suggesting that a negative rather than a positive culture is of greater value to the clinician. A negative culture effectively excludes VAP when the patient has not received antibiotics. Quantitative cultures with a high cut-off level improve specificity and adversely affect sensitivity, but can produce results comparable with invasive techniques without the need for special equipment or training.[27] Daily quantitative bacterial cultures may identify a rapid rise in bacterial counts a few days before the development of new pulmonary infiltrates; regular surveillance with endotracheal aspirates may, therefore, be helpful.[27] The identification of elastin fibers and antibody-coated bacteria may increase the ability to differentiate between colonization and pneumonia.[26]

Nonbronchoscopic techniques for sampling the distal airways

Nonbronchoscopic techniques have the advantage of being less invasive and simple to perform both by medical and nonmedical staff, such as respiratory therapists;[31] small endotracheal tubes (such as in children) can be used, although samples cannot be obtained reliably from the area of the lung where infection is suspected. The simplest technique involves distal, nondirected bronchial lavage through a standard aspiration catheter.[6] In one study mean bacterial colony counts increased significantly during the 2 days preceding the clinical onset of pneumonia, with counts falling significantly after appropriate antibiotic therapy. In another study, the sensitivity and specificity of nondirected bronchial lavage, cultured quantitatively, were both about 69% and comparable to those of bronchoscopic methods, if performed on patients with a clinical diagnosis of VAP.[32] Blind techniques using plugged catheters or PSB samples and quantitative culture have reported sensitivities between 61 and 100% and specificity at a similar level.[28]

Bronchoscopic invasive procedures

Much has been published about the value of invasive techniques for managing HAP. However, questions as to who, when and how to perform these tests and the reliability of the results remain unresolved, as does the applicability of published results to everyday clinical situations.[1] [2] [25] [26] [27]

Fiberoptic bronchoscopy provides direct visual access to the lower airways. Bronchoscopic techniques are relatively simple to carry out in patients receiving mechanical ventilation, but such patients have often received antibiotics, reducing the value of bronchoscopic studies. Invasive techniques might be considered in nonventilated patients who have moderate or severe HAP before antibiotic therapy is started. In practice immediate access to bronchoscopic techniques may be limited and the procedure itself may on occasions precipitate cardiorespiratory failure in a spontaneously breathing but hypoxic patient, necessitating ventilatory support earlier than anticipated. Consequently nonbronchoscopic techniques are generally used for such patients, including on occasions invasive techniques such as percutaneous lung needle aspiration. Transtracheal aspirates are rarely used.

Protected specimen brush

The double catheter PSB (Fig. 35.4) is effective in avoiding contamination during passage through the bronchoscopic suction channel. Attention to correct technique is important for obtaining the specimen and transferring the brush to transport medium for quantitative culture. [26] [27] Briefly, the brush catheter is passed bronchoscopically to the segment from which the sample is to be obtained; the inner sheath is then extended, thus expelling the wax plug. Next, the brush is extended and then withdrawn back into the inner sheath. The catheter is then removed from the bronchoscope, the inner sheath end wiped with a 70% alcohol swab, and the brush cut aseptically, once it has been advanced from the inner sheath, into 1ml sterile normal saline. The sample is then immediately vortex-mixed and plated out in dilutions for quantitative culture. Numerous studies have reported a sensitivity of 33–100% and a similar specificity, using a threshold concentration of $=10^3$ cfu/ml on quantitative bacterial culture.[27] [28]

Bronchoalveolar lavage

For BAL, the bronchoscope is wedged into a subsegmental airway and the bronchoalveolar area is lavaged; volumes of over 100ml sterile normal saline are required to

reach the distal alveoli (Fig. 35.5).

The advantage of this technique is that a large part of the lung is sampled and the specimen allows microscopic analysis to assess the presence of intracellular bacteria, neutrophils and elastin fibers and cytologic evaluation if required. This can be particularly useful if the diagnosis of pneumonia is in doubt and malignancy is a diagnostic

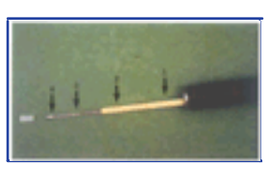

Figure 35-4 An extended protected specimen brush protruding from the end of a fiberoptic bronchoscope. Note the outer plastic sheath (arrow 1) and the inner protective yellow plastic cover (arrow 2) with the microbiologic brush pushed out (arrow 3). The protective gelatin plug occludes the end of the outer cover (arrow 4) until ejected before obtaining the specimen. *Reproduced from Macfarlane JT, Finch RG, Cotton RE. A Colour Atlas of Respiratory Infections. London: Chapman & Hall; 1993.*

possibility. Contamination of the BAL fluid in the bronchoscopic channel is one disadvantage and a careful technique is required to avoid this. After wedging the tip of the bronchoscope in the relevant subsegment, 50ml normal saline at 98.6°F (37°C) is instilled. This aspirate samples airways rather than the alveoli, is best referred to as a 'bronchial wash'[33] and is more likely to be contaminated with bacteria present in the suction channel. This sample should therefore be processed separately from the second, third and, if necessary, fourth aliquots of 50ml, which should be pooled. Sensitivity and specificity of BAL quantitative cultures have ranged from 42 to 100% and 69 to 100%, respectively, using threshold concentrations of $=10^4$ cfu/ml.

When compared with PSB performed at the same time, BAL has greater sensitivity but a marginally reduced specificity. Combining both techniques overcomes this problem and appears to provide the best results in experienced centers.[28] [34] An alternative is to perform a protected BAL using a balloon-tipped catheter (to allow effective wedging and isolation of a pulmonary subsegment) with a distal ejectable plug. This is reported to improve specificity compared with BAL and sensitivity compared with PSB, but adds to cost.[28] [35]

Percutaneous invasive techniques

Percutaneous lung needle aspirate

Percutaneous lung needle aspirate (PLNA) has been used successfully to investigate nonventilated patients who have lung shadowing. The technique can be performed at the bedside with minimal equipment. The use of a 25-gauge ultrathin needle reduces the chance of pneumothorax. In one study of 98 patients who had HAP outside the ICU, the sensitivity was 61%, the specificity 100% and the pneumothorax complication rate 3.5%. The latter reduces the usefulness of this technique in patients receiving mechanical ventilation. Animal models suggest a high sensitivity and specificity. [26] When compared with histologic diagnosis of pneumonia on lung biopsy immediately postmortem as a 'gold standard', PLNA had the lowest sensitivity (25%) but the highest specificity (79%) of the invasive techniques discussed. However, recent studies have questioned the value of immediate postmortem lung biopsies as the 'gold standard' for the diagnosis of pneumonia.[25] [36]

Transtracheal aspiration

Transtracheal aspiration is now rarely used due to the ready availability of fiberoptic bronchoscopy. However, its value was demonstrated for the investigation of patients who have suspected HAP on general medical and surgical wards.[20]

Influence of invasive techniques on management of HAP

The literature supports the view that PSB, BAL and tracheal aspirate specimens cultured quantitatively can provide useful and reliable information about the likely presence and cause of HAP in patients who have the clinical features of pneumonia, particularly in the ICU.[28] Their value is considerably diminished if the patient is already receiving antibiotics, which is the usual situation.[37] There is controversy as to whether these tests improve patient management and outcome in routine clinical practice. The effect of PSB results on antibiotic management was shown in one study of 110 mechanically ventilated patients who had suspected HAP.[38] Antibiotics were stopped in the majority before PSB was performed. Quantitative PSB culture supported the clinical diagnosis of pneumonia in only 41% of patients. The PSB results suggested that the initial treatment was appropriate in one-third of all patients, inappropriate in a further one-third (patients were receiving antibiotics that were not considered necessary) and the situation was unclear in the remaining one-third. Of the patients who had pneumonia, over one-third had their antibiotics changed because of the PSB result.

Although this study suggests that invasive techniques may influence immediate management, the literature does not generally show that using these techniques improves outcome. Randomized studies, summarized elsewhere, have also shown that invasive techniques lead to more antibiotic changes, increase costs, but do not affect mortality rate or morbidity.[2] [27] Only one randomized study, from France, has shown a bronchoscopic strategy including quantitative cultures of PSB and BAL specimens to be superior to a clinical strategy using qualitative tracheobronchial aspirates, in terms of 2-week mortality rate and overall morbidity.[39]

For now the clinician can consider using a diagnostic algorithm for patients with suspected VAP proposed by the recent evidence-based guidelines for the diagnosis of VAP,[27] [40] which provides an option of either starting directed treatment based on the results of quantitative culture of tracheobronchial samples obtained invasively or noninvasively, or starting immediate empiric treatment, obtaining tracheal samples for qualitative culture and then adjusting treatment according to culture results or response to treatment (Fig. 35.6). This suggests that invasive techniques and quantitative cultures should only be performed if the clinical and laboratory expertise is available and if the results are consistently applied to management decisions as part

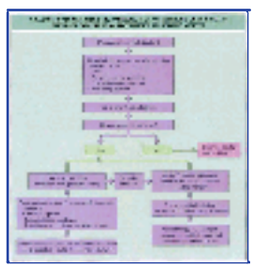

Figure 35-6 A diagnostic algorithm for the management of ventilator-associated pneumonia, depending on whether an empiric treatment approach or an investigation approach, (using quantitative culture of bronchoscopically or nonbronchoscopically obtained specimens), is adopted. *Adapted from Ioanas et al.[27] and Grossman et al.[40]*

of an agreed management protocol.[1] In practice, quantitative culture is time-consuming and demanding and is not performed routinely in all laboratories, which limits its usefulness in many hospitals.

MANAGEMENT

General factors

The general management of the patient who has HAP is important. Such patients frequently have underlying disease, which may be worsened by the infection and require additional therapy. Careful attention to fluid balance and oxygenation is essential, and chest physiotherapy may be helpful. Not infrequently the diagnosis of HAP may be uncertain and additional empiric therapy (e.g. anticoagulation for possible pulmonary embolus) may be started, pending results of appropriate investigations. Even with effective management, the prognosis may be poor because of the underlying disease or overwhelming infection. In only a proportion of patients dying with HAP is death directly attributable to the infection.

Guidelines for empiric antibiotic therapy

Guidelines from the ATS,[1] the Canadian Consensus Conference[15] and more recent reviews[2] have been published and provide a useful basis for the practical, empiric management of HAP. The decision tree is summarized in Figure 35.2 and Table 35.1 , Table 35.2 , Table 35.3 , Table 35.4 and depends on assessment of severity, the description of 'core' pathogens, the identification of risk factors for specific pathogens and time of onset to guide empiric antibiotic therapy. In a similar way to the empiric management of community-acquired pneumonia, patients who have severe infection are identified early and start by receiving combination antibiotic therapy to cover all likely pathogens. For nonsevere HAP, single antibiotic therapy is usually appropriate to cover the 'core' pathogens, unless additional risk factors are present.

Mild-to-moderate HAP; no risk factors for other pathogens; 'core' pathogens likely

In this situation a single agent effective against the 'core' pathogens, including Gram-positive organisms, *H. influenzae* and EGNB is appropriate.[10] [27] [41] Options include a second- or third-generation cephalosporin, such as cefuroxime, ceftriaxone or cefotaxime, or a combination of a ß-lactam antibiotic with a ß-lactamase inhibitor (e.g. amoxicillin or ticarcillin, together with clavulanic acid) or a new-generation fluoroquinolone with enhanced pneumococcal cover (e.g. levofloxacin or moxifloxacin; see Table 35.1). Oral therapy can be used if appropriate.

Mild-to-moderate HAP; risk factors present for specific pathogens in addition to 'core' pathogens

In this situation the specific risk factors will provide some guidance about whether additional antibiotic therapy may be required to cover pathogens such as anaerobes, more resistant EGNB and *Legionella* infection as well as the 'core' pathogens. Combination therapy may be required, including the antibiotic appropriate to cover the 'core' organisms (see Table 35.2).

Severe HAP

'Early' severe HAP occurring soon after hospital admission is likely to be caused by the 'core' organisms, in particular *S. pneumoniae*,

S. aureus and *H. influenzae* and is treated like nonsevere infection, except that the parenteral route should be used (see Table 35.1). For 'late' severe HAP occurring after 5 days of hospitalization, empiric therapy should cover *P. aeruginosa* and *Acinetobacter* spp. in addition to the 'core' organisms. Combination antibiotics providing antipseudomonal cover are required, including an antipseudomonal ß-lactam antibiotic (such as piperacillin/tazobactam, or ceftazidine or carbapenems (meropenem or imipenem/cilastatin) together with either an aminoglycoside or a fluoroquinolone (such as ciprofloxacin), or both. Methicillin-resistant *S. aureus* has become a problem in many institutions and requires the addition of vancomycin (see Table 35.4).[42]

Duration of therapy

There is no clear evidence on which to base a decision about the duration of treatment and clinical judgement is required, supported by improvement in observations, tracheobronchial secretions, inflammatory markers such as C-reactive protein and white cell count, and radiological shadowing. Generally there is a tendency to treat patients for longer than those with community acquired pneumonia (which is usually treated for 5–7 days). In particular, treatment for *Pseudomonas* or *Legionella* spp. may require up to 14 days or longer of antibiotics, particularly if lung cavitation is present with *Pseudomonas* infection. When possible oral therapy should be substituted for the parenteral route, if clinical progress in satisfactory and the oral route is available. Patients on the ICU or receiving mechanical ventilation or following surgery may have problems with enteral absorption and require continued intravenous therapy. A balance must be struck because prolonged antibiotics run the risk of promoting the selection of resistant organisms in the patient and in the unit, and also causing antibiotic side-effects such as *Clostridium difficile*-associated colitis.

Factors to consider when assessing response

Assessment of the response of the patient who has HAP is difficult because of the complex relationship between the infection and the underlying disease. Factors to consider if the patient is not responding to empiric therapy are shown in Table 35.6 , and have been reviewed elsewhere. *P. aeruginosa* and MRSA are the two pathogens most frequently associated with treatment failure.[1] [2]

TABLE 35-6 -- Factors to consider when a patient with hospital-acquired pneumonia is not improving with initial management.

FACTORS TO CONSIDER WHEN A PATIENT WITH HOSPITAL-ACQUIRED PNEUMONIA IS NOT IMPROVING WITH INITIAL MANAGEMENT	
Factor	**Action**
Improvement expected too soon	Continue therapy — review again
Deterioration in underlying disease	Optimize general management
Diagnosis of hospital-acquired pneumonia incorrect	Review situation
	Consider differential diagnosis
Additional pathologic process present	Review situation
	Consider differential diagnosis
Additional or unexpected pathogen present	Review microbiologic data
	Consider alternative or invasive tests
Pathogen resistant to antibiotic	
Local intrathoracic complication (e.g. empyema, lung abscess)	Review chest radiographs
	Consider CT scan, bronchoscopy
Metastatic infective complication (e.g. endocarditis, arthritis, abscess)	Detailed clinical examination and appropriate tests
Reason for pneumonia persisting (e.g. aspiration, bacteremia from distant focus)	Review history
	Repeat blood cultures
Secondary complications (e.g. intravenous line infection, pulmonary emboli)	Detailed clinical examination and further studies (e.g. V/Q scan)
General factors (e.g. dehydration, nutrition, hypoxia)	Manage appropriately
Allergic reaction to antibiotics (often after several days of therapy)	Look for rash and recurrence of fever
	Consider stopping/changing antibiotic
Patient not actually receiving or taking the antibiotic	Check

Chapter 36 - Lung Abscesses and Pleural Abscesses

Julie E Mangino

INTRODUCTION

Lower respiratory tract infections (LRTIs) are a major indication for antimicrobial therapy in developed countries. Although many LRTIs are self-limiting, those caused by necrotizing organisms are invariably serious; they may lead to abscess formation in the lung and can spread to the pleural space.

EPIDEMIOLOGY

The etiologies of lung abscess and pleural abscess, or empyema, vary in different parts of the world. The common denominator is usually aspiration pneumonia, acquired either in the community or in the hospital. Nosocomial pneumonia is a major cause of morbidity and lengthened hospital stay, with enormous economic impact. Aspiration pneumonia leading to necrotizing pneumonia or lung abscess, with or without empyema, is a continuum; any stage or all stages may be encountered. Underlying diseases, associated trauma or surgery and the timeliness of appropriate therapy are the major factors in determining clinical presentation and prognosis.

Lung abscess

A lung abscess is arbitrarily defined as a localized area of pulmonary necrosis caused by infection, with a solitary or dominant cavity measuring at least 2cm in diameter. When cavities are multiple and smaller than 2cm, the infection is usually referred to as a necrotizing pneumonia.[1] [2] [3] Most abscesses are suppurative bacterial infections caused by aspiration.

Primary lung abscesses typically present in patients who have no predisposing disease other than a predilection to aspirate oral secretions; they are more common in males than in females. Secondary lung abscesses occur in patients who have an underlying condition such as a partial bronchial obstruction or lung infarct, or in those who are otherwise immunocompromised because of chemotherapy, malignancy, organ transplantation or HIV infection. Lung abscesses may be termed non-specific or putrid, referring, respectively, to the often unclear etiology and the offensive odor of the sputum.[3] [4]

Over the past five decades, the incidence of bacterial lung abscess in the USA has diminished considerably and the mortality rate has decreased from 30–40% to 5–10%. Factors associated with a worse prognosis include advanced age, prolonged symptoms, concomitant disease, nosocomial infection and (according to some studies) larger cavity size. In the past, tuberculosis was responsible for a higher proportion of lung abscesses. In recent years, more lung abscesses have been associated with pulmonary malignancies or other underlying conditions.[3] [4] [5] [6] [7]

Empyema

A pleural effusion associated with pneumonia, lung abscess, or bronchiectasis is referred to as a parapneumonic effusion. These occur in up to 40% of people who have bacterial pneumonia; they are the most common cause of exudative pleural effusions in the USA.[8] Empyema, or pleural pus, is an infected parapneumonic effusion with characteristic changes in the composition of the pleural fluid. It has been declining in frequency and changing in etiology. [6] Mortality ranges from approximately 2% to 50%, with the lowest rates in young, healthy people and the highest rates in the elderly and immunocompromised. The prognosis is poorer when pathogens are resistant to antimicrobial drugs or when appropriate treatment is delayed.[8] [9] [10]

PATHOGENESIS AND PATHOLOGY

Micro-organisms gain access to the lower respiratory tract by a variety of routes, including inhalation of aerosolized particles, aspiration of oropharyngeal secretions and hematogenous spread from distant sites (Fig. 36.1). Less frequently, infection occurs by direct extension from a contiguous site. Lung abscess is caused only by organisms that cause necrosis but empyema can result from infection by any pathogen that reaches the pleural space.

Lung abscess

Of the inhaled respiratory pathogens, only the mycobacteria (see Chapter 37 and Chapter 38) and the dimorphic fungi (see Chapter 39) commonly cause lung abscesses. Bacterial abscesses are usually caused by aspiration of oropharyngeal secretions or, occasionally, by hematogenous seeding. [1]

Aspiration of small quantities of oropharyngeal secretions occurs intermittently in everyone, particularly during sleep. Despite the frequency of aspiration, the airways below the level of the larynx are normally sterile. Highly efficient clearing mechanisms are in place; these include cough, a mucociliary system that carries particles cephalad to be swallowed, phagocytosis by alveolar macrophages and neutrophils aided by opsonizing antibodies and complement, and lymphatic trapping with sequestration in regional lymph nodes. Risk factors for pneumonia after aspiration include conditions that increase the inoculum of pathogenic organisms in aspirated secretions, conditions that increase the likelihood of aspiration and conditions that increase the volume of the aspirate (Table 36.1). Under these circumstances, aspirated oropharyngeal secretions are more likely to cause chemical irritation and infection. When an anaerobic pleuropulmonary infection occurs in an edentulous patient, the diagnosis of bronchogenic carcinoma should be considered.[1] [2] [3] [11]

The composition of the oropharyngeal flora at the time of aspiration determines the potential etiologic agents for LRTIs. Those organisms that are most numerous or virulent proliferate and emerge as single or predominant pathogens. Although the classic non-necrotizing respiratory pathogens *Streptococcus pneumoniae* and *Haemophilus influenzae* can cause disease by this mechanism, normal oropharyngeal secretions contain many more streptococci of various species and more anaerobes (approximately 10^8 organisms/ml) than aerobes (approximately 10^7 organisms/ml). Some of the streptococcal species are microaerophilic (i.e. they require supplemental carbon dioxide to grow on artificial media).[12] [13] The pneumonia that follows aspiration, with or without abscess formation, is typically polymicrobial with between two and four bacterial species present in large numbers. In

Figure 36-1 Causes of LRTIs in adults. Oropharyngeal streptococci and anaerobes, *Staphylococcus aureus*, Enterobacteriaceae, *Pseudomonas aeruginosa*, the dimorphic fungi (*Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*) and mycobacteria frequently cause necrosis and subsequent abscess formation.

TABLE 36-1 -- Risk factors for aspiration pneumonia and lung abscess.

RISK FACTORS FOR ASPIRATION PNEUMONIA AND LUNG ABSCESS	
Increased bacterial inoculum	Periodontal disease, gingivitis, tonsillar or dental abscess, drugs that decrease gastric acidity
Impairment of consciousness	Drugs, alcohol, general anesthesia, metabolic encephalopathy, coma, shock, cerebrovascular accident, cardiopulmonary arrest, seizures, surgery, trauma
Impaired cough and gag reflexes	Vocal cord paralysis, intratracheal anesthesia, endotracheal tube, tracheostomy, myopathy, myelopathy, other neurologic disorders
Impairment of esophageal function	Diverticula, achalasia, strictures, disorders of gastrointestinal motility, neoplasm, tracheoesophageal fistula, pseudobulbar palsy
Emesis	Nasogastric tube, gastric dilatation, ileus, intestinal obstruction

general, 50% or more of these infections are caused by purely anaerobic bacteria, 25% are caused by mixed aerobes and anaerobes, and 25% or fewer are caused by aerobes only. Among hospitalized patients, progressive colonization with *Staphylococcus aureus*, Enterobacteriaceae and *Pseudomonas aeruginosa* occurs, and these aerobic organisms are frequent causes of nosocomial aspiration pneumonia and lung abscess.[6] [12] [14] [15]

The anaerobic organisms that are associated with pleuropulmonary infection, using current nomenclature,[16] [17] are shown in Table 36.2 . The primary pathogens are *Streptococcus* spp., *Peptostreptococcus* spp., *Fusobacterium nucleatum* and *Prevotella* spp. Additionally, *Porphyromonas* spp. are commonly associated with periodontal disease and may also be isolated. Although not consistently part of the normal oropharyngeal flora, members of the

(Note: *Porphyromonas* spp. include organisms previously named *Bacteroides melaninogenicus* subsp. *asaccharolyticus*, *B. endodontalis* and *B. gingivalis*. *Prevotella* spp. include organisms previously named *B. melaninogenicus* subspp. *melaninogenicus* and *intermedius*, *B. oralis* and *B. denticola*. *Gemella morbillorum* was previously named *Streptococcus morbillorum*. *Peptostreptococcus* spp. include organisms previously named *Peptococcus* spp.)		

Bacteroides fragilis group of organisms are isolated from approximately 15% of patients.[2] [11] [12] [13] [14] [16]

A variety of virulence factors associated with oropharyngeal streptococci and anaerobes have been identified. Properties that facilitate attachment include capsular polysaccharides, fimbriae, hemagglutinin and lectin. Tissue breakdown and the metabolic activity of organisms provide reducing substances and a low redox potential; these factors facilitate bacterial proliferation. Volatile fatty acids, sulfur compounds, indoles, amines and hydrolytic enzymes (hyaluronidase, chondroitin sulfatase and heparinase) produced by damaged tissue lead to subsequent abscess formation.[18]

The pathology of aspiration pneumonia is characterized by alveolar edema and infiltration with inflammatory cells. Foci of aspiration pneumonia most commonly develop in the subpleural regions of the gravity-dependent segments of the lungs, particularly the superior segments of the lower lobes and the posterior segments of the upper lobes. The right lung is the more frequent location, presumably because of the less acute angle in the take-off of the right main stem bronchus. In general, the right upper and lower lobes are most commonly involved, followed by the left lower lobe and right middle lobe.[1] [3] [19] [20]

The degree and rate of progression of aspiration pneumonia vary considerably. These infections may be acute, subacute or chronic, depending on differences in the etiology, size of inoculum and host factors. If the process is indolent, fibrosis limits the spread of infection. Abscesses typically communicate with a bronchus, producing the familiar air-filled cavity, often with an air-fluid level that can be seen on radiographs. These are usually not apparent until the infection has been present for 1–2 weeks, when multiple adjacent microscopic abscesses filled with necrotic material (pulmonary gangrene) slough to form a gross cavity (Fig. 36.2).[5]

Although less common than aspiration, hematogenous seeding of the lung, or septic emboli, may also result in lung abscesses or necrotizing pneumonia. There may be a solitary infiltrate or cavity or, more often, multiple bilateral lesions. The most common etiologic agents are the nosocomial pathogens *S. aureus* and aerobic Gramnegative bacilli (see Fig. 36.1). When the primary focus is in the abdomen, anaerobes, particularly *B. fragilis*, may be present.

Infective endocarditis (predominantly right-sided), intravenous drug injection and indwelling right atrial catheters placed for vascular access are commonly associated with septic pulmonary emboli. Any organism that is part of the skin flora or contaminants in injected material may be responsible. *Staphylococcus aureus* and streptococci are the most common pathogens but *P. aeruginosa* and *Candida* spp. may also be responsible, causing serious infections.[21]

Some uncommon causes of lung abscess should be considered in appropriate circumstances. Inhaled micro-organisms such as *Legionella* spp., *Chlamydia* spp., *Mycoplasma pneumoniae* and viruses are rare causes of lung abscesses. *Cryptococcus*, *Aspergillus*

Figure 36-2 Cross-section of a lung abscess.

and *Rhizopus* spp. occasionally cause disease in normal hosts but are more commonly opportunistic pathogens. Patients who have advanced HIV disease may have cavitary lesions caused by atypical mycobacteria, particularly *Mycobacterium kansasii*, and other organisms such as *Rhodococcus equi* and *Nocardia asteroides*.[22] *Burkholderia pseudomallei* is endemic to South East Asia, particularly Thailand, and typically causes upper lobe cavities. In endemic areas, the parasites *Paragonimus westermani* and *Entamoeba histolytica* may cause abscess by contiguous extension.

Empyema

The pleural space is normally sterile. It is most commonly contaminated by direct extension from a contiguous focus of infection, usually pulmonary, or by direct inoculation at the time of trauma or surgery (Table 36.3).[8] [23] [24] The pleural space may also become involved through hematogenous seeding from a distant focus of infection, particularly in the presence of hemothorax or pleural malignancy.

The initial stage in the pathogenesis of empyema associated with pneumonia is the development of a sterile parapneumonic effusion, which has varying characteristics depending on its stage of evolution (Table 36.4).[8] [24] The effusion is initially transudative but rapidly becomes exudative with an influx of leukocytes and increasing permeability of the visceral pleura. Neutrophils, lactate dehydrogenase (LDH) and protein increase, and glucose and pH decrease. Fibrin is deposited on the pleural surfaces and loculations may occur. With time, a final organizing stage occurs in which pleural fibroblasts produce an inelastic membrane or pleural peel that encases the lung and restricts inflation. Invasion with bacteria accelerates the fibropurulent reaction. Empyema fluid is relatively deficient in opsonins and complement and it becomes progressively more acidic as the infection ensues. Occasionally, an empyema may spontaneously drain through necrotic lung tissue into a bronchus (bronchopleural fistula) or communicate through the chest wall (empyema necessitans).[8] [10] [24]

The various respiratory pathogens have different propensities to cause empyema. *Streptococcus pneumoniae*, the most common cause of pneumonia, is frequently associated with a parapneumonic pleural effusion, yet pneumococcal empyema is relatively uncommon. Aspiration pneumonia more frequently progresses to empyema.[8] Empyema is also more common with organisms, such as *S. aureus* and *P. aeruginosa*, that produce potent extracellular enzymes that breach the integrity of the pleura, allowing penetration to the pleural space.

Overall, the relative frequencies of various organisms causing empyema have changed over time. Prior to the antibiotic era, most

TABLE 36-3 -- Causes of empyema.

CAUSES OF EMPYEMA	
Pulmonary infection	Pneumonia
	Lung abscess
	Bronchiectasis
Mediastinal disease	Tracheal fistula
	Esophageal perforation
Subdiaphragmatic infection	Subphrenic abscess
	Hepatic abscess
Skeletal infection	Paravertebral abscess
	Vertebral osteomyelitis
Direct inoculation	Trauma
	Thoracentesis
Postoperative	Hemothorax (infected)
	Pneumothorax (infected)
	Bronchopleural fistula

TABLE 36-4 -- **Characteristics of pleural fluid associated with bacterial LRTIs.***

CHARACTERISTICS OF PLEURAL FLUID ASSOCIATED WITH BACTERIAL LRTI				
Pleural fluid characteristic	**Transudate**	**Exudate**		**Empyema**
		Uncomplicated parapneumonic effusion	**Complicated parapneumonic effusion**	
Appearance	Clear	Variable	Variable	Pus
White blood cell count (cells/ml)	<1000	Variable	Variable	>15,000
Differential cell count	Variable	Neutrophils	Neutrophils	Neutrophils
Protein (g/dl)	<3.0	>3.0	>3.0	>3.0
Glucose (mg/dl)	Same as serum	>60	40–60	<40
pH	Greater than serum	>7.2	7.0–7.2	<7.0
Lactate dehydrogenase (units/ml)	<200	<1000	>1000	>1000
Bacteria	Absent	Absent	Absent	Present
The values may overlap. Complicated pleural effusions are those with fluid characteristics that indicate the potential need for tube drainage. When the glucose is 40–60mg/dl or the pH is 7.0–7.2, repeat thoracentesis may be helpful. When the glucose is <40mg/dl or the pH is less than 7.0, a chest tube is indicated even if bacteria are not present by smear or culture.				

** Data from Light[8] and Sokolowski et al.[25]*

FREQUENCY OF ORGANISMS ISOLATED FROM BACTERIAL EMPYEMAS			
Organism	**% of isolates**		
	1971–1973[28] (*n* = 214)	**1969–1978[9] (*n* = 93)**	**1973–1985[29] (*n* = 343)**
Haemophilus influenzae	<1	0	3
Streptococcus pneumoniae	2	7	20
Other streptococci (including microaerophiles)	13	22	8
Staphylococcus aureus	8	8	17
Enterobacteriaceae	9	10	11
Pseudomonas spp.	5	9	3
Other aerobes	5	2	2
Bateroides spp.	11	14	8
Anaerobic cocci	15	9	10
Fusobacterium spp.	7	8	6
Prevotella spp.	6	4	6
Other anaerobes	19	7	6

empyemas were caused by *S. pneumoniae* and, to a lesser extent, by *S. aureus* and *Streptococcus pyogenes*. Between 1955 and 1965, penicillin-resistant *S. aureus*

was the predominant pathogen.[8] [26] In the early 1970s, coinciding with a surge of interest in anaerobic infections, anaerobic empyemas were recognized more frequently (Table 36.5).[27] [28] At that time, about 50% of empyemas were caused by aerobes, with Gram-positive cocci being more common than Gram-negative bacilli. About 25% were caused by anaerobes and about 25% were mixed aerobic-anaerobic infections. *Streptococcus pneumoniae* was most frequent in young ambulatory patients, anaerobes were most frequent after aspiration, and *S. aureus* and aerobic Gram-negative bacilli were most frequent after thoracotomy. [9] [28] [29] [30] Because one-quarter of all empyemas are now associated with trauma or surgery, there has been a relative increase in the proportion of staphylococcal infections and a decrease in anaerobic infections.[8] With the widespread use of *H. influenzae* type b vaccination, empyema due to this organism, previously common in children, has become rare.

PREVENTION

Minimizing the risks of aspiration in people who are unconscious, undergoing anesthesia or subject to seizures will reduce the incidence of pneumonia with subsequent abscess formation or empyema. If pneumonia does occur, the timely administration of appropriate antibiotics reduces the likelihood of progression. Pleural effusions should be aspirated for diagnosis and drained, if indicated, to abort progressive suppurative complications.

CLINICAL FEATURES

Lung abscess

Aspiration is usually subtle and unrecognized but may lead to pneumonia and lung abscess. If overt, it may be followed by symptoms and signs such as choking, cough, wheezing, cyanosis or asphyxia, which are related to the particulate, liquid and chemical nature of the material aspirated. Within hours, there may be fever, tachypnea, diffuse rales and hypoxemia.[11] [30] If pneumonia develops, patients usually present within 1 week with a productive cough, a temperature over 102°F (38.9°C) and a leukocyte count of more than 15,000 cells/mm^3 .[30] Aspiration pneumonia is not readily distinguishable from pneumococcal pneumonia, although true rigors are uncommon in aspiration pneumonia and symptoms have usually been present for longer before presentation to medical care. A condition predisposing to aspiration is also more likely to be present. Among community-acquired cases, common conditions that predispose to aspiration are alcoholism, seizures and drug overdose. Among hospital-acquired cases, patients tend to have neurologic disorders, such as cerebrovascular accidents and brain tumors, or metabolic disorders that result in stupor or coma. Only a minority of patients who have aspiration pneumonia have putrid sputum, which, if present, tends to develop 1–2 weeks into the course when an abscess has formed.[6] [12] [14] [30]

Lung abscesses may also present in a more indolent fashion with weeks to months of productive cough, malaise, weight loss, low-grade fever, night sweats, leukocytosis and anemia. The patient may become debilitated as if with tuberculosis. Findings that are suggestive of a suppurative lung abscess rather than tuberculosis include a shorter duration of symptoms, putrid sputum and leukocytosis. Lung abscess must also be distinguished from a necrotic neoplasm. Patients who have neoplasms often lack risk factors for aspiration, symptoms of respiratory infection, fever and leukocytosis. The possibility

of tuberculosis or a noninfectious cause of a lung cavity (neoplasm, infarct, or vasculitis) should be suspected in a patient treated for presumed lung abscess who does not respond to appropriate antimicrobial therapy.

In the pre-antibiotic era, lung abscess characteristically ran a chronic course with the potential for sudden, severe complications. These included brain abscess, massive hemoptysis, endobronchial spread to other portions of the lung, and rupture into the pleural space with the development of a bronchopleural fistula and pyopneumothorax. With modern antimicrobial therapy, these complications have become rare.

Empyema

Symptoms of empyema include fever, chills, cough, dyspnea and chest pain associated with a recent pulmonary or contiguous infection in the oropharynx, mediastinum or subdiaphragmatic area. The occurrence of persistent fever and leukocytosis with pleural effusion despite appropriate antibiotics should suggest the presence of empyema. There may also be severe constitutional manifestations such as shock, tachypnea, altered consciousness and respiratory failure. Typical findings on physical examination include diminished breath sounds, dullness to percussion and a pleural friction rub. Patients who have an empyema secondary to an aerobic pneumonia tend to present with an acute illness, whereas those who have an anaerobic pneumonia have subacute or indolent illness with findings such as putrid sputum to suggest the etiology. [1] [5] [30]

DIAGNOSIS

Radiography

Both lung abscess and empyema may be suspected from clinical symptoms but the chest radiograph is the primary tool for diagnosing these infections. Radiographs obtained soon after aspiration usually demonstrate localized or diffuse alveolar infiltrates within 1–2 days. There is nothing distinctive about the appearance of aspiration pneumonia except that infiltrates are usually in dependent segments of the lung.

The characteristic appearance of a lung abscess is that of a density or mass with a cavity, frequently with an air-fluid level indicating communication with the tracheobronchial tree (Fig. 36.3). The time required for cavitation after a known episode of aspiration is about 1–2 weeks. With necrotizing pneumonia, multiple small lucencies in circumscribed areas of opacification may develop more rapidly.[2] [5] [6] Abscesses

Figure 36-3 A lung abscess showing an air-fluid level.

due to tuberculosis are less likely to have an air-fluid level and are more likely to have a dense fibronodular infiltrate that surrounds the cavities.[20] Those associated with a malignancy may be more sharply defined or have an eccentric-shaped cavity with a thick, irregular wall (Fig 36.4).

A pleural effusion, visible on posterior-anterior and lateral upright chest radiographs, suggests the possibility of empyema. On a decubitus film, with the suspect side down, free pleural fluid can be visualized between the chest wall and the dependent lung. If the layer of pleural fluid is greater than 1cm thick, it should be aspirated for diagnostic studies. A decubitus film with the suspect side up is also useful because it permits assessment of any underlying parenchymal infiltrate, less obscured by the effusion.[8] [24]

Ultrasound and computerized tomography (CT) may be helpful in defining pleuropulmonary lesions. Ultrasound can define loculated collections of pleural fluid, and portable equipment is available for unstable or critically ill patients. Computerized tomography can define abscesses that are not apparent on plain radiographs and can distinguish between parenchymal and pleural disease (Fig. 36.5). Loculated empyema with a bronchopleural fistula may resemble a lung abscess. Features on CT that tend to favor lung abscess are the presence of thick walls and lesions that are round or oblong, whereas empyemas have thinner walls with a smooth luminal margin and exterior.[31] Both ultrasound and CT may be used to guide aspiration of fluid from abscesses or the pleural space.

Investigations

The first step in determining the specific etiology of any LRTI is the evaluation of lower respiratory tract secretions by Gram stain. These are most likely to be useful if they are obtained before the administration of effective antimicrobial treatment. If stains of expectorated specimens show neutrophils and alveolar macrophages, without

Figure 36-4 A lung abscess associated with a multinodular bronchogenic carcinoma.

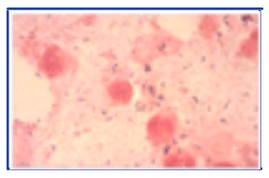

Figure 36-6 Gram stain of lower respiratory tract secretions. The patient had a lung abscess caused by oropharyngeal streptococci and anaerobes.

squamous epithelial cells (indicative of contamination with saliva), they are useful for defining the offending pathogen(s). In aerobic pneumonia there is usually a single predominant organism; in aspiration pneumonia there is usually a mixed flora, representing the diverse morphotypes of the oropharyngeal flora. Typically, there are various sizes of Gram-positive cocci and pleomorphic Gram-negative coccobacilli and bacilli, which may be tapered and are generally smaller and poorer-staining than the Enterobacteriaceae (Fig. 36.6). [1] [2] [11] [13] [32] Although some of the individual organisms may resemble pathogenic aerobes such as *S. pneumoniae*, there is no predominant pathogen.

Invasive procedures, such as endotracheal aspiration and bronchoscopy, may be useful to obtain lower respiratory secretions for evaluation. Tracheal aspiration through the nose or the mouth is of limited use because these specimens are often contaminated with oropharyngeal flora. Bronchoscopy with bronchoalveolar lavage is useful because large samples can be obtained with relatively little contamination. They can be concentrated by cytocentrifugation, permitting multiple microbiologic and cytologic evaluations. The bronchoscopic techniques of protected catheter aspiration and protected specimen brushing reduce contamination considerably but they provide relatively scanty specimens and rely on quantitative cultures to help distinguish the significance of cultures. In general, counts that indicate more than 10^5 cfu/ml of respiratory secretions for an appropriate organism (see Fig. 36.1 , Table 36.2) are indicative of infection.[1] [5] [15] [33]

Specimens of lower respiratory tract secretions that have passed through the mouth should be cultured for aerobes but not for anaerobes. Growth of recognized aerobic pathogens is helpful for interpreting Gram stains and for providing isolates for susceptibility testing. The absence of aerobic pathogens in specimens from untreated patients should indicate the possibility of anaerobic infection. When specimens are contaminated by saliva, the streptococci and anaerobes that comprise the normal oropharyngeal flora will always grow in culture, whether or not infection is present, and they provide no insight into the pathogenicity of the organisms isolated.

The problem of contamination of respiratory tract secretions by saliva can be avoided if specimens of lower respiratory secretions are obtained by transtracheal aspiration. A catheter is passed through the cricothyroid membrane and specimens are collected by suction.[1] [12] [14] Although infrequently used today, this technique established the role of anaerobes in suppurative pleuropulmonary infections in the early 1970s. Another method for obtaining uncontaminated material for culture is percutaneous transthoracic needle aspiration (percutaneous abscess drainage). Today, this procedure is more frequently performed under fluoroscopic or CT guidance for the diagnosis of malignancy than to obtain material for culture. It can be used, however, to aspirate peripheral abscesses, particularly if bronchoscopy does not provide an adequate specimen for microbiologic diagnosis.

If appropriate specimens from the lower respiratory tract are obtained for culturing anaerobes, they should be expeditiously transported to the laboratory, with minimal exposure to air, for proper processing. If tuberculosis or fungal infection is in the differential diagnosis, appropriate smears and cultures should be requested. If a malignancy is suspected, cytologic stains should be performed.

In addition to lower respiratory tract secretions, blood and pleural fluid, if present, should also be sent to the laboratory for microbiologic evaluation. In anaerobic lung infections, blood cultures are rarely positive. Pleural fluid, if present, requires analysis of protein, LDH and glucose, and determination of pH, as well as microbiologic evaluation. With empyema, the Gram stain usually indicates the pathogens.[8]

MANAGEMENT

Lung abscess

In the past, penicillin G was the preferred drug for treating aspiration pneumonia and lung abscesses, as well as for all anaerobic infections above the diaphragm caused by oropharyngeal flora. In a study of over 70 patients hospitalized with lung abscesses in the 1960s, nearly all responded to intravenous penicillin G. Oral penicillin V in a dose of 3g/day was also effective and those rare patients who failed to respond to penicillin could be satisfactorily treated with tetracycline.[6]

In the 1970s, when transtracheal aspiration was used to define the microbiology of pneumonia and lung abscesses, concern over the use of penicillin was raised because of occasional therapeutic failures and the isolation of penicillin-resistant *B. fragilis* from some patients.[1] [14] However, in one study that compared clindamycin, a drug that is active against *B. fragilis*, with penicillin G in the treatment of aspiration pneumonia and primary lung abscess, there was no difference in rates of defervescence, radiographic clearing or ultimate outcome. Notably, seven patients from whom *B. fragilis* was isolated responded to penicillin.[34]

Subsequently, in a prospective study published in 1983 of 39 patients who had lung abscess, there were 0/19 failures with clindamycin and 4/20 failures with penicillin G. Resolution of fever and putrid sputum was more rapid with clindamycin (4.4 days) than penicillin G (7.6 days). Patients who did not respond to penicillin G ultimately responded to clindamycin.[35] In a 1990 study of 37 patients who had lung abscess or necrotizing pneumonia,[36] only 1/19 patients failed to respond to clindamycin, whereas 8/18 failed with penicillin G. In this study, patients underwent transtracheal aspiration or protected specimen brushing to culture for anaerobes; 9/10 of the penicillin-G-resistant strains were ß-lactamase producers. It is now recognized that there has been a change in the susceptibilities of the oropharyngeal Gram-negative anaerobes since the 1970s. Many, in addition to *B. fragilis*, are now ß-lactamase producers and resistant to penicillin. In a study of 449 isolates, which included *Bacteroides* spp. other than *B. fragilis*, *Fusobacterium* spp., *Prevotella* spp. and *Porphyromonas* spp. from 28 US medical centers, 57.9% of isolates were ß-lactamase producers.[37]

Today, transtracheal aspiration and other invasive procedures are rarely performed to determine the microbiologic etiology of aspiration pneumonia and lung abscesses in non-immunocompromised patients. Treatment is usually empiric and largely effective.[6] Clinical outcome

for most anaerobic infections seems to correlate with *in-vitro* data as broadly applied, and detailed study of individual cases does not seem to be necessary. Monitoring trends in susceptibility patterns and detailed study in problematic individual cases suffices.[30]

The in-vitro spectrum and clinical utility of antimicrobials for the treatment of lower respiratory tract bacterial infections is summarized in Figure 36.7 . For community-acquired infections that result from aspiration, and where oropharyngeal streptococci and anaerobes are the likely pathogens, penicillin G (or ampicillin or amoxicillin) remains an excellent foundation for treatment, but the addition of a ß-lactamase inhibitor or metronidazole is advisable owing to the frequency of ß-lactamase production among Gram-negative anaerobes.[30] [37] [38] Clindamycin is also a primary therapeutic agent, despite in-vitro resistance among some

Bacteroides and *Fusobacterium* spp. Resistance rates vary significantly in different geographic regions, so surveillance of resistance is important in assessing the utility in a given area.[4] [6] [32] [38] [39] Metronidazole alone is

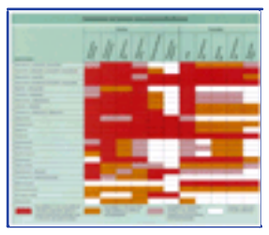

Figure 36-7 Antimicrobials for bacterial lung abscesses and empyemas. Information for *Streptococcus pneumoniae* is for penicillin-susceptible strains — selected cephalosporins or vancomycin should be used for resistant strains. Information for *Staphylococcus aureus* is for methicillin-susceptible strains — vancomycin should be used for resistant strains. Vancomycin is the drug of choice for ß-lactam-resistant Gram-positive organisms.

not effective because of its inactivity against the aerobic and microaerophilic streptococci. [6] [38] [40]

For hospital-acquired infections, where *S. aureus* and aerobic Gram-negative bacilli are common components of the oropharyngeal flora, piperacillin or ticarcillin (rather than penicillin or ampicillin) with a ß-lactamase inhibitor provide better coverage of likely pathogens. Appropriate alternatives are imipenem alone, clindamycin plus an aminoglycoside or ciprofloxacin, or an expanded spectrum cephalosporin such as cefotaxime, ceftizoxime, ceftriaxone or cefoperazone plus metronidazole. Many cephalosporins, for example ceftazidime, have little or no activity against anaerobes and should not be used unless the etiology has been defined and found to involve aerobic Gram-negative bacilli.[6] [10] [40]

Tetracyclines, which were used for lung abscess and empyema in the 1960s, are no longer recommended for the treatment of aerobic/anaerobic pleuropulmonary infections because of high rates of resistance. Chloramphenicol has an excellent spectrum of activity but it is

rarely recommended because of potential hematotoxicity and the availability of alternative agents.[6] [40] The macrolides and azalides have inconsistent in-vitro activity against oropharyngeal anaerobes and there is little clinical precedent for their use.[41] Aminoglycosides and quinolones should be used only for their activity against aerobic Gram-negative bacilli and need to be combined with a drug that is active against streptococci and anaerobes. A newer quinolone, such as moxifloxacin, has greater activity than ciprofloxacin or ofloxacin against oropharyngeal streptococci and anaerobes, and might prove to be more useful.[42] [43] Other agents that have suboptimal or no activity against oropharyngeal streptococci and anaerobes include aztreonam and trimethoprim-sulfamethoxazole. The antistaphylococcal penicillins and vancomycin should be reserved for staphylococcal infections.

The duration of antimicrobial therapy necessary to treat pleuropulmonary infections is variable: 1–2 weeks may suffice for simple aspiration pneumonia but necrotizing pneumonia and lung abscesses may require 3–24 weeks. Parenteral therapy is generally employed until the patient is afebrile (most are afebrile in 7 days) and able to have a consistent enteral intake.[30] For most community-acquired infections, amoxicillin-clavulanate and clindamycin are excellent oral drugs that can be used for continued treatment after initial parenteral therapy. A less costly oral alternative is penicillin V plus metronidazole. If aerobic Gram-negative bacilli are present, oral treatment is more problematic and must be based on the results of susceptibility tests; ciprofloxacin or ofloxacin plus a penicillin or clindamycin may be appropriate. Prolonged therapy is advisable, with treatment continued until the cavity is gone or until serial radiographs show considerable improvement or a small stable residual scar (Fig. 36.8). The time to cavity closure depends largely on the size of the cavity when treatment is initiated and the condition of the patient.

Surgical drainage of lung abscesses is rarely indicated because drainage occurs naturally via the tracheobronchial tree. If spontaneous drainage is not adequate, even with the aid of postural drainage and percussion, clinical improvement is impeded; CT-guided percutaneous abscess drainage may then be beneficial. The drainage catheter can be left in place until there is clinical improvement and drainage has diminished, usually within several days to 1 week. This

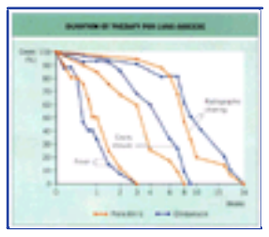

Figure 36-8 Duration of therapy for lung abscess. Response of patients who had lung abscess to penicillin G (17 patients) and clindamycin (16 patients).

technique may also be used to reduce the risk of endobronchial spread of infection to other areas of the lungs as well as in patients who are too ill to undergo lung resection to remove necrotic tissue, persistent cavities, or nonfunctional lung.

Empyema

The antimicrobial treatment of empyema is similar to that of aspiration pneumonia and lung abscess but single-organism infections with a defined etiology are more common, thus facilitating antibiotic choice. Antibiotics should be administered in full doses for 2–4 weeks. Therapy may need to be prolonged further, particularly if drainage is not optimal. Antibiotic levels in pleural fluid are comparable to those in serum, and so standard systemic doses provide adequate pleural fluid levels. [24]

The proper assessment and management of parapneumonic effusions associated with LRTIs is critical for a successful outcome. Most small effusions clear with antimicrobial treatment and need not be drained. However, if fluid persists more than a few days or layers to more than 1cm on a decubitus radiograph with the involved side dependent, it should be aspirated and analyzed. The characteristics of the fluid are used to determine the need for tube drainage (see Table 36.4).

Effusions are termed 'complicated' when characteristics indicate a potential need for tube drainage. Complicated effusions are termed 'empyemas' if they are frankly purulent and bacteria are present; tube drainage is mandatory. Chest tubes are placed using negative pressure until the lung is expanded, and then to an underwater drainage system until the fluid is scanty and clear, and then gradually withdrawn over a period of several days. Lack of prompt clinical improvement may indicate the need to reposition the tube to facilitate and continue drainage.

Chest tube drainage of complicated parapneumonic effusions is successful in most patients. It should not be delayed, because these effusions can progress from free-flowing to loculated fluid rapidly. When the fluid becomes loculated, drainage by repeated thoracentesis or tube insertion may not be adequate. The presence of loculated fluid should be suspected if the patient remains ill or febrile or has a persistent leukocytosis. After appropriate evaluation by ultrasound or CT, options for management include image-guided percutaneous drainage by an interventional radiologist [44] or instillation of thrombolytic agents (urokinase or streptokinase) through a catheter or chest tube.[45] If administered before fibrosis occurs, these agents attack the fibrin membranes causing the loculations. Successful therapy leads to an increase in the amount of drainage from the pleural space and can be administered for up to 2 weeks. Thoracoscopy to mechanically lyze adhesions and inspect the pleural cavity has also been used to assist in management.[8]

If patients do not respond to the above measures, contrast material can be injected into the chest tube to evaluate the empyema cavity. Open drainage, evacuation of all infected material and decortication of the pleura should be considered. This is a major surgical procedure that requires rib resection and may not be tolerated by debilitated patients. Open drainage, without decortication, may be better tolerated in these patients, but it is followed by a prolonged period of convalescence with an open chest wound.[8]

A serious complication of empyema is a bronchopleural fistula. The presence of a peripheral air-fluid level radiographically suggests the presence of a bronchopulmonary fistula, although such an air-fluid level may occasionally be due to the presence of gas-forming bacteria. Adequate tube drainage is mandatory to minimize spread of infection to other portions of the lungs. Empyema with a bronchopleural fistula after pneumonectomy is a disastrous surgical complication. The fistula often does not close with antibiotics, tube drainage and irrigation, and complex surgical procedures are usually necessary.[8]

Chapter 37 - Tuberculosis

Jon S Friedland

INTRODUCTION

Mankind has been plagued throughout history by tuberculosis (TB). It has been identified in skeletons over 6000 years old and remains the most prevalent infectious disease in the world. Among a long list of notable patients are Samuel Johnson, Jean-Jacques Rousseau, John Keats and Fyodor Dostoyevsky. This chapter focuses on current understanding of the pathophysiology, epidemiology and clinical aspects of tuberculosis.

EPIDEMIOLOGY

Worldwide incidence and prevalence

Mycobacterium tuberculosis is estimated to infect 1.6 billion people worlwide or approximately one-third of the world's population.[1] Usually infection is contained by the immune system so that about 15 million people have clinical disease at any one time. Tuberculosis kills around 2–3 million people each year, which is more than any other single bacterial infectious disease. Recent data on TB incidence rates are shown in Figure 37.1 . In most countries, there is a statutory requirement to notify cases of TB, but collection of data is notoriously incomplete, with under-reporting of cases.[2] Confounding factors in the global collection of incidence and prevalence data include effects of treatment, difficulties in identifying extra-pulmonary disease and those associated with tuberculin testing (see 'Testing for exposure' later in chapter). However, the size of the TB problem is such that it has been uniquely identified as a 'global emergency' by the World Health Organization (WHO).

Over 96% of TB-related deaths occur in the poorer nations of the world and the disease has huge social and economic costs. In wealthier nations, the rates of TB have been falling over the past 80 years, partly as a result of the development of effective treatments, active case finding and use of the bacille Calmette-Guérin (BCG) vaccine. Recently, this trend has been halted in some countries because of the increased incidence of TB in high-risk population groups, including poorer communities, immigrants and patients who have HIV infection. Levels of disease in homeless populations in developed countries can be as high as 2%.[3]

Impact of HIV and immunosuppression

Approximately 8 million people are coinfected with HIV and TB, the majority of whom live in sub-Saharan Africa, the Indian subcontinent and South East Asia (Fig. 37.2). HIV-positive patients appear more susceptible to infection by *M. tuberculosis*. Subsequently, approximately 50% of people who have dual infection will develop clinical TB, and reactivation rates may be over 20 times greater than in similarly aged controls.[5] Clinical TB is associated with shorter survival in people who have AIDS.[6]

In many developed countries (e.g. USA, France, Germany and The Netherlands) HIV infection has led to well-documented increases in localized and disseminated TB. In the USA and elsewhere, people who have TB are offered screening for HIV. Miliary TB accounted for less than 1.5% of cases of TB in the USA for 20 years, but recently, in some areas, disseminated disease has accounted for up to 10% of cases.[7] In contrast, in the UK and some Scandinavian countries, the increased incidence of TB has been associated with economic deprivation rather than HIV infection.[8]

Diagnosis of dual infection can be difficult because HIV infection predisposes to atypical, nodal and extrapulmonary TB. In addition to HIV infection increasing the incidence of clinical TB, infection with *M. tuberculosis* appears to increase viral replication and HIV disease progression.[9] This is in part because tuberculosis activates nuclear factor kappa B (NF-?B)-dependent transcription of the HIV genome (see Chapter 120).[10] [11] In more affluent countries and in settings in which TB is unexpected, malignancies, chemotherapy and other systemic illnesses characterized by immunosuppression can lead to reactivation of TB. For example, the incidence of TB is very high in renal dialysis patients.[12] More recently, the use of specific antibodies to neutralize tumor necrosis factor (TNF) activity in rheumatoid arthritis has been associated with TB.[13]

Multidrug-resistant tuberculosis

Drug-resistant TB emerged rapidly. Isolated resistance to streptomycin therapy was noted in the 1940s almost immediately after the drug was introduced. The emergence of multidrug-resistant TB (MDR-TB), defined as resistance to a minimum of isoniazid plus rifampin (rifampicin), is a more recent phenomenon. It was noted in HIV-positive patients in the first part of the last decade in New York[14] and has since been widely reported. Resistance to second-line drugs has also emerged. [15] Multidrug resistance is caused by the sequential acquisition of single-drug resistance traits.[16] This has been a consequence of poor prescribing practice by doctors, patient non-compliance with treatment and the endogenous mutation rate of *M. tuberculosis*. The WHO has estimated the incidence of MDR-TB worldwide and this is shown in Figure 37.3 .

Spread of infection

Spread of infection is dependent on inhalation of aerosols from individuals who have pulmonary infection. Proximity to and duration of association with an index case are critical factors. There have been widely reported instances of spread of TB to airplane passengers from index cases traveling on the same flight. These cause considerable alarm, but the risk to fellow travellers is small and the WHO has issued guidelines for domestic and international flights, which are available on their web site.

Up to one-quarter of household contacts of an index case may acquire infection, although the extent to which individual genetic predisposition or immunologic impairment contributes to this is uncertain. The role of factors such as vitamin D deficiency and iron overload in the spread of TB are unknown. Spread of infection is quite separate to the development of disease, which occurs in less than 10% of infected persons and is significantly increased by impaired cell-mediated immunity. Congenital transmission of TB is not a significant factor in the natural spread of disease.

Transmission in closed institutions

Overcrowding contributes to the spread of TB among the poor. Close proximity to infected individuals is a significant issue in any closed institution and for health care workers. Many countries have specific guidelines for tuberculosis control in institutions (see 'Prevention'). Genetic techniques using restriction fragment length polymorphism (RFLP) analysis — often of the insertion sequence IS6110 — to provide DNA fingerprints has proved useful in documenting local outbreaks of TB, including those involving MDR organisms.[18]

In prisons, the situation is complicated by the fact that there is often an increased prevalence of HIV infection among inmates and inmates are regularly moved to other prisons or back into the community with little warning and are frequently poorly managed in terms of health services. Because prisoners are often released into poor circumstances and crowded hostels, the consequence of undetected or inadequately treated TB may be rapid spread of disease. An effective public health program with an active community care component can overcome such problems.

PATHOGENESIS AND PATHOLOGY

The pathogen

Mycobacterium tuberculosis, a restricted human pathogen, is a member of the order Actinomycetales, which is characterized by a complex cell wall rich in mycolic acids together with peptidoglycan and arabinogalactan, a complex polysaccharide molecule that surrounds the cell membrane. Many cell wall components are of pathogenic significance. Lipoarabinomannan (LAM) stimulates monocyte proinflammatory activity, principally by binding to the CD14 receptor, which is also the binding site for bacterial lipopolysaccharide. *Mycobacterium tuberculosis* was one of the first pathogens for which a complete genome sequence was obtained, which opens up the potential for novel diagnostic and therapeutic avenues.[19] The genome has a high G + C content (mean approximately 65%) and contains genes for aerobic, microaerophilic and anaerobic growth. Many genes are involved in lipid metabolism pathways. Details of other metabolic pathways within *M. tuberculosis* and of assimilation of nutrients such as iron, which is stored in association with mycobactins, are reviewed elsewhere.[20] Mycobacteria contain many proteins associated with growth, virulence and intracellular survival.[21] Among the most critical are the 10, 65, 70 and 90kDa families of heat shock proteins (hsps), the production of which is upregulated by environmental stress. Heat shock proteins are molecular chaperones involved in protein folding and assembly. Exactly how hsps confer survival advantage on *M. tuberculosis* is unknown. In addition, proteases that are involved in local tissue destruction have been isolated from mycobacteria.

Host immune factors

Monocytes, macrophages and phagocytosis

The principal tissue immune response in TB is the formation of granulomas comprising cells of the monocyte lineage, including multinucleate giant cells and T cells (Fig. 37.4). In the initial stages of the immune response, neutrophils are present, whereas more advanced disease is characterized by caseous necrosis and eventually deposition of calcium. After inhalation, *M. tuberculosis* is phagocytosed by the alveolar macrophage; similar fixed tissue cells are present elsewhere in the body. Pulmonary surfactant protein may enhance the process of phagocytosis. The phagocytosing macrophage initiates the host immune response (Fig. 37.5). Phagocytosis involves the complement receptors CR1, CR3 and CR4 as well as mannose receptors and

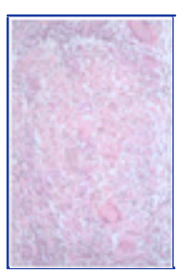

Figure 37-4 Detailed histology of the tuberculous granuloma. Monocytic cells and smaller T cells are shown together with multinucleate giant cells on the edge of an area of caseation.

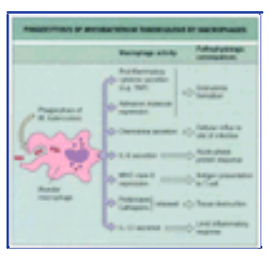

Figure 37-5 Phagocytosis of *Mycobacterium tuberculosis* by macrophages. Phagocytosis initiates many critical pathways involved in host defense to infection.

adhesion molecules.[22] Intracellular mycobacteria partly inhibit phagolysosome fusion, which prevents acidification of the vacuole. However, some mycobacterial components are detectable in the cytoplasm.

Phagocytosis is a potent stimulus to gene expression and secretion of proinflammatory cytokines such as TNF, interleukin (IL)-1 and IL-6. Phagocytosis of *M. tuberculosis* activates the transcription factors NF-IL-6 and NF-?B, both of which are important in proinflammatory cytokine gene activation.[23] The known consequences of TNF secretion include fever and cachexia, two prominent symptoms in TB. Tumor necrosis factor also has a pivotal role in granuloma formation and is found at sites of human infection. Injection of anti-TNF antibodies in a murine model decreased granuloma formation and increased replication of *Mycobacterium bovis*, BCG strain.[24] At early stages of infection, cellular recruitment to the granuloma is essential, and macrophage-derived chemokines are important in this process.[25] [26] The granuloma in TB is well circumscribed and it is likely that downregulatory cytokines such as IL-10 are involved in limiting inflammatory responses. Interestingly, when monocytes die by apoptosis there may be associated killing of intracellular mycobacteria, although how crucial this is in humans is unknown.[27] Surprisingly little is known about what exactly kills *M. tuberculosis* in humans.

Infected macrophages are probably involved in the tissue damage characteristic of TB although the exact cause of typical caseous necrosis remains unknown. Macrophages secrete proteases such as collagenase and gelatinase, the actions of which are opposed by tissue inhibitors of metalloproteinases (TIMPs). TIMP genes are closely regulated, with the transcription factor activator protein-1 having a central role, and their expression is increased by macrophage-derived cytokines TNF and IL-1ß. Other monocyte-derived proteins involved in tissue destruction include lysosomal proteases such as cathepsins, which function best at acid pH, and the plasminogen activator urokinase. Activation of the plasminogen system is followed by activation of the clotting system and laying down of fibrous tissue, a process in which macrophage-derived transforming growth factor ß has a central role.[28]

T cells

In immunity to TB aß and ?d $CD4^+$ T cells are critical.[29] Patients who have reduced T cell function or numbers are at higher risk of clinical TB. *Mycobacterium tuberculosis* may impair macrophage antigen presentation to T cells by downregulating the co-stimulatory molecule B7-1. Cells of the T-helper (T_H)1 subclass, which secrete interferon-? and IL-2, are central to the control of infection in murine models. In human disease the situation is more complex with T_H 1, T_H 2 (which produce

IL-4, -5, -6, -10 and -13) and intermediate cell types detectable,[30] although T_H 1 cells appear to concentrate at sites of infection such as pleura.[31] The dual presence of T_H 1 and T_H 2 cells may account for the fact that, although TB is limited within the granuloma, the organism is not usually completely killed off by the immune response.

The involvement of ?d T cells in immunity to human TB remains controversial, although they appear critical in murine models of infection. The percentage of ?d cells at sites of TB in the few studies performed in patients have been conflicting but their presence has been correlated with effective immune responses. These cells have the potential to recognize important, conserved mycobacterial antigens such as the 65kDa hsp.[32] ?d T cells may be involved in macrophage aggregation and activation, in lysis of infected cells and in cytokine secretion.[30] [33]

Other T-cell phenotypes involved in immunity to TB include $CD8^+$ lymphocytes,[34] although their exact role in humans is still to be defined. In addition, there are double-negative T cells lacking CD4 and CD8, which recognize mycobacterial lipoglycan antigens presented via CD1, proteins that have distant homology to the major histocompatibility complex.[35]

Humoral response

Many proteins, carbohydrates and lipids of *M. tuberculosis* contain epitopes that stimulate antibody production. Such antibodies have been used to characterize important antigens of *M. tuberculosis*, such as the 12, 65 and 72kDa hsps. However, in terms of pathogenesis, it has proved difficult to identify specific antibody responses of importance in host defense in the sera of patients who have TB.

Interest in antibody responses in TB has centered upon the development of diagnostic tests.

Local tissue responses

Granuloma formation is the consequence of a complex interaction between the organism and the immune system and the local release of tissue factors and proteases. Gross pathology reflects the relative influence of these factors in a particular patient. This process may be modulated by systemic or local production of hormones such as 1,25-dihydroxyvitamin D_3 .[36] Caseous necrosis, typical of mycobacterial granulomas, is probably caused by the delayed-type hypersensitivity response, although it is not known why it is so very rare in nontuberculous granulomas.

Host genetic factors

There is undoubtedly a genetic component to host resistance to *M. tuberculosis*. Identical twins have been shown to be concordant for TB and it has been suggested in the USA that black patients are more susceptible to infection.[37] Human leukocyte antigen (HLA) haplotypes associated with susceptibility to TB include A8, A10, B8, Bw15 and DR2. It is likely that many genetic polymorphisms influence susceptibility to TB to varying degrees. Much interest has focused on non-HLA-linked genes such as the *bcg* gene, located on human chromosome 2. Its product, the protein *Nramp* (natural resistance associated membrane protein), is a major determinant of disease susceptibility in murine systems[38] and is involved in human susceptibility to infection. Certain families that are susceptible to atypical mycobacterial infections have deletions in the interferon-? receptor gene.[39] However, it is likely that no single gene has a dominant effect in terms of population susceptibility to TB and this was confirmed in a genome-wide search in an African population.[40]

PREVENTION

Public health measures

Strategies to prevent the spread of TB aim:

- first, to identify and promptly treat infectious patients; and
- second, to prevent respiratory spread of infection.

Many countries have a system, often legally enforced, of infectious patient notification to a central body that traces infected contacts of index cases. In addition, high-risk patients or communities, such as intravenous drug users, may be screened so that definitive or prophylactic therapy may be instituted. In its simplest form, case finding involves clinical assessment and examination of sputum smears, although radiologic examination may be a useful adjunct. Skin testing may be appropriate in countries with low rates of infection and no routine immunization of the population. It is important to distinguish between disease relapse and reinfection, and RFLP analysis has proved useful.[41] Prevention programs may require incentives for successful implementation; they should be linked to educational initiatives and involve social services.

Infectious patients should be isolated until effective treatment has been instituted. In the USA, laminar airflow and negative pressure ventilation rooms are provided for patients who have known or suspected TB, particularly those who have MDR disease. Detailed guidelines have been produced in the USA from several sources which are useful,[42] but are potentially extremely costly to implement.[43] For example, expensive respirator masks have been advocated but are likely to represent a poor use of funds, particularly in developing countries. Shortwave ultraviolet illuminators to kill organisms in clinics and shelters have been used, although their efficacy has yet to be tested in comparative trials with other control methods. In many parts of the globe, basic patient isolation and possibly specified, ventilated rooms for procedures that generate aerosols is all that is feasible. Appropriate control measures should be defined in advance in high-risk procedure rooms, during patient transport and in all at-risk institutions.

Testing for exposure

Mantoux test

The Mantoux test is the commonest test used to screen for TB exposure and depends on the intradermal injection of a specified quantity of an internationally standardized purified protein derivative (PPD) of tuberculin. PPD solution should not be left in syringes because it may be variably adsorbed to their surface. Tuberculin positivity manifests as induration at the site of testing after 48 hours. Induration less than 5mm diameter after a standard injection of 10 units PPD is regarded as negative and greater than 15mm diameter as positive. However, PPD may have a booster effect on immunologic memory and a second Mantoux test should be performed a week after a negative test to confirm the finding.

Induration in the 5–15mm diameter range may be indicative of exposure to mycobacteria, previous immunization or disease in the immunosuppressed patient, all of which have unpredictable confounding effects on Mantoux testing. In the USA, induration greater than 5mm is taken as positive in patients who have HIV infection, a close contact with TB or a fibrotic chest radiograph, and induration above 10mm diameter is positive in any other high-risk group. Patients who are immunosuppressed, such as those who have HIV infection (particularly if $CD4^+$ T-lymphocyte count is <400 cells/mm^3) or who have measles or sarcoidosis, have a strong tendency to anergy. Systemic illness, including miliary TB, is also associated with anergy. The Centers for Disease Control and Prevention, Atlanta, USA, has recommended concurrent testing for generalized anergy, but the relationship between general anergy and tuberculin negativity is unclear. False-negative tests may also occur at the extremes of age in patients on high-dose corticosteroids, after the use of inadequately stored tuberculin or as a result of poor injection technique. Skin testing is not a useful exercise in low-risk children. PPD may restimulate previous hypersensitivity producing the booster Mantoux effect whereby a second Mantoux test 8 weeks after a negative test becomes positive. To avoid confusion negative Mantoux tests should be repeated within 2 weeks.

Heaf test

This Heaf test involves placing PPD on the skin of a subject and then using a multiple puncture gun to pierce the skin in six places; the response is then graded (Fig. 37.6 , Table 37.1). Heaf guns must be resterilized between patients; a disposable head is preferred.

Tine test

The tine test is similar to the Heaf test except that the puncture needles (usually four not six) are precoated with tuberculin. There has been considerable controversy

about the reliability of this technique and it is being used increasingly infrequently.

Figure 37-6 A Heaf test grade 2 response. *With permission from James DG, Studdy PR, A colour atlas of respiratory diseases, 2E. London: Mosby; 1992.*

TABLE 37-1 -- The Heaf test grades.

THE HEAF TEST GRADES	
Heaf test grade	**Response**
0	No induration at puncture sites
1	Discrete induration at a minimum of four needle sites
2	Induration at needle sites merge to form ring but leave clear center
3	One large induration site seen (5–10mm diameter)
4	Induration over 10mm diameter

New approaches

In part as a result of increased understanding of the TB genome, immune responses to novel antigens are being investigated as potential ways to detect early infection. Enumeration of antigen-specific T cells specific for the antigen ESAT-6 which is specific to the *M. tuberculosis* group of organisms, has been proposed as a means of contact tracing and spatial tracking of TB, but to date studies are small.[44]

Chemoprophylaxis

Chemoprophylaxis may be primary in unexposed individuals or secondary in those exposed to *M. tuberculosis* who do not have clinical disease. Secondary prophylaxis is practiced most commonly and successfully in TB control programs in the USA. This approach, which is based on regular skin prick testing, is not possible when vaccination is common or resources are inadequate. Isoniazid, 300mg daily for 6–12 months, is the usual preventative regimen and, as in treatment schedules, is associated with a significant incidence of (principally hepatic) toxicity, which is particularly important because the subjects are well. In addition, with the increase in drug resistance, it is likely that significant numbers of organisms will not respond to isoniazid. A variety of regimens are used for prophylaxis of drug resistant infection and some authorities recommend full treatment courses for such patients. Chemoprophylaxis has been advocated for all HIV-positive patients because of the increased incidence of clinical disease in patients exposed to *M. tuberculosis* (see Chapter 129). However, if the diagnostic facilities are poor, there is a significant chance of inadvertently treating established TB, which would hasten the emergence of isoniazid resistance. The issues, which include economic factors, are complex and the validity of prophylaxis for HIV infection is vigorously debated.[45] In contrast, the use of secondary chemoprophylaxis in potential transplant recipients is established. Chemoprophylaxis should be deferred in pregnant women, a group who may be more prone to isoniazid hepatitis.

Figure 37-7 BCG response at 6 weeks. (a) Clinical evidence of a cell-mediated immune response is clearly apparent at 6 weeks. (b) The healed BCG scar. *With permission from James DG, Studdy PR, A colour atlas of respiratory diseases, 2E. London: Mosby; 1992.*

Vaccines

Bacille Calmette-Guérin

The BCG vaccine, developed by Albert Calmette and Camille Guérin, was first used in 1921. Since then many strains have been used clinically, although the current reference type is the Pasteur strain. Vaccination leads to a local immune response and ultimately scar formation (Fig. 37.7). Keloid may form in susceptible individuals. Adverse reactions other than local irritation are uncommon and anaphylaxis is extremely rare. Local abscesses or ulcers usually reflect poor technique. Adenitis, sometimes suppurative, occurs at a rate of 25 cases per 1,000,000 vaccinations. Lupoid reactions, infected osteitis and disseminated BCG disease are very rare, the latter two necessitating therapy with rifampin and isoniazid (BCG is resistant to pyrazinamide).

The extent of immunity after BCG vaccination depends on the strain used, environmental factors, the genetics of the population being vaccinated and individual host factors such as age. There is a poor correlation between tuberculin reactivity after vaccination, which develops to maximal levels within 3 months, and protection against disease. Reviews indicate that BCG vaccine efficacy is about 60–80%,[46] although in certain parts of the world, such as Malawi, even repeated vaccination offered no protection against TB; it did, however, decrease *Mycobacterium leprae* infection rates.[47] Giving BCG to infants provides significant protection from TB in household contacts.

