmission, the safest course is abstinence. In spite of these statistics, many travelers continue to engage in high-risk sexual behavior, often without the protection of condoms.[56] In all situations, alcohol contributes to increased risk behavior.

OTHER DISEASES AND CONSIDERATIONS

Dengue fever, a viral disease (see Chapter 184) transmitted by *Aedes* mosquitoes, has seen a resurgence throughout Asia, sub-Saharan Africa, the Caribbean basin and Latin America and has become a theoretical risk in the south-eastern USA.[57] Recent outbreaks have also occurred in Hawaii. Dengue is characterized by the sudden onset of fever, headache, myalgias and arthralgias, abdominal discomfort, rash and mild liver abnormalities. Severe disease can progress to a hemorrhagic shock syndrome. There is no vaccine currently available for prevention, so travelers need to exercise precaution against this daytime feeding mosquito. Complying with the measures outlined in Table 143.4 will help to prevent not only dengue and malaria, but also the other less common insect-transmitted diseases such as leishmaniasis, trypanosomiasis, filariasis and rickettsial infection. East African trypanosomiasis has recently been seen in several travelers to Tanzanian game parks.[58]

Schistosoma spp. (see Chapter 167) can infect travelers who swim in fresh water in endemic areas of the Caribbean, South America, Africa and Asia. Travelers to these areas should avoid all fresh-water swimming unless it is in a chlorinated pool. Letting water stand for 48 hours or warming it to 50°C for 5 minutes will render it safe from the *Schistosoma* parasites. Fresh-water swimming, particularly after periods of flooding, can be a risk for acquisition of leptospirosis.

Although the viral hemorrhagic fevers — Ebola, Lassa and Marburg (see Chapter 183) — garner a great deal of media attention, they are generally not a risk for travelers. Current outbreaks of disease can be followed by subscribing to the listserv ProMED or by checking the disease outbreak sites of the WHO and CDC web pages (see Sources of Information). Any returning traveler who is suspected of having a viral hemorrhagic fever should be managed according to WHO guidelines.[59]

Access to medical care overseas can be accomplished in several ways. Travelers can purchase a travel health insurance package that should include the following: help in locating medical care, paying for the care upfront and, if necessary, providing for emergency evacuation. There are several air ambulance and insurance companies (www.travel.state.gov/medical.html). Embassies or consulates may provide names of physicians and mission hospitals can be a source of care. Tattooing, injections and dental instruments should be avoided to decrease the risk of acquiring blood-borne pathogens such as hepatitis B and C and, less likely, HIV. The International Association of Medical Assistance to Travelers (www.iamat.org) will provide a list of English-speaking physicians throughout the world. A small first-aid kit that contains analgesics, bandages, a thermometer and any over-the-counter medications frequently used is helpful as it is often difficult to find even the simplest medicines overseas.

Finally, it is important to alert travelers to recognize major problems, such as fever, persistent diarrhea or rash, that may occur after return. Although routine posttravel follow-up for short-term travelers is usually not necessary, anyone who experienced major illness overseas or new-onset illness after return should be evaluated.[60] After a history, physical examination and targeted laboratory testing, a predominant syndrome can be described and a differential diagnosis generated. Each potential diagnosis can be matched against its incubation period, geographic area of risk, frequency of occurrence

and the traveler's preventive measures. The appropriate evaluation and interventions should then be pursued. A more detailed discussion of individual syndromes and diseases is provided in other chapters.

SOURCES OF INFORMATION

There are a number of helpful sources of information in travel medicine. Major ones are listed.

United States resources

Chapter 144 - Diarrhea and Food-borne Illness

Andrew T Pavia

INTRODUCTION

It has been said that 'travel broadens the mind and loosens the bowels'. Although diarrhea is not the most serious travel-related condition, it is by far the most common illness among travelers and expatriates from developed countries who visit less developed nations.[1] In the first 2 weeks abroad, 20–50% of travelers will develop diarrhea. A large proportion will still have symptoms when they return home. In one study, 12% first developed symptoms after returning home. Travelers' diarrhea is usually defined as the passage of three or more unformed stools with associated symptoms, including nausea, vomiting, abdominal pain or cramps, tenesmus or passage of mucus or blood. The median duration of symptoms is 2–3 days, but 10–15% have symptoms lasting more than 1 week. In two large studies, 0.9% of Swiss travelers[1] and 1.7% of Peace Corps volunteers[2] developed persistent diarrhea lasting more than 1 month.

The risk of developing diarrhea is related to destination, the age and mode of travel and the care taken in selecting food and drink (Fig. 144.1). The highest incidence of diarrhea is associated with travel to or residence in Africa, Asia, the Middle East and Latin America. Intermediate risk areas include central and southern Europe and some Caribbean islands. The incidence is highest among children younger than 2 years old[3] and among young adults (age 15–24).[4] [5] Eating in private homes is generally safer than eating in restaurants and, not surprisingly, eating food from street vendors is associated with markedly increased risk. The prevalence of diarrhea episodes peaks in the first few weeks and declines with prolonged residence in an endemic region.

The range of causative pathogens and the clinical spectrum of diarrheal illness among travelers parallel diarrheal illness among children living in the country. Intensive studies of the etiology of travelers' diarrhea over the past 30 years have shown a wide range of causative agents. The most important pathogens among travelers are, in decreasing order of frequency, enterotoxigenic *Escherichia coli* (ETEC), *Shigella* spp., *Campylobacter jejuni*, *Salmonella* spp., *Plesiomonas shigelloides*, noncholera *Vibrio* spp. and *Aeromonas* spp. (Table 144.1).[6] [7] [8] [9] More than one pathogen is isolated in 10–20%. Rotavirus has been detected in 0–24% of travelers with diarrhea, but generally is found with similar frequency among asymptomatic travelers. *Cyclospora* has been recently described as a cause of travelers' diarrhea,[10] as have microsporidia sp.[11] Enteroadherent *E. coli* which demonstrate local, diffuse or aggregative adherence to HEp-2 cells have been implicated in travelers' diarrhea.[12] [13] Recent data demonstrate that these organisms are a frequent cause of illness, perhaps second only to ETEC.[14]

PRESENTING SIGNS AND SYMPTOMS THAT POINT TO A DIAGNOSIS

Acute diarrhea

It is difficult to make an etiologic diagnosis for most episodes of diarrhea in the returning traveler. Most illness is of moderate severity and resolves spontaneously; empiric antimicrobial therapy is highly effective. ETEC is the most common pathogen, yet it cannot be detected in most clinical laboratories. Because of the wide range of potential pathogens, an unfocused laboratory evaluation will be far reaching and expensive. Therefore, a stepwise focused approach is recommended. There is substantial overlap in the clinical manifestations of different pathogens and it is impossible to determine reliably the etiology of travelers' diarrhea based on the presentation.[15] [16] Nonetheless, clinical and epidemiologic clues can point to a diagnosis and are a valuable guide to therapy and diagnostic approach (Table 144.2).

Vomiting

Illnesses that manifest as vomiting alone are generally short-lived and less likely to be seen after the traveler returns. Toxin-mediated food-borne illness caused by *Staphylococcus aureus* or *Bacillus cereus* may occur among travelers because of exposure to foods that were not adequately refrigerated. Vomiting may be the only symptom among adults with viral gastroenteritis. Vomiting and intense abdominal pain that persists may suggest anisakiasis. This syndrome is caused by invasion of the gastric or intestinal mucosa by larvae of *Anisakis* spp. or *Pseudoterranova* spp. after eating raw fish, including herring, salmon, cod, halibut, pollack, greenling and mackerel.

Watery diarrhea

Acute watery diarrhea is the most common presentation of travelers' diarrhea; ETEC is the most frequent cause of this syndrome. Vomiting is present in 10–20% of patients. Vomiting may suggest gastroenteritis caused by Norwalk-like viruses (norovirus), astrovirus or calicivirus rather than ETEC infection.[17] The sudden onset of vomiting after a short incubation period suggests toxin-mediated food-borne illness caused by *Staph. aureus* or *B. cereus*. Explosive watery diarrhea that is short-lived may be caused by preformed toxin from *Clostridium perfringens* or *B. cereus*. Outbreaks of food-borne illness caused by preformed toxin, Norwalk virus, ETEC and *Shigella* spp. have been common on cruise ships. Airline meals have been implicated in outbreaks of *Shigella* and cholera.

A history of seafood ingestion suggests infection with *Vibrio parahaemolyticus, Vibrio cholerae* non-O1, other *Vibrio* spp. or *Aeromonas* spp. Profuse dehydrating diarrhea may occasionally be caused by toxigenic *V. cholerae* O1 or O139. The diarrhea caused by *Cryptosporidia* and *Cyclospora* spp. is most often watery, profuse and prolonged; fever is uncommon.[10] [18]

Although most acute diarrhea among travelers will not be associated with a larger outbreak, physicians should be alert to this possibility. Prompt reporting of cases (along with the travel history) to local or national public health authorities may lead to identification of widely dispersed outbreaks.

Inflammatory or bloody diarrhea

Symptoms of inflammatory diarrhea include the passage of bloody or mucoid stools, high fever, abdominal pain and tenesmus; white

Figure 144-1 Food-borne transmission probably accounts for the majority of diarrheal illness in travelers and expatriates. The high rates of shigellosis and campylobacteriosis compared with cholera among travelers in cholera-endemic areas suggest that they may be better able to avoid exposure to contaminated water than to contaminated food.

blood cells are often present in the stool. Approximately 10–20% of episodes of diarrhea will be bloody. Pathogens associated with inflammatory or bloody diarrhea include *Shigella* spp., *C. jejuni*, nontyphoidal *Salmonella* spp., *V. parahaemolyticus, Entamoeba histolytica, P. shigelloides, Clostridium difficile* and enteroinvasive *E. coli* (EIEC). Of these, *Shigella* spp. and *Campylobacter* spp. are the most common in most settings. *Vibrio parahaemolyticus* is common among Japanese travelers and should be suspected if there is a history of seafood consumption. *Clostridium difficile* should be considered in a patient who has previously been treated with antimicrobials. The presence of fecal leukocytes suggests infection with an invasive organism, most often *Shigella* spp., *Campylobacter* spp. or *Salmonella* spp.

Leukocytes are not invariably present in these

TABLE 144-1 -- Etiology of diarrhea in travelers by region.[*]

ETIOLOGY OF DIARRHEA IN TRAVELERS BY REGION					
Organism	**Nepal (%)**	**South East Asia (%)**	**India (%)**	**Latin America (%)**	**Africa (%)**
Enterotoxigenic *E. coli*	20–28	6–30	24	26–72	25–75
Enteroadherent *E. coli*	13–18	3–8	19	15	-
Enteroinvasive *E. coli*	0–3	0–3	-	2	0
Shigella	10–23	2–7	10	0–22	0–15
Campylobacter	4–28	15–58	3	2–15	1–5
Salmonella	3–4	3–17	10	0–16	0–5
Yersinia	0–2	1–3	-	-	0
Vibrio spp.	0–1	5–13	5	-	3
Plesiomonas	4	2–13	7	-	2–7
Aeromonas			3	-	2
Rotavirus	3–11	8	5	0–24	0–6

Cyclospora	11	-	-	-	-
No pathogen	40–53	25–42	45	22–50	29–64
Results are compiled from studies of varying populations ranging from short-term tourists to military personnel and Peace Corps volunteers. Not all pathogens were sought in all studies.					

** Adapted from references*[6] [7] [8] [9] [29] .

infections; assays for fecal lactoferrin have greater sensitivity and specificity than microscopy but are not widely used.[19] In one study, fecal leukocytes were detected by microscopy in 67% of patients who have *Shigella* infection,[20] 24% of those with *Campylobacter* and 27% of those with *Salmonella*. Fecal leukocytes are strikingly absent in amebic dysentery caused by *E. histolytica.*

Patients who have typhoid fever may present with diarrhea and abdominal pain, and diarrhea is a more common manifestation of typhoid among children. In some instances, diarrhea may persist for 1–2 weeks; fecal leukocytes are usually present. The stepwise increase in fever along with associated symptoms, such as headache, confusion, weakness, cough or myalgia, should raise the suspicion of typhoid. A febrile patient who has a relatively slow pulse should be suspected of having typhoid.

Among sexually active homosexual men, proctitis caused by *Neisseria gonorrhoeae* or *Chlamydia trachomatis* can potentially be mistaken for inflammatory diarrhea if a sexual history is not obtained. Another diagnostic pitfall is the failure to consider malaria in a person with high fevers, headaches and myalgias, because patients who have acute malaria may complain of diarrhea or vomiting.

Diarrhea with neurologic symptoms

Several types of food-borne illness that have distinctive neurologic manifestations may occur in travelers.[21] Nausea, vomiting, diarrhea and abdominal cramps followed by paresthesias, myalgias, arthralgias, reversal of hot and cold sensation and a sensation of loose teeth are symptoms of ciguatera poisoning. Ciguatera follows ingestion of large predatory reef fish, usually barracuda, grouper, amberjack and snapper, which contain high concentrations of toxins produced by dinoflagellates. Symptoms may persist for anything from several days to months. Shellfish that contain toxins from the toxin-producing planktonic dinoflagellates (*Gonyaulax catenella* and *Gymnodinium breve*) cause paralytic and neurotoxic shellfish poisoning. Paralytic shellfish poisoning manifests after an incubation period of between 5 minutes and 4 hours, with symptoms of paresthesias of the mouth, lips, face and fingers, followed by dysarthria, dysphonia, muscle weakness and respiratory compromise. The symptoms of neurotoxic shellfish poisoning are similar but less severe.

Because of the relatively long incubation period of food-borne botulism (median 24 hours, range 12 hours to 7 days) and the potential subtlety of symptoms, travelers with this disease might not

TABLE 144-2 -- Characteristics of selected food-borne and diarrheal illnesses of importance to travelers, arranged by incubation period.

CHARACTERISTICS OF SELECTED FOOD-BORNE ILLNESSES						
Organism	**Incubation period in hours median (range)**	**Vomiting**	**Diarrhea**	**Fever**	**Other symptoms**	**Common vehicles**
Histamine fish poisoning (scombroid)	5 min to 1 hour	+	+++	-	Headache, flushing, urticaria	Tuna, mackerel, bonito, mahi-mahi, bluefish
Staphylococcus aureus	3 (1–6)	+++	++	-		Ham, poultry, cream-filled pastries, potato and egg salad
Bacillus cereus (emetic syndrome)	2 (1–6)	+++	+	-		Fried rice
Ciguatera	2 (1–6)	+	++	-	Paresthesias, myalgias, headache, arthralgia	Barracuda, snapper, grouper, amberjack
Bacillus cereus (diarrheal syndrome)	9 (6–16)	+	+++	-	Abdominal cramps	Beef, pork, chicken

present until after their return home. Symptoms include dysphagia, dysphonia, blurred vision, dry mouth and diplopia; up to 50% will initially have nausea, vomiting and diarrhea. Home canning and unregulated commercial canning pose a risk of food-borne botulism. Type E botulism is associated with foods of marine origin, and travelers with a taste for exotic food might be at risk. Vehicles of type E botulism include fermented seal and whale blubber, and dried salted whitefish.

Persistent diarrhea

Persistent diarrhea is usually defined as diarrhea that lasts for 14 days or more. Although only about 3% of travelers will have diarrhea lasting at least 2 weeks and perhaps 1% will have symptoms for more than 1 month, these patients account for many physician visits and a substantial amount of time lost from work. [1] The etiology of persistent diarrhea in travelers (Table 144.3) has not been systematically investigated and is not well understood.[22]

Protozoal agents are relatively uncommon causes of acute travelers' diarrhea, but are much more likely to be responsible for protracted illness.[11] *Giardia lamblia* has long been recognized as a cause of prolonged diarrhea, often associated with bloating, malabsorption and offensive flatus. The incubation period is 1–2 weeks. *Cryptosporidium parvum* infections cause prolonged illness even in immunocompetent hosts. In one study of Finnish travelers and in several outbreaks in the USA, the median duration of diarrhea ranged from 9 to 12 days. *Cyclospora cayetanensis* is a recently described cause of diarrhea (originally referred to as blue-green algae, cyanobacteria-like organism and coccidia-like), which has been identified in North, South and Central America, Africa, Europe and Asia. In studies in Nepal, and in produce-associated outbreaks in North America, the illness was intermittent, lasted a median of 7 weeks and was associated with anorexia, weight loss and pronounced fatigue.[10] [18] *Isospora belli* can also cause persistent diarrhea; it was identified in 1.4% of military personnel with persistent diarrhea in Vietnam. *Entamoeba histolytica* and *Dientamoeba fragilis* are less common protozoal causes in travelers. Helminths may occasionally cause persistent diarrhea, including *Strongyloides stercoralis, Schistosoma mansoni, Trichuris trichiura* and *Capillaria philippinensis*. Schistosomiasis should be considered if there is fever, hepatosplenomegaly, eosinophilia and a history of immersion in fresh water in an endemic region. Eosinophilia strongly suggests helminthic infection but is unusual in protozoal disease. The exception to this rule is isosporiasis, in which eosinophilia is common. However, eosinophilia may be an unrelated finding, caused by coexistent helminthic infection with agents such as hookworm, which is not responsible for the diarrhea.

Bacterial agents are also important causes of persistent diarrhea. ETEC, *Shigella* spp., *Campylobacter* spp., *P. shigelloides* and *Aeromonas hydrophila* may cause prolonged diarrhea. These infections may be associated with passage of blood and mucus. Enteroadherent *E. coli* strains are important causes of persistent diarrhea in children in tropical countries [23] [24] and they may be important in travelers as well.[14] [25] Three classes are currently recognized by adherence pattern to HEp-2 cells. Locally adherent *E. coli* include most classic EPEC

TABLE 144-3 -- Causes of persistent diarrhea in travelers and expatriates.

CAUSES OF PERSISTENT DIARRHEA IN TRAVELERS AND EXPATRIATES		
Infectious		
Persistent bacterial infection	**Persistent protozoal infection**	**Helminth infections**
Salmonella spp.	*Giardia lamblia*	*Strongyloides stercoralis*
Campylobacter spp.	*Cryptosporidium parvum*	*Schistosoma* spp.
Yersinia spp.	*Cyclospora cayetanensis*	*Capillaria philippinensis*
Enteroadherent *E. coli* (3 subgroups)	*Entamoeba histolytica*	
Clostridium difficile	*Isospora belli*	
Aeromonas spp.	*Dientamoeba fragilis*	
Plesiomonas spp.	*Balantidium coli*	
Noninfectious		
Dietary	**Gastrointestinal pathology**	
Lactose intolerance	'Postdysenteric irritable bowel syndrome'	
Osmotic diarrhea	Crohn's disease	
	Ulcerative colitis	
	Bacterial overgrowth	
	Celiac disease	
	Collagenous colitis	
Unclassified (likely infectious)		
Tropical sprue		
Chronic idiopathic ('Brainerd') diarrhea		
Within each category, the causes are listed in roughly the order of frequency. Enteroadherent *Escherichia coli* includes three subgroups of organisms, grouped on the basis of patterns of adherence to HEp-2 cells: enteroaggregative, locally adherent (EPEC) and diffusely adherent.		

strains. Diffusely adherent *E. coli* are currently of uncertain significance. Enteroaggregative *E. coli* (EAggEC) display a unique 'stacked brick' adherence and may elaborate a unique enterotoxin. Studies in adult volunteers show that some strains cause prolonged illness in normal hosts but suggest that there is substantial heterogeneity.[22]

In many patients who have persistent diarrhea the infectious etiology will not be identifiable despite intensive investigation. In some patients, lactose intolerance may be present. Small bowel overgrowth with aerobic and anaerobic flora may follow acute enteric infection and lead to chronic non-specific symptoms. Gastrointestinal problems such as inflammatory bowel disease and carcinoma of the colon may occur coincidentally with travel or perhaps be exacerbated or unmasked by acute travelers' diarrhea. A syndrome of intermittent diarrhea and abdominal pain after acute enteric infection in patients who have no demonstrable infections, structural abnormality or evidence of malabsorption has been termed postdysenteric irritable bowel syndrome, for lack of a better term. These patients usually improve over time and appear to respond to fiber supplement and dietary modification.

Tropical sprue is a rare but serious syndrome of persistent diarrhea, usually seen in persons who have resided overseas for prolonged periods. It is suggested by symptoms of chronic malabsorption, including bulky, greasy stools, weight loss, anemia and neuropathy. Some travelers with persistent diarrhea appear to have a disease resembling 'Brainerd diarrhea', named after a town in Minnesota, USA, where a large outbreak of chronic diarrhea occurred as a result of consumption of unpasteurized milk.[26] This illness is characterized by 10–20 daily bouts of painless, urgent watery diarrhea, and lasts 1–2 years. Water-borne outbreaks of this illness have occurred in Illinois, USA, and among travelers to the Galapagos Islands.

DIFFERENTIAL DIAGNOSIS BY GEOGRAPHICAL AREA

Studies of travelers' diarrhea from different geographic areas are summarized in Table 144.1 . Varying microbiologic techniques limit direct comparison of studies. However, ETEC is the most common organism in virtually all regions. *Campylobacter* infections have been identified more commonly in studies of travelers, expatriates and military personnel from Nepal and South East Asia. *Vibrio* and *Aeromonas* infections have been primarily reported among travelers to South East Asia. *Giardia* and *Cryptosporidium* infections have been prominent among travelers to St Petersburg, Russia. *Capillaria philippinensis* has only been reported in the Philippines region. Certain regions appear to be at high risk for tropical sprue: Puerto Rico, Haiti, the Dominican Republic, India, Nepal, Myanmar (formerly Burma) and the Philippines.

Season may also provide a clue to the likely etiology: ETEC infections are most common during the wetter and warmer season in several regions. Studies among travelers to Mexico and Morocco found that *Campylobacter* infections are more common in the winter months.

INVESTIGATIONS TO CONFIRM THE DIAGNOSIS

The evaluation of the returned traveler with diarrhea should begin with a careful travel history and details of the onset, duration and character of the symptoms. The presence of signs of inflammatory diarrhea (fever, bloody or mucoid stools) raises the likelihood of infection with an invasive pathogen and usually should lead to obtaining cultures for *Shigella* spp., *Salmonella* spp. and *Campylobacter* spp. Fecal lactoferrin is a more sensitive assay to identify polymorphonuclear cells, but staining a fresh stool specimen with methylene blue is quick and inexpensive and can be used in resource-poor settings to identify patients most likely to benefit from antimicrobial therapy. An additional benefit is that *Giardia* trophozoites may be identified occasionally. Seafood consumption will raise the likelihood of *Vibrio* or *Plesiomonas* infection. The incubation period, if known, is helpful. Incubation periods of less than 18 hours suggest toxin-mediated food-borne illness and further diagnostic testing is not helpful. Incubation periods of more than 5 days suggest diarrhea caused by protozoa or helminths.

Acute diarrhea

In patients who have milder illness of less than a few days' duration, rehydration and an antidiarrheal medication (loperamide or bismuch

Figure 144-2 A suggested approach to the evaluation and management of acute diarrhea in the returned traveler. The most likely pathogens for each scenario are given.

subsalicylate) alone may suffice (Fig. 144.2). For patients who have moderate to severe acute watery diarrhea, many physicians favor an initial empiric course of antimicrobial therapy (see below). ETEC is the most likely organism in this setting. If watery diarrhea persists despite empiric antimicrobial therapy, *Giardia, Cryptosporidium* and *Cyclospora* infection should be considered. Antigen detection assays for *Giardia* spp. and *Cryptosporidium* spp. are more sensitive than routine examination of stools for ova and parasites and can be performed initially.[11] If symptoms continue, three liquid stool samples should be examined for ova and parasites. In settings in which resources are limited, an empiric trial of metronidazole (250mg q8h) can be used as a therapeutic trial to treat *Giardia* infection.

For patients who have inflammatory diarrhea or dysentery and those who have failed antimicrobial therapy, stool cultures for *Shigella* spp., *Salmonella* spp. and *Campylobacter* spp. and up to three ova and parasite examinations to look for *E. histolytica* are indicated. In patients who have taken antibiotics, assays for *C. difficile* toxin should be performed.

Persistent diarrhea

Persistent diarrhea warrants a more complete evaluation. The evaluation can be time consuming, costly and frustrating. The approach should be stepwise (Fig. 144.3). At least one specimen should be examined for bacterial agents. Selective media such as thiosulfate citrate bile salts sucrose agar may enhance recovery from *Vibrio* spp., but many strains can be identified from conventional media such as McConkey agar if the laboratory is alerted to look for oxidase-positive organisms. A careful parasitologic examination of three liquid stools should include concentration techniques and staining to improve the identification of *Isospora* spp. and *Cyclospora* spp., because both respond well to treatment with trimethoprim-sulfamethoxazole (co-trimoxazole). If a potential pathogen is identified, it does not prove causation, but a trial of specific therapy is warranted. Identification of enteroinvasive, enterotoxigenic and enteroadherent *E. coli* strains requires carefully standardized adherence assays and DNA probes, which are only available in research laboratories. Because diagnosing these infections is impractical, a trial of 5–7 days of a fluoroquinolone may be reasonable. When diarrhea persists, especially if there is weight loss, bloody stools or symptoms of malabsorption, a complete evaluation for malabsorption and endoscopy with biopsies should be considered. HIV infection should always be considered in unexplained chronic diarrhea.

The management of persistent diarrhea is difficult if diagnostic resources are limited. A trial of antimicrobial therapy, preferably with a fluoroquinolone, can be given. If this fails, and symptoms suggest *Cyclospora* or *Isospora* infection, a 2-week trial of trimethoprim-sulfamethoxazole (co-trimoxazole) can be considered. Empiric therapy with metronidazole for persistent diarrhea may treat giardiasis, *Balantidium coli* and *C. difficile*.

IMMEDIATE MANAGEMENT

All patients who have diarrheal illness need careful attention to hydration. In adults, oral rehydration with mineral water, weak tea or dilute fruit juice along with a source of sodium chloride (salty crackers, dilute broth) is usually sufficient. Oral rehydration

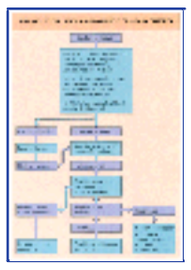

Figure 144-3 A suggested approach to the evaluation and management of chronic diarrhea in the returned traveler. The presence of significant weight loss or evidence of malabsorption should influence the pace and aggressiveness of the evaluation. This approach is designed for use in a Western setting.

solutions such as the WHO/UNICEF oral rehydration solution or commercial products such as Pedialyte or Ricelyte take advantage of glucose-coupled transport and provide more physiologic replacement of fluid, sodium, bicarbonate and potassium (see Chapter 161 and Chapter 222). They should be used for young children and persons with significant dehydration. Popular remedies such as tea, soft drinks and sports drinks are very low in sodium and should not be used alone. Bismuth subsalicylate has been clearly shown to provide symptomatic relief.[27] Antimotility agents such as loperamide (4mg initially followed by 2mg after each loose stool) provide prompt decrease in the number of stools. Short-term use of loperamide has been proven safe in studies of travelers' diarrhea and can be used in addition to antimicrobials. Because of the risk of toxic megacolon, loperamide should be avoided in patients who have dysentery and in young children. Patients who have diarrhea may develop secondary lactose intolerance and should avoid diary products until the diarrhea is resolved. Foods with high fat content and spicy foods may also aggravate symptoms. Although there are no scientific data evaluating dietary modification, some experts advise beginning with plain carbohydrates, such as rice, pasta or breads, then adding protein and finally fats as the symptoms resolve.

The preferred agents for empiric treatment of diarrhea in travelers are trimethoprim-sulfamethoxazole, 1 double-strength tablet twice daily for 3 days, or a

fluoroquinolone (ciprofloxacin 250–500mg q12h, ofloxacin 200–300mg q12h, or norfloxacin 200mg q12h).[28] For severe travelers' diarrhea, a 3-day course is generally recommended. Single-dose therapy with ofloxacin and ciprofloxacin has shown equivalent efficacy compared to 3-day courses in clinical trials, and clearly reduces the cost of treatment. In inland Mexico during the summer, trimethoprim-sulfamethoxazole remains effective but in many regions, resistance to this agent among ETEC and *Shigella* is common and recently, increasing resistance to fluoroquinolones has been reported. Fluoroquinolones should not be used in pregnant women and should be used with great caution in prepubertal children. Azithromycin has been successfully used in regions where quinolone-resistant *Campylobacter* spp. are prevalent.[29] Rifaxamin, a poorly absorbed oral antimicrobial, is under investigation but appears equivalent to fluoroquinolones. [30]

Specific treatment of protozoal and helminthic infections is covered in Chapter 242 , Chapter 243 , Chapter 244 , Chapter 245 , Chapter 246). The management of tropical sprue is discussed in Chapter 163 . For further discussion of the management of bacterial gastrointestinal infections, see Chapter 43 and Chapter 93 .

COMPLICATIONS

Most cases of diarrhea in travelers are self-limiting. Serious electrolyte abnormalities are uncommon in adults, with the exception of those with toxigenic *V. cholerae*. Inappropriate rehydration solutions may lead to hyponatremia or hypokalemia, especially in children and those on diuretics. Hypoglycemia and seizures are less common complications.

Rectal complaints are common in patients who have chronic diarrhea. Hemorrhoids can result in rectal bleeding, which may be confused with bloody diarrhea. Weight loss, skin changes, anemia and neuropathy caused by folate and vitamin B12 deficiency are complications of malabsorption caused by chronic diarrhea resulting from giardiasis, strongyloidiasis, tropical malabsorption and sprue. Extraintestinal complications of amebiasis are unusual but can include liver and brain abscesses.

Although diarrheal illnesses remain among the leading killers of children, the greatest impact of diarrhea on adults is economic. In addition to the effect on tourist income in developing countries and the direct medical costs, diarrhea among travelers results in a substantial amount of lost productivity.[1] [31] Despite recent advances, improved strategies for prevention, treatment and diagnosis are still needed.

Chapter 145 - Fever

Anthony D Harries

INTRODUCTION

There has been a marked increase in international travel in the past 20 years and it is estimated that over 50 million people from industrialized countries visit the developing world each year.[1] Infectious diseases cause considerable morbidity among travelers and fever in returning travelers, including children, has become a relatively common clinical problem.[2] [3] [4] [5] [6] [7] Fever is an elevation of body temperature above the peak normal range and is normally considered to be present if the oral temperature is above 100.2°F (37.8°C).

As a result of the high prevalence of infections and parasitic diseases in the tropics, febrile illnesses are more common after a visit to tropical countries than after a visit to more developed countries. In one report, about 3% of 8000 German-speaking Swiss tourists reported a high fever or chills after a short-term visit to a tropical country compared with 1% of tourists who visited Greek or Canary Islands.[8] Among returned travelers who are managed in specialist tropical disease centers, fever tends to be a common clinical problem. For example, of 1084 patients admitted to the Hospital for Tropical Diseases, London, UK, during a 12-month period, nearly 50% presented with 'fever'.[9]

Travelers are liable not only to the usual causes of fever seen in temperate climates, but also to more exotic infections such as malaria, dengue fever and typhus. Because some tropical infections, such as malaria, may be rapidly fatal if undiagnosed or poorly treated and others, such as typhoid fever, can be a public health risk, this chapter focuses on the diagnosis and management of fever in travelers returned from tropical countries.