Novel vaccines

There are several novel vaccine approaches:

- the first of these involved using an environmental commensal *M. vaccae* to enhance protective immune responses, but it proved unsuccessful; [48]
- the second approach involved naked DNA vaccines encoding for immunogenic mycobacterial antigens — this has been successfully used in an animal model in which injection of the DNA coding for the mycobacterial 65kDa hsp was protective against challenge with virulent *M. tuberculosis*; [49]
- third, there is research interest in subunit, recombinant or genetically engineered vaccines in which either BCG serves as a vector for specific antigens of *M. tuberculosis*, or an attenuated *M. tuberculosis* is created by deletion of specific virulence factors, or antigens are administered, possibly with an adjuvant.

CLINICAL FEATURES

In this section, the diverse clinical presentations of primary, pulmonary and miliary TB are reviewed together with the characteristic changes found on radiologic examination. The principal extrapulmonary manifestations of TB are also covered.

Primary and childhood infection

Primary TB is acquired by inhalation of infected particles, usually in childhood, although in affluent countries the first encounter with TB may be as an adult. A single bacillus can cause disease but usually 50–200 organisms are required to develop active infection. Inhaled bacilli pass into the lung where damage is often but not always confined to one segment with concurrent involvement of draining, frequently hilar, lymph nodes. This gives rise to the primary Ghon complex. Clinical disease develops in less than 5% of people exposed to *M. tuberculosis*, although infection is established in about 30% of cases. After initial infection, the only sequelae may be scar tissue, which is often calcified and later may be identified on routine chest radiography. After the first year of infection, there is a 3–5% lifetime chance of

reactivation of the disease in individuals who do not have HIV infection. In addition, a patient exposed to TB may be infected by a second strain of *M. tuberculosis* later in life and this may account for up to one-third of adult clinical presentations.

Symptomatic patients present with cough with variable amounts of sputum and hemoptysis, together with localized pleuritic chest pain and dyspnea. In addition, systemic features such as fever, night sweats, anorexia and weight loss occur. A minority of patients have retrosternal pain, sometimes exacerbated by swallowing and increased by sternal pressure that is thought to relate to lymphadenopathy. Primary TB is seen as asymmetric hilar adenopathy, which may be associated with consolidation on chest radiography. In children, who like the very elderly are more susceptible to TB, isolated lymphadenopathy is more common. Less typical chest radiographs of primary infection include those that appear normal or have widespread disease, lobar consolidation and pleural effusions. An unusual complication of primary TB is bronchial obstruction caused by pressure of a node on a main bronchus. This phenomenon, sometimes called epituberculosis, may lead to secondary bronchiectasis. Untreated primary disease will progress to involve the entire lung and will also disseminate. Symptoms are present at this stage and may be severe, with continuous cough and sputum production, severe dyspnea, high fevers, drenching sweats and cachexia. Chest radiography reveals widespread patchy consolidation, with areas of collapse and cavitation.

Endobronchial TB is usually a complication of primary infection, although it may occur during reactivation. It may follow adhesion of inflamed lung parenchyma or lymph nodes to bronchi or may arise via lymphatic or hematogenous spread of infection and even from direct seeding of inhaled bacilli. Endobronchial TB probably frequently goes undiagnosed — it was found in over 400 of 1000 consecutive autopsies on patients who had TB.[50] The classic clinical presentation is with a barking cough and wheeze. Sputum production may be exacerbated when the mucosa is breached and caseous material extruded. Parasternal pain, dyspnea, symptoms caused by collapse and consolidation of distal lung tissue and systemic manifestations of TB may be found. The most important late complication of endobronchial infection is bronchiectasis.

Pulmonary infection

Risk factors for reactivation

Most cases of TB are caused by reactivation of infection acquired years earlier. The stimulus to reactivation may be frank immunosuppression or may be more subtle when factors such as malnutrition and vitamin D deficiency are involved. The role of corticosteroids in reactivation of TB has not been fully defined. High doses may cause reactivation, which often presents atypically or is detected belatedly because the symptoms of infection may mimic symptoms of the disease for which corticosteroids were being prescribed. However, TB does not appear more common in asthmatics maintained on daily low-dose prednisolone. Other conditions associated with reactivation of TB are end-stage renal disease, diabetes mellitus, silicosis, gastrectomy and transplantation; in the latter, disease usually results from immunosuppression, although occasionally infection is transmitted by the implanted organ. Although TB and lung malignancy may coexist and the symptoms of TB may mimic those of cancer, TB is not a risk factor for lung cancer. However, lung malignancy is a systemic risk factor for reactivation of TB and may invade and disrupt old tuberculous lesions leading to active infection. Tuberculosis has frequently been associated with sarcoidosis. Some workers have detected mycobacterial DNA in patients who have sarcoid but others have not, and whether there is any link between these diseases is unresolved.

Clinical presentation

In one prospective study, symptoms of reactivation of pulmonary TB were cough in 78% patients, weight loss in 74%, fatigue in 68%, fever in 60% and night sweats in 55%.[51] Some patients have only mild feelings of nonspecific malaise. Hemoptysis occurs in about one-third of patients. It may be massive from either enlarged bronchial arteries around tuberculous cavities (Rasmussen's aneurysms) or more frequently from erosions involving other bronchial or pulmonary arteries. Dyspnea suggests extensive disease and is a late symptom. Pleuritic chest pain indicates inflammation in and possibly infection of adjacent pleura. Clinical examination may be misleading in the early stages of reactivation and radiologically apparent changes of consolidation and cavitation hard to detect. Noninfectious complications of TB may be present (see below). It is important to recognize that patients can present with advanced disease in acute respiratory failure progressing rapidly to the acute respiratory distress syndrome (ARDS).

Chest radiography shows disease localized to the apical and posterior segments of the upper lobes of the lung in over 85% of patients, with other sites often secondarily affected. The apical segment of the lower lobe is also frequently involved. Infiltration and cavitation secondary to caseous necrosis may be associated with air-fluid levels. On treatment most cavities heal completely leaving residual scarring, which is often calcific. Tuberculous chest radiographs frequently show fibrotic changes with lobar atelectasis, elevation of hilar nodes and deviation of the trachea. A wide range of less common findings are described, for example pneumonic consolidation (Fig. 37.8). It is notoriously difficult to distinguish early reactivation from chronic healed lesions without follow-up radiographs. Computed tomography (CT) findings include cavitation with scarring as well as characteristic nodules and branching linear structures sometimes referred to as a 'tree-in-bud pattern'.

Other investigations in pulmonary TB may reveal leukocytosis or more specifically a monocytosis. It is common for the leukocyte count to be normal and rare for it to be decreased. Anemia, generally normochromic and normocytic, is typical. An acute phase response is almost invariably present with elevated C-reactive protein (CRP) concentrations in the plasma, raised erythrocyte sedimentation rate (ESR) and, in more chronic cases, decreased serum albumin. Hyponatremia occurs in about 10% of patients as a result of antidiuretic hormone-like activity. A much smaller percentage of patients have hypercalcemia, probably caused by abnormal vitamin D processing by macrophages within granulomas.[52]

Complications

The principal acute complications of pulmonary TB are hemoptysis, as discussed above, and pneumothorax. Bronchopleural fistulas may heal spontaneously, but more often require tube drainage and sometimes surgery. The prognosis is good because of the formation of scar tissue in TB. Chronic complications of lung TB relate to parenchymal damage and scarring. Aspergillomas may develop within healed cavitating

---

lesions in up to 20% of cases;[53] patients usually present with hemoptysis. Localized bronchiectasis (see Chapter 33) may only become clinically significant many years later and is best defined by high-resolution CT scanning. Tissue destruction may be severe enough to cause respiratory failure.

Pleural tuberculosis

Pleural TB classically occurs 3–6 months after primary disease, but the onset may be delayed and pleural disease may be the first sign of reactivation. Pleural disease may accompany lung infection or be the predominant feature. Tuberculosis and malignancy are the principal differential diagnoses of massive effusions that are exudates (protein concentration >3g/dl [>30g/l]). Effusions are usually straw colored but may be bloodstained and occasionally frankly bloody. Glucose concentrations in tuberculous effusions are frequently, but not always, less than 40mg/dl (2.22mmol/l). Pleural fluid lysozyme, lactate and pH may be elevated in tuberculous effusions, as in bacterial infections. Elevated adenosine deaminase (ADA), derived from CD4 lymphocytes, is characteristic. Low ADA levels are against a diagnosis of TB but high concentrations are nonspecific. The leukocyte count of tuberculous effusions is usually raised and may be as high as 5000 cells/ml (5,000,000 cells/l). Lymphocytes are generally the most prevalent cell type. Monocytes are also characteristic but mesothelial cells are scanty. Neutrophils may be present and may even predominate in acute disease.[54]

Chest radiography usually demonstrates a unilateral effusion, more often on the right. An effusion may be massive and bilateral effusions occur in approximately 10% of patients. Ultrasound may reveal loculated effusions containing fibrinous tissue, reflecting activation of the fibrinolytic system. Ultrasound and CT scanning are useful to document underlying disease and to aid diagnostic and therapeutic aspirations.

Miliary tuberculosis

Miliary TB follows blood-borne dissemination of *M. tuberculosis* and therefore clinical presentation is varied. Factors involved in the development of miliary infection include decreased immune responses, mycobacterial virulence factors, mycobacterial load and the number of organisms able to gain entry to the bloodstream. At least

50% of patients who have miliary disease in developed countries are immunosuppressed, most commonly by alcohol. Diabetes, chronic renal failure, underlying malignancies and immunosuppressive drugs are other risk factors. Disseminated infection caused by *M. bovis*, BCG strain, may follow instillation of the organism into the bladder when it is used as an adjuvant to chemotherapy for malignancy.

Miliary TB may manifest as fever of unknown origin or with symptoms attributable to involvement of one or more organ systems. Commonly there are widespread pulmonary granulomas and central nervous system (CNS) disease and occasionally cardiac involvement (pericardial, myocardial and endocardial manifestations have all been reported).

The differential diagnosis is often wide and clinicians must be alert to the possibility of miliary TB. Acute miliary TB tuberculosis presenting with shock and ARDS has a mortality rate that may approach 90%. In chronic cases, cachexia is prominent and localizing features may be few. Widespread macular and papular skin lesions (tuberculosis miliaris disseminata) are suggestive of miliary infection. Choroidal tubercles, 0.5–3.0mm in diameter, are essentially diagnostic of miliary disease (Fig. 37.9).

The chest radiograph of miliary TB shows well-defined nodules less than 5mm in diameter throughout both lung fields (Fig. 37.10). Radiographic changes may only develop after a patient has been admitted to hospital, so patients must be reassessed frequently. Larger nodules and a pulmonary focus occur in approximately one-third of patients. CT scanning, which is seldom of diagnostic value, may show smaller nodules not seen on radiography. Ultrasound scanning may show increased echogenicity in the liver but is not diagnostic. Hematologic investigations are similar to those found in tuberculous pneumonia but a neutrophilia may be seen and should

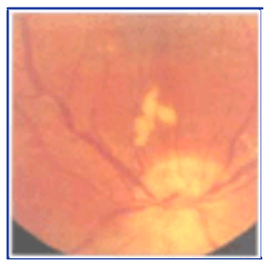

Figure 37-9 Choroidal TB. Choroidal disease is a manifestation of TB which is very highly suggestive of miliary disease. *With permission from James DG, Studdy PR. A colour atlas of respiratory diseases, 2E. London: Mosby; 1992.*

not put the diagnosis in doubt or cause empiric therapy to be restricted to antibacterials. Rarer abnormalities include disseminated intravascular coagulation and the hemophagocytic syndrome. Sterile pyuria and organisms in the absence of urinary leukocytes have been reported, but the exact frequency of such renal manifestations is uncertain. Delay in microbiologic diagnosis is a contributory factor to the high mortality rate in miliary disease.

Extrapulmonary tuberculosis

This section reviews those forms of extrapulmonary TB not considered in detail elsewhere and refers readers to other key chapters where further information is to be found.

Lymph node disease

Lymphadenitis or scrofula or the 'King's evil' (so-called because in Europe in the Middle Ages the royal touch was thought to be curative) is a very common extrapulmonary presentation of TB. In Europe, Australia and the USA, atypical mycobacteria (*Mycobacterium scrofulaceum* and *M. avium-intracellulare* complex) are

Figure 37-11 Vertebral TB. Tuberculosis of the spine or Pott's disease. Kyphosis is secondary to anterior destruction of vertebral bodies resulting in wedging of adjacent vertebrae and loss of disk space clearly seen by radiography. *(a) and (b) Courtesy of Professor J Cohen, Brighton, UK; (c) Courtesy of Dr A Wightman, with permission from Edmond RTD, Rowland HAK, Welsby PD, A colour atlas of infectious diseases, 3E. London: Mosby; 1995.*

also a frequent cause of lymphadenitis in children,[55] unlike the situation in adults in whom *M. tuberculosis* predominates. Peripheral nodes are usually infected through hematogenous spread of *M. tuberculosis* from the lung. The most commonly involved nodes are those in the cervical region, sometimes in association with axillary, inguinal or hilar lymphadenopathy. Patients may present with painless lymphadenopathy or with marked systemic symptoms. There may be associated sinuses and abscess formation. Hilar nodes may be associated with thoracic pain and, if untreated, may infrequently result in esophageal erosion or a bronchoesophageal fistula. Unusual symptoms such as obstructive jaundice have been reported in specific association with anatomically defined local lymph nodes.

Tuberculosis of the head and neck

Aside from cervical node disease, TB of the head and neck is relatively uncommon and usually arises secondarily to pulmonary infection. Laryngeal TB may manifest with hoarseness, pain on speaking or swallowing, hemoptysis and respiratory obstruction. Cough may reflect lung disease or involvement of the superior laryngeal nerve. Untreated, widespread local tissue destruction may occur with secondary laryngeal stenosis. A plain chest radiograph may be suggestive, but in one series radiographic changes were minimal in two-thirds of patients.[56] In this study from a specialist center, coexistent squamous cell carcinoma of the larynx was present in 10% of patients. Therefore, all laryngeal lesions should be biopsied to exclude malignancy.

Tuberculosis rarely involves the middle ear, where it may manifest with a local, painless discharge from which the organism may be cultured. There may be destruction of the ossicles, hearing loss and invasion of the facial nerve canal and sinuses and extension into the posterior cranial fossa. Secondary pyogenic infection may obscure the diagnosis. Tuberculosis of the nose, nasopharynx and adenoids is rare, even in areas in which infection is endemic, and symptoms such as epistaxis reflect local tissue damage. Tuberculosis in the oral cavity generally occurs as a solitary, often inflamed ulcer with irregular borders. There may be secondary infection of salivary glands.

Musculoskeletal infection

Vertebral infection (Pott's disease) is the commonest presentation of tuberculous osteomyelitis, accounting for about 50% of all bony TB (Fig. 37.11). The male to female ratio is approximately 2 to 1. The thoracic spine is the most frequently involved, followed by lumbar and then cervical regions. Presentation is usually with back or neck pain. Systemic symptoms tend to be less marked than in pulmonary disease. Neurologic symptoms, such as weakness, numbness and disturbances of gait, occur in about one-third of cases. Some patients have an associated flank mass or other evidence of extraspinal TB. In more advanced cases, vertebral body collapse and gibbus formation lead to kyphosis of the spine. Destructive lesions with invasion of the joint space and deformity may be seen on plain radiographs, although CT or

ideally magnetic resonance imaging (MRI) are better imaging modalities for spinal pathology.

Osteomyelitis is otherwise most frequently found in the metaphysis of long bones, although the ribs, pelvis and skull may be infected. In children in countries in which TB is prevalent, osteomyelitis is a significant cause of crippling deformity. Direct extension from the ribs to the lung is rare, as is meningitis or tuberculomas in patients in whom there is skull involvement. Bony TB may be accompanied by sinus tracts or soft tissue masses. Diagnosis may be difficult because lesions can appear osteolytic or sclerotic on radiography and malignancy may be suspected first. Like radiographs, ^{99m} technetium bone scans have no pathognomonic features. Trauma does not predispose to tuberculous osteomyelitis.

Tuberculous arthritis most frequently manifests in the hips and other weight-bearing joints, although any joint may be involved. Polyarticular disease occurs in less than 20% of patients, but evidence of TB elsewhere, generally the lung, is present in about 50% of cases. Synovial fluid is usually turbid with a high leukocyte count and up to 60% may be neutrophils rather than mononuclear cells. Organisms are found in less than one-quarter of cases, although positive cultures are more frequent and ideally a synovial biopsy should be examined histologically and microbiologically. Prosthetic joints may be infected with *M. tuberculosis* after either hematogenous spread or contiguous reactivation of infection. Tenosynovitis is rare and generally associated with adjacent osteomyelitis.

Figure 37-12 Abscess formation in TB. This patient had multiple TB abscesses particularly affecting the psoas and quadriceps muscle groups.

Tuberculous abscesses may form in most soft tissues, including muscle (Fig. 37.12). This is usually secondary to contiguous spread of infection but may follow hematogenous dissemination. The classic abscess site is in the psoas muscle, and such an abscess can occur with or without localizing signs, so a high index of clinical suspicion is necessary for the appropriate imaging to be arranged in advance of diagnostic aspiration.

Abdominal infection

The abdomen is a frequent site of TB, especially in patients from the Indian subcontinent, where rates are up to 50 times higher than in Europe, and in those immunosuppressed with HIV infection. Disease is usually secondary to hematogenous spread of mycobacteria, but can be secondary to local invasion or ingestion of organisms. However, any infected person can present with disease in the abdomen and as TB frequently mimics other pathologies, such as gastrointestinal malignancy, diagnosis is often delayed. In the gut, TB most frequently affects the ileocecal region, then the small bowel and then the colon, with involvement of the duodenum occurring in less than 2.5% of cases and involvement of the stomach and esophagus in less than 1% of patients. Approximately one-third of patients have evidence of TB elsewhere, usually in the lung.

Symptoms reflect site of involvement but may be non-specific with fever, weight loss, chronic abdominal pain, nausea and anorexia. Diarrhea occurs in less than 20% of cases and reflects either secondary overflow caused by obstruction or stimulation of the gastrointestinal tract by cytokines. Ileocecal TB may manifest as acute surgical abdomen secondary to obstruction of the bowel lumen or appendix, or after bowel perforation. Any tuberculous lesion, particularly those in the colon, may manifest with massive gastrointestinal bleeding, but this is rare. Lesions may be ulcerative or hypertrophic and can be associated with fistulas, which are probably partly the result of secondary bacterial involvement. Unusual sites of intra-abdominal TB include the pancreas and the adrenal glands; in the latter, disease occurs very rarely as an adrenal crisis, but more commonly with an insidious onset of symptoms that may be difficult to distinguish from those associated with infection. Tuberculous peritonitis is an important manifestation of disease and is discussed in Chapter 47 . Hepatobiliary infection is considered in Chapter 49 . Chapter 71 provides a detailed review of urogenital TB.

Central nervous system and eye disease

Tuberculous meningoencephalitis and CNS tuberculomas are extremely important, carrying high morbidity and mortality rates. They are considered further in Chapter 22 and Chapter 24 , respectively.

Ocular TB is relatively uncommon but important because, if overlooked, blindness may result. The commonest manifestation is choroidal disease (see Fig. 37.9) secondary to hematogenous spread in the context of miliary TB, which may rarely spread to the retina. Conjunctival TB may be caused by accidental self-inoculation by an infected person, spread from skin or very rarely by direct spread from another infected individual. Infection may be ulcerative or nodular, although occasionally focal tuberculomas, sometimes appearing polypoid, are seen. Tuberculosis of the sclera and cornea are rare, as is uveitis.

Pericardial infection

Tuberculous pericarditis is potentially fatal. A detailed description of this disease is provided in Chapter 58 .

Dermatologic disease

Lupus vulgaris is the best documented manifestation of dermatologic TB. Details of the dermatologic manifestations of primary and miliary infection can be found in Chapter 12 .

Clinical manifestations in people who have HIV infection

Tuberculosis is an AIDS-defining event in HIV-positive patients in the USA and a common secondary infection in HIV-positive patients living in countries in which TB is more prevalent. The clinical manifestations of TB in HIV-positive and -negative patients are generally similar. However, TB may be more widespread, have more atypical features and is more often extrapulmonary in HIV-positive patients (see Chapter 129). Many unusual or rare presentations of TB have been reported, bronchoesophageal fistula being one example.[57] *Mycobacterium tuberculosis* bacteremia is much more frequent in HIV-positive patients. [58] In Africa, CNS and disseminated TB occur more often in patients who have peripheral $CD4^+$ T lymphocyte counts less than 200 cells/mm^3 (200,000/1).

Making the correct diagnosis can be difficult when HIV and TB coexist. Non-specific systemic features of TB, such as fever, malaise and a prolonged acute phase protein response, are also characteristic of HIV infection. In Africa, both HIV and TB contribute to the wasting entity recognized as Slim disease. Many opportunistic infections in HIV, including those caused by the *M. avium-intracellulare* complex, may cause similar symptoms to those of TB, adding to diagnostic confusion. In addition, low peripheral T-cell counts may secondarily reduce leukocyte counts in TB-infected pleural fluid, which may be diagnostically confusing.

Noninfectious complications

Erythema nodosum is the most common noninfectious complication of primary TB; it also occurs in other granulomatous diseases (e.g. leprosy, sarcoidosis). It is particularly associated with primary disease. Arthritis occurs in up to 1% of patients who have acute infection and may also complicate reactivation. Poncet's disease is a reactive polyarthritis associated with TB, which resolves with antimycobacterial chemotherapy. Bazin's disease is a vasculitic skin reaction to TB that usually manifests as a purpuric rash on the lower extremities. Another important immunologic complication of TB is renal interstitial nephritis.

Bronchogenic carcinoma was thought for many years to occur more frequently in patients who had TB, but this has not been borne out in careful studies. Hypertrophic pulmonary osteoarthropathy, principally associated with bronchogenic carcinoma, has been reported in TB,[59] although some attribute the finding to undiagnosed lung malignancy. Another report described clubbing in 21% of patients in a Nigerian hospital, but this figure is much higher than experienced by most physicians.[60] The syndrome of inappropriate antidiuretic hormone secretion is more common in pulmonary and miliary disease.

DIAGNOSIS

Clinical approach

The definitive diagnosis of TB requires identification of the mycobacterial pathogen in a patient's secretions or tissues. Therapy is often initiated before a definitive diagnosis has been made, but one should always be pursued. Identification of the organism is necessary for drug susceptibility testing, which guides local treatment policies and individual therapeutic regimens. Sputum examination has a high diagnostic yield, identifies the majority of infectious patients and is cheap to perform. Sputum should be collected on three separate occasions, but additional specimens are not cost-effective.[61] Induced sputums obtained in properly ventilated and isolated areas can be useful, but bronchoscopy with alveloar lavage has the best diagnostic yield.[62] Routine screening of induced sputums for TB in HIV-positive patients is not useful. *Mycobacterium tuberculosis* is seen infrequently on aspiration of pleural fluid and is cultured in under 50%

Figure 37-13 2-Fluoro-deoxy glucose positron emission tomography (FDG-PET) scan in bilateral apical pulmonary TB (arrowed). Tracer is excreted via the renal tract and is clearly seen in the bladder.

of cases. However, pleural biopsy reveals granuloma or results in culture of the pathogen in over 90% of cases. Thoracoscopy may be indicated in exceptional circumstances because it allows visually guided biopsy of lesions. Tests such as an elevated pleural fluid ADA concentrations may support a diagnosis of TB but their specificity is limited. More recently 2-fluoro-deoxy glucose positron emission tomography (FDG-PET) scanning has been used to identify occult disease although such scans are also positive in malignancy (Fig. 37.13).

In extrapulmonary or miliary infection, appropriate body fluids and/or tissues must be obtained for microbiologic and histologic examination, with the aid of ultrasound, CT or MRI scanning if available. Liver biopsy and bone marrow aspiration are useful investigations in disseminated or occult disease.[63] An acid-fast stain of buffy coat leukocytes may be diagnostic in immunosuppressed patients.

For tuberculous lymphadenitis, fine-needle aspiration is the initial investigation of choice because it is easy to perform, and has a high specificity and sensitivity when both microbiologic and cytologic specimens are collected. Fine-needle aspiration does not preclude subsequent lymph node biopsy. Needle aspiration remains of value in countries in which TB is common but resources, including trained laboratory staff, are scarce.[64] It can also be used for other manifestations of suspected extrapulmonary disease such as tuberculous arthritis.

Specimens from potentially infected patients are normally analyzed in local laboratories, but drug sensitivity testing and more specialized facilities are ideally concentrated in centralized laboratories. All laboratories must be arranged to deal with hazardous, possibly drug-resistant pathogens. Safety measures include containment areas, approved safety cabinets, centrifuges, gowns, gloves, sinks and facilities for disposal of contaminated waste and treatment of spillages. Special training for the staff is essential.

The usual principles of microbiologic safety apply to the collection of specimens into sterile containers. Tissue biopsies should be divided and a fresh specimen sent for microbiologic and one in formalin for histologic examination. Tissue is better for culture than necrotic material and old pus, which may contain acids that are toxic to mycobacteria, a fact to be considered when selecting biopsy sites. Blood and bone marrow specimens can be injected directly into blood culture bottles. Examination of cerebrospinal fluid for *M. tuberculosis* is usually an emergency investigation, with the clinician forewarning the laboratory. Specimens from gastric lavage should be rapidly transported to the laboratory because stomach acidity may kill mycobacteria. Feces are not useful in the diagnosis of *M. tuberculosis* in HIV-negative patients.

If no diagnostic results are forthcoming in patients in whom TB is a possibility, the clinician may reasonably resort to a trial of therapy. Improvement of symptoms and a decrease in the acute phase response (monitored by ESR, CRP, etc.) are sufficient indication to move from the diagnostic trial to full therapy. Any diagnostic trial of therapy should last a minimum of 2 weeks and ideally 4 weeks.

Microbiologic diagnosis

The standard method for staining clinical specimens for *M. tuberculosis* is that of Ziehl-Neelsen (Fig. 37.14), which requires application of heat, whereas a modification, the Kinyoun method, does not. Both methods utilize the fact that the stained cell wall is resistant to decolorization by acid alcohol although the biochemical reason for this is unknown. Auramine staining has facilitated rapid screening of diagnostic specimens and has greater sensitivity (Fig. 37.15). Mycobacteria are often scanty and specimens should be reviewed by an experienced operator. Diagnostic microscopy is most successful in patients who have extensive disease and cavitation on chest X-ray and has an overall sensitivity of 50–90% depending on case mix.

Mycobacterium tuberculosis is traditionally cultured on egg and potato-based media such as Middlebrook 7H10/11. Such media are of limited value in the analysis of clinical specimens because of overgrowth by more rapidly dividing commensal organisms. Selective media such as Lowenstein-Jensen or Petragnani are used, with Middlebrook being reserved for subcultures. Cultures must be maintained for up to 8 weeks. *Mycobacterium tuberculosis* is

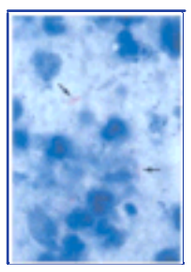

Figure 37-14 Ziehl-Neelsen-stained sputum specimens containing *Mycobacterium tuberculosis.* *Courtesy of Dr F Ahmed, Ealing Hospital, UK.*

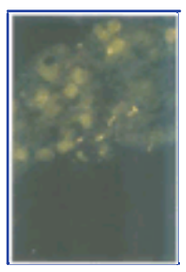

Figure 37-15 *Mycobacterium tuberculosis* in sputum detected by auramine staining. *Courtesy of Mr M Croughan, with permission from Edmond RTD, Rowland HAK, Welsby PD, A colour atlas of infectious diseases, 3E. London: Mosby, 1995.*

identified as slow-growing, rough, whitish colonies with a tendency to cord formation. More specific biochemical tests detect a range of characteristics, including the ability of the organism to produce niacin, reduce nitrate and produce a heat-sensitive catalase. To speed diagnosis, broth-based growth systems containing Middlebrook 7H12 with ^{14}C-labeled palmitic acid as the only carbon source are widely used. This is the BACTEC system, which detects release of radioactive $^{14}CO_2$ from dividing mycobacteria and approximately halves the time to diagnosis in smear-positive and negative patients. The BACTEC system has been refined for specific identification of *M. tuberculosis*. Failure of a mycobacteria to grow in a BACTEC NAP vial (containing p-nitro-a-acetylamino-ß-hydroxypropiophenone) indicates that it is either *M. tuberculosis*, *M. bovis* or *M. africanum*. *Mycobacterium tuberculosis* can also be identified from a fatty acid profile obtained by high-performance liquid, gas-liquid or thin-layer chromatography. A novel colorimetric diagnostic method is the mycobacteria growth indicator tube that contains 7H9 Middlebrook broth and an oxygen-sensitive fluorescent indicator that indicates bacterial growth. Once the indicator is positive, detection by genetic means is possible. Such methodology may

have a particular role in the rapid detection of drug-resistant organisms in clinical specimens. Several cheaper approaches to rapid microbiological diagnosis have been investigated and the use of an inverted microscope to detect mycobacterial growth within days rather than weeks is one of the most promising.[65]

There are four methods of susceptibility testing of *M. tuberculosis* to determine whether the majority of pathogens are sensitive to the drugs being prescribed:

- the absolute concentration method uses a series of cultures containing a graded range of dilutions of the drug being tested, as well as a control to determine the minimum amount of drug that inhibits growth of any isolate;
- the resistance ratio method, commonly used in the UK, is similar, but results are related to the sensitivity of a known strain of *M. tuberculosis* such as H37-Rv;
- the proportion method, frequently employed in the USA, compares the number of colonies growing on a standard medium with the number on a drug-containing medium; and

in many countries, BACTEC bottles containing various drugs are now used because of their rapidity and reliability.

Pyrazinamide-sensitivity testing presents specific problems in that it must be carried out at pH5.5 and this degree of acidity can inhibit the growth of some strains of *M. tuberculosis* independently of drug action. An alternative approach has been to screen isolates for production of pyrazinamidase.

In the future, genetic techniques screening for relevant mutations are likely to have a role in rapidly identifying resistant organisms, but will not detect novel mutations.

Genetic techniques

The polymerase chain reaction (PCR) has the potential to allow rapid detection of low levels of infection with the possibility of immediate probing for known drug resistance genes. The usual targets for amplification are the DNA insertion sequence IS6110, which is found in all the *M. tuberculosis* complex of organisms (*M. tuberculosis, M. bovis, M. africanum* and *M. microti*) or rRNA. The main current usage of PCR-based technology is for the rapid diagnosis of drug-resistant TB and MDR-TB once standard cultures are positive. Since nearly all rifampin drug resistance is due to mutations in the RpoB (RNA polymerase B) gene and because rifampin resistance is highly associated with isoniazid resistance, testing for this mutation is used for early identification of patients with MDR-TB. Considerable methodologic problems with PCR have been encountered so this has not yet replaced traditional microbiological techniques as a primary diagnostic tool.

Several large-scale studies have reported high sensitivity and specificity using culture positivity as the gold standard.[66] However, in one study only 70% of laboratories could make the diagnosis in samples containing 10,000 *M. tuberculosis* (lower limit for detection by microscopy) and 22% of laboratories identified the organism in negative control samples.[67]

PCR is potentially of most use in smear-negative culture-positive disease, for which it should be able to identify over 50% of cases.

Another problem is that PCR positivity in sputum may persist during treatment and after clinical cure.[68]

It is likely that PCR will be useful in diagnosing extrapulmonary TB, but large studies of sensitivity are awaited. One interesting observation is that about 50% of patients are positive on blood-based PCR analysis for *M. tuberculosis*, which suggests that a blood test might be diagnostically useful.[69]

PCR tests are good at distinguishing isolates from the *M. tuberculosis* family from other mycobacteria, which can be important in HIV patients who are susceptible to disseminated infection by *M. avium-intracellulare* complex organisms. Although PCR is finding an increasing role in the diagnosis of TB, it has not yet replaced microscopy and culture and, in view of its cost, it is unlikely to do so soon in most areas of the world in which TB is prevalent.

The use of reporter phages encoding genes for luciferase from the firefly *Photinus pyralis* represents the main alternative genetic approach to the diagnosis of TB. On introduction of a phage such as TM4 into mycobacteria in the presence of luciferin and ATP, oxidization results in the generation of luciferyl-AMP and then oxyluciferin, which gives out 0.85 photons per molecule of substrate. This is measured in a luminometer, thus allowing detection of mycobacterial growth in a few hours. Subsequently, efficacy of drug activity can be rapidly screened within 48 hours by monitoring changes in luminescence.[70]

Serodiagnosis

Serodiagnostic techniques are not in routine use in most laboratories. Enzyme-linked immunosorbent assays (ELISAs) have been developed to detect a number of mycobacterial proteins, such as the 16kDa hsp, the 30kDa antigen, the 38kDa antigens and LAM, but the sensitivity of antibody testing is not sufficiently high in ELISAs with adequate specificity to warrant their regular use. Local testing for antibodies at sites of infection, such as in pleural effusions, has not proved useful. Antibody levels are also often low in culture-negative individuals in whom alternative diagnostic approaches are needed. Alterations in antibody levels over time are not a useful guide to the clinical response to treatment. Finally, the impaired antibody response makes serology of negligible value in HIV-positive patients.

MANAGEMENT

First-line antimycobacterial drugs and their toxicities

This and the next section briefly outline the principal characteristics of the most important antituberculous drugs. More detail concerning mode of action and dosage regimens can be found in Chapter 202 .

Isoniazid

Isoniazid (INH or isonicotinic acid hydrazide: $C_6 H_7 N_3 O$) is a bactericidal drug (MIC generally <0.1mg/ml), the biologic activity of which resides in a pyridine ring and a hydrazine group. Isoniazid is well absorbed, minimally bound to plasma proteins, has a half-life of 1–3 hours depending on patient acetylator status and is excreted into urine. Concentrations achieved in most tissues are similar to those in serum, with the important exception of the CNS in which concentrations are approximately 20% of those in serum. Thus, the drug is used at double the normal dose in CNS disease. Isoniazid enters *M. tuberculosis* by diffusion and by oxygen-dependent active transport where it inhibits mycolic acid synthesis and the nicotinamide adenine dinucleotide pathway and interacts with the catalase-peroxidase enzyme system. Mutations in the *kat* G gene encoding the catalase-peroxidase enzyme confer resistance to INH and account for approximately 25% of cases of drug resistance.[71] Mutations in the *inh* A gene, which encodes an enoylacyl carrier protein reductase probably involved in mycolic acid synthesis, appear important in drug resistance to INH and ethambutol in some mycobacteria but not *M. tuberculosis*.

The most important, potentially fatal, side-effect of INH is hepatotoxicity, which is more common in patients over 60 years of age, in the presence of coexisting liver disease and possibly in pregnancy. Asymptomatic, usually transient, rises in transaminases occur in about 20% of patients. A greater than threefold increase in enzyme levels above the normal range is an indication to discontinue therapy. In practice, it is often impossible to separate INH hepatotoxicity from that caused by rifampin or pyrazinamide but, interestingly, reintroduction of these drugs singly rather than in combination usually avoids a second episode of hepatotoxicity. The other major side-effect is a peripheral and rarely optic neuritis caused by interference with niacin metabolism. This is prevented by concomitant administration of vitamin B_6 (pyridoxine) 10mg daily. Less common side-effects include nausea, vomiting and arthralgia and rarely hypersensitivity reactions, lupus-like reactions, cerebellar ataxia, convulsions, psychoses, hyperglycemia, agranulocytosis and in malnourished patients pellagra.

Rifampin

Rifampin is a bacteriocidal drug with excellent antituberculous activity. Rifampin undergoes first-pass metabolism in the liver where it is deacylated; it is excreted into bile and then into the gut where there is a minor degree of enterohepatic circulation. Rifampin is a potent inducer of hepatic enzymes and therefore has many clinically significant interactions with other drugs (Table 37.2). Rifampin targets the RNA polymerase ß subunit, blocking initiation but not

TABLE 37-2 -- Drug interactions with rifampin.

DRUG INTERACTIONS WITH RIFAMPIN	
Drug category	**Example**
Antibacterials	Chloramphenicol
Antifungals	Fluconazole
Corticosteroids	Prednisolone
Anticoagulants	Warfarin
Analgesics	Methadone
Immunosuppressive therapy	Ciclosporin
Ulcer-healing drugs	Cimetidine
Respiratory drugs	Theophylline
Cardiac drugs	
ß blockers	Propranolol
Calcium channel blockers	Diltiazem
Cardiac glycosides	Digitoxin (only member of class affected)
Antiarrhythmics	Disopyramide
Lipid-lowering drugs	Fluvastatin
CNS drugs	
Anti-epileptics	Phenytoin
Anxiolytics	Diazepam
Antidepressants	Tricyclic compounds
Antipsychotics	Haloperidol
Endocrine drugs	
Antidiabetics	Tolbutamide
Estrogens & progesterones	Combined & progesterone only contraceptive pill
Thyroid replacement	Thyroxine
These are the principal classes of drugs for which metabolism is increased (plasma concentration decreased) when taken with rifampin. The examples are not exhaustive and clinicians should check interactions with related drugs in appropriate formularies. (See Chapter 129 for interactions with drugs used to treat HIV.)	

elongation of mRNA transcripts. Mutations in the *rpoB* gene, which encodes this subunit, are associated with drug resistance. A worrying development has been the emergence of rifampin-resistant TB through an *rpoB* mutation in a patient taking rifabutin prophylaxis for *M. avium-intracellulare* complex infection.[72]

Patients should be warned that rifampin turns all body secretions, including urine and tears, orange (Fig. 37.16). This is a useful side-effect in terms of monitoring compliance. Rifampin may cause hepatic injury, particularly in the presence of pre-existing liver disease. Gastrointestinal side-effects seldom necessitate stopping therapy and include anorexia, nausea, vomiting, abdominal pain and diarrhea. Pseudomembranous colitis caused by *Clostridium difficile* toxin production is occasionally described. Immune-mediated problems associated with rifampin include rashes, urticaria, conjunctivitis and rarely hemolysis or thrombocytopenic purpura. A 'flu-like' syndrome may be troublesome, particularly in intermittent therapy regimens, and very rarely may be severe with circulatory collapse and respiratory failure.

Pyrazinamide

Pyrazinamide, a structural analog of nicotinamide, is a bactericidal drug that is well absorbed via the gut and distributed widely, including in the CNS where concentrations are the same as those in serum in patients who have tuberculous meningitis. Serum half-life is about 10 hours and excretion is urinary. Pyrazinamide principally acts intracellularly at relatively acidic pH, although it may also have some cidal action on extracellular bacteria. The drug penetrates macrophages where an enzyme from *M. tuberculosis* converts it into

Figure 37-16 Rifampin urine testing. Patients should be warned that rifampin turns urine and other body secretions orange. This fact can be helful in monitoring compliance with drug treatment. *Courtesy of Dr W Lynn, Ealing Hospital, UK.*

active pyrazinoic acid. Little is known about mechanisms of drug resistance to pyrazinamide, although some strains of *M. tuberculosis* produce an enzyme called pyrazinamidase.

Hepatotoxicity ranging from elevation of liver transaminases to frank jaundice and liver failure is the principal side-effect of pyrazinamide. More common are mild gastrointestinal problems and an arthralgia associated with raised serum urate concentrations secondary to inhibition of tubular secretion of uric acid by pyrazinamide; gout is rare. Sideroblastic anemia has been reported.

Ethambutol

Ethambutol is a bactericidal drug that is rapidly and well (over 80% of the dose) absorbed in the gut, with peak serum levels occurring 2 hours after a dose. It is then rapidly excreted in urine. Ethambutol appears to alter *M. tuberculosis* RNA synthesis and the transfer of mycolic acids into cell wall. Changes in cell wall lipids have been noted in organisms resistant to the drug.

The most important complication of ethambutol therapy is retrobulbar neuritis manifest by impaired visual acuity, color-blindness and restricted visual fields. Except in patients who have pre-existing ophthalmic disease, optic neuritis is extremely rare when ethambutol is used at standard doses (15mg/kg). In affluent countries, it is appropriate to have patients assessed by an ophthalmologist before treatment is begun, but lack of this facility should not prevent the use of ethambutol. Patients should be warned to report symptoms of visual change immediately and ethambutol should generally be avoided in children. Very rarely ethambutol causes a peripheral neuritis.

Streptomycin

Streptomycin, the first clinically useful drug discovered in the fight against TB, is an aminoglycoside that has to be given intramuscularly. Streptomycin penetrates cerebrospinal fluid and other remote tissues (e.g. prostate and eye) poorly. There is an immediate and a delayed pathway of excretion via the renal tract. The persistence of the drug at low doses is one factor in the development of side-effects. Streptomycin binds to the 30S rRNA subunit, which results in decreased protein synthesis and misreading of mRNA. Mutations, including those in the 30S subunit, arise readily in response to isolated streptomycin therapy and lead to drug resistance. The principal side-effects of aminoglycosides are ototoxicity and nephrotoxicity.

TABLE 37-3 -- Second-line therapy in TB.

SECOND-LINE THERAPY IN TB			
Drug (chemically closely related drug)	**Mechanism of action**	**Toxicity**	**Usual initial adult dose**
PAS	Competes with mycobacterial dihydropteroate synthetase	Gastrointestinal intolerance, hypersensitivity, hypothyroidism, crystaluria	12g/day (divided doses)
Ethionamide (prothionamide)	Inhibits cell wall mycolic acid synthesis	Gastrointestinal intolerance, hepatitis, hypersensitivity, convulsions, depression, alopecia	0.5–1.0g/day (divided doses)
Ciprofloxacin (ofloxacin)	Inhibits topoisomerase II	Gastrointestinal intolerance, crystaluria, tremor, convulsions, rash, hepatitis, renal failure	750mg q12h
Capreomycin (viomycin)	Binds 30S and 50S ribosomes	Nephrotoxic, ototoxic, hypersensitivity	1g/day
Kanamycin	Binds 30S ribosome	Nephrotoxic, ototoxic, hypersensitivity	15mg q12h*
Amikacin	Binds 30S ribosome	Nephrotoxic, ototoxic, rash, neuromuscular blockade, eosinophilia	7.5mg/kg q12h*
Cycloserine	Competitive D-alanine analog	Seizures, psychoses, various CNS effects	250mg q12h/q8h
Thiacetazone	Bacteriostatic ?exact mechanism	Gastrointestinal intolerance, Stevens-Johnson syndrome bone marrow depression, ototoxic, hepatitis	150mg daily
Second-line drugs used in treatment of TB are presented together with their mechanisms of action and toxicity.			

* peak drug levels should be less than 3mg/dl (30mg/l) and trough less than 1mg/dl (10mg/l)

Rarer side-effects are neuromuscular blockade and hypersensitivity reactions with maculopapular rashes, fever and eosinophilia.

Second-line drugs

Second-line agents are becoming increasingly important with the advent of MDR organisms. Information about these drugs is listed in Table 37.3 , although the use of many has not been confirmed in clinical trials. The value of proved efficacious drugs such as ethionamide is limited by toxicity. There is evidence to suggest that the role of other drugs such as imipenem in the treatment of TB should be reevaluated.[73] The potential second-line role of clofazamine, used in the treatment of *M. leprae*, is also uncertain. It remains a poor reflection on the wealthier nations that thiacetazone, which has a dangerous side-effect profile, continues to be widely used in developing countries because it is all that can be afforded. More details about these agents can be found in Chapter 202 .

Treatment regimens

Many trials, notably those involving the British Medical Research Council, have established short-course chemotherapy as the preferred treatment of pulmonary, pleural, nodal and most other forms of TB. Such regimens are dependent on using the potent antituberculous drugs isoniazid and rifampin throughout a 6-month course in addition to a 2-month initial treatment with pyrazinamide. An additional drug such as ethambutol or streptomycin is frequently used in

TABLE 37-4 -- Short-course chemotherapy.

SHORT-COURSE CHEMOTHERAPY			
Drug	**Adult dose (orally)**	**Duration of treatment**	**Modification of drug dose in renal failure**
1. Isoniazid*	5 mg/kg (maximum 300mg)	6 months	No
2. Rifampin*	10 mg/kg (maximum 600mg)	6 months	No
3. Pyrazinamide*	30mg/kg (maximum 2.0g)	2 months	? dose or ? dosage interval
4. Ethambutol	15mg/kg†	2 months	? dose or ? dosage interval
or			
Streptomycin	15mg/kg im (maximum 1.0g)	2 months	?? dose or ?? dosage interval
Short-course chemotherapy regimen for treatment of TB and necessity for drug dose modifications in renal impairment.			

* Isoniazid and rifampin are marketed as a single combination tablet ± pyrazinamide which may facilitate compliance
† Some authorities use ethambutol at 25mg/kg for 2 months only (longer courses should be at 15mg/kg)

the induction period and must be used if drug resistance is a possibility. Single drug resistance occurs at frequencies of up to 20% in West Africa and 10% in the USA.[74] The aim of therapy is to kill all *M. tuberculosis*, with multiple drugs countering the spontaneous emergence of drug-resistant mutants.

One standard treatment protocol is given in Table 37.4 . Alternative regimens are essential in the presence of drug resistance and are possible when drugs are in short supply. For example, 7 months' isoniazid and ethambutol therapy can substitute for isoniazid and rifampin in the period after 2 months' quadruple therapy. For sensitive organisms, drug therapy in compliant patients is very efficacious, with cure rates approaching 100%. However, it may be 2 weeks before clinical improvement becomes apparent, which is important in empiric trials of therapy and for appropriate patient expectations. Radiologic improvement lags further behind and it may take 3–5 months before all that remains is residual scarring on the chest radiograph. Drug therapy must be linked with the public health measures discussed above.

The necessary duration of treatment for extrapulmonary TB is debated. Limited trials in osteomyelitis, regarded as a difficult site to treat, indicate that 9 months' therapy is effective, providing both isoniazid and rifampin are used. In miliary disease, the 6-month regimens have been very successful. If TB involves the CNS, a minimum of 12 months of therapy is required. Complications may develop during the treatment of disease, partly as a result of an

influx of leukocytes. The consequences of this depend on the site of infection and include pneumothoraces, the expansion of intracerebral granulomas or discharge from subcutaneous nodes.

Patient isolation

It is critical that infectious patients admitted to hospital are nursed in full respiratory isolation. Specific assessment should be made of the likelihood of MDR-TB when negative pressure isolation is mandatory although the reality is that countries with a high incidence of MDR-TB are unlikely to have such facilities. Procedures that may induce aerosols such as sputum induction should be avoided if possible and bronchoscopy of suspected TB patients must be performed in appropriately ventilated facilities with staff trained in respiratory isolation procedures. Patients with drug sensitive TB are thought to become noninfectious within 2 weeks although recent genetic studies on disease transmission using various DNA fingerprinting techniques have cast some doubt on this and better data are required. Acid-fast bacilli may be recovered in sputum up to 1 month after the initiation of therapy, but growth in culture indicates noncompliance with treatment or drug-resistant disease. The identification of drug-resistance may be delayed in patients in whom initial culture is negative or if facilities for PCR testing are not available with the possible

consequence of transmission of MDR-TB. Isolation is not normally required for extrapulmonary disease.

Directly observed therapy

Compliance with therapy is critical for successful treatment and to limit the development of drug-resistant strains. Many social, personal, public health and economic factors influence patient noncompliance with treatments.[75] The WHO and others strongly advocate directly observed therapy, short-course (DOTS). When patients are in hospital, normal treatment regimens may be used, but for patients in the community intermittent therapy is preferred (Table 37.5). DOTS programs do not simply involve watching patients take their medications, but also incorporate case finding by smear microscopy, ensuring a good supply of effective drugs for short-course chemotherapy, reporting of treatment outcomes and ensuring government commitment to TB control which may be very effective in controlling TB.[76] Although there is little doubt that DOTS may be extremely useful in certain patient groups, randomized controlled trials suggest that not all patients benefit from DOTS.[77] DOTS programs often recruit from non-DOTS programs and the total detection of sputum-positive disease has only increased 5% despite the massive increase in DOTS use.[78]

TABLE 37-5 -- Intermittent chemotherapy regimens for TB.

INTERMITTENT CHEMOTHERAPY REGIMENS FOR TB		
Drug	**3 times/week dose**	**2 times/week dose**
1. Isoniazid	15mg/kg for 6 months (maximum dose 900mg)	15mg/kg for 6 months (maximum dose 900mg)
2. Rifampin	10mg/kg for 6 months (maximum dose 900mg)	10mg/kg for 6 months (maximum dose 900mg)
3. Pyrazinamide	50mg/kg for 2 months (maximum dose 3.0g)	70mg/kg for 2 months (maximum dose 4.0g)
4. Ethambutol	30mg/kg for 2 months	50mg/kg for 2 months (some authorities reduce this dose by 5mg/kg)
or		
Streptomycin	25mg/kg for 2 months (some authorities reduce this dose by 5mg/kg; maximum 1.5g dose)	30mg/kg for 2 months (some authorities reduce this dose by 5mg/kg; maximum 1.5g dose)

Treating multidrug-resistant organisms

Patients should never be prescribed less than three drugs initially and seldom less than four if there is any chance of resistance or a history of previous therapy, irrespective of the sensitivity of the organism initially isolated. Treatment protocols for MDR disease must be designed for the individual, but the aim is to use as many of the first-line drugs as possible before adding second-line drugs. In view of the fact that at least four drugs and possibly more should be given, options are frequently limited. A second-line therapeutic regimen should be continued for 18–24 months after cultures are negative. It is critical that affected patients are adequately isolated and that health care workers are protected from infection. Adjunctive surgical therapy may have a role in circumscribed lesions. Treatment of MDR TB can be difficult and response rates in HIV-negative patients vary from 56[79] to 96%.[80]

Patients with HIV infection

HIV infection does not adversely influence the response to short-course chemotherapy in the absence of drug resistance.[75] [81] The rate of relapse of TB treated with first-line drugs is less than 5% in compliant patients, but increases significantly if rifampin and isoniazid are not used. However, HIV-positive patients who have TB have a 5-to 14-fold increased risk of dying, although superinfection and disease caused by other opportunistic pathogens contribute to the mortality rate. In patients who have HIV infection and TB, four drugs should probably be given routinely in the induction phase of treatment. In contrast, the prognosis of patients who have MDR disease is poor and worse than that of HIV-negative patients. HIV-positive patients are more likely to have adverse reactions to antituberculous medication, particularly to thiacetazone, but also to other drugs.[82] Antituberculous and antiretroviral medications, including protease inhibitors and non-nucleoside reverse transcriptase inhibitors have numerous and complex interactions; the CDC provide updated guidance on this topic via their useful web site (see also Chapter 129).

Use of corticosteroids

Corticosteroid therapy is often advocated but seldom proved to be of benefit in TB. In pericardial TB, corticosteroids have been shown to decrease the acute mortality rate from pericarditis and reduce the need for pericardiocentesis. [83] Corticosteroids may have a role in pleural disease but further data are needed before they can be recommended.[84] Corticosteroids are used during the treatment of CNS tuberculomas to limit their expansion caused by cellular influx and to prevent raised intracerebral pressure. Evidence in favor of using corticosteroids in tuberculous meningitis is conflicting but they are probably beneficial in severe infection and spinal disease.[85] Retrospective studies investigating the role of corticosteroids in military TB have shown no benefit. In all cases, steroid metabolism is increased by rifampin. (See also Chapter 40.d .)

Pregnancy

Pregnancy probably does not increase the severity or reactivation rate of TB or responses to therapy.[86] However, there may be a significant increase in spontaneous abortions and labor difficulties. Congenital TB is very rare and usually presents with hepatosplenomegaly, respiratory distress and fever;[87] it carries a high mortality rate. Tuberculosis frequently requires treatment during pregnancy and this should not be deferred. Isoniazid, rifampin and ethambutol are not teratogenic but few data exist on pyrazinamide. Streptomycin is associated with fetal hearing loss and should be avoided. Little is known about second-line drugs in pregnancy except para-aminosalicyclic acid, which appears to be safe. The presence of antituberculous drugs in breast milk is seldom a problem unless both mother and

child are on treatment, in which case up to 20% more isoniazid than indicated may be taken by the child and bottle feeding is preferable. Breast-feeding children of mothers taking isoniazid require pyridoxine supplementation.

Surgical therapy

Surgical techniques such as artificial pneumothoraces, phrenic nerve paralysis, plombage and thoracoplasty are part of the history of TB before the era of chemotherapy. Now surgeons are most often involved in diagnostic rather than therapeutic procedures relevant to TB. However, resection of tissue may be necessary in patients who have MDR infection, massive hemoptysis (after embolization has failed) and in the management of tuberculous empyema, draining sinuses and bronchopleural fistulas. Surgery has been widely used in the treatment of spinal TB but is only indicated for the presence of progressive neurologic abnormality, spinal instability and to drain large paravertebral abscesses in which CT-guided drainage is not possible. Surgery may be required after destructive TB involving weight-bearing joints. Surgery may have an adjuvant role in nodal TB if a fluctuant mass persists. In laryngeal infection, temporary tracheostomy may be necessary and a few patients may require complex surgery such as partial laryngectomy.

Immunotherapy and the future

Drugs remain at the forefront in the treatment of TB but new compounds are urgently needed. The long-term aim must be to produce true short-course therapy of a few weeks' rather than months' duration. Novel approaches are required in the face of drug resistance. The cytokines interferon-? and IL-2 have been used with success in *M. leprae* infection and such compounds have potential in TB. At present, it is only possible to speculate on other options such as encouraging cellular recruitment to areas of infection, but it remains vital that the necessary basic research is supported.

Chapter 38 - Nontuberculosis Mycobacteria

David E Griffith

INTRODUCTION

The nontuberculous mycobacteria (NTM) encompass all mycobacterial species that are not included in the *Mycobacterium tuberculosis* complex. There are more than 100 species, most of which do not or only rarely cause human disease. A few NTM species, however, are important pathogens in both immunocompetent and immunocompromised hosts. In the past, patients with NTM disease were described as having 'atypical tuberculosis', regardless of the site of disease or the NTM species isolated. Because of the need for specific therapy directed at individual NTM species, 'atypical tuberculosis' or even 'atypical mycobacteria' have become obsolete. Clinicians must now be knowledgeable about the virulence (i.e. potential for human disease), sites of infection and treatment of individual NTM species.

Nontuberculous mycobacteria classification systems have generally not been helpful to the clinician. The most widely used classification scheme in the past, the Runyon system, was based on microbiologic characteristics of the organisms, such as rate of growth and colony pigment formation. Familiarity with the Runyon system remains useful for presumptive laboratory identification of possible NTM pathogens; however, positive identification of NTM species is now largely based on biochemical and molecular biologic techniques. Classification of NTMs based on the organ system of primary involvement (lung, lymph node, disseminated, skin and soft tissue) is more useful to the clinician and is used in this chapter.[1] [2]

EPIDEMIOLOGY

The prevalence of NTM infection can only be estimated because NTM infections are not reportable and the clinical significance is not always clear. There is evidence that the prevalence of NTM disease is increasing, in both the AIDS and non-AIDS populations. In the USA, two surveys of NTM isolates during the years 1979–83 have been published.[3] [4] Using data from these national surveillance studies, the prevalence of NTM disease, largely pulmonary, was estimated to be 1.8/100,000 population. *Mycobacterium avium* complex (MAC) accounted for 1.1/100,000 population, followed in frequency by '*Mycobacterium fortuitum* complex' and *Mycobacterium kansasii*. These prevalence figures are, at best, estimates as the surveys were not comprehensive and the authors could only estimate the number of clinically significant NTM isolates.

A more recent study, covering the period 1991–92, demonstrated an apparent increase in the prevalence of NTM infection in the USA.[5] Despite the increase in *M. tuberculosis* isolates noted in the USA during these years, there were more isolates of MAC than of *M. tuberculosis* in this study. The emergence of disseminated NTM disease in AIDS patients probably had a significant impact on the increased number of NTM isolates in the early 1990s. A bimodal age distribution in NTM isolates was found, with peaks in young adults and in elderly patients, probably reflecting the age peaks in prevalence for disseminated and pulmonary NTM infections.[5] Before the advent of highly active antiretroviral therapy, disseminated NTM infection was almost entirely due to MAC and occurred in 20–40% of AIDS patients.[6] [7]

There is a consensus among investigators in the field that the number of significant NTM isolates continues to rise, especially MAC lung disease, and that the number of immunocompetent patients with NTM disease (primarily lung disease) is increasing. The factors that may be contributing to this increase include:

- an increased total number of clinical specimens submitted for acid-fast bacilli (AFB) analysis;
- better clinical recognition of NTM disease, especially chronic pulmonary disease, in immunocompetent patients; and
- improved laboratory techniques, which have made identification and isolation of NTM more accurate and rapid.

Nontuberculous mycobacterial disease prevalence worldwide is also difficult to estimate but may show geographic clusters (see Table 38.1). For instance, *Mycobacterium xenopi*, a rare pathogen in the USA, is the second most common cause of NTM lung disease in areas of Canada and the UK.[8] *Mycobacterium malmoense*, also a rare pathogen in the USA, is the second most common cause of NTM lung disease in Scandinavia and other areas of northern Europe.[9]

Although MAC disease has a worldwide distribution, disseminated MAC is rarely seen in people from central Africa who have AIDS, even though MAC can be recovered from that environment.[10] One possible explanation is that people who have AIDS in Africa may die from infection with other pathogens before their immunosuppression becomes severe enough for them to develop disseminated MAC.

PATHOGENESIS AND PATHOLOGY

Evidence is mounting to show that the environment is the major source of human NTM infection. Nontuberculous mycobacteria are ubiquitous in the environment and have been isolated from water, soil, dust, domestic and wild animals, milk and food. It is now generally accepted, however, that water is the source of infection for most NTM infections in both immunocompetent and immunocompromised hosts. [2]

DNA fingerprinting techniques that include restriction fragment length polymorphism analysis by pulsed field gel electrophoresis and major polymorphic tandem repeat probe sequence analysis have been especially useful for epidemiologic investigation (Fig. 38.1 and Fig. 38.2). These techniques also may provide clues to pathophysiologic differences between NTM species. For instance, there appears to be great genetic variability between MAC isolates from different patients and sometimes even from the same patient (see Fig. 38.2).[11] In contrast, clinical *M. kansasii* isolates generally have very closely related genotypes, suggesting that most clinical isolates are clonal.[12] This clonal nature of most clinical isolates of *M. kansasii* would seem very unusual for an environmental species (such as MAC), and suggests that their colonization of environmental sites of human disease acquisition (e.g. municipal water supplies) is quite recent and involves only select genotypes.

Pulmonary disease

The evidence for environmental transmission of MAC in pulmonary disease is mostly circumstantial. It grows well in natural waters and is readily aerosolized above bodies of water.[13] *Mycobacterium avium* complex strains with plasmids, possibly associated with virulence, have been shown to be preferentially aerosolized.[14] Recovery rates of MAC from the environment in the USA are highest in the states bordering the Atlantic Ocean and the Gulf of Mexico and this is also the area with the highest rates of MAC infection.[15] In a skin

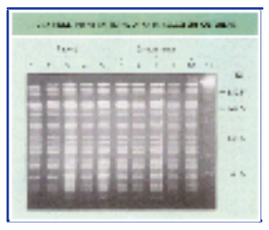

Figure 38-1 DNA fingerprint patterns of 10 Mycobacterium abscessus isolates from an outbreak of M. abscessus infection in a hemodialysis center. Lanes 1–5 are identical strains of *M. abscessus* recovered in blood cultures from five different patients, indicating a common source of infection. Lanes 6–10 are the same strain of *M. abscessus* recovered by sampling a water treatment system contaminated by *M. abscessus*, the source of the patients' isolates. *Courtesy of Dr Yansheng Zhang and Dr Richard J Wallace Jr.*

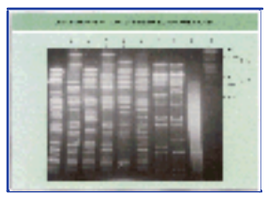

Figure 38-2 DNA fingerprint patterns of nine *Mycobacterium avium* complex (MAC) respiratory isolates (lanes 1–9) collected over an approximately 7-year period from a 67-year-old woman with nodular- bronchiectatic MAC lung disease. Each of the MAC isolates has a distinct DNA fingerprint pattern that suggests repeated reinfection by new MAC strains rather than relapse of infection from a single MAC strain.

test survey performed on 275,000 naval recruits, each of whom had resided from birth in a single county, positive reaction to an MAC skin test antigen (purified protein derivative (PPD)-B) was heavily distributed among those who had lived along the Gulf Coast and Southern Atlantic states.[16] Although the skin test is not specific for MAC, these results support the correlation between geographic environmental exposure and infection in humans.

Pulmonary infection by *M. kansasii* also probably occurs via an aerosol route. Whereas MAC appears to be acquired in rural areas, *M. kansasii* is more likely acquired in urban environments.[17] *Mycobacterium kansasii* isolates of the same phage type as those isolated from patients have been recovered from urban drinking water distribution systems.[18] Clinical isolates and tap water isolates of the same genotype, determined by DNA fingerprinting, have also been identified.[19]

Isolation of *M. kansasii* from tap water can be intermittent, which may explain why some investigators have failed recover it from that source. No other environmental (water or soil) source of *M. kansasii* has been identified.

Disseminated disease

Environmental exposure to NTM in people who have AIDS also probably occurs from aqueous sources, resulting in gastrointestinal or pulmonary acquisition of NTM, usually MAC. Following ingestion of NTM there is direct tissue invasion and, at some point with a declining host immunity, NTM bacteremia. One study using DNA fingerprinting directly linked an environmental source of MAC (hospital tap water) with clinical disseminated MAC disease in some people who had AIDS who were exposed to this water source.[20]

Localized skin and soft tissue infections

Skin and soft tissue infections in immunocompetent patients are probably the result of direct exposure to contaminated water sources through inoculation after accidental trauma, surgery or injection. *Mycobacterium marinum* inhabits water and marine organisms. Infection in humans may be introduced into the skin:

- during cleaning of fresh water fish tanks ('fish tank granuloma');
- by scratches or puncture wounds from organisms such as saltwater fish and shrimp and from fins; and

- through abrasions in nonchlorinated swimming pools ('swimming pool granuloma').

Mycobacterium xenopi has been recovered from hot water taps within hospitals, and in one study a clinical isolate and hospital water isolates were found to be identical by DNA fingerprint analysis.[21] Investigations of nosocomial outbreaks caused by *M. fortuitum, Mycobacterium chelonae* and *Mycobacterium abscessus*, including the use of DNA fingerprinting, have demonstrated that tap water, ice prepared from tap water, processed tap water used for dialysis and distilled water used for preparing solutions are the source of these organisms in nosocomially acquired infection (see Fig. 38.1).[22] [23]

Transmission

There is no firm evidence of human-to-human or animal-to-human transmission of NTM disease. Although family groupings of NTM infection have occasionally occurred in humans, these groupings have been assumed to be due to a common environmental exposure. *Mycobacterium avium* complex is an important cause of disease in poultry and swine, but recent DNA fingerprint studies have shown that strains infecting human and animals are different.[24] [25]

Histopathology

Nontuberculous mycobacterial disease is characterized histopathologically by the presence of caseating and noncaseating granulomatous inflammation, epithelial histiocytes and occasional giant cells. Nontuberculous mycobacterial infection cannot be differentiated histopathologically from tuberculosis. Poorly formed granulomas with histiocytic reactions are more commonly reported in immunodeficient patients, especially those who have AIDS, but they can be seen in immunocompetent patients because not all NTM stimulate granuloma formation equally well.

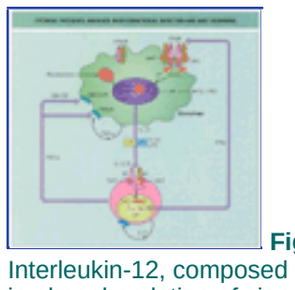

Figure 38-3 Cytokine pathways involved in mycobacterial infection and host response. Mycobacteria infect macrophages and stimulate production of interleukin (IL)-12. Interleukin-12, composed of p35 and p40 subunits, recognizes its receptor on T cells or natural killer (NK) lymhocytes, causing phosphorylation of the cytoplasmic kinases, Tyk2 and Jak2. This results in phosphorylation of signal transducer and activator of transcription (STAT)4, leading to production of interferon (IFN)-?, tumor necrosis factor (TNF)-a and granulocyte-macrophage colony stimulation factor (GM-CSF). Interleukin-12 also stimulates production of IL-2, which feeds back on the T or NK lymphocyte. Interferon-? binds to its receptor on the macrophage, causing aggregation of IFN-?R1 and IFN-?R2 and phosphorylation of the cytoplasmic Janus kinases, Jak1 and Jak2. Consequently, cytosolic STAT1 is phosphorylated, homodimerized and transported to the nucleus, where it upregulates IFN-? responsive genes. Interferon-? and GM-CSF stimulate macrophages to produce TNF-a, which in conjunction with IFN-? drives forward the production of IL-12 and reactive oxygen intermediates, such as superoxide and nitric oxide. *Adapted with permission from Holland SM. Host susceptibility factors in mycobacterial infection: genetics and body morphotype. Infect Dis Clin North Am 2002;16:163–86.*

Interaction between nontuberculous mycobacteria and host defenses

An understanding of the interaction between NTM and host defenses is emerging. The critical interaction, which determines whether NTM infection is established, is between the mycobacterium and the macrophage. Mycobacteria are successful intracellular pathogens that not only penetrate host defense cells but also replicate within them. The mycobacterial cell wall, composed of glycopeptidolipids, including lipoarabinomannan, is probably a key element responsible for the survival and multiplication of NTM within the hostile intracellular environment of the macrophage.[26] Organisms engulfed by the macrophages are taken into intracellular vacuoles, and the prevention of acidification of the intracellular vacuole may be an important mechanism of mycobacterial evasion of host defenses and a virulence factor.[27] If the organism persists and multiplies within the macrophage, then a lymphocyte-mediated immune response, including $CD4^+$ T cells and natural killer (NK) cells, is triggered by the infected macrophage. The role of neutrophils in controlling NTM infection is not clear. The expanded immune response may result in augmented killing of intracellular mycobacteria by the macrophage or destruction of the infected macrophage itself by NK cells. The macrophage-lymphocyte interaction may result in granuloma formation and ultimately determines whether the NTM infection is limited (i.e. controlled) or whether it progresses.

Infected macrophages and stimulated lymphocytes produce soluble factors, including cytokines and prostaglandins, that modulate a complicated immune interaction (Fig. 38.3). Important components of this immune response to mycobacteria include:

- interleukin (IL)-12;
- tumor necrosis factor (TNF)-a;

- interferon (IFN)-?;
- IL-2, IL-6 and IL-10; and

¦ granulocyte-macrophage colony stimulating factor.

Macrophages from normal hosts that phagocytose mycobacteria respond with production of IL-12,[28] which activates T-cells and NK cells through binding to the IL-12 receptor.[29] [30] Binding results in phosphorylation of associated cytoplasmic kinases, which in turn lead to transcription of IL-12 responsive genes, in particular IFN-?. Interferon-? activates neutrophils and macrophages to produce superoxide and nitric oxide, increase surface display of major histocompatibility complex (MHC) molecules and Fc receptors, decrease lysosomal pH and increase the intracellular concentration of certain antibiotics. [31] [32] [33] Interferon-? signals ultimately influence IFN-? responsive genes such as IL-12, MHC genes and TNF-a.[32] [34] The positive feedback loop between IFN-? and IL-12 is pivotal in the immune response to mycobacteria and other intracellular infections. Defects in any of these receptors or cytokine genes may negatively affect the production of IFN-? or IL-12 (or both) and consequently enhance mycobacterial susceptibilitly.[35]

Tumor necrosis factor-a is produced by activated macrophages and NK cells and is also an important immunomodulator for controlling mycobacterial infection. Tumor necrosis factor-a has a significant additive effect on macrophage killing of MAC.[36] The release of TNF-a is stimulated by and is probably responsible for the antimycobacterial effects of IFN-?.[36] Interleukin-2 greatly augments the capacity of NK cells to lyse MAC-infected monocytes, and IL-2-stimulated NK cells also enhance intracellular monocyte killing of MAC, again probably via TNF-a. [37] As noted above, IL-12 is a major stimulant for T cells and NK cells to produce IFN-? and TNF-a and, in turn, IL-12 release is stimulated by IFN-? and TNF-a.[38] [39] Granulocyte-macrophage colony stimulating factor is produced by MAC-infected monocytes and NK cells, and it appears to augment mycobacterial killing.[40] In contrast, IL-6 and IL-10 down-modulate the inflammatory response, especially the effect of TNF-a, and are therefore permissive factors for proliferation of intracellular mycobacteria.[41] [42]

These immune modulators act in a complicated fashion and it is difficult to isolate and measure in vivo any single aspect of the inflammatory cascade. Nevertheless, this line of investigation provides important clues to NTM disease pathogenesis. A practical application of this research is illustrated by a family with a monocyte defect in IL-12 production that was associated with disseminated MAC infection in the absence of HIV infection. This defect was overcome by exogenous administration of IFN-? in addition to other antimycobacterial therapy, resulting in successful treatment of the disseminated MAC infection.[43] [44] Recent identification of specific genetic defects in the IFN and IL-12 response pathways, especially receptor deficiencies, has elucidated key pathways in immune surveillance and NTM control and identified other patients at risk of disseminated NTM infection.[45] To date, however, no immune deficiency has been identified for patients with NTM lung disease.

Body morphotype is another possible predisposition to NTM lung disease. Some patients with pulmonary NTM infections (nodular disease associated with bronchiectasis) appear to have similar clinical characteristics and body types, including scoliosis, pectus excavatum, mitral valve prolapse and joint hypermobility. [46] [47] The constellation of phenotypic abnormalities seen in pulmonary NTM disease may represent a *forme fruste* of a connective tissue disease.

Because most NTM are nonpathogenic, there is intense interest in identifying virulence factors for NTM. Plasmids may encode virulence genes and are more common in MAC isolates from people who have AIDS than in environmental isolates. [48] [49] Other potential virulence factors include:

¦ prevention of acidification of phagocytic vesicles,[27]
¦ prevention of phagosome-lysosome fusion,[50]
¦ delay in TNF secretion by infected host cells,[51] and
¦ catalase activity.[52]

Which factor or factors are most important and whether they can be favorably modified remains to be determined.

CLINICAL FEATURES

Pulmonary disease

Chronic pulmonary disease in the most common clinical manifestation of NTM infection in the USA. It is unclear whether the increased numbers of respiratory NTM isolates recently observed is due to an increasing prevalence of disease or better recognition of existing disease.[4] Several NTM species can cause lung disease in the immunocompetent host (Table 38.1); however, MAC, *M. kansasii* and *M. abscessus* are the most common respiratory pathogens.[2] Whether these ostensibly immunocompetent hosts have an unrecognized defect in host defences is unknown.

Signs and symptoms of NTM pulmonary disease are variable and non-specific and include chronic cough, sputum production and fatigue. Malaise, dyspnea, fever, hemoptysis and weight loss can also

TABLE 38-1 -- Nontuberculous mycobacteria that cause pulmonary disease in the immunocompetent host.

NTM THAT CAUSE PULMONARY DISEASE IN THE IMMUNOCOMPETENT HOST		
Mycobacteria		**Clinical comment**
Common	*Mycobacterium avium* complex	Cavitary disease in male cigarette smokers with COPD; nodular/bronchiectatic disease in elderly nonsmoking women; southeast USA, worldwide
	Mycobacterium kansasii	Clinically and radiographically closely resembles tuberculosis; south central USA, UK, Europe
	Mycobacterium abscessus	Clinically resembles nodular/bronchiectatic form of MAC lung disease; southeast USA
Uncommon	*Mycobacterium fortuitum*	Single isolate usually not clinically significant; unusual lung pathogen except in the setting of gastroesophageal disease with chronic aspiration
	Mycobacterium xenopi	Canada, UK, Europe
	Mycobacterium simiae	Single isolate frequently not significant; southwest USA, Israel
	Mycobacterium szulgai	One culture positive specimen adequate for diagnosis
	Mycobacterium malmoense	One culture positive specimen adequate for diagnosis; Scandinavia, northern Europe
Rare	*Mycobacterium celatum*	
	Mycobacterium asiaticum	
	Mycobacterium shimodei	
NTM that usually represent contamination of respiratory specimens from immune competent hosts: *M. gordonae*, *M. genavense*, *M. smegmatis*, *M. nonchromogenicum*, *M. haemophilum*, *M. vaccae*, *M. thermoresistable*, *M. flavescens*		
COPD, chronic obstructive pulmonary disease.		

occur, usually with advanced disease, but are less common than with tuberculosis.

Nontuberculous mycobacterial lung disease produces variable radiographic features, ranging from apical cavitary lung disease, typical of reactivation tuberculosis, to nodular disease associated with bronchiectasis. Although there are differences in the radiographic features of NTM lung disease compared with those of *M. tuberculosis*, there are no radiographic findings that discriminate with certainty between tuberculosis and NTM lung infection. Similarly, it is difficult to differentiate, on either a clinical or radiographic basis, between NTM species causing lung disease.