CLINICAL FEATURES

The common final diagnoses in febrile patients returned from the tropics and admitted to centers specializing in tropical medicine are malaria, typhoid fever, viral hepatitis and dengue fever (Table 145.1). In an appreciable proportion of patients the cause of fever is one that occurs worldwide such as an upper respiratory tract infection, community-acquired pneumonia and urinary tract infection. In addition, many fevers are undiagnosed and settle spontaneously and presumably are due to a non-specific viral infection.

History

A detailed history allows an appropriate differential diagnosis to be made and is useful in guiding initial investigations. Specific presenting symptoms and a full medical history (including a drug history) must be documented. Although complaints such as headache, lassitude and sweating have no useful diagnostic or localizing value, other symptoms such as cough and pleuritic chest pain (suggesting pneumonia) or dysuria and loin pain (suggesting acute pyelonephritis) may provide a clue to the anatomic site of disease. Several important travel-related topics also must be addressed.

Travel history

Arrival and departure dates, countries visited, duration of stay in each country, places visited within each country and activities should be precisely determined. Most tropical infections are transmitted more easily in rural than in urban areas. The backpacker or volunteer who travels in such areas and has closer contact with the local population therefore has a greater risk of acquiring a tropical infection than the person who stays in first-class hotels in the capital city. However, the affluent traveler who stays in air-conditioned hotels is sometimes at risk of contracting enteric bacterial infections and respiratory infections such as Legionnaires' disease.

A knowledge of incubation periods will help to eliminate the possibility of several potential infections and to narrow the differential diagnosis (Table 145.2). For example, malaria would not be considered in a febrile patient whose potential exposure was less than 7 days earlier. Likewise, dengue fever would be unlikely in a patient who had returned from an endemic area more than 10 days previously. Some tropical infections such as malaria due to *Plasmodium vivax* or *Plasmodium ovale*, African trypanosomiasis and visceral leishmaniasis may present weeks, months or even years after departure from the tropics (see Chapter 157 , Chapter 166 and Chapter 172).

Vaccination and prophylaxis

A history of vaccination against yellow fever, hepatitis A and hepatitis B virtually rules out these infections. If there is doubt about vaccination status, it is important to check vaccination certificates as patients may be confused about what inoculations they have received.[10] Oral and injectable typhoid vaccines are from 70% to 90% effective and prophylactic intramuscular human immunoglobulin against hepatitis A is effective for up to 6 months, with the protective efficacy declining with increasing time after administration. Childhood vaccinations against polio, measles and diphtheria may not be protective if boosters have not been given (see Chapter 143).

With the progressive spread of drug-resistant *Plasmodium falciparum* malaria and the recent emergence of chloroquine-resistant *P. vivax*, no chemoprophylactic antimalarial regimen is 100% protective even if compliance is excellent.[1] [11] Poor compliance with chemoprophylaxis, both during and after travel, increases the risk of breakthrough malaria. Antimosquito measures (screened rooms for sleeping, pyrethroid-impregnated bed nets and insect repellents) provide useful additional protection, and if they are used during travel in endemic areas they will decrease the risk of contracting malaria.

Specific exposures

Sometimes there are unique exposures that point to a specific diagnosis (Table 145.3). [2] [6] African tick typhus is strongly suspected if there is a history of a tick bite followed by fever, rash, regional lymphadenopathy and skin eschar. Unprotected sexual intercourse with commercial sex workers in high HIV seroprevalence areas in sub-Saharan Africa or parts of Asia may point to a diagnosis of acute HIV syndrome in a patient with a 'glandular fever'-like illness. Leptospirosis should be considered as a cause of fever in adventure travelers who have freshwater contact (such as rafting) in South East Asia.[12] It is also useful to find out whether the patient traveled in a party and if so whether other members have also been ill. There have been several outbreaks of acute schistosomiasis

TABLE 145-1 -- Common final diagnoses in the returned traveler with 'fever'.

COMMON FINAL DIAGNOSES IN THE RETURNED TRAVELER WITH 'FEVER'			
	Hospital for Tropical Diseases, London [9]	**McGill Centre for Tropical Disease, Montreal [4]**	**Hospital for Tropical Disease, London [5]**
Number of patients	523	587	195
Percentage with:			
Malaria	44	32	42
Hepatitis	11	6	3

Dengue fever	–	2	6
Typhoid fever	5	2	2
Respiratory infection	5	11	4
Urinary tract infection	2	4	3
Diarrheal illness	3	5	7
No diagnosis	7	25	25

TABLE 145-2 -- Usual incubation periods for selected infections.

USUAL INCUBATION PERIODS FOR SELECTED INFECTIONS	
Short (about 1 week or less)	• Arboviral infections (including dengue fever)
	• Enteric bacterial infections
	• Legionnaires' disease
	• Relapsing fever (*Borrelia* spp.)
	• Crimean-Congo hemorrhagic fever
	• Plaque
Intermediate (1–3 weeks)	• Malaria
	• Typhoid fever
	• Typhus
	• African trypanosomiasis (*Trypanosoma brucei rhodesiense*)
	• Viral hemorrhagic fevers (e.g. Lassa, Marburg, Ebola)
	• Brucellosis
	• Leptospirosis
Long (>3 weeks)	• Malaria
	• Viral hepatitis
	• Acute schistosomiasis
	• HIV infection
	• Miscellaneous infections (e.g. amebic liver abscess, brucellosis, melioidosis, visceral leishmaniasis, African trypanosomiasis (*Trypanosma brucei gambiense*), filarial lymphangitis)

('Katayama fever') among parties of nonimmune travelers after exposure to infected fresh water in sub-Saharan Africa.[13] A 'swimmers itch' may occur at the time of schistosomal cercarial penetration, followed several weeks later by a febrile illness associated with eosinophilia. In the spring of 2003, an acute febrile respiratory illness with sometimes severe pneumonia was described initially in southern China and Vietnam. The syndrome, severe acute respiratory syndrome (SARS) spread to all continents due to air travel and is associated with considerable morbidity and mortality. It is presumably of viral origin with the leading candidate being a member of the corona virus family.

Physical examination

Temperature patterns

The temperature and pulse rate must be measured initially and regularly thereafter. Some patients who are being investigated for fever are in fact afebrile or the fever may settle spontaneously

TABLE 145-3 -- Specific exposures that assist in the diagnosis of infections.

SPECIFIC EXPOSURES THAT ASSIST IN THE DIAGNOSIS OF INFECTIONS	
Exposure	**Infection or disease**
Raw or uncooked foods	Enteric bacterial infections, viral hepatitis
Untreated water	Enteric bacterial infections, viral hepatitis
Unpasteurized milk	Brucellosis, salmonellosis, abdominal tuberculosis
Fresh water swimming	Schistosomiasis, leptospirosis
Promiscuous sexual contact	HIV infection, viral hepatitis B, syphilis, gonococcal bacteremia
Mosquito bite	Malaria, dengue fever, filarial lymphangitis
Tick bite	Typhus, borreliosis, Crimean-Congo hemorrhagic fever, babesiosis
Louse bite	Typhus, borreliosis
Tsetse fly bite	African trypanosomiasis
Reduviid bug bite	Chagas' disease
Sand fly bite	Visceral leishmaniasis, arboviruses
Animal contact	Q fever, brucellosis, anthrax, viral hemorrhagic fevers, histoplasmosis, rabies, plague
Infected person contact	Viral hemorrhagic fevers (Lassa, Ebola, Marburg, Crimean-Congo), viral hepatitis, typhoid fever, meningococcal disease

before a diagnosis is reached. Such patients should be reassured and discharged because it is usually unrewarding to pursue investigations retrospectively.[9] For patients with a documented fever, the height of the temperature curve may assist in establishing a diagnosis. High temperatures above 106.8°F (41.5°C) are uncommon and may be caused by infections such as malaria, bacteremia, meningoencephalitis and typhoid fever or by noninfectious disease such as heat stroke, intracerebral hemorrhage and drugs.

Although fever patterns are not pathognomonic for particular infections, they can occasionally provide diagnostic clues:

¦ a pattern of short paroxysms of high fever accompanied by rigors and separated by periods when the temperature is normal (intermittent fever) is often a feature of malaria, pyogenic abscesses, miliary tuberculosis and bacteremia;
¦ paroxysms occurring every third or every fourth day occur typically with *P. vivax* and *P. ovale* (benign tertian malaria) and *P. malariae* (benign quartan malaria), respectively;

¦ a temperature that remains elevated throughout the day with minor fluctuations (continuous fever) may be caused by typhoid fever or typhus;
¦ dengue fever typically presents with 'saddle back' fever (i.e. two febrile periods separated by an afebrile interval of 1–3 days' duration, as shown in Fig. 145.1);

¦ several episodes of fever alternating with periods of normal temperature may occur in relapsing fever due to *Borrelia* spp.

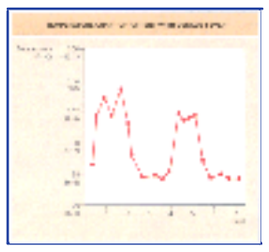

Figure 145-1 Temperature pattern in a patient with dengue fever.

For every 1.8°F (1°C) that the temperature rises above normal, the pulse rate rises by about 10–15 beats/minute. A slower pulse rate than is predicted from the temperature chart (relative bradycardia) is sometimes seen in typhoid fever, meningitis, brucellosis and Legionnaires' disease; it may also indicate factitious fever.

Physical signs

Physical findings in many tropical infections are non-specific and often overlap, although it can be rewarding to carefully examine the skin (Table 145.4), the liver, spleen and lymph nodes, and any other organ system associated with symptoms. Generalized lymphadenopathy is a feature of many infections, although a localized enlarged tender lymphadenopathy (bubo) suggests plague and tenderness over lymphatic vessels suggests filarial lymphangitis. Hepatosplenomegaly occurs in several tropical infections such as malaria, viral hepatitis and typhoid fever. Tender hepatomegaly suggests amebic liver abscess and splenomegaly of more than 10cm below the left costal margin suggests visceral leishmaniasis.

The absence of physical signs can be helpful. Malaria is an unlikely diagnosis in the febrile patient who has lymphadenopathy or a maculopapular rash.

Differential diagnosis by geographic area

Several infections have a worldwide distribution among tropical countries. These include malaria, dengue fever, hepatitis, typhoid fever, tuberculosis, HIV infection and amebic liver abscess. However, the risks of infection can be higher in certain geographic regions (see Chapter 142):

¦ among travelers from Europe and North America, malaria due to *P. falciparum* occurs most often after travel to sub-Sahara Africa, whereas malaria due to *P. vivax* is more common after travel to India and South East Asia;[14] [15]
¦ travelers to Central and South America are particularly at risk of dengue fever due to the growing incidence of the infection in this region;[16]
¦ although schistosomiasis occurs widely, Katayama fever in travelers is usually a result of exposure in sub-Saharan Africa;[17] and
¦ high HIV infection rates are found in commercial sex workers in sub-Saharan Africa and increasingly in India, Thailand and Cambodia;
¦ SARS in travellers to South East Asia.

TABLE 145-4 -- Skin lesions that provide diagnostic clues.

SKIN LESIONS THAT PROVIDE DIAGNOSTIC CLUES	
Skin lesion	**Infection**
Eschar	Tick typhus, scrub typhus, anthrax
Chancre	African trypanosomiasis
Rose spots on trunk	Typhoid fever
Urticaria	Acute schistosomiasis
Orbital edema (bilateral)	Trichinosis
Orbital edema (unilateral)	Chagas' disease
Maculopapular rash	Dengue fever, other arbovirus infections, viral hemorrhagic fever, typhus, leptospirosis, meningococcal bacteremia, syphilis, African trypanosomiasis
Petechiae and hemorrhage	Viral hemorrhagic fever, meningococcal bacteremia, louse-borne relapsing fever, louse-borne typhus

TABLE 145-5 -- Tropical infections with limited geographic distribution.

TROPICAL INFECTIONS WITH LIMITED GEOGRAPHIC DISTRIBUTION	
Region	**Infection**
Sub-Saharan Africa	• African trypanosomiasis
	• Ebola, Lassa and Marburg viral hemorrhagic fever
	• Specific arbovirus infections (e.g. Rift Valley fever)
	• African tick typhus
Asia and South East Asia	• Scrub typhus
	• Japanese encephalitis
South and Central America	• Chagas' disease
	• Specific arbovirus infections (e.g. Argentine hemorrhagic fever)

Some infections have limited geographic distribution (Table 145.5). In sub-Saharan Africa, trypanosomiasis has a sporadic distribution in rural savanna areas and game forests, so the safari enthusiast has the highest risk of acquiring this disease. African tick typhus due to *Rickettsia africae*[18] and Asian scrub typhus due to *R. tsutsugamushi*[19] are contracted by walking in grass or scrubby vegetation in the countryside.

DIAGNOSIS

Initial investigations include:

¦ thick and thin blood films for malaria parasites plus a simple diagnostic strip test (*Para*Sight F test) for *P. falciparum*,
¦ full blood count with differential white cell count,
¦ urinalysis, and
¦ chest radiograph (if indicated).

Thick and thin blood films plus simple diagnostic strip test for *Plasmodium falciparum*

Malaria is a great 'imitator' of other diseases and blood films should always be examined for malaria parasites if the patient has visited an endemic area. Thick films have greater sensitivity for identifying malaria parasites, whereas thin films are better for differentiating the species and, in *P. falciparum* infection, for estimating the degree of parasitemia. The films should be examined by someone who has relevant experience to avoid missing a low-grade parasitemia. Sometimes no parasites are

found in blood films as a result of ongoing malaria chemoprophylaxis, partial antimalarial treatment or sequestration of parasitized red cells in deep capillaries in the case of *P. falciparum* infection. A simple diagnostic strip test for *P. falciparum* malaria (*Para*Sight F test, Becton Dickinson Advanced Diagnostics), which detects a water-soluble antigen produced by the blood stages of *P. falciparum*, has high sensitivity and specificity for the initial assessment of *P. falciparum* in returning travelers.[20] The test does not remove the need for blood film examination but has a useful role in screening, especially where laboratory staff are not experienced in diagnosing malaria. If malaria is still suspected despite negative initial screening, blood films and a *Para*Sight F test should be repeated and smears of blood-stained tissue from an intradermal puncture may help in difficult cases (see Chapter 166). Hemolytic jaundice and thrombocytopenia are valuable pointers to malaria, although thrombocytopenia may also be due to an arbovirus infection or bacteremia.

Blood films are essential in the diagnosis of relapsing fever (*Borrelia* spp.) and acute infection with trypanosomiasis (*Trypanosoma brucei rhodesiense*). Spirochetes of *Borrelia* spp. are plentiful and easily recognized, whereas several blood films may need to be examined to find trypanosomes.

Differential white blood cell count

This simple investigation can be rapidly performed and the results help to focus the differential diagnosis and further investigations (Table 145.6).[21]

In patients who have a neutrophil leukocytosis, the additional findings of anemia, raised serum alkaline phosphatase and elevated right hemidiaphragm on chest radiography strongly suggest amebic liver abscess. Liver ultrasound may initially be negative, but the

TABLE 145-6 -- Differential white blood cell (WBC) count and diagnostic possibilities.

DIFFERENTIAL WBC COUNT AND DIAGNOSTIC POSSIBILITIES		
WBC differential	**Diagnostic possibilities**	**Further investigations**
Neutrophil leukocytosis	• Bacteremia	Blood culture
	• Deep sepsis	Ultrasound, CT scan
	• Amebic liver abscess	Ultrasound, serology
	• Relapsing fever	Blood films
	• Leptospirosis	Serology, culture of body fluids
Eosinophilia	• Schistosomiasis	Serology, microscopy of stool, urine, rectal snips
	• Fascioliasis	Serology
	• Trichinosis	Creatinine phosphokinase, serology
	• Lymphatic filariasis	Nocturnal blood film, serology
Leukopenia	• Brucellosis	Serology, blood and bone marrow culture
	• Disseminated tuberculosis	Biopsies (multiple sites), CT scans
	• Visceral leishmaniasis	Serology, bone marrow or spleen aspirate for amastigotes
Normal WBC count and differential	• Arbovirus infection	Serology
	• Typhus	Serology
	• Typhoid fever	Blood and stool culture

amebic immunofluorescent antibody test is very sensitive and usually positive in proven cases.

At the onset of acute schistosomiasis (Katayama fever), microscopy for ova may be negative and the eosinophilia may be mild, so a high index of suspicion may be required to make the diagnosis.

Tuberculosis is rarely contracted by short-term travelers. However, the risk increases with the duration of stay and the diagnosis must be strongly considered and aggressively investigated in immigrants and foreign students. Diagnosis can be difficult and in some patients with disseminated tuberculosis, the chest radiograph may remain normal until after treatment has started.

Blood cultures are often positive in the first week of illness in typhoid fever and in the second and subsequent weeks the stool cultures become positive. Previous treatment with antibiotics decreases the positive yield of blood cultures; in these cases, bone marrow culture may prove more sensitive.

Other investigations

If the initial screening tests prove nondiagnostic, further investigations will be needed and noninfectious diseases such as connective tissue disease, granulomatous disease and malignancy must be considered. In viral hepatitis, the liver function tests usually show a marked elevation of serum transaminases and these may also be mildly to moderately raised in malaria, typhoid fever and typhus. It is advisable to store an 'acute' serum specimen for antibody detection that can be used with a paired convalescent specimen at a later date.

MANAGEMENT

Recognition and treatment of malaria

The first step in management is to ensure that malaria due to *P. falciparum* is diagnosed and correctly treated (Table 145.7). Falciparum malaria in the returning traveler can be regarded as severe or complicated if:

- the patient is unable to take oral medication,
- there is any sign of specific organ failure,
- parasitemia is greater than 2%, or
- there is hypoglycemia.[22] [23]

If falciparum malaria is suspected in an ill patient but no malaria parasites are found, it is reasonable to treat the patient empirically

TABLE 145-7 -- Immediate management for the returned traveler who was fever.

IMMEDIATE MANAGEMENT FOR THE RETURNED TRAVELER WITH FEVER
Step 1: Blood films for malaria parasites (if from endemic area)
Step 2: Malaria parasites identified
• Uncomplicated falciparum malaria — treat with quinine sulfate and pyrimethamine-sulfadoxine **or** mefloquine **or** halofantrine **or** artemether
• Non-falciparum malaria — treat with chloroquine
• Complicated falciparum malaria — treat with parenteral quinine or quinidine together with pyrimethamine-sulfadoxine **or** artesunate **or** artemether
Step 3: Malaria suspected, patient ill, no parasites identified
• Treat as for complicated falciparum malaria — *Para*Sight F test useful for diagnosis of falciparum malaria and serology useful for retrospective diagnosis

• Blood cultures followed by antibiotics as for suspected bacteremia
Step 4: Possibility of viral hemorrhagic fever (VHF)
• Obtain expert advice
• If possibility of VHF is high, no further blood specimens or body secretions sent to the routine laboratory until VHF excluded
• If VHF confirmed, transfer patient to special isolation facility and perform all investigations in a high-security laboratory
Step 5: Clinical diagnosis made but unconfirmed by tests
• Perform appropriate investigations first and commence empiric treatment
Step 6: No clinical diagnosis and patient not seriously ill
• Avoid empiric treatment and perform appropriate investigations
Step 7: Exotic tropical infection identified
• Consider transfer to hospital facility specializing in tropical medicine

with parenteral quinine. Several sets of blood cultures should also be taken and antibiotics started as treatment for a possible bacteremia. Blood films for malaria parasites should be examined daily during treatment and other causes of fever rigorously pursued (see Chapter 166) .

Exclusion of viral hemorrhagic fever

The rare possibility of viral hemorrhagic fever should be considered in all febrile patients who have been in endemic areas during the 3 weeks before the onset of illness. Lassa, Ebola, Marburg and Crimean-Congo hemorrhagic fever viruses can all be transmitted from person to person through close contact with infected blood or other body secretions, so placing health and laboratory personnel at high risk. These infections are serious and cause a high mortality, although ribavirin (tribavirin) is useful in treating Lassa fever and Crimean-Congo hemorrhagic fever. [24] Clinical diagnosis is difficult as the differential diagnosis is wide (see also Chapter 183 and Chapter 186a).

Particular risk factors for travelers to endemic areas include:

- camping in the bush,
- staying in rural farming areas,
- contact with sick animals, and
- tick bites.

If viral hemorrhagic fever is suspected, it is vital to seek expert advice promptly. [25] Many such patients in fact have falciparum malaria, which in its own right requires rapid diagnosis and treatment.

Empiric treatment

If a clinical diagnosis has been made with or without initial screening tests, empiric treatment can be commenced while awaiting results of specific investigations. For example, in suspected typhoid fever, treatment can be commenced with a quinolone antibiotic after three sets of blood cultures and a stool culture have been obtained. African tick typhus can be diagnosed on clinical grounds and treated with doxycycline.

If no diagnosis has been made after the initial screening procedures and the patient is not seriously ill, empiric treatment is best avoided and investigations are continued as appropriate. For a deteriorating patient who has suspected disseminated tuberculosis, it is sometimes justified to start (and observe the response to) empiric therapy with specific antituberculosis drugs such as isoniazid, pyrazinamide and ethambutol while awaiting results of mycobacterial cultures.

Exotic tropical infections

Exotic tropical infections, such as African trypanosomiasis or visceral leishmaniasis, are uncommon and cases are best referred to specialist tropical centers because treatment is potentially toxic, of long duration and requires expert parasitologic monitoring.

Infection control procedures

Many tropical infections, such as malaria, dengue fever and typhus, can be managed without special isolation facilities. Typhoid fever, some enteric bacterial infections, viral hepatitis, HIV infection and plague can be transmitted from person to person, and appropriate measures must be instituted to prevent transmission. The rare viral hemorrhagic fevers are extremely dangerous and suspected cases should be managed in a high-security isolation facility (see Chapter 186a).

COMPLICATIONS

Many of the common infections in returned travelers do not cause long-term sequelae and are not transmitted to immediate family members. However, some arbovirus infections (including dengue fever) are associated with postviral fatigue syndromes, hepatitis B and hepatitis C can cause chronic active hepatitis and liver cirrhosis, and almost all patients infected with HIV will eventually develop features of AIDS.

If *P. vivax* or *P. ovale* malaria is not treated with an appropriate course of primaquine, relapsing malaria can occur for several years after leaving a malaria-endemic area, and trypanosomiasis with central nervous system involvement may relapse after inadequate treatment with melarsoprol B.

Some pathogens may be transmitted to family members either by the enteric route (e.g. *Salmonella typhi* in the chronic typhoid carrier, hepatitis A and E), by sexual intercourse (HIV, hepatitis B and C) and by nasopharyngeal spread (*Neisseria meningitidis*). In such cases, family members must be counseled and offered appropriate vaccination (hepatitis B) or chemoprophylaxis (*N. meningitidis*).

Viral infections are usually associated with prolonged immunity to the particular virus serotype, but most bacterial or parasitic infections in the short-term traveler confer no useful immunity for the future. Malaria acquired during last year's visit to Africa will not protect against malaria for next year's African safari!

Chapter 146 - Coma and Confusion

Geoffrey Pasvol

INTRODUCTION

Although infrequent, the management of returning travelers with signs of confusion and/or any level of impaired consciousness, ranging from disorientation to coma, presents a particular challenge to the clinician.[1] [2] The management of any comatose patient is difficult because of the wide number of possible diagnoses (Table 146.1)[3] and because the urgency for diagnosis and specific treatment constitutes a medical emergency.[4] In addition to all the common non-infection-related etiologies, such as those associated with trauma (e.g. subdural hematoma), hyperpyrexia, alcohol poisoning, drug overdose, cerebrovascular lesions and diabetes mellitus, the differential diagnosis will also include more exotic and less well-known causes of coma that could result from the patient's travels. Travel can also be associated with many factors that could exaggerate and complicate an acute confusional state, such as alcohol intoxication or withdrawal, psychologic stress, sleep deprivation, jet lag and sensory overload. Confusion in elderly travelers is especially common, even in the presence of non-neurologic conditions such as pneumonia and urinary or biliary tract infections. The combination of air travel, dehydration, alcohol ingestion and relative hypoxia can be enough to induce confusion in elderly travelers.

Patients from tropical destinations may also present with multiple pathologies, for example an HIV-positive patient with *Salmonella* sepsis or a patient who has cerebral malaria and meningitis.

The most common consideration for any traveler returning from an area where malaria is endemic and presenting with a decreased level of consciousness is the possibility of malaria, although equally important diagnostic possibilities are meningitis and encephalitis. In any patient presenting with an alteration in conscious state, it is imperative to exclude malaria either as a cause or complicating factor by means of a thick and thin blood film.

CLINICAL FEATURES

For patients with confusion or coma it is important to obtain a history from accompanying travelers or attending ambulance or aircraft cabin crew (Table 146.2). It is important to establish whether the onset of confusion or coma was rapid or gradual, part of an ongoing known disease process, unpredictable in someone with a known underlying condition (e.g. epilepsy) or entirely unexpected. The patient may present with rambling speech, abnormally aggressive behavior, disorientation, impairment of memory, hallucinations or any decrease in level of consciousness, including coma. Fever or the history of fever suggest the presence of an infection.

Examination needs to be careful and thorough. The level of consciousness may be best monitored serially using the Glasgow Coma Scale.[5] Since the reticular activating system in the brain stem plays such an important role in consciousness level, elucidation of signs of brain stem involvement is essential. This requires careful attention to pupillary size and response to light. Any change might suggest uncal herniation as might occur in conditions that cause unevenly distributed changes in intracranial pressure. The oculocephalic ('doll's eye') and oculovestibular (elicited by instilling ice cold water into the external auditory meatus) responses may be tested to indicate whether the brain stem is intact. The corneal response is usually retained until coma is deep. Brain stem involvement may also manifest as an abnormality in respiratory pattern with tachypnea, long-cycle periodic breathing or Cheyne-Stokes respiration. This should not be confused with the deep sighing breathing of metabolic acidosis (Kussmaul's breathing) or that due to a respiratory cause.

Examination of the fundi is important, with special attention to the appearances of papilledema, hemorrhage and the changes of hypertensive or diabetic retinopathy.

Patients who have **malaria** have a history of travel to an endemic area, often with inadequate or no prophylaxis. They may present with complications, other than cerebral malaria, that may impair consciousness (e.g. repeated convulsions or even status epilepticus, metabolic acidosis, hypoglycemia, sepsis, respiratory involvement with hypoxia, renal failure and severe anemia; see Chapter 166).[6] A history of mosquito bites neither suggests nor refutes the diagnosis. The shortest possible incubation period for falciparum malaria is about 7 days and patients who have progressed to confusion or coma have usually been ill for a number of days, often with a flu-like illness.

In children it is important to distinguish cerebral malaria from transient postictal coma, which may last anything up to an hour after a fit. It is also important in cases of malaria to determine that the decreased level of consciousness is not due to sedative drugs (e.g. benzodiazepines) or hypoglycemia. In cerebral malaria the gag reflex is usually preserved. Grinding of the teeth (bruxism) has been observed in some patients. Examination of the fundus may reveal retinal hemorrhages, extramacular whitening and vessel changes in which the vessels turn white in isolated segments, especially at branch points.

Typhoid is suggested by travel to a highly endemic area, particularly the Indian subcontinent, and a compatible food history. Symptoms are predominantly abdominal, with a fever and a dry cough. The symptomatology is generally not abrupt and has an onset over a few days with increasing fever. The so-called characteristic features of typhoid, such as rose spots (Fig. 146.1), relative bradycardia, pea soup stools or constipation, may be absent. The early neurologic manifestations of typhoid are often subtle, with mild disorientation and a 'glazed', vacant look.

A wide range of **viral infections**, especially arboviral, may present with neurologic manifestations, including dengue fever, which is the most frequent in travelers. Patients with dengue may have a characteristic blanching erythematous rash, which is often confused with sunburn. In more severe infections there may be petechiae and even evidence of frank hemorrhage into the skin. West Nile virus more commonly causes fever, arthralgia and a rash rather than alterations in consciousness. Japanese B encephalitis is more dramatic and can produce a severe meningoencephalitis with altered sensorium. It can also cause a newly recognized polio-like acute flaccid paralysis syndrome.

TABLE 146-1 -- Causes of confusion and coma in a traveler.

CAUSES OF CONFUSION AND COMA IN A TRAVELER	
Infections	**Other**
Cerebral malaria	Drug-induced
Bacterial meningitis	Alcohol abuse
Viral meningitis	Cerebrovascular accidents, including subarachnoid hemorrhage
Encephalitis including arboviral such as:	
Dengue	
Japanese B	Head trauma
West Nile	Dehydration

Viral hemorrhagic fevers	Hepatic encephalopathy (e.g. hepatitis)
Lassa	
Marburg	Renal failure
Ebola	Hypoglycemia
Typhoid	Diabetic ketoacidosis
AIDS-related infections	Epilepsy and postepileptic states
Toxoplasmosis	Space-occupying lesions (especially abscess or tumors)
Cryptococcal meningitis	
Tuberculous meningitis	
AIDS dementia	
Protozoan infections	
Trypanosomiasis	
Toxoplasmosis	
Naegleria	
Acanthamoeba	
Relapsing fevers (Louse and tick-borne)	
Other spirochetal infections	
Leptospirosis	
Lyme disease	
Neurosyphilis	
Helminthic infections	
Schistosomiasis	
Cysticercosis	
Hydatid disease	
Strongyloidiasis	
Paragonimiasis	
Angiostrongylus	
Rabies	
Any severe infection, especially septicemia, endocarditis, pneumonia (especially Legionnaires' disease), pyelonephritis or cholecystitis	

Figure 146-1 Rose spots. In *Salmonella typhi* and *S. paratyphi* infections (enteric fever) classic rose spots of 1–3mm diameter can be found, especially on the abdominal wall, lower thorax and back of the trunk. These are small erythematous macular lesions, which tend to come and go during infection. *Courtesy of Anthony Bryceson.*

Incubation of the **viral hemorrhagic fevers** (which include Lassa, Ebola, Marburg and Crimean-Congo hemorrhagic fevers) ranges from 3 to 21 days. Symptoms include sustained fever, malaise and headache as well as muscle and joint pains. Nausea, diarrhea and vomiting may occur. In the case of Lassa fever there is often a history of travel to west Africa, contact with infectious patients and a characteristic illness beginning with pharyngitis and circumoral pallor. Ebola and Marburg diseases may produce a measles-like rash after 4–7 days. Overt bleeding is a late or terminal event in these infections.[7]

In **trypanosomiasis** there may be a history of travel to game parks in east Africa and a painful tsetse fly bite followed by a local chancre, a rash (Fig. 146.2) and lymphadenopathy.

Leptospirosis occurs worldwide, particularly in those participating in recreational water sports or working with animals. It is usually the patients with jaundice, conjunctival hemorrhage (Fig. 146.3) and renal failure that present with confusion.

Lyme disease due to *Borrelia burgdorferi* more commonly leads to fatigue and personality disorders than alterations in conscious level.

Figure 146-2 Trypanosomal rash. In fair-skinned individuals, each peak of fever may be accompanied by a remarkable skin eruption in the form of annular patches of erythema. In other cases, the rash may be more generalized, as seen here on the sixth day of an infection with *Trypanosoma brucei rhodesiense*. *Courtesy of Anthony Bryceson.*

Figure 146-3 Subconjunctival hemorrhages and jaundice in leptospirosis. Asymptomatic or atypical infection probably occurs in 90% of cases and, in some tropical areas, leptospirosis may account for up to 15% of all patients with undiagnosed pyrexia. While this form can be mild, the infection may develop into a generalized septic form with confusion within 1–2 weeks. This is characterized by fever, myalgia and often subconjunctival hemorrhages. The patient illustrated was in the second week following the onset of symptoms. The most dangerous form (Weil's disease) may be very severe and can involve several organs, with jaundice, renal failure, haemorrhagia, vascular collapse and obtundation.

TABLE 146-2 -- Features suggesting the cause of confusion and coma in a traveler.

FEATURES SUGGESTING THE CAUSE OF CONFUSION AND COMA IN A TRAVELER	
Symptom or sign	**Possible diagnosis**
General	

Fever	Malaria
	Meningitis/encephalitis
Jaundice	Malaria
	Hepatic encephalopathy, especially hepatitis
Lymphadenopathy, oral thrush, shingles scar	HIV infection associated with cerebral toxoplasmosis, cryptococcal meningitis or tuberculous meningitis
Venepuncture marks	Injection drug abuse
Dehydration	Diabetic coma
Acidotic breathing	Severe malaria
	Diabetic ketoacidosis
	Renal failure
Sweating	Malaria
	Hypoglycemia
Rash	Meningococcal infection
	Dengue fever
	Louse-borne typhus
	Erythema migrans of Lyme disease
Game park visit and tsetse fly bite	Trypanosomiasis
Hyperpigmentation	Addisonian crisis (tuberculosis)
Drug history	Mefloquine or chloroquine
	Isoniazid
	Cannabis
	Other drug abuse (e.g. opiates, cocaine, barbiturates, amphetamines)
Recent head injury	Concussion
	Contusion
	Laceration
	Subdural hematoma
Fetor	Alcohol intoxication or withdrawal
	Diabetic ketoacidosis
Water contact	Leptospirosis
	Cerebral schistosomiasis
	Cysticercosis
	Cerebral hydatid
Cardiovascular	
Bradycardia (relative)	Typhoid
	Yellow fever
Irregular pulse, significant murmur	Cerebral embolus, endocarditis
Raised blood pressure	Hypertensive encephalopathy
Low blood pressure, postural drop	Hypoadrenalism
Respiratory	
Cyanosis, hypoxia	Respiratory failure
Respiratory distress	Severe pneumonia
	Severe malaria
Consolidation	Meningitis (including tuberculous)
	Cerebral abscess
Abdominal	
Pain, constipation, diarrhea	Typhoid
Jaundice	Hepatitis
	Leptospirosis
	Severe malaria
Neurologic	
Cuts, abrasions, fractures	Trauma
Neck stiffness, positive Kernig's or Brudzinski's sign	Meningitis
	Meningoencephalitis
	Subarachnoid hemorrhage
Seizures	Malaria
	Idiopathic epilepsy
	Focal neurologic lesions
Constricted pupils	Opiate drug abuse
	Organophosphate poisoning
Retinal hemorrhage	Cerebral malaria
Subhyaloid hemorrhage	Subarachnoid hemorrhage
Decerebrate/decorticate rigidity	Cerebral malaria
Focal neurologic deficits as suggested by hemiplegia, unequal pupil size, external ophthalmoplegia, asymmetric reflexes	Cerebral abscess
	Cerebral tumor (e.g. pituitary adenoma)

Relapsing fevers. In louse-borne relapsing fevers due to *Borrelia recurrentis* and tick-borne fevers due to *Borrelia duttonii* there may be a history of a visit to an endemic area and evidence of a bite that develops into an eschar associated with a more generalized rash. Tick-borne relapsing fever is usually milder than the louse-borne form.

Neurosyphilis patients can present with a history of a gradual onset of confusion.

Helminthic infections, which sometimes involve the central nervous system, need to be considered especially when the clinical findings suggest a focal lesion. These infections more commonly present with a fit than with confusion. They include neurocysticercosis (*Taenia solium*), hydatid disease due to *Echinococcus granulosis* or *Echinococcus multilocularis* and schistosomiasis. Less likely are *Strongyloides stercoralis*, *Trichinella spiralis* from undercooked

Figure 146-4 Meningococcal septicemia. Meningococcal infections are common in the tropics, most notably in the relatively dry 'meningococcal belt' of sub-Saharan Africa, stretching from Senegal and the Gambia in the west to Ethiopia in the east. The nonblanching skin rash and the petechiae and purpura are often difficult to see in individuals with pigmented skin, as is demonstrated in this patient.

meat (usually pork) and *Paragonimiasis* spp. from freshwater crustaceans.

Cerebral abscesses of whatever cause are another important differential in focal neurologic presentations. It is important to ensure that these do not relate to infective endocarditis.

Meningitis and encephalitis. If acquired when traveling, these infections do not necessarily differ from meningitis and encephalitis occurring elsewhere. The meningococcal rash is sometimes difficult to see in individuals with pigmented skin (Fig. 146.4). The specific cause of an encephalitis may be suggested by the region of travel (see below) and this applies especially to some of the less common causes of viral meningitides and encephalitides. Eosinophilic meningitis due to *Angiostrongylus cantonensis* (rat lungworm) is found in South East Asia, the Pacific Basin and more recently in the Caribbean. While most cases occur sporadically and are self-limited, outbreaks have been reported and neurologic sequelae and sometimes death do occur. Headache with raised intracranial pressure associated with paresthesias or hyperesthesias, and cerebrospinal fluid (CSF) pleocytosis, with or without eosinophilia, in a traveler should alert clinicians to the possibility of eosinophilic meningitis (Fig. 146.5). Amebic infection due to *Naegleria fowleri* (usually from freshwater) and *Acanthamoeba* spp. from brackish warm water can lead to a meningoencephalitis.

While **rabies** and **tetanus** usually occur in the setting of an individual who is conscious, brain stem rabies is an exception and can present with profound obtundation.

Drug (heroin, cocaine, barbiturate or amphetamine) **and alcohol abuse** are important considerations in the differential diagnosis in returning travelers who are confused. A history of personality change and self-neglect, together with sleep disturbance and poor appetite, are suggestive factors. Needle tracks, superficial thrombophlebitis or bruising are telltale signs. **Insecticide poisoning** is another possibility, which is particularly common in India and Sri Lanka. Occasionally **antimalarials**, most notably mefloquine and chloroquine, can lead to neuropsychiatric symptoms and manifest as confusion in a traveler.

It is important to determine whether the unconsciousness developed suddenly or gradually. The former might suggest a subarachnoid hemorrhage, whereas the onset of coma due to trypanosomiasis or an intracranial tumor is gradual except when there is hemorrhage into a tumor. The onset of coma in malaria may be heralded by a grand mal seizure.

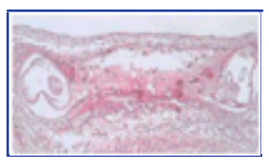

Figure 146-5 Section of *Angiostrongylus cantonensis* larvae in meninges of human brain. Humans may be infested by ingesting third-stage larvae in raw or inadequately cooked intermediate hosts such as snails, prawns, frogs or fish, or in contaminated salads. The larvae migrate to the brain, where they cause eosinophilic meningitis or meningoencephalitis. The diagnosis is aided by the serologic examination of paired specimens, using a specific antigen from adult worms. *Courtesy of Colonel JC Crook, RAMC.*

Symptoms and signs that may suggest the cause of confusion and coma in a traveler are given in Table 146.2 .

If there are any indications in the history of risk factors for HIV infection or any findings on clinical examination suggesting HIV infection, such as oral candidiasis, generalized lymphadenopathy or shingles, an HIV test should be done. This is important as the causes of coma, and therefore the clinical approach, are quite different in the HIV and non-HIV setting.[8] In an HIV-positive individual, diagnoses such as toxoplasmosis, tuberculosis, cryptococcal and coccidioidal meningitis, as well as HIV dementia, become important. A simple algorithm for distinguishing between some of the important diagnoses in the traveler with confusion or coma is shown in Figure 146.6 .

Differential diagnosis by geographic area

In attempting to distinguish the different causes of confusion and coma in the traveler, a clear history of the exact details of travel can be helpful and sometimes diagnostic.

The majority of cases of falciparum malaria are acquired in sub-Saharan Africa and the Indian subcontinent. A few cases are acquired in Papua New Guinea and Vanuatu and occasionally in South East Asia and South America. Knowledge of the rainy season in a particular area and the altitude of the places visited can also assist in the assessment of the risk of malaria.

Typhoid occurs worldwide, but especially in the Indian subcontinent.

The major endemic areas for louse-borne relapsing fever are the highlands of Ethiopia and Burundi. Tick-borne disease has a much wider distribution in both the Old and New Worlds.

Dengue fever is most frequent in travelers who have visited the Caribbean, Central and South America and most of Asia, but is also acquired in west Africa.

Lassa fever is endemic in rural west Africa. Most cases have been acquired by health care workers in the rural areas of Nigeria, Liberia and Sierra Leone.

Ebola virus disease has occurred in central (Zaire, Congo, Uganda, Sudan and Gabon) and west Africa (Ivory Coast).

Japanese B encephalitis is most commonly found in rural areas of Asia, tick-borne encephalitis virus in central Europe and Murray Valley encephalitis virus in Australia. West Nile virus is found across much of Africa, southern Europe and the Middle East. Recent outbreaks of West Nile encephalitis have occurred in several parts of the USA and in Israel.

Figure 146-6 Management of a confused or comatose traveler who has suspected viral hemorrhagic fever, malaria or an HIV-related problem.

Marburg virus disease has occurred in laboratory workers handling the African green monkey from Uganda. Crimean-Congo hemorrhagic fever has occurred in sporadic outbreaks in the areas indicated by its name (e.g. Greece, Turkey and Albania) and in east and west Africa, central Asia and the former USSR. Transmission is by tick bite.

Lyme disease occurs in the north east, mid-west and western USA and many parts of Europe, including Scandanavia.[9]

DIAGNOSIS

All patients who are in a coma require blood tests for glucose (and lactate), electrolytes, urea and creatinine, liver function tests, a full blood count, prothrombin time, a screen for drug abuse if suspected and, in certain cases, arterial blood gas measurement.

Malaria must be excluded for all patients with a fever (or a history of fever) who have visited a malaria-endemic area (see Chapter 166). The cornerstone in the diagnosis of malaria is provided by thick and thin blood films, which may need to be repeated if negative or if there is any doubt. Malaria can be responsible for coma even after the parasites have cleared, especially in the context of renal failure (Fig. 146.7).

In typhoid the most important investigations are blood, bone marrow and stool cultures.

For suspected trypanosomiasis, lymph node aspiration and examination of the blood and CSF for the parasite may be required.

Leptospirosis and Lyme disease are usually clinical diagnoses and are confirmed serologically.

Suspicion of the very many other causes of confusion and coma in a returning traveler will dictate specific further investigations.

Figure 146-7 Peripheral blood film of a patient with past malaria. The patient had returned 5 days previously from Malawi, having been treated there for malaria. At this stage no parasites were visible on the film. She was confused and delirious on admission and was found to have a profound acidosis (pH 6.98) and acute renal failure, thought to be due to the malaria. She was hypotensive, which suggested a secondary bacterial infection, and was found to have a *Salmonella* sepsis. Secondary bacterial infections are not uncommon in severe malaria associated with immunosuppression. The only evidence on blood film for malaria was the presence of malarial pigment (hemozoin) in many of the neutrophils, one of which is demonstrated here (arrow).

Computerized tomography

A contrast-enhanced computerized tomography (CT) scan of the brain should be carried out if there is any suspicion of raised intracranial pressure, as suggested by focal neurologic signs, which include abnormal patterns of respiration, loss of oculocephalic (doll's

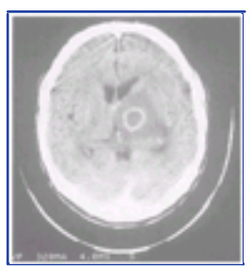

Figure 146-8 Toxoplasmosis. This patient presented to the hospital confused, with a right-sided stroke. An astute doctor requested an HIV test, which was positive. The CT scan carried out with injected contrast shows a typical ring-enhancing lesion in the left internal capsule with considerable surrounding edema. Further lesions were noted on different sections. The *Toxoplasma* IgG was positive and the patient made a full response to anti-*Toxoplasma* therapy.

eye) or oculovestibular (caloric) reflexes, or papilledema. A cerebral abscess, cerebrovascular event, subdural hematoma, subarachnoid hemorrhage or significant cerebral edema may be diagnosed in this way. If the patient has HIV infec-tion, features suggestive of toxoplasmosis (Fig. 146.8), a tuberculous lesion (Fig. 146.9), cryptococcal meningitis or cerebral atrophy may be detected. Space-occupying lesions such as those due to helminth infections can also be recognized by CT (e.g. cysticercosis (Fig. 146.10), schistosomiasis, hydatid disease, paragonimiasis, etc.), as can those due to abscesses, tumors or hemorrhage.

Lumbar puncture

For patients with fever and stable neurologic signs it is important to proceed with a lumbar puncture to exclude meningitis, encephalitis or hemorrhage into the subarachnoid space, which can be missed on CT. The CSF in malaria is usually normal apart from showing a raised lactate concentration. An India ink stain, or preferably an antigen agglutination test, is necessary to diagnose cryptococcal meningitis. In trypanosomiasis examination of the CSF is essential to determine whether there is central nervous system involvement with the presence of trypanosomes, leukocytes above 4/µl and/or protein above 0.4g/l. The CSF must also be examined to determine the extent of neurologic involvement in syphilis.

Magnetic resonance imaging

This is of particular value for a suspected demyelinating illness such as a viral encephalitis, for which the sensitivity of CT is limited, and in situations of brain stem or cerebellar involvement.

MANAGEMENT

Coma is a life-threatening condition until vital functions are stabilized and the underlying cause is identified and corrected. The first priority for a comatose patient is to preserve vital functions. Resuscitation may be necessary, paying special attention to airway protection, support of respiration and circulation, and the urgent

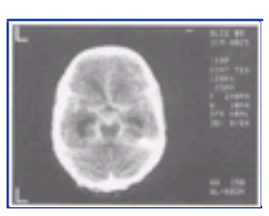

Figure 146-9 Tuberculous meningitis. A CT scan of the brain showing increased uptake of contrast around the vessels at the base of the brain in the circle of Willis in a patient with tuberculous meningitis. Obtundation in a patient presenting with tuberculous meningitis is an indication for the use of steroids.

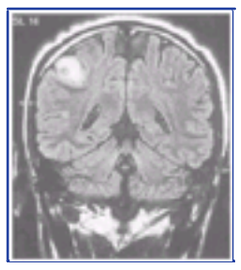

Figure 146-10 Coronal section of brain in cerebral cysticercosis. This magnetic resonance imaging scan shows a cyst with a surrounding white area of edema. While this 22-year-old man presented with focal convulsions of his left arm, edematous lesions placed more centrally, especially within the brain stem, can lead to both confusion and coma.

treatment of hypoglycemia after blood has been taken for various biochemical, hematologic, microbiologic and toxicologic tests. Other metabolic causes of coma other than hypoglycemia, such as acidosis, electrolyte abnormalities and drug intoxication, may need urgent attention. Once the patient is stable the next priority is to establish a diagnosis, which is critical if specific therapy is to be instituted.

All patients who have confusion or are comatose should be managed using the highest level of care appropriate for the particular health care setting. Unconscious patients may need to be moved to the intensive therapy unit. The risk of infection to others needs to be reviewed initially for all travelers, especially if there is any suspicion that the patient has a viral hemorrhagic fever or if he or she is to be moved to a ward area rather than to an isolation unit (see Chapter 186a). Until a diagnosis is made, drugs should be used sparingly. Haloperidol (5–30mg) or chlorpromazine (25–50mg) given intramuscularly may be used for restless or confused patients at risk of injuring themselves or attending staff and to allow diagnostic procedures such as imaging (CT or magnetic resonance imaging) or lumbar puncture. Haloperidol has fewer sedative and hypotensive effects and can be administered by different routes. Travelers with confusion will be in unfamiliar surroundings and are disoriented with regard to time, place and person. It is important that, during recovery, simple but firm communication as to the location and date, a visible clock and the presence of a relative are considered in the overall management of such patients.

Chapter 147 - Skin Rashes and Ulcers

Roderick J Hay

INTRODUCTION

In most developing and tropical countries skin disease is the second or third most common reason for presentation in primary health care. The majority of the diseases that are seen are infective and easily treatable. It is therefore not surprising that people who have visited tropical areas should return with skin disease and are often alarmed that this may have been acquired during their stay overseas. It is important to consider the possible predisposing factors that may have affected the acquisition of skin disease.

PREDISPOSING FACTORS THAT POINT TO A DIAGNOSIS

Diseases endemic to specific geographic areas

As with other diseases, some skin conditions are confined to specific endemic areas. Most of these are infectious diseases and geographic localization depends on climate or the presence of an appropriate vector or host. Examples include onchocerciasis and cutaneous leishmaniasis, in which climatic factors and the appropriate vectors are both specific to certain regions. Endemic dermatoses are not necessarily restricted to the tropics — other infections show similar geographic restrictions. For example, erythema chronicum migrans, an annular erythema caused by primary infection with *Borrelia burgdorferi*, may be acquired during a visit to an area in the USA, Scandinavia or Central Europe, where Lyme disease is endemic.[1]

Activities that predispose to skin disease

Certain activities expose travelers to unusual environments that may affect the development of skin disease. These vary from overland trekking through desert or rainforest to sunbathing on the beach. The beach, in particular, is a potential source of skin diseases, including those due to sun exposure (e.g. discoid lupus erythematosus, polymorphic light eruption) as well as the acquisition of larva migrans from sitting in contaminated sand. Trekking exposes the traveler to other noninfectious hazards, such as contact with plants that may cause allergic or irritant contact dermatitis. Under this heading, reactions to drugs, such as antimalarials, that have been taken during the trip should also be considered.

Climate

Climatic conditions also affect the development of skin disease. Factors identified as important include increased ambient temperature or high levels of atmospheric humidity, both of which have an effect on bacterial growth on the epidermis. Infections due to *Staphylococcus aureus* are much more common in hot and humid climates than in colder climates. Some other infections, such as pityriasis versicolor, are also more frequent in hot and humid environments.

Table 147.1 shows a list of additional questions that are important in taking a history from a patient returning from a trip overseas.

MAKING A DIAGNOSIS

It is important to differentiate between:

- skin diseases in travelers that were already present before the patient left home and skin diseases to which the patient is susceptible and that may have been exacerbated during travel;
- skin diseases that have been caused by exposure to a different climate or environment; and
- newly acquired skin diseases that are normally confined to the area visited.

Skin disease seen in travelers can therefore be considered under the following three main headings.

Conditions made worse by travel

Almost any pre-existing skin condition can be affected by travel, although certain conditions are more likely to present for treatment on return. These include acne vulgaris, which is often considerably worsened in a tropical environment with rapid spread of new pustular lesions. Pre-existing photosensitivity (which includes polymorphic light eruption, discoid lupus erythematosus and solar urticaria) is also exacerbated by sun exposure. Atopic eczema behaves differently in different environmental conditions. For instance, it may be improved by exposure to mild sunlight and sea-bathing, but it is usually made worse by very hot and humid conditions. It is also exacerbated by travel to very cold areas, because this increases skin dryness.

Some forms of dermatophytosis are also more common in the tropics and patients who have pre-existing tinea pedis, for instance, often have an exacerbation when visiting a hot climate; the infection may spread beyond the initial site to affect other areas such as the groin or trunk.

Conditions acquired by exposure to different environmental conditions

Although it is always possible for patients to acquire new skin diseases under different environmental conditions (e.g. light-exacerbated psoriasis), the common presentations are very specific to travel.

Pityriasis versicolor is a common superficial fungal infection that is caused by *Malassezia* yeasts, which are normal commensals on the skin surface.[2] They become pathogenic under certain conditions, one of which is climatic change and sun exposure. The condition presents with widespread scaly hypopigmented or hyperpigmented macules, which tend to become confluent on the trunk and neck (Fig. 147.1). It is not itchy and discoloration is the usual reason for seeking medical help, often a few weeks after return from overseas. Although the definitive diagnosis is best made by microscopic examination of skin scrapings, a simple measure is to demonstrate the presence of fine scales by scratching the lesions. The treatment is ketoconazole shampoo, topical azole antifungal creams (e.g. clotrimazole, miconazole) or oral ketoconazole (200mg daily for 3–5 days) or itraconazole (200mg daily for 5 days). There is no reliable way of preventing this infection, although some habitual sufferers treat themselves

TABLE 147-1 -- Additional useful questions in taking a history from travelers with skin lesions.

ADDITIONAL USEFUL QUESTIONS IN TAKING A HISTORY FROM TRAVELERS WITH SKIN LESIONS
What countries have you visited during your vacation or trip?

Try to find out where they have been within these countries and any potential exposures (e.g. camping by a fast-flowing river in an area endemic for onchocerciasis). Also, it is important to find out whether they were traveling rough or using luxury hotels — there is sometimes a difference in disease exposure.
Before you went overseas did you have any skin problems?
Find out about potential reactions to sunlight and atopic disease, acne, etc.
What sort of things did you do on your trip — bathing in the sea or lake, trekking, sunbathing on a beach?
Were you taking any medications during your stay overseas?

Figure 147-1 Pityriasis versicolor. The rash shows confluent scaly macules.

during their vacations with a single application of selenium sulfide or ketoconazole shampoo.

A related condition, often misdiagnosed as acne, is *Malassezia* folliculitis, which characteristically presents with small itchy pustules on the shoulders and upper chest after sun exposure.[3] The distribution and the itching, as well as the absence of comedones, distinguish this condition from acne. It too responds best to oral itraconazole or ketoconazole.

Infections acquired specifically overseas

Although the common infections seen in tropical communities are scabies, bacterial pyoderma, pediculosis and fungal infections (Table 147.2), they are not as common in travelers as in local people. They are usually acquired as a result of close contact (rather than casual contact) with infected people and they are particularly associated with overcrowding in houses. Likewise, tropical ulcer (see below), which is very common in certain areas of the tropics, is seldom seen in visitors unless they stay for long periods and share the living conditions of the local inhabitants.

Specific examples of conditions acquired overseas are discussed below.

INSECT BITE REACTIONS

Most people become tolerant of the biting insect fauna of their local area; for example, reactions to mosquito bites decline with increasing age owing to sensitization to mosquito salivary antigens.[4] (There

TABLE 147-2 -- Skin symptoms and signs in travelers and potential infective causes.

SKIN SYMPTOMS AND SIGNS IN TRAVELERS AND POTENTIAL INFECTIVE CAUSES

Dermatophytosis (e.g. tinea imbricata)
Annular erythema
Borreliosis

are exceptions to this in people in whom severe hypersensitivity persists.) However, exposure to a new set of antigens from mosquitoes has been associated with an increased level of sensitivity and it is therefore not surprising that insect bites are a very common cause of complaint in travelers. The range of clinical manifestations of bite reactions includes small papules, blisters, dermal nodules and small ulcers. In particular, it is not uncommon for these to become secondarily infected by *Streptococcus* spp. or *Staphylococcus aureus*, which make lesions become more indurated and weepy.

Clues to the diagnosis of prolonged bite reactions are the presence of multiple itchy lesions, in some cases clustering on exposed sites, and a history of evolution over a few days. It is important, though, to exclude secondary infection and treat with appropriate antibiotics. In some cases, cutaneous leishmaniasis may present with indurated itchy papules and nodules that may mimic bites where, of course, they originated. If in doubt, a skin biopsy is often helpful, because a dense polymorphic

cellular infiltrate in the debris with large numbers of eosinophils is highly suggestive of a bite reaction.

Other common bite or sting reactions that may be found in travelers, apart from scorpion sting and snake bite, which require more immediate attention, include jellyfish stings and sea urchin granulomas.

Jellyfish stings[5] usually present with a linear rash on an exposed area. The rash typically consists of multiple papules or small bullae. However, patients usually know what has caused this reaction because the symptoms are virtually instantaneous. Application of cool packs or vinegar may provide immediate relief. In severe cases, such as those due to the Portuguese man-of-war jellyfish, stings may be accompanied by systemic symptoms such as fever, diarrhea and cardiovascular shock.

The spines of sea urchins cause localized clusters of small dermal granulomas. The presence of spines can, if necessary, be confirmed by radiograph. However, in addition, sarcoid-like granulomas that do not contain spines may form in the area of the puncture wound; these persist for months. Recent studies suggest that a small proportion of such wounds may be infected with *Mycobacterium marinum*.[6] Once again, patients know the cause of a sea urchin injury but may delay consultation until their return from overseas. The main treatment is removal of spines if these are still present.

This may be difficult if much time has elapsed after the injury, and broad-spectrum antibiotic cover is also advisable.

Tunga penetrans (the jigger flea) may cause a localized tender nodule on the feet and toes. It may ulcerate and is usually itchy. It is usually covered with a small crust or pustule but where this is carefully removed the presence of a dark posterior segment can be seen. Treatment is by covering the lesion with Vaseline and once the larva appears it can be removed by forceps; alternatively excision after exploration is usually curative. Myasis or infestation with fly larva can also occur and although this affects other sites, the presentation, a tender nodule or ulcer, is similar.

BACTERIAL INFECTIONS

These are not common in travelers except when they are secondary to some pre-existing skin lesions such as insect bites or varicella.[7] Cutaneous diphtheria is still possible in patients who have been traveling rough in some areas such as the Saharan region, and it should be considered in those presenting with ulcers that are covered with a grayish slough. Tropical ulcer, a synergistic bacterial infection, is rare in travelers.[8] One condition that is seen regularly in those working or vacationing in some parts of the Mediterranean region or Africa is the initial ulcer of tick bite or boutonneuse fever. This is caused by *Rickettsia conori*, which is endemic in eastern Africa and some Mediterranean countries.[9] The presence of a necrotic localized ulcer, and often a fine macular rash, in a patient who has an undiagnosed fever is highly suggestive; patients can sometimes describe the tick that caused the reaction. The treatment is with doxycycline (200mg daily for 7 days).

FUNGAL INFECTIONS

Most of the unusual endemic fungus infections are exceptionally rare in travelers, although existing infections may be exacerbated.[10] However, two fungal infections that may occur are *Scytalidium* infections and tinea imbricata.

Scytalidium dimidiatum, a plant pathogen, and *S. hyalinum* are both found in a wide range of tropical environments and both cause superficial infections that mimic those caused by the dermatophyte *Trichophyton rubrum*. Although they are not common in travelers, they occasionally cause nail infections which in Caucasians may present with patchy melanonychia (black discoloration of the nail-plate; Fig. 147.2). [11] Treatment is difficult, because neither of these infections responds to conventional antifungal agents.

Trichophyton concentricum is a dermatophyte that causes the infection tinea imbricata in remote areas of the Western Pacific and in Central and South America. It may occur in travelers, particularly if they have been traveling rough. It presents with very typical

Figure 147-2 Onychomycosis caused by *Scytalidium dimidiatum* in a traveler.

lesions with concentric rings of scales.[12] It responds best to oral terbinafine (250mg daily) or itraconazole (200mg daily).

PARASITIC INFECTIONS

The common diseases of the developing world, such as scabies and pediculosis, are also seen in travelers. A variety of parasitic diseases are seen in those spending short periods in the tropics.

Cutaneous leishmaniasis

This is discussed in detail elsewhere (see Chapter 172). Leishmaniasis can affect travelers who have visited a wide range of countries in the Middle East, Africa and Central and South America. It is also seen in certain areas of Europe around the Mediterranean such as northern Greece, Turkey, Spain and the Balearic Islands, although it is not common in these areas. [13] [14]

Patients present with either single or multiple lesions. These range in morphology from indurated nodules to ulcers. Occasionally they form a chain of nodules along a lymphatic vessel, as in sporotrichosis (see Chapter 13). The typical history is that they appear like an insect bite that persists after return home. It is important to take a biopsy of such lesions.

Onchocerciasis

Onchocerciasis (see Chapter 170 and Chapter 174) may appear in those traveling to endemic areas of Africa, Central and South America and the Yemen.[15] The usual skin presentation of onchocerciasis in the traveler is acute papular onchodermatitis[16] with localized areas of small itchy papules that are often confined unilaterally to a limb or the waist or shoulder region. There is also a form of dermal edema that resembles *peau d'orange* (Fig. 147.3). The diagnosis is made by demonstrating microfilariae in skin snips. The skin changes in travelers are often very subtle and the presence of localized itching and a history of travel, often involving camping by a river, are helpful clues.

Cutaneous larva migrans

Cutaneous larva migrans (creeping eruption; see Chapter 174) is not uncommon in travelers, particularly those who have visited tropical beaches, and is caused by skin infection with animal hookworm larvae such as *Ancyclostoma brasiliense, A. caninum* and *Uncinaria stenocephala*. Often, patients have returned from a vacation during which they have sat on the beach. Lesions present with an itchy

Figure 147-3 Acute papular onchodermatitis. There is a combination of dermal edema and a papular rash.

cluster of lesions on an exposed site such as the legs or buttocks. The morphology of the lesions varies. In some cases there is a typical sinuous track, but in other cases the lesions are nodular but grouped in a specific area. In cases where the lesion is clearly worm-like, diagnosis is easy; otherwise it may be necessary to biopsy lesions. Treatment with albendazole (400mg daily for 3 days) is usually curative. [17]

Other parasites

Other tropical parasites very occasionally cause imported infections in travelers.

Cercarial dermatitis

Cercarial dermatitis[18] presents as an itchy rash that often occurs after swimming. Patients describe intense itching after exposure to water, sometimes accompanied by papules or small weals. Although it is usually a harmless symptom caused by contact with avian cercaria in areas that are endemic for schistosomiasis, it can be an early symptom of exposure to pathogenic schistosomes.

Katayama fever

In patients returning from areas that are endemic for schistosomiasis, the development of urticaria, joint pains and fever should be regarded with suspicion, because it is an early sign of sensitization in the early stages of schistosomiasis. [19] These symptoms usually occur several weeks after exposure.