Figure 38-4 Apical cavitary infiltrates similar to those caused by pulmonary tuberculosis in a 60-year-old male cigarette smoker with *Mycobacterium avium* complex lung disease.

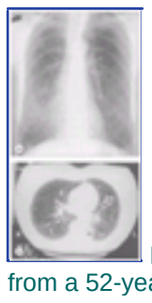

Figure 38-5 *Mycobacterium avium* complex lung disease. (a) Interstitial nodular midlung field infiltrates (right>left) in a 64-year-old female with MAC lung disease. (b) Chest CT scan from a 52-year-old woman with MAC lung disease demonstrating three abnormalities that are common in MAC lung disease: bronchiectasis, a cavity and small (<5mm) nodules.

Mycobacterium avium *complex infection*

Mycobacterium avium complex is the most common cause of NTM lung disease. In the majority of patients in the USA, MAC lung disease is due to *Mycobacterium intracellulare*; in other geographic areas *M. avium* infection is equally common.[53] [54] Lung disease caused by MAC has traditionally been diagnosed in middle-aged or older men, usually with a history of cigarette smoking and underlying lung disease such as chronic obstructive pulmonary disease, previous tuberculosis, pneumoconiosis or bronchiectasis.[17] [55] The majority of these patients have cavitary changes on chest radiography (Fig. 38.4). This form of disease can be aggressive and causes extensive lung destruction.

It is now clear that MAC lung disease has a more heterogeneous clinical presentation, in particular in elderly female nonsmokers who have no known underlying lung disease.[56] These patients present radiographically with mid- and lower-lung field disease characterized by a combination of discrete, small (<5mm) pulmonary nodules and accompanying bronchiectasis — abnormalities that are especially apparent with high-resolution computerized tomography (CT) of the chest (Fig. 38.5). [57] Because this form of disease is radiographically atypical for mycobacterial disease, diagnosis may be delayed, even in patients who have persistent cough and progressive radiographic abnormalities. Disease progression is usually indolent; however, this form of MAC lung disease can be associated with significant morbidity and mortality.[56]

It has also become apparent recently that patients with noncavitary MAC lung disease who are infected by one MAC genotype can be reinfected by another MAC genotype (i.e. polyclonal infections are possible; see Fig. 38.2).[11] These patients would previously have been considered treatment failures, but in fact they are actually reinfected by new MAC strains. This phenomenon complicates the evaluation of a patient who has successfully completed therapy but has sputum that again becomes culture-positive for MAC.

Mycobacterium kansasii *infection*

Mycobacterium kansasii produces pulmonary disease that most closely parallels clinical disease caused by *M. tuberculosis*. Patients with *M. kansasii* lung disease are characteristically older men from urban environments who are cigarette smokers with one or more underlying pulmonary diseases including chronic obstructive pulmonary disease, previous tuberculosis, bronchiectasis or pneumoconiosis.[17] The chest radiographic changes are also very similar to those of reactivated pulmonary tuberculosis, with an upper lobe predilection and cavitation in approximately 90% of patients (Fig. 38.6).

Figure 38-6 Far-advanced *Mycobacterium kansasii* bilateral lung disease in a 42-year-old male cigarette smoker with extensive cavitary destruction of the left upper lobe.

Some patients with noncavitary disease (similar to those with MAC lung disease) have also been identified with *M. kansasii* disease.

Mycobacterium abscessus *infection*

Patients who have *M. abscessus* lung disease are typically elderly female nonsmokers with no known underlying or predisposing lung disease.[58] This disease clinically and radiographically most closely resembles noncavitary (nodular bronchiectatic) pulmonary MAC disease. *Mycobacterium abscessus* and MAC are sometimes isolated concurrently or consecutively in some patients.[58]

Lymphadenitis

Mycobacterial lymphadenitis presents as an insidious, painless, unilateral process involving one or more nodes in a regional distribution with only rare associated systemic symptoms. Upper anterior cervical, submandibular, submaxillary and preauricular lymph nodes are the most commonly involved. Lymphadenitis is the most common disease manifestation of NTM in children. This presentation is most commonly due to MAC (in 60–80% of cases), whereas tuberculosis accounts for only 10–20% of mycobacterial lymphadenitis in this age group.[59] The predominance of MAC is a change from 20 years ago when most geographic areas reported *Mycobacterium scrofulaceum* as the most common etiologic agent.[46] In contrast, mycobacterial lymphadenitis in people over 12 years of age is due to *M. tuberculosis* in approximately 95% of cases. In children, and especially adults, the main differential diagnosis is therefore tuberculosis.

Nontuberculous mycobacterial lymphadenopathy is not usually associated with a history of tuberculosis exposure; tuberculin skin testing in the patient and family are negative and the chest radiograph is normal. Confirming the diagnosis may be difficult because aspiration, biopsy and culture of the involved nodes yields positive cultures in only approximately 50% of the cases.[60] Other NTM that are uncommon causes of lymphadenitis include *M. malmoense, M. fortuitum, M. chelonae, M. abscessus, M. kansasii* and *Mycobacterium haemophilum*.

Disseminated disease

Disseminated NTM disease is most commonly encountered in people who have AIDS with advanced immunosuppression, but it can also occur in people who have severe immunosuppression unrelated to AIDS, such as occurs as a result of chronic corticosteroid use, organ transplantation management or leukemia. More than 95% of disseminated NTM disease in people who have AIDS is due to isolates of MAC. In contrast to MAC pulmonary disease, 90% of MAC isolates in disseminated disease are *M. avium*.[54] [61] Polyclonal MAC infection

Figure 38-7 Disseminated *Mycobacterium chelonae* disease. This manifests itself here by subcutaneous nodules on the lower extremities in an 81-year-old woman receiving high-dose corticosteroids for rheumatoid arthritis.

in AIDS patients appears common and may occur in up to 20% of patients with disseminated MAC infection.[62] Other NTM species also produce disseminated disease, including *M. kansasii, M. chelonae, M. abscessus, M. xenopi, M. malmoense, M. genavense, M. conspicuum, M. gordonae* and *M. haemophilum*. Although disseminated MAC disease presents as a febrile wasting illness, disseminated disease caused by *M. chelonae, M. abscessus* and *M. haemophilum* may present as diffuse subcutaneous nodules or abscesses (Fig. 38.7). Some NTM isolates that cause disseminated disease in people who have AIDS have been considered nonpathogenic when isolated from immunocompetent hosts (see Table 38.1); all NTM isolates from people who are severely immunocompromised, and especially from people who have AIDS, should be regarded as potential pathogens, at least initially.

Disseminated MAC disease in people who have AIDS accompanies severe immunosuppression, with the average $CD4^+$ lymphocyte count at the time of dissemination being approximately 25/mm^3 . Patients who have less than 100 $CD4^+$ lymphocytes/mm^3 and who are not receiving prophylaxis develop disseminated MAC at a rate of approximately 20% per year.[61] Presenting symptoms usually include several weeks of fever, sweats, diarrhea and wasting. Nausea, vomiting and intractable abdominal pain are indicative of the gastrointestinal involvement that frequently occurs. Physical findings include weight loss, hepatosplenomegaly and intra-abdominal lymphadenopathy. Worsening anemia and an elevated alkaline phosphatase level that is out of proportion to hepatic transaminase elevation occur late with continuous bacteremia. Localized pulmonary disease caused by MAC occurs in fewer than 5% of people who have AIDS with MAC infection (see also Chapter 129).[63]

Mycobacterium kansasii infection in AIDS patients, unlike MAC infection, frequently causes disease with the same symptomatology as in people who are immunocompetent.[64] It will disseminate in approximately 35% of AIDS patients who have the infection, usually in association with far-advanced pulmonary disease. Radiographic manifestations of *M. kansasii* pulmonary disease in people who have AIDS are somewhat atypical, with noncavitary changes in approximately 50% of patients. Clinical symptomatology is non-specific and similar to that of disseminated MAC infection; however, disseminated *M. kansasii* may also present with multiple subcutaneous nodules. As in disseminated MAC disease, $CD4^+$ lymphocyte counts average 24/mm^3 in patients with disseminated *M. kansasii* disease, and not surprisingly these patients may have coexistent disseminated MAC infection.

Nontuberculosis mycobacteria rarely cause infection of the central nervous system (CNS) but the most common setting for NTM CNS involvement is as part of disseminated disease in a patient with severe immunocompromise, such as seen with advanced AIDS[65] in which MAC, *M. kansasii, M. gordonae* and *M. genavense* predominate. A very small number of cases of NTM CNS infections have been reported in nonimmunocompromised patients, especially as a result of *M. fortuitum* infection and associated with trauma, surgery, or chronic infections (otitis, mastoiditis). Presenting symptoms for NTM CNS infections are variable and include neuropsychiatric symptoms, headaches, altered mental status, meningismus, cranial nerve abnormalities and problems with co-ordination. Not suprisingly these patients also sometimes have concomitant CNS infections caused by other pathogens.

Differential diagnosis

Disseminated NTM disease must be differential from other infections complicating advanced AIDS. These include disseminated cytomegalovirus, histoplasmosis and, of course, tuberculosis. *Mycobacterium tuberculosis* infection tends to occur earlier in the course of AIDS than NTM infection does, but there are no reliable clinical indicators to distinguish

Figure 38-8 Nodular lesions on the hand caused by *Mycobacterium marinum.* This 45-year old man contracted *M. marinum* after penetrating trauma while cleaning his boat in salt water.

between disseminated NTM and disseminated tuberculosis. In general, a positive AFB specimen from a person who has AIDS must be assumed to be due to tuberculosis until proven otherwise (see Chapter 129).

Localized skin and soft tissue infection

Localized abscess formation after direct inoculation of organisms is most often due to *M. fortuitum, M. abscessus* or *M. chelonae*.[2] Nosocomial skin and soft tissue disease caused by these three species includes infections of long-term intravenous or peritoneal catheters, postinjection abscesses and surgical wound infections, including those after augmentation mammoplasty or cardiac bypass surgery. *Mycobacterium marinum*, MAC, *M. fortuitum, M. abscessus, M. chelonae* and *M. kansasii* have all been implicated in chronic granulomatous infection in tendon sheaths, bursae, joints and bones. *Mycobacterium haemophilum, M. nonchromogenicum* and *M. smegmatis* are rare causes of localized skin and soft tissue disease.

Mycobacterium marinum produces solitary papules on an extremity, especially on the elbows, knees and dorsa of the feet and hands, and subsequently progresses to shallow ulceration and scar formation (Fig. 38.8). Occasionally, multiple 'ascending' subcutaneous lesions resembling sporotrichosis may develop. *Mycobacterium marinum* requires low temperature incubation for isolation; if it is suspected, the laboratory should be notified. Disseminated infection by *M. marinum* has occurred in people who have AIDS and is presumably acquired in the same fashion by these patients as it is by immunocompetent hosts.

Mycobacterium ulcerans causes indolent necrotic lesions of the skin and underlying tissue. The lesions occur most commonly in children and young adults and can result in severe deformities of the extremities if left untreated. *Mycobacterium ulcerans* infections occur in tropical areas of the world, including tropical parts of Australia, but have not been reported in the USA (see Chapter 147).

DIAGNOSIS

All mycobacteria are 'acid-fast' and the fluorochrome method (auramine stain) is the preferred method for microscopic recognition of NTM in clinical samples. The appearance of NTM by microscopy is sometimes indistinguishable from that of *M. tuberculosis*, and therefore confirmation of the presence of NTM still requires cultures. Cultures should be inoculated onto one or more solid media (e.g. Lowenstein-Jensen or Middlebrook 7H10 or 7H11) and into a liquid medium as well, given the more rapid recovery of all mycobacteria in broth systems such as the BACTEC system. All skin or soft tissue samples should be incubated at 95°F (35°C) and at 82.4–89.6°F (28–32°C), because a number of pathogens that infect these tissues, including *M. haemophilum* and *M. marinum*, may grow only at the lower temperatures.

The majority of clinical and public health laboratories now use one or more rapid diagnostic methods for mycobacterial species identification. These rapid methods include high-performance liquid chromatography and commercial DNA probes, which are available for identifying isolates of *M. tuberculosis, M. gordonae, M. kansasii, M. avium* and *M. intracellulare*. These probes are highly sensitive and specific and can provide species identification using a culture directly from both media.

A variety of skin test reagents have been prepared from various species of NTM, including PPD-A from *M. avium* and PPD-B from *M. intracellulare*; however, they are not specific, lack standardization and are not clinically useful in the diagnosis of NTM disease. The use of NTM skin test reagents is currently confined to epidemiologic studies.

Pulmonary disease

Unlike the situation in tuberculosis, a single positive NTM culture from a respiratory specimen, especially if it contains only a small number of organisms, is not always

sufficient to diagnose NTM lung disease or initiate therapy. No single diagnostic algorithm is satisfactory for interpreting the clinical significance of all NTM respiratory isolates. For example, a single positive sputum culture for *M. kansasii* in the appropriate setting is diagnostic. The same is probably true for *M. abscessus, M. szulgai* and *M. malmoense*, and possibly even for MAC. For relatively nonvirulent pathogens, such as *M. fortuitum* and *M. simiae*, a single isolate from sputum is almost never adequate to confirm the diagnosis. Determining the significance of a respiratory NTM isolate requires knowledge of:

- the virulence of the NTM isolated;
- the frequency and quantity with which the NTM was isolated;
- the patient's symptoms, chest radiograph appearance and comorbid conditions; and
- the rapidity of disease progression.

With increasing experience, the process will inevitably evolve to the point that diagnostic criteria will emerge for each NTM species, thereby eliminating the need for 'universal' NTM diagnostic criteria.

Diagnostic criteria for NTM lung disease in the past discriminated between patients with cavitary and noncavitary disease, with more diagnostically rigorous criteria applied to noncavitary disease.[1] Recently proposed diagnostic criteria are applicable to all patients with suspected NTM lung disease regardless of radiographic presentation (Table 38.2).[2]

TABLE 38-2 -- Proposed diagnostic criteria for nontuberculous mycobacterial pulmonary disease.*

PROPOSED DIAGNOSTIC CRITERIA FOR NTM PULMONARY DISEASE
Compatible clinical presentation based on symptoms, radiographic findings (chest radiograph or high-resolution CT scan) and exclusion of other diagnoses
Collection of at least three sputum and/or bronchial wash specimens
One culture-positive sputum or bronchial washing that is either heavily (2+ or greater) smear positive or heavily (2+ or greater) culture positive
or
One culture-positive sputum or bronchial washing associated with multiple smear-positive specimens
or
Multiple positive cultures (at least three) over 1 year, regardless of smear positivity
For unusual radiographic presentation or nondiagnostic sputum analysis, lung biopsy (bronchoscopy with transbronchial biopsy) demonstrating granulomatous inflammation or culture positive for NTM
In questionable cases, obtain expert consultation.

* *Adapted from Wallace et al.*[2]

The term 'colonization' has been used to describe the intermittent or occasional isolation of NTM from respiratory specimens. The significance of 'colonization' in this setting, with its implied benignity, has never been rigorously tested or validated. It may not be clear, for instance, whether a single isolate of an NTM from sputum is due to 'colonization' (superficial or noninvasive infection), slowly progressive or indolent infection, or contamination of the cultured specimen by an NTM from the environment of the patient or of the laboratory. In the case of NTM species that are known to cause pulmonary disease, it is the responsibility of the patient's physician to ensure that a patient with slowly progressive disease is not misidentified as being 'colonized' by the NTM. Isolation of a potential pulmonary NTM pathogen may require the clinician to follow the patient with serial sputum AFB analysis and periodic chest radiographs over a long period of time, perhaps years, in order to judge the significance of the isolated NTM. The worst mistake a clinician can make in managing a patient with NTM lung disease is not a short-term delay in starting therapy, but a failure to provide appropriate clinical and laboratory follow-up for a patient who then has significant progression of NTM lung disease.

Lymph node disease

Nontuberculous mycobacteria disease in lymph nodes is diagnosed by culture of NTM infection in the presence of granulomatous inflammation found on biopsy of infected tissue. The use of fine-needle aspiration for obtaining diagnostic material is controversial because it will yield a positive culture in only 50% of cases.[60] Additionally, a simple diagnostic biopsy or incision and drainage of the involved lymph nodes can be followed by fistula formation with chronic drainage. Because complete excision of involved nodes constitutes adequate therapy for most NTM lymphadenitis, it may also be an appropriate diagnostic procedure.

Disseminated disease

Diagnosis of disseminated NTM infection in people who are immunocompromised, including those who have AIDS, is made by culture of organisms from sterile closed sites, such as blood, liver or bone marrow, or from biopsy of a skin lesion. A single positive blood culture is considered diagnostic of disseminated NTM in an AIDS patient. The isolation of MAC from the sputum or stool of a patient who has AIDS is not diagnostic for disseminated MAC infection; however, the presence of MAC in these specimens is a harbinger for disseminated MAC.[66]

The diagnosis of NTM CNS involvement is difficult, and therefore it is extremely important to suspect the diagnosis on the basis of the clinical setting. [65] Nontuberculosis mycobacteria are rarely found on routine AFB smear analysis of cerebrospinal fluid (CSF), so that a positive AFB culture is usually required to make the diagnosis. The role of rapid diagnostic techniques applied to CSF, such as high performance liquid chromatography analysis, is unknown. The CSF in NTM disease usually shows an elevated white blood cell count with either a neutrophilic or lymphocytic predominance. Cerebrospinal fluid protein and glucose values may vary widely from within normal limits to far outside the normal range. Radiographic evaluation of NTM CNS involvement is usually not diagnostic and can be complicated by radiographic abnormalities caused by concomitant CNS infections due to other pathogens.

Localized skin and soft tissue infections

Diagnosis of NTM infection in skin, soft tissue, bones and joints is made by culture of the specific pathogen from drainage material or tissue biopsy. It is important from a therapeutic standpoint to differentiate between skin and soft tissue lesions related to penetrating injury and those associated with disseminated NTM infection.

MANAGEMENT

The introduction of agents such as clarithromycin, azithromycin and rifabutin has dramatically improved the treatment outcome for some NTM infections. Treatment recommendations for NTM diseases in both immunocompetent and immunocompromised hosts will probably continue to evolve as new agents with activity against NTM are introduced; therefore, recommendations in this chapter may soon become outdated.

The treatment of NTM infections is complicated by the observation that response to therapy for some NTM infections does not correlate with in-vitro drug susceptibilities, especially to antituberculous drugs. Treatment of NTM infections is therefore not as simple or dependent on in-vitro drug susceptibilities as the treatment of tuberculosis; some familiarity with the treatment idiosyncrasies of each NTM is necessary. For instance, clinical response to multidrug antituberculous regimens for *M. kansasii* correlates only with in-vitro susceptibility to rifampin (rifampicin). Response of MAC disease to antituberculous drug regimens in the past frequently had no correlation with in-vitro drug susceptibilities. In contrast, there is a strong correlation between successful treatment of NTM infections, including MAC infection, with clarithromycin and azithromycin and the in-vitro macrolide susceptibility of the specific NTM. Patients with either pulmonary or disseminated MAC infection that is resistant to macrolides will not respond favorably to macrolide-containing regimens.[53] [67] Clarithromycin monotherapy for disseminated or pulmonary MAC disease is associated with a genetic mutation conferring resistance to macrolides and should therefore be avoided.[68]

Recommendations for treating NTM pulmonary disease are given in Table 38.3 . Potential toxicity and drug interactions of commonly used drugs are listed in Table 38.4 . Because of the duration of therapy required and the potential toxicity of the medications, not all patients with NTM lung disease will benefit from therapy. For some patients, the treatment is in essence worse than the disease. Elderly patients who have few symptoms and minimal or very slowly progressive disease or,

alternatively, have severe comorbid conditions and limited life expectancy may not benefit from drug therapy directed at some NTM pathogens, especially MAC. These patients should be selected to receive treatment only after very careful evaluation.

Patients undergoing therapy for NTM pulmonary disease require frequent follow-up:

- to evaluate symptomatic and objective response to therapy and medication toxicity, and
- to collect specimens for AFB analysis.

Serial sputum AFB analysis is the most important element of disease monitoring. The sputum analysis is a critical measure of medication efficacy and may provide evidence for treatment failure (which may be due to the emergence of selective drug resistance), disease relapse or reinfection. Additionally, the duration of therapy for some patients is determined by the duration of time sputum is AFB culture negative while on therapy. Patients who have NTM lung disease should not be placed on therapy for extended periods of time without repeated sputum AFB evaluation. Although periodic chest radiographs are also helpful, the chest radiograph is likely to improve only very slowly.

Drug treatment is not successful for all patients with NTM lung disease. Surgical resection of limited disease remains an important option, although surgical morbidity and mortality dictates that the surgical approach should be undertaken only by surgeons experienced with mycobacterial disease.[71] [72] Other approaches, such as cytokine therapy (especially IFN-?), are promising but remain investigational.[43] [73] Unfortunately, since clarithromycin and azithromycin

TABLE 38-3 -- **Treatment recommendations for selected nontuberculous mycobacteria causing lung and disseminated disease.**

TREATMENT RECOMMENDATIONS FOR SELECTED NTM CAUSING LUNG AND DISSEMINATED DISEASE			
NTM species	**Suggested drug regimen**	**Duration of therapy**	**Comments**
M. avium complex[69] [70] [75] 85,86	Clarithromycin 1g or azithromycin 600mg MWF plus rifabutin 300mg or rifampin 600mg MWF plus ethambutol 25mg/kg MWF	12 months of sputum AFB culture negativity for pulmonary disease, or lifetime therapy for disseminated disease unless immune status restored	Clarithromycin or azithromycin should not be used as monotherapy; consider surgical resection of limited pulmonary disease; add streptomycin initially (2–3 months) 500–1000mg im MWF or amikacin 400mg/day iv for severe disease; rifampin contraindicated with protease inhibitors (consider rifabutin 150mg/day with indinavir)
M. kansasii[1] [2] (rifampin susceptible in vitro)	Rifampin 600mg/day plus INH 300mg/day plus ethambutol 25mg/kg/day for 2 months followed by 15mg/kg/day	18 months and 12 months of sputum AFB culture negativity for pulmonary disease or lifetime for disseminated disease unless immune status restored	Add streptomycin 500–1000mg im MWF or clarithromycin 1g/day initially (2–3 months) for advanced disease; treatment success with this regimen is dependent upon in-vitro rifampin susceptibility; PZA is not effective
M. kansasii (rifampin resistant in vitro or patient on protease inhibitor)	Clarithromycin 0.5g q12h plus ethambutol 25mg/kg/day for 2 months followed by 15mg/kg/day plus INH 900mg/day (B6 50mg/day) plus sulfamethoxazole 1.0g po q8h plus streptomycin 500–1000mg im MWF (initial 2–3 months)	12 months of sputum AFB culture negativity for pulmonary disease or lifetime for disseminated disease unless immune status restored	In-vitro rifampin resistance occurs as a consequence of treatment failure (noncompliance) for rifampin-susceptible *M. kansasii* lung disease; rifabutin 150mg/day can be used with indinavir (see text for other options in AIDS patients)
M. abscessus	Clarithromycin 1g/day or azithromycin 500mg MWF ± cefoxitin, imipenem, amikacin	12 months of sputum AFB culture negativity	No drug regimen of proven efficacy; surgical resection of limited pulmonary disease most effective therapy; first-line antituberculosis drugs not useful
M. fortuitum	Two agents including: ofloxacin 800mg/day or ciprofloxacin 1500mg/day; doxycycline 100mg q12h; sulfamethoxazole 1g q8h; clarithromycin 0.5g q12h	6 months	Therapy based on in-vitro antibiotic susceptibility; only 50% of *M. fortuitum* isolates susceptible to clarithromycin; for severe disease amikacin 400mg/day iv or cefoxitin 12g/day iv until favorable clinical response; first-line antituberculosis drugs not useful
M. chelonae	Clarithromycin 1g/day	6 months	Macrolide monotherapy effective in this clinical situation
Other NTM respiratory pathogens that likely would respond to macrolide-containing regimens: *M. xenopi*, *M. malmoense*, *M. simiae*, *M. szulgai*			
Other disseminated NTM pathogens that likely would respond to macrolide-containing regimens: *M. gordonae*, *M. haemophilum*, *M. genavense*			
AFB, acid-fast bacilli; INH, isoniazid; PZA, pyrazinamide; MWF, Monday, Wednesday and Friday.			

became available, there have been few new drugs introduced with activity against NTM. Linezolid, a new oxazolidinone, has in-vitro activity against some NTM species, including *M. abscessus, M. chelonae* and MAC,[74] but this is not consistent or predictable for all isolates. Linezolid is also associated with frequent and severe side-effects, such as anemia. Clearly, better antibiotic agents for treatment of NTM infections are needed.

Recommendations for treating disseminated NTM disease in AIDS patients are listed in Table 38.3 (see also Chapter 129). Treatment of disseminated MAC, as well as other NTM pathogens such as *M. kansasii*, results in clinical and bacteriologic improvement as well as increased survival. Treatment of these infections has been complicated by the introduction of protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs) for the treatment of HIV infection, which interact with rifamycins.[76] There are several options for treating disseminated NTM disease for patients who are also undergoing therapy for HIV infection. One strategy is the use of three nucleoside reverse transcriptase inhibitors (NRTIs) as initial therapy for HIV disease, which would allow use of rifampin in a multidrug regimen for disseminated NTM infection. Efavirenz, with appropriate dosage adjustment (800mg/day if used with rifampin), can also be added to a multidrug HIV treatment regimen that contains NRTIs, and the patient could still receive a rifampin-containing regimen for NTM disease. For patients receiving the PIs indinavir, nelfinavir and amprenavir or the NNRTIs nevirapine or evafirenz, rifabutin could be used instead of rifampin in the NTM treatment regimen. Recently, a strategy for boosting PI levels by giving ritonavir has been developed, which might also allow concommitant administration of rifampin with the PIs, but dose adjustments are still required. Clearly, the treatment of NTM disease in HIV-infected patients can be very complicated. Inappropriate combinations of drugs may result in treatment failure of one or both infections as well as significant drug-related toxicity. Physicians who do not routinely treat HIV-infected patients or who are not familiar with the drugs involved should seek expert consultation for the management of these patients. Effective regimens for prophylaxis against disseminated MAC are outlined in Table 38.5 . The successful treatment of NTM CNS diseases is difficult because of the relative antibiotic resistance of the organisms, the poor CNS penetration of important agents, such as clarithromycin, and the usually far advanced underlying disease of the host. [65]

Treatment of skin and soft tissue infections due to *M. fortuitum, M. abscessus*, or *M. chelonae* unrelated to disseminated disease involves regimens similar to those recommended for pulmonary or disseminated disease (see Table 38.3).[81] [82] Surgical debridement is important for extensive or poorly responsive disease. Several regimens administered for 3 months are effective for the treatment of *M. marinum* infection, including:

- clarithromycin 500mg q12h,
- doxycycline 100mg q12h,

- trimethoprim-sulfamethoxazole (co-trimoxazole) 160/800mg q12h, and
- rifampin 600mg/day plus ethambutol 15mg/kg/day.

TABLE 38-4 -- Adverse events and drug interactions associated with medications commonly used to treat nontuberculous mycobacterial infections.

ADVERSE EVENTS AND DRUG INTERACTIONS ASSOCIATED WITH MEDICATIONS FOR NTM INFECTIONS

Drug	Adverse events	Drug interactions
Clarithromycin	Bitter taste, nausea, vomiting, abnormal liver enzymes, hearing loss	Blocks cytochrome p450 enzyme metabolism of multiple agents including rifabutin; rifamycins (rifamycin, rifabutin) accelerate hepatic metabolism of clarithromycin
Azithromycin	Nausea, vomiting, diarrhea, abnormal liver enzymes, hearing loss	No known effect on cytochrome p450 enzymes or hepatic metabolism of other drugs
Rifabutin	Nausea, vomiting, abnormal liver enzymes, polyarthralgia, polymyalgia, leukopenia, thrombocytopenia, anterior uveitis	Promotes cytochrome p450 enzymes (less than rifampin) with increased hepatic metabolism of multiple drugs, including clarithromycin; severe side-effects (uveitis) almost exclusively with combined clarithromycin therapy
Rifampin	Nausea, vomiting, abnormal liver enzymes, flu-like syndrome, thrombocytopenia, renal failure, hypersensitivity response	More potent cytochrome p450 enzyme promoter than rifabutin; increased hepatic metabolism of multiple drugs, including clarithromycin, protease inhibitors
Ethambutol	Optic neuritis with loss of red-green color discrimination, loss of visual acuity	

TABLE 38-5 -- Effective agents for prophylaxis against disseminated *Mycobacterium avium* complex lung disease in patients who have AIDS.

EFFECTIVE AGENTS FOR PROPHYLAXIS AGAINST DISSEMINATED MAC LUNG DISEASE		
Regimen	**Dose**	**Comments**
Rifabutin[77] [78]	300mg/day	Rifamycin (rifampin) resistance can emerge with rifabutin monotherapy in patients with occult active tuberculosis; not compatible with some protease inhibitors
Clarithromycin[79]	1g/day	Well tolerated; clarithromycin resistance will emerge if monotherapy used for active disseminated MAC infection
Azithromycin[80]	1.2g/week	Well tolerated; macrolide (clarithromycin) resistance will emerge if monotherapy used for active disseminated MAC infection
Azithromycin[80] plus rifabutin	1.2g/week plus 300mg/day	Very effective prophylaxis regimen; high incidence of rifabutin toxicity

Again, surgical debridement may be necessary for extensive disease.

Complete surgical excision is the standard treatment for NTM lymphadenitis and is usually curative.[83] Antimycobacterial therapy is seldom necessary, except in patients who are immunocompromised. Regimens that contain the newer macrolides are effective for eradicating disease in patients who are unable to have surgery or who undergo incomplete excision of MAC lymphadenitis. [84]

Chapter 39 - Endemic Mycoses

L Joseph Wheat

INTRODUCTION

The endemic mycoses are restricted geographically to areas where environmental and other factors favor the growth of these organisms in the soil. Histoplasmosis and blastomycosis mostly afflict patients in the Mississippi and Ohio river valleys, while coccidioidomycosis occurs primarily in the desert south west USA. Infection occurs when humans are exposed to the organism in the soil, most often by inhalation of aerosolized spores but, in the case of sporotrichosis, also by direct inoculation into the skin and subcutaneous tissues. These mycoses are increasing in importance as causes of opportunistic disease in immunocompromised patients.

HISTOPLASMOSIS

MYCOLOGY

Histoplasma capsulatum var. *capsulatum* is a dimorphic fungus that grows as a mold in the soil and in culture at room temperature and as a yeast in the tissue and when cultured at 98.6°F (37°C). Other varieties of *H. capsulatum* cause African histoplasmosis (*H. capsulatum* var. *duboisii*) and infection of horses and mules (*H. capsulatum* var. *farciminosum*). This chapter will focus on histoplasmosis caused by *H. capsulatum* var. *capsulatum*. Mold cultures grown on Sabouraud's agar appear as white, tan or light brown colonies with abundant aerial hyphae, and require 2–4 weeks for isolation. Definitive identification requires transformation to the yeast at 98.6°F (37°C), exoantigen testing or nucleic acid hybridization. Yeast cells appear as oval structures measuring 2–3 × 3–4µm in diameter. Microscopically the mould is characterized by tuberculate macroconidia measuring 8–15µm and smaller microconidia (2–4µm).

EPIDEMIOLOGY

Histoplasmosis is the most common endemic mycosis and a major cause of morbidity in patients who live in endemic areas (Fig. 39.1). It has emerged as an important complication of AIDS. *Histoplasma capsulatum* is endemic in areas of North and Latin America but can be found throughout the world. Factors accounting for its geographic distribution include humid environmental conditions and acidic, permeable soil characteristics. Heavily contaminated soils, which may harbor up to 105 viable particles per gram, are more common in environments populated by birds or bats, such as bird roosts, chicken coops and chimneys with plentiful bird droppings, old uninhabited buildings and caves with large numbers of bats. Bird and bat excrement enhances growth of the organism in soil by accelerating sporulation.

PATHOGENESIS

Infection develops when conidia are inhaled and germinate into yeast in the tissues (Fig. 39.2) or when old foci of infection reactivate.[1] Cellular immunity plays the key role in defense against *H. capsulatum*. [2] With development of specific T-cell-mediated immunity, interferon-? and interleukin-12 arm macrophages to kill the fungus and halt progression of the disease. These defense mechanisms are sufficient to control the infection in immunocompetent individuals, explaining the subclinical or self-limited course characteristic of acute histoplasmosis. Reactivation of latent infection may account for some cases occurring in individuals who have had histoplasmosis in the past and who become immunocompromised.

CLINICAL FEATURES

The majority of patients remain asymptomatic or develop self-limited disease following exposure. Low inoculum exposure leads to symptoms in approximately 1% of individuals, but 99% have a clinically undetectable infection. Following a high inoculum exposure, the frequency of symptomatic infection is much higher (approximately 50–100%).[3]

Asymptomatic infection

In endemic areas, half to more than 80% of adults are infected with *H. capsulatum*, most cases being asymptomatic. Asymptomatic cases are usually identified by radiographs made for other reasons, which show calcified mediastinal lymph nodes or pulmonary or splenic granuloma.

Primary pulmonary histoplasmosis

The severity of illness correlates with the intensity of exposure. Following heavy exposure, patients may present with diffuse pulmonary involvement. Symptoms of fever, chills, sweats, headache, myalgia, anorexia, cough and chest pain characterize these illnesses, and respiratory failure and death may ensue. Chest radiographs show diffuse reticulonodular or miliary pulmonary infiltrates in 90% of cases, sometimes with mediastinal lymphadenopathy. Some patients may manifest progressive extrapulmonary dissemination. Although patients may recover from heavy-inoculum exposure without treatment, illness is often severe and recovery slow. Thus, treatment is advised. Adjunctive corticosteroid treatment may accelerate improvement in such cases, as the inflammatory response may contribute to the pathogenesis of the respiratory injury.

Following the more typical low-level exposure, the pulmonary illness is more commonly subacute and mild, or even asymptomatic. Chest radiographs show enlarged hilar or mediastinal lymph nodes with patchy infiltrates, but may be normal. While rapid improvement in 2–3 weeks is characteristic, fatigue may linger or inflammatory complications, including rheumatologic syndromes, pericarditis and granulomatous mediastinitis may develop.

Mediastinal granuloma

Enlarged mediastinal lymph nodes may impinge upon the airways, pulmonary vessels or vena cava, or the esophagus, occurring in fewer than 10% of patients who have acute pulmonary histoplasmosis.[3] These findings may first present years after the initial infection, because of smoldering inflammation and necrosis in the involved node. Symptoms include chest pain, cough, hemoptysis, dyspnea

Figure 39-1 Endemic distribution of histoplasmosis in the Americas. This is based upon skin testing surveys.

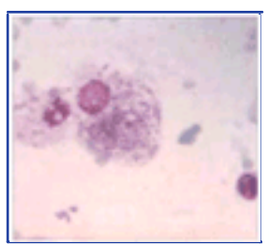

Figure 39-2 Cytologic specimen from bronchoalveolar lavage fluid showing intracellular *Histoplasma capsulatum.*

and dysphagia. Caseous necrosis may lead to fistula formation between the necrotic node and adjacent structures, including the pericardium, skin or esophagus. Calcification may be seen in the involved node, in other mediastinal nodes or in parenchymal granulomas, indicating that the infection occurred years earlier. The affected lymph nodes may form cystic masses containing a necrotic center surrounded by granulomatous tissue and encased in a fibrous capsule. Biopsy of such nodes may lead to drainage of the cheesy central core. Fungal stains and cultures of the node are often negative. Diagnosis usually is made on clinical grounds and supported by positive tests for antibodies to *H. capsulatum*, or by histopathology findings or cultures in patients who undergo node biopsy. Although enlarged mediastinal nodes usually shrink and symptoms resolve without treatment, obstructive syndromes may be severe and the masses may persist for years. Antifungal therapy may be helpful but studies of the effect of treatment have not been conducted. Mediastinal granuloma is not thought to progress to fibrosing mediastinitis and treatment to prevent such an outcome is not advised.

Pericarditis

Pericarditis is a local inflammatory or immunologic reaction to the adjacent mediastinal histoplasmosis, occurring in about 10% of symptomatic cases. [4] Pericarditis rarely may be a complication of disseminated histoplasmosis. Hemodynamic compromise occurs in 40% of patients. Patients usually respond to anti-inflammatory medications without antifungal therapy, while those who have hemodynamic compromise may require corticosteroid therapy or drainage of the pericardial fluid. Outcome is excellent, with rare progression to constrictive pericarditis. Resection of the pericardium to prevent later restrictive disease is not recommended.

Rheumatologic syndrome

This syndrome represents a systemic immunologic reaction following acute histoplasmosis.[3] Arthralgia or arthritis may be the sole finding, or may be associated with pulmonary complaints. Half of patients exhibit erythema nodosum. Joint radiographs are normal, while chest radiographs may show pulmonary histoplasmosis. The joint symptoms usually resolve in response to anti-inflammatory therapy.

Chronic pulmonary histoplasmosis

Patients present with chronic cough, dyspnea, chest pain, fatigue, fevers, sweats and fibrotic apical infiltrates, with cavitations on chest radiographs or computerized tomography (CT) scans. This manifestation occurs mostly in patients who have underlying emphysema.[5] [6] Sputum production is common, facilitating diagnosis by isolation of *H. capsulatum* from respiratory secretions. The illness is progressive, manifested by cavity enlargement, development of new cavities, spread to other areas of the lungs and formation of bronchopleural fistulas. In addition to underlying emphysema, vascular compromise, tissue necrosis and fibrosis are characteristic pathologically.

Fibrosing mediastinitis

Fibrosing mediastinitis represents a fibrotic response to a prior episode of histoplasmosis and is characterized by invasion and obstruction of mediastinal structures.[7] Some 90% of cases occur in persons less than 45 years old and half in women. Active infection is not felt to play a role in the pathogenesis of fibrosing mediastinitis, however, judging from the rarity with which *H. capsulatum* is isolated from the tissues and the lack of response to antifungal therapy.

The clinical features of fibrosing mediastinitis are varied and are caused by obstruction of mediastinal structures. Commonly reported symptoms include cough, dyspnea, chest pain, hemoptysis, pleurisy, facial or upper extremity swelling or congestion, varicose veins on the head, neck, arms or abdomen, dizziness, headache and rarely syncope caused by obstruction of the superior vena cava. Obstruction may involve the superior vena cava, airways, pulmonary arteries or veins, or esophagus. Recurrent and often serious hemoptysis may result from parenchymal damage caused by airway obstruction and vascular compromise. Very rarely the thoracic duct, recurrent laryngeal nerve, or atrium may be involved. Progressive right heart failure and respiratory insufficiency occur in one-third of cases. Recurrent pneumonia also may complicate fibrosing mediastinitis.

Subcarinal or superior mediastinal widening is seen on chest radiograph, while CT scans reveal restriction and invasion of mediastinal

structures.[8] Ventilation-perfusion lung scans may show reduced blood flow in patients who have pulmonary artery obstruction. Pulmonary artery or venous contrast studies may be required to define the extent of obstruction in patients who have severe manifestations and are under consideration for surgery. While fungal stains of tissues are positive in two-thirds of cases, cultures are positive in only 10%,[8] supporting the hypothesis that fibrosing mediastinitis is an excessive scarring reaction to a past infection. Serologic tests are positive in two-thirds of cases at titers of more than 1:32.

Broncholithiasis

Mediastinal nodes and pulmonary granulomas eventually calcify. Rock-like structures may erode into bronchi, causing ulceration or obstruction manifested by cough, hemoptysis and purulent sputum production.[9] Patients may expectorate 'stones', which represent calcified lung tissue or lymph nodes. Fungal stains of tissue may demonstrate organisms but cultures are usually negative and antifungal therapy is not felt to be helpful. Surgical resection of the damaged tissue may be required in patients who have significant hemoptysis, recurrent obstructive pneumonia or broncho-esophageal fistulas. Airway obstruction and lung damage predispose to bacterial pneumonia, necessitating antibiotic therapy.

Disseminated histoplasmosis

Progressive disseminated histoplasmosis occurs in about one in 2000 acute infections, usually in patients who are immunosuppressed or at the extremes of age.[10] [11] Severity varies with the degree of immune deficiency. An acute, rapidly fatal course with diffuse reticuloendothelial involvement characterizes the infection in infants and others who are severely immunosuppressed, while a chronic course with a more focal organ distribution is more typical in nonimmunocompromised children and adults. [10] Patients who have AIDS or those who are receiving immunosuppressive medications may present with shock, respiratory distress, hepatic and renal failure, obtundation and coagulopathy.[12] Severe manifestations may also occur if immunosuppressive medications are administered for a mistaken diagnosis of sarcoidosis. Fever and weight loss are the most common symptoms. Examination reveals hepatomegaly or splenomegaly in about half of cases and lymphadenopathy in a third. Meningitis or focal brain lesions occur in 10–20% of cases.[13] Other common sites of dissemination include the oral mucosa, skin and adrenal glands, seen in 5–10% of cases. Chest radiographs are abnormal in 70% of patients, usually showing diffuse interstitial or reticulonodular infiltrates.

DIAGNOSIS

Antigen detection

The approach to diagnosis has recently been reviewed.[14] Detection of antigen in the body fluids offers a valuable approach to diagnosis

TABLE 39-1 -- Laboratory tests for histoplasmosis.

LABORATORY TESTS FOR HISTOPLASMOSIS			
	Sensitivity (% true positives)		
Test	**Disseminated**	**Chronic pulmonary**	**Self-limited***
Antigen	92	21	39
Culture	85	85	15
Histopathology	43	17	9
Serology	71	100	98

* Self-limited manifestations include acute pulmonary histoplasmosis, rheumatologic syndromes and pericarditis.

in severe cases, including those with disseminated and extensive pulmonary histoplasmosis, providing results within 24–48 hours. Antigen is found in the blood, urine and bronchoalveolar lavage fluid of most individuals who have disseminated histoplasmosis (Table 39.1) and in up to 75% of those who have diffuse lung involvement during acute pulmonary histoplasmosis. Positive results caused by cross-reacting antigens occur in patients who have African histoplasmosis, blastomycosis, paracoccidioidomycosis and *Penicillium marneffii* infection.[15] Cross-reactions have not been recognized in patient who have candidiasis, cryptococcosis, aspergillosis or coccidioidomycosis.

Mycologic tests

Fungal staining permits rapid diagnosis but with a lower sensitivity than culture or antigen detection. *Pneumocystis carinii*, *Candida glabrata*, *Blastomyces dermatitidis*, *Toxoplasma gondii* and *Penicillium marneffii* may be misidentified as *H. capsulatum*. Cultures are most useful in disseminated and chronic pulmonary cases, positive in about 85% of cases if multiple specimens are submitted. In disseminated histoplasmosis, the highest yield is from bone marrow or blood. Cultures are usually negative in patients who have mild acute pulmonary, pericardial or rheumatologic manifestations, and need not be performed.

Serologic tests

Antibodies to *H. capsulatum* measured by immunodiffusion or complement fixation develop in most patients.[16] Enzyme immunoassay and radioimmunoassay methods for measurement of antibodies are not reliable and should not be performed. Limitations of tests for antibodies include: a 4- to 8-week delay in diagnosis while antibodies are being produced following acute infection; false-negative results in immunocompromised patients; and false-positive results in patients who have blastomycosis, coccidioidomycosis and paracoccidioidomycosis. In addition, antibodies persisting following an earlier episode of histoplasmosis may cause confusion in patients who have other diseases.

Histoplasmin skin test

Skin tests are not useful diagnostically because of high background rates of skin test positivity (50–80%) in endemic areas, false-positive results in patients who have other fungal diseases and false-negative results in patients who have disseminated disease. Furthermore, skin tests boost antibody levels, compromising the interpretation of serologic tests. The skin testing reagents are no longer available.

MANAGEMENT

Although histoplasmosis resolves without therapy in most individuals, severe illness may follow heavy exposure even in the absence of immunosuppression. In addition, some patients who have acute histoplasmosis experience persistent symptoms due to either the infection or the accompanying inflammatory response. Most patients who have underlying emphysema have chronic pulmonary infection that does not clear spontaneously. Patients who have disseminated histoplasmosis rarely recover without therapy. Treatment guidelines have recently been published.[17] [18]

Acute, diffuse pulmonary disease

Patients who have extensive acute pulmonary histoplasmosis and are dyspneic or hypoxic should receive antifungal therapy. Amphotericin B 0.7–1mg/kg per day, or the liposomal formulation at 3mg/kg per day,[19] is recommended in those who have more severe manifestations, followed by oral therapy with itraconazole after the patient has improved clinically. Corticosteroids (60mg daily tapered over 2–4 weeks) also are helpful in severe cases. Patients who have milder manifestations may be treated with itraconazole alone. A 3-month

course of itraconazole is recommended, but studies to support this duration of therapy are lacking.

Subacute, localized pulmonary disease

Antifungal therapy is unnecessary in most patients who have localized disease, as they recover without treatment within a month. Some patients, however, may remain symptomatic longer and may possibly benefit from therapy. Treatment is recommended in patients who have moderately severe symptoms and have not improved after 2–4 weeks of observation. Itraconazole given for 3 months is recommended in such cases.

Chronic pulmonary disease

Treatment is indicated in all patients who have chronic pulmonary histoplasmosis. The illness is slowly progressive, causing loss of pulmonary function and even death; and treatment halts progression and reduces mortality. Itraconazole 200mg daily was effective in 80% of cases.[20] Fluconazole 200–400mg daily is less effective (64% response).[21] Amphotericin B is also effective, with response rates of 59–100%. Relapse occurs in 10–20% of patients, however, supporting 12–18 months of therapy and close follow-up.

Mediastinal granuloma

The role of therapy in patients who have granulomatous mediastinitis is unclear. Improvement may occur spontaneously or in response to antifungal therapy. Surgical resection of obstructive masses may be helpful if symptoms do not respond to antifungal therapy but resection of enlarged nodes to prevent progression to fibrosing mediastinitis cannot be supported. A trial of itraconazole is recommended in patients who have symptomatic infection and those who have significant impingement on the esophagus, airways or vasculature.

Pericarditis or rheumatologic syndromes

These inflammatory or immunologic responses to the infection are not treated with antifungal therapy.[4] Symptomatic patients respond to anti-inflammatory therapy. If corticosteroids are used for more than a few weeks, itraconazole may be appropriate to reduce the likelihood of progressive dissemination.

Fibrosing mediastinitis

Many patients demonstrate nonprogressive disease without major disability, and do well without therapy.[7] Based upon the pathologic finding of extensive fibrosis, without inflammation or active infection, antifungal or anti-inflammatory treatment would not be predicted to be helpful. Nevertheless, a 3-month trial of itraconazole seems reasonable, particularly if complement fixation titers and the sedimentation rate are elevated. If follow-up imaging shows improvement, treatment should be continued for 6–12 months. Use of corticosteroids or other anti-inflammatory agents is not recommended.

The role of surgery remains controversial. Fewer than half of patients benefit and up to a quarter may die as a complication of surgery.[7] Placement of intravascular stents may be helpful in selected patients who have pulmonary vascular obstruction, and embolization may relieve pulmonary hemorrhage.

Disseminated histoplasmosis

In a study in AIDS patients who had disseminated histoplasmosis, improvement of symptoms occurred faster and mortality was lower in patients treated with liposomal amphotericin B 3mg/kg per day than with the standard deoxycholate preparation 0.7mg/kg per day.[19] Thus, liposomal amphotericin B is preferred as initial therapy in patients who have severe or moderately severe disseminated histoplasmosis. Once patients are stable (10–14 days), they can be switched to oral therapy. Itraconazole is recommended in patients who have less severe illness and following response to amphotericin B. In noncomparative trials, itraconazole was successful in 85–100% of cases.[22] If itraconazole is used as initial therapy for patients who have moderately severe manifestations of histoplasmosis, the intravenous formulation is preferred initially (3–7 days). Fluconazole is less effective than itraconazole[21] [23] and may lead to development of resistance, [24] causing relapse. Fluconazole also antagonizes the activity of amphotericin B in histoplasmosis,[25] [26] discouraging the use of the two drugs in combination. Patients who have AIDS may require lifelong therapy (see Chapter 126); other immunocompromised patients should be treated for at least 1 year.

PREVENTION

Prophylaxis in people who have AIDS with $CD4^+$ counts below 150 lymphocytes/mm^3 is highly effective and is recommended if the case rate exceeds 5 cases/100 patient-years,[27] but may encourage the development of resistance among *Candida* spp.[28]

COCCIDIOIDOMYCOSIS

MYCOLOGY

Coccidioides immitis exhibits saprophytic and parasitic life cycles. Arthroconidia measuring 2.5–4 × 3–6µm cause infection following inhalation. In the host tissue the arthroconidia transform into spherules (30–60µm), which mature with the formation of numerous endospores (Fig. 39.3). Transformation between the yeast and mold does not exhibit predictable temperature dependency. The mold phase grows rapidly on fungal media, and arthroconidia can be seen within 5–10 days.

EPIDEMIOLOGY

Coccidioidomycosis occurs in a spotty distribution in the south western USA, northern Mexico and Central America (Table 39.2). There are an estimated 100,000 new infections yearly, of which half or more are subclinical.[29] Bat and rodent droppings enhance growth in the soil. Hot summers, mild winters and arid conditions characterize climates in the endemic areas. Exposure is heaviest in the late summer and autumn, when the soil is dry and conditions are windy, especially following rainy winters. Experience following the Northridge earthquake in southern California indicated that exposure to subsequent dust storms increased the risk of coccidioidomycosis. [30] Workers exposed to soil are at increased risk of coccidioidomycosis.[31] It is notable that nearly 50% of cases in persons

TABLE 39-2 -- Fungi causing infection in normal and compromised hosts.

FUNGI CAUSING INFECTION IN NORMAL AND COMPROMISED HOSTS				
Fungus	**Incidence**	**Geographic distribution**	**Epidemics**	**Form**
Histoplasma capsulatum var capsulatum	Common*	River valleys between latitudes 45°N and 30°S	Occasional	Dimorphic
Coccidioides immitis	Common*	South western USA, Central America, Argentina	Occasional	Dimorphic
Blastomyces dermatitidis	Uncommon	Ohio and Mississippi river valleys	Uncommon	Dimorphic
Sporothrix schenckii	Uncommon	Worldwide	Uncommon	Mold
Paracoccidioides brasiliensis	Common*	Mexico, 23°N to Argentina, 34°S	Uncommon	Dimorphic

* In endemic areas

who have AIDS are identified outside the endemic area,[32] [33] occurring in travelers who have visited these regions.[32] [34] Also of note is the increasing incidence in elderly persons who have moved to Arizona in recent years.[35]

PATHOGENESIS AND PATHOLOGY

Infection occurs following inhalation of arthroconidia of the mycelial phase of the fungus, which enlarge to form thick-walled spherules containing multiple endospores in the tissues (see Fig. 39.3). Spherules rupture, releasing endospores that spread locally and disseminate hematogenously. Cellular immunity and neutrophils are both involved in host defense in coccidioidomycosis. Pathologically, coccidioidomycosis is characterized by a pyogranulomatous reaction, often resulting in the development of large abscesses. Fibrosis may be prominent in the lungs or meninges.

CLINICAL FEATURES

About 40% of nonimmune individuals experience symptoms following exposure to *C. immitis*, while the others have subclinical infection.[36] Pulmonary illness is most common. Over 90% of symptomatic patients recover without treatment and fewer than 1% develop chronic pulmonary or extrapulmonary complications. The illness is more severe in immunosuppressed individuals, African-Americans and Filipinos. Unlike the normal hosts, two-thirds of immunosuppressed patients exhibit disseminated disease. Clinically recognized pulmonary involvement is present in most cases in transplant patients and in well over 90% of those who have AIDS.[37] Although coccidioidomycosis is reported to be more severe during pregnancy, recent reports indicate that the course is more favorable than was previously thought.[38]

Primary pulmonary disease

Flu-like symptoms, including chest pain, nonproductive cough, fever and malaise, develop within a few weeks following exposure.[34] [36] Patients who have more extensive pulmonary infection may experience dyspnea or respiratory failure. Chest radiographs show patchy infiltrates, often with mediastinal adenopathy. Nodular coin lesions (coccidiomas) and thin-walled cavities may follow in 5% of patients. Pleural involvement is uncommon (<10%), and may lead to pneumothorax, bronchopleural fistula or empyema. Pericardial effusions may also be seen. Joint pain occurs in a third of cases[34] and erythema nodosum is particularly common in women.[30] [38] A non-specific maculopapular rash also is common, especially in adolescents.[34] Airway involvement has been described,[39] involving the trachea, larynx or bronchi. Airway lesions may present as friable masses, small nodules with yellow centers, hyperemic patches or cobblestone patterns, and ulcers have been noted in autopsy reports.

Chronic pulmonary disease

Several types of pulmonary disease can develop after the initial infection. These include the formation of pulmonary nodules (coccidiomas), cavitary disease and progressive pneumonia. The nodules are typically solitary, measuring 2–3cm in diameter, representing areas of granulomatous organization of coccidioidal pneumonia and raising concern for lung cancer. Thin-walled cavities are seen in approximately 0.1% of all patients and often (35–50%) resolve spontaneously within 2 years. Thick-walled cavities are more likely to progress. Chronic fibrocavitary infection with progressive fibrosis and retraction similar to that seen with histoplasmosis may also be seen in coccidioidomycosis, occurring primarily in those with underlying emphysema.

Disseminated disease

Extrapulmonary dissemination occurs in fewer than 1% of persons who have coccidioidomycosis, typically during the first year following exposure. [36] Dissemination occurs more frequently in the very young or very old, certain racial or ethnic groups, those who have AIDS or other immunosuppressive disorders, and during the second half of pregnancy or postpartum. Pulmonary involvement is manifested as reticulonodular infiltrates in most cases. Tissues most commonly involved are skin, bone, joints and meninges, and tenosynovitis and sinus tract formation have been reported. A septic shock syndrome associated with respiratory failure has been described in patients presenting with focal or diffuse pulmonary coccidioidomycosis who are later identified as having disseminated disease.[40] [41] Meningitis is a

frequent complication, with a poor prognosis.[42] Hydrocephalus and neurologic deficits due to cranial nerve damage are common. Other sites of infection include lymph nodes, liver, peritoneum, kidneys, epididymis, prostate, testes, retina, ears, larynx, heart, thyroid, adrenal, pituitary, esophagus and pancreas.

DIAGNOSIS

Diagnosis of chronic pulmonary or disseminated coccidioidomycosis usually can be substantiated by positive culture. Fungal stains of respiratory secretions or tissues may show typical spherules, providing a more rapid diagnosis. Bronchoscopy improves the yield for isolation

of *C. immitis* from the respiratory tract. *Coccidioides immitis* may often be recognized by culture after only 3–5 days of incubation. In contrast to histoplasmosis, blood cultures are infrequently positive in coccidioidomycosis. It is of note that laboratory workers are at risk of acquiring coccidioidomycosis if the organism is not handled using biosafety level 3 precautions.

Serologic tests are useful in coccidioidomycosis, being positive in over 80% of cases.[43] High titers of complement fixing antibodies (1:16 or greater) or rising titers suggest more extensive infection and support the need to exclude dissemination. Detection of antibody in cerebrospinal fluid at titers of 1:2 or higher is valuable for diagnosis of meningitis.

Skin test reactivity to coccidioidin precedes development of antibodies by several weeks and may be useful in diagnosis of acute coccidioidomycosis.[43] Demonstration of skin test reactivity may provide the sole basis for diagnosis in up to 20% of patients who have self-limited illness and 95% of asymptomatic cases. Cross-reactions with other mycoses are uncommon and skin tests do not induce production of antibodies to coccidioidal antigens. The standard reagent should be diluted for use in patients who have erythema nodosum, however, as severe reactions may occur. [36]

MANAGEMENT

Most patients who have newly diagnosed coccidioidomycosis and no risk factors for complications or evidence of extensive disease may be managed without antifungal therapy.[33] During the first few weeks of infection, such patients should experience spontaneous improvement in fatigue, fever and weight loss; persistence of these findings should prompt reconsideration of the need for therapy. All patients should be monitored for 1–2 years to exclude progressive pulmonary or extrapulmonary disease. Treatment guidelines have recently been published.[29] A quarter of patients with disseminated coccidioidomycosis fail therapy and a similar proportion subsequently relapse. Lifelong therapy may be appropriate in those who are immunocompromised or have meningitis.[29] The role of therapy for asymptomatic, seropositive individuals who are to undergo organ or bone marrow transplantation is unknown but is recommended by some.

Amphotericin B is recommended for initial therapy for patients who are severely ill or have diffuse interstitial infiltrates because it acts more rapidly than triazole antifungal agents.[29] In severe cases (e.g. disseminated disease in patients who have AIDS), the combination of amphotericin B and fluconazole can be used initially. If amphotericin B is used as the sole therapy at least 35mg/kg is needed to achieve satisfactory and durable responses. Fluconazole induced a clinical response in 79% of patients who had meningitis, [44] 76% of those who had cutaneous manifestations and 86% of those who had skeletal manifestations of disseminated infection.[45] Response was poorer in patients who had chronic pulmonary infection (55%).[45] Itraconazole induced a response in 57–94% of patients who had chronic pulmonary or disseminated disease.[46] [47] The two agents were equally effective in a prospective trial in persons who did not have AIDS.[48] Prolonged therapy (more than 1 year) with high daily doses (fluconazole 400–800mg and itraconazole 400mg) would seem appropriate. Chronic maintenance therapy is essential for all patients who have severe immunodeficiency, including AIDS,[29] and perhaps in others who have relapsed after appropriate therapy.

Treatment of coccidioidal meningitis offers a special challenge. The relatively poor response to amphotericin B is partially explained by its poor penetration into the cerebrospinal fluid. Previously, to circumvent this problem, amphotericin B was given intrathecally. Now, fluconazole has replaced amphotericin B for treatment of coccidioidal meningitis. In total, 80% of patients who had coccidioidal meningitis responded to fluconazole, often after failing amphotericin B.[44] Lifelong therapy to prevent recurrence is recommended in coccidioidal meningitis. [29]

Adjunctive surgical therapy

Surgical debridement or resection of infected tissue often is necessary as an adjunct to antifungal therapy in coccidioidomycosis. Chronic foci of pulmonary necrosis or cavitations may require resection to prevent progression during therapy or recurrence following therapy. Soft tissue, joint or bony abscesses may require drainage or debridement.

PREVENTION

Antifungal prophylaxis in AIDS has not been recommended. However, if the attack rate is high during an outbreak, prophylaxis should be considered. Efforts to develop an effective vaccine have been intensified but none is available to date.[49] Immunosuppressed individuals should avoid areas experiencing active outbreaks and should perhaps avoid the desert during dry windy conditions.

BLASTOMYCOSIS

MYCOLOGY

Blastomyces dermatitidis exists as a mold at room temperature and in the soil and yeast at 98.6°F (37°C) and in the tissues. The mold can usually be isolated in the laboratory in less than 2 weeks, and conversion to the yeast occurs readily, usually within 1–3 weeks. Yeast cells measure 8–15µm, and occasionally up to 30µm, and exhibit thick refractile cell walls and broad-based buds (4–5µm).

EPIDEMIOLOGY

The organism may be found in microfoci enriched with animal excreta. Cases most often occur in the mid-western and south eastern USA in a distribution overlapping that of histoplasmosis. Up to 30% of men from endemic areas demonstrate immunologic evidence of previous blastomycosis.[50] Rare isolations from soil have occurred in samples from areas inhabited by farm animals and from beaver lodges or dams.[51] Common source outbreaks have been reported, often in association with outdoor activities in wooded or swampy environments such as hunting, camping or canoeing.

PATHOGENESIS AND PATHOLOGY

Cellular immunity plays a role in defense against *B. dermatitidis* but perhaps less than against other endemic mycoses. Infection is more extensive and outcome is worse in immunosuppressed individuals. Pathologically, blastomycosis is characterized by pyogranuloma formation with central microabscesses, but not by caseation as seen in histoplasmosis. Histologic changes may resemble those of cancer, leading to a mistaken diagnosis.

Reactivation of latent infection has been reported.[52]

CLINICAL FEATURES

In an outbreak setting, half of persons who were infected were asymptomatic.[51] The commonly recognized manifestations include acute and chronic pulmonary and disseminated disease, and the illness may be fulminant.[53] [54] The acute illness may be self-limited; in one outbreak only 18% of patients were treated.[51]

Pulmonary disease

Lung involvement may be localized or diffuse, each occurring in about half of patients.[55] Presenting symptoms include fever, cough, dyspnea, chest pain and weight loss. Tracheal and endobronchial involvement may occur. Pulmonary lymphadenopathy and calcification

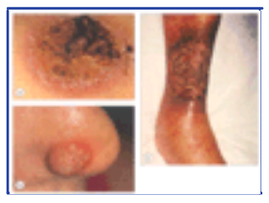

Figure 39-4 Cutaneous blastomycosis. (a,b) Skin lesions caused by *Blastomyces dermatitidis* in a normal host. (c) A large cutaneous ulcer in a patient who has multiple myeloma.

are uncommon.[56] Mass lesions may suggest cancer in about 15% of cases.[56] [57] Pleural involvement occurs in 20% of cases and may invade into adjacent tissues. About 10% of cases may present with diffuse infiltrates associated with respiratory failure. The illness resembles bacterial sepsis and carries a 50–90% mortality rate.[54] Such cases may have an underlying chronic disease in less than half of cases, and immunodeficiency in about a quarter.

Disseminated disease

Extrapulmonary dissemination is identified in a quarter to one-half of diagnosed cases of blastomycosis. Skin lesions, noted in half of patients, are usually painless erythematous nodules that develop verrucous or ulcerative surfaces (Fig. 39.4). Bone and joint lesions occur in less than half of patients. Central nervous system involvement, manifested as meningitis, brain lesions or epidural abscesses, is relatively common (~15%), occurring more often in immunocompromised individuals.[57] Laryngeal involvement may be mistaken for cancer, and cases have been described with involvement of the paranasal sinuses and ears. The kidneys, testes, prostate or epididymis, spleen, liver, pericardium, eyes, adrenal glands and thyroid may also be involved.

DIAGNOSIS

Mycology

Diagnosis usually is based on demonstration of organisms by culture or fungal stain.[57] Cultures are positive in over 90% of patients in the immunosuppressed host.[58] *Blastomyces dermatitidis* has been isolated most frequently from respiratory secretions or skin lesions but has also been detected in bronchoscopy specimens, bone, cerebrospinal fluid, brain or other less common sites of dissemination. Of note, fungal stains are often positive, providing a more rapid diagnosis.

Serology

The complement fixation test is neither specific nor sensitive and thus cannot be relied upon. The immunodiffusion test is more specific but less sensitive. Overall, the serologic tests are positive in about a quarter of cases. [51] [54] Tests for antibodies are of limited value in diagnosis of blastomycosis and are not recommended. [59]

Antigen detection

Diagnosis by antigen detection could be useful in patients who have extensive pulmonary or disseminated disease. An antigen cross-reacting with *H. capsulatum* may be detected in the body fluids in over half of patients, providing a rapid diagnosis in patients who have extensive disease.[15] Work is in progress to develop a specific antigen detection assay for blastomycosis.

MANAGEMENT

Observation would be appropriate in an individual who does not have underlying immunosuppression and was already improving when first evaluated. [60] Such patients are at risk for relapse, however, and should be monitored for at least a year. The main cause of death is overwhelming pneumonia, which may occur within the first few days following diagnosis, highlighting the importance of aggressive therapy in patients who have severe disease or underlying immunosuppressive disorders.

Amphotericin B has been effective in 70–90% of cases, with low relapse rates.[59] Amphotericin B 0.7–1mg/kg per day is recommended for initial therapy in the immunocompromised host, those who have severe manifestations or central nervous system disease, and those who have failed treatment with an azole.[60] Once the patient responds to amphotericin B (after about 1g), itraconazole should be given for at least 1 year. A higher total dose of amphotericin B of at least 2g is recommended in those who have central nervous system involvement, usually given at a dose of 0.7mg/kg q24h.[61]

Itraconazole 200mg q12h or q24h is the most effective azole, inducing remission in over 90% of cases.[59] It is recommended in patients who have mild to moderate disease and following response to a minimum dose of 500mg of amphotericin B. The duration of itraconazole therapy should be at least 6 months in most cases and 12 months in patients who have bone disease. It should be continued until all evidence of ongoing infection has subsided. Chronic suppressive therapy is recommended in those who have AIDS or ongoing severe immunosuppression.

Fluconazole at high doses of 400–800mg per day is also reasonably effective (response rate 87%[62]) and may be used in patients unable to be treated with itraconazole and perhaps in those who

have meningitis, after completing 2g of amphotericin B. In those who have central nervous system disease, the minimum fluconazole dose is 800mg daily, adjusted for renal function.

SPOROTRICHOSIS

MYCOLOGY

Sporothrix schenckii grows rapidly as a mold in the laboratory at 86°F (30°C) and transforms to yeast at 95–98.6°F (35–37°C). The yeast is characterized by cigar-shaped buds. Radial conidia of the mould are flower-like in appearance. Definitive identification requires conversion to the yeast at 95–98.6°F (35–37°C) on enriched media.

EPIDEMIOLOGY

Sporotrichosis, caused by the dimorphic fungus *S. schenckii*,[63] is most common in tropical and subtropical regions but occurs worldwide. The organism is often isolated from soil, sphagnum moss and plant debris such as thorns, timber, hay and straw. Infection usually occurs following cutaneous inoculation of the organism during outdoor activities such as forestry, gardening and farming, or manual labor in rural areas. Cases are common in children, who are exposed during outdoor play. Clusters of cases may occur following a common exposure, and outbreaks have been reported rarely.

PATHOGENESIS AND PATHOLOGY

Typically, there is a history of scratches from rose thorns, conifer needles or timber. Natural infection also occurs in wild and domesticated animals. Zoonotic infections have been traced to bites and scratches from cats, birds, rodents and armadillos. Cutaneous or lymphocutaneous disease follows local inoculation. Hematogenous dissemination can occur, leading to multifocal disease. Rarely, inhalation of organisms results in a granulomatous pneumonitis. The inflammatory response is characterized by an accumulation of neutrophils and macrophages, in the presence of giant cells and central necrosis.

CLINICAL FEATURES

Lymphocutaneous disease is the most common manifestation of sporotrichosis. Skin lesions appear at the site of inoculation and may progress to cause lymphangitis and regional lymphadenopathy. Systemic complaints are absent. The distal extremities are most often involved, although there may be lesions at any cutaneous site. These raised, nodular, erythematous lesions often ulcerate. They vary in size from tiny punctate lesions to 2–4cm in diameter. Infection advances through local lymphatic channels, producing secondary lesions that are identical to the primary lesions.

Deep inoculation can lead to the development of tenosynovitis and nerve entrapment or carpal tunnel syndromes, with or without joint involvement. Ocular infection has resulted from finger-to-eye transmission. Osteoarticular involvement most often involves the joints of the extremities. The infection is usually indolent and progresses slowly.

Pulmonary sporotrichosis may result from inhalation of the organisms or as a result of dissemination from a cutaneous focus. The usual presentation is that of a pneumonitis with non-specific respiratory symptoms, including cough, dyspnea, chest pain and sputum production, and occasionally hemoptysis. Hilar or paratracheal adenopathy may occur, and chronic pulmonary infection may evolve into fibrocavitary disease. Pleural involvement is rare.

Disseminated sporotrichosis may occur in a setting of impaired cellular immunity. Sites of dissemination include the skin, bones, joints, genitourinary tract, lungs and central nervous system. The organism has been recovered from blood and bone marrow only rarely.

DIAGNOSIS

Delay in diagnosis is common, because of the non-specific appearance of the skin lesions. Isolating the organism from the affected site generally makes a specific diagnosis. Periodic acid-Schiff staining may demonstrate cigar-shaped yeast forms, occasional hyphal forms and stellate eosinophilic material called asteroid bodies, but organisms often are scarce. Yeast may be mistaken for *H. capsulatum* var. *capsulatum*. There are no standardized serologic or antigen detection tests for diagnosis of sporotrichosis.

MANAGEMENT

Itraconazole is the treatment of choice in most patients who have sporotrichosis, reserving amphotericin B for those who have severe manifestations. [64] Amphotericin B can be changed to itraconazole once there is an improvement.[65] Patients who have meningitis or disseminated sporotrichosis should be treated with amphotericin B initially. Disseminated infection in severely immunosuppressed patients such as those who have AIDS requires lifelong therapy.[65] Surgery can play a useful adjunctive role for some localized sites of infection.

PARACOCCIDIOIDOMYCOSIS

MYCOLOGY

Paracoccidioides brasiliensis is thermally dimorphic, growing as yeast in the tissues and in culture at 95–98.6°F (35–37°C). Yeast cells measure 3–40µm and are described as 'pilot wheel'-like, resulting from small surface buds. Yeast may resemble *H. capsulatum* var. *capsulatum*. In culture at room temperature in the laboratory the mold grows slowly, requiring 3–4 weeks for isolation. Identification requires conversion from the mold to the yeast.

EPIDEMIOLOGY

Paracoccidioidomycosis (South American blastomycosis) is endemic to parts of Latin America, with most cases reported from Brazil, Columbia, Venezuela and Argentina. *Paracoccidioides brasiliensis* is found in the soil, and is most common in poor socio-economic, rural areas. Over 80% of cases are reported in Brazil, where 10% of the population exhibit skin test reactivity to paracoccidioidin. There appears to be an association ecologically with armadillo burrows. An increase in cases is predicted to accompany deforestation of rural areas of Latin America.

PATHOGENESIS

The infection is acquired by inhaling spores of the organism, causing localized pulmonary disease accompanied by hematogenous dissemination. As with the other endemic mycoses, cellular immunity is the most important host defense. Pathologically, the infection is characterized by granuloma formation, often with associated neutrophil response and suppuration.

CLINICAL FEATURES

Clinical manifestations of the disease are rarely seen in people less than 30 years of age, and men are 15 times more frequently affected than women. Most primary infections are subclinical. Although primary infection occurs in the lungs, disseminated disease involving the skin, mucous membranes, reticuloendothelial system and adrenals is common.[66] Two distinct forms of paracoccidioidomycosis have been described. A subacute form seen mostly in young adults

(approximately 5% of cases) is associated with severe manifestations and a high mortality rate. A more chronic form, which accounts for the majority of cases, is seen in older adults and is associated with a better prognosis. Pulmonary involvement predominantly involves the mid and lower portions of the lungs. Cavities and hilar adenopathy are less common. Longstanding cases often reveal fibrosis, and pulmonary hypertension may develop.

Disseminated disease often causes generalized symptoms, including fever, malaise, weakness, weight loss and anorexia. Mucosal lesions are common and involve the mouth, lips, gums, tongue, palate, larynx and pharynx. They are infiltrated or ulcerated and generally painful. Cutaneous lesions tend to be located around body orifices. They may appear warty, crusted or ulcerated, and occasionally granulomatous. Adenopathy often involves cervical, axillary, mediastinal or mesenteric lymph nodes and may be complicated by the formation of draining sinuses and fistulas. Adrenal involvement can range from minimal dysfunction to overt insufficiency. The liver, central nervous system, spleen, vascular system, bones and male genitourinary tract are involved less often.

DIAGNOSIS

Laboratory diagnosis can occasionally be made by potassium hydroxide examination of sputum or pus. Definitive diagnosis generally requires biopsy and demonstration of typical multiple budding yeast, which often produce a characteristic 'pilot-wheel' appearance. Fungal culture on Sabouraud-dextrose or yeast extract agar is also recommended. Several serologic tests are available, including immunodiffusion and the complement fixation test. Skin testing is unreliable. Based on the presence of a cross-reacting antigen in the *Histoplasma* antigen test, research is in progress to develop an antigen test for diagnosis of paracoccidioidomycosis.

MANAGEMENT

Amphotericin B is recommended in patients who have severe manifestations, and itraconazole in those who are less ill or who have improved with amphotericin B. Itraconazole induces response in about 90% of cases.[67] Limited experience with fluconazole also indicates that this drug might be useful.

PENICILLIOSIS

MYCOLOGY

Penicillium marneffei is yeast in the tissues and a mold in culture at room temperature. The yeast resembles *H. capsulatum* var. *capsulatum* but may exhibit characteristic sausage-shaped cells, some with septation. Yeast may be free or within macrophages. Identification requires differentiation from other *Penicillium* spp., based upon either morphologic differences or the exoantigen test.