Dirofilariasis

This occurs in several regions — Africa, the Far East, South America and the southern USA. The cutaneous infection is due to *Dirofilaria* species such as *D. tenuis* or *D. ursi*. Patients present with a localized itchy papule or nodule, which is often near the eye, elsewhere on the face or on the chest.[20] The diagnosis is made by biopsy.

Other important parasitic infections such as dracunculiasis, loiasis and lymphatic filariasis are uncommon in travelers, but have all been reported occasionally.

DRUG REACTIONS

Many patients take medications during trips overseas, including antimalarial agents, antidiarrheal agents and antihistamines. All may produce skin lesions; some drugs (e.g. tetracyclines) may cause photodermatitis. It is important to take an adequate drug history in those returning from overseas. The most common cause of drug rashes in this group are the antimalarial agents:

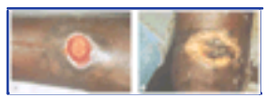

Figure 147-4 Tropical ulcer. (a) Acute. (b) Chronic.

- chloroquine can cause a range of different rashes, but the main reactions are lichenoid (lichen planus-like) reactions and pruritus;
- mepacrine causes a diffuse yellowish pigmentation of the skin;
- mefloquine can cause pruritus and urticaria;
- pyrimethamine combined with sulfodoxine can cause urticaria, erythema multiforme and toxic epidermal necrolysis — it is thought that the skin reactions are largely due to the sulfonamide component; and
- quinine can cause erythema and flushing and pruritus.

It is important to obtain a drug history to ensure that all medications, including antimalarial agents, that were taken during the trip are considered in making the diagnosis of any skin rash.

ULCERS

Ulceration of the skin is a common and important physical sign. Diagnosis of ulcers depends on the underlying clinical situation, the evolution of the condition, the area affected and the appearance. Many of the conditions discussed above may develop into small ulcers. These include leishmaniasis, insect bites and boutonneuse fever. However, there are others that are important not to miss.

Tropical ulcer

Tropical ulcer is a common condition in remote parts of the tropics mainly seen in children and teenagers and affecting the lower limbs.[8] The lesion usually starts with mild discomfort and overlying hyperpigmentation on the skin that progresses over a few days until the skin breaks down and sloughs revealing an underlying ulcer. The ulcer, therefore, is often described as occurring rapidly.

Tropical ulcer is mainly seen in Africa, India, the West Pacific and part of Indonesia and the Philippines. The disease is due to a combined infection by a number of different bacteria together with a fusiform bacterium, *Fusobacterium ulcerans*, and an as yet unidentified spirochete. The disease is associated with poor living conditions and exposure to stagnant water and mud. *Fusobacterium ulcerans* has been isolated from mud in endemic areas.

The lesion is often clean on first presentation, round, with smooth edges (Fig. 147.4a). It generally starts on the lower leg or ankle and in about 10% of cases it progresses to become an irregular, enlarged and chronic ulcer (Fig. 147.4b). The condition heals well in most patients with simple cleansing and treatment with penicillin. However, early grafting may be necessary where healing is delayed.

The differential diagnosis of tropical ulcer includes yaws, diphtheritic ulcer and leishmaniasis.

- The primary lesion of yaws is usually more exophytic and appears to stand out from the skin. It may then ulcerate before the development of secondary lesions. Although it was once controlled, yaws has resurfaced in some of the previous endemic areas of West Africa and the West Pacific, areas where tropical ulcer may also occur.
- Diphtheritic ulcer is uncommon but the lesion is more irregular and the base is covered with a gray to yellow slough. It is more often seen in desert or semidesert areas.
- Leishmaniasis can be distinguished by its slower speed of onset with a skin nodule often with surrounding plaque breaking down to produce ulceration. Inflammation around the ulcer is more intense.

Overall tropical ulcer is unlikely to occur in the traveler unless the area visited is remote and the patient has lived under local conditions.

Buruli ulcer

This condition is not often seen in travelers although it is sometimes considered.[21] Once again, it occurs in the remote parts of Africa, particularly Central and West Africa, and the West Pacific. Cases have been reported from Australia. It is caused by *Mycobacterium ulcerans* and usually affects children and young adults. Like tropical ulcer, there is an association with exposure to water. The ulceration starts as a small raised nodule that breaks down to develop into an extensive undermined and irregular ulcer that may extend for 10 cm or more. Treatment is largely surgical. The undermining is characteristic.

Other ulcers seen in travellers

Mycobacterium marinum causes ulceration of the skin preceded by the development of a nodule. In many cases it causes a characteristic form of spread involving local lymphatics (sporotrichoid or lymphangitic). The primary ulcer is followed by secondary nodules that may break down and discharge. While typically this is an infection seen in those handling tropical fish at home, it can be acquired naturally by swimming in shallow coastal waters. *Mycobacterium marinum* is a natural pathogen of fish.

Streptococcal ecthyma is also seen frequently in the tropics. This is a more severe form of impetigo where the whole epidermis and part of the dermis is involved in necrosis to give 1–2cm punched-out ulcers. It is often a secondary infection (e.g. on an insect bite or following chickenpox). It responds slowly to penicillin. It may be seen in returned travelers at the site of scratches or bites.

There is no reason why travelers cannot develop the same types of ulceration abroad as at home and the differential diagnosis should include:

- stasis, arterial or diabetic ulcers;
- ulcers due to vasculitis such as polyarteritis nodosa; and
- hemoglobinopathy-associated ulcers (e.g. sickle cell disease).

Taking a thorough history of the time course of onset of ulceration and any relevant background information is very important. Where necessary, it may also be useful to biopsy the edge of ulcers as this may provide further diagnostic information. Histology from the central area is only rarely useful.

CONCLUSION

Skin disease is common and patients not infrequently present with lesions that appear to have been acquired during the course of foreign travel. In making the diagnosis, it is important to remember that the majority of such cases are due to skin conditions that are just as likely to occur at home as overseas. However, in some patients, the condition is a genuine imported infection that has followed exposure during the course of travel.

Chapter 148 - Sexually Transmitted Diseases

Mark W Tyndall

INTRODUCTION

The incidence of sexually transmitted diseases (STDs) in the returned traveler is not known as reporting systems are sporadic, diagnosis is difficult and self-treatment is common. The risk of STD is directly related to the frequency of sexual contact, choice of sexual partner and type of exposure. Despite considerable risk, surveys conducted among travelers show that up to 25% have new sexual partners, contact with commercial sex workers is common, condom use is inconsistent and perceived risk of infection is underestimated.[1] [2] [3] [4] [5] [6]

Increased international travel through tourism, business and migration has dramatically changed the patterns of STD transmission.[7] [8] [9] [10] Many of the most popular travel destinations in Africa, Asia and the Caribbean are regions with high STD prevalence, high rates of prostitution and little capacity to implement effective STD control. The AIDS epidemic tragically illustrates how the spread of sexually transmitted pathogens transcends international borders and frustrates control efforts.[11] [12] [13] [14]

PREVENTION

Prevention of STDs among travelers is of the highest priority and should be discussed prior to departure. Contracting an STD pathogen while traveling may have serious short-term and long-term implications. Counseling should include the promotion of responsible sexual behavior, including abstinence, condom use and avoiding commercial sex. Prevention efforts to date have been inadequate as shown in surveys of both departing and returning travelers.[3] [4] [5]

CLINICAL FEATURES

Sexually transmitted disease pathogens can broadly be divided into those that cause nonulcerative lesions and those that cause ulcerative lesions. For clinical management, the nonulcerative pathogens can be further divided into anatomic sites. The most common presentation for men is urethritis, followed by epididymitis, prostatitis and proctitis. Infection involving the lower genital tract is the most common presentation in women and includes cystitis, vulvitis, vaginitis, urethritis and cervicitis. HIV infection, multiple concurrent STDs or other infectious complications, however, may alter this simplified clinical approach.

Urethritis in men

The etiology of urethritis in men has traditionally been divided into gonococcal and nongonococcal infections. This classification was developed due to the characteristic presentation of *Neisseria gonorrhoeae*, which is generally symptomatic and involves profuse, purulent, urethral discharge, occurring 2–5 days following sexual contact. The less severe clinical presentation of mucoid discharge and/or dysuria has been associated with nongonococcal infections, which include *Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma genitalium* and *Trichomonas vaginalis*. These infections have longer incubation periods of 1–6 weeks. Nongonococcal urethritis is more often asymptomatic (10–30%) and may therefore go undiagnosed. Where available, etiologic diagnostic testing should be performed due to the poor sensitivity and specificity of a clinical diagnosis.

Mucopurulent cervicitis

Most serious infections of the lower genital tract in women involve *N. gonorrhoeae* and *C. trachomatis*, either of which may result in ascending infections with severe consequences. These organisms are clinically indistinguishable and cause urethritis and/or cervicitis. Vaginal discharge and dysuria are the most common clinical presentations, but are extremely variable and the conditions are easily confused with vaginitis. Asymptomatic infections are common (<50%) and may only be detected when complications occur. Herpes simplex virus is also associated with inflammation of the urethra and cervix, but does not result in ascending infections.

Other causes of vaginal discharge

The major causes of vaginitis are *Trichomonas vaginalis, Candida albicans* and bacterial vaginosis. These are difficult to distinguish clinically and may occur together. Vulvitis and cystitis also present with lower genitourinary tract symptoms and must be distinguished from vaginal infections.

- ¦ Trichomoniasis typically presents with profuse, yellow-green, frothy vaginal discharge with erythema of the vaginal wall.
- ¦ Candidiasis presents with pruritus and white curd-like discharge. It is extremely common in women during child-bearing years and the role of sexual transmission remains controversial.
- ¦ Bacterial vaginosis presents with malodorous white vaginal discharge and is characterized by a change in normal vaginal flora. This process is likely multifactorial and, despite being a common diagnosis at STD clinics, it is not considered to be sexually transmitted.
- ¦ Vulvitis may be due to *C. albicans*, herpes simplex virus (HSV) or human papillomavirus (HPV). Pruritus, burning discomfort, edema and erythema are the common manifestations. In cases of HSV and HPV infection, characteristic lesions may be seen on close examination.
- ¦ Cystitis, which may be related to sexual activity, can usually be excluded from sexually transmitted infections by history and urine culture.

Other nonulcerative sexually transmitted diseases

Other nonulcerative STDs that may be seen in the returned traveler include:

- ¦ genital warts, caused by HPV types 6 and 11, which affect genital and anal regions and can range from asymptomatic lesions to large confluent masses;
- ¦ molluscum contagiosum, which is a benign, self-limited, papular condition affecting the skin and mucous membranes, with lesions characterized by central umbilication;

- ¦ public lice, caused by *Phthirus pubis*, which present with itching and inflammation in the pubic area. The lice can usually be seen by the naked eye and infestation is usually self-limited; and
- ¦ scabies, caused by *Sarcoptes scabiei*, is commonly sexually transmitted and may lead to severe inflammation and excoriation in the genital region, mimicking other infections.

Genital ulceration

Genital ulcer disease (GUD) is most commonly caused by HSV, syphilis or chancroid (Fig. 148.1), although in some regions donovanosis and lymphogranuloma venereum should be considered. Occasionally scabies, trichomoniasis and nonsyphilis spirochetes may present as genital ulcers. The differential diagnosis also includes

Figure 148-1 Chancroid. Characteristic purulent lesion with ragged borders, friable base and surrounding inflammation.

TABLE 148-1 -- Clinical features of genital ulcer disease.

CLINICAL FEATURES OF GUD		
Infection (pathogen)	**Incubation period**	**Clinical features and natural history**
Syphilis (*Treponema pallidum*)	Primary (14±28 days)	Single, rounded, well-defined borders, nontender, indurated base; may occur in extragenital sites; resolves spontaneously in 3±6 weeks
	Secondary (1±12 weeks following primary lesion)	Systemic features; papular rash classically affecting palms and soles; condylomata lata in moist areas
	Tertiary (uncommon) (years)	Neurosyphilis; cardiovascular syphilis; late benign syphilis
Chancroid (*Haemophilus ducreyi*)	4±10 days	Single or multiple, deep, painful, ragged borders; inguinal swelling (bubo) occurs in 30% and may suppurate; progressive and destructive
Herpes (HSV-2)	2±7 days	Multiple vesicular ulcers, which break down; superficial and painful; resolve spontaneously in 1±3 weeks, but may recur
Granuloma inguinale or donovanosis (*Calymmatobacterium granulomatis*)	1±10 weeks	Single or multiple elevated, painless, beefy red; progressive verrucous lesions; systemic illness
Lymphogranuloma venereum (*Chlamydia trachomatis* serovars L1, L2, L3)	Primary disease (3±12 days)	Penile and urethral which resolves spontaneously in days; urethritis
	Secondary disease (10±30 days)	Lymph node disease; persistent and destructive; inguinal swelling (groove sign); proctitis, lymphangitis; sinus formation; systemic illness

noninfectious causes such as a fixed drug eruption, Behçet's syndrome, Reiter's syndrome, trauma and malignancy. Table 148.1 describes the classic clinical presentation of the major infectious etiologies but, as with other STDs, there is considerable variation in presentation and mixed infections are common.[15] [16]

SEXUALLY TRANSMITTED DISEASES WITH THE GREATEST GLOBAL SIGNIFICANCE

The persistent viral STDs, which include HIV-1, HIV-2, human T-lymphocyte leukemia/lymphoma virus-1 (HTLV-1), cytomegalovirus, HSV, HPV and hepatitis B and hepatitis C viruses, represent the most serious long-term health risks for the sexually active traveler. Ironically, most of these infections do not present with genital symptoms. Table 148.2 shows the estimated sexual transmission efficiency and clinical manifestations of these viral agents. There is convincing evidence that the transmission of these viral pathogens is facilitated by other genital infections, both ulcerative and nonulcerative. [17] [18] [19]

Historically, the complications of STDs have primarily affected women, manifesting with severe local disease, pelvic inflammatory disease, infertility and complications in pregnancy. Although this remains true, the persistent viral infections pose serious long-term risks for both men and women:

- HIV infection continues as a global pandemic with heterosexual transmission being the predominant route of infection;
- HPV is widespread and has resulted in high rates of cervical cancer, especially among women in developing countries;
- hepatitis B produces chronic liver disease and liver cancer and the role of sexual transmission is important;
- sexual transmission of hepatitis C virus appears to be less efficient than that of hepatitis B virus, but does occur;
- herpesviruses type 1 and type 2, and cytomegalovirus are now widespread global infections with major implications in the immunocompromised; and
- the implications of retroviruses (e.g. HTLV-1), other than HIV, lead to a range of illnesses and sexual contact may play a role in transmission.

TABLE 148-2 -- Persistent viral sexually transmitted diseases: transmission efficiency, clinical manifestations and epidemiology.

PERSISTENT VIRAL STDs: TRANSMISSION EFFICIENCY, CLINICAL MANIFESTATIONS AND EPIDEMIOLOGY			
Virus	**Estimated efficiency of sexual transmission**	**Clinical manifestations**	**Endemic areas**
HIV-1	Low-moderate	Immunosuppression/AIDS	Sub-Saharan Africa, India, South East Asia
HIV-2	Low-moderate	Immunosuppression/AIDS	West Africa
HTLV-1	Unknown	Adult T-lymphocyte leukemia/lymphoma, HTLV-1-associated myelopathy or tropical spastic paraparesis	Japan, Caribbean
Cytomegalovirus	Moderate-high	Systemic disease in the immunosuppressed	South East Asia, Africa
HSV-1 and HSV-2	Moderate-high	Recurrent genital ulcers	Worldwide
HPV	Moderate-high	Cervical cancer in women, anal cancer in men, recurrent genital warts	Worldwide
Hepatitis B virus	Moderate-high	Chronic hepatitis, cirrhosis, hepatic failure, carcinoma	South East Asia, Africa
Hepatitis C virus	Low	Chronic hepatitis, cirrhosis, hepatic failure, carcinoma	Worldwide

DIAGNOSIS

Laboratory diagnosis

The diagnostic work-up for STDs in the returned traveler does not differ significantly from the approach used for locally acquired infections, although knowledge of the geographic distribution of infection

TABLE 148-3 -- Diagnostic testing for pathogens causing nonulcerative and ulcerative infections in men and women.

DIAGNOSTIC TESTING FOR PATHOGENS CAUSING NONULCERATIVE AND ULCERATIVE INFECTIONS		
Infection (pathogen)	**Specimen collection**	**Diagnostic tests**
Gonorrhea (*Neisseria gonorrhoeae*)	Men: meatal swab/urine; women: cervical swab/urine	Gram stain (Gram-negative diplococci) or media culture or nucleic acid amplification (LCR/PCR)
Chlamydiosis (*Chlamydia trachomatis*)	Men: endourethral swab/urine; women: cervical swab/urine	Tissue culture or ELISA or nucleic acid amplification (LCR/PCR)
Trichomoniasis (*Trichomonas vaginalis*)	Men: endourethral swab/urine; women: vaginal fluid	Microscopy (motile trichomonads) or media culture

Candidiasis (*Candida albicans*)	Women: vaginal fluid	Microscopy (wet mount or potassium hydroxide preparation showing yeast and mycella); media culture
Bacterial vaginosis (*Gardnerella vaginalis*, mycoplasmas, anaerobic bacteria)	Women: vaginal fluid	Microscopy (clue cells), vaginal pH <4.5, potassium hydroxide test, white discharge
Syphilis (*Treponema pallidum*)	Serum	Nontreponemal serology: RPR, VDRL; treponernal serology: MHA-TP, FTA-ABS
	Ulcer scrapings	Dark-field microscopy
Chancroid (*Haemophilus ducreyi*)	Ulcer swab or bubo aspirate	Media culture, nucleic acid amplification (PCR)
Herpes (HSV-2)	Ulcer swab	Tissue culture, nucleic acid amplification (PCR)
		Type-specific HSV-2 antibody serology
Donovanosis (*Calymmatobacterium granulomatis*)	Ulcer tissue or scrapings	Giemsa or Wright staining (identify Donovan bodies)
Lymphogranuloma venereum (*Chlamydia trachomatis* serovars L1,2,3)	Serum	Serology (complement fixation or immunofluorescent antibody tests)
	Ulcer scrapings	Tissue culture
FTA-ABS, fluorescent treponemal antibody-absorbed test; LCR, ligase chain reaction; MHA-TP, microhemagglutination-*Treponema pallidum*; RpR, rapid plasma reagin; VDRL, Venereal Disease Reference Laboratories test.		

may assist with the differential diagnosis. Although an efficient and rational approach to diagnosis should be taken, it may be necessary to order several diagnostic tests simultaneously because of the poor sensitivity and specificity of clinical examination, the propensity of STD pathogens to occur together and the variability in test performance. In addition, the potential complications of infection and the risk of further transmission demand that the infection is identified and treated expeditiously.

Test availability, patient circumstances and controversies in test performance preclude rigid diagnostic algorithms. In general, first-line tests should include microscopy, which can be conducted in a clinic setting and may provide a rapid diagnosis. Media-based cultures and serology require 48–72 hours, but are inexpensive and should be used as first-line tests when available. Tissue culture and amplification procedures are the most expensive tests and should be used with restraint. It is anticipated that with the development, commercial availability and affordability of sensitive and specific amplification procedures, many of the current culture-based methods will be replaced. Table 148.3 outlines the specimen collection and diagnostic testing available for the most common nonulcerative and ulcerative pathogens.

The risk of HIV infection and other viral STDs introduces a special problem in the approach to patient care. Presentation with a bacterial STD is essentially a marker for potential exposure to viral STDs. Among viral STDs the focus initially is on HIV infection, which arguably has the most serious consequences, and early treatment may alter disease progression. Most HIV screening currently tests for both HIV-1 and HIV-2, although the transmission of HIV-2 remains unusual outside West Africa. Screening for other persistent viral infections should be evaluated on an individual basis. For other viruses, the risk is not immediate and there are no specific interventions to block or delay chronic infection. The implications for current and future sex partners, however, are important and screening may be warranted.

Diagnosis by geographic region

A comprehensive picture of the global epidemiology of STDs is not available. Much of what is known about the geographic prevalence of infection is based on ad hoc surveys in selected populations.[6] The highest prevalence of STDs is found in resource-poor countries, which have the least capacity for monitoring and recording information. Sporadic cases and outbreaks of STDs are common and can occur in any region.

Prevalence figures for HIV-1 infection, which are more complete, generally indicate that it is common in regions in which other STDs are prevalent such as sub-Saharan Africa and South and South East Asia. Sexually transmitted diseases are prevalent in any geographic area that is characterized by poverty, prostitution and social disruption.

Genital ulcer diseases are one group of STDs for which knowledge of the geographic distribution may be useful. They appear to occupy specific geographic niches, knowledge of which may aid in the differential diagnosis. Table 148.4 indicates regions where etiologic-specific GUDs are endemic.

The persistent viral STDs have spread globally, although endemic regions are well described (see Table 148.2). Although HIV-1 infection has been the most lethal of these viral pathogens, cervical cancer caused by HPV and hepatic diseases caused by hepatitis B virus have serious consequences and are much more prevalent globally.

Knowledge of antibiotic resistance patterns in various geographic locations may be useful for empiric therapy, but as with STD prevalence figures, the data are sparse and the patterns change rapidly. In high-prevalence regions, the capacity to monitor antibiotic resistance and disseminate this information is inadequate. It is the returned traveler who fails to respond to recommended antimicrobials who

TABLE 148-4 -- Geographic distribution of genital ulcer disease.

GEOGRAPHIC DISTRIBUTION OF GUD	
GUD	**Endemic areas**
Syphilis	Sub-Saharan Africa, India, eastern Europe
Chancroid	Sub-Saharan Africa, South East Asia, central America
Herpes	Worldwide
Granuloma inguinale (donovanosis)	South-east India, New Guinea, Caribbean, Brazil, Vietnam, Japan, central Australia, Zambia, South Africa
Lymphogranuloma venereum	East Africa, West Africa, South East Asia, South America, Caribbean

may indicate emerging resistance. In fact, penicillinase-producing *N. gonorrhoeae*, which is now found globally, was first isolated from an American traveler returning from South East Asia.[19] The overuse and misuse of antimicrobials has promoted the emergence of *N. gonorrhoeae* resistance to penicillin, tetracycline and fluoroquinolones in many parts of the world.[20] Although the recommended empiric treatments should be available and effective for most returning travelers, ongoing surveillance for emerging resistance is a priority for reference laboratories.

MANAGEMENT

An STD in a returned traveler has major implications beyond diagnosis and treatment. The psychologic stress can range from minimal to debilitating. Issues of confidentiality, reporting and contact tracing may result in serious social disruption. Infection with a persistent viral infection may have long-term health consequences. An experienced health care team that can request appropriate diagnostic testing, monitor response to treatment, provide counseling, organize contact tracing and arrange longer term follow-up is essential.

The immediate management will be guided by a detailed history, including frequency of sexual exposure, type of exposure (e.g. oral, anal, vaginal), selection of partner (e.g. commercial sex worker, traveling companion), use of condoms and previous treatment (e.g. local, self-administered). It is not uncommon for travelers to have sought treatment abroad and often these individuals do not know what they received.

A thorough genital examination is important, despite the limitations of establishing an accurate etiologic diagnosis. This is especially true for women, for whom complications of infection are common and multiple anatomic sites might be involved. If an STD is suspected but rapid diagnostic testing is unavailable or inconclusive, empiric treatment is required, due to the risk of:

- developing complications,

¦ transmission to other partners, and
¦ potential loss to follow-up.

Table 148.5 summarizes the recommended treatments for the major nonulcerative and ulcerative pathogens. It is recommended that the treatment for gonorrhea always include treatment for chlamydia and that the treatment for chancroid always include treatment for syphilis. Beyond this, the choice of empiric treatment must be based on:

¦ severity of illness,
¦ knowledge of local infections,
¦ availability of diagnostic tests, and
¦ opportunity for follow-up.

Contact tracing in the returned traveler is generally concerned with informing and screening any sexual partners since returning. This is usually carried out by public health authorities who respond to

TABLE 148-5 -- Recommended treatment for nonulcerative and ulcerative STDs.

RECOMMENDED TREATMENT FOR NONULCERATIVE AND ULCERATIVE STDS		
Infection		**Empiric treatment**
Nonulcerative	Gonorrhea	Cefixime 400mg po single dose or ciprofloxacin 500mg po single dose or ceftriaxone 125mg im single dose
	Chlamydiosis	Azithromycin 1 g po single dose, doxycycline 100mg po q12h for 7 days
	Trichomoniasis	Metronidazole 2g po single dose
	Ureaplasma infection	Doxycycline 100mg po q12h for 7 days
	Bacterial vaginosis	Metronidazole 2g po single dose
Ulcerative	Syphilis	Benzathine penicillin G 2.4 million units im single dose
	Chancroid	Azithromycin 1g po single dose or
		Ceftriaxone 250mg im single dose or
		Ciprofloxacin 500mg po q12h for 3 days or
		Erythromycin 500mg po q8h for 7 days
	Herpes	Aciclovir 400mg po q8h for 7–10 days or
		Aciclovir 200mg po five times a day for 7–10 days or
		Famciclovir 250mg q8h po for 7–10 days or
		Valaciclovir 1g po q12h for 7–10 days
	Lymphogranuloma venereum	Doxycycline 100mg po q12h for 21 days or erythromycin 500mg po q6h for 21 days
	Donovanosis	Doxycycline 100mg po q12h for at least 21 days or
		Trimethoprim-sulfamethoxazole one DS q12h for at least 21 days

reports of STDs in the community. With the variability in symptoms and delays in seeking treatment, it is not uncommon to transmit infection and many imported STDs are diagnosed only after symptoms appear in secondary contacts.

HIV-1 screening

Perhaps the most difficult issue for the returned traveler is whether to screen for persistent viral infections. This may be a concern of returned travelers and should be discussed by the health care worker if it is not. The decision for HIV-1 screening must be made after an informed discussion and a careful evaluation of the risk. Testing for HIV-1 should be strongly recommended for those who:

¦ have engaged in unprotected sex with a commercial sex worker;
¦ present with any GUD (especially chancroid);
¦ have failed standard treatment;
¦ have developed a flu-like illness associated with the STD (which may indicate a seroconversion illness); or
¦ are pregnant.

Testing should also be offered to anyone contracting an STD while traveling in high-prevalence areas, including those who are worried but well.

Chapter 149 - Jaundice

Hilton C Whittle

INTRODUCTION

The common afflictions experienced by the returned traveler are diarrhea and malaise.[1] However, jaundice in the returned traveler excites fears of highly infectious and serious exotic infections. In fact, since the advent of vaccines for hepatitis A virus and hepatitis B virus, jaundice in returned travelers is unusual and is equally likely to be due to mundane causes that are common in the developed world.

Jaundice is caused by the accumulation of bilirubin, resulting in yellow discoloration of the sclera and the skin. It is exacerbated when an infection causing hemolysis or hepatic damage occurs in a person who has pre-existing liver damage or in a person who has a congenital tendency to hemolysis.[2] The discussion in this chapter is limited to frank jaundice that is due to infection in a traveler recently returned from a developing country or a nonendemic zone or in a repatriated person who has worked or resided in such a place.

HISTORY

A precise and thorough history is the key to diagnosis. In the excitement and drama of the onset of jaundice, especially if it is associated with mental confusion, the vital question of the recent whereabouts of the patient may be overlooked.

Figure 149.1 and Figure 149.2 show the distribution of some exotic viral infections that can cause jaundice. The duration of stay, mode of travel and lifestyle at home and abroad, including eating, drinking and sexual and drug habits, affect the risk of infection during travel. For example, a young student adventurer intent on meeting and living like the locals is obviously in danger of being infected through contaminated food, water or insects. Pot-holing, caving and fresh water sports represent a risk for leptospirosis. Did this young traveler attend a local health center to receive injections or a blood transfusion? On the other hand, a businessman frequenting luxury hotels and nightclubs is in less danger of endemic infections but is at higher risk of alcoholic hepatitis and sexually transmitted hepatitis B. Drug abuse is common among some travelers, who share cheap drugs and dirty needles with their local counterparts, thus placing themselves at high risk of viral hepatitis and other infections. An expatriate doctor, nurse or researcher working with contaminated blood in a rural hospital is in obvious danger of needle-stick injuries, which can transmit viral and other infections that may cause hepatitis and jaundice. Other obvious questions, which are often forgotten, relate to illness in fellow travelers, outbreaks of infection with or without jaundice in local communities, and exposure to toxins such as methyl alcohol in local potions or the ingestion of raw shellfish or other inadequately cooked food. Behind all these questions is the crucial one; is this person likely to have been nonimmune before exposure to infection during travel in an endemic or epidemic area?

Past medical history

The past medical history contains essential information. Was the traveler immunized against hepatitis A virus, hepatitis B virus, yellow fever and typhoid? What antimalarials did the traveler take? Does the traveler use recreational drugs such as ecstasy or cocaine or take other medications, such as isoniazid, dapsone or methyldopa, that may cause hepatitis? Was local food eaten and local water drunk? Was any attempt made to prevent mosquito bites? A previous history of chronic liver disease due to alcohol or viral hepatitis or a tendency to hemolysis (as in some hemoglobinopathies or enzyme deficiencies, such as glucose-6-phosphate dehydrogenase deficiency) may explain exacerbation of jaundice associated with infections of the liver.

SIGNS, SYMPTOMS AND DIFFERENTIAL DIAGNOSIS

A simple classification of jaundice and a list of common infectious causes is found in Table 149.1 , and their likely geographic origins are shown in Figure 149.1 and Figure 149.2 . Other noninfectious causes of jaundice must also be kept in mind (e.g. alcoholic and other causes of cirrhosis, autoimmune hepatitis, gallstones or metastases blocking the bile ducts, drugs such as isoniazid or chlorpromazine, and poisons such as aflatoxin).

A full and thorough clinical examination is obviously mandatory and this must include a good examination of cerebral function. If cerebral function is disturbed, jaundice may be due to hypoglycemia, which is found in severe malaria, especially in children, or it may be due to liver damage itself; headache and meningeal irritation are common in leptospirosis. Signs of chronic liver disease should be looked for because chronic liver disease is sometimes the backdrop to a fulminant infection.

Hemorrhage in skin or mucosa suggests viral hemorrhagic fever, relapsing fever, leptospirosis, severe bacteremia (e.g. meningococcemia) or fulminant hepatitis itself. Assess the size of the liver. If it is small and hard, cirrhosis may be the cause; if it is large and severely tender, ascending cholangitis, flukes or gallstones may be the cause; if there is localized tenderness between the ribs, or inflamed localized swelling, an amebic abscess or another type of abscess may be the cause. The chest should be examined carefully and radiography performed if possible. Severe pneumonia can cause jaundice; a raised diaphragm on the right suggests liver abscess.

Other diagnostic clues

The incubation period is of obvious importance, whether a patient presents with an infection while traveling or after returning. Thus, hepatitis B virus, which has an incubation period of up to 6 months, may cause jaundice long after the holiday is forgotten,[3] whereas the acute hemorrhagic fevers present within 3–6 days of infection, often precipitating emergency removal from the area of travel.[4] The incubation period of leptospirosis is of intermediate duration, being 7–12 days,[5] similar to that of malaria, although the incubation of malaria may be prolonged as a result of inadequate use of prophylactic or curative drugs.[6]

Blood transfusion

In tropical or developing countries blood transfusion is fraught with danger because screening procedures are often not as rigorous

Figure 149-1 Distribution of human malaria.

Figure 149-2 Distribution of some viral hemorrhagic fevers that cause jaundice.

TABLE 149-1 -- Differential diagnosis of jaundice due to infection in the returned traveler.

DIFFERENTIAL DIAGNOSIS OF JAUNDICE DUE TO INFECTION IN THE RETURNED TRAVELER				
Type of jaundice		**Cause**	**Diagnostic test**	**Comments**
Prehepatic	Hemolysis	Malaria; *Bartonella* spp.	Thick and thin blood film	Hemolysis is severe in 'blackwater' fever; *Bartonella* spp. are found in Columbia, Peru, Ecuador
Hepatic	Viruses	Hepatitis viruses A–E, hemorrhagic fevers (yellow fever, Rift Valley fever, Crimean-Congo hemorrhagic fever)	Serum IgM antibody, antigen detection tests, polymerase chain reaction	Was patient transfused? Any local outbreak of jaundice? Jaundice is uncommon in most hemorraghic fevers
	Bacteria, spirochetes	Any severe bacteremia, leptospirosis	Blood culture, micro-agglutination test	Any contact with infected soil or water?
	Protozoa	Amebic or pyogenic liver abscess	Amebic antibodies	East coast of Africa, Mexico and South East Asia are notorious 'hot' spots
Posthepatic	Bile duct obstruction	*Ascaris*, liver flukes, clonorchiasis opisthorchiasis, fascioliasis	Examination of stool for eggs	Unusual in schistosomiasis. Has traveler been eating raw fish?

as in the Western world. Malaria, hepatitis B, C and D viruses, Epstein-Barr virus and cytomegalovirus are possible blood-borne agents that may cause jaundice, especially in subjects who have underlying immunodeficiencies or who are pregnant. Travelers in developing countries should avoid blood transfusions if possible.

Malaria

Malaria is probably the most common cause of fever in the returned traveler. Jaundice caused by massive hemolysis and a degree of hepatocellular necrosis may be manifest during severe *Plasmodium falciparum* malaria in adults, and milder forms are apparent in *Plasmodium vivax* and *Plasmodium ovale* malaria. Underlying liver disease or red cell enzyme deficiencies exacerbate this tendency, and primaquine used to treat *P. vivax* and *P. ovale* may precipitate hemolytic jaundice in some patients who have glucose-6-phosphate dehydrogenase deficiency (see Chapter 166).

Hepatitis viruses

Hepatitis viruses are the next most common cause of fever in the returned traveler, although a minority of those infected develop jaundice.[7] The incubation periods of hepatitis A and E virus are around 15–50 days after contact with infected food or water. Pregnant women are particularly prone to severe hepatitis E virus infection.[8] Hepatitis B, which has a much longer incubation period of 3–6 months, may be transmitted in contaminated blood or needles, as may hepatitis C, which has an incubation period of 2 months. Fever accompanied by general malaise is seldom ascribed to these viruses (see Chapter 48).[9]

Yellow fever and other hemorrhagic fevers

Yellow fever causes jaundice in 1 in 10 infections; Rift valley fever and Crimean-Congo hemorrhagic fever are less common causes. The other hemorrhagic fevers — Lassa, Junin, Ebola, Marburg, Hanta or Dengue — are not noted to cause jaundice, except occasionally in very severe cases (see Chapter 183). All cause hemorrhage and some degree of hepatic and renal damage, the latter being manifest by uremia and proteinuria.

Yellow fever is characterized by the acute onset of fever, chills, muscle aches, nausea and vomiting, followed by jaundice. The pulse may be slower than expected from the degree of fever. Leukopenia is common. After a brief remission of a day or more, a toxic state may develop, with liver and renal failure. Serologic diagnosis is achieved by demonstrating antigen or viral DNA in serum or liver or by IgM antibody.

There are two types of transmission cycle, a sylvatic or jungle cycle involving *Aedes* spp. of mosquitoes and nonhuman primates and an urban cycle involving humans and *Aedes aegypti*. Endemic areas now include parts of Africa and Latin America (see Chapter 222).

Leptospirosis

Weil's disease, a severe form of leptospirosis, is characterized by jaundice, fever, rashes, which may be hemorrhagic, and renal failure.[5] Severe headache, conjunctivitis and myalgia are characteristic, along with a history of working in an environment infested by rats. The organism, which lurks in contaminated food, soil and water, enters through abrasions in the skin or through intact mucous membranes (see Chapter 181).

Relapsing fever

The louse-borne type of relapsing fever is particularly likely to cause jaundice and petechiae in its severe form.[10] The more common, tick-borne form of relapsing fever seldom causes jaundice (see Chapter 182).

Bacterial infections

Severe bacterial infections caused by *Salmonella typhi*, *Streptococcus pneumoniae*, *Staphylococcus aureus* or *Neisseria meningitidis* can cause mild jaundice, especially in patients who have cirrhosis or hemoglobinopathies. *Bartonella bacilliformis*, which is endemic in the western Andes, infects red blood cells and causes hemolytic anemia and jaundice.

Differential diagnosis by geographic area

Knowledge of the geography of infections causing jaundice is essential when weighing the relative risk of each. However, the risk is also related to the level of endemicity and, in the case of malaria, to the level of drug resistance; these are variable within countries and often poorly documented. Thus, the following notes are offered only as a rough guide and should be interpreted with caution.

Malaria

The worldwide distribution of malaria is shown in Figure 149.1 .[6]

Africa

Sub-Saharan tropical Africa is the major focus of *P. falciparum* malaria. *Plasmodium malariae* is widespread, but *P. vivax* is uncommon. Low-level transmission of *P. vivax* occurs in northern Africa. Chloroquine resistance is now widespread in Africa.

Asia

Plasmodium vivax is common in India, Pakistan, Sri Lanka and New Guinea, whereas multidrug-resistant *P. falciparum* occurs in many parts of South East Asia, New Guinea and the islands of the Pacific.

Americas

Plasmodium vivax is the common cause of malaria in central America, whereas *P. falciparum* predominates in Haiti and both infections are found in the low-lying areas of South America.

Hepatitis viruses

Hepatitis A and B viruses are very widespread.[7] The level of endemicity is low in northern Europe and North America, intermediate in southern Europe and high in Africa, India, Asia and parts of South America. Thus, if the risk of hepatitis A virus infection to the unvaccinated British person traveling in France and Scandinavia is considered to be 1, the relative risk in Spain is 5, in eastern Europe 20, in the Middle East 85, in sub-Saharan Africa 235, in South America and the Caribbean 243 and in the Indian subcontinent a massive 1835.[11]

Hepatitis E virus infection, which occurs in large outbreaks transmitted mainly to young adults by the fecal-oral route, has been described in Afghanistan, India, Pakistan, South East Asia, Ethiopia, Yemen, Mexico and in a colossal outbreak in the Xinjiang region of China.[8] Sporadic disease is also a major problem in India and, no doubt, in other parts of the developing world where it is yet to be diagnosed. Even more hepatitis viruses await discovery.

Viral hemorrhagic fevers

The distribution of the viral hemorrhagic fevers that are most likely to cause jaundice are shown in Figure 149.2 .[12]

During outbreaks, yellow fever is transmitted by mosquitoes from monkeys to humans and from human to human. Hunters, expatriate or otherwise, may be exposed to mosquitoes infected from monkeys.

Rift Valley fever virus, a bunyavirus, is mainly a disease of sheep and goats but it can be transmitted to humans by mosquitoes or by direct contamination from infected animals.

Crimean-Congo hemorrhagic fever is transmitted mainly by ticks but air-borne infections occur in both hospital and laboratory environments.

Spirochetes

Leptospirosis occurs worldwide.[5] Infected rodents that associate with infected domestic animals, such as cattle, horses, pigs and dogs, are the chief source of infection. Farmers and other people working with or in contact with these animals are infected by their urine. Louse-borne relapsing fever is endemic in the highlands of Ethiopia but outbreaks occur in Sudan, Somalia, western Africa and Vietnam.

Protozoa

Entamoeba histolytica is very widespread.[13] It can cause colitis and hepatic abscess, which is occasionally associated with jaundice. The invasive form is prevalent in the forest zones of western Africa and on the east coast of Africa, in the whole of South East Asia and in Mexico and the west coast of South America.

Metazoa

Ascaris lumbricoides, which is very widespread, is the most common metazoic cause of obstructive jaundice. Relapsing cholangitis caused by *Opisthorchis* sp. occurs in north and north-eastern Thailand, Laos and Cambodia, where humans may eat infected raw fish, which are the second intermediate hosts. The parasite usually cycles between its definitive hosts (cats, dogs and fish-eating mammals). Clonorchasis, caused by *Clonorchis sinensis*, is associated with eating raw fish in Japan, Korea, China, Taiwan and Vietnam, and occasionally causes an obstructive cholangitis. Fascioliasis is common in sheep in many parts of the world. The common causative organism, *Fasciola hepatica*, is cycled through snails. Infected water cress grown in snail-infested waters is the common source of infection in humans. Extensive outbreaks of fascioliasis have occurred in France and Cuba but infections are also found in the USA, including Hawaii, the Middle East and Asia.[14]

DIAGNOSIS

First-line tests

Simple dipstick tests for both blood and urine are available to measure levels of glucose, bilirubin and urobilinogen. Conjugated bilirubin in the urine indicates hepatocellular or obstructive jaundice; the froth after the urine is shaken is yellow and the urine is dark brown. Urobilinogen, which can be detected by dipstick or Ehrlich's reagent, indicates hemolysis. Biochemical tests for serum conjugated and unconjugated bilirubin, serum aspartate, alanine aminotransferase and alkaline phosphatase are useful in differentiating the two types of jaundice. Viral hemorrhagic fevers are distinguished from viral hepatitis by aspartate aminotransferase concentrations being disproportionally high compared with the alanine aminotransferase concentrations. Blood glucose and urinary protein should be measured if the patient's level of consciousness is altered. Thick and thin blood films may reveal malaria parasites or spirochetes; leukocytosis with a predominance of polymorphs suggests bacteremia, leptospirosis, amebic abscess or cholangitis. Stool microscopy may show ova of *Ascaris*, *Opisthorchis*, *Clonorchis* or *Fasciola* organisms.

TABLE 149-2 -- Basis of treatment of common infections that cause jaundice.

BASIS OF TREATMENT OF COMMON INFECTIONS THAT CAUSE JAUNDICE		
Infection	**Therapeutic agent**	**Comment**
Severe malaria	Quinine or artemether	Quinine resistance increasing in South East Asia
Viruses	Ribavirin	Ebola and possibly Crimean-Congo hemorrhagic fever virus[15]
Leptospirosis	Penicillin or tetracycline	Jarisch-Herxheimer reaction in severe infection
Relapsing fever	Tetracycline, or erythromycin for pregnant women and children	Jarisch-Herxheimer reaction common in severe louse-borne type; relapse common in tick-borne type
Amebic liver abscess	Metronidazole or tinidazole	Aspirate if large
Ascaris	Mebendazole	Surgery often required for obstructive jaundice
Clonorchis, Opisthorchis	Praziquantel	Only one dose necessary
Fascioliasis	Triclabendazole or bithionol	Multiple courses may be required

Specialized tests

These are outlined in Table 149.1 but are usually available only at centers specializing in tropical diseases or at large public health laboratories. Serum IgM antibody tests have the advantage of early diagnosis using a single specimen. Antigen detection tests are also becoming available for malaria and may prove very useful because microscopy, although simple in concept, requires experience and skill if mistakes are to be avoided. Polymerase chain reaction tests are now available for

most human viral infections. They are rapid, reliable and safe for samples that are inactivated during the extraction procedure.

MANAGEMENT

General measures

Acute hepatitis is often poorly managed, especially in its severe form, which is characterized by deep jaundice, liver flap of the hands and confusion or coma. Signs of previous chronic liver disease, such as spider angioma, a small liver, ascites and a history of alcohol abuse, bode ill, as does the presence of renal failure. Full details of the complexities of the management of severe liver failure and severe infections can be found in standard texts.

Specific treatment

The primary issue at stake is what the likely cause of the jaundice is and whether this is treatable (Table 149.2). Good clinical skills and simple diagnostic tests, available even in resource-poor countries, allow a rational decision, which often hinges on the following questions.

- Is the jaundice due to underlying liver disease?
- Is it due to a virus that is not treatable?
- Is it due to an infection that is treatable?

Other considerations

Important and agonizing decisions hinge on whether the patient should be treated locally or referred to a specialist hospital or, in extreme cases, to a high-containment facility. The decision is doubly difficult if the patient presents in a developing or resource-poor country because transport by air is expensive and may endanger the patient and, if the cause of the jaundice is highly infectious, the vehicle and other people in it may be contaminated.

In this respect the viral hemorrhagic fevers are greatly feared, although in these cases the most likely routes of human-human transmission are by direct contact, blood and contaminated syringes rather than by aerosol droplets. [4] However, the patient may be confused, bleeding and severely infected by high titers of virus and thus should be isolated when the diagnosis of viral hemorrhagic fever is suspected, and attendants should be protected by gowns, mask and gloves.[16]

Patients who have yellow fever are usually viremic only during the first 4 days of illness. By the time hepatitis occurs they pose little risk except from residual virus in viscera. The exact duration of viral excretion and level of infectivity of convalescent patients who have other hemorrhagic fevers is variable, but there is no evidence of long-term chronic carriage.

The proper disposal of excreta after inactivation by disinfectants is mandatory even in small hospitals or clinics. Laboratory specimens should be kept in sealed, plastic containers and handled and stored with care. They may be highly infectious (see Chapter 186a). [4]

In summary, when in a developing country do not transfer the patient unless there is a strong reason to think that this will be of real benefit to the patient. This caveat applies to any patient who has acute viral hepatitis; it is simpler, cheaper and easier to send specimens. In a developed country, most patients will be sent to a specialist hospital, particularly if the exact cause of viral hepatitis is not known. Other infections are more likely to be treated locally.

PREVENTION AND PROPHYLAXIS

Sensible behavior should be the order of the day; travelers should eat well-cooked food and drink boiled water, sleep under a mosquito net, preferably one treated with insecticide, and bring their own sterile needle and syringe if they need an injection.[17] Immunization status should be checked well before traveling because optimal regimens are available for vaccines against yellow fever, hepatitis A or B virus, rabies and meningococcal disease. These regimens should be used before entering an endemic or epidemic area, especially if the traveler intends to stay there. Booster polio and tetanus vaccines are also available.

Chapter 150 - Eosinophilia in the Returned Traveler

Peter F Weller

INTRODUCTION

Eosinophilia represents increased numbers of eosinophils in the blood and/or tissues and is defined as when eosinophils exceed 450/µl blood. Eosinophilia can be a feature of a diverse array of infectious, allergic, neoplastic and other diseases (Table 150.1). [1]

Of the infectious etiologies, helminthic parasites are the predominant agents associated with eosinophilia. Therefore, for travelers returning from brief or prolonged stays in regions where parasitic infections are endemic, infections with various helminths are likely causes of eosinophilia.[2] Analyses of the frequency or risks for developing eosinophilia in travelers are not available. One retrospective study of asymptomatic expatriates who had returned from the tropics indicated that the sensitivity of eosinophil counts as a screening test for acquired infections due to filariasis, schistosomiasis or strongyloidiasis was 38%, with a positive predictive value of 9%. It concluded that in this population eosinophil counts contributed little to detecting these three parasitic infections if asymptomatic patients had full stool examinations and specific serologic testing. [3] Nevertheless, eosinophilia provides a valuable clue to the presence of many helminthic infections.

Travelers who have eosinophilia differ from other eosinophilic patients:

- first, as a consequence of their travel, they may have had recent exposures to infectious agents or medications that cause eosinophilia;
- second, the duration of travel, whether brief or prolonged, constitutes a definable time period for the onset of potential infection — the limited exposure period of travelers is important because they may return with infections in early stages of evolution; and
- third, travelers do not usually have any previous exposure to helminthic parasites, and so their response to helminths may differ from that of residents in endemic areas who have had lifelong exposure to helminthic infections — several helminthic infections result in more pronounced immune reactions and eosinophilia in travelers or temporary residents than in long-term inhabitants.

Evaluation of eosinophilia in a traveler is therefore largely targeted at helminthic infections, although other etiologies for eosinophilia must also be considered.

ETIOLOGIES OF EOSINOPHILIA IN TRAVELERS

Bacterial and viral infections

Acute bacterial or viral infections characteristically produce eosinopenia. The development of a bacterial, viral or protozoan (i.e. malaria) infection in patients who have eosinophilia due to helminthic or allergic diseases suppresses the blood eosinophilia.

Eosinophilia may accompany HIV infection for several reasons:

- leukopenia may lead to an increased eosinophil percentage in the absence of a true eosinophilia;
- reactions to medications may elicit eosinophilia;
- eosinophilia may arise from adrenal insufficiency resulting from cytomegalovirus and other infections in patients who have AIDS;
- a modest and rarely marked eosinophilia is observed in some patients who have HIV infection; and
- eosinophilia accompanies eosinophilic folliculitis in HIV infection.

Eosinophilia is also seen with human T-cell lymphotropic virus-1 (HTLV-1) infections.

Fungal infections

Two fungal diseases are associated with eosinophilia:

- aspergillosis, in the form of allergic bronchopulmonary aspergillosis; and
- coccidioidomycosis.

Eosinophilia is a feature of primary coccidioidal infection and at times disseminated coccidioidomycosis. In travelers to the south western USA, where *Coccidioides immitis* is endemic, eosinophilia may reflect infection with this organism.

Protozoan infections

Infections with single-celled protozoan parasites do not elicit blood eosinophilia. This is true of all intestinal-, blood- and tissue-infecting protozoa with two exceptions: *Dientamoeba fragilis* and *Isospora belli*.

Helminthic infections

Infections with many helminthic parasites elicit eosinophilia (Table 150.2).[4] Although eosinophilia can be a hematologic indicator of helminthic infections, neither the absence of blood eosinophilia nor the presence of only low-grade or episodic eosinophilia excludes such infections. The eosinophilic response to helminths is determined both by the host's immune response and by the parasite, including its distribution, extent of tissue migration and development within the infected host.

For several types of helminth infections, the migration of infecting larvae or subsequent developmental stages through the tissues is greatest early in infections and at these times the eosinophilia will be most marked (Table 150.3). For a detailed description of the parasitology see Chapter 174 & Chapter 246 .

Eosinophilia may be absent in established infections when the parasites are antigenically sequestered within tissues (e.g. intact echinococcal cysts) or present only in the intestinal lumen (e.g. adult *Ascaris*, tapeworms).

For some established infections, there may be episodic blood eosinophilia. Intermittent leakage of fluids from echinococcal cysts can elicit episodic increases in blood eosinophilia and allergic (urticaria, bronchospasm) reactions. For tissue-dwelling helminths, the eosinophilia may increase during the migration of adult parasites, as in loiasis and gnathostomiasis.

Intestinal nematodes

Ascaris lumbricoides infections

These are acquired by ingesting fecally derived eggs, which may contaminate agricultural products or foods. Larvae derived from the

TABLE 150-1 -- Diseases associated with eosinophilia.

DISEASES ASSOCIATED WITH EOSINOPHILIA	
'Allergic' diseases	Atopic and related diseases
	Medication-related eosinophilias
Infectious diseases	Parasitic infections, mostly helminth infections (see Table 150.2)
	Specific fungal infections: allergic bronchopulmonary aspergillosis; coccidioidomycosis
	Other infections — infrequent, including HIV-1 and HTLV-1 infections
Hematologic and neoplastic disorders	Hypereosinophilic syndrome
	Leukemia
	Lymphomas, including nodular sclerosing
	Hodgkin's disease
	Tumors
	Mastocytosis
Diseases with specific organ involvement	Skin and subcutaneous diseases, including urticaria, bullous pemphigoid, eosinophilic cellulitis (Well's syndrome), episodic angioedema with eosinophilia
	Pulmonary diseases, including acute or chronic eosinophilic pneumonia, allergic bronchopulmonary aspergillosis
	Gastrointestinal diseases, including eosinophilic gastroenteritis
	Neurologic diseases (e.g. eosinophilic meningitis)
	Rheumatologic diseases, especially Churg-Strauss vasculitis; also eosinophilic fasciitis
	Cardiac diseases (e.g. endomyocardial fibrosis)
	Renal diseases, including drug-induced interstitial nephritis, eosinophilic cystitis; dialysis
Immunologic reactions	Specific immune deficiency diseases: hyper-IgE syndrome, Omenn's syndrome
	Transplant rejection: lung, kidney, liver
Endocrine	Hypoadrenalism: Addison's disease, adrenal hemorrhage
Other	Atheroembolic disease
	Irritation of serosal surfaces, including peritoneal dialysis
	Inherited, sarcoidosis, inflammatory bowel disease

eggs pass hematogenously to the liver and lungs. About 1–2 weeks after infection, larvae in the lungs penetrate from the capillaries into the alveoli and mature into third-stage larvae. These ascend the tracheobronchial tree and are swallowed to enter the intestine. In the intestine, the larvae mature into adult male and female worms, which begin producing eggs 2–3 months after the initial infection.

The first manifestations of *Ascaris* infections during the transpulmonary passage of larvae produce a syndrome of eosinophilic pulmonary infiltrates (Loeffler's syndrome).[5] [6] Symptoms develop when the larvae are within the lungs, about 9–12 days after ingesting the *Ascaris* eggs. A nonproductive cough, burning substernal discomfort, low-grade fever and wheezing are common. Eosinophilia increases after several days of symptoms and resolves slowly over many weeks. Chest radiographs reveal round or oval infiltrates up to several centimeters in size, which clear over many weeks.

A diagnosis of early-phase pneumonic ascariasis is made with certainty by detecting *Ascaris* larvae in respiratory secretions or gastric aspirates. At least 40 days must elapse before the intrapulmonary larvae responsible for *Ascaris* pneumonia will have matured to produce eggs detectable on stool examinations. Negative stool

Fasciolopsiasis
Filariases: lymphatic (*Wuchereria* spp., *Brugia* spp.), loiasis, mansonelliasis, onchocerciasis, tropical pulmonary eosinophilia
Gnathostomiasis
Heterophyiasis
Hookworm (*Ancylostoma* spp., *Necator* spp.)
Hymenolepsiasis
Metagoniamiasis
Nanophyetus salminocola
Opisthorchiasis
Paragonimiasis

Schistosomiasis: schistosome dermatitis, *Schistosoma mansoni, Schistosoma haematobium, Schistosoma japonicum, Schistosoma intercalatum*
Sparganosis
Strongyloidiasis
Trichinosis
Trichostrongyloidiasis
Trichuriasis
Visceral larva migrans: *Toxocara canis, Bayllascaris* spp

TABLE 150-3 -- Helminthic parasitic diseases causing marked eosinophilia (>3000/mm^3). [5]

HELMINTHIC PARASITIC DISEASES CAUSING MARKED EOSINOPHILIA	
Disease	**Notes**
Angiostrongylus costaricensis	
Ascariasis	Early transpulmonary larval migration, often absent when mature
Hookworm infection	Early transpulmonary larval migration, often mild when mature
Strongyloidiasis	
Trichinosis	
Visceral larva migrans	Primarily pediatric
Gnathostomiasis	
Filariasis: tropical pulmonary eosinophilia	
Filariasis: loiasis	Especially in expatriates
Filariasis: onchocerciasis	
Flukes: schistosomiasis	During early infection in people who are not immune (Katayama fever)
Flukes: fascioliasis	During early infection
Flukes: clonorchiasis	During early infection
Flukes: paragonimiasis	During early infection
Flukes: fasciolopsiasis	During early infection

examinations during or soon after acute infection do not exclude *Ascaris* as an etiology. Finding that the stools are free of eggs during pneumonic involvement but contain *Ascaris* eggs 2–3 months later

supports the role of *Ascaris* as the etiologic agent of acute eosinophilia and pneumonitis.

Hookworm

Infections with hookworms (*Necator americanus* or *Ancylostoma duodenale*) are acquired when larvae in fecally contaminated soil penetrate the skin. Even brief exposures of travelers to contaminated soil may be sufficient because as few as three larvae can produce infection. Larval penetration of the skin often produces a pruritic maculopapular eruption, and in those who have been previously infected there are serpiginous tracks of larval migration, as in cutaneous larva migrans.

In experimental infections pulmonary symptoms have not developed (although larvae penetrate through to the lungs), but gastrointestinal symptoms, including nausea, diarrhea, vomiting and abdominal pain, are common. Blood eosinophilia increases after 2–3 weeks and peaks after 5–9 weeks of infection.

In untreated hookworm infections the eosinophilia slowly diminishes, but the eosinophil count can remain elevated for several years due to the attachment of adult worms to the intestinal mucosa. Eggs are detectable in feces about 6–8 weeks after infection with *N. americanus*. The larvae of *A. duodenale* may persist within the tissues before returning to the intestine so egg laying can be delayed. Cutaneous larva migrans from other animal hookworm species is commonly associated with eosinophilia when humans become infected as accidental hosts.

Tissue and intravascular nematodes

Filariasis

Infection occurs following the introduction of infective larvae by biting insect vectors (see Chapter 170). Early infections with lymphatic-dwelling (*Brugia* and *Wuchereria* spp.) filariae can cause lymphadenitis, lymphangitis and eosinophilia, usually without detectable microfilaremia. Infections with *Loa loa* in long-term residents of endemic areas in equatorial West and Central Africa are manifested by microfilaremia, episodic angioedema (Calabar swellings), transocular migration of adult worms and modest eosinophilia. In contrast, among those who acquire loiasis after temporary residence, microfilaremia is less common, episodic angioedema is more severe and elevations in serum IgE, antifilarial antibody titer and eosinophilia are more pronounced. Eosinophilia and inflammatory reactions are more prominent in acute filariasis among previously nonimmune patients who exhibit immunologic hyper-responsiveness to infection than among long-term residents of endemic regions who develop partial immunity to infections.

Trichinosis

Trichinosis is acquired by consuming the meat of carnivores that contains viable encysted larvae of *Trichinella* spp. The muscle phase of trichinosis begins about 1 week after infection when the larvae from the intestine disseminate hematogenously and begin to encyst in striatal muscle. Patients may experience subconjunctival, retinal and subungual splinter hemorrhages, and periorbital and facial edema. As the larvae encyst in muscle, myalgias, fatigue, elevated muscle enzymes and eosinophilia develop. Eosinophilia is present in over 90% of those who have symptomatic trichinosis and abates slowly over months. As *Trichinella* spp. are globally distributed, travelers are at risk of acquiring trichinosis if they ingest undercooked meats from domestic and wild pigs, wart hogs, boars, bears, walruses or horses containing *Trichinella* larvae.

Visceral larva migrans

The ingestion of eggs of the dog ascarid, *Toxocara canis*, produces a syndrome of visceral larva migrans. This is most common in young children who ingest soil contaminated with fecally derived eggs and is less frequently seen in adults, when it is potentially acquired by ingesting foods contaminated with *Toxocara canis* eggs. Most infections are subclinical and marked only by blood eosinophilia. Eosinophilia is also prominent with heavier infections.

Trematodes

Acute schistosomiasis

Schistosomiasis (see Chapter 167) is acquired by exposure of the skin to fresh water containing cercariae of *Schistosoma* spp. A distinct syndrome of acute schistosomiasis (Katayama fever) develops principally in previously unexposed individuals who have heavy infections. Patients develop fever, chills, anorexia, weight loss, abdominal pain, diarrhea, urticaria, myalgias, a dry cough and bronchospasm 2–8 weeks after infection. Blood eosinophilia is very prominent. In the later stage of

this syndrome, antischistosomal antibodies develop and egg laying begins and schistosome eggs become detectable in the stools, urine and rectal mucosa. The syndrome is self-limiting and resolves over 1–2 months, but can be shortened by treatment with corticosteroids and antischistosomal therapy.

Paragonimiasis

Paragonimiasis (see Chapter 168) results from infection with the lung fluke (*Paragonimus* spp.). *Paragonimus westermani* is endemic in Asia, whereas other *Paragonimus* spp. cause infections in other regions of the world. Infection is acquired by ingesting freshwater crabs or crayfish that harbor metacercariae. After ingestion, the metacercariae excyst in the duodenum, penetrate the gastrointestinal wall and migrate within the peritoneal cavity. Most young flukes penetrate the diaphragm to migrate within the pulmonary parenchyma, where they become surrounded by an inflammatory infiltrate and later a fibrous capsule. After 7–8 weeks of infection mature flukes begin egg production within the capsule, which enlarges and ruptures, often into a bronchiole.

Eosinophilia is most pronounced in the early phase of paragonimiasis. In this phase, larval migration into the pleural cavity may result in a pleurisy and exudative eosinophil-rich pleural effusions. Chest radiographs reveal transient migratory pulmonary infiltrates and eosinophilia is prominent.

Diagnosis of early-phase paragonimiasis before egg production has been initiated is difficult and often based presumptively on compatible clinical findings in a patient who has eosinophilia and a history of exposure in an area where paragonimiasis is endemic.

Fascioliasis

Infection with *Fasciola hepatica*, the liver fluke of sheep and cattle, is acquired by ingesting cysts attached to aquatic plants (e.g., wild watercress). In early-stage fascioliasis marked eosinophilia is common as the parasites burrow into the liver and enter the bile ducts. The symptoms may be minimal or include fever, abdominal pain, malaise, pruritus, urticaria and coughing. Hepatomegaly and cholestatic liver function test abnormalities develop. Because there are no eggs in the stool or biliary or duodenal fluid samples until about 3 months after infection, the diagnosis of acute fascioliasis will be suggested by the triad of fever, marked eosinophilia and hepatomegaly.

Intestinal flukes

Eosinophilia is prominent in the early stages of infections with several intestinal flukes. *Fasciolopsis buski* is acquired by ingesting metacercariae on water plants such as water chestnuts, *Metagonimus yokogawai* or *Heterophyes heterophyes* by ingesting metacercariae in raw or undercooked fish, and *Nanophyetus salminocola* by ingesting salmon.

Chronic helminthic infections

One hallmark of helminthic infections in addition to their characteristic elicitation of eosinophilia is their ability to survive within infected human hosts for prolonged periods of time. Some can cause eosinophilia lasting for years (e.g. hookworm, strongyloidiasis, filariasis, hepatic trematodes). In contrast to their early phases, the diagnostic stages of the helminthic parasites will have formed in mature infections.

Other travel-related causes of eosinophilia

Ectoparasites (e.g. scabies) may be associated with eosinophilia. Eosinophilia can also accompany adverse drug reactions and can occur with numerous travel-related medications.