EPIDEMIOLOGY

Penicillium marneffei is endemic to South East Asia, and is the fourth leading opportunistic infection in patients who have AIDS in Thailand.[68] [69] [70] [71] The natural habitat has not been clearly defined but it is thought to grow in the soil. *Penicillium marneffei* infects a variety of animals, including the bamboo rat, which serves as a healthy carrier of the fungus. It is more common in inhabitants of rural areas.

PATHOGENESIS AND PATHOLOGY

Penicilliosis is acquired by inhalation. Individuals who have impaired cell-mediated immunity are at risk for disseminated disease, supporting animal studies that demonstrate the importance of $CD4^+$ and $CD8^+$ T cells. The pathologic features include necrotizing granulomas and microabscess formation.

CLINICAL FEATURES

Most patients present with disseminated infection manifested by fever and weight loss often accompanied by lymphadenopathy, hepatosplenomegaly, skin lesions and bone and joint involvement.[68] [69] [72] A variety of skin lesions may be noted but are not characteristic. These include nodules, maculopapular eruptions, ulcers, folliculitis and maculopapular lesions. Localized pulmonary disease is uncommon but the lungs are frequently involved in patients who have disseminated infection.

DIAGNOSIS

A rapid diagnosis may be established by touch smears and Wright's stain of bone marrow aspirates or other tissue biopsies. The organism appears as oval, round or sausage-shaped yeasts. Central septation is characteristic of *P. marneffei*, differentiating it from *H. capsulatum*, which divides by budding. The diagnosis is confirmed by culture using routine fungal media.

MANAGEMENT

Penicillium marneffei is susceptible to amphotericin B, 5-flucytosine, ketoconazole and itraconazole.[73] Studies in AIDS have demonstrated the effectiveness of amphotericin B and itraconazole but not fluconazole.[74] [75] Amphotericin B is recommended for more severe cases and itraconazole 400mg/day in milder cases. Maintenance therapy with itraconazole is required to prevent relapse. [76] Prophylaxis with itraconazole may also be useful in highly endemic areas.

Chapter 40 - Practice Points

40.a Aspiration of pleural fluid: pleural biopsy

Wei-Shen Lim
John T Macfarlane

Introduction

Pleural effusions result from diverse disorders ranging from malignancy to cardiac failure. In the context of infection, parapneumonic effusions (literally 'by the side of pneumonia') are common; they are present in up to 40% of cases of bacterial pneumonia. All such effusions of any significance should be sampled; one in ten will need specific treatment such as tube drainage or a surgical procedure.

Pathogenesis

Pleural effusions are divided into transudates and exudates. Transudates occur when increased systemic or pulmonary capillary pressures (e.g. in cardiac failure) or reduced systemic oncotic pressures (e.g. in hypoalbuminemia or liver failure) result in pleural fluid formation exceeding removal.

Exudates usually result from disease of the pleural surfaces. Three suggested mechanisms are:

- an increase in protein production (e.g. parapneumonic effusions);
- a decrease in lymphatic absorption (e.g. in malignancy); and
- a decrease in pleural pressure caused by bronchial obstruction.

More than one of these mechanisms may operate simultaneously.

Parapneumonic effusions progress seamlessly through three stages. The exudative stage is characterized by the accumulation in the pleural space of sterile fluid with a high protein content. It occurs in response to pleural inflammation. In the fibropurulent stage, leukocytes and fibrin accumulate in the pleural space and loculations eventually develop. In the final stage of organization, fibroblasts invade and produce an inelastic pleural peel, which encases the affected lung.

Microbiology

Empyema is defined as the presence of pus in the pleural fluid or a positive Gram stain or culture of the pleural fluid. Most empyemas (55%) develop as a complication of pneumonia; surgery and trauma account for the remainder of cases.

Pure aerobic infections account for 40–62% of empyemas, pure anaerobic infections for 15–30% and mixed aerobic and anaerobic infections for 8–20%. *Staphylococcus aureus*, *Streptococcus pneumoniae* and other *Streptococcus* spp. make up the majority of aerobic Gram-positive isolates, and *Pseudomonas* spp., *Escherichia coli* and *Klebsiella* spp. are the most common aerobic Gram-negative isolates. *Bacteroides* spp. are the most common anaerobic isolates, although microaerophilic streptococci may be isolated in up to 10% of anaerobic infections. In 28–43% of empyemas, multiple organisms are responsible (see Chapter 36).

The incidence of *Mycobacterium tuberculosis* as a cause of pleural effusion is related to local epidemiology.

Clinical features

Patients who have parapneumonic effusions may present with fever, chills, breathlessness or chest pain: symptoms very similar to those of pneumonia. The physical examination may be limited to findings of an effusion, which is sometimes not apparent on initial presentation and only develops later. An empyema should be suspected if there is a recrudescence or persistence of symptoms of infection after initial recovery from pneumonia. The patient may then also complain of malaise, weight loss, dull pleural pain and unresolving fever.

Investigations

The proper management of pleural effusions is crucially dependent on obtaining adequate samples for diagnosis. The analysis of both pleural fluid and pleural tissue is complementary in this regard.

Pleural aspiration

Large effusions can be safely aspirated at the bedside. Ultrasound guidance is useful when aspirating small or loculated effusions. The patient should be sitting comfortably, with arms stretched out in front and resting on a support. Aspiration is performed one interspace below the level of the effusion posteriorly or in the axilla using a 21-gauge needle attached to a 50ml syringe. The needle is passed perpendicular to the chest wall just above a rib, avoiding the neurovascular bundle. About 30ml of fluid should be aspirated for diagnostic purposes. Local anesthetic is not required if a single pass is

successful. If large-volume aspiration is intended, the skin and chest wall should be infiltrated with local anesthetic and an 18-gauge cannula used and connected to a three-way tap after removal of the needle.

We recommend that pleural fluid is sent for measurement of protein content, lactate dehydrogenase (LDH) level and for cytologic and microbiologic analysis, including mycobacterial culture. A serum sample for measurement of protein and LDH should be taken simultaneously.

The value of other tests, including pH, glucose level and amylase, is limited to specific circumstances (Table 40a.1). Samples for pH estimation need to be collected anaerobically in a heparinized syringe and analyzed promptly, the process being similar to arterial blood gas analysis.

Pleural biopsy

Pleural biopsy is a safe bedside procedure when performed by an experienced operator. It is important to obtain pleural biopsy specimens, if indicated, before complete removal of pleural fluid. The positioning of the patient and the approach is as for pleural aspiration. The use of an Abram's needle is described here, although a Cope's needle may also be used.

The biopsy site is cleaned and adequate local anesthetic infiltrated down to the pleural surfaces. A diagnostic pleural tap should be performed at this stage to confirm free entry into the pleural space and to avoid blood contamination after biopsy. A small vertical skin incision is made to allow easy passage of the Abram's needle through the skin. With the side hole in the closed position, firm but controlled pressure is applied in a twisting movement until the pleural space is breached. There is usually a sudden 'give' when the parietal pleura is first penetrated. Care must be taken not to plunge the needle into underlying lung. A 20ml syringe is attached to the

end of the needle and its positioning

TABLE 40.a-1 -- Pleural fluid examination.

PLEURAL FLUID EXAMINATION			
Investigation	**Result**	**Possible causes**	**Comment**
Visual inspection	Turbid (turbid supernatant)	Chylothorax, pseudochylothorax	Triglycerides >110mg/dl (1.2mmol/l), Cholesterol >200mg/dl (5.2mmol/l)
	Pus	Empyema	
	Blood	Malignancy, tuberculosis, trauma, embolism	Pleural fluid hematocrit >50% of that of peripheral blood
Smell	Putrid	Empyema	Anaerobic infection
Protein	<3g/dl (30g/l)	Transudate (but also seen in malignancy, parapneumonic effusions)	See Light's criteria
	>3g/dl (30g/l)	Exudate, effusion in diuretic treated cardiac failure	See Light's criteria
Lactate dehydrogenase	Pleural fluid to serum ratio >0.6	Exudate	Indicates pleural inflammation
	Pleural fluid level >two-thirds upper limit normal serum level		
Amylase	Raised salivary amylase	Esophageal rupture, malignancy	
	Raised pancreatic amylase	Acute or chronic pancreatitis	
Glucose	<60mg/dl (3.3mmol/l)	Malignancy, tuberculosis, rheumatoid arthritis, parapneumonic	
pH	In parapneumonic effusions:	Uncomplicated parapneumonic effusion	
	=7.3		
	>7.2 and <7.3	May progress to empyema	Requires close observation. Expert advice recommended
	=7.2	Empyema	Tube drainage recommended
Ultrasound	Loculations	Empyema	Consider tube drainage

in the pleural space is confirmed by opening the side hole and aspirating pleural fluid. Keeping the side hole open, the needle is now withdrawn slowly, at an acute angle to the upper chest wall, until it 'catches' on the parietal pleura. While continuing to apply outward and lateral pressure in order to hold the pleura in the open side hole, the inner cylinder is rotated clockwise thus closing the side hole and cutting a biopsy of the pleura (Fig. 40a.1). (A common error is to fail to maintain outward pressure when closing the side hole.) The entire needle is then quickly removed and the biopsy site covered to minimize air entry while the biopsy is placed in a suitable container. The procedure is repeated with the side hole of the needle in different positions until adequate tissue has been obtained. A biopsy is not taken with the side hole at 12 o'clock so as to avoid damage to the neurovascular bundle running underneath each rib.

We recommend obtaining at least six good samples, five to be placed in formalin for histology and the sixth in sterile normal saline for microscopy and mycobacterial culture. In some centres where the relevant expertise is available, medical thoracoscopy may replace blind pleural biopsy as the initial diagnostic procedure of choice.

Management

Initial management of a pleural effusion is based on differentiating between transudates and exudates. Using a pleural protein level of >3.0g/dl (30g/l) alone to identify exudative effusions will miss some parapneumonic and malignant effusions because these effusions exhibit a wide range of protein levels. With Light's criteria (sensitivity 98%, specificity 77%, accuracy 95%), an exudate is identified by one or more of:

- pleural fluid to serum protein ratio >0.5;
- pleural fluid to serum LDH ratio >0.6; or
- pleural LDH more than two-thirds the upper limit of normal serum LDH.

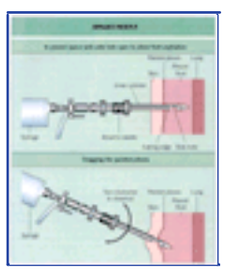

Figure 40.a-1 Abram's needle. The curved arrow shows clockwise rotation of the inner cylinder to close the side hole.

The management of parapneumonic effusions includes:

- sampling of the effusion to confirm the diagnosis and to determine whether it is complicated;
- deciding whether drainage is needed; and
- antibiotic therapy directed at likely or proven underlying infection.

Drainage is necessary in all cases of empyema or if loculations are seen on imaging. In the latter situation, ultrasound-guided catheter placement may be preferred. Ultrasound enables better visualization of loculations and small effusions, which enables better positioning and the use of smaller catheters, resulting in greater patient comfort. The effectiveness of tube drainage should be evident within 24 hours. Otherwise, the early use of intrapleural fibrinolytics should be considered before organization occurs.

Less evidence exists to aid the early identification of parapneumonic effusions that are likely to progress to empyema and hence require tube drainage. The pleural pH is of value in this situation. Sterile, nonpurulent effusions with pH >7.3 are very unlikely to develop a complicated course. A pleural pH of <7.2 predicts the need for pleural drainage with 80% sensitivity and 90% specificity. Tube drainage is generally recommended for these cases. Parapneumonic effusions with pH >7.2 but <7.3 fall in middle ground. Close observation with repeat thoracentesis according to clinical progress is a reasonable approach in some cases.

In all circumstances, antibiotic therapy should be guided by the underlying cause of pneumonia, if known. For ill patients in whom empiric therapy is required in the absence of positive microbiology, a second- or third-generation cephalosporin is recommended with the addition of metronidazole if anaerobic infection is suspected.

40.b sternotomy wound infection

Michael T Poshkus

Definition of the problem

Sternotomy infections are serious complications of cardiac surgery, ranging from mild cases of cellulitis, subcutaneous tissue and fat necrosis, osteomyelitis, chondritis and more seriously, mediastinitis. The incidence ranges from 0.4% to 9.7% with mortality ranging from 7.2% to 14% for deep sternal infections. Early diagnosis and aggressive management are the important factors determining patients' survival. Most cases occur within 14 days after surgery but some cases have been reported more than a year following surgery.

Several studies have determined clinical risk factors for sternal wound infections, including: obesity, diabetes mellitus, smoking, peripheral vascular disease, a high NYHA heart failure classification, prolonged ventilator support, bilateral use of internal mammary arteries, skin shaving technique and emergency surgery. Nasal carriers of *Staphylococcus aureus* have a higher chance of developing *S. aureus* wound infections.

Most sternal wound infections are secondary to direct intraoperative contamination. Other sources include hematogenous spread from distant infections (e.g. infections of indwelling catheters, the lungs, gastrointestinal tract, genitourinary tract or leg wounds).

In addition, the body's defenses are compromised by cardiopulmonary bypass, which impairs both cell-mediated and humoral immunity. The use of bilateral internal mammary artery grafting increases the chance of wound infection to five times that of saphenous vein grafting and three times that of single internal mammary artery grafting. The presence of hematomas and foreign bodies and inappropriate timing of preoperative antibiotic prophylaxis all increase susceptibility to infections.

Most sternal wound infections are monomicrobial and about 90% are caused by *Staphylococcus* spp. — both *S. aureus* and coagulase-negative staphylococci (CNS). CNS is more often associated with wound dehiscence and *S. aureus* more often with a stable sternum. Patients who require reoperation more often have Gram-negative infections.

The clinical presentation of sternal wound infections varies according to the extent of infection. One must have a high index of suspicion for sternal wound infections in febrile postoperative cardiothoracic patients. Early signs and symptoms may be nonspecific and simply include fever and leukocytosis. Following cardiac surgery patients often have tenderness, erythema and serous drainage at the surgical site. Sternal instability with purulent discharge implies deeper tissue involvement. Sternal dehiscence suggests underlying infection. Hamman's sign, a 'crunching' sound appreciated upon ausculation of the chest wall, indicates mediastinal emphysema and possible infection.

Typical case

A 63-year-old man with history of poorly controlled diabetes mellitus, multivessel coronary artery disease and a 40 pack-year smoking history undergoes coronary artery bypass grafting. He received cefazolin prophylactically prior to surgery. Prolonged intubation and elevated body temperatures to 100.7°F (38.1°C) complicate his postoperative course. On the ninth postoperative day, his sternal wound, which had initially been described as 'clean, dry and intact', is noted to be erythematous with yellow-tinged drainage. Sternal instability is appreciated. His laboratory evaluation reveals leukocytosis with 16,000 cells/μl (1.6×10^{10} cells/l) with 10% bands. The patient is treated empirically with pipercillin/tazobactam. CT scan of the chest shows pneumomediastinum. Blood cultures and superficial cultures of the sternal wound grow methicillin-resistant *S. aureus* and the patient is treated with vancomycin.

The patient is taken to the operating room for a sternal wound debridement and a bilateral pectoralis major myocutaneous advancement flap with greater omental transposition. His recovery is uncomplicated and he is discharged 35 days postoperatively on vancomycin.

Diagnosis

The diagnosis of sternal wound infections is usually clinical. Patients generally will have fevers, increased pain over the sternum and increased erythema or drainage from the wound. Cellulitis or superficial infections can be easily diagnosed by examination. Deeper infections, including mediastinitis, often require imaging and CT is considered the 'gold standard', having a sensitivity of 93–100% and specificity of 33–100%, showing localized mediastinal fluid and pneumomediastinum. Patients with mediastinitis have bacteremia approximately 50% of the time. A deep substernal aspiration can also be done to help with the diagnosis. Patients with this picture are generally taken to the operating room where the diagnosis of a deep sternal infection is confirmed and an organism can be identified by Gram stain and culture. The fluid should be sent for Gram stain, aerobic/anaerobic culture, acid-fast staining and culture and fungal culture.

Management options

Other than cellulitis, most sternal wound infections need both medical and surgical treatment. Aggressive surgical debridement is necessary with removal of all foreign bodies. Depending on the extent of the involvement, more radical debridement may be necessary, including removal of the sternum. The wound is then either left open with irrigation and packing or closed with drainage. Using muscle or omental flaps following sternal debridement has been shown to decrease length of hospital stay, improve survival and decrease need for further debridement or reinfections.

Antibiotic therapy should begin when sternal wound infection is suspected and after appropriate cultures are taken, if possible (including blood cultures and wound drainage cultures). The initial regimen should be broad and cover likely organisms with local resistance patterns in mind. Hospitals with a high incidence of methicillin-resistant *S. aureus* should have a regimen containing vancomycin as the first choice. Gram-negative rods should also be covered initially, pending cultures, and treated empirically with a third-generation cephalosporin, a carbapenem, a quinolone or an aminoglycoside. If all foreign bodies or necrotic tissues have not been removed, rifampin can be added to provide additional synergy for staphylococcal spp. and to better penetrate into the biofilm layer surrounding those areas. Treatment can be narrowed down later once the causative organism is known. Duration of treatment ranges from 10–14 days for those with cellulitis to 4–6 weeks for those with deeper tissue involvement.

40.c The pros and cons of antibiotics for pharyngitis and otitis media

Jenifer Leaf Jaeger

Acute upper respiratory infections are the most common illnesses of humans and occur with greater frequency in children than adults. Sore throat is one of the most common complaints and otitis media is the leading indication for outpatient antibiotic use in the USA. Although most infections are relatively mild and resolve spontaneously, most physicians agree that antimicrobial therapy for group A streptococcal (GAS) pharyngitis and acute otitis media (AOM) is useful and often necessary to prevent suppurative and nonsuppurative complications and data support this. However, controversy exists regarding optimal treatment practice. Understanding the epidemiology and natural history of these infections is an essential component in the decision to treat. It is the lack of rigor in adhering to criteria for

establishing these diagnoses that leads to overdiagnosis and promotes selection of resistant bacteria.

Pharyngitis

Group A streptococci (*Streptococcus pyogenes*), the leading bacterial cause of pharyngitis, accounts for approximately 5–17% of adult and 15–36% of pediatric cases of pharyngitis. The majority of patients therefore have a nonstreptococcal illness and will not benefit from therapy. During the 1990s, an estimated 6.7 million adults in the USA annually presented as outpatients with a complaint of sore throat. Seventy-three percent of these visits resulted in the prescription of an antibiotic. Concurrent with the emergence of resistant bacteria there was an increase in the use of more expensive and broader spectrum antibiotics, with 80% of those adults receiving antibiotics being given nonrecommended antibiotics as first-line agents.

Viruses are the most common causative agents identified in pharyngitis, accounting for up to 90% of all upper respiratory infections. Herpes simplex virus, Epstein-Barr virus, rhinovirus (usually in the setting of cough and coryza) and adenovirus infections commonly present as pharyngitis. Enteroviruses that are responsible for herpangina, lymphonodular pharyngitis and hand-foot-mouth disease are important in the differential diagnosis, as is the acute retroviral syndrome associated with primary infection with HIV, which may present with pharyngitis.

Bacterial causes of pharyngitis other than GAS are rare. Non-group A streptococci, particularly groups C and G streptococci, cause pharyngitis in older children and will respond to antimicrobial therapy. These ß-hemolytic streptococci can be isolated by throat culture but will not be identified by rapid antigen tests and have been associated with acute glomerulonephritis but not acute rheumatic fever (ARF). *Arcanobacterium* (formerly known as *Corynebacterium*) *haemolyticum* is an infrequent infection that may be indistinguishable from GAS infection. *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* infections may present with pharyngitis with concurrent lower respiratory tract involvement.

The peak age range for GAS pharyngitis is 5–15 years, accounting for 15–20% of cases. GAS is prevalent in the late winter/early spring and close contact with an infected person(s) increases the likelihood of true infection. Signs and symptoms suggestive of GAS infection, including sudden onset of sore throat, fever, headache, nausea, pharyngeal erythema with patchy exudate, and tender, enlarged anterior cervical chain lymph nodes, may be present in only 30–50% of patients. Antigen detection tests for GAS are highly specific (90–100%) but not as sensitive (55–90%) as throat culture. Neither can distinguish between acute infection with GAS and the carrier state in people who have pharyngitis due to some other etiology.

The goals of therapy are straightforward:

- to hasten clinical recovery,
- to prevent transmission to others,
- to avoid suppurative complications, and
- to prevent development of rheumatic fever.

Strategies for achieving these goals are less clear.

The earlier in the course of the infection that antibiotics are begun, the greater the potential impact. Of patients treated appropriately 95% will become noninfectious within 24 hours, allowing an earlier return to work or school. However, early therapy may be associated with an increased recurrence rate as a result of an abortive antibody response. The development of protective, type-specific antibodies is slow and thus early treatment may interfere with the immunologic response. Local infections, such as retropharyngeal and peritonsillar abscess as well as invasive GAS disease, including streptococcal toxic shock syndrome, are known complications of GAS pharyngitis. However, there is no proven benefit of early treatment in decreasing the risk of these complications. Antibiotic therapy is effective in preventing ARF even if therapy is delayed up to 9 days after disease onset.

Since most patients do not have a GAS infection and will not benefit from antibiotic treatment empiric therapy is not justified. However, the indiscriminant use of throat culture or antigen tests contributes to excessive cost of health care, increases the likelihood of obtaining a 'false-positive' result (i.e. identifying a carrier), leads to substantial overuse of antibiotics and encourages development of resistant bacteria. Group A streptococci may be carried in the pharynx of untreated patients for several weeks or months and approximately 25% of patients who have been adequately treated become GAS carriers. Carriers are at low risk of developing invasive GAS disease or acute rheumatic fever and are unlikely to transmit GAS to contacts. Identification and treatment of the carrier state may be necessary if the patient or household contact is at risk for rheumatic fever.

Accurate diagnosis is facilitated by employing algorithms which include epidemiologic and clinical factors to identify individuals at low risk of having GAS pharyngitis. In those patients in whom GAS infection cannot be ruled out, throat culture or rapid antigen detection is indicated. A properly performed throat culture has a sensitivity of >90% and the delay of 24–48 hours to obtain definitive results does not negatively impact on the efficacy of therapy. A cost-effective strategy is the initial use of the antigen detection tests; a positive test allows prompt specific therapy, but a negative result must be followed by culture held for 48 hours. Rapid antigen tests are not as sensitive as conventional culture, particularly in children and adolescents, and a negative rapid test should be confirmed by culture. In those patients who appear acutely ill and in whom there is a strong possibility of GAS, it may be appropriate to initiate therapy after culture has been obtained. However, it is imperative to discontinue therapy when a negative result is returned. Surveillance of physician practices in the USA has revealed that 40% of physicians admit to continuing therapy despite negative culture results and many acknowledge not following through with results.

Treatment of GAS pharyngitis is based on cost, efficacy, palatability and spectrum of activity. Penicillin remains the drug of choice in non-allergic patients. There have been no documented cases of penicillin-resistant GAS. Penicillin has a narrow spectrum of activity and is safe, well tolerated and inexpensive. Amoxicillin is an acceptable alternative. It has the advantage of improved taste and is inexpensive. Although there are no data specifically assessing its efficacy in preventing ARF it is likely to be as effective as penicillin. The broader spectrum of activity of the aminopenicillins may exert greater selective pressure on the development of resistant bacteria. Macrolides are the drugs of choice for allergic patients in regions where resistance rates are low. Resistance rates to erythromycin as high as 40% have been reported in Japan and Finland. Decreasing availability of erythromycin in Finland has been associated with subsequent decreases in the number of resistant organisms. Clarithromycin and azithromycin appear to be as effective as erythromycin, have wider spectrums of activity and are more expensive. Extended-spectrum macrolides have been shown to induce resistance among GAS isolates in vitro. For these reasons the use of these agents is discouraged. Oral narrow-spectrum cephalosporins may be another alternative in penicillin-allergic patients, although cross-reactivity occurs in 15–20%. Cephalosporins are slightly more effective in eradicating the carrier state than penicillin, but given the benign nature of the carrier state this therapy may not be worth the added expense. A 10-day course of therapy is effective in approximately 90% of children. Shorter courses of therapy are less effective, except for azithromycin, where a 5-day course is acceptable based on the extended half-life of this drug. A 5-day course of a cephalosporin has been suggested by some investigators, but further study is necessary to confirm initial results. Whether

use of a broader spectrum drug for a shorter period will impede the development of resistant organisms remains to be demonstrated. This topic is reviewed in Chapter 31 .

Otitis media (see also Chapter 32)

Acute otitis media is one of the most frequent infections in childhood and accounts for more than one-quarter of all antibiotic prescriptions in the USA. Although there is considerable evidence supporting the use of antimicrobials in the treatment of AOM, the treatment effect is small. Tympanocentesis or needle aspiration of middle ear effusion has demonstrated a bacterial pathogen in only two-thirds of children who have AOM (*S. pneumoniae* accounts for 25–50% followed by nontypable *Haemophilus influenzae* in 15–30%) and two-thirds of patients improve without intervention. However, there is no reliable method of determining which children require treatment. Overdiagnosis of AOM and unnecessary use of antibiotic therapy for otitis media with effusion (OME) contribute to the development of resistant organisms. Rigorous attention to distinguishing between AOM and OME and withholding antibiotics in the latter group alone would eliminate 6–8 million unnecessary prescriptions in the USA per year.

Acute otitis media is defined as the presence of fluid in the middle ear, with inflammation of the tympanic membrane in association with the rapid onset of signs and symptoms of local or systemic infection, whereas OME is characterized by an asymptomatic middle ear effusion in the absence of inflammation. Following appropriate therapy for AOM, middle ear effusion persists in 50% of patients at 1 month and in 10% at 3 months. Thus, the presence of middle ear fluid in a child recently treated for AOM does not indicate treatment failure and does not warrant therapy.

Of the 16 antibiotics labeled for use in the treatment of AOM in the USA, only two reach sufficiently high levels in middle ear fluid to be effective against penicillin-resistant pneumococci: high-dose amoxicillin (80–100mg/kg/day) and intramuscular ceftriaxone. Extended spectrum ß-lactamase-stable agents do not appear to improve clinical cure rates. Previously accepted second-line agents, including trimethoprim-sulfamethoxazole and erythromycin, may be ineffective and have been shown to permit the emergence of resistant organisms during treatment.

There is an increased risk of infection and colonization with penicillin-resistant pneumococci in children receiving antimicrobial agents. Therapy should be reserved for those children who have effusion in the setting of new onset of illness or who have evidence of middle ear effusions accompanied by bilateral hearing loss for at least 3 months. These guidelines reflect the concern that persistent middle ear effusion may contribute to hearing impairment and subsequent language and cognitive deficits. A causal relationship between the modest conductive hearing impairment associated with otitis media and subsequent developmental deficits, however, has not been established. Other disadvantages to therapy include cost and potential side-effects of antimicrobial agents.

Antibiotic prophylaxis for control of recurrent AOM is indicated in the setting of three or more episodes in a 6-month period or four or more episodes in a 12-month period. Numerous studies have demonstrated that continuous treatment with low-dose amoxicillin or sulfisoxazole significantly reduces the number of new infections compared with placebo. The greatest benefit from this regimen is derived in those patients who have frequent recurrences, those under 2 years of age and in those attending day care. An alternative approach to antimicrobial prophylaxis is myringotomy and placement of tympanostomy tubes. Although tympanostomy tubes are somewhat less effective than antibiotics in reducing the number of recurrences, they are more effective in reducing the period during which an effusion is present. Their use is recommended in the context of hearing loss. The latest development in the treatment of AOM is the use of quinolone ototopical solutions for the treatment of acute otitis media with tympanostomy tubes as well as for otitis externa and chronic suppurative otitis media. These preparations are safe with no demonstrable effects on hearing and have equal or greater bacterial eradication compared with cortisporin drops or amoxicillin/clavulanate. Additional strategies to prevent recurrent AOM include eliminating smoking in the household, encouraging of breast-feeding and removing the child from day care.

Several vaccination strategies have been shown to reduce the incidence of AOM. Vaccinating against *H. influenzae* in infancy and pneumococci in children over the age of 2 years has a limited role. The pneumococcal conjugate vaccine, licensed in the USA in 2000, has been shown to markedly reduce the incidence of AOM as well as to inhibit transmission of antibiotic-resistant pneumococci. Several studies have shown that vaccination of preschool children against influenza virus significantly reduces the risk of AOM. Yearly vaccine against influenza also reduces the number of antibiotic prescriptions and over-the-counter medications in adults. Otitis media is reviewed in detail in Chapter 32 .

In summary, the evidence supports treating acute GAS pharyngitis and AOM. It is the injudicious use of antibiotics for those infections that are not likely to benefit from therapy and that often resolve spontaneously which contributes greatly to the development of resistant bacteria. Pressure from patients/parents has been cited by physicians as the major reason for treating primarily viral infections. During the past 2 years multidimensional interventions such as community-wide education directed toward health care practitioners and the public have resulted in reduced antibiotic prescription rates. It is imperative that physicians continue to take the time to educate themselves and their patients regarding the problem of antimicrobial resistance.

40.d When to use corticosteroids in noncentral nervous system tuberculosis

Anur R Guhan
John T Macfarlane

Introduction

Tuberculosis, a chronic necrotizing infection, can involve any organ in the body. The clinical manifestations represent breakdown in local or systemic immunity against the causative organism, *Mycobacterium tuberculosis*. In this context, it might appear paradoxic that corticosteroids, with their known immunosuppressive effects, should even be considered in the treatment of tuberculosis. Indeed, this topic continues to be controversial.

Both cellular immunity and cytokines are involved in the pathogenesis of tuberculosis. Caseating granulomas, the pathognomonic lesions of the disease, represent the attempt by the immune system to contain the bacilli. Cytokines (tumor necrosis factor-a and interferon-?) released by sensitized tissue macrophages and peripheral blood mononuclear cells are thought to be responsible for the necrosis of lesions, the tissue edema and the constitutional symptoms (such as fever, anorexia, weight loss and night sweats) that are seen in patients who have tuberculosis. Healing results in fibrosis, causing local architectural change, which may affect physiologic function.

Adjuvant role of corticosteroids

The anti-inflammatory properties of corticosteroids have been used to modulate these harmful immune-mediated changes. Supported by case-control studies, the adjunctive use of corticosteroids with antituberculous medication was widely practiced in the 1950s and 1960s, especially with fulminant disease. However, the advent of short-course regimens containing rifampin (rifampicin) in the 1970s and the general decrease in the prevalence of tuberculosis in the Western world led to reduced need for adjuvant corticosteroid therapy except in selected situations.

With the resurgence of tuberculosis worldwide and the prospect of florid disease in the immunocompromised host, it is important to reevaluate the adjuvant role of corticosteroids in the treatment of tuberculosis. The topic is discussed in this chapter, basing recommendations on supporting evidence from the literature.

The anti-inflammatory properties of corticosteroids are well known and their use in the treatment of tuberculosis is based on their known capacity to:

- control the systemic effects of cytokines and other immune mediators;
- reduce immune-mediated tissue edema that occurs before and with treatment;
- suppress the clinical manifestations of hypersensitivity to tubercular proteins; and
- reduce the extent of fibrosis associated with the healing process.

Corticosteroids should only be used together with effective antituberculous chemotherapy.

Evidence of efficacy

The strength of evidence supporting the adjuvant use of corticosteroids in the treatment of tuberculosis is based on a few prospective, randomized, placebo-controlled trials, several retrospective, case-controlled trials and numerous case reports. Most of these studies were conducted before the newer, more effective antituberculous medications became available. However, there is no reason why these results cannot be extrapolated to the newer drugs. The following clinical situations are supported by evidence from prospective, randomized, placebo-controlled trials (RCTs).

Patients with *extensive pulmonary tuberculosis* have shown a more rapid clinical improvement with adjuvant corticosteroids, with faster normalization of body temperature, weight loss and other constitutional symptoms and earlier radiological resolution of pulmonary cavities.

Conversely, a RCT from India of patients on short-course chemotherapy failed to show any benefit of additional corticosteroid, at a dose of prednisolone 20mg/day, which is half that recommended with the rifampin-containing regimen (see below). The dose of prednisolone employed is probably important.

Patients with *tubercular pericarditis* receiving adjuvant prednisolone in a large RCT from South Africa had significantly faster resolution of symptoms and effusion and significantly reduced acute mortality than those receiving placebo. The need for later pericardectomy was not affected. Similar evidence is available for *tubercular pleural effusions*.

However, recent Cochrane Reviews of the above concluded that the evidence was insufficient on account of low numbers and recommended further RCTs.

Children with *tubercular mediastinal lymphadenopathy* causing extrabronchial compression who received adjuvant corticosteroid made significantly better radiological and bronchoscopic recovery.

Risk of progressive tuberculosis with adjuvant corticosteroids

Studies have shown either a benefit or no benefit from adjuvant corticosteroids; there is no evidence of increased risk of disease progression when corticosteroids are given together with effective antituberculous chemotherapy. However, adjuvant corticosteroid therapy could have systemic side effects related to their influence on the metabolism of bone, protein and carbohydrate. Monitoring of blood sugar is important in patients who have diabetes mellitus as a comorbid condition.

Use of adjuvant corticosteroids in tuberculosis

There are no agreed standards on the corticosteroid dosage or the duration of adjuvant treatment. Most authors, including ourselves, use the regimen suggested by Crofton and Douglas for most clinical situations: prednisolone 30–40mg/day for 2 weeks, gradually tapered over 6 weeks. Higher initial doses are suggested for tuberculous pericarditis: prednisolone 60–80mg/day for 4 weeks, tapering over 8 weeks.

Rifampin increases the catabolism of corticosteroids by hepatic microsomal enzyme induction, effectively halving the bio-availability of any administered dose of prednisolone. It is important to bear this in mind, particularly when corticosteroid replacement is instituted for tubercular Addison's disease.

The use of corticosteroids as adjuvant therapy in tuberculosis can be thought of under two headings:

- supported by evidence and general agreement (Table 40d.1); and
- not supported by unequivocal evidence (Table 40d.2).

The doses and duration of treatment suggested are what we would use in a particular clinical situation with a chemotherapy regimen that contains rifampin.

There is as yet insufficient information on the effects of adjuvant corticosteroids in patients who have HIV infection and tuberculosis. Co-infection with HIV and *M. tuberculosis* modifies the manifestations of clinical tuberculosis, making it difficult to extrapolate the results of trials on the use of adjuvant corticosteroids in the HIV-negative population to the HIV-positive population. However,

TABLE 40.d-1 -- Adjuvant use of corticosteroids supported by evidence and general agreement.

ADJUVANT USE OF CORTICOSTEROIDS SUPPORTED BY EVIDENCE AND GENERAL AGREEMENT		
Clinical situation	**Aim and comments**	**Suggested regimen**
Fulminant pulmonary tuberculosis with toxemia	Buy time for chemotherapy to take effect	Prednisolone 30–40mg/day until improvement in constitutional symptoms and erythrocyte sedimentation rate, then gradually taper by 2.5mg/day and stop
Miliary tuberculosis	Buy time for chemotherapy to take effect.	Prednisolone 40mg/day until improvement in constitutional symptoms and erythrocyte sedimentation rate, then gradually taper by 2.5mg/day and stop
	Important to monitor for occult adrenal insufficiency	
Adrenal insufficiency	Corticosteroid replacement: monitor progress with short ACTH stimulation test	Prednisolone 60–80mg/day. Long-term maintenance therapy may be required
Tuberculous pericarditis and tamponade	Expedite fluid resolution, symptom control and improve acute survival	Prednisolone 60–80mg/day for 4 weeks, tapering over 8 weeks. Insignificant effect on need for later pericardectomy
Massive tuberculous effusion with toxemia	Expedite fluid resorption, temperature control and reduce risk of adhesions	Prednisolone 30–40mg/day for 2 weeks, tapering over 2 weeks
Extrabronchial compression or atelectasis caused by tuberculous mediastinal lymphadenopathy	Reduce lymph node enlargement and improve lumen and lobar aeration	Prednisolone 30–40mg/day until radiologic resolution of atelectasis, tapering over 6 weeks
Endobronchial tuberculosis	Reduce risk of post-treatment structures	Prednisolone 30–40mg/day for 3 weeks, tapering over 12 weeks
Drug hypersensitivity reactions	Suppress manifestations of hypersensitivity while sequentially reintroducing antituberculous drugs.	Prednisolone 20–30mg/day, while the suspected putative drug is reintroduced gradually in increasing doses. Cautious tapering of corticosteroid dose
	Dose and duration need to be titrated to the individual. At least two effective antituberculous drugs must be introduced before corticosteroids are added	
Hypersensitivity phenomenon — tuberculides, episcleritis, scleritis, Eale's disease (retinal periphlebitis)	Modulate immunopathogenesis and reduce risk of scarring. Lesions are manifestations of hypersensitivity to tuberculoprotein and can occur with or without overt tuberculosis. Antituberculous chemoprophylaxis is required; in case of active tuberculosis, full-course chemotherapy is required	Ocular tuberculides, episcleritis and scleritis: topical corticosteroids
		Cutaneous tuberculides: topical corticosteroids; systemic corticosteroids occasionally needed
		Eale's disease: in consultation with an ophthalmologist, prednisolone 30–40mg/day for 3 weeks tapering over 8–12 weeks

TABLE 40.d-2 -- Adjuvant use of corticosteroids not supported by unequivocal evidence.

ADJUVANT USE OF CORTICOSTEROIDS NOT SUPPORTED BY UNEQUIVOCAL EVIDENCE		
Clinical situation	**Aim and comments**	**Suggested regimen**
Tuberculosis of the upper respiratory tract	Reduce risk of stricture formation after healing	Prednisolone 30–40mg/day for 3 weeks, tapering over 6 weeks. Endoscopic monitoring advisable
Tuberculous peritonitis	Expedite fluid resorption and reduce risk of adhesions	Prednisolone 30–40mg/day for 3 weeks tapering over 6 weeks
Tuberculosis of the genitourinary system	Reduce the risk of stricture formation and deformity	Prednisolone 30–40mg/day for 3 weeks tapering over 6 weeks
Tuberculosis and AIDS	Modulate the deleterious effects of cytokines and other immune mediators and buy time for chemotherapy to take effect	Similar to non-AIDS population. Prednisolone 30–40mg/day until improvement in constitutional symptoms and erythrocyte sedimentation rate, then gradually taper by 2.5mg/day and stop.
		Essential to be aware that AIDS patients may have co-existing cryptogenic opportunistic infections, which could progress under cover of corticosteroids

evidence from cohort studies suggests that HIV-positive patients with all manifestations of tuberculosis fare better when receiving adjuvant corticosteroids compared with matched control groups. Further research is needed.

It is important to bear in mind that patients with AIDS may have other co-existing but unrecognized opportunistic infections, which may progress under corticosteroid cover unless specific therapy is instituted.

Conclusion

Adjuvant corticosteroid therapy is effective in selected patients who have tuberculosis, producing useful and faster clinical recovery from

the disease. Its role in pleural tuberculosis needs further elucidation. When used under cover of effective antituberculous chemotherapy, there is no risk of disease progression. It should never be used when resistance to more than one drug is suspected. The recommended corticosteroid doses with rifampin-containing regimens take into account increased hepatic metabolism and reduced bio-availability. Conversely, with regimens that do not contain rifampin the recommended doses should be halved.

40.e How to manage a patient on anti-TB therapy with abnormal liver enzymes

L Peter Ormerod

Introduction

Although isoniazid, rifampin (rifampicin) and pyrazinamide are all potentially hepatotoxic, when pyrazinamide is added to the other drugs there does not seem to be an increase in the incidence of hepatitis. However, in unselected cases outside clinical trials, pyrazinamide is the drug with the highest monthly rate of hepatitis.

The incidence of hepatic reactions to antituberculosis drugs depends on the drug itself, age, and possibly sex and ethnic group. Hepatic reactions to antituberculosis drugs were reported in 4% of cases treated with isoniazid/rifampin with or without pyrazinamide in a UK trial, and in 3% in a large clinical series. The overall rate of adverse reactions increases with age. Liver function tests (LFTs), particularly serum bilirubin and transaminases — aspartate aminotransferase (AST) and alanine aminotransferase (ALT) — should therefore be checked before treatment. Pre-treatment liver function testing is not advised for children receiving treatment for latent infection (chemoprophylaxis) because of the very low incidence of reactions. This may, however, be required if rifampin/pyrazinamide for 2 months is used to treat latent infection in adults, a regimen not advised in the UK where rifampin/isoniazid for 3 months is the alternative to isoniazid.

Testing of liver function

Regular monitoring of liver function is not required for those with no evidence of pre-existing liver disease and normal liver function pre-treatment. Patients and their family doctors should, however, be informed of possible side-effects and the indications for stopping medication and seeking medical advice, preferably in writing in their native language. Tests of liver function only need to be repeated (and treatment stopped) if fever, vomiting, jaundice, malaise or unexplained deterioration occur. In such circumstances virologic tests to exclude coexistent viral hepatitis (A or B) should also be considered.

Management of elevated tests of liver function

Modest elevations of hepatic transaminases (AST/ALT) are not uncommon in tuberculosis patients even without known liver disease. They are also to be expected in patients with chronic liver diseases including alcoholism, chronic active hepatitis, cirrhosis and in chronic carriers of hepatitis B or C. Monitoring of such patients should be as in Figure 40e.1 . If the pre-treatment AST/ALT is more than twice normal, liver function should be monitored weekly for 2 weeks then 2-weekly until normal. If the pre-treatment AST/ALT is less than twice normal, liver function should be repeated at 2 weeks. If the transaminase levels have fallen further repeat tests are only needed for symptoms. However if the AST/ALT rises to above twice normal, management should be as above (see Fig. 40e.1).

If the AST/ALT rises to above five times normal, or the bilirubin becomes elevated then isoniazid, rifampin and pyrazinamide should be stopped. Immediate management then depends on the severity of the patient's illness, and whether they are infectious as judged by positivity on sputum smear-microscopy within 2 weeks of treatment commencement (Fig. 40e.2). If the patient is not unwell and had a form of tuberculosis that is non-infectious, no treatment is needed until liver function returns to pre-treatment levels. If the patient is unwell or the sputum is smear-positive within 2 weeks of commencing a rifampin/isoniazid-based regimen, some form of drug treatment needs to be given until liver function returns to pre-treatment levels, preferably as an inpatient because of the monitoring required. In such

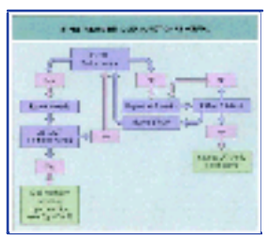

Figure 40.e-1 Management of elevated tests of liver function if pre-treatment liver function is abnormal. *Derived from Ormerod LP, Skinner C, Wales J. Hepatotoxicity of antituberculosis drugs. Thorax 1996;51:111–13, with permission from BMJ Publishing Group.*

Figure 40.e-2 Management of elevated tests of liver function if antituberculosis drugs (rifampin/isoniazid/pyrazinamide) stopped because AST/ALT over five times normal or bilirubin elevated. *Derived from Ormerod LP, Skinner C, Wales J. Hepatotoxicity of antituberculosis drugs. Thorax 1996;51:111–13, with permission from BMJ Publishing Group.*

cases a regimen of streptomycin and ethambutol with appropriate renal and visual checks is advised unless there are clinical contraindications or drug resistance to these agents is known or suspected. If second-line drugs are used, any potential hepatotoxicity (e.g. with macrolides, quinolones, prothionamide or ethionamide) should be considered. Occasionally patients with serious liver disease and active tuberculosis have very abnormal LFTs, with raised bilirubin and AST/ALT over five times normal pre-treatment levels. In these circumstances a risk/benefit analysis needs to be made, and often the risk of death (and infectivity) from untreated tuberculosis

TABLE 40.e-1 -- Order of re-introduction of antituberculosis agents following drug-associated hepatotoxicity.*

ORDER OF RE-INTRODUCTION OF ANTITUBERCULOSIS AGENTS FOLLOWING DRUG-ASSOCIATED HEPATOTOXICITY
Start:
Ethambutol (15mg/kg) plus isoniazid 50mg/day for 2–3 days then
plus isoniazid 150mg/day for 2–3 days then
plus isoniazid 300mg/day for 2–3 days and continue
If no reaction then:
Ethambutol (15mg/kg) plus isoniazid 300mg/day plus rifampin 75mg/day for 2–3 days then
plus rifampin 300mg/day for 2–3 days then
plus rifampin 450mg/day (under 50kg) or
rifampin 600mg/day (=50kg) for 2–3 days and continue
If no reaction then:
Ethambutol (15mg/kg) plus isoniazid 300mg/day plus rifampin 450/600mg/day and add sequentially:
pyrazinamide 250mg/day for 2–3 days then
pyrazinamide 1g/day for 2–3 days then
pyrazinamide 1.5g (<50kg) or
pyrazinamide 2g (=50kg) for 2–3 days and then continue if no reaction

Ethambutol can then be withdrawn if not required on drug resistance probability grounds
This is carried out with daily monitoring of clinical condition and regular LFTs.

** Derived from Ormerod LP, Skinner C, Wales J. Hepatotoxicity of antituberculosis drugs. Thorax 1996;51:111–13, with permission from BMJ Publishing Group.*

significantly exceeds that of additional hepatotoxicity. Standard treatment may then be appropriate under corticosteroid cover with regular monitoring of liver function.

Once liver function has returned to normal or pre-treatment levels, challenge doses of the original drugs can be re-introduced sequentially (Table 40e.1). Such re-introduction is best carried out in parallel with treatment with ethambutol 15mg/kg to prevent the possible emergence of drug resistance during the re-introduction. The patient's condition should be monitored daily together with liver function. Sequential re-introduction of isoniazid, rifampin and pyrazinamide is advised. Isoniazid should be started initially at 50mg/day increasing to 150mg/day after 2–3 days and then 300mg/day after a further 2–3 days if no reaction occurs, which is then continued. After a further 2–3 days without reaction rifampin at a dose of 75mg/day can be added, increasing to 300mg/day after 2–3 days, and then to 450mg (<50kg) or 600mg (>50kg) according to patient's weight after a further 2–3 days without reaction, and then continued. Finally pyrazinamide can be added at 250mg/day, increasing to 1.0g after 2–3 days and then to either 1.5g (<50kg) or 2.0g (=50kg). If there is no further reaction standard chemotherapy can be continued and any alternative drugs introduced temporarily may then be withdrawn. Ethambutol may need to be continued in the initial phase if indicated by local drug resistance profile and national treatment guidelines.

Management of further reactions following re-introduction of therapy

If there is a further reaction during the re-introduction (Table 40e.3), the offending drug should be excluded and an alternative regimen constructed. If pyrazinamide is the offending drug then a regimen of rifampin and isoniazid for 9 months, supplemented by ethambutol for 2 months will be required. For other drugs an alternative regimen may need to be on the advice of an experienced TB physician. Sometimes, because for example of drug resistance, the choice of drugs is so limited that if reactions occur, desensitization and re-introduction of the offending drug may be necessary using conventional protocols.

Such densensitization may need to be carried out under the cover of two other antituberculosis drugs to avoid the emergence of drug resistance.

40.f The place of antibiotics in the management of COPD

Robert Wilson

Chronic obstructive pulmonary disease (COPD) encompasses several conditions (airflow obstruction, chronic bronchitis, bronchiolitis or small airways disease and emphysema) that often co-exist. Tobacco smoking is the main etiological factor. Patients suffer exacerbations of their condition that are usually associated with increased breathlessness and they often have increased cough that may be productive of mucoid or purulent sputum. Exacerbations have different causes and several of these may be involved during a single exacerbation. There is considerable diversity in the severity of COPD and in the contribution made by the different pathologies listed above. Patients with chronic bronchitis are more susceptible to bacterial bronchial infections than those at the emphysema or asthma end of the spectrum. Although impairment of respiratory function does not in itself make patients more susceptible to infection, it does influence the outcome of a lower respiratory tract infection. Severe airflow obstruction, hypoxemia and the presence of hypercapnia all increase the risk of a poor outcome following an exacerbation. Therefore decisions about antibiotic treatment will be determined not only by the likelihood of bacterial infection and consideration of the species commonly involved, but also by the type of patient and concern about the outcome if bacterial infection is present and left untreated.

When COPD patients are admitted to hospital there is also concern about their susceptibility to nosocomial infections, even if bacterial infection was not the prime cause of the exacerbation. In a recently published study of severe exacerbations of COPD requiring admission to hospital and either noninvasive ventilatory support or mechanical ventilation, patients were randomized to receive either antibiotic (ofloxacin 400mg once daily) or placebo. Although additional antibiotics could be prescribed at any time at the physician's discretion, mortality was five times higher in the placebo arm. The timing of the deaths suggested that although some infections were present on admission, the majority were acquired in hospital.

Bacteriology

There is a general agreement that the bacterial species most commonly isolated from sputum during acute exacerbations of COPD are nontypeable *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Moraxella catarrhalis*, but several studies have shown that the same bacteria can also be isolated from patients during stable periods. However, since these species are upper respiratory tract commensals, bacteria may be picked up in the nasopharynx during expectoration of sputum and not represent true lower respiratory tract colonization or infection. A number of recent studies have used bronchoscopic techniques to avoid this contamination and have shed light on whether bacteria are pathogenic or simply commensal passengers.

Monso and colleagues studied 40 COPD patients during a stable phase of their illness and found positive protected specimen brush (PSB) cultures defined as $=10^3$ colony-forming units (cfu)/ml in one quarter. *H. influenzae* and *S. pneumoniae* were the predominant species isolated. Another group of patients were studied during an exacerbation. The number with positive PSB cultures was about 50% and although the same species were predominant, the bacterial counts were higher. Twenty-four percent of patients had more than 10^4 cfu/ml during an exacerbation, compared with only 5% of stable patients. Other studies have confirmed that higher bacterial numbers are associated with increased neutrophilic inflammation and that asymptomatic lower airway bacterial colonization (LABC) occurs in about 25% of COPD patients. One study has shown that LABC by itself is associated with airway inflammation.

Several recent studies have shown that Gram-negative species, more commonly associated with bronchiectasis, cause exacerbations in severe COPD. *H. influenzae* is still the most common isolate overall in these studies. In patients with mild airflow obstruction, *S. pneumoniae* and other Gram-positive cocci are more frequently isolated, whereas *Pseudomonas aeruginosa* and other Gram-negative bacilli account for a significant number of isolates in patients with severe airflow obstruction (defined as FEV1 =50% of predicted), but are rare in milder cases. This raises the possibility that unsuspected bronchiectasis may be present in some COPD patients prone to frequent infections. The role of atypical species such as mycoplasma and chlamydia in exacerbations of COPD is also debated. However, most studies have shown a low prevalence.

How often is bacterial infection involved in exacerbations of COPD?

The etiology of exacerbations is often multifactorial. Viral infections, particularly rhinovirus, probably trigger an exacerbation in about half of cases. Bacteria can also be isolated in about half of cases and this proportion increases to over 70% when there is more severe airflow obstruction. Furthermore, the more thoroughly a patient is investigated, the more often that infection, either viral or bacterial or both, is found to be implicated in the exacerbation. Air pollution (including tobacco smoke), cold weather and allergic responses will also contribute in some cases.

A cycle of events is illustrated in Figure 40f.1 . LABC occurs in COPD because the local airway defenses are impaired. Further studies are required to confirm whether LABC is associated with increased airway inflammation and a higher frequency of exacerbations. Bacterial infections can occur de novo or may represent an

Figure 40.f-1 A schematic representation of the role played by bacteria in COPD. There is limited evidence at the present time for the steps indicated by broken arrows which suggest that inflammation might be caused by lower airway bacterial colonization (LABC) and that airway infections might lead to progression of COPD.

increase in resident bacterial numbers when a new insult such as a viral infection reduces the host defenses even more. There is insufficient evidence to say whether repeated infections increase the rate of progression of airflow obstruction in COPD. The Lung Health Study which included large numbers of patients suggested that this might be the case, at least in those who continued to smoke.

Antibiotic treatment of exacerbations of COPD

In the study of Anthonisen and colleagues 173 patients with COPD were followed for 3.5 years during which time they had 362 exacerbations. Antibiotics or placebo were given in a randomized, double-blind, cross-over fashion. Three levels of severity of exacerbation were recognized: the most severe (type 1) comprised worsening dyspnea, increased sputum volume and purulence; type 2 was any two of these symptoms and the least severe grade (type 3) was any one of these symptoms with evidence of fever or an upper respiratory tract infection. Three antibiotics were used: amoxicillin, trimethoprimsulfamethoxazole and doxycycline, the choice being made by the physician. Overall there was a significant benefit from antibiotics that was largely accounted for by patients with type 1 exacerbations, whereas there was no significant difference between antibiotic and placebo in patients who had only one of the defined symptoms. However, even with type 1 exacerbations 43% of patients recovered in the placebo group within 21 days.

This emphasizes the important point that in most cases bacterial infections in COPD are mucosal infections which will resolve without antibiotic treatment when the host defenses overcome the infection. Therefore antibiotic treatment should have two aims. The most important is to prevent progression of an exacerbation into pneumonia or respiratory failure. The risk of this is greater in patients with more severe COPD. The second aim is to hasten recovery, although evidence that antibiotics have a major impact is lacking, particularly in those with mild disease. The Anthonisen study showed that for those patients with multiple exacerbations, which in other studies correlates with more severe COPD, the duration of antibiotic-treated exacerbations averaged 2.2 days less than those treated with placebo. However, when all

patients were considered and treatment failures were eliminated from the analysis, the benefit from antibiotics on speed of recovery was only 0.9 days.

The British Thoracic Society have adopted the Anthonisen criteria in their guidelines on the management of COPD exacerbations. My own opinion would be to give more weight to neutrophilic sputum purulence, which has been shown to accurately identify the presence of bacteria. In Figure 40f.2 I have outlined a simple scheme that might be used to decide whether antibiotics should be given. More difficult questions are which antibiotic to choose, what dosage and for how long; these questions are outside the scope of this chapter. There is little evidence in the literature to help in making these decisions.

In recent years there has been a dramatic rise in antibiotic resistance among common respiratory pathogens; for example, penicillin and macrolide resistance in *S. pneumoniae* and ß-lactamase production by *H. influenzae* and *M. catarrhalis*. The frequency with which antibiotics are used in a community is reflected in the amount of antibiotic resistance in a particular class. Antibiotics should not be prescribed for trivial illnesses which resolve spontaneously, including exacerbations of mild to moderate COPD, particularly if the sputum is not purulent. Although there is very wide variation in the prevalence of these strains from country to country, and even in different parts of the same country, there is some evidence to suggest that patients with a history of more frequent exacerbations, who have received several antibiotic courses beforehand, are more likely to carry resistant strains. I have used these principles in the choice of antibiotics outlined in Figure 40f.2 .

An antibiotic containing a ß-lactamase inhibitor, such as amoxicillin/clavulanate, or a respiratory quinolone, e.g. moxifloxacin, would be

Figure 40.f-2 A decision tree outlining how choices about whether or not to prescribe an antibiotic for patients with airway diseases can be made. There is very little evidence that one antibiotic is superior to another, but concern about antibiotic resistance will influence choice in severe cases. An antibiotic which is resistant to ß-lactamase enzyme and potent against the major pathogens should be chosen. Ciprofloxacin is indicated when there is concern about *Pseudomonas aeruginosa*. Evidence shows that this bacterium is usually only a consideration in patients with FEV1 =50% predicted, although in my own experience it is only patients with even more severe airflow obstruction in whom it occurs or in those patients who also have bronchiectasis.

appropriate for severe cases. In moderately severe cases, for patients who have not recently received antibiotics older agents such as amoxicillin or doxycycline are appropriate. In hospital most exacerbations of COPD will be treated with an antibiotic. A second-generation, e.g. cefuroxime, or third-generation, e.g. cefotaxime or ceftriaxone, cephalosporin given intravenously, an intravenous preparation of amoxicillin/clavulanate or a respiratory quinolone might be used for a few days until clinical improvement is evident when switch to an oral preparation should be made. An oral antibiotic throughout will be appropriate in some cases. *P. aeruginosa* is resistant to all oral antibiotics except ciprofloxacin.

There have been nine prospective placebo-controlled trials to investigate whether continuous antibiotic treatment reduces frequency of exacerbations. Five trials showed no reduction in the frequency, whereas four did show a benefit versus placebo. Two of the five trials that showed no benefit did show significantly less time lost from work in the antibiotic group. Patients most likely to benefit from continuous antibiotic treatment were found to be those suffering frequent exacerbations which was judged to mean =4 per year. My own practice is to only use antibiotic prophylaxis as a last resort and then only during the viral season from October to April. Much more commonly I prescribe a course of antibiotics for the at-risk patient to keep at home,

to begin when the symptoms of an exacerbation persist for a couple of days and immediately the sputum becomes purulent. The patient can then make an appointment for my clinic so that progress can be monitored.

40.g Management of the infected cystic fibrosis patient

Daniel Rosenbluth

Definition of the problem

The airways of persons with cystic fibrosis (CF) are chronically infected with bacteria, usually *Staphylococcus aureus* and *Pseudomonas aeruginosa* (typically mucoid strains). This persistent infection and the accompanying inflammatory response result in mucus hypersecretion with obstruction of smaller airways, bronchiectasis and the symptoms of chronic cough, sputum production and dyspnea. While chronic symptoms are slowly progressive, intermittently patients may have a more accelerated decline associated with increases in the bacterial burden in the airways with additional symptoms, usually referred to as an acute respiratory exacerbation. Optimal management of the infected CF patient necessitates strategies to combat both the chronic airway infection and acute exacerbations.

Typical case

Persons with cystic fibrosis typically exhibit symptoms of chronic cough, sputum production and dyspnea on exertion if they have more advanced obstructive lung disease at baseline. Exacerbations of their lung disease are usually characterized by an increase in cough and sputum production, a change in the color (to darker or more green) or character (thicker and more viscous) of the sputum, dyspnea and worsening exercise tolerance. These exacerbations may also be accompanied by generalized fatigue, fevers, decreased appetite, weight loss and, in diabetic patients, worsening glycemic control. Acute exacerbations may be highlighted by massive hemoptysis, a true medical emergency (Table 40g.1).

Physical exam may demonstrate new physical findings such as wheezes or crackles, use of accessory muscles of respiration, tachycardia, cyanosis and decreased oxyhemoglobin saturation. Chest X-rays may reveal a new infiltrate or evidence of increased mucus plugging on a background of chronic bronchiectatic changes. Many patients with acute exacerbations will not demonstrate any change in their radiograph. On occasion the onset of an exacerbation may be insidious and occur over weeks. Under these circumstances patients may not fully appreciate the magnitude of their decline unless questioned carefully. In these cases pulmonary function testing (discussed

TABLE 40.g-1 -- Signs and symptoms of acute exacerbations of CF-related lung disease.

SIGNS AND SYMPTOMS OF ACUTE EXACERBATIONS OF CF-RELATED LUNG DISEASE
Increase in cough and sputum production
Change in the color or character of sputum
Dyspnea and worsening exercise tolerance

New wheezes or crackles
Use of accessory muscles of respiration
Tachycardia
Cyanosis
New radiographic infiltrate
Decrease in FEV1

below) will usually detect a significant change from the patient's baseline and this by itself is an indication for intensification of therapy.

Diagnosis

Diagnosis of an acute respiratory exacerbation of cystic fibrosis-related bronchiectasis is best made by a clinician experienced in the care of patients with CF. It is usually made when a patient presents with a combination of some or all of the above-mentioned signs and symptoms, in association with a decrease in their forced vital capacity (FVC) and forced expiratory volume in one second (FEV1). These pulmonary function tests or spirometry are the best objective measure of a patient's status and during exacerbations will usually demonstrate worsening airway obstruction and a decline of at least 10%.

Management options

Optimal management of the infected patient with CF requires the identification of specific pathogens which infect the individual patient. Early in life infection with *Staphylococcus aureus* and *Haemophilus influenzae* is common but as patients age, infection with *Pseudomonas aeruginosa* and other Gram-negative organisms, such as *Achromobacter xylosoxidans, Stenotrophomonas maltophilia* and *Burkholderia cepacia*, predominates. Infections with *Burkholderia cepacia* can be difficult to treat, and have been associated with an accelerated decline in lung function in some patients and with epidemic outbreaks at some CF care centers. This organism may not grow readily in culture; therefore all respiratory samples from patients with CF should be cultured on media specific for this organism, in addition to the other organisms mentioned above.

Many patients will be infected with multiple organisms or multiple colony types of the same organism that may have different susceptibility patterns. It is therefore recommended that all organisms and their differing microcolonies be identified in culture and have their susceptibility patterns determined to facilitate the selection of the optimal antibiotic regimen. Persons with cystic fibrosis may become infected with nontuberculous mycobacteria. Therefore their respiratory secretions should be evaluated for the presence of these pathogens if they do not respond to routine antimicrobial therapy.

In the treatment of acute exacerbations (Table 40g.2) selection of specific antimicrobials should be guided by results of sputum culture and sensitivity results. Mild exacerbations may sometimes be treated with oral and/or inhaled antibiotics if effective agents are available. Response to therapy should be closely monitored and if ineffective, a switch should be made to parenteral therapy. More severe exacerbations should be treated parenterally and in general two antipseudomonal agents are chosen, usually a third- or fourth-generation cephalosporin or antipseudomonal penicillin, along with an aminoglycoside. Therapy should be modified based on culture results. The antipseudomonal penicillins or carbapenems may be more active against *Achromobacter xylosoxidans*, and carbapenems such as meropenem may have increased activity against *Burkholderia cepacia*. Infections

MANAGEMENT OF ACUTE EXACERBATIONS OF CF-RELATED LUNG DISEASE

Parenteral antimicrobial therapy based on respiratory culture results (typically two antipseudomonal agents)
Enhanced airway clearance
Bronchodilators
Mucolytics
Pulmonary rehabilitation
Nutritional support

with *Stenotrophomonas maltophilia* are sometimes best treated with ticarcillin/clavulanate, minocycline or trimethoprimsulfamethoxazole. Patients with CF often exhibit high volumes of distribution and increased antimicrobial drug clearance; therefore higher doses of antibiotics should be utilized. Aminoglycosides should be administered on an 8-hour dosing schedule with target peak levels of 8–12µg/ml and trough levels less than 2µg/ml. Some have reported successful therapy with single daily dosing regimens. Typically 2–3 weeks of parenteral therapy is required.

Therapy of the chronically infected CF patient who is not in the midst of an acute exacerbation may include inhaled suppressive antibiotic therapy. In clinical trials, a preservative-free formulation of tobramycin (TOBI®) has been shown to improve lung function and decrease the risk of hospitalization in patients colonized with *Pseudomonas aeruginosa* who inhaled this medication for three cycles of twice-daily administration for 28 days followed by 28 days off medication. Patients are often treated with other inhaled antibiotics such as colistin; however, the use of these agents is less well studied or standardized. A study of oral cephalexin prophylaxis in infants and young children with cystic fibrosis failed to demonstrate a clinical benefit.

In addition to antimicrobial therapy, airway clearance is an essential component in the management of the infected airways of patients with CF. This may be accomplished via traditional chest percussion and postural drainage or with the assistance of various devices such as percussors, pneumatic compression vests or the Flutter valve. Bronchodilators facilitate airway clearance and decrease airway obstruction and are commonly used by patients with CF. Dornase alpha (Pulmozyme®) degrades extracellular DNA in the airway secretions of patients with CF. The DNA is released from neutrophils which have entered the airway and contributes to the viscoelasticity of CF sputum. Daily inhalation of dornase alpha thins the CF sputum to allow improved airway clearance and has been shown to improve lung function and decrease the need for parenteral antibiotics in patients with CF.

Other adjunctive therapies for the infected CF patient include regular exercise and aggressive nutritional support to address the increased metabolic needs and malabsorptive problems which these patients may exhibit. Since the inflammatory response in the CF lung may contribute to the morbidity of the chronic airway infection, anti-inflammatory therapy may benefit some patients. Short courses of corticosteroids may benefit some patients; however, while long-term corticisteroid use may slow the decline in lung function, their benefit is outweighed by side effects of the therapy. High-dose ibuprofen may slow the decline in lung function in young patients with mild disease but this therapy should be closely monitored. Identification and evaluation of more specific and less toxic anti-inflammatory agents is currently being actively researched.

Optimal management of infected CF patients requires an effective infection control strategy to prevent patient-to-patient transmission of virulent organisms. This strategy should include both the inpatient and outpatient settings and conform to local infection control guidelines. Frequent handwashing is extremely important. Patients infected with *Burkholderia cepacia* should be segregated from other CF patients who are not infected with this organism. Since children infected with *Pseudomonas aeruginosa* have decreased lung function and survival when compared with children only infected with *Staphylococcus aureus*, some advocate segregating these groups of patients.

Conclusion

Management of the infected patient with cystic fibrosis requires strategies to address both the chronic infection and acute exacerbations of infection. This necessitates routine symptomatic and physiologic evaluation of patients, along with frequent microbiologic surveillance of airway secretions. These should guide aggressive but

appropriate use of oral, inhaled, and parenteral antibiotics, along with adjunctive therapies such as bronchodilators, mucolytics, airway clearance, pulmonary rehabilitation, and nutritional support. Finally an effective infection control policy should be in place to prevent patient to patient transmission of potentially harmful organisms.

Chapter 41 - Orocervical and Esophageal Infection

Robert C Read

Infections of the oral cavity and neck include dental and periodontal infections, deep fascial space infections of the neck that are often odontogenic or caused by contiguous spread from pharyngeal foci, nondental oral infections, including ulcerative and gangrenous stomatitis, and infections of the salivary glands. Infections of the esophagus mostly occur in the context of severe underlying disease.

DENTAL AND PERIODONTAL INFECTIONS

EPIDEMIOLOGY

Dental caries is the commonest infectious disease in humans. The incidence of the disease is closely related to the use of derivatives of cane sugar and began to take on epidemic proportions in Europe in the 19th century. Dental caries first becomes evident in infancy and is most noticeable on the chewing surfaces of the molar teeth. The likelihood of dental caries is increased by high sugar intake, poor oral hygiene and any factors that reduce salivary flow — notably drugs (e.g. antidepressants).[1]

Periodontal disease, including gingivitis, is mainly related to poor oral hygiene and increasing age. Increased incidence of periodontal disease is also evident in diabetics and during hormonal disturbances, including puberty and pregnancy.[2] It is suspected that most periodontal disease arises from an inflammatory response to the accumulation of dental plaque in the gingival margin. Plaque contains mainly *Streptococcus* spp. and *Actinomyces* spp., which probably generate an early gingivitis leading ultimately to periodontitis.[3] These processes occur over many years with incremental destruction of periodontal tissue.[4]

PATHOGENESIS AND PATHOLOGY

The indigenous oral flora includes a large number of aerobic and anaerobic bacteria and varies by site within the oral cavity. There are of the order of 10[11] micro-organisms per gram wet weight of oral secretions, with the majority being obligate anaerobes. *Streptococcus* spp., *Peptostreptococcus* spp., *Veillonella* spp., *Lactobacillus* spp., *Corynebacterium* spp., *Bacteroides* spp., *Prevotella* spp. and *Actinomyces* spp. form the majority of oral flora.[5]

Dental caries is characteristically polymicrobial with no fixed pattern of microbial etiology, except that *Streptococcus mutans* has emerged as the only organism consistently isolated from carious teeth compared with normal teeth. In contrast, gingivitis has characteristic microbial specificity; the normal flora of the periodontium (i.e. *Streptococcus sanguis* and *Actinomyces* spp.) is replaced by anaerobic Gram-negative rods, notably *Prevotella intermedia*. With chronic gingivitis there is ulceration of the mucosa, loss of attachment of periodontal tissue, loss of enamel and necrosis of the dental pulp, and an increase in complexity of microbial flora with a preponderance of anaerobic Gram-negative rods, including *Porphyromonas gingivalis*.[2] When abscesses form, for example periapical abscesses, the flora is always polymicrobial with species such as *Fusobacteria*, pigmented *Bacteroides*, *Peptostreptococcus*, *Actinomyces* and *Streptococcus*.

In healthy individuals teeth are protected from decay by the cleansing action of the tongue and buccal secretions, the buffering effect of saliva and the acquired pellicle — the fluid microenvironment of the tooth surface. With poor dental hygiene the acquired pellicle is colonized and replaced by plaque that contains bacteria, notably *Strep. mutans*. This process is accelerated by intermittent exposure to carbohydrates and simple sugars. The presence of subgingival plaque leads to inflammation of the gingival epithelium and to destruction of the periodontium.[5] The normal resident polymicrobial flora provides an important defense against invasion of gingival epithelium by pathogenic bacteria. Normal saliva also protects the epithelium by irrigating it with enzymes, including lysozyme and lactoperoxidase, and other antimicrobial substances such as lactoferrin. Secretory IgA provides additional protection by aggregating organisms and preventing bacterial adherence. The importance of intact phagocytic defenses is reflected by the high prevalence of periodontal infections in patients who have cyclic neutropenia and chronic granulomatous disease.[3] Some oral micro-organisms involved in periodontal disease secrete IgA proteases. [6] Host factors credited with leading to periodontitis include psychosocial stress, diet, smoking, alcoholism and intercurrent disease. [7]

The usual cause of deep-seated odontogenic infection is necrosis of the pulp of the tooth followed by bacterial invasion through the pulp chamber and into the deeper tissues.[8] If a pulp abscess is allowed to progress, infection will spread toward the nearest cortical plate (Fig. 41.1).

PREVENTION

Prevention of dental and periodontal infections includes interference with transmission and suppression of *Strep. mutans* colonization once it has occurred. There is a strong correlation between maternal salivary *Strep. mutans* infection and the presence of this organism in children. Acquisition of *Strep. mutans* by infants has been prevented by aggressive treatment of *Strep. mutans* infection in mothers.[9] Existing infections can be suppressed by regular cleaning with agents that include fluoride and antimicrobial substances such as chlorhexidine. Periodontal disease can be prevented by good oral hygiene and regular rinsing with chlorhexidine. The use of controlled-release antibiotics is currently under investigation.[10]

CLINICAL FEATURES

Subgingival dental caries is asymptomatic, but destruction of enamel results in invasion of the pulp with subsequent necrosis, eventually leading to a periapical abscess. The tooth becomes sensitive to temperature and pressure once the enamel is penetrated, and toothache results.

In simple gingivitis there is usually discoloration of the gum margin with occasional bleeding after brushing of the teeth. There may be halitosis. If gingivitis is allowed to become chronic there may be destruction of periodontal tissue with loosening of the teeth. This

Figure 41-1 Spread of dental infection. A spreading tooth abscess will encroach upon the nearest cortical plate and its subsequent spread depends on the relationship of that site to muscle attachment. *Adapted from Peterson.*[6]

Figure 41-2 Painful vestibular abscess. *Courtesy of Professor I Brook.*

may be relatively asymptomatic or the patient may have itchy gums, temperature sensitivity and halitosis.

COMPLICATIONS

Dental pulp infections can lead to involvement of the maxillary and mandibular spaces (Fig. 41.1). Spread of infection from maxillary (upper) teeth most commonly leads to vestibular abscesses (Fig. 41.2). Erosion of canine pulp abscesses can lead to canine space abscesses if the abscess points above the insertion of the levator labii superioris. This results in swelling lateral to the nose, which usually obliterates the nasolabial fold. Buccal space abscesses can result when pulp abscesses of the molar teeth erode above or

Figure 41-3 Buccal space abscess originating from right lower molar infection. The buccal space lies between the buccinator muscle and the overlying skin and fascia. *Courtesy of Professor I Brook.*

Figure 41-4 Submandibular abscess originating from a 2nd molar tooth infection. *Courtesy of University of Sheffield School of Dentistry, UK.*

below the attachment of the buccinator muscle; these point below the zygomatic arch and above the inferior border of the mandible (Fig. 41.3).

When infection spreads from mandibular (lower) teeth the commonest result is again vestibular abscess. Deeper abscesses may point into the sublingual and submandibular spaces. The sublingual space lies underneath the oral mucosa and above the mylohyoid muscle (Fig. 41.1). Posteriorly, it communicates with the submandibular space. Infection within the sublingual space results in swelling of the floor of the mouth, which may spread to involve both sides and be sufficiently pronounced to lift the tongue. This space is involved if the infected tooth apex giving rise to the disease is superior to the insertion of the mylohyoid (e.g. premolars and first molars).

The submandibular space lies between the mylohyoid muscle and the skin. It becomes involved if the apex of the infected tooth is inferior to the insertion of the mylohyoid muscle (e.g. third molar). Clinically, infection in this space causes extraoral swelling (unlike sublingual space infections) that begins at the inferior lateral border of the mandible and extends medially to the digastric area. Occasionally the abscess may point spontaneously and rupture (Fig. 41.4).