EVALUATION OF EOSINOPHILIA IN TRAVELERS

History

Although many helminths are widely distributed, some have more discrete geographic distributions.[7] The parasite causing clonorchiasis is found in Asia. *Angiostrongylus cantonensis*, a cause of eosinophilic meningitis, is principally but not exclusively found in the Pacific Basin. Of filarial parasites, *Loa loa* is limited to Central and West Africa and *Onchocerca volvulus* is found in equatorial Africa and elevated regions in Central America.

Dietary history is pertinent for several helminthic infections, including anisakiasis (raw fish), fish tapeworm (fish), *N. salminocola* (salmon), *Taenia solium* (pork), *Taenia saginata* (beef), fascioliasis (watercress), fasciolopsiasis (horse chestnut), gnathostomiasis (freshwater fish, eels, frogs, snakes and poultry and pigs fed on fish), *A. cantonensis* (land snails or slugs, freshwater shrimps, crabs, some marine fish) and trichinosis (pork, boar, bear meat, horse meat, walrus, wart hog). Exposure in sheep-rearing areas is pertinent for *Echinococcus granulosus*.

A history of swimming in or having contact with fresh water is relevant in areas where there is snail-borne schistosomiasis. Contact with fresh or salt water followed by a rash on water-exposed skin and eosinophilia suggests schistosome dermatitis, which can be caused by avian schistosome species. Skin contact with soil potentially contaminated with human or dog feces, as may occur by walking barefoot or occupational exposure, is relevant for the acquisition of cutaneous larva migrans, hookworm or *Strongyloides* infections.

Clinical features

Because diagnostic-stage parasites are not detectable in early helminthic infections, the clinical findings are especially important:

- trichinosis is suggested by eosinophilia in a patient who has myositis, periorbital edema and subungual splinter hemorrhages;
- in stronglyloidiasis, a migratory serpiginous linear urticarial eruption ('larva currens') due to larvae migrating in the skin is a pathognomonic manifestation experienced by some patients;
- urticaria can be a feature of several helminthic infections, including acute ascariasis, strongyloidiasis, acute schistosomiasis, acute fascioliasis and echinococcosis;
- angioedematous subcutaneous (Calabar) swellings and subconjunctival migrations of adult worms are cardinal manifestations of *Loa loa* infections; and
- gnathostomiasis causes subcutaneous swellings with eosinophilia.

Investigations

Although stool examinations help in the identification of enteric helminths, many helminths capable of eliciting eosinophilia, either tissue- or blood-dwelling helminths or those causing early-phase enteric infections, cannot be identified by fecal examination. Among the established helminthic infections capable of inducing eosinophilia that are not diagnosable from stool examinations are trichinosis, filariasis, anisakiasis, gnathostomiasis, visceral larva migrans and echinococcosis. Even some intestinal helminths, notably hookworm and *Strongyloides*, may not be readily detectable on routine stool examinations.

Other diagnostic tests include examination of respiratory secretions (sputum, bronchoalveolar lavage fluid) for larvae of *Strongyloides*, hookworm and ascaris, or for eggs of *Paragonimus* spp.

For a diagnosis of filariasis, blood should be examined for microfilariae by blood filtration. Blood-borne microfilariae include those of:

- lymphatic-dwelling *Wuchereria bancrofti* and *Brugia* spp. — generally the yield is greatest from night-time blood samples;
- *Los loa* — yield is greatest from morning samples; and
- *Mansonella perstans* and *Mansonella ozzardi*.

Skin snips should be obtained to detect the microfilariae of *Onchocerca volvulus, M. ozzardi* and *M. streptocerca*. Urine is examined for the eggs of *Schistosoma haematobium*. Tissue biopsies may help in diagnosing trichinosis (muscle biopsy), schistosomiasis (rectal biopsy, liver biopsy) and loaisis or gnathostomiasis (involved soft tissues).

Serologic testing can be valuable for several helminthic parasites. For *Strongyloides stercoralis*, enzyme-linked immunosorbent assay serology has proved useful, even when stool examinations are unrevealing. Because of the difficulty in detecting this parasite and its potential for persisting and causing later serious infections, serologic evaluation for strongyloidiasis is indicated for a patient who has eosinophilia. Serologic tests are the most expedient way for diagnosing visceral larva migrans. In trichinosis diagnostic serologic titers may not rise until the third week of infection. Serologic tests are also helpful in diagnosing schistosomal and filarial infections, cysticercosis and echinococcosis. In echinococcosis, the serology may be negative, even when there are obvious lesions; the tests are positive in only 50% of patients who have isolated pulmonary lesions and in 85–90% of those who have hepatic hydatid cysts (Chapter 169).

Management

Treatment should be directed at identified parasites. Although some advocate presumptive therapy with mebendazole or thiabendazole for undiagnosed eosinophilias in travelers, it is preferable to pursue an etiologic diagnosis for eosinophilia and to exclude the presence of undetected intestinal or extraintestinal helminths. This is especially important because *Strongyloides stercoralis*, with its potential for long-term persistence, may cause prolonged eosinophilia.

Following the initiation of anthelmintic therapy, blood eosinophilia may increase for several weeks before subsiding. The magnitude of the post-treatment eosinophilia correlates with the number of parasites present before treatment and is an immune reaction to killed parasites. Resolution of eosinophilia can be monitored as one measure of the efficacy of anthelmintic therapy, with hematologic studies being repeated in the months after therapy.

Complications

Sustained blood eosinophilia (the idiopathic hypereosinophilic syndrome) can lead to cardiac complications, including the development of intraventricular thrombi and endomyocardial fibrosis with secondary mitral or tricuspid regurgitation. [8] Most patients who have eosinophilia develop no endomyocardial damage, but such damage has been noted occasionally in Americans and Europeans who have eosinophilia due to loiasis and acute trichinosis. Patients who have sustained eosinophilia should be monitored by echocardiography.

Chapter 151 - Cough and Respiratory Tract Infections

Thomas C Jones

EPIDEMIOLOGY

Acute respiratory illness (ARI) is common throughout the world. As a result, respiratory illness is common among travelers.[1] There are over 4 million childhood deaths due to ARI each year in the developing world.[2] Especially common causes of these deaths are:

- respiratory syncytial virus (15–20%),
- pneumococcal pneumonia (20%),
- hemophilus pneumonia (10–20%),
- postmeasles pneumonia (15%),
- pertussis (10%), and
- parainfluenza virus (7–10%).

These statistics show that the traveler is highly exposed to respiratory pathogens. It has been reported that 2.2% of travelers return with symptoms of rhinitis and 1–2% have acute respiratory tract infection with fever.[1] These infections are primarily due to respiratory viruses but mycoplasma, legionella and other less common organisms also contribute.

Atypical causes of respiratory illness can occur in the traveler because of exposure to unusual microbes. Although these illnesses are rare, they are very important for the physician caring for a traveler with respiratory illness because they are potentially serious, transmissible and treatable. Although pneumonia due to *Streptococcus pneumoniae, Mycoplasma pneumoniae, Mycobacterium tuberculosis* or influenza makes up less than 0.001% of diseases in travelers, it can account for up to 10% of cases of febrile disease involving the respiratory tract presenting to a physician. These patients must be diagnosed and managed in the same way as nontraveling patients with community-acquired pneumonia.[3] [4] Hidden in this group of travelers with pneumonia are a few patients whose diseases are specifically a result of exposure to agents or environmental conditions associated with their travel. These diseases may be misdiagnosed because of their rarity.

This chapter is directed at the microbial causes of respiratory illness, and of cough in particular. Nonmicrobial causes can also affect the traveler and require carefully managed medical intervention.

PATHOGENESIS AND PATHOLOGY

The physician caring for the traveler with cough must be aware of the potential causes, both common and rare, of respiratory disease throughout the world. Toxins, allergens, viruses, mycoplasma, chlamydia, rickettsia, bacteria, fungi, protozoa and helminths may each be responsible for respiratory signs and symptoms.

Toxins or allergens

A cause of cough in travelers is exposure to respiratory toxins or allergens that are not present in his or her home environment. Some of these, along with their associated pulmonary illnesses, are listed in Table 151.1 . High levels of air pollution in large cities can cause respiratory tract irritation and exacerbate cough. A new environment may also expose an allergic traveler to grasses, pollens and dust in much higher concentrations than normal. This is particularly a problem for the young traveler, who may not have developed full immunotolerance for potential allergy-producing substances. For example, among Cambodian refugees on the Thailand border, the most common respiratory illness, 'Khao-I-Dang lung', was due primarily to dust inhalation.

Of special relevance to the traveler is exposure to unusual concentrations of respiratory allergens such as inhaled fungi. The best example of this is bronchopulmonary aspergillosis, caused by inhalation of *Aspergillus* spp. (see Chapter 237). In 'farmer's lung', the likely allergenic organisms are various molds that accumulate in silos.

Viral, mycoplasmal, chlamydial and rickettsial causes

The microbial agents in these groups that cause respiratory symptoms are listed in Table 151.2 , along with their most common related illnesses. As in the home environment, respiratory viruses cause a significant number of the pulmonary signs and symptoms that affect travelers.[1] [3] The traveler enters an environment that is foreign to his or her immune system and is likely to develop illness due to the different rhinoviruses, adenoviruses and other respiratory viruses that are prevalent in the communities visited.

The chances of contracting a viral illness during air travel are enhanced by crowding, spread of respiratory droplets and by rapid turnover of dry cool air, which reduces airway defenses. Alcohol and fatigue further increase the likelihood of an overt respiratory illness shortly after returning home.

TABLE 151-1 -- Toxins and allergens as causes of respiratory signs and symptoms in the traveler.

TOXINS AND ALLERGENS AS CAUSES OF RESPIRATORY SIGNS AND SYMPTOMS IN THE TRAVELER		
Causative agent		**Main pulmonary disease**
Toxins	Smoke fumes	Rhinitis, bronchitis, pneumonia
	Carbon monoxide, sulfur dioxide, ozone	Bronchitis
	Halides, phosgene, pesticides	Bronchitis, pneumonia
Environment	Hypobaric conditions during air travel	Stress bronchoconstriction, hypoxia
	Mountain sickness	Pulmonary edema
Allergens	Dust and mites	Rhinitis, conjunctivitis, bronchitis, asthma
	Pollens and grasses	Rhinitis, conjunctivitis, bronchitis, asthma
	Aspergillus spp. (allergic bronchopulmonary aspergillosis)	Asthma, eosinophilic pneumonia
	Molds (farmer's lung)	Eosinophilic pneumonia

TABLE 151-2 -- Viral, mycoplasmal, chlamydial and rickettsial causes of cough in travelers.

VIRAL, MYCOPLASMAL, CHLAMYDIAL AND RICKETTSIAL CAUSES OF COUGH IN TRAVELERS

	Condition/microbial agent	Sources of infection	Main illness
Viruses	Influenza	Worldwide, varied seasons, epidemics, pandemics	Fever, bronchitis, pneumonia
	Rhinovirus, adenovirus and other respiratory viruses	Worldwide, varied seasons	Rhinitis, pharyngitis, bronchitis
	Hantavirus	Worldwide	Respiratory distress syndrome
	Chickenpox, measles	Contact with infected patient	Fever, pneumonia, rash
	Coronavirus	Contact with infected patient	Fever, severe pneumonia, SARS
Mycoplasmas	Atypical pneumonia: *Mycoplasma pneumoniae*	Worldwide, crowding	Acute pneumonia
Chlamydiae	*Chlamydia pneumoniae*	Worldwide	Acute pneumonia
	Chlamydia trachomatis	Worldwide, children	Paroxysmal cough, pneumonia
	Psittacosis: *Chlamydia psittaci*	Contact with psittacine birds	Acute pneumonia
Rickettsiae	Q fever: *Coxiella burnetii*	Contact with sheep, cattle, goats, ticks	Acute pneumonia

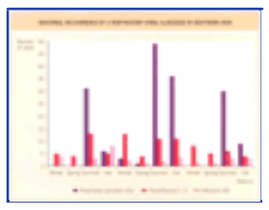

Figure 151-1 Respiratory illness in southern Asia (February 1985 to December 1987). *Data modified from reference* [5] .

Seasonal patterns related to the spread of viruses differ in various parts of the world. For example, many respiratory viruses that are spread from December to April in the northern hemisphere are spread from May to September in the southern hemisphere, and most often during the rainy season in tropical countries. Figure 151.1 shows the frequency of three groups of viruses in southern India during different seasons over a 3-year period. The highest prevalence occurred in the summer and fall, rather than the winter as recorded in temperate regions in the north.[5]

The most important and best-documented virus in travelers is influenza. For example, during the pandemic of 1957, influenza reached the USA from Asia, beginning at a conference in the midwest and spreading throughout the country as the participants returned home.[6] Another example comes from the war in Vietnam, when military personnel in the Philippines often had holidays in Hong Kong. In 1968, thousands of cases of influenza occurred among these people and their contacts in the Philippines owing to the new antigenically shifted virus (H3N2) that had emerged that year in Asia. A recently recognized epidemic due to a Coronavirus has emerged from Asia. This new virus causes the illness now termed Severe Acute Respiratory Syndrome (SARS).[7] [8] [9]

A newly recognized cause of respiratory illness is hantavirus, which is transmitted as aerosolized virus from rodents. It has caused localized epidemics in many parts of the world including the USA, Europe, South America and Asia.

In the past, careful attention has been given to the possibility that a traveler with the first respiratory signs of smallpox might infect a large number of people on the airplane or at the airport before the tell-tale signs of cutaneous eruption had appeared. Smallpox remains a threat as an agent of bioterrorism and patients with chickenpox or measles could have only cough and fever at the beginning of the illness. It is important for the physician caring for a traveler with cough to document any potential exposure to these diseases.

TABLE 151-3 -- Bacterial and fungal causes of cough in travelers.

BACTERIAL AND FUNGAL CAUSES OF COUGH IN TRAVELERS			
	Condition/infecting agent	**Geographic distribution and sources of infection**	**Main illness**
Bacteria	Pneumococcal pneumonia	Worldwide	Acute pneumonia
	Tuberculosis	Worldwide, infected patients	Chronic pneumonia
	Legionellosis	Aerosolized water, cooling systems	Acute pneumonia
	Bordetella pertussis	Worldwide	Acute glottitis and chronic cough
	Actinomycosis	Worldwide, soil	Draining sinuses, chronic pneumonia
	Plague: *Yersinia pestis*	Infected patients or rodents, fleas	Lymphadenitis, pneumonia
	Meningococcal pneumonia	Worldwide epidemics, central Africa	Pharyngeal carriage, pneumonia, meningitis
	Tularemia	Contact with infected small mammals	Lymphadenitis, pneumonia
	Bacillus anthracis	Animal hides, bioterrorism	Skin lesions, pneumonia
	Melioidosis	South East Asia	Pneumonia, systemic illness
Fungi	Histoplasmosis	Worldwide, decayed vegetation, bat caves	Erythema nodosum, acute or chronic pneumonia, hilar adenopathy
	Coccidioidomycosis	Aerosolized soil, south-west USA	Acute or chronic pneumonia
	Paracoccidioidomycosis	South America	Acute or chronic pneumonia
	Blastomycosis	Southern USA	Pharyngeal lesion, pneumonia
	Cryptococcosis	Contact with feces from pigeons	Pneumonia, meningitis
	Penicilliosis	Northem Thailand	Skin lesions, pneumonia
	Pneumocystis pneumonia	Worldwide, pneumocystis	Acute pneumonia in those who are immunodeficient (i.e. HIV)
	Aspergillosis	Worldwide	Aspergilloma: pneumonia in those who are immunodeficient

Mycoplasmal pneumonia can cause cough in travelers. *M. pneumoniae* is transmitted in crowded conditions, as has been demonstrated among military recruits. There are three important chlamydial causes of pneumonias:

- *Chlamydia pneumoniae*, an increasing cause of community-acquired pneumonia,
- *Chlamydia trachomatis*, particularly in children, and
- *Chlamydia psittaci*, the cause of psittacosis.

Psittacosis is transmitted by contact with either psittacine birds such as parrots or with people who have psittacosis. Although rare in wild birds, psittacosis occurs when birds are housed together.

Q fever is a cause of pneumonia in those exposed to rickettsia aerosolized from or in the secretions of infected farm animals. Small epidemics have occurred in many parts of the world, and have been well studied in Australia, California, Israel and Switzerland. A detailed history of possible exposure to these microbes is the key to

correct diagnosis.

Bacterial and fungal causes

Table 151.3 lists bacterial and fungal causes of cough in travelers. The most common cause of bacterial pneumonia among travelers is the same as among nontravelers — *Strep. pneumoniae*. This must always be considered in a recently returned traveler who has acute symptoms of fever, cough, purulent sputum and chest pain.

Legionellosis has recently been identified as an important disease among travelers because of the presence of the organism in the air conditioning systems and spas of hotels and ships.[10] [11]

M. tuberculosis is a major cause of lung disease worldwide. Recently, spread of the infection among airline passengers has been reported.[12] Figure 151.2 shows a diagram of the rear section of the airplane and the evidence that six passengers and one flight crew member were exposed to tuberculosis during the 11-hour flight. Tuberculosis is particularly noteworthy at present because it is increasing in frequency after being brought under partial control early in the 20th century and as it now demonstrates increased multiantibiotic resistance.

Pneumonia caused by the plague bacillus *Yersinia pestis* must be considered in the differential diagnosis of pneumonia for a patient who has been in countries where plague may occur near ports or

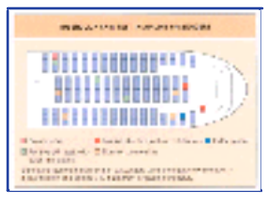

Figure 151-2 Significant tuberculin skin tests in passengers and one flight crew member in the rear section of a Boeing 747 flight from Chicago to Honolulu.

among wild rodent populations.[13] The pulmonary disease occurs in an environment where the more common from of the disease (bubonic plague) is being reported. Epidemic spread of this organism to the patient's contacts and health care workers may occur and is a true medical emergency.

Tularemia is another potential cause of pneumonia in those exposed to small wild animals or those who have been bitten by infected flies or ticks. Tularemia is geographically restricted and outbreaks have occurred in North America, Europe, the former Soviet Union and Japan (*Francisella tularensis*). Anthrax can be acquired by exposure to animals during slaughter, or to their hides or fur, and if the organism, *Bacillus anthracis*, is used as an agent of bioterrorism.

Pertussis, caused by the organism *Bordetella pertussis*, has been controlled by vaccine in most countries but because of incomplete immunization of children in many regions of the world, and waning immunity in adults, travelers are at risk. Recent outbreaks have occurred in the former Soviet Union and among adults in Europe.[14] It

TABLE 151-4 -- Protozoal and helminthic causes of cough in a traveler.

PROTOZOAL AND HELMINTHIC CAUSES OF COUGH IN A TRAVELER			
	Condition/infecting agent	**Sources of infection**	**Main illness**
Protozoa	Malaria	Mosquitoes in Africa, Asia, South America	Fever, hemolysis, hepatitis, 'flu syndrome'
	Amebiasis	Tropics and subtropics	Fever, liver abscess, secondary pneumonia
Helminths	Filariasis	Worldwide, mainly tropics, particularly India	Eosinophilic pneumonia
	Strongyloidiasis	Contact with fecally contaminated soil	Transient pneumonia, diarrhea, severe pneumonia in those who are immunodeficient
	Ascariasis	Ingestion of fecally contaminated food or water	Transient pneumonia, intestinal obstruction
	Paragonimiasis	Ingestion of raw crabs	Chronic pneumonia
	Echinococcosis: *Echinococcus granulosus*	Contact with dog feces in cattle or sheep regions	Hepatic or lung cyst
	Echinococcus multilocularis	Contact with feces of wild carnivores in the northern hemisphere	Chronic invasive lung lesion
	Acute schistosomiasis	Contact with cercariae while swimming	Fever, dry cough

can be the cause of both acute upper respiratory illness and prolonged paroxysmal cough. The illness is underdiagnosed because physicians have become unfamiliar with the characteristic 'gasping' cough and because special PCR or serologic tests are required for diagnosis.

Other infrequent causes of either an acute or chronic cough in the traveler include melioidosis, brucellosis, actinomycosis and pulmonary meningococcosis. The likelihood of each of these is increased by relevant exposure, for example to:

- soil in South East Asia (melioidosis);
- animals or animal products (brucellosis); and
- epidemic meningococcal disease.

The most important fungal disease acquired by the traveler is histoplasmosis. This is particularly common in travelers who have explored bat caves or areas where dead and decaying trees allow aerosolization of the organism *Histoplasma capsulatum*.[15]

Cryptococcus neoformans can be aerosolized from pigeon droppings and lead to respiratory illness, although the illness most commonly associated with this organism is meningitis.

Aspergillus fumigatus can cause pulmonary pathology other than allergic alveolitis. It is more likely to cause symptomatic disease in a traveler with previously damaged lungs.

Travelers to south-west USA may acquire an acute or chronic respiratory illness caused by *Coccidioides immitis*,[16] which is inhaled with contaminated soil. Diagnosis requires the use of appropriate serologic tests and application of skin test antigens. In South America a similar disease is caused by *Paracoccidioides brasiliensis*. Blastomycosis is endemic in the southern USA. Penicilliosis, caused by *Penicillium marneffei*, has recently been recognized in Thailand. It causes skin lesions and pulmonary symptoms.

Protozoal and helminthic causes

Table 151.4 lists important protozoa and helminths that can cause cough in a traveler. The most important protozoal cause of respiratory illness is malaria, not because the lung usually exhibits the pathology of malaria but because early in the infection malaria is often misdiagnosed as 'flu syndrome'.[17]

Entamoeba histolytica infection (amebiasis) must be considered in travelers with cough. Although the lung may be involved in severe amebiasis, cough is more commonly caused by an amebic liver abscess elevating the right diaphragm; this results in segmental atelectasis of the lung and the patient presents with a secondary bacterial pneumonia. Even without this complication, the patient may present with cough due to diaphragmatic irritation and chest pain due to the enlarged inflamed

liver.

Among the most interesting patients are travelers with eosinophilia and cough (see Chapter 150). After evaluating the patient for hypersensitivity reactions that can cause cough, allergic aspergillosis and asthma, helminthic causes need to be considered. Three diseases are due to the migration phase of helminths:

- *Ascaris lumbricoides* is acquired by ingesting the eggs in fecally contaminated food or water;
- *Schistosoma* spp. are acquired by exposure to lakes or rivers containing infected cercariae; and
- *Strongyloides stercoralis* is acquired by walking near fecal deposits.

These helminths cause transient, usually undetected, febrile pulmonary illnesses unless, as in the case of strongyloidiasis, the traveler is immunosuppressed, in which case a serious and potentially fatal pneumonia may develop.

Tropical pulmonary eosinophilia (Weingarten's syndrome) is usually due to *Wuchereria bancrofti* or *Brugia malayi* and is found mainly in southern Indians and in Indonesians. Symptoms are characterized by cough, wheezing, fever with eosinophilia and fluffy infiltrates on chest X-ray. *Dirofilaria* can cause similar symptoms but usually present as a 'coin lesion' on chest X-ray.[18]

Paragonimiasis, caused by *Paragonimus* spp., most commonly *P. westermani*, is characterized by chronic cough and pulmonary symptoms very similar to those of tuberculosis. It is acquired by ingesting uncooked fresh-water crabs that contain the intermediate stage of the organism. The diagnosis is made by identifying the characteristic operculated eggs in sputum or stool.

Echinococcus multilocularis causes disease in wild animals in the northern parts of the world. Exposure to the feces of the primary hosts (wild wolves, dogs and other carnivores) primarily through eating contaminated berries or plants can lead to infection, which is manifest as progressive invasion and damage to the liver and lung. *Echinococcus granulosus* can be transmitted by the feces of dogs in domestic farms. This helminth occasionally causes lung cysts, although usually the abdominal viscera are involved.

PREVENTION

Physicians should advise appropriate vaccinations for travelers visiting potentially epidemic regions (e.g. influenza, pertussis, measles and even pneumococcal vaccine[19] and BCG[20] in some situations). Of

course, influenza strains and pneumococcal serotypes may differ in the visited areas from those contained in the vaccines. Physicians should warn travelers of any epidemics in the regions to be visited. Care regarding exposure to new agents (such as SARS) includes wearing face masks and protection against spread by finger/hand contact on contaminated surfaces.

CLINICAL FEATURES

The time and character of the onset of cough must be carefully recorded because these will be closely related to its cause and so to the differential diagnosis and treatment. For example, respiratory symptoms caused by toxins or allergens occur within hours of exposure, viral illnesses occur 3–5 days after exposure and slowly progressive diseases such as tuberculosis may bring the patient to the physician weeks or months after exposure.

The nature of the patient's illness — fever, malaise and chest pain, the rapidity of onset and the degree of associated general toxicity — can distinguish acute illnesses (e.g. influenza, malaria, pneumococcal pneumonia, legionellosis, plague, psittacosis) from more chronic diseases (e.g. tuberculosis, melioidosis, paragonimiasis, tropical pulmonary eosinophilia).

The type of cough may be helpful; for example, the paroxysmal cough of chlamydial infection or pertussis can be distinguished from the rhinitis and cough of viral infections caused by rhinoviruses.

Signs and symptoms in organs other than the lung may provide important clues to the etiology, for example:

- fever and splenomegaly in malaria;
- lymphatic buboes and marked toxicity in plague;
- hepatic tenderness in amebiasis; and
- meningitis in cryptococcosis and meningococcal disease.

In many conditions, symptoms are most common in patients with pre-existing pulmonary disease. For example, on exposure to allergens or viruses asthmatic patients may wheeze and be short of breath or may present with cough and increased respiratory secretions, whereas patients with pre-existing chronic pulmonary disease may simply show a deterioration in pulmonary function demonstrated by dyspnea.

DIAGNOSIS

There are a number of questions that should be asked of the traveler with cough (Table 151.5). Once answered, the physician can begin to focus on whether special tests need to be done for unusual diseases. A flow chart for the diagnosis and treatment of cough in the traveler is shown in Figure 151.3

Immediate tests should include:

- a complete blood count and differential;
- chest radiography;
- sputum and blood culture;
- sputum Gram stain and acid-fast stain; and
- as appropriate on the basis of history of exposure, serologic or polymerase chain reaction (PCR) tests for mycoplasma, influenza, legionella, psittacosis, pertussis and the specific tests for the more unusual diseases listed above.

Patients with fever, malaise and cough who have returned from an endemic malaria area should have a malaria smear. If the patient has eosinophilia, stool and sputum examination for helminth eggs or larvae should be considered. If the patient has a leukocytosis, investigations should include serologic testing for amebiasis in addition to appropriate cultures for bacteria and fungi.

TABLE 151-5 -- Questions to ask a patient who has traveled.

QUESTIONS TO ASK A PATIENT WHO HAS TRAVELED
Where/when/how long?
• Which countries did you visit?
• What time of year was your trip?
• How long was the trip and when did you return?
Medical History
• Do you have a history of allergy; if so to what?
• Do you have a history of lung disease such as bronchitis, emphysema, tuberculosis, bronchiectasis?
Special activities
• Did you visit caves or assist in activities such as clearing trees or debris?

• Did you experience dry, dusty or moist environmental conditions?
• Did you eat uncooked vegetables, berries or fish, or drink untreated water?
Special contacts
• Did you inhale dust, smoke or toxic fumes?
• Did you have contact with domestic or wild animals?
• Did you have contact with ill people? What illness?
• Were you bitten by mosquitoes, ticks or other arthropods?

Differential diagnosis

To determine whether a patient has a common, easily managed infection or one that is difficult to diagnose and manage is a major task for the physician. A key decision to be made is whether hospitalization and full work-up are indicated (Fig. 151.3). Malaria smears or sputum examinations for paragonimus eggs on each traveler would be inappropriate. However, viewing every illness as 'flu syndrome' is inviting disaster. The correct diagnosis is arrived at by a balanced review of the detailed history, the type and severity of the signs and symptoms, and the initial laboratory tests.

Sometimes the differential diagnostic process must include the response to initial treatment. This will be helpful, for example, in distinguishing pneumococcal pneumonia, in which a response generally occurs within a few days, from other bacterial pneumonias. A diagnosis of tropical eosinophilia may not be confirmed until the patient has responded to diethylcarbamazine.

Most importantly, the physician must imagine being in the environment the traveler has been in. He or she will then take the right steps towards the correct diagnosis and treatment.

MANAGEMENT

The appropriate treatment will become clear as the correct diagnosis is made. Empiric therapy with antibiotics is seldom necessary; however, hospitalization followed by appropriate cultures and therapy for the most likely serious diagnoses is appropriate for an acutely ill patient with pneumonia. Depending on the history, in some patients with respiratory infections not requiring hospitalization, macrolide antibiotic therapy is appropriate.

Patients with respiratory symptoms after exposure to chickenpox or measles should be advised that a rash may follow and that they should avoid putting others at risk of acquiring the infection. It should be determined whether the patient has an immunodeficiency that warrants the use of immunoglobulins. The possibility of contagious disease in a traveler should be immediately reported to local public health authorities and the Centers for Disease Control in the USA.

Chapter 152 - Lymphadenopathy, Splenomegaly and Anemia

Tom Doherty

INTRODUCTION

Lymphadenopathy is a common feature of many infectious diseases. It may be generalized or localized to one group of lymph nodes. Usually, the cause is obvious; it is commonly the result of local sepsis. Both non-specific viral infections and bacterial skin infections are common among travelers. Occasionally, however, lymphadenopathy may be due to something more exotic, particularly in travelers returning from tropical parts of the world.

Splenomegaly implies an underlying systemic illness. Anemia, unless it is very mild and has an obvious cause, requires further evaluation. Both splenomegaly and anemia are uncommon among returned travelers but both should be sufficient reason for further investigations.

'Travelers' are a heterogeneous group of people — young people in search of a bit of excitement, members of the international business community, people returning from developed countries to their original country of origin, aid workers, volunteers, missionaries and, increasingly, holidaymakers. With such an ill-defined group, it is difficult to make precise recommendations that apply to everyone. Travelers may well suffer from 'exotic' conditions such as brucellosis or Katayama fever; however, it is worth emphasizing that some preexisting or relatively mundane disease may often explain their symptoms. For example, 9% of travelers returning from the tropics who required admission to hospital with a febrile illness were found to have a urinary tract infection, community-acquired pneumonia or a streptococcal sore throat, and another 25% were assumed to have a non-specific viral infection that settled spontaneously.

LYMPHADENOPATHY

A diagnosis of lymphadenopathy is usually a clinical one; it is therefore subjective and not uncommonly wrong. Other conditions to bear in mind include:

- abscesses, particularly in the early stages before they have become fluctuant;
- cystic lesions (in the context of tropical diseases, cysticerci and *Trichinella* deserve special mention);
- lipoma and other similar lesions such as dermoid tumors;
- aneurysms, particularly if they are full of clotted blood and therefore less likely to be pulsatile;
- migratory helminthic infections, particularly gnathostomiasis, the Calabar swellings associated with loaiasis, and onchocercal nodules;
- pyomyositis, which can develop spontaneously; and
- myiasis or 'tumbu fly'.