Figure 41-5 Ludwig's angina. (a) This patient had painful cellulitis within the submandibular and sublingual spaces. (b) Brawny edema was present within the floor of the mouth, pushing the tongue upwards. *Courtesy of University of Sheffield School of Dentistry, UK.*

Ludwig's angina refers to a severe cellulitis of the tissue of the floor of the mouth with involvement of the submandibular and sublingual spaces (Fig. 41.5). The source of infection is almost always the second and third mandibular molars. If the infection is allowed to continue there may be local lymphadenitis, systemic sepsis and extension of the disease to involve deep cervical fascia with a cellulitis that extends from the clavicle to the superficial tissues of the face. Other potential complications include asphyxia, aspiration and mediastinitis. The disease is almost always polymicrobial, including a-hemolytic streptococci and anaerobes such as *Peptostreptococcus* spp., *Prevotella melaninogenica* and *Fusobacterium nucleatum*.[11]

Very rarely, spread of infection from maxillary teeth may cause orbital cellulitis or cavernous sinus thrombosis (see Chapter 24). The latter is distinguished by toxemia, venous obstruction within the eye and orbital tissues (Fig. 41.6), involvement of the III, IV and VI cranial nerves and meningismus.

MANAGEMENT

Treatment of dentoalveolar infections includes elimination of the diseased pulp and deep periodontal scaling or tooth extraction. Any dentoalveolar abscess present should be surgically drained. If drainage is not complete, antibiotic therapy is appropriate. Treatment of periodontal disease includes appropriate debridement and short-term antimicrobial therapy with oral metronidazole 400mg q8h or oral phenoxymethylpenicillin 500mg q6h. Periodontal and vestibular abscesses should be treated by drainage.

Treatment of maxillary and submandibular space infections should always be by surgical drainage of pus. Ludwig's angina is a life-threatening condition and the first aim of treatment is protection of the airway, if necessary by emergency intubation or occasionally

Figure 41-6 Cavernous sinus thrombosis. A patient who displays evidence of severe orbital swelling caused by obstruction of orbital veins is shown. In this patient, the originating focus was infection of soft tissues of the nose. *Courtesy of University of Sheffield School of Dentistry, UK.*

tracheostomy. Intravenous antibiotics should be administered. Benzylpenicillin 1.2g q4h plus metronidazole 400mg q8h or clindamycin 450mg q8h are appropriate.

Management of cavernous sinus thrombosis is by surgical decompression and high-dose intravenous antibiotics, the choice of which is influenced by whether the originating focus is dental or within soft tissues.

DEEP CERVICAL SPACE INFECTION

Infections of the lateral pharyngeal space, the retropharyngeal space and the prevertebral space are uncommon but life-threatening problems. The lateral pharyngeal space is funnel shaped, with its base at the sphenoid bone at the base of the skull and its apex at the hyoid bone. It is bounded by the medial pterygoid muscle laterally and the superior pharyngeal constrictor medially. Posteromedially it extends to the prevertebral fascia and communicates with the retropharyngeal space. The carotid sheath and cranial nerves are within the posterior compartment of the space. The retropharyngeal space lies posteromedial to the lateral pharyngeal space, between the superior constrictor muscle and the alar portion of the prevertebral fascia. Superiorly, it extends from the skull base of the pharyngeal tubercle down to the level of C7 where the superior pharyngeal muscle and the prevertebral fascia fuse.[8]

Unlike the lateral pharyngeal space it has few contents apart from lymph nodes, but its importance as a site of infection relates to its proximity to the airway and to the contents of the superior mediastinum. The prevertebral space extends from the skull base inferiorly to the diaphragm. It is bounded by the two layers of prevertebral fascia: the alar and prevertebral layers.

EPIDEMIOLOGY AND PATHOGENESIS

Parapharyngeal infections can complicate peritonsillar abscess (see Chapter 31), but a larger proportion of infections are odontogenic or secondary to intravenous drug abuse. [10] Rarer sources include parotitis, otitis and mastoiditis. The incidence of parapharyngeal infection has declined sharply in the antibiotic era and such infections now form less than 30% of all deep cervical infections. [11] [12]

Infections of the retropharyngeal and prevertebral spaces most commonly result from lymphatic spread of infection in the pharynx or sinuses, with subsequent suppuration of the retropharyngeal lymph nodes. Retropharyngeal infections are therefore commonest in children mainly because retropharyngeal lymph nodes are more numerous.[13] Occasionally retropharyngeal infections may be caused by accidental perforation of the pharynx, for example during emergency intubation. The bacteriology of deep cervical space infections reflects the microbial flora of the originating source. Thus, infections arising from the pharynx are often caused by *Streptococcus pyogenes*, whereas odontogenic infections are polymicrobial and include *Strep. mutans* and anaerobic pathogens such as *F. nucleatum, P. melaninogenica, Peptostreptococcus* spp., *Eikenella corrodens* and *Actinomyces* spp.

CLINICAL FEATURES

The characteristic feature of lateral pharyngeal space infection is severe trismus, which results from involvement of the pterygoid muscle and other muscles of mastication. There is also swelling of the lateral pharyngeal wall, which pushes the tonsil toward the midline. Occasionally there is lateral neck swelling below the angle of the mandible. The disease can be confused with peritonsillar abscess, although the latter should not produce trismus. The patient experiences fever, painful swallowing and pain that occasionally radiates to the ear. The infection tends to be severe and progresses rapidly. Posterior extension of the process into the carotid sheath can result in suppurative jugular thrombophlebitis, carotid artery erosion or interference with cranial nerves IX–XII. There is hyperacute sepsis, with rigors and high fever. There may be pain and swelling below the mandible, marked swelling of the lateral pharyngeal wall, torticollis and neck rigidity. There may be metastatic abscesses within the brain, lungs and bone. Suppurative thrombophlebitis of the internal jugular vein secondary to oropharyngeal infection was described by Lemierre and the syndrome bears his name.[14] The major organism associated with this complication is *Fusobacterium necrophorum*, which is usually obtained from blood cultures, but may require several days of anaerobic culture to grow.

Patients who have retropharyngeal abscess may present with fever and rigors that usually follow on from a streptococcal pharyngitis, but often there is no history of sore throat.[15] A child with a retropharyngeal abscess may be withdrawn and irritable. Adults may complain of sore throat, dysphagia, neck pain and dyspnea. The neck may be hyperextended, and there may be drooling and stridor. Examination of the throat by indirect laryngoscopy may reveal bulging of the posterior pharyngeal wall. Potential complications include upper airway obstruction as a result of anterior displacement of the posterior pharyngeal wall into the oropharynx, and spontaneous rupture of the abscess with aspiration pneumonia (which may complicate attempted insertion of an endotracheal tube). Other potential complications include purulent pleural effusion, pericardial effusion and posterosuperior mediastinitis.[16]

Patients who have AIDS, particularly intravenous drug users, have a higher incidence of deep neck infections, most commonly caused by *Staphylococcus aureus*, which is often methicillin resistant. In contrast to immunocompetent patients, there is often no leukocytosis.[17] Diabetics are also at increased risk of deep neck infections, and in addition to *Staph. aureus*, Gram-negative organisms, notably *Klebsiella* spp., may be isolated from these patients.[12]

DIAGNOSIS

If lateral pharyngeal space infection is suspected, the diagnosis is best confirmed by CT or MRI scanning. Plain radiographs are usually unhelpful. In contrast, a retropharyngeal space abscess can be diagnosed

Figure 41-7 Retropharyngeal abscess. Lateral radiograph of the neck in a patient who has a retropharyngeal abscess, showing gross expansion of prevertebral soft tissue. *Courtesy of Mr R Bull.*

by a lateral radiograph of the neck (Fig. 41.7). The average width of the prevertebral soft tissue should be no more than 7mm (average 3.5mm) at C2 and no more than 20mm (average 14mm) at C6.[18] The neck should be fully extended during evaluation. The major clinical differential diagnosis of retropharyngeal abscess includes cervical osteomyelitis and meningitis. The latter can usually be discounted when there is obvious pharyngeal swelling, but cervical osteomyelitis may require MRI scanning of the cervical vertebral bodies for exclusion.

MANAGEMENT

In any patient with a suspected deep neck infection, maintenance of the airway is always the first consideration; about one-third of patients who have retropharyngeal abscess will require tracheostomy.[12] Incision and drainage of involved spaces and intravenous antibiotic therapy should be performed promptly in order to produce rapid and complete resolution of the infection with minimal likelihood of complications. Radiologic evidence of gas within soft tissues increases the urgency, because expansion of lesions containing anaerobes is usually rapid. Lateral pharyngeal and retropharyngeal abscesses can be drained by an incision along the anterior border of the sternocleidomastoid muscle followed by blunt dissection and drainage. Extensive surgery should be unnecessary if infections are treated promptly and high-dose intravenous antibiotics are used. Appropriate intravenous antibiotics include penicillin 1.2–1.8g q3h plus clindamycin 300–600mg q8h or metronidazole 400mg q8h, plus ceftriaxone 2g q12h.

CERVICAL NECROTIZING FASCIITIS

Cervical necrotizing fasciitis is a rare and extremely dangerous complication of odontogenic and deep cervical space infection. The disease is characterized by involvement of more than one neck space (usually bilaterally) and contiguously spreading necrosis of connective tissue, with cellulitis that extends below the hyoid bone to the chest wall, onto the face and into the mediastinum. Most cases are odontogenic, particularly after dental abscesses, but some cases follow on from tonsillar abscess or from surgical trauma to the oropharynx. Almost all cases are polymicrobial, often with a single aerobic isolate (e.g. *Streptococcus* spp.) plus two or more anaerobes (mostly *P. melaninogenica* and *F. nucleatum*), although any of the oral anerobes can be involved. The typical clinical presentation is

usually with dental pain and submandibular swelling over a few days, followed by rapid evolution of fasciitis, which is extremely tender on palpation and usually associated with crepitus. Mediastinal extension can be clinically silent and detectable only by CT of the chest, but can lead to pericarditis, pneumonia or empyema. Predisposing conditions include diabetes mellitus, alcoholism and malignancy. Management includes surgical drainage via incision along the sternocleidomastoid muscle followed by blunt dissection of the neck. Appropriate intravenous antibiotic therapy is benzylpenicillin 1.2–1.8g q3h plus clindamycin 600mg q8h.[19]

ACTINOMYCOSIS

Actinomycosis is a chronic suppurative bacterial infection that principally affects the head and neck but can involve almost any system. It spreads directly through tissue, skin and bone, and therefore is able to form sinuses and fistulas.

EPIDEMIOLOGY AND PATHOGENESIS

The agents that cause actinomycosis are facultative anaerobic Gram-positive commensals of the mouth. *Actinomyces israelii* is the most common pathogen, but *Actinomyces naeslundii*, *Actinomyces viscosis*, *Actinomyces odontolyticus* and *Arachnia propionica* may also cause the disease. These agents commonly inhabit carious teeth, dental plaque and cavities and also the normal intestinal tract. Head and neck infection usually occurs in the context of dental disease or dentistry, during which the normal mucosal barriers are broken down. Thoracic involvement usually follows aspiration of infected oropharyngeal secretions in patients who have poor dentition. Lesions of actinomycosis consist of areas of acute inflammation surrounded by fibrosing granulation tissue. Such material contains 'sulfur granules' (colonies of organisms forming an amorphous center surrounded by a rosette of clubbed filaments); these usually contain associated organisms, including *Actinobacillus actinomycetemcomitans*, *Haemophilus* and *Fusobacterium* spp., which probably contribute to the pathogenesis of the disease.

Any age group can be infected, including infants and children. Males outnumber females by three to one.

CLINICAL FEATURES

The most common manifestation of actinomycosis is soft tissue swelling of the head, face or neck, usually over or underneath the mandible.[20] Occasionally the swelling is very extensive and waxes and wanes over many months, spreading to involve other parts of the head and neck, including the scalp, palate, eyes, larynx, salivary glands, middle ear and paranasal sinuses. Sinuses and tracts develop that open into the mouth and the skin (Fig. 41.8). Involvement of local bone (e.g. the mandible) can result in periosteal reaction or frank osteomyelitis.

DIAGNOSIS

The diagnosis is usually obvious in patients who have head and neck swelling, particularly in the context of poor dentition and discharging sinuses yielding sulfur granules. The granules can be trapped in gauze placed over the sinus opening or by injecting and aspirating saline from the sinus; by shaking the aspirate, the granules can be seen with the naked eye. Sulfur granules can also be seen in sputum on microscopic examination. Any material obtained can be cultured under anaerobic conditions. In formalin-fixed tissues, immunofluorescence can be used to identify species. There is no reliable serologic test; laboratory diagnosis depends on microscopy and culture of material from the patient.

Figure 41-8 Actinomycosis. (a) This patient had chronic disease over the mandible which (b) healed with several months of antibiotics, leaving a residual chronic sinus. *Courtesy of Professor I Brook.*

MANAGEMENT

Most patients who have actinomycosis will respond to intravenous benzylpenicillin, 1.2–1.8g q3h for 3–6 weeks, followed by oral penicillin V, 2–4g/day for 6–12 months. Alternative treatments include intravenous amoxicillin or ampicillin, followed by oral amoxicillin. Chloramphenicol, erythromycin, tetracycline and clindamycin have also been used successfully. Prolonged treatment with penicillin results in complete resolution of the disease, although there may be some residual fibrosis or scarring (Fig. 41.8). Whilst intravenous benzylpenicillin has been the traditional treatment for this condition there have been reports of the use of intravenous agents that can be given in once-daily dosing for home therapy, including ceftriaxone and imipenem.

INFECTIONS OF THE ORAL MUCOSA: GANGRENOUS STOMATITIS

Acute necrotizing ulcerative gingivitis, or trench mouth, is an ulcerative necrosis of the marginal gingivae. The disease may spread to other oral structures, including the tonsils or pharynx, to cause Vincent's disease or may result in rapid necrosis and sloughing of facial structures, producing the classic features of cancrum oris (noma).

EPIDEMIOLOGY

The disease is mostly seen in developing countries in the context of severe debilitation and malnutrition. In addition, poor oral hygiene, HIV infection, measles, local irritation from food impaction and smoking are associated factors. [21]

PATHOGENESIS

Necrotizing gingivitis may begin as an aseptic necrosis secondary to mucosal capillary stasis. In infections in which the disease spreads superficially to involve the pharynx, it is most likely secondary to a combination of *F. nucleatum* and Gram-negative anaerobic organisms

Figure 41-9 Acute necrotizing gingivitis. *Courtesy of Professor I Brook.*

(*Bacteroides* subsp. *intermedius*). If the disease spreads deeper into facial tissues to cause cancrum oris, fusospirochetal organisms such as *Borrelia vincenti* and *F. nucleatum* are consistently cultured. *Prevotella melaninogenica* may also be present. Biopsies of any advancing lesion often reveal a mat of predominantly Gram-negative thread-like bacteria that cannot be positively identified.[22]

CLINICAL FEATURES

The earliest feature is a small painful red lesion that may be vesicular on the attached gingiva and often in the premolar or molar region of the mandible, with sudden onset of painful gums (Vincent's disease; Fig. 41.9). The disease may then progress rapidly to produce halitosis and gingival bleeding. If there is involvement of the tonsils and pharynx (Vincent's angina) there is searing pain in the pharynx with high fever, regional lymphadenopathy and anorexia. If the disease spreads into deeper tissues (noma) a necrotic ulcer rapidly develops with painful cellulitis of the lips and cheeks, which often sloughs, exposing underlying bone, teeth and deeper tissues (Fig. 41.10).

DIAGNOSIS

Although the infection is usually polymicrobial, material should be obtained for Gram stain and aerobic and anaerobic culture. Debrided material is optimal for anaerobic culture. Gram stain may reveal fusospirochetal Gram-negative organisms as well as Grampositive cocci and Gram-negative rods.

MANAGEMENT

In early acute necrotizing ulcerative gingivitis (Vincent's infection), treatment with oral penicillin V 500mg q6h and metronidazole 400mg q8h is usually sufficient. In patients who have noma, high doses of intravenous penicillin and metronidazole are required, with the dose being dependent on the age and size of the patient. An antibiotic to treat aerobic Gram-negative rods, such as ceftriaxone, may be necessary. Gangrenous tissues should be removed and loose teeth extracted. The patient should be carefully rehydrated. Once the infection has been controlled, reconstructive surgery is often necessary.

INFECTIONS OF THE ORAL MUCOSA: PRIMARY HERPETIC GINGIVOSTOMATITIS

EPIDEMIOLOGY

Herpes simplex virus (HSV)-1 and HSV-2 can cause a primary infection of the oral cavity, although type 1 is much more frequently responsible. The disease can occur in infants, although this is becoming

Figure 41-10 Noma. This is a destructive process extending from oral structures, which is a sequel of necrotizing gingivitis and (a) is seen most commonly in patients in developing countries, although (b) occasionally it is seen in the elderly debilitated in developed countries. *Courtesy of Professor I Brook.*

Figure 41-11 Primary HSV-1 stomatitis.

increasingly uncommon. Oral lesions caused by HSV-2 are seen in sexual contacts of patients who have genital herpes and are clinically indistinguishable from those caused by HSV-1.

CLINICAL FEATURES

The disease may be very mild, with a few painful ulcers and no systemic features, or it may be more severe with fever, sore throat, malaise, headache and regional lymphadenopathy. Oral lesions tend to appear 1–2 days after the onset of pain and lead to a painful, red gingiva or palate. These symptoms generally persist for approximately 2 days. The vesicles occur as 2–4mm ulcers on a red background. When lesions coalesce they can resemble aphthous ulcers (Fig. 41.11). At this point the disease is highly infectious. The clinical course of unmodified primary herpetic gingivostomatitis usually lasts 2 weeks.

DIAGNOSIS

The clinical differential diagnosis of oral herpetic gingivostomatitis includes herpangina, varicella, herpes zoster and hand, foot and mouth disease. These diseases can usually be distinguished on the basis of concomitant cutaneous features. Primary herpes infection of the mouth can occasionally be recurrent and several other recurrent diseases have similar oral lesions — these include minor aphthous ulcers, Behçet's syndrome, cyclical neutropenia and erythema multiforme. A laboratory diagnosis of herpes can be verified by direct immunofluorescence or viral culture of material obtained by swabbing the ulcers.

MANAGEMENT

In primary herpetic gingivostomatitis oral aciclovir 200–400mg q8h is appropriate therapy.

OTHER INFECTIONS OF THE ORAL MUCOSA

HERPANGINA

Herpangina produces characteristic oropharyngeal vesicles, generally at the junction of the hard and soft palates (Fig. 41.12). It primarily affects children and teenagers and generally occurs in epidemics during the summer. Several different coxsackieviruses, notably coxsackievirus A (types 1–10, 16 and 22) and less commonly coxsackievirus B (types 1–5), have been associated with this disease. Other enteroviruses, including echovirus, have been implicated. Patients usually have mild disease, but they can complain of sudden fever, anorexia, neck pain, extremely sore throat and headache. The lesions are often more vesicular than herpetic lesions and consist of multiple, small, white papules with an erythematous base that appears less inflamed than that with herpetic lesions. These lesions usually spontaneously rupture within 2 or 3 days and seldom persist for more than 1 week. There may be cervical lymphadenopathy but this is unusual. A laboratory diagnosis can be obtained by culturing swabbed material from the lesions. Herpes simplex virus infection can usually be distinguished on clinical grounds, but can be rapidly excluded by direct immunofluorescence. Management consists of topical analgesia only.

HAND, FOOT AND MOUTH DISEASE

Hand, foot and mouth disease is caused by systemic infection with Coxsackie group A viruses (usually serotype 16) and primarily affects children, but occasionally adults. The disease consists of vesicular eruptions on the hands, wrists, feet and within the mouth. Lesions

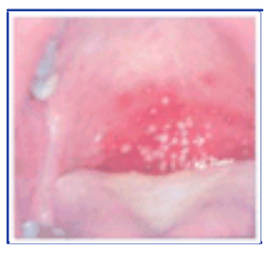

Figure 41-12 Herpangina in a teenager with severe throat pain.

on the hands are almost always present, but oral lesions are present in 90% of patients and can occasionally be the only manifestation of the disease.[23] The oral vesicles are often on the palate, tongue and buccal mucosa and may range from a few isolated lesions to a marked stomatitis. In addition patients may suffer fever, malaise, conjunctival injection, headache and abdominal pain and occasionally diarrhea. The lesions on the feet and hands are flaccid, grayish vesicles, most often on the sides of the fingers, instep and toes.[24] If the disease is confined to the oral cavity it is almost indistinguishable from primary herpetic gingivostomatitis. Laboratory diagnosis of the disease can be confirmed by culture of feces or swabs obtained from the lesions. Management is symptomatic. The disease is usually self-limiting and rarely persists for more than 2 weeks.

APHTHOUS STOMATITIS

The cause of aphthous ulceration is unknown but a number of infectious agents, including viruses, have been implicated. It usually manifests as small ulcers of the buccal and labial mucosa, often affecting the floor of the mouth or the inferolateral aspect of the tongue, almost always within the anterior part of the oral cavity; the palate and pharynx are rarely involved. The ulcers are characteristically exquisitely painful, particularly during eating, and in the most severe form can lead to anorexia. Humoral and cytotoxic T cell-mediated immune responses to oral mucosa have been demonstrated in some patients, suggesting an autoimmune process. The lesions are usually raised and appear grayish yellow, but in severe cases they may be herpetiform with secondary bacterial infection and cervical lymphadenopathy. Major aphthous ulcers may persist for months, but minor lesions usually heal over 2 weeks. They often recur, with periods of remission lasting as long as a few years. Cultures of swabs from aphthous ulcers are negative on viral culture. Treatment is usually symptomatic with mouth washes and anesthetic lozenges. Oral prednisolone has been used in some patients but is generally unhelpful. Severe aphthous ulcers have been successfully treated with oral thalidomide. The risk of teratogenicity precludes the use of this drug in women of child-bearing potential. Ulcers are particularly severe in HIV-infected patients.

PRIMARY SYPHILIS

Primary chancres can occur in the mouth approximately 3 weeks after oral sex. An ulcerating papule develops at the site of initial contact of *Treponema pallidum* with the oral mucosa. The papule is painless but is accompanied by significant regional cervical lymphadenopathy. At presentation patients are often seronegative, but dark-ground microscopy of material obtained from the ulcer may reveal spirochetes, although care should be taken to avoid contamination of the material obtained with saliva because other *Treponema* species inhabit the mouth and may be easily mistaken for *T. pallidum*. Treatment is discussed in Chapter 75 .

CANDIDA INFECTIONS OF THE MOUTH

Oral candidiasis is a common problem that usually signals local or generalized disturbance of host defenses.

EPIDEMIOLOGY

Most patients who have oral candidiasis are at the extremes of age, but any individual who has recently taken oral or inhaled steroids or broad-spectrum antibiotics is at risk. The disease is also seen in patients wearing dentures and patients who have diabetes mellitus.[25] Between 1980 and 1989, rates of oropharyngeal candidiasis in

hospitalized patients increased from 0.34 to 1.6 cases per 1000, caused mainly by the HIV epidemic.[26]

PATHOGENESIS

Yeasts are common colonizers of the oral cavity of healthy individuals. *Candida albicans* is the most common of oral yeast isolates (up to 50%).[27] *Candida albicans* can adhere to complement receptors, various extracellular matrix proteins and carbohydrate residues on oral epithelial cells and oral micro-organisms. [28] The organism exists in yeast and hyphal forms. Invasion of tissue is probably related to secreted hydrolytic enzymes and hyphal formation, each of which is possibly initiated by contact with epithelial cells. The immunopathology of mucosal candida infections is unclear, although suppression of normal oral microflora by antibiotics probably permits proliferation of yeasts. Salivary antibodies inhibit bacterial adherence to buccal epithelial cells and are protective in animal models.[29] Saliva also contains a number of antifungal proteins, including histatins and calprotectin, that protect the mouth in concert with local antibody and cell-mediated defense. A disturbance of cell-mediated immunity is partly responsible for overproliferation in patients who have HIV-1 infection and malignancy.

CLINICAL FEATURES

In patients using broad-spectrum antibiotics or who suffer candidiasis as a result of denture use, lesions are often erythematous with a burning sensation of the tongue, which displays diffuse redness of the entire dorsum. Most patients who have denture-related oral candidiasis are asymptomatic. Patients who have cell-mediated defects (i.e. diabetics, those on oral steroids or immunosuppressed patients) mostly have the characteristic syndrome of thrush, a pseudomembranous form of the disease in which there is a layer of white curd-like flecks of material that can be wiped off to leave an erythematous surface, beneath which there may be bleeding points.

DIAGNOSIS

The diagnosis is usually clinically obvious in patients who have thrush, but in patients who have erythematous lesions diagnosis can be made by scraping the mucosa and identifying characteristic ovoid yeasts with hyphal forms on microscopy. The organism can be cultured on Sabouraud's agar, but culture alone is insufficient to make the diagnosis since the organism can be recovered from the mouth of approximately 10% of completely normal individuals with no symptoms.

MANAGEMENT

In normal individuals the disease can usually be terminated by removing the cause — either inhaled steroids or broad-spectrum antibiotics — or by removing dentures at night. If necessary, patients can use 7–14 days of topical antifungal therapy, such as nystatin or clotrimazole, which is usually quite sufficient to ablate the infection. Immunocompromised individuals, particularly those with advanced immunosuppression, may require systemic therapy. For a full discussion of candidiasis in patients who have AIDS see Chapter 126 .

OTHER ORAL FUNGAL INFECTIONS

Histoplasma capsulatum is endemic in the midwestern USA and Central and South America. The organism is generally associated with lower respiratory tract infection, but oral lesions can occur, particularly in elderly, debilitated patients who have disseminated disease. The lesions tend to appear as erythematous areas that may ulcerate.[30] Biopsy is usually required to established a diagnosis. Because the infection is usually disseminated, systemic therapy with amphotericin B is generally required (see Chapter 39 and Chapter 238).

The dimorphic fungus *Paracoccidioides brasiliensis* is a major cause of systemic mycosis in Central America and South America and should be considered in patients originating from this region. Most patients have an oral mucosal ulcer with some surrounding edema. There may be perioral lesions that may be ulcerated or warty. Diagnosis can be made by smear and culture and treatment with oral imidazole compounds is generally sufficient (see Chapter 208 and Chapter 238).

ORAL LESIONS IN PATIENTS WHO HAVE MALIGNANCY

A common problem among cancer patients undergoing chemotherapy or radiotherapy is severe mucositis and stomatitis that occurs approximately 1 week after the onset of chemotherapy.[31] At this point, destruction of oral epithelium is at its height with an accompanying disturbance of immune surveillance of oral mucosal microorganisms. This leads to opportunist bacterial[32] or fungal infection. Patients nearly always complain of pain and tenderness in the mouth with or without formation of a pseudomembrane. Symptoms can persist long after chemotherapy has been terminated. Management should include a vigorous search for a microbial etiology; a short course of metronidazole is sometimes helpful. Some prevention can be achieved by careful oral hygiene and effective management of xerostomia associated with chemotherapy. Once there is established mucositis, topical therapy with antiseptic and anesthetic preparations is indicated. Aluminum hydroxide gel can be used to provide symptomatic relief of painful inflammation.

INFECTIONS OF THE SALIVARY GLANDS

The commonest cause of parotitis is mumps virus, but parotitis can occasionally be caused by bacteria or other viruses, including parainfluenza virus, coxsackievirus, echovirus, Epstein-Barr virus and HIV.

EPIDEMIOLOGY

The incidence of mumps has markedly decreased in the era of childhood measles, mumps and rubella (MMR) vaccination, which confers lifelong immunity. Despite this, mumps virus remains the most common cause of parotitis. It is highly contagious by air-borne droplet transmission. Mumps infections occur in late winter and early spring; enterovirus infections, including parotitis, are mostly seen in mid to late summer. Before the introduction of the MMR vaccine in the UK in 1988, the annual incidence of mumps was approximately 5 per 100,000 population, but in the postvaccine era this has declined to less than 0.5 per 100,000.[33]

Most patients who have primary bacterial parotitis are over the age of 60 years and are frequently debilitated because of chronic illness or have underlying diseases such as diabetes. Patients who have dehydration, whatever the cause, are at greatest risk. Medications that lead to xerostomia include anticholinergic and occasionally diuretic agents. Poor oral hygiene increases the chances of reflux of bacteria into the salivary gland.[34]

PATHOGENESIS

Mumps virus is a paramyxovirus and gains entry via the respiratory tract. The subsequent viremia allows access of the virus to tissues for which it has tropism, including salivary gland tissue, gastrointestinal tissue such as pancreas, testicular tissue and the central nervous system. The incubation period is 18–21 days.

Bacterial infection of the salivary glands is normally prevented by constant salivary flow, which removes contaminants from the ductal systems. Dehydration, xerostomia or obstruction of the ducts can lead to bacterial proliferation within the salivary glands and subsequent parotitis.

CLINICAL FEATURES

The most common clinical manifestation is gradual onset of painful swelling of either one or both of the parotid glands, which occurs 14–21 days after contact with an infected individual. Pain within the parotid gland can be initiated by salivation during meals, and the glands are tender. Occasionally submandibular salivary glands are involved, but inflammation of sublingual glands is extremely rare. Orchitis is present in approximately 10–20% of individuals and is bilateral in 5%, but there is no firm evidence that it causes male sterility. Mumps meningoencephalitis may occur in concert with parotitis, but patients who have mumps meningitis often do not have parotitis. In the pre-MMR era mumps was a relatively common cause of viral meningitis in children less than 15 years old in whom permanent unilateral deafness was a recognized complication. Pancreatitis is rare. On examination there is smooth tender swelling that obliterates the angle of the jaw and may raise the pinna. Rarely, the outlet of Stensen's duct may be inflamed. There may be generalized symptoms, including fever, arthralgia, malaise and headache, that generally persist for up to a week. Culturable virus is present in the saliva for up to 1 week after gland enlargement. Management is essentially symptomatic.

Recurrent episodes of glandular swelling, particularly of the parotid gland, can occur in children with a history of mumps. Clinical features include recurrent parotid swelling with general malaise and pain frequently after a meal. Viridans streptococci are usually cultured from exudate from the Stensen's duct.

In primary bacterial parotitis there is usually rapid onset of pain, swelling and induration of the involved gland (Fig. 41.13). Manual palpation of the gland is exquisitely painful and can result in discharge of pus from the duct. In addition there are usually systemic features, including fever, rigors and a neutrophilia. The most frequently isolated organisms are *Staph. aureus, Strep. pyogenes*, viridans streptococci and *Haemophilus influenzae*.

HIV-associated salivary gland swelling most commonly occurs as a bilateral cystic enlargement of the parotid glands, occasionally in

Figure 41-13 Suppurative parotitis (a) in a diabetic patient who had a recent history of dehydration secondary to diabetic ketoacidosis. (b) Pus was manually expressed from Stensen's duct from which *Staphylococcus aureus* was cultured. *Courtesy of Dr E Ridgway.*

association with xerostomia, dry eyes and arthralgia. Salivary gland involvement can occur very early on in HIV infection but is most commonly seen in late disease. Histologically, there are numerous epithelium-lined cysts, some up to several centimeters in size, containing macrophages and lymphocytes. The commonest identified opportunist infection of salivary glands is CMV; about 15% of postmortem submandibular glands of all patients who have AIDS have evidence of CMV inclusion bodies.[35] In children, there is a strong association between HIV-parotid swelling and lymphocytic interstitial pneumonitis. Examination usually reveals smooth bilateral swelling. Uneven swelling should be biopsied because 10% of salivary gland disease in HIV-infected patients is caused by lymphoma.[36]

DIAGNOSIS

In mumps, this can be achieved by detection of salivary IgM or by culture of salivary washings or of viral throat swab. A convalescent rise in complement-fixing antibody occurs. In established viral parotits there is elevation of serum salivary-type amylase. Rarely, there may be biochemical evidence of pancreatitis.

PREVENTION

The MMR vaccine consists of live attenuated measles, mumps and rubella viruses. Immunization provides protection for 90% of recipients for measles and mumps and over 95% for rubella. The antibody response to the mumps component is too slow for effective post-exposure prophylaxis. After the first dose of MMR, malaise, fever or rash may occur about 1 week after immunization, although this syndrome usually self-terminates within 3 days. Febrile convulsions occur in approximately 0.1% of children between 1 and 2 weeks after administration of the vaccine (similar to the attenuated live measles vaccine), and by the fourth week parotid swelling is seen in approximately 1% of infants.[37]

MANAGEMENT

Management of viral parotitis is symptomatic. Bacterial parotitis can usually be managed by prompt fluid replacement and parenteral antibiotic therapy using amoxicillin/clavulanate 1.2g q8h or intravenous cefuroxime 750mg q8h. Drainage of the duct should be assisted by manual massage. Occasionally steroids are necessary to

suppress inflammation and potentiate drainage. Surgical drainage of a salivary gland abscess is rarely necessary.

PAROTITIS CAUSED BY *MYCOBACTERIA* SPECIES

Nontuberculous mycobacterial infections of the parotid gland are now increasingly seen in children, in whom they present as unilateral painless indurated swellings that can be mistaken for neoplasm. Diagnosis can be made by fine needle aspiration with cytology and culture, which may reveal organisms such as *Mycobacterium scrofulaceum, Mycobacterium avium-intracellulare* or *Mycobacterium malmoense*. Management is conservative. *Mycobacterium tuberculosis* infection of the parotid gland is rare, but is one of the differential diagnoses of parotid tumor and should be rigorously excluded by histology of needle biopsy or fine needle aspiration cytology before unnecessary deforming surgery is undertaken.[38] The disease responds well to conventional antituberculous chemotherapy.

ESOPHAGEAL INFECTION

Normally there are relatively low numbers of micro-organisms within the esophagus; those present include a-hemolytic streptococci, lactobacilli, *Candida* spp. and low numbers of oral bacteria. Bacterial esophagitis is virtually unknown in the normal host, although occasionally the esophagus may be involved in generalized *M. tuberculosis* infection. Clinically important infections are fungal or viral and occur only in the context of immunosuppression or other underlying systemic diseases. The three most common causes of infective esophagitis in immunosuppressed patients are *Candida* spp. and, less commonly, HSV and CMV.

EPIDEMIOLOGY

Esophageal infection with *Candida* spp., HSV or CMV is generally seen in HIV-infected patients during the late stages of disease once the patient is profoundly immunodeficient, usually once the $CD4^+$ count is less than 200 cells/mm^3 . Each of these infections is an AIDS-defining illness in its own right. *Candida* esophagitis has been described in some patients during seroconversion illness as a result of the profound transient immunosuppression.[39] Patients who have solid tumors undergoing chemotherapy are at risk of *Candida* and HSV esophagitis. Mucositis caused by antineoplastic drugs predisposes patients to deep-seated candidiasis, including esophagitis. Solid organ transplant recipients are also susceptible to esophagitis caused by *Candida* spp., HSV and CMV.

PATHOGENESIS

Candida albicans is the predominant cause of superficial and deep-seated candidiasis, but other significant pathogens include *Candida tropicalis* (an important pathogen in neutropenic patients) and *Candida parapsilosisz*. *Candida glabrata, Candida lusitaniae* and *Candida krusei* have also been associated with esophageal disease and noted to be resistant to certain antifungal drugs.[40] Deep-seated candidiasis can be seen in patients rendered neutropenic as a result of an underlying malignancy or its treatment, or with significant cell-mediated immune defects as seen in AIDS.

CLINICAL FEATURES

Patients who have infective esophagitis can experience dysphagia or retrosternal esophageal pain (odynophagia), or both. The clinical features of AIDS-related esophagitis associated with *Candida* spp., CMV and HSV are similar, but patients who have AIDS-related esophageal candidiasis often complain of dysphagia rather than pain, whereas odynophagia and retrosternal episodic pain without swallowing, in addition to dysphagia, are more commonly encountered in patients who have HSV esophagitis and CMV esophagitis.[41]

DIAGNOSIS

In the context of oral candidiasis, radiologic or endoscopic investigation of esophageal symptoms is not absolutely necessary, because a therapeutic trial with antifungal agents will suffice. Otherwise, endoscopy is indicated to exclude HSV or CMV infection and also rarer causes of esophageal symptoms in AIDS, particularly lymphoma, Kaposi's sarcoma, mycobacterial infection, histoplasmosis or squamous cell carcinoma. The endoscopic appearance of *Candida* esophagitis ranges from diffuse mucosal hyperemia, with or without discrete white mucosal patches on the mucosa, to gross mucosal ulceration and perforation. In HSV and CMV disease there are usually discrete single ulcers of the distal third of the esophagus. With CMV disease these tend to be serpiginous, whereas in HSV they are small and punched out. These features can also be seen on barium studies of the esophagus; in candidiasis there is usually mucosal irregularity whereas in HSV disease ulcers can sometimes be seen in the distal third of the esophagus. At endoscopy, brushings are taken for detection of *Candida* spp. by direct microscopy or culture, for rapid diagnosis of HSV by direct immunofluorescence, and for viral culture of HSV and CMV. Biopsy of an ulcer edge may reveal cells with dense intranuclear inclusion bodies indicative of CMV disease, although their absence does not rule out the disease. Alternatively, esophageal biopsies may reveal epithelial cells with ballooning degeneration and occasional inclusion bodies suggestive of HSV infection.

MANAGEMENT

For a full discussion of treatment of esophageal *Candida* spp., HSV and CMV infection, see Chapters 125 , Chapter 126 , Chapter 215 and Chapter 237 .

Chapter 42 - Gastritis, Peptic Ulceration and Related Conditions

John C Atherton
Andrew F Goddard

INTRODUCTION

Until recently the inclusion of gastritis and peptic ulcer in a textbook of infectious diseases would have seemed incongruous. However, in 1983, Marshall and Warren described the bacterium now known as *Helicobacter pylori* (see Chapter 230) and suggested that it may be important in the pathophysiology of chronic active gastritis and peptic ulceration.[1] They were proved correct, and it is now accepted that *H. pylori* infection:

- causes chronic active gastritis;
- is the main cause of duodenal and gastric ulceration; and
- is an important risk factor for gastric adenocarcinoma and lymphoma.

The term 'gastritis' is often erroneously applied to the macroscopic appearance of 'inflamed' (erythematous) gastric mucosa seen at endoscopy (Fig. 42.1a). However, these appearances correlate poorly with histologic inflammation, for which the term 'gastritis' should be reserved. Gastritis may be subtyped from the histologic appearance and distribution within the stomach, and these features often indicate etiology and risk of associated disease (Table 42.1). The main cause of gastritis is *H. pylori* infection. Two other helicobacters, namely *Helicobacter bizzozeronii* (formerly called *Helicobacter heilmannii* or *Gastrospirillum hominis*) and *Helicobacter felis*, are tight spiral bacteria present in 2–6% of the population of a developed country and thought to be zoonotically acquired, as both commonly colonize domestic pets.[3] [4] They usually cause mild gastritis and although there are case reports of associated disease and response to anti-helicobacter treatment, this is rare and a causal link is not well established.[3] [4]

Peptic ulcers may be associated with some types of gastritis. A peptic ulcer is a macroscopic break in the gastric or duodenal mucosa with obvious depth and definite size (usually defined as greater than 0.5cm; Fig. 42.1). Erosions are smaller breaks in the mucosal surface, which usually reflect the ulcer diathesis and should be managed similarly. Although gastric and duodenal ulcers share some characteristics, there are notable differences in their etiologies and pathogeneses (Table 42.2).

EPIDEMIOLOGY

Prevalence and incidence

The age prevalence of *H. pylori* differs markedly between countries, but two broad patterns are found (Fig. 42.2).

- In group 1 countries (predominantly developing countries), there is a rapid rise in prevalence before 20 years of age, after which point prevalence stabilizes at above 80%, implying that *H. pylori* is acquired in childhood and persists throughout life.
- In group 2 (usually developed) countries, the prevalence of infection increases steadily with age at a rate of roughly 1%/year of life. Most epidemiologic evidence suggests that this is the result of a birth cohort effect.[5] According to this theory, about 30% of 30-year-olds have acquired the infection in childhood, as compared with 60% of 60-year-olds, because of a changing incidence of infection in childhood over the past 60 years.

Associations

Aside from associations with age and geographic area, *H. pylori* is closely associated with socio-economic conditions, particularly in childhood. This may explain the different prevalences of infection found in different ethnic groups within the same geographic area.[6] Markers of childhood socio-economic status that have been correlated with prevalence of infection include general level of hygiene, water supply and sanitation and level of crowding in the household. These associations further support the view that most *H. pylori* acquisition is in childhood, from when it persists throughout life in the absence of effective treatment.

Although most infected adults became infected as children, there are well-documented examples of *H. pylori* being acquired de novo in adult life and several studies have suggested that crowding and poor sanitation are risk factors for this.[7] [8] However, marital status is only weakly associated with infection (and in some studies not associated), supporting the view that infection between adults is rare.

Transmission

Helicobacter pylori is thought to be acquired by direct human-to-human contact. Although monkeys and domestic cats may become infected, these are not an important reservoir for human infection. *Helicobacter pylori* DNA has been isolated from drinking water supplies in developing countries but *H. pylori* has not been cultured consistently from these sources and most data do not support an environmental source of infection. It is unclear whether *H. pylori* is transmitted by the fecal-oral or oral-oral route, or both. The bacterium has been cultured with difficulty from the feces of people who have *H. pylori* infection in both developing and developed countries, but it is more easily cultured from gastric refluxate into the mouth and from vomitus. However, it appears not to persist in the mouth as, although *H. pylori* DNA has been found in dental plaque, persistent colonization is not confirmed by culture. In past years, transmission of *H. pylori* has been documented following insufficient sterilization of endoscopy or gastric pH measuring equipment, although with adequate sterilization this is no longer a problem. Acute *H. pylori* infection by this route is thought to be the cause of the occasional outbreaks of epidemic acute hypochlorhydria[9] observed before the discovery of *H. pylori*.

PATHOGENESIS AND PATHOLOGY

Helicobacter pylori is primarily a gastric infection, although it may colonize areas of gastric metaplasia in the duodenum and esophagus, and rarely heterotopic gastric tissue elsewhere in the gastrointestinal tract. In the stomach, infection causes chronic active gastritis characterized by continuing neutrophil and lymphocyte infiltration, epithelial damage and thinning of the mucus layer (Fig. 42.3a). This is in

Figure 42-1 Endoscopic pictures of the stomach and duodenum. (a) Erythema of the gastric antrum. This appearance correlates poorly with histologic gastritis and may be a normal finding. (b) Duodenal ulceration. (c) Gastric ulcer. Note the clot in the base indicating recent bleeding and high risk of rebleed and the endoscope entering the stomach through the cardia.

TABLE 42-1 -- Classification of chronic gastritis according to the updated Sydney system.*

CLASSIFICATION OF CHRONIC GASTRITIS ACCORDING TO THE UPGRADED SYDNEY SYSTEM	
Type of gastritis	**Etiology**

Nonatrophic	*Helicobacter pylori*
Atrophic	
Autoimmune	Autoimmunity
Multifocal atrophic	*Helicobacter pylori* ± dietary and other environmental insults
Special forms	
Chemical	Aspirin/NSAIDs, bile and possibly other agents
Radiation	Radiation
Lymphocytic	Idiopathic, overt or latent celiac disease, drugs (ticlopidine), possibly *H. pylori*
Noninfectious granulomatous	Crohn's disease, sarcoidosis, vasculitides, foreign substances, idiopathic
Eosinophilic	Food sensitivity, possibly other allergies
Other infectious gastritides	Bacteria other than *H. pylori* (particularly *H. bizzozeronii* or '*H. heilmanii*' and *H. felis*, mycobacteria and syphilis), viruses (particularly cytomegalovirus), fungi (particularly *Candida* spp. *Histoplasma capsulatum* and Mucoraceae)
Non-helicobacter infectious gastritides are very rare, usually occur in immunocompromised patients and are not discussed in this chapter.	

** Data from Dixon et al., with permission.* [2]

contrast to gastritis caused by chemical agents, including nonsteroidal anti-inflammatory drugs (NSAIDs), which is characterized by regenerative epithelial changes and a paucity of inflammatory cells (Fig. 42.3b). *Helicobacter pylori* gastritis is associated with several important pathologic conditions including:

- duodenal ulceration,
- gastric ulceration,

- gastric adenocarcinoma arising from the distal stomach but not from the gastric cardia,
- gastric lymphoma, and
- a form of Ménétrier's disease.[10]

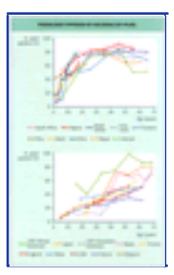

Figure 42-2 Prevalence patterns of *Helicobacter pylori*. Prevalence of *H. pylori* infection in 10 developing countries (Group 1) and 10 developed countries (Group 2). *Adapted with permission from Pounder and Ng.*[5]

TABLE 42-2 -- Causes of duodenal and gastric ulceration (with estimated proportions).

CAUSES OF DUODENAL AND GASTRIC ULCERATION (WITH ESTIMATED PROPORTIONS)			
Cause		**Duodenal ulcer (% of cases)**	**Gastric ulcer (% of cases)**
Infection	*Helicobacter pylori*	90	60–70
Drugs	Aspirin and NSAIDs	5–10	25–30
Neoplasms	Zollinger-Ellison syndrome	Rare	Rare
	Lymphoma	Rare	Rare
	Gastric adenocarcinoma	-	2–5
	Other adenocarcinoma	Rare	Rare
	Leiomyoma	-	Rare
Others	Crohn's disease	Rare	Rare
	Systemic mastocytosis	Rare	Rare
	Severe systemic illness	Rare	Rare

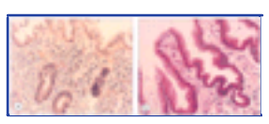

Figure 42-3 Appearances of *Helicobacter pylori* and NSAID antral gastritis. (a) Antral gastritis in *H. pylori* infection with active (neutrophil) and chronic inflammation of the lamina propria and glands. The epithelial surface is typically ballooned. *Helicobacter pylori* organisms are not readily apparent on a hematoxylin and eosin stain. (b) Antral gastritis associated with NSAID use. Foveolar hyperplasia with a mild chronic inflammatory infiltrate and smooth muscle cells are seen in the lamina propria. *Courtesy of Dr MM Walker.*

There is controversy over the association of gastric *H. pylori* infection with gastroesophageal reflux disease (GERD); it appears to offer a degree of protection in a subset of people.[11] There is also controversy over whether *H. pylori* is the cause of symptoms in a small subset of people with a macroscopically normal upper gastrointestinal tract (so-called 'functional dyspepsia').[12]

Approximately 80% of people who have *H. pylori* infection do not develop any of these diseases in their lifetime. Whether an infected person develops disease and which disease develops is becoming better understood and is dependent on a combination of bacterial strain virulence, host genetic susceptibility and environmental cofactors.

Duodenal ulcer disease

Approximately 90% of patients who have duodenal ulceration have *H. pylori* infection; the remaining 10% are aspirin or NSAID users or have other rare conditions (see Table 42.2). Few people now doubt that *H. pylori* causes ulcers; the best evidence is that eradication virtually abolishes ulcer relapse. [13] [14]

Several characteristics are found more commonly in ulcer-associated than in non-ulcer-associated *H. pylori* strains. The two best characterized are:

- presence of the *cag* (cytotoxin-associated gene) pathogenicity island, and
- production of an active vacuolating cytotoxin, VacA.

The *cag* pathogenicity island is a genetic region containing over 30 genes.[15] The island encodes a type IV secretory apparatus, best thought of as a syringe, through

which one *cag*-encoded protein, CagA, is 'injected' into epithelial cells.[16] CagA induces the epithelial cell to undergo several changes including the secretion of pro-inflammatory cytokines, which leads to increased gastric inflammation.[15] CagA is also highly immunogenic and anti-CagA antibody detection can be used as a serum test for the presence of the island. About 70% of strains in the USA are *cag*$^+$ and these strains colonize the gastric mucosa more densely, cause more inflammation and are more likely to be associated with ulcers than are *cag*$^-$ strains.[17]

The vacuolating cytotoxin, VacA, is a pore-forming toxin that increases epithelial permeability and causes massive epithelial cell vacuolation in vitro. It is particularly suited to the stomach because it is activated by acid, then becoming acid and pepsin resistant.[18] Although only about 40% of strains isolated in the USA exhibit cytotoxin activity, all have *vacA*, the gene encoding the cytotoxin. However, only some *vacA* genotypes are associated with the toxigenic phenotype and infection with strains of certain *vacA* genotypes is associated with increased prevalence of peptic ulcer disease.[19] Virtually all toxigenic strains are *cag*$^+$, although the relative importance of the toxin and *cag*-encoded proteins and how they interact are unclear.

There has been considerable recent research into other virulence factors present in only some strains and these may turn out to be as important as the *cag* island and VacA. They include an adhesin, BabA, a bacterial outer membrane proinflammatory protein, OipA, and a restriction enzyme, IceA, and its associated methylase.[20] Other bacterial factors are also thought to be important for pathogenesis in terms of colonization and the induction of inflammation, such as the enzyme urease and the ability to adhere to gastric mucosa, but these are present in all strains and so do not explain why only some strains cause ulcers.

Recently, the pathogenic link between infection in the stomach and ulceration in the duodenum has become better understood. Duodenal ulcers arise in patients with antral-predominant gastritis. Infection of the gastric antrum leads to a reduction in somatostatin-producing D-cells resulting in hypergastrinemia, as somatostatin inhibits gastrin production.[21] Both inflammation and hypergastrinemia are more marked in infection with *cag*$^+$ strains. High gastrin levels lead to increased stimulated acid output from parietal cells in the gastric corpus, which is most marked when the corpus is relatively spared of infection. The resulting increased acid load entering the duodenum leads to the formation of adaptive gastric metaplasia.[22] This can be colonized by *H. pylori* and local inflammation and release of toxic bacterial products can lead to ulceration.

Specific host factors predisposing to antral-predominant gastritis and duodenal ulceration have not been identified. However, environmental factors are important and, in particular, smokers who have *H. pylori* infection are much more likely to develop ulcers than are nonsmokers who have the infection. Aspirin and NSAIDs can cause ulcers independently of *H. pylori* infection and further increase the risk of ulcers in people with *H. pylori*.

Gastric ulcer disease

Helicobacter pylori-associated gastric ulcers usually arise in junctional mucosa between antral- and corpus-type tissue, typically on the lesser curvature. They usually occur in patients with pan-gastritis rather than antral-predominant gastritis and are not associated with increased stimulated acid output. Their pathogenesis is uncertain, but infection with virulent strains and smoking increase risk. Although *H. pylori* infection is the most common cause of gastric ulceration, the proportion caused by aspirin and NSAIDs is higher than for duodenal ulcers.

Gastric adenocarcinoma

The World Health Organization has classified *H. pylori* as a type 1 or causal carcinogen.[23] It is a risk factor for distal adenocarcinoma with a relative risk of 4–9, but it is unrelated to carcinoma of the cardia, which is now the most common type of gastric carcinoma in the USA. Distal gastric adenocarcinoma usually arises in patients with pan-gastritis and patients who have previous duodenal ulceration (usually with antral-predominant gastritis) are less likely than others to develop gastric cancer. Both *cag*$^+$ and cytotoxic strains are more likely to be associated with carcinoma than other strains. Host genetics are also important; people with genetic polymorphisms that lead to high-level secretion of the proinflammatory cytokine interleukin-1 in response to bacterial infection are more likely to develop gastric cancer.[24] Young age at infection, smoking and dietary factors (high nitrosamines, low antioxidants) have also been associated with increased risk. The pathogenesis of gastric carcinoma is unclear and may differ between the two main types, intestinal and diffuse cancer. Intestinal-type gastric cancer is thought to occur by a step-wise process from superficial gastritis through atrophy to intestinal metaplasia, dysplasia and ultimately carcinoma. [25] One possibility is that the hypochlorhydria associated with pan-gastritis and with atrophy may allow survival of DNA-damaging oxygen and nitrogen free radicals. Hypergastrinemia may also be important and is increasingly recognized as a risk factor for gastrointestinal tract tumors.

Gastric lymphoma

Primary gastric lymphomas arise in lymphoid tissue which is only present in the *H. pylori*-infected stomach. B-cell mucosa-associated lymphoid tissue (MALT) lymphomas are particularly interesting as they are driven by chronic stimulation by *H. pylori* antigens. When histologically low grade, the majority regress following *H. pylori* eradication.[26]

Protection against gastroesophageal reflux disease

There is increasing epidemiologic evidence that people with *H. pylori* infection, especially those with pathogenic strains, are less likely to develop GERD and its rare sequelae — Barrett's esophagus and esophageal adenocarcinoma.[11] This is of considerable interest because the incidence of these conditions is increasing rapidly in developed countries. Evidence suggests that reduced risk is associated with pan-gastritis and reduced acid production, presumably because gastroesophageal refluxate is less damaging. In those with *H. pylori* infection, treatment may improve, worsen or not affect GERD symptoms and esophagitis. Thus, there is no clinical reason not to treat *H. pylori* in those with an indication for eradication.

Functional dyspepsia

Most people with a macroscopically normal upper gastrointestinal tract do not benefit from *H. pylori* eradication. Most studies show that a small subgroup of about 10% will benefit, but this may be a group with undiagnosed ulcer disease. Thus, there is little evidence that *H. pylori* infection causes symptoms in the absence of ulceration or malignancy.

PREVENTION

Prevention of *H. pylori* infection is difficult in view of our paucity of knowledge about its transmission, although improved living conditions, clean water and improved health should reduce the incidence in developing countries. In developed countries *H. pylori* incidence is falling steadily[5] and specific preventive measures may not be necessary.

Helicobacter pylori vaccine research is ongoing, with encouraging early results in animal models. However, whether an effective human vaccine can be developed remains uncertain.

CLINICAL FEATURES

Acute *Helicobacter pylori* infection

The clinical features of acute infection in the community are unknown. However, where high doses of cultured *H. pylori* have been self-administered, upper abdominal discomfort and pain occurred 3 days after dosing, followed by vomiting and finally a resolution of symptoms by the end of the week.[27] A similar pattern of symptoms was observed in patients with acute epidemic hypochlorhydria,[9] an illness that occurred in volunteers undergoing nasogastric intubation for acid secretion studies in the 1970s and presumed to be iatrogenic acute *H. pylori* infection. *Helicobacter pylori* is most commonly acquired in childhood, but whether initial colonization is usually symptomatic or asymptomatic is not known

Chronic *Helicobacter pylori* infection

Chronic *H. pylori* infection is characterized by chronic active gastritis, but this condition is asymptomatic. Chronic infection is therefore only manifest symptomatically if complications develop, such as duodenal ulceration, gastric ulceration or gastric cancer.

DIAGNOSIS

Diagnosis of *H. pylori* infection can be made by endoscopic biopsy-based tests or by noninvasive tests. Most patients require endoscopy to assess indications for treatment, and so tests for *H. pylori* are usually performed at this time. The choice of endoscopic-based test depends upon the information required, cost and convenience; usually only a urease test on a mucosal biopsy is used. As infection is very likely in non-NSAID-associated duodenal ulcer, some regard testing for *H. pylori* in this context as unnecessary. Our practice,

however, is to make a positive diagnosis before prescribing potentially harmful multiple antibiotic treatment regimens. Nonendoscopic tests (the urea breath test (UBT), serology or the stool antigen test) are useful in primary diagnosis only if a treatment indication already exists (e.g. in a patient with demonstrated previous ulcer).

Following *H. pylori* treatment, some consider retesting unnecessary due to the high efficacy of modern treatment regimens. We prefer to monitor treatment success or failure as a prognostic guide and as an aid to managing recurrent symptoms. Repeat endoscopy is usually unnecessary and the UBT, which is well suited for assessing treatment success, is becoming more widely available. However, in situations where endoscopy is conventionally repeated (e.g. to check healing of gastric ulcers to exclude malignancy) biopsy-based tests are equally suitable. Tests must be delayed for at least 4 weeks after finishing treatment or false-negative results may occur; even in primary diagnosis, testing within 4 weeks of treatment with intercurrent antibiotics or bismuth compounds or within 2 weeks of dosing with proton pump inhibitor may give false-negative results. Serologic tests are not suitable for checking the success of treatment as specific antibody levels fall only slowly.

Endoscopic tests

Endoscopic tests are based on mucosal biopsy specimens. Infection may be patchy, and so if possible two biopsies should be taken from the usually more uniformly infected antrum to minimize sampling error. In some situations, notably after treatment, during acid suppressive therapy or when intestinal metaplasia and atrophy are likely (e.g. in the elderly), the infection may be more marked in the corpus and at least two additional biopsies should be taken from there.

Culture

Helicobacter pylori can be cultured from gastric biopsies, although sensitivity is often low compared with that of other tests. Biopsies should be put into a sterile solution and transferred as soon as possible to the laboratory. Methods for culture and identification are discussed in Chapter 230 . Cultured bacteria can be tested for antibiotic sensitivities and the main indication for culture is previous failed treatment.

Histology

Chronic superficial gastritis seen on standard hematoxylin and eosin staining is strongly indicative of *H. pylori* infection, but unless specialized stains are used (e.g. modified Giemsa, Gimenez (Fig. 42.4), Warthin-Starry or Genta) the infection may be missed. Histology is expensive, but sensitive in experienced hands, and may provide other useful information, such as the presence of epithelial dysplasia.

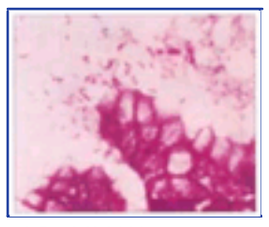

Figure 42-4 *Helicobacter pylori* (Gimenez stain). Other special stains that can be used are the modified Giemsa stain or a silver stain such as Warthin-Starry stain. *Courtesy of Dr MM Walker.*

Biopsy urease test

In this test, two gastric biopsies or one large biopsy are placed in a gel or solution containing urea and a pH indicator. If *H. pylori* is present, its urease enzyme catalyzes urea hydrolysis and a color change occurs. These tests can be performed in the endoscopy room and are sensitive, specific, cheap, convenient and quick. A positive result can be obtained in a few minutes, although for most commercial tests a 24-hour wait is necessary to ensure that the test is negative.

Nonendoscopic tests

Urea breath tests

Several protocols exist, but in essence the patient drinks urea solution isotopically labeled with either stable ^{13}C or ultra-low dose radioactive ^{14}C. If *H. pylori* is present, the urea is hydrolyzed and labeled carbon dioxide can be detected in breath samples. Both isotopes are safe, although it is sensible to avoid ^{14}C in pregnant women and children. The best UBT protocols are as specific as biopsy-based tests and are perhaps more sensitive as sampling error is avoided. The UBT is the most widely used and appropriate test to check for treatment success in situations where repeat endoscopy is unnecessary, but must be performed at least 1 month after any antibiotic, bismuth or proton pump inhibitor treatment.

Stool antigen tests

These newly described simple stool tests are an alternative to UBTs and indications for use are the same.[28] Whether they are as accurate remains to be determined.

Serology

Many commercial and in-house assays, usually enzyme-linked immunosorbent assays, are available to test for specific IgG and IgA in serum. The best are as sensitive and specific as other tests and serologic testing is more convenient and cheaper than even the UBT. This makes it the most suitable test for infection when there is a known indication for treatment and endoscopy is not required. A fall of over 40% in specific IgG titer 6 months after treatment accurately reflects treatment success, but testing paired pre- and 6 months posttreatment samples presents a storage problem and a long wait for results, and offers little cost advantage over the UBT. Rapid in-office tests for *H. pylori* are being heavily marketed to primary care physicians, but these usually perform poorly in independent studies and are not currently recommended.

MANAGEMENT

The medical and surgical management of gastric adenocarcinoma are not within the context of this book. Here we address the management of *H. pylori*-associated peptic ulcer disease and infection.

Peptic ulcer disease

Until recently, treatment of peptic ulcers was based upon acid-suppressing drugs. When the treatment was stopped, the ulcers often relapsed. However, eradication of *H. pylori* not only heals ulcers but also prevents their recurrence. Therefore, once an ulcer is diagnosed by endoscopy or barium meal, *H. pylori* infection should be sought and, if found, treated (Fig. 42.5). This is usually done immediately, but if there is a delay in performing diagnostic tests for *H. pylori*, ulcer healing can be started with acid-suppressing drugs and *H. pylori* treatment can be added when the infection has been confirmed.

Duodenal ulcers are virtually always benign, but gastric adenocarcinoma can present as gastric ulceration. Therefore, additional biopsies for histologic examination should be taken when there is gastric ulceration, with follow-up endoscopy performed to confirm healing.

Figure 42-5 Decision algorithm for the management of duodenal ulcer disease diagnosed at upper gastrointestinal endoscopy.

Uninvestigated dyspepsia

To reduce the number of endoscopies performed (and therefore cost) and to increase patient comfort and convenience, most national and other guidelines now recommend noninvasive *H. pylori* testing and, if the organism is present, immediate eradication in patients with persistent dyspepsia younger than a locally defined age cut-off.[29] The reason for performing endoscopy in older people is to avoid delay in diagnosing gastric cancer, and so age cut-off depends on the local incidence and demographics of this disease, but it is usually between 40 and 55 years. All patients with 'alarm' symptoms or signs such as weight loss, dysphagia, persistent vomiting, gastrointestinal bleeding, unexplained anemia, epigastric mass, previous gastric ulcer or gastric surgery should be referred for upper gastrointestinal endoscopy and/or other investigations regardless of age, both to exclude malignancy and to make a positive diagnosis.

***Helicobacter pylori* treatment regimens**

First-line treatment is with 'low-dose triple therapy' consisting of either a proton pump inhibitor, amoxicillin and clarithromycin, or a proton pump inhibitor, clarithromycin and metronidazole (see

TABLE 42-3 -- *Helicobacter pylori* treatment regimens.

***HELICOBACTER PYLORI* TREATMENT REGIMENS**	
First-line treatments	
Regimen 1[*]	
Omeprazole 20mg q12h[†]	7–14 days
Clarithromycin 500mg q12h	
Amoxicillin 1g q12h	
Regimen 2	
Omeprazole 20mg q12h[†]	7–14 days
Clarithromycin q12h	
Metronidazole q12h	
Second-line treatments[‡]	
Omeprazole 20mg q12h[†]	14 days
Bismuth subcitrate[§] 120mg q6h	
Tetracycline HCl 500mg q6h	
Metronidazole 400mg q8h	

* Many physicians use regimen 1 rather than regimen 2 for first-line therapy as it avoids use of metronidazole, which is an important constituent of second-line therapy.
† Other proton pump inhibitors are equally effective or, in regimens 1 and 2, ranitidine bismuth citrate 400mg.
‡ An alternative to 'blind' second-line therapy is to culture *H. pylori* and be guided by antibiotic sensitivities. Patients failing second-line therapy should be referred to a specialist and *H. pylori* culture will usually be necessary.
§ Bismuth subsalicylate may be used instead of bismuth subcitrate.

Table 42.3) .[29] Knowledge of local antibiotic resistance patterns is helpful in choosing an optimal *H. pylori* treatment as regimens are less effective if *H. pylori* has in-vitro resistance to a component antibiotic. Metronidazole-resistant *H. pylori* is common in:

- developing countries;
- in many ethnic populations within developed countries; and
- in individuals who have previously taken metronidazole for concurrent illnesses, even in the distant past.

Clarithromycin resistance is still rare, but increasing as the antibiotic becomes more commonly used for respiratory tract infections. Amoxicillin resistance is very rare.

For any *H. pylori* treatment regimen, patients should be warned of the importance of compliance and potential side-effects. Providing written instructions may be the most effective strategy. The success of treatment should be assessed by UBT or endoscopy, 4 weeks or more after treatment finishes.

Patients in whom treatment is unsuccessful often have antibiotic-resistant strains, and even if this is not the case unsuccessful treatment often induces antibiotic resistance. Two approaches are commonly used: administration of 'blind' second-line therapy (see Table 42.3) or endoscopy for *H. pylori* culture and sensitivity testing and guided therapy. After two treatment failures referral for endoscopy and culture is always indicated.

For whom is *Helicobacter pylori* eradication justified?

As discussed above, *H. pylori* treatment is now frequently recommended in young people with uninvestigated dyspepsia who do not have 'alarm' symptoms or signs. For patients who do undergo endoscopy, three groups of patients who have *H. pylori* infection should unequivocally receive eradication treatment:

- those with an active or previous duodenal ulcer;
- those with a nonmalignant gastric ulcer; and
- those with a MALT lymphoma, particularly if at an early stage.

In this last group, some patients will require additional chemotherapy.

The benefits of treating other groups of patients should be balanced against the potential risks of treatment.[30] These risks include:

- development of antibiotic resistance (both by *H. pylori* when treatment has failed and by other organisms within the body);
- adverse drug reactions; and
- rarely, pseudomembranous colitis.

Patients for whom there is some evidence that *H. pylori* eradication may be beneficial include those with reflux esophagitis requiring long-term proton pump inhibition

and those with high-grade gastric dysplasia. Some evidence suggests that people in the former group have an increased risk of developing accelerated atrophic gastritis, which is thought to be an early step in the progression to adenocarcinoma. [31] However, whether the risk of gastric adenocarcinoma is increased and whether *H. pylori* eradication prevents this are both unknown. Until the situation is clear, it may be prudent to err on the side of caution and treat patients in this group. Outside these situations there is no accepted indication to treat *H. pylori* infection for the primary prevention of gastric malignancy, although many physicians treat the infection if there is a family history of gastric adenocarcinoma. Occasional patients with nonucler dyspepsia have a good symptomatic response to *H. pylori* eradication.[12] However, there is no method for selecting which patients will respond and we do not recommend *H. pylori* treatment for this indication.

Chapter 43 - Enteritis, Enterocolitis and Infectious Diarrhea Syndromes

Martin Montes
Herbert L DuPont

EPIDEMIOLOGY

Infectious diarrhea illness is a public health problem for both the industrialized and the developing countries. The highest prevalence occurs in the latter where it is associated with increased morbidity and mortality among children under the age of 5 years. Recurrent episodes of diarrhea occur routinely in these regions where each child may experience up to six or more bouts of diarrhea on an annual basis.[1] The highest rates of illness in these areas occur in infants younger than 2 years whose fatality rate is five times higher than older children. Over the past two decades and because of the introduction of oral rehydration therapy (ORT) and the promotion of breast-feeding and measles vaccination programs, there has been a significant decline in child mortality secondary to diarrhea. In 1980, an estimated 5 million children died secondary to the disease; these numbers decreased to 3.3 million cases in 1990 and to 1.5 million in 1999. [2] However, diarrhea still represents 12% of the causes of death in children worldwide, second only to the respiratory diseases. Many deaths still occur in developing tropical regions because of a number of factors, of which malnutrition is often the most important. Malnutrition is associated with about 50% of all death among children.[3] Some of the main factors associated with death in patients with diarrheal disease include:

- malnutrition;
- complications of diarrhea, including dehydration, pneumonia, sepsis and the hemolytic-uremic syndrome (HUS);
- Infection by an agent more likely to cause dehydration, such as *Vibrio cholerae* and rotavirus;
- infection by an invasive pathogen such as *Shigella* spp.;
- lack of access to rehydration and/or antimicrobial therapy;
- persistent diarrhea, defined as illness lasting 14 days or longer.

In the industrialized nations, the prevalence of diarrhea is lower in the general population. It is estimated that children under 5 and adults in the USA will experience about 1–2 bouts of diarrhea annually.[4] However, in certain individuals the rate of infectious diarrhea is substantially higher. These persons at higher risk include international travelers visiting tropical and semitropical regions, institutionalized elderly, infants in daycare centers, hospitalized patients, especially those exposed to broad-spectrum antibiotics, and military personnel deployed to conflict areas. Change in travel plans, work leave for parents caring of sick children and extended hospital stay are just a few examples of the clinical and financial burdens of diarrhea in the developed world.

It is estimated that the cost of dealing with *Clostridium difficile*-associated diarrhea in US hospitals exceeds $1.1 billion per year.[5] Outbreaks of acute gastroenteritis also affect military personnel. The most common cause of disability among soldiers was related to Norwalk-like virus (NLV) diarrhea outbreaks in Operations Desert Storm and Desert Shield. There have been recent similar reports during military operations in Afghanistan.[6]

People living with HIV-AIDS are also at a higher risk of developing diarrhea. This is true for all continents but more evident in Africa and South Asia where the prevalence is higher and the access to treatment and living conditions are lower. Table 43.1 gives general estimates of the expected frequency of diarrhea development for a variety of populations. Figure 43.1 shows the number of deaths secondary to diarrhea in the year 2000, by age group and world regions.

PATHOGENESIS AND PATHOLOGY

Pathogens known to cause diarrhea in humans include bacteria, viruses and protozoa. After overcoming the host's defense factors (e.g. gastric acids, intestinal mucus, gut motility, normal intestinal flora and immune mechanisms), pathogenic microbes produce diarrhea through one of four different but not exclusive mechanisms:

- increased active intestinal secretion of electrolytes that induces fluxes of water and ions, usually mediated by enterotoxins (watery diarrhea);
- malabsorption of nutrients and electrolytes secondary to damage to the brush border;
- increased intestinal osmolality secondary to disaccharidase deficiency when the brush border is damaged, with resultant lactose intolerance;
- altered intestinal motility.

The first mechanism is most frequently involved in acute diarrhea; the other three are most important in chronic forms of diarrhea.

The inoculum necessary to cause diarrhea illness varies among the different pathogens. Table 43.2 shows a few examples of the minimum number of viable organisms required to produce diarrhea in 25% of exposed persons (ID_{25}).

Bacterial enteropathogens

The pathogenesis of diarrheal illness caused by bacterial enteric organisms in the gastrointestinal tract involves attachment or adherence to the intestinal mucosa, production of toxins and mucosal invasiveness (Table 43.3).

Adherence to the intestinal mucosa

Adherence is the ability of the organism to attach to and colonize the intestinal mucosa where the disease is caused. It is the first step for production of an infection, which can be followed by toxin production, signal transduction or invasion. Adherence capacity is defined by the bacteria exhibiting mannose-resistant adhesion to HeLa or HEp-2 tissue culture cells. Using these cell lines and varying the conditions of the adhesion assay, three classic distinct patterns of *Escherichia coli* adherence have been observed.

- *Localized adherence.* This is the characteristic form of enteropathogenic *E. coli* (EPEC) where tight clusters of organisms can be seen in microcolonies attaching to the cell surface.
- *Diffuse adherence.* These *E. coli* (DAEC) attach in a scattered pattern onto the whole cell surface.
- *Enteroaggregative adherence*: The *E. coli* (EAEC) attach in clumps of organisms with a 'stacked brick' appearance to cells and cover slips.

TABLE 43-1 -- Rates of endemicity of diarrhea in various populations.

RATES OF ENDEMICITY OF DIARRHEA IN VARIOUS POPULATIONS	
Population	**Prevalence/incidence of diarrhea**
Infants (<2 years) in developing countries	3–6 bouts/person/year
Older children and adults in developing countries and all age children and adults worldwide	1–2 bouts/person/year

Travelers from industrialized regions during stays in developing tropical or semitropical areas	15–40% per trip
Patients who have AIDS:	
Africa	40%
North America	15%
Other high risk persons: elderly, gay men, infants in daycare centers, persons receiving antimicrobials	>1–2 bouts/person/year

The pattern of adhesion is directly related to the mechanism by which *E. coli* produce diarrhea. EPEC adheres to the intestinal mucosa and produces a characteristic histopathologic lesion, referred to as an attaching and effacing (A/E) lesion.[7] [8] The A/E lesion is characterized by dissolution of the intestinal brush border, loss of microvillus structures (effacement) and F-actin polymerization beneath the site of bacterial attachment as a result of localized

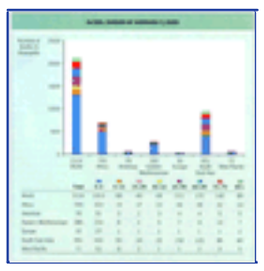

Figure 43-1 Global burden of diarrhea illness. Estimated number of deaths secondary to diarrhea in the year 2000, by age group and world regions. Numbers are expressed in thousands. *Source: Global Burden of Disease 2000, World Health Organization.*

cytoskeletal breakdown.[9] [10] The A/E lesion that appears to be a specific marker for EPEC and enterohemorrhagic *E. coli* (EHEC) can be detected by the fluorescent-actin staining reaction (FAS). The localized EPEC adherence property is mediated by bundle-forming pili (bfp), which cause the characteristic bacterial aggregation to each other and to the microvilli. This inducible adherence property is conferred by a 50–70mDa plasmid encoding the EPEC adherence factor.[11] [12] After adhering to the enterocyte, the next step is the induction of signal transduction pathways in the host cell. The bacterial genes are located on a 35kb pathogenicity island called the locus of enterocyte effacement (LEE), which encodes a bacterial adehesin called intimin. Without this intimate adherence process, the bacteria are unable to produce its effects on the enterocytes. These multiple signal transduction pathways originate an increment of the intracellular calcium levels which is responsible for the cytoskeletal changes observed and the inhibition of NaCl absorption and increment in Cl^- secretion producing the secretory component of EPEC diarrhea. The gene encoding intimin, eae (attaching and effacing), is also present in EHEC strains showing A/E histopathologic lesions. Finally A/E lesions are also responsible for severe losses of absorptive microvilli leading to diarrhea through malabsorption (Fig. 43.2)

EAEC does not hybridize with the EPEC adherence factor probe, is fluorescent-actin staining negative and does not produce A/E lesions. A lesion characterized by shortening of villi, hemorrhagic necrosis and mild inflammatory response of the submucosa is observed in rabbit and rat ileal loops.[13] EAEC possesses a 55–65mDa plasmid that encodes for fimbriae similar to bundle-forming pili of EPEC and mediates aggregative adhesion and hemagglutination.[14] EAEC

TABLE 43-2 -- Dose of viable microbes responsible for disease production (ID_{25}).

DOSE OF VIABLE MICROBES RESPONSIBLE FOR DISEASE PRODUCTION (ID_{25})	
Enteropathogen	**ID_{25}**
Shigella spp	10–100
Giardia and *Cryptosporidium parvum*	30–100
Shiga toxin *E. coli* 0157:H7	10–100
Norwalk-like virus	100
Salmonella	10^3 –10^5
Campylobacter	10^3 –10^6
Vibrio cholerae	10^6
ETEC	10^8

was isolated from US travelers to Mexico and from Mexican and Indian children with protracted diarrhea.[15] [16] [17] DAEC is distinct from localized adhering EPEC because it does not hybridize with the EPEC adherence factor probe and is negative in the FAS test.[18] [19] The pathogenic capability and epidemiologic significance of DAEC are controversial. [20]

The HEp-2 adherence is also exhibited by enterotoxigenic *E. coli* (ETEC), and some *Salmonella* and *Shigella* strains. ETEC produces a specific type of mannose-resistant pili that is important for the adherence and colonization of the mucosa. This adherence capacity is mediated by the production of bacterial surface adhesions called colonization factor antigens (CFA), which are genetically encoded by plasmids.

Toxin production

The toxins produced by enteric bacteria causing diarrhea can be classified as enterotoxins neurotoxins and cytotoxins.

Enterotoxins

These are bacterial products that act on the epithelial cells of the small intestine and produce a fluid secretion without any structural

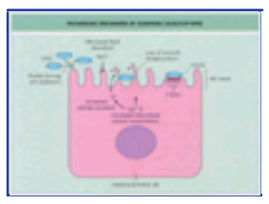

Figure 43-2 Pathogenic mechanism of diarrhea caused by EPEC. Figure shows attachment of EPEC to the enterocyte, villous destruction and formation of the A/E lesion.

TABLE 43-3 -- Pathogenic mechanisms of diarrhea caused by enteric bacteria.

PATHOGENIC MECHANISMS OF DIARRHEA CAUSED BY ENTERIC BACTERIA			
Pathogenesis	**Mode of action**	**Clinical presentation**	**Examples**
Mucosal adherence	Attachment, colonization and effacement of intestinal mucosa	Secretory diarrhea	Localized adhering EPEC, enteroaggregative *E. coli*, diffuse adhering *E. coli*, ETEC
Toxin production:			
Neurotoxin	Action on the autonomous nervous system	Enteric symptoms	Staphylococcal enterotoxin b, *Clostridium botulinum*, *Bacillus cereus*

Enterotoxin	Fluid secretion without damage to the mucosa	Watery diarrhea	*Vibrio cholerae*, ETEC, *Salmonella* spp., *Campylobacter* spp., *Clostridium difficile* toxin A, *Clostridium perfringens* type A
Cytotoxin	Damage to the mucosa	Inflammatory colitis, dysentery	*Shigella dysenteriae* serotype 1, *E. coli* 0157:H7, *Clostridium difficile* toxin B, *Salmonella* spp., *Campylobacter* spp.
Mucosal invasiveness	Penetration into the mucosa and destruction of epithelial cells	Dysenteric syndrome	*Shigella dysenteriae* serotype 1, *Shigella sonnei*, *Shigella flexneri*, EIEC, *Campylobacter* spp., *Yersinia* spp.

damage to the mucosa. *Vibrio cholerae* toxin (CT) and ETEC heat-labile toxin (LT) are oligomeric toxins that share very similar structure and mode of action and are similar to the enterotoxins produced by other watery diarrhea-causing bacteria, such as *Salmonella* spp., *Campylobacter* spp., *C. difficile* toxin A and *Clostridium perfringens*

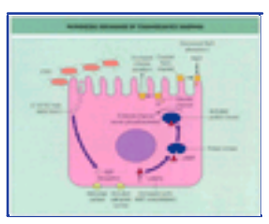

Figure 43-3 Pathogenic mechanism of toxin-mediated diarrhea.

type A. CT and LT are conformed of a single A-subunit surrounded by five identical B-subunits. The toxin binds via the B-subunit pentamer to the GM1 ganglioside receptor on the membrane of the enterocyte. The A-subunit enters the cell where it is proteolytically cleaved to yield the A1 and A2 peptides joined by a disulfide bond. A1 peptide activates adenylate cyclase located in the baso-lateral membrane, thereby increasing intracellular cAMP concentrations.[21] [22] [23] The cAMP activates a cAMP-dependent protein kinase, which subsequently leads to excess phosphorylation of chloride channels located in the apical epithelial cell membranes. It is postulated that the major chloride channel activated by LT and CT is CFTR, the ion channel defective in cystic fibrosis. [24] The end result is increased Cl^- secretion by cryptic cells and inhibition of coupled influx of Na^+ and Cl^- across the brush border of the enterocyte. The combination of oversecretion and underabsorption of ions by the small intestine leads to passive transport of water into the lumen, thus producing watery diarrhea (Fig. 43.3). One of the main differences between LT and CT is the failure of the former to release serotonin. In addition, prostaglandins, platelet-activating factor and the enteric nervous system appear to be involved in the secretory response demonstrated mostly by CT.[22] [25] [26]

ETEC can also produce another type of enterotoxin responsible for diarrheal illness: a low molecular weight, heat-stable enterotoxin (ST). ST is a monomeric toxin containing multiple cysteine residues with disulfide bonds accounting for the heat stability of this toxin. There are two different classes of ST named STa and STb. STa, which contains 18–19 amino acids, binds to small bowel mucosa cells via a receptor in the apical membrane of the enterocytes called guanylate cyclase C (GC-C) and increases intracellular levels of cGMP, which leads to the secretory effect of the enterotoxin. Other enteropathogenic bacteria also produce STa, including *Yersinia enterocolitica* and *V. cholerae* non-01.[22] Another type of enterotoxin produced mainly by ETEC, STb, causes noncyclic nucleotide-dependent bicarbonate secretion in piglet loops, but its role in human disease remains unclear.[27] The genes controlling the production of LT and ST reside on transferable plasmids.

Cytotoxins

Cytotoxins are defined by their ability to produce damage to the mucosa that often results in inflammatory colitis, usually by inhibition of protein synthesis. The prototype of this group is the Shiga toxin, which is produced by *S. dysenteriae* serotype 1. This toxin is immunologically and structurally related to the cytotoxin produced by all strains of EHEC 0157:H7, which is associated with HUS. Using DNA hybridization and planned restriction patterns, this cytotoxin has also been shown for other *E. coli* serotypes. These cytotoxins, also known as verotoxin or Shiga-like toxins, are composed of an enzymatically active A cytotoxic subunit and a B-subunit pentamer that binds to the glycolipid globotriosyl ceramide Gb3 cell receptor. The A-subunit cleaves the adenosine-4324 in the 28S rRNA of the 60S ribosomal subunit and permanently blocks protein synthesis by inhibiting elongation factor-1.[28] Histopathologic examination of human and animal tissues has suggested that vascular endothelial cells are a target for verotoxin. This finding is consistent with the capillary lesions of the gastrointestinal mucosa and renal glomerulus in the hemorrhagic colitis and hemolytic uremic syndromes, respectively.

Strains of *C. difficile* isolated from patients who have antibiotic-associated diarrhea produce a potent cytotoxin that causes cellular damage in tissue cultures. *C. perfringens* also produces a cytotoxin that displays a similar effect to Shiga-like toxin in HeLa cells and in animal models. *Salmonella* strain elaborate an enterotoxin that activates cAMP and a cytotoxin that inhibits protein synthesis.

Neurotoxins

These include staphylococcal enterotoxin b, *Clostridium botulinum* and *Bacillus cereus* emetic toxin. These toxins cause enteric symptoms, primarily because of their action on the autonomic nervous system.

Invasiveness

Invasiveness is defined by the ability to penetrate into the intestinal mucosa and destroy the epithelial cells, causing a dysentery syndrome. Enteroinvasive *E. coli* (EIEC) and *Shigella* spp. are the prototypes

of invasive enteric pathogens. The invasiveness of certain strains of *Shigella* and EIEC is demonstrated in the laboratory by the guinea-pig Séreny test, which manifests destruction and invasion of the superficial corneal epithelium in guinea pigs. This property is mediated by proteins encoded by 120–140mDa plasmids found in *Shigella sonnei, Shigella flexneri* and EIEC [29] [30] and appears to be dependent at least in part on additional chromosomally encoded products and a lipopolysaccharide structure.

Viral enteropathogens

The exact mechanisms by which viruses produce diarrhea are not completely understood. The most studied model of viral enteritis is rotavirus (RV). Animal models of RV infection and viral replication in human intestinal epithelial cells have demonstrated that a multifactorial process is involved. After attachment to the cell surface and subsequent entry to the enterocyte, RV induces multiple cell-signaling pathways. The glycoprotein receptor and exact mode of entry have not been identified yet.[31] [32] Diarrhea is produced partly by intestinal fluid secretion attributed to the enterotoxin NSP4, the first described viral enterotoxin. NSP4 induces intracellular Ca^{2+} mobilization, Cl^- secretion and secretory diarrhea.[33] There are no structural similarities between NSP4 and the bacterial enterotoxins and NSP4 does not involve cyclic nucleotide signaling. The loss of absorptive villous enterocytes, the site of RV replication, also contributes to the malabsorption component of RV diarrhea. It is also believed that RV stimulates the enteric nervous system (ENS), thus prolonging diarrhea. The adenovirus and the calicivirus (including the NLV) are noncultivable viruses and little is known about their pathogenesis.

Intestinal protozoa

Diarrhea caused by the intestinal protozoa like *Giardia* and *Cryptosporidium* is usually self-limited in the normal host. The virulence factors leading to persistent diarrhea in the immunocompromised host and in certain individuals are a matter of intense research. The main mechanisms by which protozoa induce diarrhea are attachment and colonization of the intestinal epithelial cells, loss of villous absorptive cells and subsequent malabsorption. [34] [35] [36] Additionally, *Entamoeba histolytica* is capable of disrupting the intestinal mucosa, producing invasive disease, localized ulcerations, ameboma, dysentery syndrome and hematogenous dissemination.

PREVENTION

The major measure for the prevention of enteric infections in the general population is continuous vigilance over water supply and sanitation facilities. The morbidity

caused by this type of illness has diminished notably in developed nations with improvement in public health measures. The manufacture and distribution of nutritional products require extraordinary precautions from the food industry and continuous surveillance from the health authorities. Personal hygiene, especially handwashing, is of vital importance, particularly after contact with animals or animal products or after contact with hospitalized patients.

Travelers to areas with high prevalence of enteric infections may be able to reduce the probability of developing diarrhea by careful selection of food and beverages. It is important to encourage the consumption of well-cooked food, pasteurized milk and potable or processed water or bottled drinks. There is vast evidence that contaminated foodstuffs and water are the most important vehicles of diarrheal illness transmission in developing countries. Many public restaurants and street vendors often fail to meet adequate food hygiene standards and food is frequently contaminated with bacteria like ETEC, *Shigella, Campylobacter, Salmonella* and *Aeromonas*. The benefit of using chemoprophylactic agents such as antimicrobials and bismuth subsalycilate (BSS) against travelers' diarrhea (TD) has been demonstrated in the past. The development of resistance to commonly used antibiotics in different areas of the world,[37] short-lived protection and the possibility of side effects of the drugs during travel preclude the widespread use of antimicrobials as prophylactic agents. Although BSS showed a protective efficacy of up to 65% when taken at high doses (2.1g/day), the amount of tablets (two four times daily) needed for optimal protection, the required level of compliance and possible side effects make BSS unattractive for prophylaxis of TD.[38] Therefore, chemoprophylaxis is currently recommended only for those travelers with concomitant serious medical illness or in very special cases like short-term travelers in whom temporary incapacity from TD would be unacceptable.

The development of vaccines to prevent diarrheal illness in the general population in areas with high prevalence and travelers has been studied extensively, with different outcomes. Two large field trials of the inactivated whole cell *V. cholerae* plus B-subunit oral cholera vaccine (WC/BS) were conducted in Bangladesh and Peru. Five-year follow-up data in the Bangladesh study demonstrated that the protective efficacy of three doses of WC/BS was age and biotype dependent (less protective in children less than 5 years old and in those infected with the biotype El Tor); protection was lost after the second or third year of follow-up. [39] The cholera vaccine in the Peruvian trial used a B-subunit produced by recombinant genetic technology (WC/rBS). Two initial doses of WC/rBS were insufficient to provide protection against cholera infection, but a boost dose after 10 months of the initial doses reduced the overall number of cholera episodes by 61% and the number of hospitalizations by 82%.[40] Other forms of cholera vaccines are still under development, including a live attenuated form.[41]

In 1998 a rotavirus vaccine was approved for routine childhood immunization. This vaccine, a tetravalent rhesus-based vaccine (RRV-TV), was found to have a protective efficacy of about 50% and 70–100% against all RV diarrhea and severe diarrhea/hospitalizations respectively. Unfortunately, after several case reports of intestinal intussusception in recipients of the vaccine, RRV-TV was withdrawn from routine use in the USA in November 1999.[42]

Two different typhoid vaccines are currently available for use. An oral live-attenuated vaccine made from the Ty21a strain of *Salmonella typhi* is given every other day for four doses. The second is a purified Vi capsular polysaccharide vaccine, Typhim Vi, given parenterally. These vaccines have demonstrated an overall efficacy of approximately 70%. Protection after vaccination with any of these two vaccines occurs 2 weeks after completion of the primary vaccine series; therefore, vaccination should not preclude meticulous attention to food and beverage hygiene precautions.

Novel methods of delivery of enteric vaccines are being explored, including transcutaneous immunization. A combined recombinant ETEC colonization factor 6 (CF6) with heat-labile enterotoxin (LT) has proved to be immunogenic in volunteers.[43]

The widespread and indiscriminate use of broad-spectrum antibiotics is not only leading to the emergence of resistant pathogens but also contributes to the increased incidence of hospital antibiotic-associated diarrhea, most commonly caused by *C. difficile*. Judicious use of antibiotic and hospital measures such as strict handwashing and patient isolation precautions may help to decrease these complications.

CLINICAL FEATURES

On the basis of the clinical-pathologic features, diarrheal illness may be classified into a number of syndromes:

- watery diarrhea;
- dysenteric syndrome;
- antibiotic-associated diarrhea;
- enteric or typhoid fever;
- travelers' diarrhea;
- HIV-AIDS-associated diarrhea;
- diarrhea in homosexual men (Table 43.4).

TABLE 43-4 -- Major clinical-pathologic features and causes of infectious diarrhea.

MAJOR CLINICAL-PATHOLOGIC FEATURES AND CAUSES OF INFECTIOUS DIARRHEA		
Watery diarrhea		Cholera
		ETEC
		EPEC
		Salmonella gastroenteritis
		Shigella (initial phase)
		Cryptosporidium parvum
		Clostridium perfringens
		Bacillus cereus
		Giardia lamblia
		Rotavirus
		Norwalk-like virus
Dysenteric syndrome	Acute dysentery	Shigellosis
		EIEC
		EHEC
		Vibrio parahaemolyticus
		Salmonella enteritidis
		Yersinia enterocolitica
		Campylobacter jejuni
	Parasitic dysenteric-like syndrome	*Entamoeba histolytica*
		Schistosoma japonicum
		Schistosoma mansoni
		Trichinella spiralis
		Strongyloides stercoralis
Antibiotic-associated diarrhea		*Clostridium difficile* (pseudomembranous colitis)
		Clostridium perfringens type A
		Staphylococcus aureus

Enteric fever	*Salmonella typhi*
	Salmonella paratyphi A
	Salmonella schottmuelleri
	Salmonella hirschfeldii
Enteric fever-like syndrome	*Yersinia enterocolitica*
	Yersinia pseudotuberculosis
	Campylobacter jejuni

Watery diarrhea

This is a noninflammatory process that is confirmed by the absence of fecal leukocytes. There is usually a large volume of stool and a modest increase in the number of stools because the colonic reservoir is intact. This disorder is often manifested by nausea and vomiting, but other associated symptoms include cramping, abdominal pain, arthralgias, myalgias, chills and rarely fever. The diarrhea is mediated by bacterial enterotoxins that alter fluid and electrolyte transport (*V. cholerae*, ETEC, EPEC, *Salmonella enteritidis, Salmonella typhimurium, Cryptosporidium* spp., *C. perfringens, B. cereus*) or organisms that characteristically affect the proximal small bowel (e.g. ETEC, *Giardia*, RV, NLV).

Cholera is the prototypic model of enterotoxigenic diarrhea. After an incubation period that varies from several hours to 5 days, the illness may begin with sudden onset of profuse, watery diarrhea or anorexia and abdominal discomfort followed by diarrhea. The stool has a characteristic 'rice water' appearance, because of the mucus content, and a mild fishy smell. Tenesmus is absent and vomiting often occurs a few hours after onset of diarrhea.[44] Signs and symptoms of cholera infection result from the severity of dehydration caused by the fluid and electrolyte losses from the intravascular and extracellular spaces into the gut lumen. Only 2–11% of patients infected with toxin-producing *V. cholerae* 01 develop cholera gravis as a result of rapid fluid loss (500–1000ml/h). This leads to tachycardia, hypotension and severe hypovolemic shock.[45] Patients are typically afebrile, but low-grade fever occurs in up to 20% of cases. Patients may experience abdominal pain, muscle cramps, nausea, vomiting, thirst and faintness as a result of the fluid loss. The electrolyte imbalance may also cause leg cramps. Most cholera complications are related to fluid and electrolyte losses and include altered consciousness, acidosis, hypoglycemia, hypokalemia (rarely resulting in intestinal ileus, weakness and cardiac arrhythmias), hypernatremia and renal failure.

Salmonella gastroenteritis is characterized by crampy abdominal pain, nausea, vomiting and diarrhea that begins 8–48 hours after ingestion of contaminated food. Diarrhea varies from cholera-like watery diarrhea to dysentery. Patients may have moderate fever. Approximately 1–4% of patients develop transient bacteremia. The most common serotypes that cause gastroenteritis are *S. typhimurium, S. enteritidis, S. newport* and *S. anatum*.

NLV diarrhea usually affects adults of all ages and is the most common cause of nonbacterial food-related diarrhea outbreaks. The onset of illness is abrupt (24–28h) and the duration is relatively short (12–60h). NLV symptoms include diarrhea, abdominal cramps and nausea but it is the high frequency of projectile vomiting that characterizes its presentation.

Acute dysentery

This inflammatory or invasive process involves the colon and occasionally the distal small intestine. The finding of numerous leukocytes in feces indicates the diffuse colonic inflammation or invasion of the colonic mucosa. *Shigella dysenteriae* is the prototypic pathogen of bacillary dysentery, particularly in the developing world. Elsewhere, other species may predominate, for example, *Shigella flexneri* in Mexico, South America and most other tropical countries, and *S. sonnei* in the USA. This condition is characterized clinically by fever, passage of low-volume stools that contain blood, mucus and leukocytes (dysentery), and variable degrees of fever, chills, abdominal cramping, tenesmus and vomiting. The patient feels the urge to defecate frequently, and may pass only small-volume stools, flatus or mucus. This is caused by the colonic infection and decreased reservoir capacity of the colon. [46] Occasionally young infants with early shigellosis will have hyperpyrexia and febrile convulsions, initially without enteric symptoms. *S. dysenteriae* 1 produces a more serious form of diarrhea and has been associated with HUS, disseminated intravascular coagulation and sepsis.

EIEC can cause a clinical illness that is indistinguishable from that produced by shigellosis. EAEC has been reported as causing diarrhea in 6% of travelers to Mexico and in 3% of US troops in the Middle East.[47] [48]

A form of dysentery that differs from that associated with EIEC is the bloody diarrhea (hemorrhagic colitis) caused by EHEC serotype 0157:H7 and, less commonly, a variety of other serotypes including 026:H11. This syndrome appears both as sporadic cases and in food-borne outbreaks characteristically associated with the consumption of undercooked ground beef in fast-food restaurants. *E. coli* 0157:H7 can cause asymptomatic infection, nonbloody diarrhea, hemorrhagic colitis, HUS and thrombocytopenic purpura. The disease begins with severe abdominal cramps and nonbloody diarrhea. By the second or third day of illness the individual may pass high-volume bloody stools. Nausea and vomiting are present in half of the patients. Unlike EIEC and shigellosis, high fever and abundant fecal leukocytes are not

a feature of *E. coli* 0157:H7 infection. The HUS, which is a major cause of acute renal failure in children, develops in about 6% of patients and is usually diagnosed 2–6 days after onset of diarrhea.[49] [50] The thrombocytopenic purpura, which is usually diagnosed in adults, has the clinical manifestations of the HUS, but the renal injury is less severe and the neurologic complications, including seizures, coma and hemiparesis, are more prominent. The clinical features of the hemorrhagic colitis can be confused with noninfectious diseases, such as ulcerative colitis, inflammatory bowel disease, intussusception, ischemic colitis, diverticulosis and appendicitis.

Other enterobacteria that cause dysentery syndrome are *Vibrio parahaemolyticus* and *C. difficile* (pseudomembranous colitis). *Salmonella enteritidis* and *Campylobacter jejuni* involve the small bowel and have the potential for developing acute inflammatory bowel disease. Some parasites may produce dysentery-like illness. Although *Entamoeba histolytica* is the best-known pathogen, *Schistosoma japonicum, Schistosoma mansoni, Trichinella spiralis* and *Strongyloides stercoralis* infections may all result in bloody diarrhea during the acute phase of infection.

Antibiotic-associated diarrhea

The onset of antibiotic-associated diarrhea is usually between 4 and 9 days after starting antibiotics. The most commonly implicated antibiotics are clindamycin, cephalosporins and penicillins. The clinical manifestations vary from mild watery or mucoid green diarrhea to dysenteric syndrome with bloody diarrhea, high fever, marked abdominal tenderness, the presence of fecal leukocytes, colonic thickening on computed tomography and findings of characteristic mucosal changes on endoscopy. *Clostridium difficile* is documented in about 20% of cases of antibiotic-associated diarrhea. Colitis results from cytotoxins produced by *C. difficile* that alter mucosal function and integrity. Sigmoidoscopy typically reveals the presence of small raised pseudomembranous nodules or plaques that may become confluent over an erythematous mucosa in the distal colon, sigmoid, or rectum (pseudomembranous colitis). Complications of pseudomembranous colitis include hypovolemic shock, toxic megacolon, peritonitis, fecal perforation, hemorrhage and sepsis. This disorder should be suspected when bloody diarrhea develops in hospitalized patients who are receiving antibiotics. Inflammatory bowel disease, ischemic colitis and other enteric pathogens such as *Salmonella* and *Shigella* spp., EIEC, *E. histolytica, Campylobacter, Yersinia* and *Strongyloides* spp. should always be considered in the differential diagnosis of pseudomembranous colitis.

Other causes of antibiotic-associated diarrhea include other enteric pathogens (*C. perfringens* type A, *Staphylococcus aureus*), direct effect of the antibiotics in the intestinal mucosa (erythromycin, clavulanate) or the metabolic consequences of the changes in the intestinal flora (see also Chapter 44).

Enteric fever

The enteric fever syndrome is an acute systemic illness characterized by fever, headache and abdominal discomfort. This syndrome is classically produced by *S. typhi* and referred to as typhoid fever; however, *Salmonella paratyphi* A, *S. paratyphi* B (*S. schottmuelleri*) and *S. typhi* C (*S. hirschfeldii*) may cause a similar but less severe clinical syndrome, referred to as paratyphoid fever. *S. typhi* is a food-borne and water-borne organism for which humans are the only natural hosts. *Salmonellae* are ingested orally and must traverse the acid barrier of the stomach as well as the various pancreatic enzymes, bile and intestinal secretions, and secretory IgA, which are effective antimicrobial factors. The postgastrectomy state, hypochlorhydria, altered intestinal motility and prior antibiotic use are known conditions predisposing to salmonellosis. In addition, salmonella infection is a common occurrence in patients who have sickle cell anemia, chronic liver disease and immunodeficiency of CD4

cell-mediated immunity accompanying neoplastic diseases and AIDS.

Salmonellae transcytose the infact distal small bowel mucosa, possibly via microfold cells over Peyer's patches. After replicating in the regional lymphatic nodules, organisms spread to the bloodstream through the lymphatic route and replicate in reticuloendothelial cells in lymph nodes, liver, bone marrow and spleen. The presence of mononuclear cells in the stool examination when diarrhea is present indicates that the intestinal mucosa is not damaged. The incubation period varies from 5 to 21 days, depending on the inoculum and the immune status of the patient. The onset is insidious, characterized by nonspecific manifestations of remittent fever, headache and abdominal pain. Diarrhea is present in approximately 50% of patients. Physical findings in patients who have typhoid fever include abdominal tenderness, splenomegaly, hepatomegaly, evanescent maculopapular rash on the upper abdomen and lower thorax ('rose spots'), relative bradycardia and mental confusion (at times delirium).[51] Complications of enteric fever occur during the third week of the illness and later as symptoms resolve. They may be related to recurrent bacteremia with dissemination of the organism, which may result in pneumonia, endocarditis, osteomyelitis, arthritis or meningitis, or to local organ involvement, such as erosion of blood vessels in Peyer's patches, which may result in intestinal hemorrhage or perforation of the ileum.[52] The case fatality rate in the USA is approximately 2%.

Yersinia enterocolitica, Y. pseudotuberculosis and *Campylobacter jejuni* may also be responsible for an enteric fever-like syndrome indistinguishable from that of typhoid fever. This syndrome has frequently been reported in patients who have underlying diseases such as chronic liver disease, thalassemia, kwashiorkor and amyloidosis.[53] [54]

Travelers' diarrhea

Travelers' diarrhea is defined as the passage of three or more unformed stools per day in a resident of an industrialized country visiting a developing nation. The onset of travelers' diarrhea usually occurs within the first 2 weeks after arrival in the foreign country, most often within the first week. Approximately 30–50% of the travelers from industrialized countries that spend at least 3 weeks in a less developed area will experience diarrhea. The illness is more common among young travelers.

Travelers' diarrhea is acquired through the ingestion of fecally contaminated food and/or water. A wide array of pathogens, including bacteria, viruses and protozoa, has been reported to cause it[55] [56] [57] (Table 43.5). ETEC is the most commonly isolated organism, responsible for 40–70% of cases of travelers' diarrhea in Latin America, Africa and Asia.[58] *Shigella* and *Salmonella* spp., *E. histolytica*, *G. lamblia*, *C. jejuni, Cryptosporidium, Vibrio, Aeromonas* and *Plesiomonas* spp. are other enteric pathogens responsible for travelers' diarrhea limited to certain geographic areas and seasons. Recently EAEC has been suggested as a cause of travelers' diarrhea. These findings represent about 19–33% of the cases in different world regions, second only to ETEC. [59] Giardiasis and cryptosporidiosis watery diarrhea are frequently seen in travelers to Russia and national parks in the USA. *Cyclospora cayetanensis* has been associated with prolonged and intermittent, but eventually self-limiting diarrheal illness in travelers to Nepal, in staff physicians at a Chicago hospital and in Peruvian infants and children living in the slums of Lima.[60] [61]

In summary, travelers' diarrhea is a bacterial illness and close to 80% of cases will respond to antibiotic therapy. On the other hand, viruses like rotavirus, NLV and adenovirus may represent about 10–12% of the etiology of travelers' diarrhea.

Travelers' diarrhea is almost always a self-limiting illness, rarely lasting more than 5 days even when untreated. However, 30% of travelers with diarrhea will be confined to bed and another 40% will have to modify their travel plans.[62] The diarrhea is accompanied by

TABLE 43-5 -- Etiologies of travelers' diarrhea in Latin America, Asia and Africa.*

ETIOLOGIES OF TRAVELERS' DIARRHEA IN LATIN AMERICA, ASIA AND AFRICA			
Organism	**Latin America (%)**	**Asia (%)**	**Africa (%)**
ETEC	40–70	20–34	36
EAEC	26–33	?	33
EIEC	6	3	2
Shigella spp.	2–30	2–13	2–15
Salmonella spp.	0–16	11–15	0–4
Campylobacter jejuni	1–7	2–15	1–28
Aeromonas hydrophila	2	1–57	1–8
Rotavirus	4–36	18	0–6
Giardia lamblia	0–9	0–6	0
Undiagnosed	23–30	33–53	15–33
Highest rates of ETEC occur in rainy summertime; highest rates of *Campylobacter jejuni* occur in dry wintertime.			

** (Modified from Arduino RC, DuPont HC. Travelers' diarrhea. In: Gracy M, Bouchier IAD, eds. Clinical gastroenterology: infectious diarrhea. London: Baillière Tindall; 1993;7:365.)*

abdominal pain and cramps in 20–60% of episodes. Nausea and vomiting are present in about 50% of the illnesses. Approximately 10% of patients develop fever. This clinical presentation is variable and depends on the etiologic agent, microbial virulence, size of the inoculum and host response. Travelers' diarrhea can frequently be separated into four syndromes:

- noninflammatory or watery diarrhea (ETEC, *Salmonella* spp., *C. jejuni*, *Shigella* spp. and *V. cholerae*);
- inflammatory or dysenteric diarrhea (*Shigella* spp., *C. jejuni*, nontyphi *Salmonella* spp., *E. histolytica*, *V. parahaemolyticus*, EIEC and *Aeromonas* spp.);
- vomiting out of proportion to diarrhea (*Staph. aureus*, *B. cereus*, rotavirus and NLV);
- and persistent diarrhea lasting longer than 2 weeks (*Giardia*, *Entamoeba*, *Cryptosporidium* spp. and *Cyclospora cayetanensis*).

Diarrhea may also occur in travelers within days of their return to their country of origin. In 1–2% of travelers, it lasts for longer

TABLE 43-6 -- Diarrhea in HIV-positive patients: causes of diarrheal disease in relation to the absolute $CD4^+$ lymphocyte count.*

than 1 month. Bacterial pathogens such as *Shigella, Salmonella* and *Campylobacter* spp. are the most common causes of chronic diarrhea or remitting symptoms. In addition to parasites such as *G. lamblia*, the most common parasite acquired by travelers worldwide, *Cryptosporidium* spp., *Cyclospora cayetanensis* and *E. histolytica* can cause prolonged diarrhea. An idiopathic condition known as Brainerd diarrhea may produce diarrhea among international travelers. This illness lasts on average 2 years before complete recovery.

Diarrhea in HIV-AIDS patients

Gastrointestinal symptoms are common in persons infected with HIV and diarrhea is one of the most frequent presenting complaints of patients with AIDS. Diarrhea occurs in up to 50% of patients who have AIDS in the USA and Europe, and in up to 90% of those in developing countries.[63] [64] [65] [66] A wide array of pathogens, including bacteria, viruses and protozoa, can be associated with diarrheal disease in HIV-infected patients. A pathogen can be identified in 50–80% of patients who have AIDS and diarrhea. Infection of the mucosa by HIV itself, infection with unrecognized or unidentified pathogens, dysregulation of the enteric immune system, fat malabsorption and small bowel bacterial overgrowth are potential causes of diarrhea and weight loss in some HIV-infected patients without detectable pathogens ('AIDS enteropathy'). Table 43.6 shows the potential small and large bowel pathogens that cause diarrheal disease in relation to the absolute $CD4^+$ lymphocyte count.

Parasitic infection is the most common form of pathogen-identified illness in patients with AIDS-associated diarrhea. *Cryptosporidium parvum* enteritis is commonly found in these patients. It occurs in up to 20% of AIDS patients in the USA and 50% of patients in Africa and Haiti who have AIDS and diarrhea. *C. parvum* primarily causes a small bowel disease characterized by chronic voluminous watery diarrhea. Patients may have anorexia, nausea, vomiting, crampy upper abdominal pain, low-grade fever and marked weight loss. Although *C. parvum* is generally restricted to the small bowel, it may involve the stomach and the colon, as well as the gallbladder, the pancreatic and biliary ducts or the respiratory tract. *Isospora belli* occurs in fewer than 3% of AIDS patients in the USA, but it is an

important cause of diarrhea in Haiti and Zaire. This parasite has also been reported in South America, Africa and South East Asia.[67] *Cyclospora cayetanensis* has been identified in stool specimens from HIV-infected patients who have chronic diarrhea in Haiti and Mexico [68] [69] but this pathogen is uncommon among AIDS-associated diarrhea in the USA. *Enterocytozoon bieneusi* and to a lesser extent *Septata intestinalis* are two microsporidia species associated almost exclusively with AIDS patients. Prevalence rates of *E. bieneusi* among patients with AIDS-associated chronic diarrhea range from 7% to 50%. Enteritis is observed in patients who have a $CD4^+$ lymphocyte count below 100/ml. The clinical features of isosporiasis, cyclosporiasis and microsporiasis are indistinguishable from those seen in patients who have cryptosporidiosis. *Giardia lamblia, E. histolytica* and *Blastocystis hominis* are not significantly more frequently found among AIDS patients than among HIV-negative homosexual men.

Mycobacterium avium complex infection may present with fever, night sweats, abdominal pain, diarrhea, severe weight loss and anemia. *Salmonella* and *Shigella* spp. may cause protracted, severe and bacteremic infections in HIV-infected individuals despite relatively minor gastrointestinal symptoms. EPEC, EAEC, or both, have been found on colonic biopsy from AIDS patients who have chronic diarrhea, malabsorption and weight loss.[70]

Disseminated fungal infections, such as those caused by *Cryptococcus*, *Histoplasma* and *Aspergillus* spp., may also be accompanied by diarrhea. The colon is the site most commonly involved by *H. capsulatum*.

The colon is also the gastrointestinal site most commonly involved by cytomegalovirus. The clinical presentation includes diarrhea with hematochezia, urgency, tenesmus, crampy abdominal pain and occasionally rebound tenderness. Fever, malaise, anorexia and weight loss frequently accompany the colitis. Herpes simplex virus is a common disease among HIV-infected patients, usually confined to the perianal region, rectum and esophagus. In addition to painful perianal ulcers, involvement of the distal rectum may result in low-volume bloody stools, constipation, painful defecation, inguinal lymphadenopathy, tenesmus and mucopurulent discharge that may be misinterpreted as diarrhea. Rarely, extension to the sigmoid colon leads to proctocolitis and mild diarrhea. Rotavirus and adenovirus have also emerged as significant potential pathogens in patients who have AIDS and diarrhea.

Diarrhea in homosexual men

There is a high prevalence rate of acute rectal and enteric infections in homosexual men. This high prevalence varies widely depending on promiscuity, certain sexual practices (receptive anal intercourse) and the incidence of asymptomatic and untreated infections. Where fecal contamination of the oral cavity commonly occurs, these enteric infections are often polymicrobial.[71] Oral-fecal contamination, which might occur during anal intercourse or oral-anal contact, appears to be the major risk factor for the transmission of enteric pathogens. In addition, anorectal infections with conventional venereal pathogens are caused by receptive rectal intercourse. The predilection of enteric infections for certain segments of the gastrointestinal tract and the patient's symptoms allow division of the disease into four syndromes. Enteritis is an inflammation of the small intestine; patients may present with symptoms of diarrhea, abdominal cramps and bloating. Pathogens commonly associated with enteritis include *G. lamblia, Cryptosporidium* spp. and *Strongyloides stercoralis*. Proctocolitis refers to an inflammation throughout segments of the colon and rectum that causes diarrhea and lower abdominal cramps in addition to the symptoms of proctitis. Sigmoidoscopy is often abnormal beyond 15cm. Proctocolitis is associated with isolation of *Campylobacter* spp., *Shigella flexneri, Salmonella* spp., *E. histolytica, C. difficile* and *Chlamydia trachomatis* lymphogranuloma venereum serovar. Proctitis implies inflammation limited to the rectum that causes anorectal pain, mucopurulent anal discharge, constipation, tenesmus and rectal bleeding. Anoscopy is often abnormal and evidences rectal exudate, mucosal friability, ulceration and bleeding. Proctitis is commonly associated with *Neisseria gonorrhoeae*, herpes simplex virus, *C. trachomatis* and *Treponema pallidum*. The perianal disease is a dermatologic disorder involving the anus and perianal area that causes perianal discomfort, pruritus and external lesions such as those produced by syphilis, herpes simplex virus, chancroid, granuloma inguinale, condyloma acuminata and human papilloma virus.

DIAGNOSIS

In the diagnostic approach to a patient who has diarrhea, the physician should obtain a careful exposure history and physical examination. Important diagnostic clues are history of antibiotic use, recent and remote travel, duration of diarrhea, weight loss, water supply, hobbies, pets, use of drugs that can cause diarrhea, other cases of diarrhea in the family and diet (e.g. lactose intolerance, intake of unpasteurized dairy products, raw or uncooked meat or fish). Once epidemiologic features of the illness and selective clinical characteristics are determined, it may be useful to distinguish between small and large bowel diarrhea. Large volume and relatively infrequent or nocturnal diarrhea suggests small intestine involvement. It is often associated with bloating, gas and periumbilical pain. On the other hand, frequent small-volume stools with infraumbilical pain on either side and rebound tenderness suggest colonic involvement. Rectal symptoms such as tenesmus, incontinence and urgency occur with colonic and anorectal inflammation. Fever is common, indicating an inflammatory process. Fecal leukocytes and blood in the stool (dysentery) result from diffuse colonic mucosal inflammation. Patients who have colitis can develop severe weight loss, often as a complication of the pathogens causing diarrhea rather than malabsorption.

Laboratory tests for stool samples are time consuming and expensive. Final identification requires a battery of media that is not available in all clinical laboratories.

Thus, in nonhospitalized patients who have mild to moderate diarrhea (five unformed stools or fewer without fever and/or cramps, pain, nausea and vomiting) routine stool culture is not justified from a cost-benefit point of view. Supportive treatment can be given. Fluid and electrolyte replacement and diet modification will usually be followed by spontaneous recovery. On the other hand, in patients who have more severe diarrhea (six unformed stools or more, presence of the aforementioned clinical symptoms and/or positive fecal leukocytes), persistent diarrhea (lasting >2 weeks), dehydration, requiring admission to hospital, who are very young, debilitated or with immunodeficiency diseases, or during an outbreak, laboratory tests can offer invaluable help in diagnosis and management (Table 43.7).

Direct examination

Microscopic examination of fecal smears can give rapid and useful information at a low cost. This test should be done in any patient who has moderate to severe diarrhea. One drop of stool, preferably including blood and mucus, is mixed with two drops of methylene blue on a glass slide and a cover slip is placed. The finding of numerous polymorphonuclear leukocytes, using high-power magnification (40×), indicates diffuse colonic (mucosal) inflammation caused by an invasive or inflammatory enteric pathogen, but does not specify the etiology. Mononuclear leukocytes may predominate in patients who have typhoid fever or amebic dysentery. The most common enteric pathogens that cause positive fecal leukocytes are *Shigella,*

TABLE 43-7 -- Indications for laboratory tests and findings.*

INDICATIONS FOR LABORATORY TESTS AND FINDINGS		
Test or procedure	**Indications**	**Positive findings**
Fecal leukocyte test or fecal lactoferrin	Fever and/or dysentery	Infectious:
	Moderate to severe diarrhea	*Shigella*, *Salmonella*, *Campylobacter* spp.; less frequently, *Clostridium difficile*, *Yersinia enterocolitica*, *Vibrio*, *parahaemolyticus*, *Aeromonas hydrophila*, EIEC, EHEC
	Hospitalized patients	
		Noninfectious:
		ischemic colitis, Crohn's disease, ulcerative colitis, diverticulitis, pseudomembranous colitis, necrotizing enterocolitis
Stool culture	Fever and/or dysentery	*Shigella*, *Salmonella*, *Campylobacter* spp.
	Moderate to severe diarrhea	
	Hospitalized patients or hospital admission	
	Diarrhea and dehydration	
	Diarrhea >1 week in duration	
	Patients with immunodeficiency diseases	
	Diarrhea outbreak	
Parasitic examination	Diarrhea >2 weeks in duration	*Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium* spp.
	Bloody stool with few leukocytes	
	Recent travel to developing countries, Russia or Rocky Mountains	
	Diarrhea in homosexual men or in infants in daycare centers	
Proctosigmoidoscopy	Chronic diarrhea	White-yellowish plaques in pseudomembranous colitis, selective sampling of ulcers in amebiasis, biopsy to rule out other pathologies
	Severe antibiotic-associated diarrhea with equivocal test for *C. difficile* toxin	
	Amebiasis	
	Idiopathic inflammatory bowel disease	
	Hiv-positive with large-bowel diarrhea or acute proctitis	
	History of anal manipulation	
Gastroduodenoscopy	HIV-positive patients who have small-bowel diarrhea	*Giardia lamblia*, *Cryptosporidium parvum*, *Enterocytozoon bieneusi*, *Septata intestinalis*, *Mycobacterium tuberculosis*, *Mycobacterium avium* complex

** (With permission from Arduino RC, DuPont HL. Diarrhea in the critically ill: causes and treatment in five clinical settings. J Crit Illness 1992;6:715–24.)*

Salmonella and *Campylobacter* spp. Other disorders associated with feces containing leukocytes are *C. difficile*, *Y. enterocolitica, Aeromonas hydrophila, V. parahaemolyticus*, EIEC and EHEC. The finding of numerous fecal leukocytes is an indication for performing stool culture and giving antibiotic treatment. The examination of feces on saline wet mount preparations by dark-field or phase-contrast microscope for motility can reveal *Campylobacter* or *Vibrio* spp., which show 'darting motility'.

Examination for parasites is indicated in all patients who have diarrhea lasting longer than 2 weeks, diarrhea acquired while traveling to the Rocky Mountains, Russia or developing countries, persons in daycare centers, male homosexual patients or HIV-infected patients. Wet mounts can be performed using a drop of iodine solution. With low-power magnification (10×) eggs, larvae, cysts and trophozoites can be detected. Special stains are used when trophozoites of amoeba are suspected. *Giardia lamblia* is missed in half of these cases. If *G. lamblia* is suspected but the examination is negative, it is recommended to continue by collecting a small bowel fluid sample, performing a small bowel biopsy, using the nylon string test, or treating the patient empirically (see Chapter 209).

Modified Kinyoun's acid-fast stain and trichrome staining of stool should be done, particularly in immunocompromised patients, for cryptosporidiosis, isosporiasis and microsporidiosis. The oocytes stain red against a blue background with these stains. Stool concentration techniques and duodenal aspirates increase the sensitivity of examination for parasites. *Microsporidia* spores can be demonstrated in stool by light microscopy using Gram, Weber chromotrope-based, Giemsa or chitin-binding fluorochrome stains. However, small bowel aspirates or jejunal biopsy may be required for identification of these organisms (see Chapter 243). Electron microscopy is a valuable adjunct for the identification and taxonomy of *Microsporidia* in infected tissues and fluids.

Monoclonal-based immunofluorescence stains and enzyme-linked immunosorbent assay (ELISA) have been developed for the

direct detection of *Isospora, Giardia, Cryptosporidium* spp. and *E. histolytica* antigens in feces. Diagnosis of cyclosporiasis can be improved by concentrating oocysts from fecal samples without the use of formalin, to allow them to sporulate at room temperature in 5% potassium dichromate, and visualizing the sporocysts by autofluorescence using ultraviolet light or by modified acid-fast stain.

Stool culture

Bacteria cause 15–50% of cases of diarrhea in adults, depending upon the severity and duration of illness when studied. Clinical laboratories are able to identify the

most commonly recognized invasive pathogens, such as *Shigella, Salmonella* and *Campylobacter* spp. Routine use of media for the isolation of other pathogens varies depending on the geographic location and patient history. For example, history of exposure to coastal areas and seafood should prompt culture for vibrios (*V. cholerae, V. parahaemolyticus* and others). These organisms require a selective thiosulfate citrate bile salt sucrose agar. Culture of *Y. enterocolitica* may require the selective process of cold enrichment, alkali treatment or selective cefsulodin-irgasan-novobiocin agar, but these methods are not cost effective for routine diagnosis of diarrhea.

Unfortunately, there are no specific biochemical tests to detect any one of the different groups of diarrheagenic *E. coli* in stool. The ETEC, EPEC, EIEC, enteroaggregative *E. coli* and EHEC belong to different serotypes based on their O and H antigens. Although certain serotypes have been associated with these different types of *E. coli*, routine serotyping in sporadic cases is of limited value. Immunospecific tests including ELISA, receptor ELISA, latex and coagglutination have been developed to detect both STa and LT. Unlike most other *E. coli* serotypes, most strains of *E. coli* O157:H7 do not ferment sorbitol rapidly; here, sorbitol-containing MacConkey agar can be used as a culture medium for stool for patients who have bloody diarrhea, nonbloody diarrhea who may have been exposed to the organism or the HUS. Sorbitol-negative colonies that agglutinate with O157 antiserum can be presumptively identified as *E. coli* O157:H7. Commercial testing reactions are available to detect *E. coli*, which produces Shiga-like toxin. Diagnostic DNA probes from genes encoding virulence factors have been developed to find complementary sequences of DNA by hybridization, and to identify the different groups of diarrheagenic *E. coli*.

Stool cultures for *C. difficile* or tests for the presence of its toxins in stools are indicated in patients who have diarrhea and history of prior antibiotic use. An ELISA method to detect both toxins A and B is now available.

Stool studies to detect virus are not used routinely in medical practice. They are useful in investigation of nonbacterial diarrhea outbreaks. The recent advances in molecular laboratory methods like PCR and RT-PCR have changed what was known about the epidemiology of viral diarrhea. NLV, a noncultivable virus, has been identified as the cause of about 70–90% of nonbacterial diarrhea outbreaks in developed countries. These methods also help to detect viral particles in food and beverages and to better understand their way of transmission.

Blood culture

Blood cultures are recommended in patients ill enough to require hospitalization, in those in whom typhoid fever or bacteremia is suspected or in those with systemic enteric infections, nosocomially acquired diarrhea or who are immunocompromised.

Endoscopic examination

Proctosigmoidoscopy may be very helpful in the differential diagnosis of patients who have bloody diarrhea, prior antibiotic use, history of anal manipulation, who are HIV positive with large bowel diarrhea or acute proctitis. It is valuable in diagnosing pseudomembranous colitis (characterized by whitish yellow plaques), amebiasis (selective sample of ulcers) and idiopathic inflammatory bowel disease.

In HIV-positive patients who have no pathogen identified in stool and/or blood, gastroduodenoscopy is important in establishing the diagnosis in those with small bowel diarrhea, colonoscopy in those with symptoms suggesting colitis, or both, when it is not possible to differentiate between small and large bowel diarrhea. Examination of small bowel biopsies from the distal duodenum or proximal jejunum should include light and electron microscopy, viral (i.e. cytomegalovirus) and mycobacterial cultures, and special stains for acid-fast bacteria, viral inclusions, fungi and parasites. Examination of colonic biopsies includes light and electron microscopy, mycobacterial and viral cultures (i.e. cytomegalovirus, adenovirus, herpes simplex virus) and special stains for viral inclusion, acid-fast bacteria and fungi.

MANAGEMENT

There are four therapeutic approaches in the management of patients who have acute diarrhea: fluids and electrolytes, diet, symptomatic drugs and antimicrobial agents.

Fluids and electrolytes

Fluid and electrolyte replacement is the cornerstone of therapy for acute diarrhea.[72] It may be life saving for infants and the elderly with dehydrating illness. For severe cholera-like dehydrating diarrhea, fluid therapy has two phases: rehydration phase over the first few hours of treatment and then the maintenance phase to match continuing losses. Patients who have severe dehydration are ordinarily treated with intravenous fluids and electrolytes. Ringer's lactate is the preferred intravenous solution. For most patients who have diarrhea, oral rehydration solution can be used for both phases of fluid therapy. The World Health Organization's (WHO) oral rehydration salts (ORS) have contributed to the significant decrease in mortality secondary to diarrhea around the world.

The oral therapy usually recommended for adults and children with cholera diarrhea consists of one of the higher sodium-containing solutions (approximately 90mmol/l sodium) and plain water. For acute noncholera diarrhea, not associated with moderate or severe dehydration, the reduced osmolarity ORS (30–60mEq/l sodium) has been proved to decrease the amount of stool output and frequency of vomiting. A new formulation of the reduced osmolarity ORS, including 75mEq/l of sodium and 75mmol/l of glucose with a total osmolarity of 245mmol/l, has been tried in adults and children with cholera diarrhea and proved to be safe and to reduce the need for intravenous therapy in 33% of cases. The main concern is the development of hyponatremia; these studies demonstrated a small but statistically significant decrease in serum sodium in those patients receiving reduced osmolarity ORS. However, no symptoms were described. The WHO scheduled the use of this new ORS formula for all types of diarrhea in 2002.[73]

Diet alteration

During a bout of illness the diet should ordinarily be modified as the intestinal tract may have difficulty absorbing certain food items.[72] Milk other than breast milk for an infant should be withheld during the early stages of illness. To facilitate enterocyte renewal, calories should be taken in during a bout of acute diarrhea. For infants breast milk or lactose-free formula may be administered. For older children and for adults, appropriate foods include boiled starches and cereals such as potatoes, noodles, rice, wheat and oats with some salt added. Crackers, yogurt, bananas, soup and boiled

TABLE 43-8 -- Symptomatic therapy of older children and adult patients who have acute diarrhea.

SYMPTOMATIC THERAPY OF OLDER CHILDREN AND ADULT PATIENTS WHO HAVE ACUTE DIARRHEA		
Pharmacologic agent	**Dose**	**Comment**
Bismuth subsalicylate	30ml or two tablets each 30 minutes for eight doses for no more than 48 hours	Will turn stools and tongues black; is 50% effective in reducing number of stools passed
Loperamide	4mg initially, then 2mg after each unformed stool, not to exceed 8mg/day (over-the-counter dosage) or 16mg/day (prescription dosage) for no more than 48 hours	This agent is 80% effective in reducing number of stools passed; the drug may rarely worsen invasive forms of diarrhea and may produce post-treatment constipation
Rocecadrotil	Not established	In development
Zaldanide		
Provir		

TABLE 43-9 -- Empiric therapy of acute diarrheal disease.

EMPIRIC THERAPY OF ACUTE DIARRHEAL DISEASE		
Clinical syndrome	**Adults**	**Children**

Febrile dysenteric diarrhea in industrialized regions or moderate to severe travelers' diarrhea	Ciprofloxacin 500mg bid or levofloxacin 500mg qd for 3–5 days	Azithromycin 5–10mg/kg/d for 3–5 days Trimethoprim-sulfamethoxazole 5–25mg/kg/d in two equally divided doses for 3–5 days plus erythromycin 40mg/kg/d in four divided doses for 5 days
Persistent diarrhea (=14 days in duration) in industrialized countries	Consider anti-*Giardia* therapy: metronidazole 250mg tid for 7 days	Consider anti-*Giardia* therapy: metronidazole 20mg/kg/d in three divided doses for 7 days

vegetables may also be eaten. When stools are formed, diet may return to normal.

Symptomatic therapy

Although the major objective of therapy for diarrhea in young infants and in the elderly is amelioration of complications of illness such as dehydration, in most older children and nonelderly adults an important objective is amelioration of morbidity and suffering. Symptomatic drugs do play a role in reducing the number of stools passed and duration of illness in most forms of diarrhea. Nonspecific therapy may be employed where improvement in symptoms is the objective. Table 43.8 describes common agents used to improve symptoms of diarrhea. These drugs can be useful in nondehydrated patients to reduce unpleasant symptoms of enteric illness, helping to return patients to school, work or leisure activities. These drugs do not cure illness and they are not indicated for infants with diarrhea, particularly in developing regions. In these infants and in the elderly with severe diarrhea, the focus should be on fluid and electrolyte therapy alone.

Antimicrobial therapy

Although antimicrobial therapy is primarily used for the treatment of pathogen-specific illness, these drugs can be used in one of several clinical syndromes in which an etiologic agent is suggested by the resultant illness.[74] Patients living in industrialized regions with febrile dysentery (presence of fever and passage of bloody stools) often have enteric infection caused by an invasive enteric bacterial pathogen, such as *Shigella* spp. and *C. jejuni*. Empiric therapy in this setting is appropriate. Table 43.9 lists recommended drugs and dosage for children and adults. For adults one of the fluoroquinolones is recommended. For children azithromycin is recommended after infection with Shiga-like toxin producing pathogens has been excluded. The same drugs are used for adults and children with moderate to severe travelers' diarrhea, in which a variety of bacterial pathogens may be encountered. A single drug, furazolidone, may be used in children with travelers' diarrhea[75] although resistance to the drug has become common.[37] When diarrhea persists for 2 weeks or longer, a work-up for the etiology should be undertaken. Many would use empiric anti-*Giardia* therapy for a subset of these patients, usually metronidazole given for 7 days. For young children furazolidone is preferred because a pediatric suspension form of the drug is available.

In Table 43.10 , specific recommendations for therapy are provided according to the etiologic agent identified.

It is advisable to treat all patients who have proven shigellosis in view of the potential for transmission of the infecting organism to susceptible contacts. In the case of intestinal *Salmonella* spp. infection, the decision to use antimicrobials often depends on the severity of clinical illness together with the presence of certain host conditions known to predispose to more serious infection by the organism. Indications for treating intestinal salmonellosis include presence of high fever and systemic toxicity suggesting bacteremic illness, or one of the conditions known to predispose to bacteremic illness and higher risk for fatal illness. These conditions include: age greater than 65 years or less than 3 months, malignancy, inflammatory bowel disease, hemodialysis, uremia, renal transplantation, aortic aneurysm and patients who have AIDS. For these patients, treatment is given for 10–14 days. Other patients who have less severe cases of salmonellosis without underlying medical conditions need not be treated with antimicrobial agents. Other enteric infections where specific therapy may be given include *C. jejuni* diarrhea, diarrhea caused by diarrheagenic *E. coli* other than enterohemorrhagic *E. coli* (in which case antimicrobials may predispose to the HUS[76]), *Aeromonas* and *Plesiomonas* diarrhea, yersiniosis, giardiasis, amebiasis, isosporiasis and cyclosporiasis. Patients who have cryptosporidiosis are usually not treated, although those with advanced HIV infection may benefit from suppressive treatment with paromomycin.[77] New anticryptosporidial drugs are in development and may offer therapeutic advantages over paromomycin (see Chapter 127).

In cases of bloody diarrhea it is hard to make a decision about empiric therapy because of the fear of potentiation of HUS in patients with Shiga toxin-producing *E. coli* infection. The key aids here are the following: HUS is an important complication of Shiga toxin-producing *E. coli* infection in children and the elderly; the organism characteristically causes outbreaks of illness where the other causes of dysentery (*Shigella* and *C. jejuni* being the most important in the industrialized countries) frequently cause sporadic or single cases. Also, Shiga toxin-producing *E. coli* infection is rarely associated with important levels of fever. Thus, when we have a sporadic case of bloody diarrhea in an older child or young adult where there is fever, empiric therapy with a quinolone is appropriate. On the other hand, when an outbreak of dysentery occurs in a group of children or the elderly and fever is either absent or low grade, antimicrobial therapy should probably be withheld pending the establishment of etiology of the illness.

TABLE 43-10 -- Treatment of pathogen-specific diarrhea TMP-SMX: trimethoprim-sulfamethoxazole).

TREATMENT OF PATHOGEN-SPECIFIC DIARRHEA		
Pathogen-specific diarrhea	**Adults**	**Children**
Shigellosis	Ciprofloxacin 500mg bid for 3–5 days or levofloxacin 500mg/d for 3–5 days	Azithromycin 10mg/kg/d. If resistance suspected use ceftriaxone, cefixime or cefotaxime
Salmonellosis	Mild or asymptomatic: no therapy	If =3 months old use ceftriaxone 50mg/kg iv qd.
	With underlying illness (see text) use ciprofloxacin 400mg bid or levofloxacin 500mg qd for 5–7 days depending on response	If >3 months old and healthy with mild illness or asymptomatic, no antimicrobial therapy; with underlying illness (see text) use ceftriaxone 50mg/kg iv qd not to exceed 2g/d
	Alternative: azithromycin	
Campylobacteriosis	Azithromycin 500mg po qd for 3 days	Erythromycin stearate 40mg/kg/d in four divided doses for 5 days or azithromycin 10mg/kg/d
	Alternative: erythromycin stearate 500mg po bid for 5 days	
ETEC, EPEC, EAEC	Same as empiric therapy for febrile dysentery and travelers' diarrhea (see Table 43.9)	Same as shigellosis
EHEC (Shiga toxin and Shiga-like toxin producing *E. coli*).	No treatment (increased risk of increasing toxin release and HUS)	No treatment
Aeromonas and *Plesiomonas*	Same as empiric therapy for febrile dysentery and travelers' diarrhea (see Table 43.9)	Same as empiric therapy for febrile dysentery and travelers' diarrhea (see Table 43.9)
Yersiniosis	Same as empiric therapy for febrile dysentery and travelers' diarrhea (see Table 43.9). If severe: ceftriaxone 1g iv qd for 5 days	Ceftriaxone 50mg/kg qd for 5 days
Giardiasis	Metronidazole 250mg tid for 7 days or albendazole 400mg po qd for 5 days or tinidazole 2g po one dose	Metronidazole 20mg/kg/d in three divided doses for 7 days or furazolidone 6mg/kg/d divided in four doses for 7 days
Amebiasis	Metronidazole 500mg po tid for 10 days or tinidazole 1g po bid for 3 days. Follow with paromomycin 500mg po tid for 7 days	Metronidazole 50mg/kg/d in three divided doses iv plus di-iodohydroxiquin 40mg/kg/d in three divided doses for 20 days
Crytosporidiosis	Immunocompetent patients: nitazoxanide 500mg po bid for 3 days [78]	Nitazoxanide (children 4–11 years old) 100mg po bid for 3 days[78]
	AIDS: paromomycin 1g bid plus azithromycin 600mg qd for 4 weeks	

Isosporiasis	Immunocompetent: TMP-SMX 160–800mg po bid for 7 days	TMP-SMX 10–50mg/kg/d in two divided doses for 7 days
	AIDS: TMP-SMX 320–1600mg bid for 2–4 weeks then 16–800mg qd indefinitely	
Cyclosporiasis	Immunocompetent: TMP-SMX 160–800mg po bid for 7 days	TMP-SMX 10–50mg/kg/d in two divided doses for 7 days
	AIDS: TMP-SMX 160–800mg po bid for 10 days then once three times a week indefinitely	
Clostridium difficile colitis	Metronidazole 500mg po tid for 10–14 days. Repeat if relapse.	Metronidazole 20mg/kg/d in three divided doses for 7 days
	Alternative: iv metronidazole, po vancomycin

Chapter 44 - Antibiotic-associated Colitis/Diarrhea

Dale N Gerding
Stuart Johnson

EPIDEMIOLOGY

Diarrhea may occur as a result of administration of any antimicrobial. The vast majority of such occurrences are self-limited and resolve with discontinuation of the drug. However, a much more serious antibiotic-associated diarrhea and pseudomembranous colitis (PMC) is caused by *Clostridium difficile* infection following antimicrobial treatment. It is the major diagnosed cause of infectious diarrhea that develops in hospitalized patients in developed countries. [1] *C. difficile*-associated diarrhea (CDAD) is unique in that it occurs essentially only in association with antimicrobials and is most frequent in hospitals and nursing homes where antimicrobial use is high and the environment and personnel are most likely to be contaminated by *C. difficile* spores. The incidence and severity of CDAD appear to be increasing and the annual cost of the disease to US hospitals is estimated at $1.1 billion.[2] [3]

Clindamycin, ampicillin and cephalosporins were initially the antibiotics most frequently associated with CDAD, but the second- and third-generation cephalosporins, particularly cefotaxime, ceftriaxone, cefuroxime and ceftazidime, are now most frequent.[4] Penicillin plus ß-lactamase inhibitor combinations such as ticarcillin-clavulanate and piperacillin-tazobactam have significantly less risk.[4] [5] All antibiotics, including vancomycin and metronidazole, the most common agents used to treat CDAD, have been found to have risk of a subsequent episode of CDAD. [4]

Clindamycin has a prolonged persistent effect on the colonic flora after the drug is stopped, explaining the clinical observation of CDAD well after discontinuation of clindamycin. Clindamycin resistance was a marker for a *C. difficile* strain implicated in epidemics in four geographically dispersed US hospitals. The identical epidemic strains carried the same *ermB* resistance gene.[6] Infection with the epidemic strain was associated with clindamycin use and the epidemic ended promptly with restriction of clindamycin in one hospital.

C. difficile is carried commonly in the stool of asymptomatic patients in the hospital.[1] The rate of colonization in hospitalized adults is often 20% or greater for patients hospitalized for more than 1 week, compared to 1–3% of community residents, and the risk of *C. difficile* colonization increases in proportion to length of hospital stay.[7] Asymptomatic fecal carriage of *C. difficile* in healthy neonates is very common, often exceeding 50% in the first 6 months of life. Spores of *C. difficile* are found on environmental surfaces (where the organism can persist for months) and on the hands of hospital personnel if they are not washed between patients. The incidence of community-acquired CDAD is low (7.7 cases per 100,000 person-years of observation) compared to rates of 5–35 per 1000 hospital discharges.

Genetic or phenotypic typing studies have shown that even the most virulent of *C. difficile* organisms produce asymptomatic colonization more often than CDAD, suggesting that factors in addition to organism virulence are necessary for CDAD to occur. Molecular typing has shown that recurrent CDAD is caused by both relapses from the original infecting strain and reinfection with a new strain of *C. difficile*. Hospital outbreaks of CDAD have been caused by a single *C. difficile* strain in some institutions whereas in others a variety of strains have been found. Over 500 unique types of *C. difficile* organized into >100 distinct toxin-negative or toxin-positive groups have now been identified by *Hin*dIII restriction endonuclease analysis (REA). PCR ribotyping has identified 116 different ribotypes, suggesting wide organism diversity.

Other risks for CDAD have been identified, including gastrointestinal surgery, older patient age, longer hospital stay, greater severity of illness, use of electronic rectal thermometers, enteral tube feeding and antacid treatment.[1] [7]

PATHOGENESIS AND PATHOLOGY

Spores of toxigenic *C. difficile* are ingested, survive the acidity and other upper gastrointestinal defense mechanisms, germinate and colonize the lower intestinal tract where they elaborate toxins. In addition to the enterotoxic and cytotoxic effects of toxin A and toxin B, toxin A is a potent chemoattractant for neutrophils *in vivo*, and both toxins induce cytokine release from monocytes.

Although patients colonized with *C. difficile* were thought to be at high risk for CDAD, four prospective studies have shown that colonized patients actually had a decreased risk of subsequent CDAD.[8] Many of these patients were colonized with nontoxigenic strains (explaining their lack of clinical illness), but 56% were colonized with virulent, toxigenic strains that caused CDAD in other patients. We now propose that at least three factors influence the development of CDAD and the timing of these factors or 'hits' appears to be critical (Fig. 44.1). Exposure to antimicrobials establishes susceptibility to *C. difficile* infection. The second hit is exposure to toxigenic *C. difficile*. Prospective observations have shown that the majority of patients do not become ill after the first two 'hits'. A third factor appears to be necessary for CDAD to occur, which may be related to *C. difficile* virulence, the type and timing of the antimicrobial exposure, or the host immune response. Serum antitoxin antibody levels (prior to colonization) were comparable in those patients who later became colonized and those who developed CDAD. However, following exposure to *C. difficile*, median antitoxin A IgG levels in the serum increased significantly higher in those who became asymptomatic carriers than in patients who developed CDAD.[9] Thus, one likely 'third hit' is the anamnestic response to toxin A at the time of exposure to *C. difficile* which is protective against CDAD but not colonization, and supports the earlier observation that asymptomatic *C. difficile* carriers are at decreased risk of subsequent CDAD. A second study found that the early antibody response in those patients who developed CDAD also influenced the risk of diarrhea recurrence. Antitoxin A IgM levels on day 3 and antitoxin IgG levels on day 12 were significantly higher in those patients who did not have a CDAD recurrence.[10]

The pseudomembrane found in association with antibiotic PMC is confined to the colon and initially appears as small (1–2mm), whitish-yellow plaques along the colonic wall. The intervening mucosa

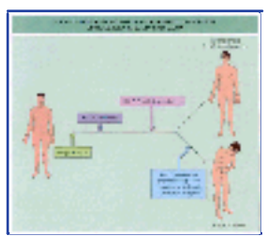

Figure 44-1 The pathogenesis model for hospital-acquired *Clostridium difficile*-associated diarrhea (CDAD). This 'three-hit' model of *C. difficile* pathogenesis shows that exposure to antibiotics establishes susceptibility to infection. Once susceptible, the patient may acquire nontoxigenic (nonpathogenic) or toxigenic strains of *C. difficile* (the second 'hit'). Acquisition of toxigenic *C. difficile* may be followed by asymptomatic colonization or *C. difficile*-associated disease, depending on one or more factors (the third 'hit'). Inadequate anamnestic IgG response to toxin A produced by toxigenic *C. difficile* strains is an important host factor determining disease outcome.[9]

appears unremarkable. As the disease progresses, the pseudomembranes may coalesce to form larger plaques and in advanced cases become confluent over the entire colon wall (Fig. 44.2). The distribution of lesions typically involves the entire colon, but rectal sparing occurs in about 10% of patients. Microscopically, the pseudomembranes contain necrotic leukocytes, fibrin, mucus and cellular debris with a point of attachment to the underlying mucosa. The superficial epithelium is commonly eroded and necrotic in focal areas and the

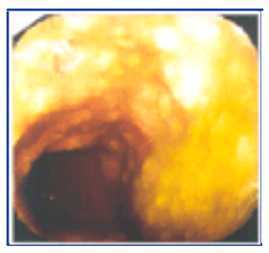

Figure 44-2 Endoscopic view of multiple pseudomembranes covering the colon in a patient with PMC.

mucosa beneath the pseudomembrane is inflamed, with a predominantly neutrophil infiltration.

PREVENTION

Control and prevention strategies for *C. difficile* infections can be divided into two types:

- barrier-isolation-disinfection procedures to prevent transmission of the organism to the patient;
- reduction of the risk of clinical illness if the organism does contact the patient.[1]

One of the latter highly successful methods is restriction of the use of specific antibiotics to reduce the risk of colonization and infection. Neither barrier precautions nor changes in antimicrobial use are easy to implement successfully, a factor that may explain the limited success of control and prevention guidelines to date.[1] Transmission prevention methods include barrier precautions, gloving, handwashing, environmental disinfection, replacement of electronic rectal thermometers and treatment of asymptomatic carriers of *C. difficile* with vancomycin or metronidazole. Of these interventions, only discontinuation of the use of contaminated electronic thermometers and wearing of gloves by personnel have reduced CDAD rates in actual hospital clinical practice. Environmental disinfection with hypochlorite solutions reduces *C. difficile* contamination in the hospital environment, presumably because hypochlorite is sporicidal; however, because of odor and bleaching of surfaces by hypochlorite, hospitals have not widely adopted its use.

Because prevention of organism transmission has been difficult, control measures have focused on reducing clinical illness if transmission cannot be prevented. Control of clindamycin, and second-and third-generation cephalosporins, has been the most effective prevention strategy.[5] [6] In the case of clindamycin, outbreaks of CDAD have correlated with *C. difficile* resistance to clindamycin and have resolved with restriction of the antibiotic.[6] Other prevention

approaches under development include a vaccine which has been successful in the hamster model, prophylaxis with the yeast *Saccharomyces boulardii*, which reduced antibiotic-associated diarrhea but not CDAD, use of *Lactobacillus* spp., that has not successfully prevented CDAD, and colonization with nontoxigenic strains of *C. difficile* that has succeeded in hamsters but is untested in humans.

CLINICAL FEATURES

Diarrhea is by far the most common symptom caused by *C. difficile*. Stools are almost never grossly bloody and range from soft and unformed to watery or mucoid in consistency with a characteristic odor. Stool frequency varies widely from three to 20 or more bowel movements per day. Clinical and laboratory findings from one large series are shown in Table 44.1 .[11] When adynamic ileus (which is seen on X-ray in about 1/5 of patients) results in cessation of stools, the diagnosis of *C. difficile* disease is frequently overlooked. Such patients are at high risk of complications of *C. difficile* infection, particularly toxic megacolon and colonic perforation. Overall, mortality associated with CDAD ranges from 0.6% to 3.5%. Extracolonic manifestations of *C. difficile* infection such as bacteremia and abscesses occur rarely, but reactive arthritis is not uncommon.

Recurrence of *C. difficile* diarrhea following treatment occurs in about 20% of patients. Recurrences may be either relapses with the same strain or reinfections with a new strain of *C. difficile*. Data from three studies suggest that nearly half of all recurrences are a result of reinfection with a new strain. Recurrence of clinical CDAD is likely a result of continued disruption of normal fecal flora by the treatment antibiotics and does not correlate with continued presence of the organism is stool following treatment (which occurs commonly), but does correlate with failure of the patient to develop serum antibodies to toxin A.[10]

DIAGNOSIS

The diagnosis of CDAD is based on a combination of clinical and laboratory criteria:

- diarrhea, e.g. a minimum of three unformed stools per 24 hours for a minimum of 2 days;
- no other recognized cause for diarrhea.

When this clinical definition is combined with either visualization of colonic pseudomembranes or toxin A or B in the stool or stool culture positive for a toxin-producing *C. difficile* organism, then the diagnosis of CDAD can be made.[1]

PMC is a more advanced form of CDAD and is visualized at endoscopy (Fig. 44.2) in only about 50% of patients with diarrhea

TABLE 44-1 -- Clinical and laboratory features of *Clostridium difficile*-associated disease.[11]

CLINICAL AND LABORATORY FEATURES OF *CLOSTRIDIUM DIFFICILE*-ASSOCIATED DISEASE	
Clinical or laboratory finding	**Number of patients (percent positive)**
Diarrhea	109/109 (100)
Pseudomembranes on endoscopy	34/67 (51)
Leukocytosis (>10,000/mm^3)	54/109 (50)
Fever >100.4°F (38.0°C)	30/109 (28)
Mucus in stools	29/109 (27)
Occult blood in stools	28/109 (26)
Abdominal pain/cramping	24/109 (22)
Ileus (as determined by abdominal X-ray)	23/109 (21)

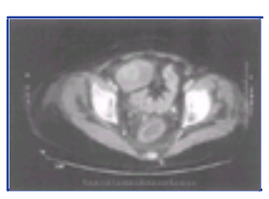

Figure 44-3 CT scan of the abdomen in a patient with fulminant PMC. The colonic and rectal walls are markedly thickened with fluid-filled colon and rectum.

who have a positive stool culture and toxin assay for *C. difficile* (Table 44.1). Endoscopy remains a valuable and rapid diagnostic tool in seriously ill patients with an acute abdomen and suspected PMC, but a negative examination does not rule out *C. difficile* disease. An abdominal CT scan may be more sensitive in this setting[3] (Fig. 44.3).

An array of tests are available for detection of *C. difficile* and its toxins (Table 44.2), but no single test has high sensitivity, high specificity and rapid results turnaround. For this reason, some clinical laboratories use two tests, often combining a specific test for toxin (cell cytotoxin or enzyme immunoassay) with stool culture to increase sensitivity; however, this approach is labor intensive and expensive. If the original specimen is negative and diarrhea persists, examination of additional stool

specimens increases the likelihood of diagnosis, but is time consuming and expensive.

The primary advantage of the cell cytotoxicity test, which can detect as little as 1pg of toxin B, is its sensitivity. Cell cytotoxicity is detected by a rounding of the cells and is confirmed as caused by *C. difficile* if cytotoxicity is neutralized by *C. difficile* (or *C. sordellii*) antitoxin. Enzyme immunoassays (EIA) use specific monoclonal or polyclonal antibodies to toxin A or toxin B (or both) to detect *C. difficile* toxin in stool specimens. These tests are more rapid than the cell cytotoxicity assay (1–3 hours), but EIA tests for toxin A will not detect some clinically important strains of *C. difficile* that do not produce toxin A. EIA tests (both toxin A and toxin A/B EIA tests) lack sufficient sensitivity to recommend these tests alone without back-up stool culture.