A list of those conditions that are associated with lymphadenopathy and of conditions that do not usually give rise to lymphadenopathy is shown in Table 152.1 .

Presenting signs and symptoms that point to a diagnosis

As with any clinical problem, the diagnosis should be based on a full and detailed history and thorough general examination. In the case of returned travelers, it is essential to determine not only where they went and when they returned but precisely what they did when they were away. One useful maxim is to try to answer four questions: why did this person, from this place, develop these symptoms at this time?

A point that may be useful and is often overlooked is a person's occupation. For example, people traveling on business and staying in international hotels are unlikely to contract trypanosomiasis but agriculturists working in rural areas are more likely to do so. Tsetse flies, the vector for African trypanosomiasis, exist only in rural parts of Africa, and their bites are extremely painful and unlikely to be forgotten. A full sexual history is important. People traveling alone may be at higher risk of acquiring sexually transmitted diseases. A dietary history is often overlooked and may provide a clue to a possible diagnosis of brucellosis (from unpasteurized milk or cheese, and more often from camel's milk than cow's milk) or gnathostomiasis (from raw fish or crustaceans). The combination of alcohol intolerance, pruritus and eosinophilia combined with lymphadenopathy is suggestive of Hodgkin's lymphoma. HIV seroconversion illness can exactly mimic infection with Epstein-Barr virus (EBV). Kikuchi's disease, which causes painful, usually unilateral, cervical lymphadenopathy and a fever, is most often seen in young Japanese women.

The size of palpable lymph nodes is worth noting. In general, palpable lymph nodes less than 0.5cm in diameter are unlikely to have clinical significance, particularly in thin people. The site of the palpable lymph nodes is also important — local sepsis is more likely to result in localized lymphadenopathy than in lymphadenopathy that is generalized. Epitrochlear lymphadenopathy is of particular significance as it suggests an underlying systemic disease, specifically secondary syphilis, HIV, or a reticulosis. Remember the anatomy — lesions of the perineum drain to the inguinal group of nodes while lesions of the testes, for example, drain to the para-aortic nodes and, ultimately, to the neck. Pre-auricular nodes usually react to a lesion of the eye or to pathogens that invade through the conjunctiva. Do not forget to examine the teeth, particularly in the context of cervical lymphadenopathy.

The consistency of enlarged lymph nodes is often claimed to be of diagnostic importance. Lymphadenopathy that is due to an infectious process is often tender and asymmetric. Lymph nodes that are enlarged as a result of lymphoma are usually described as matted and 'rubbery', whereas fixed, hard, or 'craggy' nodes are more suggestive of a metastatic lesion. In practice, in most cases, such information is subjective and unreliable, and other associated findings are of greater significance. The combination of lymphadenopathy with either hepatomegaly or splenomegaly suggests a generalized process rather than local sepsis, as does the presence of anemia.

Differential diagnosis by geographic area

Many infectious diseases that give rise to lymphadenopathy are ubiquitous, particularly viral infections such as EBV, sexually transmitted diseases such as syphilis or HIV, and tuberculosis. Others

TABLE 152-1 -- Causes of lymphadenopathy (continued over page).

CAUSES OF LYMPHADENOPATHY		
	Causes	**Notes**
Common	Local sepsis	Cause is usually obvious
	Tonsillitis	Particularly streptococcal
	EBV	Palatal petechiae, splenomegaly, atypical lymphocytes
	Non-specific viral infection	

Less common but important	HIV seroconversion illness	Transient lymphadenopathy
	HIV (established disease)	Permanent lymphadenopathy
	Kaposi's sarcoma	
	Tuberculosis	
	Trypanosomiasis	Localized lymphadenopathy in early infection with chancre; generalized lymphadenopathy in late infection
	Toxoplasmosis	
	Secondary syphilis	
	Dengue fever	Lymphadenopathy occurs in 50% of cases; usually mild
	Chancroid	Usually inguinal lymphadenopathy
	Lymphoproliferative disorder	
	Neoplasia	Usually metastatic lymphadenopathy
	Sarcoidosis	Particularly hilar lymphadenopathy
	Leishmaniasis	Cutaneous and visceral
	Typhus	Usually painful eschar
Uncommon	*Wuchereria bancrofti*	
	Brugia malayi	
	Parvovirus	
	Q fever	
	Lymphogranuloma venereum	
	Castleman's disease	
	Rheumatoid arthritis	
	Systemic lupus erythematosus	
	Leptospirosis	
	Still's disease	
	Pityriasis rosea	
	Cat-scratch fever	
Rare	Lepromatous leprosy	
	Erythema nodosum leprosum	
	Bartonellosis	Often tender
	Tularemia	
	Anthrax	
	Diphtheria	
	Plague	Extremely tender 'buboes'
	Kikuchi's disease	
	Ehrlichiosis	
	Behçet's syndrome	
	Wegener's granulomatosis	
	Midline granuloma	
	Whipple's disease	
	Weber-Christian disease	
	Podoconiosis	
Infections usually not associated with lymphadenopathy	Brucellosis	
	Loaiasis	
	Onchocerciasis	Secondary infection of scratched skin may result in lymphadenopathy
	Malaria	
	Hepatitis	
	Typhoid	Lymphadenopathy has been reported in chronic salmonellosis
	Tuberculoid leprosy	
	Schistosomiasis	May occur in acute disease
	Flaviviruses	
	South American trypanosomiasis (chronic form)	
	Intestinal helminths	
	Strongyloides spp.	
	Hydatid disease	
	Cholera	
	Tetanus	
	Melioidosis	
	Cysticercosis	
	Amebiasis	
	Fascioliasis	

have relatively well-defined areas of transmission. For example, leishmaniasis is uncommon in western and southern Africa but appears to be spreading from countries bordering the Mediterranean south into Sudan and northern Kenya, and it also occurs in Central and South America and throughout much of the Indian subcontinent. Bartonellosis is confined to the Americas. Dengue is particularly common in South East Asia, West Africa and the Caribbean and often causes epidemics.

Investigations to confirm the diagnosis

In most cases, the cause of regional lymphadenopathy is obvious and requires little further investigation, if any. A throat swab may confirm a clinical suspicion of a streptococcal sore throat (and rule out the possibility of diphtheria) and a skin swab may be useful in determining appropriate antibiotic therapy for skin sepsis.

In those cases where the lymphadenopathy is more generalized, and particularly when there are systemic features, further investigations may be warranted. A normal full blood count with differential white blood cell count is reassuring. A blood film, looking specifically for atypical lymphocytes, is suggestive of infection with EBV, although atypical lymphocytes also are a feature of other viral infections and toxoplasmosis. Both the Paul-Bunnell test and monospot test for EBV may be negative in patients with the infection, and EBV serology is a more sensitive investigation.

Serologic markers for toxoplasmosis may provide useful information, particularly if facilities are available for measuring IgM as well

as IgG. A negative Venereal Disease Research Laboratory (VDRL) test virtually excludes secondary syphilis. HIV antibody tests may be negative during a seroconversion illness, and measurement of p24 antigenemia or HIV RNA may be more informative. Serologic markers exist for cytomegalovirus and parvovirus infections, although their clinical relevance is questionable. *Leishmania* serology is nearly always negative in patients with cutaneous disease but almost always positive in those with visceral disease, as long as they are not also infected with HIV. Most patients with both HIV and visceral leishmaniasis do not mount a serologic response.

For patients with a history of systemic upset or chronic disease, markers of inflammation such as the erythrocyte sedimentation rate, C-reactive protein and serum albumin concentration may be helpful. However, the erythrocyte sedimentation rate may be greatly elevated in residents of tropical countries, particularly in Africa, as a result of non-specific hyperglobulinemia. A Mantoux test is usually positive in patients with tuberculous lymphadenopathy, unless they have miliary disease or hypoalbuminemia.

Imaging may also be useful. A chest radiograph may provide evidence of hilar lymphadenopathy and suggest sarcoidosis or tuberculosis. Abdominal ultrasonography with or without computerized tomography (CT) scanning may not only confirm the presence of intra-abdominal lymphadenopathy but also enable accurate biopsy material to be obtained. Sometimes, isotope scanning with either indium or gallium may define an unexpected local source of infection.

In certain cases, where the diagnosis is in doubt (and particularly in the context of systemic illness), more invasive investigations are warranted. Fine-needle aspiration of enlarged lymph nodes may provide a diagnosis in case of tuberculosis, trypanosomiasis and neoplastic disease. In most sites, open biopsy of enlarged lymph nodes can be performed under local anesthesia and, although it is helpful to cut across the excised node to discover tuberculous caseation, histologic examination of the tissue obtained may be necessary to provide the answer. In general terms it is advisable not to choose inguinal nodes for biopsy — those in the neck are more likely to generate useful information.

Bone marrow aspiration and liver biopsy specimens may occasionally be required to confirm or refute a diagnosis of tuberculosis or a lymphoproliferative disorder. Liver biopsy is of particular significance in patients with lymphomas as it provides information regarding the staging of the disease. To reduce the risk of iatrogenic complications, it may be appropriate to obtain biopsy material under direct imaging, either ultrasound or CT, where such facilities are available. Beware of taking biopsies from inguinal nodes in patients with suspected lymphatic filariasis — both lymphatic leakage and secondary infections occur not uncommonly.

Complications

Lymphadenopathy is unlikely to lead to any serious complications. Tuberculous nodes, especially *Mycobacterium bovis* infections in the neck, not uncommonly break down and suppurate — and the addition of oral steroids to antituberculous therapy may reduce the degree of scarring should this occur. Similarly, metastatic lymph nodes may ulcerate, but usually in the late stages of the disease. Very large intrathoracic lymph nodes can compress the major airways and other structures. The treatment depends on the nature of the underlying condition.

SPLENOMEGALY

Presenting signs and symptoms that point to a diagnosis

Splenomegaly may be part of an acute febrile illness or of a more chronic underlying process. Commonly, the differential diagnosis for these two situations differs, although there is some overlap. A list of the causes of splenomegaly is provided in Table 152.2 .

Malaria

In a traveler recently returned from the tropics with a febrile illness, the most important diagnosis is *Plasmodium falciparum* malaria; this must be excluded. In acute malaria, the spleen is often enlarged, although not greatly so; however, the absence of clinical splenomegaly is of little value in excluding the diagnosis. In a series of 482 cases of malaria admitted to a single hospital in Canada over a 12-year period, only 24% had detectable splenomegaly at the time of admission.

TABLE 152-2 -- Causes of splenomegaly.

CAUSES OF SPLENOMEGALY

Mild splenomegaly	*Malaria*
	EBV
	Hepatitis
	Typhoid and other salmonelloses
	Tuberculosis
	Dengue fever
	Katayama fever
	Toxoplasmosis
	Cytomegalovirus
	HIV
	Leptospirosis
	Brucellosis
	Sepsis
	Trypanosomiasis
	Histoplasmosis
	Rheumatoid arthritis
	Systemic lupus erythematosus
	Hemaglobinopathies
	Sarcoidosis
	Lepromatous leprosy and erythema nodosum leprosum
	Amyloidosis
Moderate splenomegaly	Lymphoproliferative disorder
	Subacute bacterial endocarditis
	Splenic abscess
	Portal hypertension due to *chronic schistosomiasis*
Marked splenomegaly	*Visceral leishmaniasis*
	Hyperreactive malarious splenomegaly
	Myelofibrosis
	Chronic myeloid leukemia
	Glycogen storage diseases
Each section reflects the importance and/or frequency of the various conditions. The italic type shows the conditions that are more likely to occur in travelers.	

Tropical splenomegaly syndrome, recently reclassified as hyper-reactive malarial splenomegaly, is a poorly understood condition. It is uncommon in travelers but does occur. Several diagnostic criteria have been proposed, including hyperglobulinemia, pancytopenia, strongly positive malaria serology (particularly IgM), a negative blood film for malaria parasites and perisinusoidal lymphocytosis on liver biopsy specimens. The condition represents an inappropriate immunologic response to malaria. Usually the splenomegaly responds to long-term treatment with antimalarial drugs, either weekly chloroquine, daily proguanil or both. Those cases that prove refractory usually turn out to be misdiagnosed cases of lymphoma.

Dengue fever

Dengue fever commonly mimics malaria and is increasing both in frequency and in geographic distribution. The 'classical' rash of dengue fever is petechial, but in practice it is more often morbilliform in the early stages, at least in travelers. A generalized erythematous reaction that blanches with pressure is suggestive of the diagnosis, but both these signs are difficult to see, particularly on dark skin (Fig. 152.1). The combination of severe low back pain, pain in the long bones and retro-orbital pain, particularly when this is accentuated by extreme lateral gaze, is very suggestive of a diagnosis of dengue. Although splenomegaly is unusual among children with the disease in endemic areas, most travelers with dengue have some degree of splenomegaly.

Figure 152-1 Early rash of dengue fever.

Typhoid

Splenomegaly is a common feature of patients with typhoid fever, particularly in the second week of the illness, and it also occurs in patients with nontyphoid salmonelloses and in patients with *Shigella* infections. Several features suggest a diagnosis of typhoid. Usually, patients with the disease are clinically extremely unwell; cough, abdominal pain with either constipation or diarrhea, and neurologic symptoms may all occur. Although the fever of malaria may spike and return to normal values, patients with typhoid usually have fevers that fluctuate to some extent but rarely return to baseline. The value of features such as a relative bradycardia has been overemphasized. Rose spots (pale pink papules on the upper trunk extending into the axillae) are difficult to see, even on Caucasian skin, and occur at least as commonly with nontyphoid salmonelloses as with typhoid. Splenomegaly is common, but again its absence does not rule out the diagnosis.

Epstein-Barr virus infection

Epstein-Barr virus (EBV) infection is common in tropical countries, particularly in Africa. It causes an acute febrile illness, often associated with a sense of misery, lethargy and profound malaise. Splenomegaly occurs in most cases; usually there is associated lymphadenopathy with or without palatal petechiae, both of which are uncommon in malaria or typhoid. An idiosyncratic morbilliform rash after ampicillin is an avoidable but characteristic sign. Although EBV infection is more common among children and young adults, it can cause severe disease even in late middle age, and has been associated with acute splenic rupture.

Visceral leishmaniasis

Kala-azar, or visceral leishmaniasis, is widely distributed in India and is currently epidemic in southern Sudan and northern Kenya. In addition, its frequency is increasing and its epidemiology is changing in response to the immunosuppression associated with HIV. Visceral leishmaniasis is found in as many as 17% of HIV-positive symptomatic people in southern Mediterranean countries.

Classically, it presents as a chronic febrile illness associated with considerable systemic upset and associated wasting. The spleen is usually firm and grossly enlarged. Pancytopenia is common. *Leishmania* serology is invariably positive in immunocompetent people but in only about 40% of patients co-infected with HIV. The parasite is often identifiable in biopsies of the reticuloendothelial system, including bone marrow, spleen, lymph nodes and liver tissue.

Schistosomiasis

Katayama fever is a poorly understood immunologic condition that is apparently triggered by the onset of ovulation by maturing schistosomulae, which usually occurs 4–6 weeks after exposure to infected water. It occurs most commonly in people who have not previously been exposed to schistosomiasis and is less common with *Schistosoma haematobium* than with either *Schistosoma mansoni* or *Schistosoma japonicum*. Only a small minority of people who become infected with schistosomiasis develop the syndrome — probably fewer than 1%.

A diagnosis of Katayama fever can only be made on clinical grounds, as there is no definitive investigation. As it occurs in response to ovulation, examination of stool or urine for schistosome ova is usually negative and serologic responses only become positive once the acute symptoms have resolved. Splenomegaly occurs in approximately 25% of affected people, usually in combination with a brisk rise in the total eosinophil count and non-specific changes in liver function tests. Urticarial reactions and hepatomegaly may also occur.

Splenomegaly is also a feature of established schistosomiasis, commonly the result of portal hypertension resulting from the periportal hepatic fibrosis associated with *S. mansoni*. However, although long-term sequelae of this kind may be common in endemic areas, they are very rare among travelers. As the liver damage that results from schistosomiasis is the result of fibrosis induced by a granulomatous response to egg antigens (with a characteristic pattern on liver biopsy), hepatic function is usually preserved when assessed with conventional liver function tests. Schistosomal serology is usually, but not always, positive. Often the adult worms have died of old age by the time the diagnosis is made, and therefore ova are not commonly found in stool or urine or in rectal snips. Similarly, eosinophilia, associated with early infection, is uncommon in established disease.

HIV

The seroconversion illness of HIV infection mimics that of EBV infection, and transient splenomegaly, lymphadenopathy, atypical lymphocytosis and a morbilliform rash may all occur. As the acute illness resolves, the spleen returns to normal. However, as the HIV syndrome continues, both lymphadenopathy and splenomegaly may recur as part of the AIDS-related complex.

Other causes of splenomegaly

Patients with acute hepatitis may have splenomegaly but the diagnosis is relatively easy to confirm. Leptospirosis is uncommon among travelers but has been reported, particularly in military personnel; exposure may occur during white-water rafting and pot-holing. Tuberculosis, brucellosis, trypanosomiasis and histoplasmosis are all uncommon among travelers but each does occur. Infectious endocarditis is well recognized as a cause of splenomegaly but is no more common among travelers than among the indigenous population. Equally, noninfectious causes of splenomegaly, such as autoimmune disease and lymphoproliferative disorders, may need to be excluded. Adult Still's disease is an uncommon condition and one that is difficult to diagnose; it is therefore easily missed, but the clinical picture includes fever and splenomegaly.

ANEMIA

Anemia is uncommon among travelers. When it does occur, the differential diagnosis is very similar to that among the indigenous population. Broadly speaking, anemia results from one or a combination of: a deficiency of iron, folate or vitamin B12; chronic blood loss; decreased red cell survival; chronic disease; or bone marrow aplasia.

Any patient with significant anemia for which there is no immediately obvious cause should ideally be admitted to hospital for investigation. The basic work up for any such patient should follow conventional lines, including a full history and clinical examination. Questions regarding blood loss, menorrhagia, systemic upset, nutrition, use of nonsteroidal anti-inflammatory drugs and pre-existing disorders such as abnormal red cell phenotypes are obviously important. Examination should focus particularly on the mucous membranes (for evidence of bleeding), the spleen and lymph nodes (for evidence of an underlying inflammatory process), a rectal and vaginal exam-ination where appropriate (for evidence of blood loss or malabsorption), and some assessment of nutritional status.

A few particular diagnoses deserve special mention. Chronic malaria, especially due to infection with *Plasmodium vivax*, can present with marked anemia and splenomegaly, but anemia is relatively uncommon in travelers with acute *P. falciparum* infection. Visceral leishmaniasis invariably results in some degree of anemia, and the anemia may be profound. Tropical sprue appears to be decreasing in frequency; although it has been reported most commonly from the Indian subcontinent, sporadic cases do occur among travelers to sub-Saharan Africa, and often these patients have a macrocytic anemia. Intestinal helminthic infections are often cited as a cause of anemia; in practice, this is very unlikely in returning travelers. Of the common intestinal helminths, only hookworm actually consume blood from the host. Each worm only consumes 0.6–1.0ml of blood per day and, in common with other helminthiases (except *Strongyloides* sp.), hookworms are unable to multiply within the gastrointestinal tract. Although people who live in tropical areas, particularly children, may have very high worm burdens as a result of repeated infection, and often survive on a poor diet with the added burden of repeated malaria attacks — all factors that make anemia very likely — such factors are uncommon in adult travelers.

INVESTIGATIONS TO CONFIRM THE DIAGNOSIS OF SPLENOMEGALY AND/OR ANEMIA

A suggested schedule for the investigation of travelers with either splenomegaly or anemia is shown in (Table 152.3). A few points are worth emphasizing. Malaria can only be excluded after repeated blood film examinations, particularly in those patients with low parasitemia and in those taking chemoprophylactic agents. Mefloquine, in particular, has a long half-life and may delay the time taken for symptoms to develop. Alternative strategies — for example, the use of dipstick techniques such as the ICT test — may replace microscopy in the future, particularly in settings where staff have relatively little experience in identifying low-density infections.

Aspiration of the spleen to confirm a diagnosis of visceral leishmaniasis is a relatively safe procedure; however, it should only be performed by experienced practitioners and ideally under ultrasound control. Any aspirate should be cultured as well as subjected to microscopy; the polymerase chain reaction is now the method of choice for identifying the infecting strain of *Leishmania*. As with liver biopsy, the procedure should only be undertaken once clotting indices and a platelet count have been measured and a supply of compatible and safe blood identified.

Fiberoptic endoscopy to biopsy the mucosa of the small intestine is the investigation of choice in cases of suspected sprue. Endoscopy has the added advantage of enabling aspiration of jejunal fluid, which can be examined for the presence of *Giardia* or *Strongyloides* spp. in particular. It is worth remembering that celiac disease is not confined to children; it can present even in late middle age. Measurement of anti-endomysial antibodies may be useful.

Other serologic tests may be useful but several measurements may be necessary to confirm a diagnosis and a change in titer may be

TABLE 152-3 -- Suggested reasons for splenomegaly and anemia in a patient recently returned from abroad.

SUGGESTED REASONS FOR SPLENOMEGALY AND ANEMIA IN A PATIENT RECENTLY RETURNED FROM ABROAD	
Initial investigations	Thick and thin blood films for malaria (repeated several times)
	Blood cultures (repeated several times)
	Full blood count (red cell indices, white cell count, evidence of hypersplenism)
	Blood film examination (atypical lymphocytes; red cell morphology; evidence of hemolysis)

If anemia predominates	Serum iron
	Transferrin, total iron binding capacity
	Red cell folate
	Vitamin B12
	Fecal occult blood (repeated several times)
	Hemoglobin electrophoresis
	Also consider: bone marrow aspirate endoscopy
Serologic investigations	EBV
	Toxoplasmosis
	Cytomegalovirus
	Malaria immunofluorescent antibody test
	Schistosomal ELISA
	Brucella
	Leishmania
	Widal agglutination test
	HIV
	Histoplasmosis
	Acute and convalescent sera for dengue fever and other flaviviruses
Imaging	Abdominal ultrasound and CT
	Chest radiography
	Indium-labeled white blood cell scan
	Labeled red blood cell survival scan
Tissue diagnosis	Liver biopsy
	Splenic aspiration
	ELISA, enzyme-linked immunosorbent assay.

more valuable than a single reading. Imaging techniques are very useful — sarcoidosis, for example, gives a characteristic appearance on chest radiograph. Tissue biopsy of bone marrow, liver or spleen may well be indicated, particularly in more complicated cases, and biopsies that are taken under either ultrasound or CT guidance are rather more likely to provide useful material.

Chapter 153 - Animal Bites and Rabies

Charles E Rupprecht

INTRODUCTION

An estimated 4.4 million persons sustain animal bites annually in the USA.[1] These bites range in severity from insignificant to fatal maulings. Sequelae include disfigurement, dismemberment, envenomation, localized infection of soft tissues and deep structures, as well as rabies and other systemic infections.[2]

Rabies is a viral zoonosis transmitted via the saliva of infected mammals. The virus spreads to the central nervous system, causing an encephalomyelitis which progresses to coma and death. On average, 1–2 cases of human rabies and 5000–10,000 cases of animal rabies are reported in the USA each year, 90% diagnosed in wild animals.[3] Worldwide, an estimated 50,000 cases of human rabies occur per year according to the World Health Organization. Between 1960 and 1979, eight (22%) of the 37 cases of human rabies diagnosed in the USA were acquired abroad, whereas 13 (33%) of the 39 cases of human rabies that occurred since 1980 were acquired outside the USA.[3] [4]

PRESENTING SIGNS AND SYMPTOMS THAT POINT TO THE DIAGNOSIS

Patients either present for first aid immediately after a bite or considerably later with signs and symptoms of a bite-related infection.

It is important to determine the extent of the injury and the structures involved in the bite. Feline teeth can penetrate deeply into tendons, bones and joints, in contrast to dog bites, which are more likely to devitalize large areas of soft tissue by crushing injury.[5] Besides the common organisms that are isolated from bite wounds, which include *Staphylococcus, Streptococcus* and *Corynebacterium* spp., the type of animal involved can also help to implicate other specific pathogens that are known to cause well-defined syndromes (Table 153.1). When a patient presents with cellulitis 12–24 hours after cat bite, the likely agent is *Pasteurella multocida* rather than the patient's skin flora, which usually requires an incubation period of 24 hours or longer. Although specific case histories have documented etiologic agents associated with animal bites other than those listed in Table 153.1 (e.g. *Francisella* spp., *Yersinia* spp., nonoxidative Gram-negative rods, etc.), these other instances appear rather uncommon.

Rabies virus is transmitted in the saliva of mammals, almost always by a bite. Rabies in humans has an incubation period of 1–3 months, but occasionally periods may be as short as a week or last as long as several years. Early symptoms include a nonspecific flu-like prodromal illness with headache, fatigue and fever associated with paresthesiae at the site of the bite or proximal to it. These symptoms are followed by the onset of an acute neurological phase with anxiety, irritability and other behavioral changes. Some patients develop classic 'furious' rabies, characterized by periods of hyperactivity, disorientation, hallucinations and other bizarre behaviors alternating with periods of calm. Additional signs and symptoms can include autonomic instability manifested as hyperthermia, tachycardia and hypersalivation, as well as hydrophobia and aerophobia. This phase of disease rapidly progresses to seizures, coma and death, usually within 10 days of the first onset. Occasionally, patients present with 'dumb' rabies and develop flu-like symptoms, paralysis and finally disorientation, coma and death.

DIFFERENTIAL DIAGNOSIS BY GEOGRAPHIC AREA

Most people who sustain an animal bite are able to provide an adequate history of the type of animal, the location and the circumstances that may have provoked the event. Thus, the differential diagnosis is not directly related to the type of trauma that caused the injury, but rather to the organisms that are likely to result in infection due to the bite. Comprehensive lists of bacterial flora that have been cultured from the mouths and bite wounds of various animals have been published elsewhere, together with case reports of rare exotic pathogens that have been transmitted by a bite at least once. In general, the organisms that most often cause bite-related infections are the Gram-positive skin flora of the victim and the bacteria that reside in the animal's mouth, which are predominantly Gramnegative rods and anaerobes.[5] There is no known variation to this generalization by major geographic regions.

In rabies, however, there is significant geographic variability in both the incidence and the species that are likely to transmit the virus. In the early 1940s in the USA, dogs were the predominant reservoir for rabies.[3] With the utilization of rabies vaccines for domesticated dogs and stray animal control laws, the total number of cases of canine rabies decreased substantially and wildlife rabies cases increased. Today, on the eastern coast of the USA, the predominant reservoir for rabies is the racoon. In California and the upper and lower mid-west, skunks account for the majority of animal rabies cases. Rabid bats have been diagnosed in all of the continental states of the USA.[3] A case of rabies occured recently in a bat-handler in Scotland. Outside the USA, regions of South East Asia, Africa and Latin America have large populations of stray dogs that are unvaccinated, and in these regions an unprovoked dog bite should always lead to active consideration of rabies. Figure 153.1 illustrates the predominant types of rabid animals in different regions. The World Health Organization maintains a list of countries that are supposedly rabies free or that have achieved secondary elimination (internet access: http://www.rabnet.who.int). Knowledge of this situation can help in deciding whether patients should receive postexposure prophylaxis (PEP).

INVESTIGATIONS TO CONFIRM THE DIAGNOSIS

Specific diagnostic tests may have limited value in the initial evaluation of animal bites. Radiographs can be used if there is concern about fractures or embedded foreign bodies. Cultures of fresh bite wounds are likely to produce positive results, but not all patients will develop infection. If infection results, the recovered organisms may not be the cause. Patients presenting later with established infections should be evaluated according to standard procedures for skin and soft tissue infections. Such evaluations should include a white blood

TABLE 153-1 -- Pathogens associated with bites from specific animals.

PATHOGENS ASSOCIATED WITH BITES FROM SPECIFIC ANIMALS		
Animal	**Pathogen**	**Comments**
Dog	*Capnocytophaga canimorsus*	Causes a sepsis syndrome in asplenic patients
Cat	*Bartonella henselae*	The agent of cat-scratch disease
	Pasteurella multocida	Causes an aggressive soft-tissue infection, usually within 24 hours of inoculation
Macaque	Herpesvirus simiae (B virus)	Macaques can be asymptomatic carriers, whereas the disease is fatal in other monkeys; postexposure prophylaxis not routinely recommended; documented infections can be treated with aciclovir[6]
Rat	*Streptobacilus moniliformis*	Cause of rat-bite fever; occurs 7–10 days after a bite with fever, chills, headache, rash on palms and soles, and arthritis
	Spirillum minus	Cause of rat-bite fever; longer incubation period with fever and regional adenopathy; arthritis and rash less prominent

Fresh-water species	*Aeromonas hydrophila*	Snake and leech bites have also resulted in *Aeromonas* infections
Salt-water species	*Vibrio* spp.	Can present with an ulcerating lesion at the site of inoculation and bacteremia
Mammal	Rabies	All mammals are capable of transmitting rabies by biting, but carnivores and bats predominate

Figure 153-1 Animal rabies cases by geographic region for 1998. A total of 32,342 cases are displayed here. According to WHO sources in the 34th World Survey (Via Rabnet document, 2000, WHO/CDS/CSR/APH/99.6), based upon data from 110 countries reporting out of 193 members, wildlife rabies predominates in some regions, such as the USA and Canada, whereas dogs remain a significant reservoir in many other countries. Values shown are percentages. (Note: Rabies has been diagnosed among bats in Australia but these do not appear in the above report.)

cell count and appropriate cultures that can be used later to adjust ad hoc antimicrobial therapy.