Stool culture for *C. difficile* is performed using a selective antibiotic-containing medium such as cycloserine-cefoxitin-fructose agar (CCFA). Colonies of *C. difficile* have a ground-glass appearance surrounded by a yellow halo on CCFA. *C. difficile* culture lacks specificity in diagnosing CDAD because nontoxigenic strains that do not cause CDAD may be detected. Specificity can be increased by testing isolates *in vitro* and reporting as positive only those specimens containing toxin producing *C. difficile*. Latex agglutination (LA) tests are rapid, but neither sensitive nor specific and are inferior to toxin assays and culture (Table 44.2).

MANAGEMENT

Treatment of uncomplicated first episodes of CDAD

CDAD will resolve in 15–23% of patients within 2–3 days after discontinuing the precipitating antimicrobial.[12] Withholding specific

TABLE 44-2 -- Sensitivity and specificity of tests for the diagnosis of *Clostridium difficile*-associated diarrhea.[*] [†]

SENSITIVITY AND SPECIFICITY OF TESTS FOR THE DIAGNOSIS OF *CLOSTRIDIUM DIFFICILE*-ASSOCIATED DISEASE[*]			
Test	**Sensitivity**	**Specificity**	**Utility of test**
Endoscopy	51%	~100%	Diagnostic of PMC and therefore CDAD
Culture for *C. difficile*	89–100%	84–100%	Most sensitive test; confirmation of organism toxicity necessary to improve specificity
Cell culture cytotoxin test	67–100%	85–100%	With clinical data is diagnostic of CDAD; highly specific but not as sensitive as culture
EIA toxin test	63–99%	75–100%	With clinical data is diagnostic of CDAD; rapid but not as sensitive as culture or cell culture cytotoxin test
Latex test for *C. difficile* antigen	58–92%	80–96%	Less sensitive and specific than other tests but gives rapid results
PMC, pseudomembranous colitis; CDAD, *Clostridium difficile*-associated disease; EIA, enzyme immunoasay; PCR, polymerase chain reaction.			

* Using both clinical and test-based criteria.

TABLE 44-3 -- Summary of randomized, comparative trials of oral therapy for initial episodes of *Clostridium difficile*-associated diarrhea.[*]

SUMMARY OF RANDOMIZED, COMPARATIVE TRIALS OF ORAL THERAPY FOR INITIAL EPISODES OF *CLOSTRIDIUM DIFFICILE*-ASSOCIATED DIARRHEA[*]					
Antibiotic	**Regimen**	**Number of patients**	**Resolution of diarrhea (%)**	**Recurrence (%)**	**Mean days to diarrhea resolution**
Metronidazole	250mg qid × 10d	42	40 (95)	2 (5)	2.4
	500mg tid × 10d	31	29 (94)	5 (17)	3.2
Vancomycin	500mg tid × 10d	31	29 (94)	5 (17)	3.1
	500mg qid × 10d	87	87 (100)	13 (15)	2.6–3.6
	125mg qid × 7d	21	18 (86)	6 (33)	4.2
	125mg qid × 5d	12	9 (75)	?	<5
Teicoplanin	400mg bid × 10d	28	27 (96)	2 (7)	2.8
	100mg bid × 10d	26	25 (96)	2 (8)	3.4
Bacitracin	25,000U qid × 10d	15	12 (80)	5 (42)	3.0
	20,000U qid × 7d	21	16 (76)	5 (31)	4.1
Colestipol	10g qid	12	3 (25)	?	<5
Placebo		14	3 (21)	?	<5

* *(Adapted from reference[17] with permission from Springer-Verlag)*

anti-*C. difficile* treatment may avoid the 20% risk of recurrence following treatment with vancomycin or metronidazole, but most patients will require specific treatment.[13] [14] General treatment guidelines include hydration and avoidance of antiperistaltic agents and opiates that may mask symptoms and possibly worsen disease. These agents have been used safely with vancomycin or metronidazole for treatment of mild to moderate *C. difficile* disease.[15] Finally, test-of-cure cultures or toxin assays following treatment are not recommended, as they do not predict subsequent recurrence, and treatment of asymptomatic patients has been ineffective.[16]

Prospective randomized clinical trials show no statistical differences in the outcome of CDAD treatment for the primary endpoint, cessation of diarrhea, among all regimens tested (Table 44.3). [17] Vancomycin has been shown to be superior to placebo. Colestipol is no better than placebo and is inferior to antimicrobials. The clinical response rate for bacitracin is 10–20% lower than for vancomycin so bacitracin use for first-line therapy should be discouraged (Table 44.3). Fusidic acid and teicoplanin are also effective agents. CDAD recurrence rates have been shown to be significantly different in only one study; the recurrence reduction for teicoplanin compared to fusidic acid.[18]

Antimicrobial therapy, particularly vancomycin, should be administered orally. Metronidazole achieves bactericidal fecal concentrations in the presence of acute diarrhea when used intravenously and anecdotal evidence supports intravenous treatment for CDAD; however, intravenous metronidazole has failed in the treatment of PMC in the presence of adynamic ileus. Response to oral therapy with vancomycin or metronidazole is =95%. Mean time to resolution of diarrhea ranges between 2 and 4 days and patients should not be deemed treatment failures until at least 6 days of treatment have been given.[19] Based on data from shorter courses of vancomycin (Table 44.3), we recommend treatment be given for 10 days, although no controlled comparisons are available. Metronidazole does not have US Food and Drug Administration (FDA) approval for *C. difficile* treatment, but is the current drug of choice in the USA and the least expensive agent. Metronidazole-resistant isolates have been reported rarely, but treatment failure has not been correlated with in vitro resistance.

Treatment of recurrences of CDAD

First recurrences of CDAD usually resolve after retreatment with metronidazole.[19] There is no standard treatment approach supported by comparative data for patients with more than one recurrence of CDAD. Biotherapeutic approaches include vancomycin or metronidazole followed by the yeast *Saccharomyces boulardii*;[20] metronidazole or bacitracin followed by *Lactobacillus* GG; vancomycin followed by synthetic fecal bacterial enema; and administration of a nontoxigenic *C. difficile* strain. *S. boulardii, Lactobacillus* GG, nontoxigenic *C. difficile* and fecal enemas are not available as pharmaceuticals in the USA and do not have FDA approval for use

in treating CDAD.

Other approaches include vancomycin in tapering doses over 21 days followed by pulse dosing for 21 days; no treatment with careful observation; vancomycin followed by the anion-exchange binding resin, cholestyramine; and combined treatment with vancomycin

and rifampin which is the approach we favor [10 days of vancomycin (125mg orally four times daily) and rifampin (300mg orally twice daily)], since it is a relatively simple and effective regimen. Treatment of antibody-deficient children with intravenous immunoglobulin (IVIG) has resulted in clinical and bacteriological improvement, but the high cost and limited availability of IVIG limit this approach to the few chronically *C. difficile*-infected antibody-deficient children.

Treatment of complications

The most difficult treatment issue is the management of the rare patient who presents with or develops toxic megacolon or ileus as a result of fulminant CDAD.[3] These patients often have no diarrhea and mimic an acute surgical abdomen. Sepsis (hypotension, fever, tachycardia, leukocytosis) is also a complication of severe *C. difficile* disease. Acute abdomen may occur with or without toxic megacolon and may have signs of obstruction, ileus, bowel wall thickening and ascites on abdominal CT (Fig. 44.3), accompanied by a marked peripheral blood leukocytosis that is often >25,000wbc/mm^3 . *C. difficile* infection should be included in the differential diagnosis of an acute abdomen, sepsis or toxic megacolon if the patient has received antibiotics within the previous 2 months, whether diarrhea is present or not. Rapid diagnosis of *C. difficile* disease can best be achieved by performing cautious sigmoidoscopy or colonoscopy to visualize pseudomembranes or by doing an abdominal CT exam[3] (Fig. 44.3).

There is no established effective treatment for these seriously ill patients. Medical management is suboptimal, in part because of the inability to achieve effective concentrations of metronidazole or vancomycin in the colon by the oral route if ileus is present. We have successfully treated six patients with severe ileus using vancomycin via nasogastric tube and by retention enema plus intravenous metronidazole.[19] Surgical intervention is indicated for patients with toxic megacolon, fulminant disease or acute abdomen who do not respond to medical management or have suspected colonic perforation. The incidence of fulminant CDAD requiring colectomy may be increasing.[3] Mortality in patients who require surgery for CDAD ranges from 38% to 80%,[3] emphasizing the need for earlier recognition and more effective diagnostic and therapeutic approaches in these patients.

Chapter 45 - Whipple's Disease

Andrew M Veitch
Michael JG Farthing

EPIDEMIOLOGY

Whipple's disease was originally described by George Whipple in the Johns Hopkins Medical Bulletin in 1907.[1] The disease is rare, with fewer than 1000 validated cases reported in the literature, although it has been estimated that two to three unpublished cases may exist for each one reported. The majority of cases have occurred in the USA, the UK, Europe, Australia, South America and South Africa, with a small number of additional cases from Japan, India and China.

The largest review to date, published in 1970, reported 19 patients who had Whipple's disease, and reviewed the literature from 1950 to 1969.[2] A further 114 patients were identified, of whom 88% were male. All 114 patients were white, with the exception of one native American and three black patients. Of the 19 patients reported, 18 were male and all were white. The mean age at diagnosis was 48 years (range 33–62 years). Other studies have confirmed this demographic distribution.

PATHOGENESIS AND PATHOLOGY

Whipple's disease is a multisystem disorder.[2A] It most commonly affects the small intestine and its lymphatic drainage, but the pathologic features of the disease have been demonstrated in most organs (Table 45.1). In the small intestinal mucosa the presence of numerous macrophages that stain strongly with periodic acid Schiff (PAS) is pathognomonic (Fig. 45.1). Whipple noted the presence of a great number of rod-shaped organisms in affected tissues, but these were only identified as bacilli when examined by electron microscopy. The bacilli are rod-shaped and approximately 0.2mm wide by 1.5–2.5mm long, with cell walls that consist of a trilaminar membrane (Fig. 45.2). These cell walls reflect the PAS-positive material within macrophages in affected tissues seen under light microscopy.

TABLE 45-1 -- Pathologic features of Whipple's disease.

PATHOLOGIC FEATURES OF WHIPPLE'S DISEASE	
System	**Feature**
Gastrointestinal tract	Transmural involvement of the esophagus, stomach, intestine and colon
	PAS-positive macrophages concentrated in lamina propria
Central nervous system	PAS-positive macrophages present throughout the brain
	Occasional microinfarcts reported as a result of microvascular occlusion
Cardiovascular system	PAS-positive macrophages in endocardium, myocardium and pericardium
	Fibrosis of heart valves
	Lymphocytic myocarditis
Respiratory system	PAS-positive macrophages predominantly in intra-alveolar septa and pleura of lungs
	Occasionally granulomatous 'sarcoid-like' reaction in tissues
Genitourinary tract	Few PAS-positive macrophages noted
Lymphoreticular system	PAS-positive macrophages in spleen and lymph nodes throughout body
Eyes	Uveitis
	PAS-positive macrophages in vitreous humor
Bone marrow	Focal collections of PAS-positive macrophages

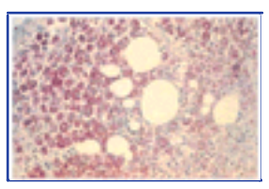

Figure 45-1 Section from a PAS-stained duodenal biopsy. There are numerous (pink-staining) PAS-positive macrophages in the lamina propria.

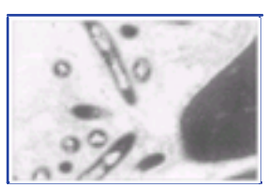

Figure 45-2 Electron micrograph of small intestinal mucosa demonstrating the typical appearance of the Whipple's disease bacillus. *Courtesy of Professor H Hodgson.*

Whipple's bacilli have been identified and classified phylogenetically using molecular genetic techniques. Bacteria can be identified by amplification of the bacterial small subunit (16S) rRNA sequence from infected tissue. rRNA is present in all living cells and is highly conserved. All genetic sequences accumulate mutations with time; the evolutionary distance between species is proportional to the number of nucleotide differences between two copies of the same gene and can be inferred from the number of rRNA sequence differences between them, thereby allowing a phylogenetic classification. The phylogenetic classification of an unknown organism can be determined by comparing its 16S rRNA with a catalog of rRNA sequences from known organisms. The polymerase chain reaction (PCR) is used to amplify and sequence minute quantities of rRNA from infected tissue. In 1991 this technique was applied to a small bowel specimen from a patient who had Whipple's disease.[3] On the basis of its 16S rRNA sequence the organism was found to be most closely related to *Rhodococcus*, *Arthrobacter* and *Streptomyces* spp. (see Chapter 226). In 1992 a unique 1321-base bacterial 16S rRNA sequence was identified in a patient who has Whipple's disease; from this sequence specific PCR primers that enabled detection of this bacillus in four other patients were designed.[4] The organism was not detectable in tissue from ten control patients. Analysis of the 1321-base 16S rRNA sequence revealed the organism to be a previously uncharacterized bacterium belonging to the subdivision of Gram-positive bacteria known as actinomycetes (Fig. 45.3). This newly characterized organism has been named *Tropheryma whipplei*. Using molecular techniques, three different types of *T. whipplei* have been identified; it remains to be clarified whether this represents three subtypes, or three closely related, species.[5] The complete genome of *T. whipplei* has recently been sequenced and analyzed.[5A]

Culture of *T. whipplei* has been elusive until recently. Successful growth in a human macrophage cell line was described in 1997,[6] but subsequent subculture was not achieved. More recently, the bacterium was grown in a human fibroblast cell line, and ongoing culture has been established.[7]

Whipple's disease bacillus has been identified using light or electron microscopy in all tissues affected by the disease. However, the pathogenesis of the disease is unknown. Electron microscopy studies of infected intestinal mucosa have demonstrated extensive epithelial cell invasion by bacilli;[8] the route of invasion appears to be from the lamina propria rather than the intestinal lumen. There is evidence of ultrastructural damage to the infected epithelial cells, but no signs of injury have been found in macrophages, polymorphonuclear leukocytes, mast cells or intraepithelial lymphocytes containing the bacilli. *T. whipplei* is cytopathic to IgA plasma cells,[9] and

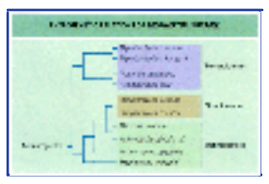

Figure 45-3 Phylogenetic relations of the Whipple's disease bacterium, *Tropheryma whipplei.*

this may explain the common finding of reduced plasma cells within the intestinal mucosa in infected patients.

Several attempts have been made to investigate whether there is a host immune defect in patients who have Whipple's disease. Subtle defects of cell-mediated immunity have been noted, with a reduction in the number of circulating lymphocytes and a decreased response to mitogens. It may be difficult to distinguish a primary immunologic defect from those that might arise as a consequence of nutritional deficiency. A decreased response to skin test antigens has been described, which persists after treatment. In addition there is a greater association with the HLA B27 haplotype in Whipple's disease patients than in controls.[10] Major histocompatibility complex (MHC) class I expression on small intestinal epithelial cells has been found to be normal, but MHC class II was markedly reduced compared with controls.[11] This defect was restored to normal after treatment, suggesting that the observed immune changes in the intestinal mucosa may occur as a result of infection rather than as a primary defect. *In vitro* culture of *T. whipplei* in macrophages required addition of interleukin (IL)-4 to the culture medium, indicating that a Th2 immune response may be necessary to sustain infection.[6] However, successful culture has been achieved in fibroblasts without addition of IL-4.[7]

The characteristic pathologic appearances of Whipple's disease are seen in the small intestine. Macroscopically the mucosa is often normal, although it may appear erythematous, with a friable mucosa and small erosions or yellow-white plaques. Microscopically the villi may be normal, reduced in height or flattened in severe cases. Enterocyte height is reduced and some show vacuolization of the cytoplasm. PAS-positive macrophages within the lamina propria and other infected tissues are characteristic but not specific. PAS-positive staining may persist after successful treatment as a result of bacterial cell wall remnants within the macrophages.

PREVENTION

The origin of the bacterium presumed to be the etiologic agent of Whipple's disease is unknown. To date there are no known preventative measures for this disease, but the detection of *T. whipplei* DNA in sewage[12] suggests a possible environmental source, which warrants further investigation.

CLINICAL FEATURES

In Whipple's original description of this disease he identified most of the important clinical and pathologic features.[1] The patient described in the original case initially presented with recurrent attacks of arthritis, progressive weakness and weight loss. This was followed by a cough and mild fever, then persistent diarrhea. The abdomen was swollen with a mass below the umbilicus and the skin was pigmented. The patient was found to be severely anemic and examination of stools revealed an excess of fat. At laparotomy, the mesenteric lymph nodes were enlarged and the diagnosis was considered to be tuberculosis. The patient died. At autopsy there was deposition of fat in the intestine and mesenteric glands, the heart was also enlarged and the aortic valve affected. The serosa of the heart, lungs and abdomen was affected and microscopy revealed extensive tissue infiltration by macrophages.

The most common symptoms and signs reported in Whipple's disease are listed in Table 45.2 . The onset is often insidious and several years may pass before a diagnosis of Whipple's disease is made. Intermittent arthralgia, low-grade fever and weight loss are common and a rheumatologic cause is often sought initially. Arthralgia may predate other symptoms by many years; in the series reported in 1970, 14 of the 19 patients suffered from arthralgia for more than 10 years before developing other symptoms.[2] Arthralgia is usually migratory, and largely involves the ankles,

TABLE 45-2 -- Common clinical features of Whipple's disease (in order decreasing frequency of occurrence).

COMMON CLINICAL FEATURES OF WHIPPLE'S DISEASE		
Symptoms	**Signs**	
Weight loss	Weight loss	Glossitis
Diarrhea	Hypotension	Abdominal tenderness
Arthralgia	Lymphadenopathy	Abdominal mass
Abdominal pain	Skin pigmentation	Ascites
Gastrointestinal bleeding	Fever	Splenomegaly
Central nervous system manifestations	Edema	Abnormal neurologic signs

knees, shoulders or wrists. The joints may become swollen and inflamed, but a chronic deforming arthropathy is rare. Weight loss may be the only presenting feature and may be profound.

Diarrhea may be watery or steatorrheic. Edema secondary to hypoalbuminemia may occur, and less commonly ascites. Tetany caused by hypocalcemia has been described, but not osteomalacia or bony fractures. Scurvy may occur. Occult gastrointestinal bleeding is common and may occasionally become frank. Five patients who had intestinal bleeding have been described; three presented with overt bleeding and the others with microcytic anemia and positive fecal occult blood tests; two showed an erythematous friable duodenal mucosa that bled on contact at endoscopy.[13] Small intestinal and rectosigmoid ulceration have also been described.

Neurologic features usually manifest late, occasionally in the absence of other symptoms, and may even develop after apparently successful treatment for other features of Whipple's disease. Central nervous system (CNS) manifestations include personality change, apathy, dementia and encephalopathy. Hypothalamic symptoms of insomnia, hypersomnia, hyperphagia and polydipsia may occur. Clonic movements, spastic paresis and hyperactive reflexes with extensor plantar responses are also described. Ocular manifestations include papilledema, nystagmus and gaze pareses. Isolated bilateral uveitis has also been described.[14]

Symptomatic cardiac involvement is rate at presentation, but congestive cardiac failure is a common terminal event in untreated disease. Sudden death caused by arrhythmia may occur in up to 20% of patients. At autopsy PAS-positive macrophages have been demonstrated in heart valves, endocardium, myocardium and pericardium. Lymphocytic myocarditis has been reported.[15] Cardiomyopathy in the absence of gastrointestinal symptoms has also been reported, although duodenal biopsy was diagnostic of Whipple's disease.[16] Endomyocardial biopsy failed to show the presence of PAS-positive macrophages, but electron microscopy revealed the presence of Whipple's bacteria within the endothelium of myocardial capillaries. Atrial tachycardia with right bundle branch block was observed. Treatment with antibiotics was associated with a recovery of cardiac function and a return to sinus rhythm.

Skin involvement in Whipple's disease is characterized by hyperpigmentation, most commonly in exposed areas and in scars. Various skin rashes have also been described. Lymphadenopathy is common and enlarged intestinal lymph nodes may occasionally result in a palpable abdominal mass.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of Whipple's disease is extensive because of the multisystem nature of the disease and the variable way in which symptoms may occur. An

initial presentation of fever, weight loss and arthralgia would be compatible with a diagnosis of rheumatoid arthritis or seronegative arthropathy. The combination of these symptoms together with skin rashes, cardiac or neuropsychiatric features may suggest a connective tissue disease such as systemic lupus erythematosus. When pulmonary manifestations are prominent, sarcoidosis may be suspected. A granulomatous inflammatory reaction with poor or absent PAS-staining may occasionally occur in Whipple's disease infected tissues, further confusing the diagnosis with sarcoidosis. Hyperpigmentation necessitates exclusion of Addison's disease. The combination of any of the above features with diarrhea, with or without frank malabsorption, should alert the clinician to the possibility of Whipple's disease. When diarrhea is the predominant symptom the differential diagnosis would include celiac disease, giardiasis or inflammatory bowel disease.

DIAGNOSIS

When the diagnosis of Whipple's disease is suspected a small bowel biopsy is the initial diagnostic investigation of choice and is usually obtained by endoscopic biopsy of the second part of the duodenum. Examination of formalin-fixed paraffin-processed biopsies stained with hematoxylin and eosin may demonstrate nonspecific enteropathic changes. However, PAS staining will demonstrate the presence of multiple PAS-positive macrophages within the lamina propria and is highly suggestive of Whipple's disease, but not specific. Systemic *Mycobacterium avium-intracellulare* infection associated with AIDS may mimic Whipple's disease clinically, with weight loss, fever and malabsorption, and histopathologically as a result of PAS-positive macrophages within an enteropathic small bowel. PAS-positive macrophages may also be found in the intestinal mucosa in histoplasmosis and macroglobulinemia, although other pathologic features may differ. The finding of Whipple's bacilli by electron microscopy of affected tissues is diagnostic.

Recently, the diagnosis of Whipple's disease has become possible by applying the molecular phylogenetic techniques described above.[3] [4] [5] PCR detection of *T. whipplei* 16S rRNA has been successfully applied diagnostically in a number of tissues including peripheral blood,[17] cerebrospinal fluid[18] and vitreous fluid.[14] PCR has become negative with successful treatment,[19] [20] but relapse with cerebral Whipple's disease has been described despite negative intestinal PCR.[19] False positive tests have been described.[21] Diagnostic PCR for the detection of *T. whipplei*, however, is a promising technique, and is cheaper, faster and potentially more readily available than electron microscopy. This technique is also likely to be particularly valuable in Whipple's disease patients without intestinal involvement, in whom the diagnosis is more difficult to establish. Serum antibodies to *T. whipplei* have been detected in a high proportion of infected patients, [7] and this may form the basis of a useful diagnostic test in the future.

Anemia is present in the majority of patients, with hemoglobin concentrations of <8g/dl in one-quarter of patients.[2] The anemia is usually microcytic and may be related to chronic gastrointestinal blood loss.[13] Megaloblastic anemia is rare. Serum vitamin B12 is usually normal, but serum folate is often reduced. The erythrocyte sedimentation rate is usually raised. Hypoalbuminemia is common and is likely to result from a combination of increased intestinal loss, decreased hepatic synthesis and protein malabsorption. Stool examination in the majority of patients will reveal an excess of fat.

Small bowel contrast radiology is abnormal in the majority of patients. The findings are non-specific but include coarsening and thickening of the duodenal and jejunal folds and occasional dilatation.

MANAGEMENT

Whipple's disease was inevitably fatal until clinical improvement was noticed in patients treated with antibiotics in the 1950s.

A number of antibiotic regimens have been used for the treatment of Whipple's disease with variable success. The antibiotic treatment and outcome of 88 patients with Whipple's disease was reviewed retrospectively;[22] of the 57 patients who responded to treatment [mean follow-up 8.2 years (range 18 months to 27 years)], 31 (54%) relapsed [mean time to relapse 4.2 years (range 2 months to 20 years)]. There were no significant differences in sex or age at diagnosis between those who relapsed and those who did not. Of those who relapsed 21 out of 31 were treated with tetracycline alone. Two patients who relapsed were treated with parenteral penicillin and streptomycin followed by oral tetracycline, but the latter drug was given for only 2 weeks. CNS relapse was common, occurring in 11 out of 31 patients — all occurred late — nine out of 11 occurred in patients treated with tetracycline alone and none in patients treated with antibiotics that penetrate the blood-brain barrier. Treatment of CNS relapse was ineffective when using drugs with poor CNS penetration. A combination of parenteral and oral penicillin and chloramphenicol followed by oral trimethoprim-sulfamethoxazole (co-trimoxazole) was effective. In a more recent review of treatment, trimethoprim-sulfamethoxazole was more efficacious than tetracycline in inducing remission (92 versus 59%) and resulted in fewer CNS relapses.[23] However, 40% of patients with cerebral Whipple's disease did relapse after treatment with trimethoprim-sulfamethoxazole alone. CNS relapse has been treated successfuly with oral chloramphenicol, although one case of CNS relapse occurring on long-term trimethoprim-sulfamethoxazole has been successfully treated with oral cefixime (400mg q12h) after failure of oral chloramphenicol. In two further cases, intravenous ceftriaxone (2g q12h) resulted in improvement of cerebral symptoms.[24] No randomized prospective trial of alternative treatment regimens has been published.

We would recommend intravenous benzylpenicillin (2.4g daily) and streptomycin (1g daily, reduced to 0.5–0.75g daily if the patient is elderly or has a body weight <50kg) for 2 weeks followed by oral trimethoprim-sulfamethoxazole (960mg q12h) for 1 year (Table 45.3). Patients allergic to penicillin and those with prominent CNS involvement at presentation should be treated with intravenous ceftriaxone (2g q12h) and streptomycin for 2 weeks, followed by oral trimethoprim-sulfamethoxazole (960mg q12h) for 1 year. The

TABLE 45-3 -- Current recommended treatment regimens for Whipple's disease.

CURRENT RECOMMENDED TREATMENT REGIMENS FOR WHIPPLE'S DISEASE		
Indication	**Antibiotic regimen**	**Duration**
No clinical CNS involvement at presentation	Benzylpenicillin 2.4g daily iv + streptomycin 15mg/kg daily iv then trimethoprim-sulfamethoxazole 960mg q12h po	2 weeks 1 year
Penicillin allergy or CNS symptoms at presentation	Ceftriaxone 2g q12h iv + streptomycin daily iv then trimethoprim-sulfamethoxazole 960mg q12h po	2 weeks 1 year
CNS relapse on treatment	Chloramphenicol 2g daily po	1 year
Streptomycin dose should be monitored and reduced as needed in patients who have impaired renal function, especially the elderly.		

duration of treatment remains empiric and relapse may occur after apparently successful treatment. Relapse may be confirmed by demonstrating the presence of Whipple's bacilli by electron microscopy in biopsy samples. The persistence of PAS-positive macrophages after treatment is common and is not diagnostic of relapse. CNS relapse on treatment should be treated with oral chloramphenicol (500mg q6h) for at least 1 year; a third-generation cephalosporin with good CNS penetration is the alternative.

In addition to specific antibiotic therapy, various symptomatic treatments and supportive measures may be required, depending upon the clinical manifestations of the disease. Pain caused by arthropathy may be treated with simple analgesics or nonsteroidal anti-inflammatory drugs. Diarrhea and malabsorption may necessitate nutritional support with protein-calorie enteral supplementation and vitamins. Antidiarrheal agents such as codeine or loperamide may provide symptomatic relief. Cardiac involvement with cardiac failure may require diuretic and angiotensin-converting enzyme inhibitor therapy. Antiarrhythmics may also be required. Occasionally mitral or aortic valve replacement has been required for those with advanced valvular involvement. The wide range of neurologic manifestations may require nursing support, physiotherapy and neurorehabilitation. Recovery may not be complete.

Chapter 46 - Parasitic Infections of the Gastrointestinal Tract

Andrew D Mackay
Peter L Chiodini

INTRODUCTION

This chapter examines the parasitic causes of gastrointestinal infection in the nonimmunocompromised host. The organisms involved are a very heterogeneous group of protozoa and helminths. They vary in size from microsporidia, which are barely visible using light microscopy, to long multicellular organisms such as *Taenia saginata*, which can reach 25m in length (Fig. 46.1). The clinical approach is emphasized here because the parasites themselves are discussed elsewhere (see Chapter 242 , Chapter 243 and Chapter 246), and diagnosis is covered in Chapter 165 . Parasitic gastrointestinal infections in HIV infection are discussed in Chapter 127 . The parasites discussed in this chapter are listed in Table 46.1 .

EPIDEMIOLOGY

In the developed world, parasitic infections appear to be uncommon causes of gastrointestinal illness. Certain populations are particularly likely to be affected:

- returned travelers,
- day care workers and patients,
- immigrant workers, and
- homosexual men.

The most common causes of parasitic gastrointestinal infection are *Giardia lamblia* and *Cryptosporidium parvum*.

In developing countries the impact of parasitic infections is of much greater significance in relation to morbidity, mortality and economic impact. Their epidemiology is varied and their control presents a complex sociopolitical problem. The most important infections are *Entamoeba histolytica*, *G. lamblia*, hookworms, *Ascaris* spp. and tapeworms.

Geographic distribution of parasites

The distribution of a parasite depends upon:

- human behavior,
- the physical environment, and
- the biological environment.

Human behavior

Behavioral factors are often dominant but the distribution of vectors, intermediate hosts and reservoir hosts is also to some extent under human control. Some parasites are worldwide in their distribution, such as *E. histolytica* and *G. lamblia*, whereas others are very localized.

Physical environment

The physical environment also affects the distribution of parasites. Temperature and humidity affect the viability of parasites in the external environment; viability is lost in cold or over-hot temperatures and most parasites require moist, aerobic conditions. Examples of parasites for which these factors are critical include:

- the cysts of protozoa with direct life cycles, such as *E. histolytica, G. lamblia, Balantidium coli* and the various gut commensal species (*Entamoeba coli, Entamoeba hartmanni, Endolimax nana, Iodamoeba butschlii*);
- the oocysts of *Isospora belli*;
- the eggs and larvae of soil-transmitted nematodes (*Ascaris* spp., hookworm[1] and *Strongyloides stercoralis* (see Fig. 46.3));
- the eggs of trematodes (*Fasciolopsis buski* and *Heterophyes heterophyes*) and cestodes before their entry into the aquatic environment; and
- the eggs of cestodes before their ingestion by the intermediate hosts (*Taenia solium* and *Taenia saginata*).

Temperature and humidity also affect sporulation of oocysts, the rates of embryonation of nematode, cestode and trematode eggs and the development times for hookworm and *Strongyloides* larvae. Parasites that have a soil stage are affected by the particular physical properties of the soil, including its particle size and water-holding capacity, and by factors such as rainfall. Susceptibility to anaerobic conditions is important for some parasites when 'night soil' (human feces) is used raw or after composting as a fertilizer.

The aquatic environment is important in the life cycle of many parasites. In the trematodes, the cercariae of *Heterophyes* spp. must survive long enough to infect the fish or shrimp and the metacerariae of *F. buski* must survive long enough to infect the human or pig hosts. *Strongyloides* larvae live in the capillary water films in soil and on low vegetation.

Biologic environment

The biologic environment also affects the epidemiology of these gastrointestinal parasites. The distribution in nature of appropriate vectors, intermediate hosts and reservoir hosts can obviously affect the distribution of parasites. Examples of animal reservoirs are *F. buski* in dogs, pigs or rabbits; *B. coli* in pigs; *C. parvum* in domestic animals, particularly cattle; and *H. heterophyes* in fish-eating mammals. Secondary hosts include snails for *F. buski* and freshwater fish for *H. heterophyes*. An important biologic factor is the presence of dung beetles that take the parasitic ova or larvae underground to a more favorable physical environment.

Human factors

Population density and urbanization

The agricultural revolution in developing countries has produced large resident human populations with the potential for direct person-to-person spread of infection and greater environmental contamination by feces. In addition, animal husbandry has created other cycles for parasite transmission, for example *Cryptosporidium* spp. in calves. Rapid urbanization, especially in the tropics, is often associated with increased poverty, poorer housing and unsanitary conditions. The result is that people may be living in a more fecally polluted environment than in rural areas, encouraging such diseases as amebiasis and giardiasis. Epidemics, such as outbreaks of cryptosporidiosis, may occur when public water supplies become fecally contaminated.

Figure 46-1 Adult beef tapeworm (*Taenia saginata*) passed in a patient's feces.

Cyclospora cayetanensis is transmitted via contaminated produce and contaminated drinking water.[2] The soil-transmitted nematodes *Ascaris lumbricoides* and *Trichuris trichiura*[3] are often more common in towns and cities. Overcrowding favors direct transmission of *Hymenolepis nana* and *Enterobius vermicularis*, especially in children when levels of hygiene and sanitation are poor.[4]

Population movements

Population changes associated with mining, political unrest or industrialization may cause people to move into at-risk areas; travelers may also visit such areas.

Dams and irrigation

Development programs in the tropics frequently involve irrigation projects, where contaminated water supplies reach greater numbers of people and larger water-borne outbreaks may occur. Irrigation and poor drainage supplies favor the breeding of flies that may have a role in spreading fecal material.

Agriculture

Cattle raising may be complicated by bovine cysticercosis (*T. saginata*), which renders carcasses unsaleable, and calves may be a source of human infection. Pigs can allow *T. solium*, the pork tapeworm,

TABLE 46-1 -- Gastrointestinal parasites.

to be spread and *F. buski*, the intestinal fluke, to prosper. *Balantidium coli* is also acquired from close contact with pigs. Fish farms in which water plants such as water calthrop are grown transmit *F. buski*, especially if human or pig feces are used as fertilizer. Foods implicated in outbreaks of cyclosporiasis in the United States include fresh raspberries, mesclun lettuce and basil.[5] The use of untreated human night soil enables soil-transmitted helminths to enter the human food chain.

Domestic environment

Sanitation, water supplies and domestic customs in hygiene and food preparation are all very important. Children are at risk of parasitic infections because of poor hand washing after defecation, finger sucking and playing with soil. Local dietary behavior is critical for parasite transmission. Ingestion of certain fish, crustacea, molluscs and aquatic vegetation can lead to fluke infection. Tapeworms are contracted by ingestion of undercooked pork or beef (*Taenia* spp.) or certain fish (*Diphyllobothrium* spp.). People who have occupations involving sewage, water or soil contact are at increased risk of parasitic infection.

Host susceptibility

Host susceptibility is affected by many factors such as nutritional status, intercurrent disease, pregnancy, immunosuppressive drugs and malignancy. Previously mild or clinically inapparent infections can produce dangerous disease when host immunity falls, such as occurs in strongyloidiasis, in which the parasite is capable of multiplying by autoinfection within its host, and fatal amebiasis that may occur if corticosteroids are administered in error.

Some protective immunity is usually acquired by the host but its effectiveness is variable. The absence of symptomatic giardiasis in adults in places where the infection is common is good evidence for acquired immunity. Re-infection and superinfection, possibly by different gastrointestinal parasite strains, is certainly common in

TABLE 46-2 -- Anatomic location of gastrointestinal parasites.

ANATOMIC LOCATION OF GASTROINTESTINAL PARASITES

		Balantidium coli

areas of endemic infection. Immunodeficiency associated with HIV infection is of paramount importance in some of the more recently recognized gastrointestinal parasitic diseases such as cryptosporidiosis and microsporidiosis (see Chapter 127).

PATHOGENESIS AND PATHOLOGY

Gastrointestinal parasites cause disease in a variety of ways. Most are present in the lumen of the gut or attached to the mucosa of the gut wall and are not capable of invasion. The coccidian parasites such as cryptosporidia can invade the epithelial cells of the small bowel. Others, such as *E. histolytica, S. stercoralis* and occasionally *B. coli*, do invade the mucosa (Table 46.2).

Gastrointestinal protozoa

Amebiasis

Amebic ulcers mostly develop in the cecum, appendix or adjacent ascending colon, although the sigmoidorectal region can be involved.[6] Amebic ulcers are formed on the mucosa. They are usually flask shaped with a small, raised opening and a larger area of mucosal destruction below. The mucosa between abscesses is normal but lesions can be confluent. Pathogenic amebae are able to resist complement-mediated lysis and they possess other virulence factors such as attachment lectins, cysteine proteases and other enzymes.[7] Amebae have tissue-lysing enzymes on their surfaces that can be released from lysosomes or after amebic rupture. In a study in Bangladeshi children, acquired immunity to amoebiasis was associated with the appearance of an intestinal IgA response to the parasite Gal/GalNAc lectin, the virulence factor required for attachment of *E. histolytica* trophozoites to human cells. An intestinal IgA response to this lectin was associated with a 70% reduction in infections in children over the 2-year study period. On the other hand, those children who developed anti-amebic IgG antibodies in the serum were more susceptible to amebiasis. Interestingly, serum anti-lectin IgG antibodies cluster in families, supporting the presence of an inherited component to susceptibility to amebic disease.[8] Based on work with *Entamoeba invadens*, a parasite of reptiles, Eichinger has suggested that interactions of amebae with intestinal mucin glycoproteins promote encystment of the parasite and thus prevent invasion. [9] This is in keeping with the finding that *E. histolytica* cyst passers are asymptomatic.[10]

Giardiasis

The histopathology of the upper small bowel varies from normal to subtotal villous atrophy in giardiasis. *Giardia* spp. seem unable to penetrate the mucosal wall in humans but are able to attach to the mucosa of the small bowel. In symptomatic cases there is increased mucus secretion and dehydration.[11] *Giardia lamblia* may undergo antigenic variation, thereby evading the human immune response.[12] Giardiasis is more common in the immunodeficiency syndromes, particularly in common variable hypogammaglobulinemia, although there is no particular increase in incidence among the HIV-infected population.

Balantidium coli

The trophozoite of *Balantidium coli* causes mucosal inflammation and ulceration, invading the distal ileal and colonic mucosa. Ulceration may be superficial or involve the full thickness of the bowel, leading to perforation.[13] Invasion may be enhanced by hyaluronidase produced by the parasite. Other products liberated by the parasite as well as host factors, such as the recruitment of mucosal inflammatory cells, may also be important.[14]

Cryptosporidiosis

Cryptosporidial infection in humans is most commonly due to *Cryptosporidium parvum*, but *C. felis, C. muris* and *C. meleagridis* have been identified in immunocompromised individuals. *Cryptosporidium parvum* has two genotypes: type 1 (human derived) and type 2 (animal and human derived) and it has been suggested that they may represent two distinct species. [15] *Cryptosporidium* infects the intracellular, extracytoplasmic area of host epithelial cells of the small bowel. The intracellular stage of *C. parvum* resides within a parasitophorous vacuole in the microvillus region of the host cell. Oocysts undergo sporogony while in the host cells. Approximately 20% of the oocysts do not form the usual environmentally resistant oocysts but are released as sporozoites that are capable of penetrating the microvillus regions of other cells within the intestine. This explains the ability of *C. parvum* to cause severe diarrhea in some patients, particularly in the immunocompromised. [16] Small bowel histology shows villous atrophy and crypt hyperplasia, usually with a mixed inflammatory cell infiltrate in the lamina propria. There is impaired absorption and enhanced intestinal secretion. There appears to be *Cryptosporidium*-associated apoptotic epithelial cell death. The precise molecular mechanism for cryptosporidial diarrhoea is not yet elucidated. There appears to be enterotoxin-like activity and it appears that attachment of *Cryptosporidium* to epithelial cells induces survival signals in those cells so that the organism is able to multiply, while at the same time causing alterations such as apoptosis in adjacent uninfected cells which impair absorption and secretion by those cells and result in clinical disease.[17]

Cyclosporiasis

The mechanism of diarrhea production has not been clearly established for *Cyclospora cayetanensis*. The organism is found within enterocytes. There is reduction in villus height with associated mucosal inflammation and increased numbers of intraepithelial lymphocytes, which suggests a direct effect on the intestinal mucosa.[18]

Isosporiasis

Mild to subtotal villous atrophy and crypt hyperplasia occurs in *I. belli* infection. Histologically, there may be infiltration of the lamina propria with large numbers of eosinophils, plasma cells, lymphocytes and polymorphs. Dilated lymphatics may be seen.[19]

Microsporidiosis

Intestinal microsporidia infect enterocytes in the small bowel and undergo sporogony, which leads to enterocyte degeneration,

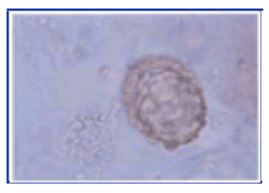

Figure 46-2 *Ascaris lumbricoides* ovum in feces. The ovum measures 50–70mm × 40–50mm and is elliptical. The rough albuminous coat gives it a mammillated appearance.

vacuolation and loss of the brush border. These cells are sloughed off and the spores are capable of infecting further enterocytes.[20] [21]

Gastrointestinal helminths

Nematode infections

Ascariasis (roundworm infection)

The embryonated eggs of *A. lumbricoides* are ingested and hatch in the stomach and duodenum, from where the larvae penetrate the intestinal wall (Fig. 46.2). They are carried to the lungs in the circulation and usually cause no symptoms unless there are a large number of larvae, in which case pneumonitis can ensue. The larvae then break out of the lung tissue and may cause some bronchial epithelial damage. Intense tissue reaction with infiltration of eosinophils, macrophages and epithelioid cells occurs.[22] Jejunal histology shows shortened villi, a decrease in the villus: crypt ratio and cellular infiltration of the lamina propria.[22]

Ancylostomiasis (hookworm infection)

Hookworm disease is caused by *Ancylostoma duodenale* and *Necator americanus*. Vesiculation and pustules can occur on the skin at the site of entry of the filariform larvae. Asthma and bronchitis occur during migration through the lungs, with small hemorrhages into the alveoli and infiltration of eosinophils and leukocytes. Adult hookworms attach firmly to the small bowel mucosa; *A. duodenale* does this by means of well-developed mouth parts and *N. americanus* by means of cutting plates. There tends to be chronic blood loss at the site where the worm attaches.

Trichuriasis (whip worm)

The egg of the nematode *T. trichiura* hatches in the small intestine and the larva penetrates the villi causing no pathologic reaction. It re-emerges after 1 week and migrates to the cecum and colorectum. When few worms are present there is little damage, but with heavy infections there is hemorrhage, mucopurulent stools and symptoms of dysentery, sometimes with rectal prolapse (the *Trichuris* dysentery syndrome).[23]

Strongyloidiasis

The life cycle of *S. stercoralis* is complex (Fig. 46.3). Human infection is acquired when filariform larvae in the soil penetrate the skin. This can cause petechial hemorrhages, congestion and edema at the site of entry. The larvae migrate into cutaneous blood vessels and are carried to the lungs, where they break out of the pulmonary capillaries and sequentially enter the alveoli, trachea, pharynx and then the mucosa of the duodenum and upper jejunum. There can be pathologic findings similar to those of bronchopneumonia with lobar consolidation. The females mature in the intestine, invade the tissues of the bowel wall and lay their eggs, which hatch and release first-stage (rhabditiform) larvae in the feces. In certain situations, the rhabditiform larvae mature in the intestine to the filariform stage, and these parasites bore into the wall of the duodenum and jejunum and initiate another cycle of infection, which eventually results in there being more adult worms in the small bowel. Filariform larvae that penetrate the bowel wall can spread throughout the lymphatic system to the mesenteric lymph glands and can enter the general circulation and hence the liver, lungs, kidneys and gallbladder. They can cause granulomas in the gastrointestinal tract and mesenteric glands. There are abscesses in the lungs and there may be granuloma in the liver. Migrating larvae may cause the patient to die from sepsis arising from the normal intestinal bacterial flora.

Trematode infections (flukes)

Fasciolopsis buski infection

The giant intestinal fluke *F. buski* is contracted by humans and pigs through eating metacercariae attached to water plants. The parasite excysts and attaches to the mucosa of the jejunal and duodenal wall causing mechanical injury and inflammation, which can lead to ulcers, bleeding or abscesses. There may be a mild anemia and low levels of serum vitamin B12, owing to the parasite's competition for the vitamin or impairing its absorption.

Heterophyes heterophyes infection

Heterophyes heterophyes is a trematode that infects humans and is found mainly in Asia. The pathology depends on the degree of infection acquired through ingestion of pickled or raw fish. The metacercariae excyst and attach to the walls of the small intestine. The adults may cause only a mild inflammatory reaction. Eggs may enter the circulation because the adults are attached deeply into the intestinal wall. Ectopic eggs can provoke granuloma formation, especially if they lodge in the heart or brain.[24]

Cestodes infections (tapeworms)

Taenia solium and *Taenia saginata*

The pork tapeworm (*T. solium*) and the beef tapeworm (*T. saginata*)[25] are acquired by the human host by ingestion of poorly cooked meat that contains the encysted larvae (cysticerci). The larva is digested in the stomach and the head of the tapeworm evaginates in the upper small intestine, attaches via the scolex to the intestinal mucosa and feeds by absorbing nutrients from the bowel. The scolex of *T. solium* has four suckers and a rostellum that contains a double row of hooks; *T. saginata* has the suckers only. Very little pathology is caused by these well-adapted adult worms, which may reach 7m and 25m in length respectively. The pathologically significant stage for humans is the cysticercus of *T. solium*. The eggs passed in feces are ingested and hatch when they are exposed to gastric juice. The oncospheres that are released penetrate the intestinal wall and are carried via the bloodstream and can potentially form a cysticercus in any organ. The cysticercus is an ovoid, milky-white bladder with the parasite head invaginated inside. The pathology is described in detail in Chapter 168 .

Dwarf tapeworm (*Hymenolepis nana*)

Once the ova of the dwarf tapeworm *H. nana* are ingested they encyst in the small intestinal villus mucosa. The adult worm reaches a length of 3–4cm and begins egg production. Heavy infections of more than 100 worms can cause some symptoms, and the competition

---

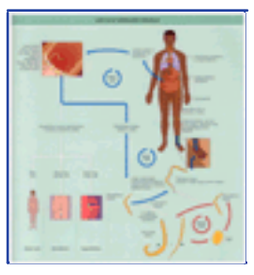

Figure 46-3 Life cycle of *Strongyloides stercoralis*.

for nutrients has been linked with growth retardation in children, although this may be more the result of insanitary conditions, poverty and malnutrition.

Fish tapeworm (*Diphyllobothrium latum*)

The fish tapeworm *D. latum* has a life cycle involving a first intermediate host of tiny aquatic invertebrates, a second intermediate host of fish and a definitive host that includes humans, other terrestrial mammals and marine mammals. The tapeworm attaches to the small intestinal mucosa by means of two longitudinal slit-like suckers (bothria). Infections are commonly multiple and may reach more than 100 individual worms, each measuring up to 10m in length. The pathology is minimal from the local effects. Tapeworm anemia has been described exclusively in Finland and has now all

but died out as a result of control measures. The anemia is caused by vitamin B12 deficiency, with worms competing for the limited dietary vitamin B12, and it is strongly associated with gastritis and achlorhydria; there is probably a genetic predisposition to this condition.

PREVENTION

The prevention and control of parasitic gastrointestinal disease can be achieved through improvement of living standards, personal hygiene and better sanitary conditions.[26] In immunocompromised patients, different recommendations need to be considered (see Chapter 123).

Public health hygiene measures

Disposal of human sewage and waste water is fundamental to the control of parasitic gastrointestinal infections. Fecal material contaminates agricultural food crops or water supplies if it is passed promiscuously in the fields or close to habitation or if it is deliberately used unprocessed on fields as fertilizer ('night soil'). Any of the gastrointestinal parasites can be transferred in this way. Following rain, fecal material is washed into rivers and pools. Giardia cysts are found in surface water in many parts of the world.

The provision of latrines can reduce these sources of environmental contamination but, unfortunately, unless they are well constructed and maintained, latrines can themselves become important foci of infection. The prevalence of *Ascaris* infection is often higher among urban latrine users than among rural non-users. The eggs of *A. lumbricoides* and also those of *T. trichiura* are very often resistant and can remain viable in the latrine environment for long periods. In addition, the moist soil around a latrine favors the survival of hookworm larvae[27] and the free-living cycle of *S. stercoralis*.

Domestic waste water (and the excreta that it accompanies) when used for irrigation puts crops and workers at risk. Sewage may enter lakes, rivers and ponds and the water then be used for drinking or irrigation. *Cryptosporidium* oocysts are particularly difficult to eliminate from water and require an efficient filtration system. Boiling water is the most reliable method of killing oocysts.

Composting is another reliable way of killing the infective forms of parasites. This takes 3–4 months. Cysts, eggs and larvae are quite rapidly killed at temperatures of 131°F (55°C) and die within a few days at 113°F (45°C). The compost heap needs turning and good maintenance or the periphery may become an intense transmission focus. Chemical treatment of excreta has been used, for example 12–24 hours in ammonium sulfate, but proper control is important to maintain efficacy and avoid toxicity to fish and plant life. Solid waste from sewage treatment plants is used as agricultural fertilizer and can contain viable parasites if inadequately processed. Sewage treatment removes or destroys parasites by sedimentation and the creation of completely anaerobic conditions. The eggs of *Taenia* spp. and *A. lumbricoides* are notoriously resistant and they sometimes survive in the solid wastes taken from sedimentation tanks or ponds.

Personal hygiene measures

Most gastrointestinal diseases could be prevented if it were easy to modify human behavior. In practice this is often very difficult, but health education can be very effective and it can take many forms. Schools can be targeted or the local press used for a health awareness campaign. The fecal-oral route of transmission is very important, especially for intestinal protozoa. For example, infected food handlers are disseminators of *G. lamblia* and *E. histolytica* cysts. There is high prevalence of infection in institutions for children or the mentally subnormal, where personal hygiene is poor. Those intestinal helminths whose life cycles can lead to fully embryonated eggs being released or formed very soon after entry into the environment (*H. nana* and *E. vermicularis*) are also spread in this way. Microsporidia are probably spread by the fecal-oral or urinary-oral routes. Simple hand-washing before preparing and eating food prevents transmission of these infections. The soil-to-skin route of infection can be inhibited by wearing shoes.[28] Infective forms of hookworm and *Strongyloides* larvae will be stopped from entering the skin. Persons dealing with composted human feces must use boots and gloves.

Good food hygiene is essential. Prevention of most of the parasites transferred by the fecal-oral route can be achieved by washing all salad vegetables and fruit before consumption. Kitchen utensils and hands should be washed frequently. Avoidance of wild-grown watercress and other water plants prevents *F. buski* infections. Proper cooking of meat and fish removes the risk of flesh-derived parasites such as *H. heterophyes* and tapeworms. Problems arise when cultural preferences dictate consuming these products raw, undercooked, salted, dried or pickled. The inspection of meat can detect the presence of cysticerci in the carcasses and allow infected meat to be condemned. Stopping the consumption of fish that is raw, pickled or salted is often impossible if it is part of a deep cultural tradition. Deep freezing of meat and fish at temperatures colder than -4°F (-20°C) for 24–48 hours kills all these parasites.

Prevention by chemotherapy

The treatment of these gastrointestinal parasites with appropriate chemotherapy is helpful in the prevention of further cases. This is particularly so in developed parts of the world. In areas where parasitic disease is endemic, generally only symptomatic patients are treated. Patients that are asymptomatic, those in whom the diagnosis is incidental and those who do not have heavy infections are usually not treated, as re-infection is probably inevitable. Mass chemotherapy has been used in amebiasis, soil-transmitted nematodes (*A. lumbricoides*, [29] hookworm, *T. trichiura*) and tapeworms (*T. saginata, T. solium*, *D. latum*).[30] Success depends upon several factors:

- the chemotherapeutic agent used should have a broad spectrum of activity and be given annually as a single oral dose;
- the drugs should be cheap to purchase and administer; and
- the drugs should have few side effects.

In the past, mass chemotherapy was used in an attempt to eradicate amebiasis but, because treatment required a prolonged course of luminal amebicides, compliance was poor and reinfection in endemic areas was high. *Fasciolopsis buski* infection in Indonesia has been treated by community-based praziquantel treatment but rapid reinfection followed. Selective or targeted chemotherapy may be of more use. *Enterobius vermicularis* infection in one child requires treatment not only of that child but also all family contacts together with education in personal hygiene.

Vaccines

As yet no vaccines have been used in humans for the control of gastrointestinal parasitic diseases.[31]

Role of prophylaxis

There is no evidence for prophylactic use of chemotherapy being helpful in prevention of these gastrointestinal parasitic diseases.

Advice for travelers on preventive measures is discussed in Chapter 143 .

CLINICAL FEATURES

The symptoms produced by gastrointestinal parasites are diverse. The most common presentation is of poorly localized abdominal pain; less commonly there is nonspecific diarrhea (Table 46.3). The severity varies from asymptomatic carriage to life-threatening

TABLE 46-3 -- Gastrointestinal parasites associated with diarrhea.

GASTROINTESTINAL PARASITES ASSOCIATED WITH DIARRHEA	
Diarrhea and fever	*Entamoeba histolytica*

	Trichuris trichiura
	Hookworm (*Necator americanus* and *Ancylostoma duodenale*)
	Strongyloides stercoralis

gastrointestinal disease, as occurs in amebiasis and cryptosporidiosis. It is important to emphasize that the identification of an infection by stool microscopy does not necessarily imply that it is the cause of a patient's symptoms. This is particularly so in the case of light helminth infections, which are often completely symptomless. Other pathologies should be excluded before attributing the patient's symptoms to the gut parasite. Some of these infections present with extraintestinal manifestations, such as iron-deficiency anemia, wasting or (in the case of hookworm infection) growth retardation.

Gastrointestinal disease caused by protozoa

*Amebiasis (*Entamoeba histolytica*)*

It is now recognized that there are two species of amebae that were formerly termed pathogenic and nonpathogenic *E. histolytica*. [32] Methods used to separate these include biochemical, immunologic and genetic data. These are now called *Entamoeba histolytica* and *Entamoeba dispar*. Only *E. histolytica* is capable of causing disease. Asymptomatic cyst carriers may excrete cysts for a variable length of time, usually only a few weeks. Confirmation that the parasite previously described as *Entamoeba histolytica* is in reality two species, *Entamoeba dispar* which is nonpathogenic and *Entamoeba histolytica* which is a pathogen, meant that the natural history of amebiasis needed reassessment. [10] Haque *et al* studied 300 preschool children in Dhaka, Bangladesh.[8] Over a 2-year period, new *Entamoeba histolytica* infections were found in half the children. Of those who were asymptomatic cyst passers, one in 10 subsequently developed diarrhea within 2 months of the start of infection; 10% of the children had diarrhea in association with *E. histolytica* and 4% were found to have amebic colitis.

Amebic intestinal disease

The incubation period of invasive amebiasis varies from a few days to 1–4 months. There is a good correlation with the presence of *E. histolytica* trophozoites containing ingested red blood cells. Patients may be asymptomatic or present with colicky abdominal pain, frequent bowel movements and tenesmus. Amebic dysentery is characterized by blood-stained stools with mucus occurring up to 10 times a day. The duration of the dysentery can be very variable and may last for only a few days or for several months with concomitant weight loss and debility. The symptoms may be confused with inflammatory bowel disease. In acute cases the clinical picture may mimic appendicitis, cholecystitis, intestinal obstruction or diverticulitis.

Amebic extraintestinal disease

Amebic dysentery progresses to invasive amebic disease in between 2% and 8% of patients. Symptoms can be gradual in onset, with right upper quadrant pain and fever (see Chapter 145). Weakness, weight loss, dry cough and sweating are less common. Tender hepatomegaly is often seen with liver function tests that are normal or only slightly abnormal. Jaundice is very unusual. The site most commonly involved is the upper right lobe of the liver, and abscesses are mostly solitary. A raised right diaphragm may be found on chest radiograph. The abscess is visualized by ultrasound, CT or MRI. Hematogenous spread to the brain (see Chapter 158), lung (see Chapter 165), pericardium and other sites is possible. Serologic tests are valuable in cases of suspected amebic abscess. The indirect fluorescent antibody test is positive in over 95% of cases after 14 days, but it should be confirmed by the cellulose acetate precipitin test.

*Giardiasis (*Giardia lamblia*)*

The clinical spectrum of giardiasis ranges from asymptomatic infection, through acute gastrointestinal infection to severe chronic diarrhea[33] with intestinal malabsorption.[34] The average incubation period is 9 days and the acute infection is self-limiting.[35] Common symptoms include nausea, diarrhea, flatulence and upper abdominal cramps with distention and nausea. Weight loss is common and there can be signs of malabsorption (steatorrhea, disaccharidase deficiency and vitamin B12 deficiency).

*Blastocystis infection (*Blastocystis hominis*)*

There is controversy surrounding *B. hominis*; it is unclear whether it causes gastrointestinal disease or not. When large numbers are found in stool in the absence of other parasites, bacteria or viruses it may be the cause of diarrhea, cramps, nausea, fever, vomiting and abdominal pain. Data from Canada indicate that, although it is commonly seen in stools, it is not pathogenic. [36] It is possible that a small subset of *B. hominis* organisms have virulence factors that are missing in most.[37]

Dientamoeba fragilis infection

Like *Blastocystis*, the pathogenicity of *Dientamoeba fragilis* is uncertain. It has been associated with a wide range of symptoms. In children, symptoms may include intermittent diarrhea, abdominal pain, nausea, anorexia, malaise, fatigue, poor weight gain and unexplained eosinophilia.[38]

*Cryptosporidiosis (*Cryptosporidium parvum*)*

The incubation period of *Cryptosporidium parvum* infection averages 3–6 days. Symptoms include a flu-like illness, diarrhea, malaise, abdominal pain, anorexia, nausea, flatulence, malabsorption, vomiting, mild fever and weight loss. In the 1993 Milwaukee water-borne outbreak of cryptosporidiosis, which affected around 403,000 people, the mean duration of illness was 12 days and the median maximum number of stools per day was 12.[17] Oocyst excretion generally occurs for 3–30 days (average 12 days) and occurs at the same time as the symptoms. Generally the symptoms are self-limiting, and prolonged disease in uncommon.[39] In immunocompromised patients the situation is different and there can be intractable, profuse, life-threatening diarrhea (see Chapter 127). [40] [41]

*Cyclosporiasis (*Cyclospora cayetanensis*)*

There is epidemiological evidence that *Cyclospora cayetanensis* is the cause of persistent diarrhea in immunocompetent patients as well as

in immunocompromised patients. Initially, the clinical findings do not distinguish cyclosporal diarrhea from other causes of diarrhea. Other common symptoms are abdominal pain, nausea, vomiting and anorexia. Cyclospora infection can last for 1–8 weeks.[18]

Isosporiasis (Isospora belli)

The predominant clinical symptom is diarrhea, which may be intermittent and last for months or even years. Stools are watery soft, foamy and offensive, which may suggest malabsorption. There is associated weight loss, abdominal pain and fever.[42] [43] In HIV-infected patients, chronic infection occurs (see Chapter 127).

Microsporidiosis

Microsporidia may cause acute self-limiting diarrhea in immunocompetent persons,[20] in patients who have immunodeficiency other than AIDS and in the elderly[21] . In HIV infection (see Chapter 127), chronic diarrhea and wasting are common.[44] *Enterocytozoon bieneusi* is one of the most important intestinal pathogens in severely immunodeficient HIV-infected patients; it is present in 7–50% of those who have otherwise unexplained chronic diarrhea. There are also increasing reports of intestinal microsporidial infections in immunocompetent people.[45] *Encephalitozoon intestinalis* (formerly *Septata intestinalis*) is a less commonly recognized cause of chronic diarrhea. *Encephalitozoon cuniculi* intestinal infection has been reported. These are covered in Chapter 127 and Chapter 243 .

Balantidiasis (Balantidium coli)

Balantidium coli, the largest and least common of the human protozoan pathogens, is capable of causing an infection resembling amebic colitis. It is particularly prevalent among people living in close association with pigs in South America, Iran, Papua New Guinea and the Philippines. Up to 80% of persons carrying the organism are asymptomatic carriers.[14] Acute diarrhea with blood and mucus begins abruptly and is associated with nausea, abdominal discomfort and marked weight loss. There can be inflammatory changes and ulceration in the proctosigmoid region but the rectum is usually spared. Peritonitis and colonic perforation can progress rapidly to death. A chronic infection occurs with intermittent diarrhea and infrequent bloody stools.

Helminthic gastrointestinal disease

The World Bank regards intestinal helminth infections as the main cause of disease burden in children from 5 to 14 years old in developing countries.

Ascariasis (Ascaris lumbricoides)

Most cases of ascariasis are asymptomic; symptomatic infections are more common in children than adults. When large numbers of larvae migrate to the lungs in a short time period, *Ascaris* pneumonitis can result. This is the clinical picture of Löffler's syndrome, which is characterized by dyspnea, dry cough, wheezing or coarse rales, fever up to 104°F (40°C), transient eosinophilia and a chest radiograph that is suggestive of viral pneumonia and that resolves within a couple of weeks. In addition, eosinophils, Charcot-Leyden crystals and larvae may rarely be found in the sputum. Symptoms of asthma and urticaria may continue during the intestinal phase of ascariasis. The adult worms occasionally migrate from the small bowel and cause biliary or hepatic ascariasis. Rarely, adult worms migrate into the biliary tree with secondary sepsis and abscess formation. Pancreatitis may result from migrating ascarids that obstruct the pancreatic duct. In people who have large numbers of adult worms intestinal obstruction can occur owing to the sheer bulk of worm bodies. Adult worms migrate more in the presence of a stimulus such as a fever of over 102°F (38.9°C) or the use of a general anesthetic, and they may block the bile duct or pancreatic duct or enter the liver or peritoneal cavity. In children, nutritional deficiencies such as reduced appetite, kwashiorkor (protein-energy malnutrition), vitamin A deficiency and growth deficit are related to the burden of the adult worms.[46]

Enterobiasis (Enterobius vermicularis)

Infection with *Enterobius vermicularis* (threadworm or pinworm) causes few or no symptoms in the vast majority of people. The predominant symptom is nocturnal pruritus ani, caused by migration of the female worms from the anus to the perianal skin in the process of laying their eggs. Scratching may be intense and secondary infection may ensue. Pruritus vulvi caused by pinworms entering the vulva is occasionally seen. In children, insomnia, loss of appetite, loss of weight, emotional instability, enuresis and irritability may also be found. [46]

Ancylostomiasis (hookworm infection, Ancylostoma duodenale, Necator americanus)

Hookworm causes ground itch, a moderate-to-severe pruritus of the skin, usually of the feet, as the hookworm larvae penetrate. Secondary infection can occur if the vesicular lesions are excoriated by scratching. A pneumonitis, caused by alveolar migration of larvae, is less common, less severe and causes less sensitization than that seen with *Ascaris* or *Strongyloides* infection. Symptoms of the intestinal phase are fatigue, nausea, vomiting, abdominal pain, diarrhea with occult bleeding, and weakness. Heavy worm burdens may have serious sequelae in young children.[47] This is particularly problematic with *A. duodenale* infection. Eosinophilia is usually present. According to the degree of worm burden, chronic infection leads to an iron deficiency anemia[27] and hypoproteinemia with pallor, edema of the face and feet, listlessness, koilonychia, cardiomegaly, heart failure and rarely mental retardation. Iron deficiency in children is associated with impaired academic performance at school and in adults with weakness and fatigue, leading to reduced productivity.

Trichuriasis (Trichuris trichiura)

Light infections with this common, ubiquitous infection rarely cause symptoms. In heavy infections (more than 10,000 eggs per gram of feces), epigastric pain, vomiting, distention, flatulence, anorexia and weight loss may occur. Rarely the *Trichuris* dysentery syndrome may occur, with blood and mucus in the stools and, in heavy infections, prolapse of the rectum. Reduced childhood growth rates, reduced food intake, iron deficiency and gastrointestinal protein loss are seen in heavy infections. The diagnosis is made when numerous worms are seen on the rectal mucosa. A 'honeycomb' effect of the small intestine has appearances similar to Crohn's disease. There may be deformity of the proximal colon and also the ileum or appendix.

Strongyloidiasis (Strongyloides stercoralis)

Strongyloides stercoralis largely causes asymptomatic infection of the small intestine, which can last for 30 years or longer.[48] The prepatent period from infection through the skin to the appearance of rhabditiform larvae in the stools is 1 month or more. Symptoms only develop with high intestinal worm loads, which can be the result of several factors. In people debilitated by concurrent disease or malnutrition, there may be massive invasion of the tissues by *S. stercoralis*. Treatment with immunosuppressive drugs in a patient harboring *S. stercoralis* can also lead to the same effect.[49] Infection with human T-cell leukemia virus 1 is important in predisposing to massive infection by *S. stercoralis*. Infection with HIV is not a common cause of the *Strongyloides* hyperinfection syndrome (see Chapter 127). Symptoms include watery mucous diarrhea, with the severity depending on the intensity of the infection. Sometimes diarrhea alternates with constipation. Malabsorption of fat and vitamin B12 with a chronic diarrhea and protein-losing enteropathy has also been described and is rapidly reversed by treatment.

There are two types of skin rash. The first is larva currens, which occurs on the trunk or near the anus and is a linear eruption in which the larvae migrate under the skin causing an itchy, non-indurated wheal with a red flare that moves rapidly and disappears in a few hours. This contrasts to the indurated and persistent track of nonhuman hookworm larvae (cutaneous larva migrans). The second type of rash is urticaria.

Features of the strongyloidiasis hyperinfestation syndrome (see Fig. 46.3) include severe diarrhea, malabsorption, edema, hepatomegaly and paralytic ileus. Gram-negative sepsis is a recognized complication. In very severe cases encephalopathy and even secondary pyogenic meningitis have been described.

Fasciolopsis buski *infection*

Fasciolopsis buski is confined to Asian countries, particularly Thailand. Symptoms are more frequent in children than adults owing to their greater exposure to water plants while at play. Like many other intestinal parasites, the majority of infected people have very minor symptoms or none at all. In heavier infections, symptoms can include diarrhea, abdominal pain, vomiting, flatulence, poor appetite, eosinophilia and fever. In very severe cases there may be ascites, edema of the face, abdomen and legs, anemia, anorexia, weakness and even intestinal obstruction. Intestinal ulceration may cause malabsorption and lead to malnutrition and wasting.[24]

Heterophyes heterophyes *infection*

Heterophyes heterophyes causes few symptoms unless the infection is heavy, which is dependent on the quantities of pickled or uncooked fish eaten in endemic areas (mostly the Middle and Far East). The adult worms produce abdominal pain, diarrhea with mucus and ulceration of the intestinal wall.

*Beef and pork tapeworm infection (*Taenia saginata *and* Taenia solium*)*

The clinical features of *T. saginata*, the beef tapeworm, and *T. solium*, the pork tapeworm, are similar. The adult worms in the gastrointestinal phase of both organisms usually cause no symptoms, but carriers can sometimes feel a proglottid emerging from the anus; the motile proglottid may be upsettingly obvious in the feces. Other associated symptoms, such as abdominal pain and distension, nausea and anorexia have been attributed to the tapeworm. There is occasionally a mild eosinophilia but there is no anemia, even in long-term infection. Cysticercosis complicates infection with *T. solium* only. Ingestion of *T. solium* eggs leads to the dissemination of oncospheres in the bloodstream; these can become lodged anywhere in the subcutaneous and intramuscular tissues,[50] where they become cysticerci; symptoms depend on the particular body site involved. The clinical findings of neurocysticercosis are discussed in detail in Chapter 168 .

*Dwarf tapeworm infection (*Hymenolepis nana*)*

As with other tapeworms, there are usually few symptoms in *H. nana* infection. Symptoms that may occur include abdominal pain, anorexia, irritability and headache. Eosinophilia is common. Symptoms are more common in heavy infections and may cause growth retardation in children.

*Fish tapeworm infection (*Diphyllobothrium latum*)*

There are few if any symptoms from infection with *D. latum*. Symptoms including diarrhea, headache and non-specific malaise all appear to be somewhat more common than in uninfected people. Tapeworm-associated anemia is probably related to vitamin B12 deficiency caused by competition for the vitamin between the tapeworm and a genetically predisposed host; however, this is now exceedingly rare.

DIAGNOSIS

Microscopic examination of the stool is fundamental to the diagnosis of all the gastrointestinal infections (see Chapter 165). A minimum of three stool specimens, examined by trained personnel using a concentration and a permanent stain technique, should be used.

Amebiasis is often suspected on clinical grounds but confirmation is always required by demonstrating cysts and trophozoites in the stools or trophozoites from the bowel mucosa. Fresh stools examined within 20 minutes for the presence of trophozoites containing ingested red blood cells enables *E. histolytica* to be distinguished from the nonpathogenic *E. dispar*. *Entamoeba hartmanni, Entamoeba coli, Iodamoeba butschlii* and *Endolimax nana* are nonpathogenic amebae, the cysts of which can be distinguished by their size and morphology (see Chapter 164). Material aspirated or scraped from mucosal surfaces at sigmoidoscopy needs microscopic examination. Culture of amebae is possible and allows zymodeme pattern analysis (a reference standard to diagnose and distinguish between *E. histolytica* and *E. dispar*). The polymerase chain reaction (PCR) can also distinguish *E. histolytica* from *E. dispar*. Monoclonal antibodies and DNA probes for this purpose are available in research centers. A recent rapid stool antigen enzyme-linked immunosorbent assay (ELISA) kit, based on antilectin antibodies, is 80% sensitive and 99% specific in diagnosing *Entamoeba* infection; another commercial test is 95% sensitive and 93% specific in distinguishing between *E. histolytica* and *E. dispar* when compared with culture and zymodeme analysis.[51] If this becomes widely accepted it may be useful in the management of asymptomatic carriers, because it would allow discrimination between pathogenic and nonpathogenic strains and avoid unnecessary treatment. Serologic diagnosis of invasive amebiasis is discussed below.

Giardial cysts and sometimes trophozoites are seen in fecal specimens. Multiple fecal specimens are required. A duodenal aspirate, biopsy or string test may sometimes be positive in the presence of negative stool microscopy. Giardial antigens can be detected in feces by a commercially available ELISA with reported sensitivity and specificity of 87–100% compared with microscopy; research laboratories can offer DNA probes or PCR diagnosis. An indirect immunofluorescence test using a cyst-specific anti-*Giardia lamblia* monoclonal antibody has been reported to detect twice the number of positive stool specimens than light microscopy.[52] This may allow more accurate diagnosis from fewer stool samples and obviate the need for biopsy or endoscopy.

Diagnosis of *Cryptosporidium, Cyclospora* and *Isospora* infections relies on identification of the oocysts in feces or on intestinal biopsy. For cryptosporidia, three staining methods are used: auramine, modified Ziehl-Neelsen and immunofluoresence using monoclonal antibodies to the oocysts.[53] Cryptosporidial antigen detection in feces and PCR techniques are research tools at present. Serologic tests are of limited diagnostic use. *Cyclospora* and *Isospora* spp. can be seen by light microscopy and identified by transmission electron microscopy *Isospora* oocysts are stained by modified Ziehl-Neelsen and they fluoresce with phenol auramine stain under ultraviolet light.

Microsporidia are so small that they are hard to detect in stool, but a modified trichrome stain or fluorescent chromotrope stain makes this possible. Histologists are able to visualize the spores in small bowel sections with Giemsa and other stains, but electron microscopy is needed for species identification. The parasitology is covered in detail in Chapter 243 .

The diagnosis of the gastrointestinal helminths depends on the finding and identification of ova, proglottids, larvae or worms in the feces on light microscopy (Fig. 46.4). Eggs are never uniformly distributed,

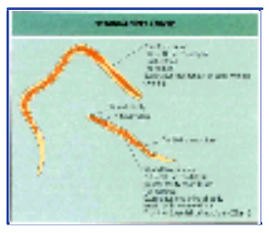

Figure 46-4 *Strongyloides* larvae.

TABLE 46-4 -- Treatment of gastrointestinal protozoal infection.

TREATMENT OF GASTROINTESTINAL PROTOZOAL INFECTION		
Condition	**Drug**	**Dosage**
Amebiasis		
Asymptomatic carrier of intestinal cysts		
1st choice	Diloxanide furoate	500mg q8h for 10 days
2nd choice	Paromomycin (aminosidine)	500mg q8h for 10 days

Intestinal infection (amebic dysentery or ameboma)	Metronidazole	750–800mg q8h for 5 days
	or	
	Tinidazole followed by	2g daily for 2–3 days
	Diloxanide furoate	500mg q8h for 10 days
	or	
	Paromomycin	500mg q8h for 10 days
Amebic liver abscess	Metronidazole	400–500mg q8h for 5–10 days
	or	
	Tinidazole followed by	2g daily for 3–5 days
	Diloxanide furoate	500mg q8h for 10 days
Giardiasis		
1st choice	Tinidazole	2g single dose
	or	
	Metronidazole	400–500mg q8h for 3 days
2nd choice	Albendazole	400mg daily for 5 days
3rd choice	Mepacrine	100mg q8h for 5–7 days
***Balantidium coli* infection**		
1st choice	Tetracycline	500mg q6h for 10 days
Alternatives	Ampicillin, metronidazole or paromomycin	
***Cyclospora cayetanensis* infection**	Trimethoprim-sulfamethoxazole (co-trimoxazole)	960mg q12h for 7 days
***Isospora belli* infection**		
1st choice	Trimethoprim-sulfamethoxazole (co-trimoxazole)	960mg [160mg (TMP)/800mg (SMX)] q12h for 7–10 days (q6h in immunosuppressed patients)
2nd choice (if intolerant to sulfonamides)	Furazolidone	100mg q6h for 10 days
All treatments are adult dosage and given orally unless stated otherwise.		

so a fecal sample should be mixed well before examination. The deposit made by a concentration method is usually used and examined by light microscopy at magnifications of 100 and 400. Chapter 165 discusses methods used in detail. The parasites are identified by appearance and size. Culture can be undertaken for *S. stercoralis*.