Before the onset of symptoms, there are no diagnostic tests for assessing exposure to rabies virus. Rather, to rule out the likelihood that a patient has been exposed to the virus, the biting animal should be captured and either put into quarantine for observation over a sufficient time frame or euthanized so that appropriate samples of brain tissue can be examined for the presence of rabies virus antigen, using the direct fluorescent antibody test http://www.cdc.gov/ncidod/dvrd/rabies/professional/publications/DFA_diagnosis/DFA_protocolb.htm). The length of time a domestic animal needs to be under observation to determine if it was rabid at the time of the bite

TABLE 153-2 -- Recommendation for rabies postexposure prophylaxis.[§]

RECOMMENDATION FOR RABIES POSTEXPOSURE PROPHYLAXIS			
Geographic area	**Mammals**[*]	**Prophylaxis recommendations**[†] [‡]	
		Bite	**Non-bite**
Group 1: Rabies enzootic or suspected in species involved in the exposure	Bat, racoon, skunk, fox, coyote; mongoose in Puerto Rico; stray dogs and cats along border with Mexico	Treat	Treat
Group 2: Rabies not enzootic in species involved in the exposure but reported in other animals in region (e.g. most of continental USA)	Most wild carnivores (wolf, cougar, bobcat, bear, etc.)	Treat	Treat or consult
	Domestic dogs, cats and ferrets	Observe or consult	Observe or consult
	Wild rodents and lagomorphs, except groundhogs	Consult or do not treat	Do not treat
	Livestock	Consult or do not treat	Do not treat
Group 3: Rabies not enzootic in species involved in the exposure and only sporadic reports in region (e.g. Pacific North-West)	Dogs, cats, other domestic animals and many wild terrestrial animals	Consult or do not treat	Consult or do not treat
Group 4: Rabies not reported in region (e.g. Hawaii, Guam, Samoa, Virgin Islands, etc.)	Any terrestrial mammal	Do not treat	Do not treat
The regimens are applicable for all age groups, including children. The deltoid area is an acceptable site of vaccination in adults and older children; the outer aspect of the thigh may be used in younger children. Vaccine should never be administered in the gluteal area. People who are previously vaccinated are those with a history of pre-exposure vaccination with HDCV, PCEC or RVA, prior postexposure prophylaxis with HDCV, PCEC or RVA, or previous vaccination with any other type of rabies vaccine and documented history of antibody response to the prior vaccination. HDCV, human diploid cell vaccine; RVA, rabies vaccine absorbed; PCEC, purifed chick embryo cell.			

§ *Information from Centers for Disease Control and Prevention, 1999.*[6]
* All mammals are susceptible to rabies, but reservoirs include bats and certain carnivores. Small rodent bites are common, but almost never require prophylaxis.
† 'Consult' means consultation with a knowledgeable state or local health department, especially if the animal is not available for testing or observation. If the risk of rabies in the species involved in the exposure is considered low and the animal's brain is available for testing, prophylaxis may sometimes be delayed for up to 48 hours, pending the results of laboratory diagnosis. A healthy domestic dog, cat or ferret that bites a person should be confined and observed for 10 days. Any illness in the animal should be evaluated by a qualified veterinarian and reported immediately to the local health unit. If signs suggestive of rabies develop, human prophylaxis is begun immediately. If the suspected animal is determined to be a stray dog, cat or ferret, rather than confined, it may be euthanized, the head removed and the package shipped, under refrigeration, for examination by a qualified diagnostic laboratory.
‡ Rabies may develop in ~<1 to >70% of untreated humans bitten by a rabid animal (depending in part upon species, route, dose, severity, etc.) and in ~>0.1 to 1–2% of those untreated after direct exposure to a rabid animal but not bitten (e.g. licked on an open wound or mucous membrane, or scratched).

depends on the species of animal. In practice, only domestic dogs, cats and ferrets undergo a 10-day observation period. Other animals are usually euthanized because the length of the viral shedding period has not been determined.[7] Rabies should be included in the differential diagnosis of any suspected acute progressive viral encephalitis, regardless of a history of animal bite.[8] Once a patient develops symptomatic rabies, available diagnostic tests include assays for viral antibodies in the serum or cerebrospinal fluid (CSF); viral isolation from CSF or saliva; viral antigen detection in biopsies of skin, corneal impressions or brain tissue; and reverse transcription polymerase chain reaction of saliva, CSF or related tissues (such as salivary glands or brain tissue).[3] [4] [8] [9]

IMMEDIATE MANAGEMENT

One of the most important steps in the initial management of animal bites to decrease the incidence of infection, including rabies, is aggressive cleansing of the wounds with copious irrigation and debridement of devitalized tissue. Issues that remain controversial are whether to apply primary sutures to the wound and whether to prescribe prophylactic antibiotics.

Most bites that receive medical attention within a few hours can be cleaned and sutured immediately, especially if rabies is not a concern, so as to avoid the opportunity of viral contamination to deeper tissues. Otherwise, wounds are packed, observed and either sutured later or allowed to heal by secondary intention. Prophylactic antibiotics may be indicated for some high-risk events, such as facial bites and involvement of deep structures such as tendons and joints.[5] In addition, patients should be up to date with tetanus vaccination.

A thorough history of the type of animal, the location and the circumstances surrounding the incident should be noted. Many animal bites are provoked. [5] Unprovoked attacks by animals exhibiting unusual behavior are more likely to be rabies exposures.[9] If the bite was caused by an animal that is likely to have rabies in that particular geographic location, that animal should be confined or euthanized.[9] If the animal tests positive or if it is unavailable for testing, the patient should receive rabies PEP (Table 153.2). Regardless of the length of the interval between true rabies exposure and presentation of the healthy patient, PEP should be initiated as soon as possible after the bite. Although rabies is uniformly fatal once symptoms have started, with proper intervention the disease is essentially completely preventable.

COMPLICATIONS

Figure 153.2 illustrates the case of a person from the USA who was bitten by a dog while traveling abroad.[10] There were multiple opportunities to receive PEP, yet it did not occur. Patients traveling to rabies-endemic regions who are likely to be more than 24–48 hours away from appropriate medical care are candidates for

pre-exposure vaccination.[9] They should be counseled that, despite pre-exposure vaccination, boosters would be required if they were to be bitten.

Recommendations for reducing the frequency of animal bites include both education and public policy initiatives. Potential owners of animals should be discouraged from trying to tame or handle wildlife, such as racoons or bats, and should consider more docile breeds of dog. Behavioral training should be directed at both dogs and children to ensure that animals are properly socialized and that children are taught proper conduct around animals. Responsible pet ownership should be promoted and all stray and wildlife should be avoided.[7] [9]

Figure 153-2 A preventable case of rabies in a returned traveler. The patient had been traveling for 6 months. She did not receive pre-exposure rabies vaccine and despite multiple opportunities, did not receive postexposure prophylaxis.[10]

Chapter 154 - Leprosy

Warwick J Britton

EPIDEMIOLOGY

Leprosy is a chronic infection of the skin and nerves with *Mycobacterium leprae* which, although rarely fatal, is a significant cause of disability. Over the past decade there have been dramatic changes in the prevalence of leprosy since the introduction of multidrug therapy (MDT).[1] [2] As a result of the shorter duration of therapy and more intensive control programs, the number of registered leprosy patients receiving chemotherapy has fallen from 10–12 million to 600,000 in 2000.[3] The annual case detection rate, however, has remained unchanged at approximately 700,000 new patients/year. This contributes to the pool of 2–3 million patients with permanent nerve impairment as a consequence of leprosy.

Leprosy is widely distributed in tropical and warm temperate countries and 1.3 billion people live in regions where there is active transmission of *M. leprae*. There has been a reduction in the number of endemic countries (prevalence rate >1/10,000) from 122 in 1985 to 15 in 2000,[3] mainly in Africa, Asia and Latin America. Currently 83% of registered cases occur in only six countries:

- India (accounting for 64% of all registered cases); and
- Brazil, Myanmar, Madagascar, Nepal and Mozambique, in order.[3]

Because of the long incubation period of leprosy, an individual from an endemic country may develop leprosy years after migration elsewhere. Delay in diagnosis is usually longer in nonendemic than endemic regions and therefore leprosy should be considered as a diagnostic possibility in any person who is from an endemic country and who has chronic lesions of the skin or peripheral nerves.

Subclinical infection with *M. leprae* is far more common than overt disease.[4] Analysis of *M. leprae*-specific immune responses[5] has demonstrated that *M. leprae* infection is common after exposure, but the majority of individuals control the infection.

The major mechanism of transmission of *M. leprae* is through nasal secretions, particularly from lepromatous patients. [4] Organisms probably enter through the mucosa of respiratory tracts and, if not controlled, they disseminate to the skin and peripheral nerves. Other possible modes of transmission include breast milk from mothers with untreated lepromatous disease and rare cases of cutaneous inoculation. Although infection with *M. leprae* has been documented in wild armadilloes and some primates, zoonotic transmission does not contribute to human disease.

Proximity to leprosy patients is important in transmission, and the relative risk for disease for household contacts is 8- to 10-fold greater for lepromatous cases and 2- to 4-fold greater for tuberculoid cases.[4] Nevertheless, the majority of leprosy cases are sporadic.

Genetic factors influence both the development of leprosy and the pattern of disease. Whole genome screening has identified susceptibility loci on chromosome 10p13, close to the gene for the mannose receptor C type 1,[6] and the HLA region with linkage to both the HLA class II and tumor necrosis factor genes,[7] in Indian and Brazilian patients respectively. The HLA locus also affects the pattern of disease; HLA-DR2 and DR3 are associated with tuberculoid disease and HLA-DQ1 with lepromatous leprosy.[5] Racial and geographic factors also influence the type of leprosy, with lepromatous leprosy being less common in Africans than Indians and most common in Chinese and Caucasians.

The incidence of leprosy peaks in two age groups (10–15 and 30–60 years of age) and there is a male predominance in most regions of about 2:1.[4] The incubation period varies widely from months to over 30 years, but is usually prolonged, averaging 4 years for tuberculoid and 10 years for lepromatous leprosy. In contrast to tuberculosis, there is no definite evidence for an association between HIV infection and clinical leprosy,[8] although one study suggested an increase in HIV prevalence in leprosy patients in Tanzania.[9]

PATHOGENESIS AND PATHOLOGY

Although *M. leprae* was the second bacterium to be associated with a human disease, it still cannot be cultivated in vitro. The organism is capable of limited multiplication in mouse footpad, with a doubling time of 11–13 days, and this has permitted drug sensitivity studies. [10] *Mycobacterium leprae* is an acid-fast, Gram-positive bacillus and is an obligate intracellular parasite with tropism for macrophages and Schwann cells. The bacilli show preference for growth in cooler regions of the body. The unique characteristic of *M. leprae* is its predilection to infect Schwann cells. The receptor complex on the Schwann cell is the G-domain of the laminin a2 chain in the basal lamina of Schwann cells and the laminin receptor, a-dystroglycan.[11] A number of ligands on the surface of *M. leprae* bind to this complex, including the specific trisaccharide of phenolic glycolipid (PGL)-I and a 21kDa surface protein.

Genetic and structural analyses have confirmed that *M. leprae* is a member of the family Mycobacteriacae. A major advance has been the sequencing of genome of an Indian isolate of *M. leprae*. [12] The genome contains 1605 genes encoding proteins and 50 genes for stable RNA molecules. Remarkably, half of the functional genes in the *M. tuberculosis* genome are absent, being replaced by many inactivated or pseudogenes. This gene decay has removed entire metabolic pathways and regulatory genes, particularly those involved in catabolism. This may render the leprosy bacillus dependent on host metabolic products and may explain its long generation time and inability to grow in culture.[12] The availability of the *M. leprae* and other mycobacterial genomes has major implications for the development of new antimycobacterial drugs [13] and *M. leprae*-specific diagnostic reagents. The complex cell wall contains important targets of the immune response, including a species-specific PGL-I and immunomodulatory lipoarabinomannan. The cell wall biosynthetic pathways are relatively intact in *M. leprae*, despite the loss of other genes, indicating that these represent the essential genes for the formation of a minimal mycobacterial cell wall.[14] *Mycobacterium leprae* is relatively inert and the host immune response is responsible for most of the tissue damage.

The manifestations of leprosy form a wide clinical spectrum determined by immunopathologic responses to the organism (Fig. 154.1).[15] Patients who have the polar forms of tuberculoid

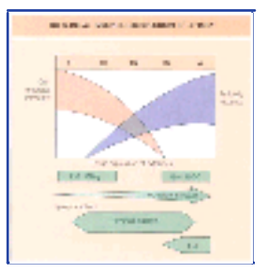

Figure 154-1 The clinical-immunologic spectrum of leprosy. This reflects the underlying host immunity as measured by the T-cell and antibody responses to *M. leprae*. Spontaneous fluctuations in the immune response are responsible for reversal reactions and erythema nodosum leprosum (ENL). TT, tuberculoid leprosy; BT, borderline tuberculoid; BB, mid-borderline leprosy; BL, borderline lepromatous leprosy; LL, lepromatous leprosy; IFN, interferon; IL, interleukin.

(TT) and lepromatous leprosy (LL) are immunologically stable, but those who have the intermediate types of borderline-tuberculoid (BT), mid-borderline and

borderline-lepromatous (BL) leprosy are immunologically unstable and subject to either a gradual decline toward the lepromatous pole or upgrading reversal reactions (RRs; see Fig. 154.1). In TT a vigorous cellular response to *M. leprae* limits the disease to a few well-defined skin patches or nerve trunks.[15] The lesions are infiltrated by interferon-? secreting $CD4^+$ T cells, which form well-demarcated granulomas containing epithelioid and multinucleate giant cells around dermal nerves.[5] Few, if any, bacilli are demonstrable. Cellular immunity may be confirmed by in-vitro lymphocyte responses to *M. leprae* antigens or skin test reactivity. Intradermal injection of heat-killed *M. leprae* causes a transient swelling at 48 hours in a sensitized subject (Fernandez reaction), followed by the development of a granulomatous nodule at 3–4 weeks (Mitsuda reaction).[5] [15] The latter confirms an individual's capacity to mount a T-cell response to *M. leprae*. Antibody responses to *M. leprae* are absent or low titer.

The hallmark of LL is the absence of *M. leprae*-specific cellular immunity and this results in uncontrolled proliferation of the bacilli with extensive infiltration of the skin and nerves and numerous lesions.[5] Histologically, the dermis contains foamy macrophages filled with multiple bacilli and a scattering of $CD4^+$ and $CD8^+$ lymphocytes, but no organized granulomas.[15] There are high titers of antibodies to *M. leprae*-specific PGL and protein antigens. In borderline cases a progressive reduction in cellular responses is associated with a greater bacillary load, more frequent skin and nerve lesions and increasing antibody levels.

The dynamic nature of the immune response to *M. leprae* is responsible for spontaneous fluctuations in the clinical pattern, termed leprosy reactions:[16]

- a type 1 reaction is usually an 'upgrading' RR caused by increased cellular reactivity to mycobacterial products, results in edema and acute inflammation of skin lesions and nerves, is most common in borderline patients and is a major cause of nerve damage; and
- a type 2 reaction or erythema nodosum leprosum (ENL) is a systemic inflammatory response to the deposition of extravascular immune complexes, leading to neutrophil infiltration and activation of complement in multiple organs,[9] and is accompanied by high circulating levels of tumor necrosis factor a and systemic toxicity.

PREVENTION

The chief means of preventing leprosy is the interruption of transmission by treating those with infectious leprosy early. Multidrug therapy was introduced because of the increasing spread of primary and secondary dapsone resistance worldwide. [1] Its advantages are its proven efficacy[2] and improved compliance, which is related to the limited duration of therapy and its monthly observed component (see Management, below). Furthermore, early treatment before the onset of nerve damage reduces the long-term disability associated with leprosy.[3] [17] The effectiveness of MDT has prompted a World Health Organization (WHO) co-ordinated campaign to implement MDT in all endemic countries, with the aim of reducing the prevalence rate of leprosy to less than 1/10,000.[3] This has been successful, with 15 countries left to attain this goal. Importantly, however, the case detection rate has not yet fallen, probably because of the prolonged incubation period of clinical leprosy, indicating that control programs must be sustained.

The response to immunization with *M. bovis* BCG has been variable, but in a major trial in Malawi BCG induced 50% protective efficacy against clinical leprosy, both tuberculoid and lepromatous forms.[18] Reimmunization enhanced the protective effect by a further 50%. The benefit of BCG has been confirmed in subsequent case-control studies. Extensive BCG immunization of children in endemic countries has probably made a significant contribution to the decline of leprosy. The addition of heat-killed *M. leprae* to BCG did not increase the observed protective efficacy of BCG in two trials.[18] Other experimental vaccines are being tested against leprosy infection at present.

Leprosy is commonly associated with poverty and overcrowding, and improved socioeconomic conditions have contributed to the decline of leprosy in Europe and some Asian countries.

CLINICAL FEATURES

Types of leprosy

Indeterminate leprosy

This is the earliest form and occurs as a single slightly hypopigmented, ill-defined macule in children, who are often contacts of leprosy patients.[19] The majority of these lesions are self-limiting and resolve without therapy. A minority (<25%) develop into defined lesions within the clinical spectrum.

Tuberculoid leprosy

These lesions occur as 1–3 large asymmetric macules or plaques with sharply defined borders and hypopigmented anesthetic centers (Fig. 154.2).[19] [20] Although leprosy lesions are usually hypopigmented, in light skins the macules may appear erythematous or dyschromic. Involvement of sweat glands and hair follicles results in dryness and loss of hair. Enlarged cutaneous nerves may be palpable at the edge of the lesion, but nerve trunk involvement is minimal.

Figure 154-2 Tuberculoid leprosy. Single hypopigmented anesthetic plaque with raised border and dry surface.

Figure 154-3 Borderline tuberculoid leprosy. Three large well-defined erythematous patches with reduced sensation, spreading borders and satellite lesions.

Borderline tuberculoid leprosy

This is the commonest form of leprosy. The skin lesions resemble those in TT leprosy, but are more frequent and variable in appearance and their borders are less well demarcated (Fig. 154.3). The outline may be irregular with adjacent 'satellite' lesions suggesting local spread. Occasionally, large patches of BT leprosy may involve a whole limb. Asymmetric enlargement of several peripheral nerves is usual and patients may present with muscle weakness or trauma secondary to sensory impairment. Progressive nerve damage is common.

Mid-borderline leprosy

This is the most immunologically unstable form with the propensity to shift rapidly toward BT leprosy during a reversal reaction or to downgrade toward BL leprosy. The skin lesions are numerous and vary in size, shape and distribution. They may be hypopigmented or erythematous. The characteristic 'target' lesion has a broad, erythematous border with a vague outer edge and 'punched-out' pale center with sensory impairment (Fig. 154.4).

Borderline lepromatous leprosy

In borderline lepromatous leprosy there are numerous small erythematous macules, which initially may be limited in distribution, but become progressively more symmetric.[19] Papules, nodules and succulent plaques may develop and, in contrast to tuberculoid leprosy, the lesions have normal sensation. The intervening skin is normal. Widespread nerve involvement is typical, especially if the patient has downgraded from BT leprosy.

Figure 154-4 Mid-borderline leprosy. Characteristic target lesion with raised erythematous annular border and 'punched-out' central area with impaired sensation.

Figure 154-5 Lepromatous leprosy. Multiple, small, slightly erythematous macules with intact sensation and symmetric distribution. The skin smears of both the lesions and intervening skin are positive for acid-fast bacilli.

Lepromatous leprosy

This is a systemic disease with a generalized bacteremia leading to widespread involvement of the skin and other organs.[19] The first manifestation may be a diffuse infiltration of the dermis, causing a smooth shiny appearance of the skin. More typically, there are numerous symmetrically distributed macules, papules or nodules (Fig 154.5 and Fig 154.6). Progressive thickening of the skin results in coarsening of the facial features and nodular thickening of the ear lobes. With time the eyebrows and eyelashes become thinned.

Bacillary infiltration is responsible for gradual tissue damage in the involved organs. The nasal mucosa is infiltrated at an early stage, resulting in discharge and obstruction. Erosion of the cartilage and nasomaxillary bones results in perforation of the nasal septum, collapse of the nose and saddle-nose deformity. Laryngeal involvement produces hoarseness and stridor. Direct bacillary involvement of the eye causes keratitis and iritis.

Infiltration of the dermal nerves results in a peripheral sensory loss similar to that of a 'glove and stocking' neuropathy,[19] which leaves the skin susceptible to ulceration and secondary infection. Reactional episodes cause edema of the feet, shins and hands. Dactylitis develops in the hands and feet and, together with trauma and osteomyelitis, results in phalangeal erosion.

Both testicular infiltration and orchitis contribute to testicular atrophy and secondary gynecomastia. Glomerulonephritis may occur and is usually associated with ENL. Secondary amyloidosis is a consequence of recurrent ENL reactions.

Figure 154-6 Nodular lepromatous leprosy. Diffuse infiltration of the skin by multiple nodules of varying size, each teeming with bacilli.

Peripheral nerve involvement

The nerves of predilection occur at superficial sites where the nerve trunks are cooler, more readily traumatized and often anatomically constricted. [19] These include the:

- ulnar nerve at the medial epicondyle of the humerus,
- median nerve at the wrist,
- lateral popliteal nerve at the neck of the fibula,
- posterior tibial nerve behind and inferior to the medial maleolus, and
- radial nerve in the humeral groove posterior to the deltoid insertion.

Easily palpated superficial cutaneous nerves include the:

- superficial radial nerve at the wrist,
- greater auricular nerves,
- supraorbital nerve, and
- sural nerves.

These nerves should be examined for enlargement and associated weakness and sensory loss. The resulting muscle imbalance leads to the characteristic deformities of clawhand, footdrop, clawtoes and wristdrop. Autonomic nerve dysfunction contributes to impaired sweating and dry skin, which is subject to cracking, infection and poor healing. The combination of insensitive feet and clawtoes leads to recurrent plantar ulceration, a major cause of disability.

In pure neural (PN) leprosy the nerve trunks are affected without any skin lesions. On biopsy the neural lesions tend to be 'lepromatous' in appearance and PN leprosy involving more than one nerve should be treated as multibacillary (MB).

Before and during therapy the function of the commonly involved nerves should be assessed at regular intervals by voluntary muscle and sensory testing (preferably with nylon monofilaments) to determine whether there is ongoing nerve function impairment. This may presage the onset of a reversal reaction before nerve pain or typical skin lesions develop. Nerve function impairment may develop or worsen despite effective chemotherapy, and early recognition and therapy prevent permanent nerve damage.[16] [17] Patients with pre-existing nerve damage at diagnosis and MB patients are at greatest risk for new nerve function impairment and should be carefully monitored.[17]

Figure 154-7 Reversal reaction. Erythema and edema in the facial lesions of a patient who has borderline-tuberculoid leprosy undergoing an upgrading reversal reaction.

Figure 154-8 Erythema nodosum leprosum. Tender papules associated with fever, arthralgia and acute neuritis in a patient who has lepromatous leprosy.

Leprosy reactions

Reversal reactions

These develop in about one-third of patients who have BT-BL leprosy, usually within the first 6 months of treatment.[16] They present with:

- increased inflammation in established BT-BL skin lesions or new swollen lesions in BL and subpolar LL patients (Fig. 154.7),
- acute neuritis with pain or tenderness in the involved nerve and loss of function, and
- recent (<6 months) or progressive nerve function impairment in the absence of painful nerves.

Silent neuritis responds to therapy for the RR.[21] Patients who have a particular risk of developing a RR are those who have facial patches, more extensive disease involving more than two body areas or *M. leprae*-specific IgM anti-PGL antibodies.

Erythema nodosum leprosum

This once affected 30–50% of BL and LL patients, but the frequency and severity of ENL have reduced since the regular use of clofazimine in MDT.[2] It may develop at any stage of therapy, but usually within the first year, and is often recurrent. An episode begins with fever and malaise and the rapid emergence of painful erythematous nodules, typically over the extensor surfaces of the limbs.[20] In severe cases widespread nodules may form pustules and ulcerate (Fig. 154.8). Painful neuritis is the most common complication. Erythema nodosum leprosum has features of widespread immune complex deposition and these may include small vessel vasculitis, iridocyclitis, polyarthritis, orchitis, lymphadenitis and glomerulonephritis.

Recurrent or uncontrolled ENL reactions can result in the development of secondary amyloidosis (amyloid A protein) within 3 months.

Eye involvement

Involvement of branches of the facial and trigeminal nerves results in lagophthalmos and corneal anesthesia, respectively, and if combined there is a considerable risk of ulceration and infection of the exposed insensitive cornea. [22]

In 25–30% of patients who have LL, infiltration of the anterior segment of the eye causes a superficial punctate keratitis and iridocyclitis, which may be painless and only recognized by slit-lamp examination. Iridocyclitis is exacerbated during episodes of ENL, but can occur independently of overt reactions. The iritis may be complicated by glaucoma or cataract, both of which contribute to leprosy-associated blindness (see Chapter 20).

DIAGNOSIS

A diagnosis of leprosy is usually straightforward if it is suspected as a cause of any skin or peripheral nerve lesion in a person from an endemic country. The cardinal signs of leprosy[19] [20] are:

- skin patch with sensory loss,
- nerve enlargement, and
- acid-fast bacilli (AFB) in the skin.

The presence of one or more of these features establishes the diagnosis, which should be confirmed with a full-thickness skin biopsy. Approximately 70% of all leprosy patients can be diagnosed by the single sign of a skin patch with sensory loss, but 30% of patients, including many MB patients, may not present with this sign, indicating the importance of nerve enlargement as an additional sign and the importance of clinical suspicion for the diagnosis.

Acid-fast bacilli are best demonstrated in slit-skin smears, which should be taken from the edges of at least two lesions and both ear lobes.[23] If these are not available a skin biopsy should be stained for AFB with a modified Wade-Fite stain. The extent of the bacillary load can be quantitated as a bacterial index[10] on a logarithmic scale of 1+ to 6+. The percentage of solid staining AFB in smears, the morphologic index,[10] is an indirect measure of the viability of leprosy bacilli. In PN leprosy a biopsy from a sensory nerve such as the superficial radial nerve may be diagnostic. Polymerase chain reaction (PCR) can be used to identify *M. leprae* DNA and, together with PCR-based detection of rifampin (rifampicin)-resistant strains, it is a valuble tool for epidemiologic studies.[24]

Lepromin testing and serology may be used for accurate classification of patients in research studies. Antibodies to PGL and other *M. leprae*-specific protein antigens are present in MB patients and their titer falls with effective therapy.[5] In patients who have BL and LL, evidence of chronic inflammation includes anemia, hypergammaglobulinemia, elevated serum amyloid A protein and positive antinuclear and anticardiolipin autoantibodies.

Other skin diseases can be differentiated from tuberculoid leprosy by the absence of anesthesia in the lesions and the presence of nerve involvement elsewhere.[20] [23] Lepromatous skin lesions are not anesthetic and biopsy may be necessary to distinguish these from those due to other systemic infections such as leishmaniasis and secondary syphilis and other nodular or infiltrative skin conditions. Other causes of nerve enlargement such as primary amyloidosis and familial polyneuropathy are excluded by biopsy and family history.

MANAGEMENT

Successful management of leprosy requires prolonged drug treatment and careful monitoring for complications and it is essential to enlist the patient as an ally in this process. The patient should be educated about:

- the importance of compliance,
- the first symptoms of a reaction, and
- the elements of self-care needed to prevent secondary tissue damage if there is sensory nerve impairment.

The most important step in disability prevention is the early initiation of bactericidal drug therapy.

Antileprosy drugs

Dapsone

This is an important antileprosy drug because of its bactericidal effect at full dosage, low cost and low toxicity.[2] When used alone stepwise dapsone resistance emerges as a major problem,[1] but this is prevented by combination therapy. Mild hemolytic anemia is common, but is only severe in the presence of glucose-6-phosphate dehydrogenase deficiency, which should be excluded where possible. Occasionally dapsone allergy, and rarely agranulocytosis, may develop after 2–6 weeks.

Rifampin

Rifampin is a key component of MDT because it is the most effective bactericidal drug against *M. leprae* when given either daily or monthly.[2] [10] Toxicity is low with monthly dosage, although thrombocytopenia, hepatitis and a flu-like syndrome occasionally occur. It must be used with at least one other effective drug to prevent rifampin resistance. Tuberculosis should always be excluded before monthly rifampin is started (see Chapter 37 and Chapter 202). Rifapentine is a long-acting rifamycin-derivative that is more bactericidal than rifampin in mice and is currently being tested in humans.

Clofazimine

This is a fat-soluble dye that is deposited within the skin, fat stores and macrophages. It has similar bactericidal activity to that of dapsone, [2] [15] and also a significant anti-inflammatory effect. It is relatively nontoxic and its only disadvantage is the associated development of a reddish skin pigmentation, which resolves after the drug has been discontinued. When used in high doses for prolonged periods, clofazimine is deposited in the small intestinal wall and can cause diarrhea and pain.

Other drugs

Three additional drugs have proved effective against *M. leprae* in human and mouse studies:[2] [23]

- ¦ the fluoroquinolones ofloxacin and moxifloxacin have moderate bactericidal activity and infrequent side-effects involving the gastrointestinal tract and central nervous system;
- ¦ minocycline, the only fat-soluble tetracycline, has moderate anti-*M. leprae* activity. It has proved effective in patients with LL and has low toxicity in adults when used as long-term therapy for acne and so is a useful alternative drug for leprosy; and
- ¦ clarithromycin has modest bactericidal activity.

Multidrug therapy

The principle underlying MDT is the use of three drugs when the bacterial load is high in MB leprosy to treat and prevent the emergence of dapsone-resistant strains. Two drugs are sufficient for paucibacillary disease. Since its introduction in 1982,[1] MDT has proved highly effective and over 10 million patients have been treated with few treatment failures and remarkably low relapse rates of about 0.1/100 patient-years.[2] [3] [25]

Multibacillary multidrug therapy

This is recommended for adult patients with BB, BL, LL, smear-positive BT and PN leprosy. In leprosy control programs in endemic

countries, a simplified form of classification is employed, based on the number of patches, so that MB leprosy >5 patches and paucibacillary (PB) "5 patches. Multibacillary MDT comprises:

- ¦ rifampin, 600mg once a month, supervised administration;
- ¦ dapsone, 100mg/day, self-administered; and
- ¦ clofazimine, 300mg once a month, supervised administration; 50mg/day, self-administered.

Originally, MB-MDT was continued for at least 2 years and then until the skin smears became negative.[1] In subsequent field trials a fixed duration of MB-MDT for 2 years was as effective[2] and this was utilized in control programs with very low rates of relapse.[25] Patients who have MB leprosy and a skin smear bacterial index of 4+ or over may require a longer duration of therapy.[2] More recently in 1998, the WHO recommended that MB-MDT of 12 months duration may be sufficient for use in control programs.[25] Although the results of continuing clinical trials comparing 12 and 24 month duration MB-MDT are not available as yet, 12 month MB-MDT is currently used in leprosy control programs in endemic countries.

Some authorities in developed countries prefer to use more frequent doses of rifampin and continue to treat until the smears are negative, which can take 5–8 years. One approach is to double the dose of rifampin to 600mg daily for two consecutive days each month,[23] while others use daily rifampin 450–600mg for 2–3 years with dapsone and clofazimine. There is no evidence, however, that daily rifampin is more effective than when given once monthly.

If clofazimine is unacceptable because of pigmentation or if dapsone hypersensitivity occurs, minocycline (100mg daily) or ofloxacin (400mg daily) may be substituted.[25] Patients who have rifampin intolerance require two new drugs, minocycline and ofloxacin, along with clofazimine (50mg/day) for 6 months and then either drug with clofazimine for another 18 months.

Paucibacillary multidrug therapy

This is recommended for indeterminate, TT and smear-negative BT leprosy[2] and in the control programs for patients with "5 patches. PB-MDT comprises:

- ¦ rifampin, 600mg once a month, supervised administration; and
- ¦ dapsone, 100mg/day, self-administered.