Serologic tests for the intestinal protozoa and helminths are helpful only in the diagnosis of amebiasis, strongyloidiasis, invasive giardiasis and cysticercosis (but not intestinal tapeworm infection). The amebic immunofluorescent antibody test is positive in 95% of cases of amebic abscess by the end of the first 14 days of illness. However, there are some false-positive results in nonamebic liver disease, so a cellulose acetate precipitin test is done to confirm the diagnosis. Anticysticercal antibodies have a useful role in the diagnosis of neurocysticercosis (see Chapter 168).

An ELISA for *Strongyloides* is useful in screening patients who have suggestive symptoms or eosinophilia. Cross-reactions occur occasionally with ascariasis and filarial infection. The filarial ELISA cross-reacts in some cases of strongyloidiasis. Serum antigiardial antibody detection is not clinically useful in highly endemic areas because people may be seropositive from past infection. The giardial immunofluorescent antibody test gives good titers if the disease has caused mucosal damage, and it is helpful in the investigation of parasite-associated malabsorption.

MANAGEMENT

Gastrointestinal protozoa

The management of gastrointestinal protozoa is summarized in Table 46.4 . Treatment regimens are discussed in detail in Chapter 209 .

Entamoeba histolytica (see Chapter 164)

Treatment of *E. histolytica* infection is divided into two types. Luminal amebicides, such as diloxanide furoate, act on organisms in the intestinal lumen and are not effective against organisms in tissue. Tissue amebicides, such as metronidazole and tinidazole are effective in treating invasive amebiasis but less effective in the treatment of organisms in the bowel lumen. There is some controversy about treating asymptomatic patients. Ideally, any amebic cysts should be tested to identify whether it is *E. histolytica* (in which case the infection should be treated to avoid the risk of developing invasive disease and to prevent secondary spread) or *E. dispar* (which does not require any treatment). However, until newer ELISA or monoclonal antibody tests become widely available it will continue to be usual to treat asymptomatic patients in nonendemic areas with diloxanide furoate 500mg orally q8h for 10 days (see Table 46.4). When asymptomatic cyst carriage persists after treatment for amebic dysentery or liver abscess, further treatment with a luminal amebicide is mandatory, otherwise relapse is frequent. The treatment of asymptomatic cyst carriers in endemic areas is of questionable value because of the high rate of re-infection. A second-choice intraluminal amebicide is paromomycin 500mg orally q8h for 10 days.[54] New broad-spectrum antiparasitic agents are being introduced as infection with multiple parasites is a common occurrence in the tropics. Nitazoxanide, a compound structurally similar to nitrobenzamide, is reported to act on a wide range of intestinal parasites, including some cestodes, nematodes and protozoa. In a study in Mexican children, Davila-Gutierrez reported a higher eradication rate for treatment of *E. histolytica/ dispar* with nitazoxanide 100mg twice daily for 3 days than with quinfamide 100mg as a single dose.[55] Further work is needed to determine whether or not nitazoxanide will become a first-line treatment for amebic cyst passage.

Proven amebic dysentery should always be treated. Drugs of choice are metronidazole (750–800mg orally q8h for 5 days) or tinidazole (2g daily for 2–3 days) followed by diloxanide furoate (see Table 46.4). Amebic liver abscess is treated with metronidazole, 400–500mg orally q8h, followed by diloxanide furoate as above. Tinidazole (2g daily orally for 3–5 days) is an alternative; chloroquine (150mg base q6h for 2 days then 150mg base q12h for 19 days) can also be used.

Giardia lamblia (see Chapter 242)

Treatment is often unnecessary because most healthy, immunocompetent patients have a self-limiting disease and recover by their own natural host defense mechanisms. Treatment of symptomatic patients reduces the duration and severity of symptoms. The treatment of asymptomatic cyst carriers is controversial in endemic areas. Generally, in a nonendemic area, asymptomatic *Giardia* cyst carriers are treated. The 5-nitroimidazole derivatives metronidazole or tinidazole are the treatment of choice and can be used in short courses.[35] Albendazole, 400mg daily for 5 days, has been shown to have useful antigiardial activity. Mepacrine, an acridine dye, has a similar efficacy but is generally less well tolerated with an incidence of 1.5% of acute psychosis. Furazolidone, a nitrofuran, has lower efficacy but is well tolerated. *In vitro* and *in vivo* resistance of *G. lamblia* has been demonstrated, although rarely, to conventional therapy, particularly to the 5-nitroimidazoles such as metronidazole and tinidazole.[56]

Blastocystis hominis

If *B. hominis* is present in the stool, the physician must not stop looking for another cause of diarrhea. Whether any treatment is required is controversial. Metronidazole

seems to be the most appropriate drug.

Dientamoeba fragilis

In adults infected with *D. fragilis*, improvement can be seen with tetracycline; in children, metronidazole is appropriate.

Balantidium coli

Tetracycline, 500mg four times a day for 10 days, is effective against *B. coli*. Doxycycline 100mg daily for 10–14 days is an alternative. Other drugs to which *B. coli* is sensitive are ampicillin, metronidazole and paromomycin. Surgery may be required for fulminant disease with perforation or abscess formation.

Cryptosporidium parvum (see Chapter 127)

Cryptosporidium parvum infection is self-limiting in those who have normal immunity. It presents a severe problem when it occurs in patients who have AIDS.[40] Where available, treatment is with HAART (highly active antiretroviral therapy) with or without antiparasitic agents. No currently available drug reliably eradicates cryptosporidial infection, but suppression of infection is possible. Agents currently in use are paromomycin, azithromycin and nitazoxanide.

Cyclospora cayetanensis

Many cases of *C. cayetanensis* infection are self-limiting. When treatment is felt to be necessary trimethoprim-sulfamethoxazole (co-trimoxazole) 960mg (160mg TMP/800mg SMX) q12h for 7 days has been found to be effective eradicating the oocysts from 94% of 16 patients in 7 days compared with 12% of 17 patients who received placebo.[57] Relapse is common in the immunocompromised but responds to a second course of treatment. Given the propensity of sulfonamide-containing drugs to cause side-effects in HIV-infected individuals, an alternative agent to co-trimoxazole is required. Verdier *et al* compared the activity of trimethoprim-sulfamethoxazole (TMP-SMX) 160/800mg orally twice daily for 1 week with ciprofloxacin 500mg twice daily for 1 week in HIV-positive patients infected with *Cyclospora cayetanensis*. [58] Nine received TMP-SMX and 11 received ciprofloxacin. Diarrhea ceased in all patients receiving TMP-SMX and in 10 of 11 patients receiving ciprofloxacin. At 7 days all those who received TMP-SMX had negative stool examinations, four of 11 treated with ciprofloxacin had persisting oocysts, one of whom still had diarrhea. All four responded to open treatment with TMP-SMX. Patients who had shown a complete response at 7 days were given maintenance therapy with TMP-SMX 160/800 three times weekly or ciprofloxacin 500mg three times weekly for 10 weeks. No recurrences were observed in the TMP-SMX group but one of seven patients who received ciprofloxacin experienced a recurrence after 4 weeks. Whilst ciprofloxacin is not as effective as TMP-SMX against *Cyclospora*, it provides an acceptable alternative for individuals who cannot tolerate a sulfonamide.

Isospora belli

Treatment of *I. belli* infection may be necessary in the immunocompromised, when oral trimethoprim-sulfamethoxazole 960mg (160mg TMP/800mg SMX) q6h daily for 7–10 days eliminates the parasite in most cases; relapse is common but retreatment is usually effective. Prophylactic trimethoprim-sulfamethoxazole may then be necessary. Pyrimethamine-sulfonamide combinations have also been proved to be effective.[59] If the patient is intolerant to sulfonamides, furazolidone 100mg four times daily for 10 days is an alternative. The macrolide antibiotic roxithromycin (2.5mg/kg every 12 hours) was reported to be successful in a single patient with AIDS and *I. belli* infection who had not responded to co-trimoxazole or pyrimethamine therapy. The 5-nitrothiazole derivative nitazoxanide is also reported to

TABLE 46-5 -- Treatment of gastrointestinal helminthic infection.

TREATMENT OF GASTROINTESTINAL HELMINTHIC INFECTION		
Condition	**Drug**	**Dosage**
Nematodes		
Round worms		
Ascaris lumbricoides	Albendazole	400mg, single dose
	Mebendazole	100mg q12h for 3 days
	Levamisole	150mg, single dose
	Piperazine hydrate	4.5g, single dose
Enterobius vermicularis	Mebendazole	100mg, single dose
	Piperazine phosphate	4g, single dose
	Pyrantel pamoate	10mg/kg, single dose
Hookworms		
Ancylostoma duodenale	Mebendazole	100mg q12h for 3 days
Necator americanus	Albendazole	200mg q24h for 3 days
	Levamisole	150mg, single dose (less effective against *N. americanus*)
	Pyrantel pamoate	10mg/kg, single dose
Trichuris trichiura	Mebendazole	100mg q12h for 3 days or 600mg, single dose
	Albendazole	400mg, single dose
Strongyloides stercoralis	Ivermectin	200µg/kg, single dose
	Albendazole	400mg q12-24h for 3 days
	Thiabendazole	25mg/kg (max 1.5g) q12h for 3 days
Trematodes (flukes)		
Fasciolopsis buski	Praziquantel	15mg/kg, single dose
Heterophyes heterophyes	Praziquantel	10–20mg/kg, single dose
Cestodes (tapeworms)		
Taenia solium	Praziquantel	10mg/kg, single dose
Taenia saginata	Niclosamide	2g, single dose
Hymenolepis nana	Praziquantel	20mg/kg, single dose
	Niclosamide	2g on day 1 then 1g/day for 6 days
Diphyllobothrium latum	Praziquantel	10mg/kg, single dose
	Niclosamide	2g, single dose
All treatments are adult dosage and given orally unless stated otherwise.		

be effective in isosporiasis in a dose of 7.5mg/kg (500mg for adults; 200mg for children less than 12 years of age) twice daily for 3 days. Biliary isosporiasis may require intravenous co-trimoxazole as both oral co-trimoxazole and oral nitazoxanide have been reported to fail in the presence of malabsorption and cholangitis due to

Isospora belli.[60] [61]

Microsporidia

The treatment of microsporidiosis in the immunocompetent is not required. Evidence and experience in treating these infections comes from HIV-infected patients (see Chapter 127) where albendazole has been shown to be useful with some species of microsporidia, notably *Encephalitozoon intestinalis*, and fumagillin has shown activity against *Enterocytozoon bieneusi* [62]

Gastrointestinal helminths

The management of gastrointestinal helminths is summarized in Table 46.5 (see Chapter 209).

Ascaris lumbricoides

Treatment is effective only against the adult worm. It is usual to treat any established infection. The drugs used are albendazole (400mg, single dose), mebendazole (100mg q12h for 3 days), levamisole (150mg, single dose) or piperazine in a single adult dose of 4g of piperazine phosphate or 4.5g of piperazine hydrate, or pyrantel pamoate in a single dose of 10mg/kg. *Ascaris* pneumonitis responds dramatically to prednisolone therapy and anthelmintics should be given for 2 weeks after lung involvement. Surgery is sometimes required for bowel perforation or obstruction.

Enterobius vermicularis

Enterobius vermicularis infection is treated with mebendazole (100mg, single dose, which is repeated if necessary after 2–3 weeks), piperazine phosphate (4g, single adult dose repeated after 14 days) or pyrantel pamoate (10mg/kg, single dose). The whole family should be treated simultaneously, fresh bedlinen and night clothes should be provided and the nails kept short and scrubbed. Repeat treatment may be required because recurrence is common.

Hookworm

Hookworm infection is treated by eliminating the adult worms and treating anemia if present; these treatments can be carried out concurrently. In endemic countries where re-infection is inevitable, light infections are treated only in children, not in adults. Mebendazole (100mg q12h for 3 days) or albendazole (400mg, single dose) are effective against both *A. duodenale* and *N. americanus*. In a single-dose comparison of albendazole and mebendazole, albendazole gave better cure and egg reduction rates. [63] Levamisole (150mg orally, single dose) is less effective against *N. americanus*, and pyrantel pamoate (10mg/kg orally) is preferred. In a study from Ivory Coast, Utzinger *et al* reported a reduction in the prevalence and intensity of hookworm infections in schoolchildren receiving praziquantel for *Schistosoma mansoni* infection. If their results are replicated they will have a significant impact upon helminth control programmes.[64]

Trichuris trichiura

In symptomatic patients and in asymptomatic carriers who have high numbers of eggs, trichuriasis is treated with mebendazole (100mg q12h for 3 days or 600mg, single dose) or albendazole (400mg, single

dose). In undernourished children who have moderate infection intensities in Jamaica, albendazole treatment also resulted in improvement in some tests of cognitive ability and in school attendance and school performance, even after controlling for socio-economic status.[65]

Strongyloides stercoralis

Strongyloides stercoralis infection should be treated in both symptomatic and asymptomatic people because of its ability to cause hyper-infection if immunosuppression occurs. Ivermectin is the drug of choice (200µg/kg orally, single dose). This regimen has proven very effective in a prospective randomized trial comparing the efficacy of ivermectin and thiabendazole in Cambodian refugees who had symptomatic chronic strongyloidiasis.[66] Ivermectin also looks very promising in HIV-positive patients infected with *S. stercoralis* (see Chapter 127). Albendazole, 400mg once or twice daily for 3 days, is also effective. Thiabendazole, 25mg/kg (maximum 1.5g) orally twice daily for 3 days, is effective but often poorly tolerated. Subcutaneous ivermectin (unlicensed in humans) has proven effective in a case of life-threatening *Strongyloides* hyperinfestation.[67]

Fasciolopsis buski

Fasciolopsis buski infection is treated with praziquantel (15mg/kg orally), which is highly effective. Niclosamide (2g orally, single dose) has also been used.

Heterophyes heterophyes

Heterophyes heterophyes infection is treated with a single dose of praziquantel (10–20mg/kg orally). Niclosamide is an alternative.

Taenia solium *and* Taenia saginata

Patients who have *T. solium* infection should be evaluated for the presence of cerebral cysticercosis before commencing therapy against the intestinal tapeworm. Praziquantel (10mg/kg, single dose) is effective therapy for the adult worm. Niclosamide (2g, single dose) has also been widely used.

Hymenolepis nana

Hymenolepis nana infection can be treated with a single oral dose of praziquantel (20mg/kg). Niclosamide (2g on day 1, then 1g daily for 6 days) is also successful.

Diphyllobothrium latum

Diphyllobothrium latum infections are treated with praziquantel (10mg/kg, single dose). Niclosamide (2g, single dose) was extensively used in the past.

Chapter 47 - Peritonitis, Pancreatitis and Intra-abdominal Abscesses

Joseph S Solomkin

INTRODUCTION

Intra-abdominal infections are common problems, ranging in severity from acute appendicitis to peritonitis from colonic perforation. There have been important advances in supportive care, diagnostic methods, anti-infective therapy and interventional techniques and these have generated both improved care and new controversies in management. Most notable is the role of routine noninvasive imaging for suspected intra-abdominal infections and the role of percutaneous or laparoscopic intervention in place of formal laparotomy. The continuing development of new antibiotics has provided new opportunities for tailoring therapy to the requirements of the individual patient.

The primary effect of these innovations has been on more accurate diagnosis and reduced morbidity, measured as length of stay. It is likely that percutaneous abscess drainage for various diseases has lessened mortality. However, even with application of state-of-the-art care, these infections can result in considerable morbidity and mortality.

Additional complexity surrounds the care of hospitalized patients for whom intra-abdominal infection occurs following elective or emergency abdominal operation. These patients are typically infected with a more difficult to treat flora and represent the current frontier in therapeutic research.

CLINICAL ASPECTS OF CARE FOR PATIENTS WITH INTRA-ABDOMINAL INFECTIONS

Diagnosis of intra-abdominal infection

The history and physical examination of patients suspected of having intra-abdominal infection are pivotal in defining the urgency of intervention and for guiding decisions regarding use of the available diagnostic techniques. A brief history should be taken during the examination and should determine how long the patient has been ill, where the pain is located, whether it has changed location or character, whether associated with anorexia, vomiting or obstipation, and whether the patient has been aware of fever or chills. A pertinent past medical history, including recent hospitalizations, medications, chronic disease diagnoses and prior operations, should also be obtained.

Plain radiographs of the abdomen may reveal free air on an upright abdominal or lateral decubitus film if a ruptured hollow viscus is the cause of peritonitis. A left lateral decubitus view, with the patient in this position for 5 or more minutes, is a sensitive test for free air (Fig. 47.1a). Other findings from plain radiographs support the diagnosis of intra-abdominal infection include pneumatosis intestinalis (Fig. 47.1b), bowel obstruction and a mass effect. There are benign causes of pneumatosis. More dramatic but less common findings are air in the portal vein (Fig. 47.1c) or extraluminal gas collections indicative of an abscess; these radiographic signs are sufficiently specific to justify immediate intervention.

The radiologic picture of intra-abdominal infection otherwise mimics that of paralytic ileus. Inflammatory exudate and edema of the intestinal wall produce widening of the space between adjacent bowel loops noted on a flat film of the abdomen. Peritoneal fat lines and the retroperitoneal psoas shadow, however, may be obliterated because of edema.

Surgical management of diffuse peritonitis

Physical findings and the patient's history routinely provide sufficient diagnostic accuracy to obviate further testing beyond plain radiographs. The primary management problem in these patients is usually hemodynamic resuscitation prior to and during operation. In the presence of continuing soiling and continuing absorption of toxins through diaphragmatic lymphatics, hemodynamic stability will not be attained until an operation is performed, and resuscitation must continue intraoperatively.[1] [2]

Operative management of peritonitis involves evacuation of all purulent collections. Perforated bowel should be resected. Controversies in the operative management of peritonitis primarily surround whether or not to perform a colonic anastamosis or ostomy, and appropriate wound closure method.[3] [4] [5] [6] [7]

Wound closure following laparotomy for diffuse peritonitis

Patients with diffuse peritonitis secondary to colonic perforation or anastomotic dehiscence typically develop abdominal wall edema as part of a generalized syndrome of increased capillary permeability. Primary closure of the abdominal incision in such patients may be difficult or even unwise. Increased intra-abdominal pressure can result in compression of mesenteric and renal veins, leading in some instances to acute renal failure or bowel necrosis. This has been defined as the abdominal compartment syndrome and patients become at risk for this when intravesicular pressures (measured through a Foley catheter) exceed 25mmHg.[8] [9] This situation can be handled by insertion of a fascial prosthesis. Abdominal wall and visceral edema typically resolves over the first week, at which time definitive closure of the abdomen can be performed.

Planned relaporotomy for diffuse peritonitis

In the 1980s, considerable work was done exploring scheduled or planned relaporotomy for diffuse peritonitis.[10] [11] [12] The notion driving this was that repetitive laparotomy would allow abdominal irrigation and thereby prevent recurrent abscess formation. However, as experience accumulated, it became clear that mortality was not decreased and that there was a substantial increase in the incidence of intestinal fistulas.[13]

Postoperative peritonitis

Postoperative peritonitis is usually due to a leak from a suture line and is typically discovered only after some delay, as a rule between the fifth and seventh postoperative days.[14] Delay in diagnosis contributes to a high mortality rate. The high mortality of anastomotic leakage or suture line breakdown after duodenal operations is explained by the fact that the duodenum is fixed in the retro-peritoneum, cannot be exteriorized and the source of infection often

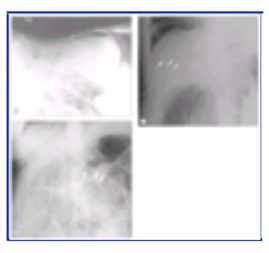

Figure 47-1 (a) Left lateral decubitus radiograph demonstrating free air outlining the liver. (b) Pneumatosis coli. (c) Air in the portal vein.

cannot be adequately controlled or closed. Consequently, infective material and proteolytic enzymes are continuously delivered into the peritoneal cavity, sustaining the infection. Drainage, controlled fistula formation, exteriorization, repair or resection and reanastomosis are employed as indicated.

Tertiary peritonitis

Patients in whom peritonitis and sepsis initially have been controlled operatively, and in whom bacteria have been eliminated by successful antibiotic therapy, may progress, a state in which host defense systems are hypothesized to produce a syndrome of continued systemic inflammation.[15]

The clinical picture is one mimicking occult sepsis, as manifested by a hyperdynamic cardiovascular state, low-grade fever and general hypermetabolism. The patient has the clinical picture of sepsis without radiographically demonstrable infection. Such patients sometimes are subjected to laparotomy seeking to provide drainage of anticipated recurrent or residual collections of infected fluid. On operation, no localized infection is identified. Management is generally supportive and any identified micro-organisms should be treated. It is important to note that this was first identified in patients managed by an open abdomen technique, patients with an ongoing serositis from such exposure.

Diagnostic imaging for suspected intra-abdominal infections other than peritonitis

In the absence of physical findings of diffuse peritonitis, diagnostic imaging with either computed tomography (CT) or ultrasound should be routinely performed in patients with clinically suspected intra-abdominal infection. The urgency is dictated by the degree of hemodynamic instability present, but in any case should be evaluated within hours.

Computed tomography is the single best modality for fully evaluating the extent of disease in most situations. Ultrasound is quite versatile and is portable, allowing procedures to be performed in the ICU. Ultrasonography is limited by bowel gas, body habitus and lower sensitivity for retroperitoneal processes and parenchymal infection. Usually the choice of modality is based on the experience and preference of the interventional radiologist.

When feasible, nonoperative (i.e. percutaneous) drainage of pus is preferable to open surgical intervention. This is because of the initial deterioration that almost always occurs following operative manipulation of intra-abdominal infection. Percutaneous drainage of an

intra-abdominal abscess is usually successful if the following criteria are met:

- there is a well-established fluid collection;
- a safe route of access is available;
- joint evaluation by a surgeon and a radiologist; and
- immediate operative back-up available in case of failure or complications.

Percutaneous drainage procedures for intra-abdominal abscesses

Percutaneous drainage and operative intervention are best viewed as complementary rather than competitive techniques. There are many situations for which percutaneous drainage is the definitive procedure of choice, others for which surgery alone is indicated and some for which both techniques are applicable, alone or in conjunction. Inflammation may manifest as a phlegmon (viable inflamed tissue), a liquefied abscess, infected necrotic (nonviable) tissue or a combination. Liquefied abscesses are drainable, whereas phlegmonous and necrotic tissue is not. Decisions regarding which modality to employ are largely based on CT findings. Specific indications for percutaneous drainage have expanded significantly over the past decade and now include multiple and/or multiloculated abscesses, abscesses with enteric communication and infected hematomas.[16]

It is important to define the goals of the procedure in evaluating indications and success. A cure is achieved when the abscess is resolved by the drainage procedure. Temporization refers to resolution of an abscess and clinical improvement, with operative intervention needed to treat the underlying cause.[17] Palliation refers to improvement in the patient's condition due to abscess drainage, despite the presence of a rapidly fatal underlying condition. We consider temporizing and palliative results to represent success.

It is important that the drainage route does not cross a sterile fluid collection or other infected space due to the risk of cross-contamination. Crossing the pleural space for thoracic and upper abdominal drainage carries the risk of empyema formation.

In most cases drainage is performed following fine needle (18–22 gauge) aspiration, with the aspirate being used to document infection and gauge the viscosity of the fluid. For most collections, a drain should be placed to ensure complete evacuation and minimize the chance of recurrence. The aspiration needle can be used for placement of a guide wire or as a guide for tandem insertion of the drain. If the patient is not already on antimicrobial therapy, this should be instituted prior to the drainage procedure to minimize the infectious complications of contaminating sterile tissue.

The choice of catheter size is determined primarily by the viscosity of the fluid to be drained. In the majority of cases, 8–12F drains are sufficient. Larger drains may be needed for collections containing debris or more viscous fluid. Drains of larger caliber can be placed, if needed, by exchange over a guide wire. There is no absolute limit on the number of drains that can be placed. While most abscesses can be drained with a single catheter, there should be no hesitation in placing as many drains as are needed to effectively evacuate the abscess(es).

Following catheter placement, the cavity should be evacuated as completely as possible and irrigated with saline until the fluid is clear. Initial manipulation of the catheter(s) and irrigation should be done as gently as possible to minimize the induction of bacteremia. Immediate imaging determines the need for repositioning of the catheter or for placing additional drains. For cavities that are completely evacuated at the initial drainage and for which there are no abnormal communications to viscera, simple gravity drainage generally suffices. For larger or more viscous collections and those with ongoing output due to fistulous connections, suction drainage with sump catheters is more effective.

MANAGEMENT OF SPECIFIC INTRA-ABDOMINAL INFECTIONS

Colonic diverticulitis

In cases with abscesses complicating diverticulitis, percutaneous drainage usually permits stabilization and allow time to optimally prepare the patient for operative therapy.[14] [18] [19] [20] Subsequent operation is indicated in most, but not all, patients and is generally simplified to a one-step procedure. In some patients who remain asymptomatic following drainage, such as those with other ultimately fatal diseases, subsequent colectomy may be avoided. It is important to perform follow-up radiographic studies to exclude the possibility of a perforated neoplasm. Initial concerns regarding persistent fecal fistulas have not been borne out by clinical experience.

The results of percutaneous drainage for abscesses complicating Crohn's disease are less positive.[21] Patients without fistulous communications to the bowel are usually cured by percutaneous drainage, whereas those with fistulas generally require bowel resection. Among

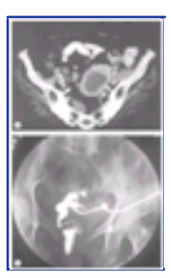

Figure 47-2 Diverticular abscess (a) before and (b) after drainage. A small fistula is seen that required further drainage but did not interfere with planned interval colectomy.

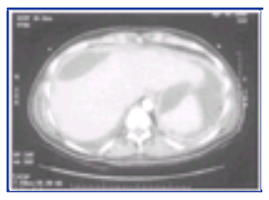

Figure 47-3 Multiple intra-abdominal abscesses following appendectomy of perforated appendicitis.

patients requiring operation, initial percutaneous drainage usually leads to significant clinical improvement and permits performance of a one-stage operation. There are no reports of iatrogenic enterocutaneous fistulas.

Low pelvic abscesses in contact with the rectum or vagina may be treated surgically by incision and drainage through these organs. The same approach can be taken using sonographic guidance and recent advances in endoluminal ultrasound techniques have facilitated such procedures. Experience with ultrasound-guided transrectal and transvaginal drainage is growing and these procedures appear to be effective and well tolerated. Good success also has been achieved in the management of tubo-ovarian abscesses complicating pelvic inflammatory disease that are refractory to medical management. In many such cases, the need for hysterectomy and oophorectomy has been obviated.

Infections complicating acute pancreatitis

Acute necrotizing pancreatitis is the antecedent cause of pancreatic infection in the majority of cases. Secondary infection of a pancreatic pseudocyst and abdominal trauma with pancreatic injury are other important causes. Abdominal pain, nausea, vomiting, distention and absent bowel sounds are frequently present. Abdominal tenderness along with a temperature greater than 102.2°F (39°C) is also very commonly present.

Pancreatic abscesses are polymicrobial, the common organisms being aerobic representatives of the fecal flora.[22]

The role of percutaneous and operative management of infection complicating necrotizing pancreatitis is in rapid flux. Pancreatic abscesses have a high failure rate with percutaneous drainage; therefore, open surgical drainage is currently preferred. The approach is transperitoneal and involves radical debridement of all necrotic tissues, followed by irrigation with saline and placement of large-bore sump suction drains. The availability of follow-up imaging and percutaneous drainage has done away with a strategy of repetitive laparotomy (every 24–48 hours). Patients are now most commonly managed with a single operative debridement, abdominal closure and expectant management. Percutaneous drainage, if needed, is utilized for peripheral or residual fluid collections.

However, there are reports that initial management by percutaneous drainage, followed by operative intervention for treatment failures, is associated with reduced mortality.[23] [24]

For localized (acute or chronic) fluid collections, percutaneous drainage is successful in most cases. Fistulous communications to the

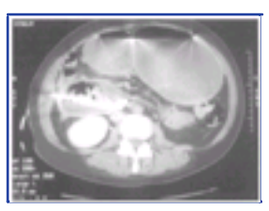

Figure 47-4 Pancreatic drainage for lesser sac infection during the course of acute necrotizing pancreatitis. The difficulty in removing necrotic debris through the narrow catheter is suggested by the abscess's persistence. Follow-up operative intervention was required.

pancreatic duct are commonly present but may be difficult to document radiographically. [25] To minimize the risk of recurrence with pancreatic fluid collections, it is especially important to document complete cessation of drainage (<25ml/day) prior to removing drains. Endoscopic retrograde cholangiopancreatography (ERCP) is valuable to document patency of the pancreatic duct, since fistulas associated with downstream obstruction are unlikely to heal and generally require operation.

Antimicrobial chemotherapy for patients with infections complicating pancreatitis should be guided by cultures of the pancreatic bed. Often patients are sequentially infected with Gram-negative enteric flora, then Gram-positive, methicillin-resistant organisms and finally *Candida* species.

Biliary infections, including acalculous cholecystitis

Ascending cholangitis, which results from biliary obstruction and secondary bacterial infection, typically presents with the clinical triad of fever, chills and jaundice. Relief of obstruction should be performed on an emergency basis. Imaging is performed to document biliary obstruction and identify the cause. The diagnosis of biliary obstruction is based on demonstration of abnormal dilatation of the common bile duct and/or its tributaries. Ultrasound is the best modality for demonstrating biliary dilatation and may also demonstrate ancillary findings such as ductal wall thickening or intraluminal gas or pericholecystic fluid collections. Intravenous contrast administration is needed to document biliary dilation with CT.

Common causes of biliary obstruction include ductal calculi, benign strictures, adenopathy and neoplastic diseases (pancreatic carcinoma, cholangiocarcinoma). Ultrasound is extremely sensitive in detecting stones in the gallbladder, but less sensitive (55%) in detecting common duct calculi. Computed tomography is less sensitive than ultrasound in identifying stones, as stones often have the same radiographic density as the surrounding bile, but superior to ultrasound for demonstrating underlying pancreatic diseases, whether inflammatory or neoplastic.

There are several pitfalls in the diagnostic imaging of cholangitis. Early obstruction may present without demonstrable biliary dilatation. Conversely, a dilated bile duct may not be functionally obstructed, but rather the dilation may be due to prior biliary obstruction with resultant ectasia. Clinical and laboratory signs of

biliary obstruction (i.e. jaundice, hyperbilirubinemia, elevated serum alkaline phosphatase activity) are generally adequate to distinguish between obstructive and nonobstructive biliary dilatation. Patients who have undergone prior biliary bypass or sphincterotomy may have gas in the biliary tree without infection.

Direct visualization of the biliary tree, via percutaneous trans-hepatic cholangiography (PTC) or ERCP, is often utilized for both diagnostic and therapeutic purposes. A thorough discussion of the relative merits of these two techniques is beyond the scope of this chapter. In most cases, cross-sectional imaging is sufficient for diagnostic purposes and intervention is utilized for therapy. If biliary obstruction is strongly suspected on clinical grounds and imaging does not demonstrate dilatation, direct visualization of the duct may be warranted to identify early nondilated obstruction. Both studies (ERCP and PTC) require transportation of the patient to a fluoroscopy suite. ERCP is less invasive and generally is the initial procedure of choice for distal obstruction, whereas PTC may be more useful for proximal obstructions. To a large extent, the choice of modalities rests with the expertise of available personnel.

Intra-abdominal infections in postoperative patients

Postoperative peritonitis generally is a consequence of anastomotic dehiscence. This is a highly lethal condition, in part because it is often diagnosed late because of reluctance to entertain the possibility of a suture line leak. This diagnosis should be considered in any patient with signs of sepsis who has undergone a gastrointestinal anastomosis. Typical findings of diffuse abdominal tenderness may be masked by incisional pain. Because laparotomy itself introduces free air into the abdominal cavity, pneumoperitoneum is a nonspecific finding in patients during the first few days after celiotomy. The most common error is to ascribe clinical deterioration to pulmonary processes that often are a consequence of peritonitis.

Ultrasound or CT will reveal peritoneal fluid which, if present, should lead to ultrasound-guided aspiration for diagnostic purposes. A Gram stain that reveals white cells or bacteria is an indication for immediate laparotomy. Surgical treatment should include either reanastomosis (small bowel) or end colostomy (colon). Postoperative

abscesses are managed as detailed above.

Management of drainage catheters

Drains should be checked regularly (at least daily) to monitor the volume and nature of the output, ensure adequate function and clinical response. Most authorities recommend periodic irrigation of the drains, once or several times per day, with sterile saline. Fibrinolytic agents may be useful for evacuation of fibrinous or hemorrhagic collections. The need for follow-up imaging studies should be determined on a case-by-case basis by monitoring clinical progress and drainage output.

Catheters should be removed when criteria for abscess resolution are met. Clinical criteria of success include resolution of symptoms and indicators of infection (fever, leukocytosis).[26] Catheter-related criteria include a decrease in daily drainage to less than 10ml and a change in the character of the drainage from purulent to serous. Radiographic criteria include documentation of abscess resolution and closure of any fistulous communications. If catheters are maintained until these criteria are satisfied, the likelihood of recurrence of the abscess will be minimized; we usually remove the drain in one step and have had no significant problem with recurrence. For sterile fluid collections, the drain should be removed as soon as possible, generally within 24–48 hours, to minimize the risk of superinfection.

Mechanical causes of failure

In evaluating the causes of percutaneous drainage failure, a number of factors are consistently identified. Among these are fluid that is too viscous for drainage or the presence of phlegmonous or necrotic debris. Technical modifications such as increasing the drain size and irrigation can salvage some of these procedures. Recognition of phlegmonous or necrotic tissue on follow-up imaging studies may lead to cessation of attempts at percutaneous drainage or a modification of the expected goal. Multiloculated collections and multiple abscesses are another cause of failure that can be minimized by using an adequate number of catheters along with mechanical disruption of adhesions with a guide wire. Fistulous communications, either unrecognized or persistent, are yet another potential cause of failure, as is drainage of a necrotic tumor mistaken by imaging to represent an abscess. Recognition of a significant soft tissue component, maintenance of a high index of suspicion and the use of percutaneous biopsies can minimize the risk of failing to appreciate the presence of tumor. Suspicious fluid also may be sent for cytology. The success rate for percutaneous drainage tends to be lower in immunocompromised patients. Lambiase *et al* found a cure rate of 53% in immunocompromised patients (including those with alcoholism, AIDS, diabetes, renal failure or steroid use) as compared to 73% in immunocompetent patients.[27]

Operative management of abscesses

The indications for open surgical drainage are failure of percutaneous drainage, inability to safely drain percutaneously, the presence of a pancreatic or carcinomatous abscess, an association with a high-output bowel fistula, the involvement of the lesser sac or the presence of multiple, isolated interloop abscesses. Abscesses in the pelvis usually are drained directly through the rectum or vagina, obviating the need for either percutaneous drainage or an abdominal operation.

Confirmation of the presence of pus is obtained by needle aspiration. It is essential to obtain specimens of the abscess content for Gram stain, aerobic and anaerobic culture and sensitivity studies. All of the abscess contents should be evacuated by suction.

After percutaneous or open drainage of an abscess, the drains are left in place until external drainage stops or is clear. The drainage track should then be irrigated and a sinogram obtained to document collapse of the cavity before the drains are moved. It may take 2–3 weeks for a large cavity to become small enough to permit drains to be removed.

THE MICROBIOLOGY OF INTRA-ABDOMINAL INFECTION

Normal bowel flora

The morbidity and mortality of intra-abdominal infection vary dramatically depending upon the level of GI tract perforation. This is because the number and type of micro-organisms vary throughout the GI tract.[28] Under normal circumstances the stomach contains less than 10^3 bacteria per mm^3 , a consequence of the very low pH within the stomach. When patients receive drugs such as H_2 blockers that raise gastric pH, the number of bacteria rapidly approaches the levels seen in the proximal small bowel. The number of bacteria per mm^3 increases as one moves down the GI tract. In the proximal small bowel there are ~$10^{4–5}$ bacteria per mm^3 , whereas the terminal ileum contains more than 10^9 per mm^3 . The highest absolute numbers of bacteria are found within the colon where there are between 10^{10} and 10^{12} bacteria per mm^3 .

Not only does the number of bacteria change, but also the type of bacteria. In the upper gastrointestinal tract facultative and aerobic Gram-negative bacteria predominate, while the colon contains many logs more anaerobic than aerobic bacteria. In the colon one finds both Gram-negative and Gram-positive anaerobic bacteria, along with facultative aerobes. Furthermore, the number of species of

bacteria isolated also is highest in the colon where there are more than 500 species of bacteria and fungi.

The vast majority of the bacteria in the colon are anaerobic species that contribute little to clinical intra-abdominal infection. The most common bacteria isolated in clinical infections are *Escherichia coli*, followed by *Enterobacter*, *Klebsiella* and *Pseudomonas* species (Table 47.1). These organisms make up less than 0.1% of the normal colonic flora. Even the most common anaerobic pathogen, *Bacteroides fragilis*, accounts for only 1% of the colonic flora. The presence of large numbers of nonpathogenic bacteria provides a measure of protection to the host by suppressing the growth of potentially pathogenic bacteria. Overgrowth of pathogenic Gram-negative aerobic bacteria is commonly seen following treatment with broad-spectrum antibiotics.[29] Many of these bacteria are associated with nosocomial infections which are much more difficult to eradicate.

Synergism involving aerobic and anaerobic bacteria

Among facultative and aerobic bacteria, Gram-negative species of the Enterobacteriaceae, particularly *E. coli, Klebsiella* and *Enterobacter* spp. predominate. Among anaerobic bacteria, the most common isolates are *Bacteroides* species. To gain insight into the relative contribution of each bacterial class experimental models were developed and investigations performed in the laboratory. [30] If pure cultures of *E. coli* were injected into animals, peritonitis developed in all animals, was associated with a high incidence of *E. coli* bacteremia and significant mortality. However, injection with *E. coli* alone did not cause any intra-abdominal abscesses, which are usually seen in patients who survive the diffuse inflammatory phase of peritonitis. In contrast, if *Bacteroides fragilis* was injected in the same experimental model, there was almost no mortality, very few *B. fragilis* recovered from the bloodstream, but nearly a 100% incidence of intra-abdominal abscesses. Injection of the combination of *E. coli* and *B. fragilis* resulted in a picture similar to that seen in human patients. There was significant mortality and virtually all survivors were found to have intra-abdominal abscesses.

The lipopolysaccharide present on the surface of Gram-negatives, including the Enterobacteriaceae, is a key virulence factor for these organisms. [31] This molecule interacts with a broad range of human cell types to induce an inflammatory response. This response consists of initial thrombosis, restricting blood supply to an area of contamination, and then induces an influx of cells which are profoundly cytotoxic for both the bacteria and resident tissue. The net effect of these responses is to reduce the numbers of organisms needed to

establish an infection, a paradoxical consequence of the inflammatory response. This paradox can be explained if the inflammatory response is considered a means of generating abscesses and tunneling to an external surface.

B. fragilis produces a capsular polysaccharide that interferes with complement activation and inhibits leukocyte function.[32] These phenomena are thought to restrict the delivery of phagocytes to the site of infection, permitting a more rapid rate of bacterial growth than would otherwise be seen.

ANTIMICROBIAL THERAPY FOR INTRA-ABDOMINAL INFECTIONS

The goals of antibiotic therapy for intra-abdominal infections that will be treated by either percutaneous or operative intervention are to hasten the elimination of infecting micro-organisms and thereby minimize the risk of recurrent intra-abdominal infection and (perhaps) shorten the clinical manifestations of infection. Since the surgical would is heavily contaminated by the infecting micro-organisms, it is important that effective antimicrobial therapy is begun prior to operation. Necrotizing fasciitis and other forms of extension of infection to the surgical wound represent catastrophic failures of antimicrobial treatment.

In patients with localized abscesses, antibiotics reduce fever and other manifestations of systemic response, but only over a 24–36-hour interval. Antibiotics should be administered after fluid resuscitation has been initiated to restore adequate visceral perfusion and provide better drug distribution. Particularly in the case of aminoglycosides, nephrotoxicity is exacerbated by impaired renal perfusion.

In practice, antimicrobial agents are often begun when the diagnosis of intra-abdominal infection is suspected. This is often prior to the establishment of an exact diagnosis and before results of appropriate cultures are available. Accordingly, the clinician must anticipate the pathogens most likely to be encountered at the site of infection. Antibiotics used for intra-abdominal infections should be active against enteric Gram-negative facultative and obligate anaerobic bacilli. The microbiology of intra-abdominal infection has been well defined. The identity and density of micro-organisms depend on the site of the gastrointestinal tract perforation. In general, gastric, duodenal and proximal jejunal perforations release small numbers of Gram-positive aerobic and Gram-negative anaerobic organisms into the peritoneal cavity. These organisms are generally susceptible to ß-lactam antibiotics and are rapidly eradicated by defense mechanisms in intact hosts. *Candida albicans* or other fungi are cultured from about 20% of patients with acute perforations of the gastrointestinal tract. Even when fungi are recovered, antifungal agents are unnecessary unless the patient has recently received immunosuppressive therapy for neoplasm, transplantation or inflammatory disease or has recurrent intra-abdominal infection.

Clinical bacterial isolates

The organisms recovered from peritonitis and intra-abdominal abscess are very similar. The organisms recovered include a mixture of aerobic and anaerobic species. Polymicrobial clinical isolates have been obtained in more than 66% of recent clinical series (Table 47.1). The precise number of bacteria isolated depends upon the vigor with which the microbiology laboratory pursues bacterial culture and on the quality of the clinical specimen (see below). In most clinical settings 2–3 aerobic species are identified and 1–2 anaerobic species. In the setting of a research-oriented microbiology laboratory, 7–10 aerobic organisms are identified, along with 10–15 anaerobic species.[33] The clinical utility of such extensive microbiologic efforts is dubious.

The concept of presumptive or empiric therapy: different standards for community-acquired and nosocomial infections

In the case of suspected community-acquired infection, knowledge of the endogenous flora giving rise to infection is a valuable guide to selection of antibiotic therapy while awaiting the results of cultures. In community-acquired infections, the encountered flora is routinely susceptible to commonly prescribed regimens and, particularly for anaerobes, there is no benefit in identification or susceptibility testing. This is also likely true for facultative and aerobic Gramnegative bacilli.

There is a strong case to be made against culturing perforated or gangrenous appendicitis. Several retrospective studies have examined the impact of such cultures on outcome and have failed to identify an association.[34] [35] [36] [37] [38] [39] [40]

There are, however, several concerns that prevent easy extrapolation of this observation to other intra-abdominal infectious settings. Firstly, all of these studies have been confined to pediatric populations with perforated, not abscessed appendicitis. Failure in this situation due to recurrent infection is extremely uncommon. In fact, this is more likely a prophylactic versus infectious setting: the inflamed viscus (the appendix) is removed and there remains no rim of an abscess cavity. The situation is

analogous to acute cholecystitis: the disease is an obstructive, inflammatory condition that is not commonly infected; the inflamed viscus is resected; and only brief antibiotic therapy is of benefit.

For other intra-abdominal infections, particularly involving the colon, failure rates are substantially higher and there is evidence that if empiric therapy is not active against any identified isolate, altering the regimen to cover identified isolates improves outcome.[41] In an observational study of *Bacteroides* bacteremia, Nguyen and colleagues found that the mortality rate among patients who received inactive therapy (45%) was higher than among patients who received active therapy (16%; $p = 0.04$).[42] Clinical failure (82%) and microbiologica persistence (42%) were higher for patients who received inactive therapy than for patients who received active therapy (22% and 12% respectively; $p = 0.0002$ and 0.06, respectively). The authors concluded that *in vitro* activity agents directed at *Bacteroides* species reliably predicts outcome: the specificity was 97% and positive predictive value was 82%. The National Committee for Clinical Laboratory Standards has now suggested that clinical laboratories strongly consider surveillance testing annually, with testing of individual solates performed in certain clinical settings.[43]

There are marked differences in susceptibility patterns in different communities and these epidemiologic data are of value.[44] Local or regional hospital antimicrobial susceptibility patterns should be heeded in selecting initial empiric therapy. This appears particularly true for facultative and aerobic Gram-negative organisms. Identification and susceptibility testing of anaerobes, a more tedious and expensive undertaking, appears unnecessary if broadly active anaerobic agents are used in settings where anaerobes are frequently encountered (colon-derived infections).

In postoperative infections, a more resistant flora is routinely encountered.[45] There is good evidence that not providing empiric therapy active against the subsequently identified pathogens is associated with significant increases in mortality and failure rates.[46] The organisms seen are similar to those seen in other nosocomial infections and anaerobes are rarely encountered. Antibiotic therapy for such infections should be guided by knowledge of the nosocomial flora seen at the particular hospital and its antimicrobial susceptibilities.

In vitro data, especially antimicrobial susceptibility tests, are predictive of the *in vivo* response of infecting bacteria to particular antibacterial agents.[41] Such data also allow selection of a specific agent or combination regimen and obviate the need for broad-spectrum

TABLE 47-2 -- Antimicrobials or combinations of antimicrobials effective for the treatment of intra-abdominal infections.

ANTIMICROBIALS OR COMBINATIONS OF ANTIMICROBIALS EFFECTIVE FOR THE TREATMENT OF INTRA-ABDOMINAL INFECTIONS
Single agents:
Ampicillin-sulbactam
Ticarcillin-clavulanic acid
Piperacillin-tazobactam
Imipenem-cilistatin
Meropenem
Ertapenem
Combination regimens:
Cefuroxime plus metronidazole
Third/fourth-generation cephalosporin (cefotaxime, ceftriaxone, ceftizoxime, ceftazidime, cefepime) plus metronidazole
Aztreonam plus metronidazole
Ciprofloxacin plus metronidazole
None of these regimens has been clearly demonstrated to be superior to another.

therapy. These are the primary reasons for obtaining cultures of sites of infection.

Selection of antibiotics

Perhaps the most common circumstance for surgeons is empiric treatment for suspected mixed flora infections, including intra-abdominal and soft tissue infections. The combination of evidence from *in vitro* data, animal studies and clinical trials has led to wide-spread acceptance of the need to provide empiric antimicrobial therapy directed against *E. coli* and other common members of the family Enterobacteriaceae and *B. fragilis*. See Table 47.2 for a list of recommended regimens. *B. fragilis* and *E. coli* are the most common isolates from intra-abdominal infections and are the organisms most likely to cause bacteremia in abdominal sepsis, further attesting to their pathogenicity.

The evidence in support of broadening therapy to cover organisms other than common facultative and obligate anaerobes such as *E. coli* and *B. fragilis* is more controversial. Initial empiric coverage of *Pseudomonas aeruginosa* is associated with a decreased likelihood of persistent or recurrent abdominal infection if these organisms are isolated from the site of infection.[47] Other clinical trials using anti-infectives not effective against *P. aeruginosa* have not found a high incidence of treatment failure with this organism.

There are a large number of agents which are broadly active against the bacteria found in intra-abdominal infection. These are best discussed as classes of drugs and include aminoglycosides, carbapenems, cephalosporins and penicillins plus ß-lactamase inhibitors, monobactams (aztreonam) and quinolones.

Aminoglycoside therapy for suspected or documented Gram-negative infection

Aminoglycosides have been the mainstay of therapy for serious Gramnegative infections for the last 30 years. Due to their potential for nephro- and ototoxicity, there has been considerable movement away from aminoglycosides as first-choice agents for community-acquired intra-abdominal infections. The use of antibiotics with clindamycin or metronidazole, ß-lactams combined with ß-lactamase inhibitors, or single agent imipenem/cilastatin or meropenem in mixed flora infections has produced clinical results equivalent to or better than those seen with aminoglycoside-based combinations. Aminoglycosides no longer represent a 'gold standard' of comparison and need not be used for community-acquired intra-abdominal infections.

The caveat to this is the use of adjunctive aminoglycoside therapy for bacteremia and shock. Approximately 10–20% of patients with nonappendiceal intra-abdominal infection are bacteremic. While Gram-negative organisms do not represent the same risk of endocarditis on normal valves or of metastatic abscess formation seen with *Staphylococcus aureus*, combination bactericidal therapy may result in more rapid clearance of organisms and abbreviate host deterioration and has been shown to improve survival in *Klebsiella* and *Pseudomonas* bacteremia.[48] [49] We believe aminoglycosides should specifically be used in the initial treatment of patients with major intra-abdominal infection and hypotension in combination with a ß-lactam agent likely effective against the anticipated Gram-negative organisms.

ß-Lactam antibiotics and ß-lactam/ß-lactamase inhibitor combinations

The terminology of first-, second- and third-generation cephalosporins is used. First-generation agents, including cefazolin, cephapirin and cephalothin, have excellent Gram-positive activity, moderate Gram-negative activity and no anaerobic activity. Cefonocid, cefamandole and cefuroxime may be grouped with these agents because none has anaerobic activity. The second-generation agents cefoxitin, cefotetan and cefmetazole all have some anaerobic activity, improved facultative Gram-negative activity and less Gram-positive coverage. The anaerobic activity of these agents against *Bacteroides fragilis* is unimpressive. In general surveys about a third to a half of tested isolates are resistant.[50] Because of the high incidence of *Bacteroides fragilis* and relatively large inoculum loads encountered in colon-derived infections, these agents are best used for prophylaxis and for treatment of low-inoculum infections such as appendicitis.

The third-generation agents, cefotaxime, ceftizoxime, cefoperazone, ceftriaxone, ceftazidime and cefepime, have considerable facultative and aerobic Gram-negative activity but no anaerobic and, excepting cefepime, limited Gram-positive coverage. Cefuroxime, commonly used in Europe in combination with metronidazole, has good Gram-negative and Gram-positive activity and is effective in combination with metronidazole. Aztreonam, termed a monobactam, has activity against facultative

Gram-negatives equivalent to third-generation cephalosporins. It has no Gram-positive or anaerobic activity. Metronidazole has remained highly effective against *Bacteroides* species, in contradistinction to clindamycin, and is now the preferred agent for combination therapy.

The choice of one extended-spectrum ß-lactam over another is not a major issue. As clinical experience with these agents has widened, it has become apparent that the differences between agents do not affect outcome results. Many hospitals have therefore taken the position that cephalosporins can be grouped into classes and that within each class the agents are therapeutically interchangeable. Commonly, acquisition costs now determine which cephalosporin is used within each class. Ceftazidime is no longer recommended for this role because broad usage is associated with decreasing susceptibility of nosocomial *P. aeruginosa*. Additionally, ceftazidime therapy is associated with an increased incidence of enterococcal superinfections.

Carbapenems

Imipenem, a carbapenem derivative, has broad activity against facultative and obligate Gram-negative anaerobes and excellent Gram-positive activity (excepting methicillin-resistant staphylococci). This agent is formulated with cilastatin, a renal dehydropeptidase inhibitor which prevents renal tubal epithelial metabolism of the drug.

This agent has been extensively tested in clinical trials of complicated infection and is highly effective.[51] [52] [53] The drug may cause seizures in situations where plasma accumulation of the drug occurs (high dose levels or renal failure). With lower dose levels (500mg) and appropriate adjustments for renal failure, this is not a problem.

Meropenem is a synthetic agent with typical broad carbapenem antibacterial spectrum, but with no evidence of an increased risk of seizures compared with cephalosporin control agents. Several clinical trials, in which serious intra-abdominal infections were treated with meropenem dosed at 1g every 8 hours, have been completed and have shown considerable efficacy.[54] [55]

Ertapenem is a newly licensed once-a-day parenteral carbapenem effective in the treatment of intra-abdominal infections. It is highly resistant to inactivation by a wide variety of ß-lactamases. It has limited activity against nonfermentative Gram-negative bacilli and enterococci, which more often are nosocomial pathogens. In a large clinical trial ertapenem was shown to be effective in comparison to piperacillin/tazobactam for complicated intra-abdominal infections. [56]

Fluoroquinolones

The currently marketed fluoroquinolones are active against facultative and aerobic Gram-negative bacteria. Streptococci and enterococci show *in vitro* susceptibility to quinolones but other, more effective agents are available. *Staphylococcus aureus* and coagulase-negative staphylococci have become progressively more resistant to fluoroquinolones.

Ciprofloxacin, levofloxacin and moxifloxacin have excellent activity against Gram-negative bacilli. For *P. aeruginosa*, ciprofloxacin has consistently shown greater *in vitro* activity.[57] [58] [59]

The pharmacodynamics of the fluoroquinolones are of some interest. A primary virtue of the quinolones is a very large volume of distribution.[60] Because of their relatively small molecular size and absence of localized electrical charges, these agents penetrate well into interstitial fluid and achieve high tissue levels, in excess of those seen with other, larger molecules.

The area of greatest concern with quinolones is the rapid development of resistance by anaerobes, in particular *B. fragilis*. The most common mechanism for this appears to be mutation on the DNA gyrase A target. Rates of resistance to these antibiotics in clinical populations are increasing. In an ongoing surveillance study, 16.4% of 1220 clinical *B. fragilis* group strains from 19 European countries were considered resistant to moxifloxacin, with minimum inhibitory concentrations (MICs) of 4µg/ml (M Hedberg, Karolinska Institute, Sweden, cited in[61]). In another broad survey, increased geometric mean MICs were observed with the fluoroquinolones and were usually accompanied by an increase in resistance rates.[62]

Importance of pharmacokinetics

Dosing of cephalosporin, carbapenem and quinolone antibiotics should be optimized based on the known pharmacodynamics of these agents.[63] [64] Cell wall active agents are effective at the MIC of the drug for the organism(s) being treated. Increasing the drug concentration substantially above about 2–4 times the MIC does not increase the rate of killing. Once the drug falls below the MIC, the organism(s) begins regrowth immediately. Dosage regimens for cell wall active agents in critically ill patients should involve dosing intervals sufficiently short to maintain serum levels above the MIC. The general rule with these agents is therefore to give relatively small doses frequently to maintain the trough level above the MIC and avoid the costs and toxicities seen with high doses. This is best accomplished by administering these drugs every four half-lives, with adjustments as needed for renal compromise. There has been interest in infrequent drug dosing with ß-lactams. This is likely to succeed primarily in mild to moderate infections in otherwise intact hosts.

Duration of therapy

Antimicrobial therapy of established infections should be limited to no more than 5 days unless it is impossible to achieve adequate source control.

Clinical signs of infection, such as fever and leukocytosis, should be used to judge the adequacy of antimicrobial therapy. Continued clinical evidence of infection at the end of the time period designated for antimicrobial therapy should prompt appropriate diagnostic investigation rather than continuation of antimicrobial treatment.

In patients who have persistent clinical evidence of infection but a negative investigation for a new or persistent infectious source, a trial of careful monitoring off all antimicrobial therapy may be warranted, since the persistent clinical symptoms and signs may be the result of ongoing tissue inflammation (the systemic inflammatory response syndrome) or a drug reaction.

Should combination therapy be employed for serious infections?

One result of the availability of multiple classes of effective antibiotics is the possibility of combination therapy with two effective agents. Combination therapy has several theoretical advantages. Firstly, a broader spectrum of pathogens may be covered, of particular importance when treatment is inititiated for suspected sepsis without an identified source. Use of agents with differing mechanisms of action may also delay or prevent emergence of resistance and superinfection. Combinations of such agents may act synergistically to enhance killing of organisms.

The time-honored tradition of providing an aminoglycoside along with a ß-lactam has recently gained support from recent studies of Gram-negative bacteremia.[48] [65] [66] These studies indicate that improved survival occurs in patients with severe acute illness treated with combination therapy as opposed to those treated with a single agent. In a similarly constructed study of *Klebsiella* bacteremia, a similar improvement in severely ill patients treated with combination therapy was noted. In both studies, survival approximated 70% in the combination therapy versus 50% in the monotherapy group.

Regimens employing two ß-lactams have been tried, primarily in the setting of febrile neutropenia. No benefit has been found and there is concern that coverage with such regimens is not as broad as that obtained with an aminoglycoside-based regimen since ß-lactams have similar mechanisms of action.

An alternative approach to a fixed duration of antimicrobial therapy is to discontinue antimicrobials when the patient's symptoms and signs of infection resolve. The risk of treatment failure appears to be quite low in patients who have no clinical evidence of infection at the time of cessation of antimicrobial therapy. This usually implies that the patients are afebrile, have normal white blood cell counts and are tolerating an oral diet.

Indications for antifungal therapy

Candida albicans or other fungi are cultured from about 20% of patients with acute perforations of the gastrointestinal tract.[67] Even when fungi are recovered, antifungal agents are unnecessary unless the patient has recently received immunosuppressive therapy for neoplasm, transplantation or inflammatory disease, or has recurrent intra-abdominal infection.[67] [68]

The antifungal of choice for confirmed intra-abdominal candidal infections is uncertain. For established *Candida* peritonitis, amphotericin B, azoles such as fluconazole or voriconazole, or an echinocandin such as caspofungin are all likely to be effective. The ultimate choice of antifungal therapy will be heavily influenced by the risks of toxicity in a given patient and presumed susceptibilities of the identified yeast.

Indications for antienterococcal therapy

Although the appropriate role of antienterococcal therapy is controversial, most authorities believe that specific antienterococcal therapy should be given only when enterococci are the only organisms isolated or are isolated from blood. Isolation of enterococci as part of a mixed Gram-positive and Gram-negative flora should not prompt addition of ampicillin or vancomycin to the antibiotic regimen.[69] The incidence of treatment failure for patients harboring enterococci and not treated for it is the same as for patients treated with imipenem or other agents effective against enterococci. Enterococci are very low-level pathogens, meaning that they incite little host response and do not cause invasive infection in intact hosts. [70] However, patients who have had one major episode of sepsis are sufficiently immunosuppressed so that isolation of enterococci from a second infectious site (including recurrent infection within the abdomen) should mandate specific antienterococcal therapy.

Identification of high-risk patients

Several attempts have been made to identify clinical features in patients with peritonitis that increase the risk of adverse outcomes.[71] The purpose of identifying such patients is to tailor both the surgical approach and antimicrobial therapy to minimize this risk. Unfortunately, most analyses have identified parameters prognostic of mortality rather than the risk of recurrent infection. As many patients die of their co-morbidities rather than as a direct result of infection, it becomes difficult to ascertain the precise role antimicrobials play in preventing mortality. In most analyses, factors independently associated with death include advanced age, higher APACHE II scores (a marker of physiologic derangement), poor nutritional status, significant cardiovascular disease and inability to obtain adequate source control.[72] [73] Prolonged prehospital length of stay may represent a marker for significant co-morbidity, previous antibiotic exposure or postoperative peritonitis, suggesting that organisms resistant to the empiric antimicrobial regimen may be responsible.

Recognition and management of treatment failure

Treatment response is defined as a diminution in the physical signs of infection, including decrease in fever, tachycardia and local findings of tenderness and organ dysfunction (such as ileus). The more localized the initial infection, the more rapidly response will occur. Conversely, extensive infections such as peritonitis or multilobar pneumonia may respond only slowly. As a general rule, infections should show definite evidence of response within 72 hours of treatment initiation. The absence of such a response is not an automatic indication that the wrong antibiotic was selected. In fact, most cases of apparent treatment failure call for continuation of the same antibiotic. A diligent search should be made for a septic focus requiring drainage, debridement or excision.

Chapter 48 - Viral Hepatitis

Stephen D Ryder

INTRODUCTION

The clinical syndrome of acute hepatitis has been recognized since antiquity and is characterized by jaundice, usually after a prodromal illness. Acute hepatitis may cause severe sequelae, including fulminant hepatitis, but the major impact on human health is chronic liver disease and hepatocellular carcinoma resulting from chronic infection.

The nomenclature of the hepatitis viruses is somewhat eclectic, being based on the time of discovery of new or putative agents rather than on any consideration of modes of transmission or clinical problems associated with that agent. There are at present five primary human hepatotropic viruses, A, B, C, D and E, which are well characterized and known to account for approximately 90% of acute and 95% of chronic viral hepatitis. Other viruses, F and G, may cause human disease.

EPIDEMIOLOGY

Hepatitis A virus

Hepatitis A virus (HAV) is distributed throughout the world and causes outbreaks of infection, usually in association with direct fecal-oral contact [1] or contaminated water supplies.[2] Most food-related outbreaks of HAV infection are sporadic and due to poor food hygiene measures, but contamination of shellfish caused by sewage contamination is well described [3] and represents a continuing problem because mollusks are able to retain and concentrate viruses from water. Homosexual men and those working with newly imported nonhuman primates are high-risk groups for HAV infection. In the 1980s the proportion of cases of hepatitis A spread by blood contact increased to 19% of reported cases in the USA; this appears to have been due to intravenous drug use.[4]

In the developed world, the proportion of people who have immunity to HAV has declined over the past two decades, owing to improved sanitary conditions in childhood. Travelers from low-risk geographic areas to high-risk areas are at substantial risk of acquiring HAV infection.[5] In the developing world, infection rates are as high as 95% by the age of 16 years. Early infection usually produces a less severe clinical illness and immunity to future infection. The incubation period is short, ranging from 15 days to 50 days (mean 30 days).

Hepatitis B virus

Hepatitis B virus (HBV) is one of the most common chronic viral infections in the world, with estimates of approximately 170 million chronically infected people.[6] Hepatitis B virus infection is relatively rare in developed countries, with an incidence of 1 per 550 population in the UK and North America. Even in areas like the UK, where acute infection appears relatively uncommon, up to 2% of the population show evidence of past infection. In high-risk areas such as South East Asia and sub-Saharan Africa up to 20% of the population have evidence of previous infection.[7] A major mode of spread in high-endemicity areas is vertical transmission from carrier mother to child, and this may account for 40–50% of all HBV infections in such areas.[8] This mode of transmission is highly efficient; more than 95% of children of carrier mothers are infected and develop chronic viral infection themselves. In low-endemicity countries, the mode of spread is predominantly by sexual transmission or blood-borne transmission through intravenous drug use. In most of northern Europe, immigration accounts for a substantial proportion of new cases of hepatitis B infection presenting to the health care services. Many asylum seekers are from areas of the world where hepatitis B infection is very common. It is estimated that in the UK 90% of new hepatitis B diagnoses are in migrant populations with chronic rather than acute infection. Between 5% and 10% of acutely infected people develop chronic viral infection. Certain groups in the Western world are known to be at higher risk of HBV exposure; these include intravenous drug users, hemodialysis patients, homosexual men and institutionalized people, particularly those with mental handicap. Males are more likely to become chronic HBV carriers than females, for reasons that are unclear. The incubation period ranges from 28 days to 160 days (mean 80 days).

Hepatitis C virus

Hepatitis C virus (HCV) infection is common, with an estimated 500 million cases worldwide. Unlike infection with HBV, this infection is very common in the developed world, with 0.3–0.7% of the UK population infected. The virus is spread almost exclusively by blood contact. Since the introduction of screening of blood products in 1990 or 1991, intravenous drug use has become the almost exclusive mode of hepatitis C transmission in northern Europe and North America. In the early 1990s, of cases in northern Europe 35% had a past history of blood transfusion and a further 40% had used intravenous drugs. Of new cases seen in the late 1990s, intravenous drug use accounted for over 75% of cases. Sexual transmission does occur, but it is unusual, with less than 5% of long-term sexual partners becoming infected.[9] Vertical transmission also occurs, but again it is unusual. It is certainly not the predominant mode of spread of HCV, with the frequency of infection in children of viremic mothers less than 5%. The mode of delivery does not affect infection rates and breast-feeding is safe.[10] The rate of infection in children of infected parents may rise in the first 10 years of life but it seems relatively difficult to acquire this viral infection from close household contact.

This leaves a substantial minority of those identified in whom no specific risk factor is present. This proportion may be up to 20% of cases. It has been postulated that this group may have acquired the infection from medical interventions. This is based on the high prevalence of infection in areas such as southern Italy, where military vaccination programs were undertaken in the period immediately after the Second World War, and in Egypt, where up to 20% of the population have HCV markers in certain geographic areas and treatment for diseases such as schistosomiasis are commonly given by injection. Hospitalization for whatever reason appears to be a risk factor for HCV infection. The incubation period varies between 14 and 60 days (mean 50 days).

Hepatitis D virus

Hepatitis D virus (HDV) or delta virus is an incomplete RNA virus that uses hepatitis B surface antigen (HBsAg) to enable replication and transfer from cell to cell. Hence, its epidemiology is closely linked to that of HBV. There are, however, considerable differences in the frequency of delta infection or superinfection in different patient groups. Intravenous drug users have a relatively high incidence of HDV infection whereas homosexual men, a high-risk group for the sexual spread of HBV, have a low incidence of delta infection. The reason for this epidemiologic paradox is unknown. Transmission of HDV is parenteral,[11] either via transfusion or close personal contact. Screening of blood products for HBsAg effectively excludes HDV-positive donors. The commonest risk factor for the acquisition of HDV infection in the Western world is intravenous drug use, with between 17% and 90% of HBsAg-positive addicts also testing positive for HDV.[12] In developing countries, HDV infection generally parallels HBV infection, although there are exceptions, particularly in areas of Asia, where HDV is rare despite a high level of HBV carriage. In general, approximately 5% of people with chronic HBsAg carriage will be co-infected with HDV, giving an estimated worldwide figure in excess of 10 million. The incubation period is quite variable.

Hepatitis E virus

Hepatitis E virus is transmitted by the fecal-oral route. Its epidemiology correlates with the presence of contaminated water. It is responsible for outbreaks of epidemic-type hepatitis in the Indian subcontinent, but sporadic cases are seen throughout the world (Fig. 48.1). The incubation period is short, ranging between 15 and 45 days (mean 40 days).

Hepatitis F virus

Hepatitis F virus was described as the cause of a fulminant giant cell hepatitis. Its pathogenicity in humans is controversial and if it does cause human disease, it is rare.

Hepatitis G virus

Hepatitis G virus has only recently been described and its potential role as a pathogen and its epidemiology are largely unknown. In the USA and Europe, initial studies suggest that up to 1% of blood donors are viremic.

PATHOGENESIS AND PATHOLOGY

The molecular structure of the hepatitis viruses is considered in Chapter 214 . The mechanisms of pathogenicity of the hepatitis

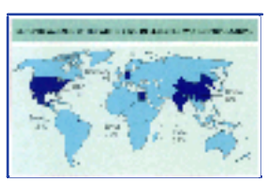

Figure 48-1 Seroprevalence of hepatitis E IgG in selected world populations.

viruses are complex and involve viral and host immune factors. The basis of any hepatitis is hepatocyte death, usually immunologically mediated in order to eliminate infected cells and to prevent further viral replication. It is highly likely that the mechanisms involved vary depending on the virus. Further differences in either the virus or the host response are involved in the development of chronic infection with HBV or HCV. Because these are the major cause of liver disease, these two viruses are considered in detail in this chapter.

Hepatitis B virus

Hepatitis B virus enters the hepatocyte by binding of determinants that are present on HBsAg. The virus replicates mainly in the hepatocyte (Fig. 48.2), although HBV DNA has been found in extrahepatic tissues, including skin, pancreas, kidneys, bone marrow and peripheral blood mononuclear cells. Hepatitis B virus has a highly unusual genetic structure, with a circular, partially ssDNA genome. When internalized in the hepatocyte, the genome is released and the negative strand is converted by ligation to a closed circular supercoiled form.[13] This form is present in the hepatocyte nucleus and forms the template for HBV RNA synthesis. Hepatitis B virus is almost unique in that its DNA is synthesized via an RNA intermediate; the same molecules are therefore used for protein synthesis and for reverse transcription to DNA.

Figure 48-2 Hepatitis B virus replication. Viral DNA present in the nucleus is transcribed to RNA, which then acts as a template for protein synthesis (viral coat-HBsAg and viral proteins essential for infectivity and replication-HBcAg). Viral particles are then assembled and secreted from the cell cytoplasm. For every complete virion a large number of incomplete particles derived from HBsAg alone are exported. HBV, hepatitis B virus; HBsAg, hepatitis B surface antigen; HBcAg, hepatitis B core antigen.

The HBV RNA template is encapsulated in hepatitis B core antigen (HBcAg) particles and reverse transcribed to produce negative-strand DNA. This is then used to synthesize an incomplete positive DNA strand and the virion is encapsulated with HBsAg before excretion from the cell.

There are a number of host mechanisms deployed to prevent initial infection and then to remove infected hepatocytes. Hepatitis B virus is not thought to be directly cytopathic except in highly specific circumstances, such as fibrosing cholestatic hepatitis seen in reinfection of liver grafts, when the host is immunosuppressed. Liver cell damage in both acute and chronic HBV infection is thought to be immunologically mediated.

Cell-mediated and humoral immune responses occur in HBV infection and both are probably important in limiting and eliminating infection. There is invariably a humoral immune response directed against HBcAg and usually against HBsAg, [14] but this response alone is not the cause of hepatitis as evidenced by liver disease in agammaglobulinemic patients. The responses of HLA class I restricted cytotoxic T cells are thought to be the major mechanism of liver cell injury.[15] The fact that patients with production of HBsAg alone in hepatocytes usually have little inflammatory liver disease suggests that the target of this attack is likely to be core antigen.

Acute HBV infection can be self-limiting, with complete clearance of the virus, or it can develop into chronic infection with the potential for the development of cirrhosis and primary liver cell cancer.

Chronic HBV infection can be thought of as occurring in phases, depending on the degree of immune response to the virus. This is particularly true of patients infected in the first few weeks of life. If infected when the immune response is 'immature', there is initially little or no immune response to HBV. The levels of HBV DNA in serum are very high and the hepatocytes contain abundant HBsAg and HBcAg, but little or no ongoing hepatocyte death is seen on a liver biopsy because of the defective immune response. This state persists for a variable period of time; usually the degree of immune recognition increases over some years. When immune recognition starts to occur, the level of HBV DNA tends to fall and the liver biopsy shows increasing inflammatory liver disease. This inflammation and hepatocyte death produces hepatic fibrosis. Once this phase of infection is initiated there are two major possible outcomes: either

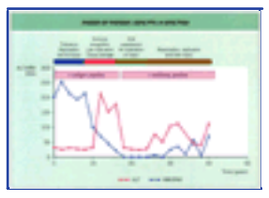

Figure 48-3 Phases of chronic hepatitis B infection. Initial infection is usually in childhood and has a long immune tolerant phase. Immune recognition then develops which can allow inactivation of hepatitis B by either clearance of infected cells (with associated liver cell damage) or suppression of viral antigen expression on infected hepatocytes. This produces viral inactivation. In a significant proportion of patients where this has occurred, a third phase develops, where replication of HBV resumes due to viral escape mutants, leading to HBV DNA again appearing in serum and the risk of chronic liver disease.

the immune response is adequate and the virus is inactivated and then removed from the system or the attempt at removal results in extensive fibrosis, distortion of the normal liver architecture and death from the complications of cirrhosis.

A third phase of hepatitis B virus infection is now recognized. This occurs late in the natural history of the immune response against HBV. In situations where the wild-type virus is inactivated but not eradicated, characterized by hepatitis B surface antigen positivity, e antigen negativity and undetectable levels of HBV DNA, there is still virus present in hepatocytes. This virus will be present in a number of forms, with viral mutants commonly produced. It is now well recognized that some of these mutant species can replicate in the presence of an adequate immune response against wild-type virus. This leads to re-emergence of HBV DNA in serum and can lead to progressive liver injury (Fig. 48.3). These mutant stains may account for up to 60% of all replicating HBV infection in Europe. Recognition of this situation clinically is both important and relatively simple, important because reactivation of HBV replication carries a significant risk of the development of hepatic fibrosis and cirrhosis and therapy is different from the usual 'wild-type', e antigen-producing HBV. It is simple to recognize as abnormal transaminases and significant levels of HBV DNA are present in the serum in patients who are HBsAg positive but e antigen negative.

Hepatitis C virus

Chronic HCV infection has a long natural history, with most patients discovered in the presymptomatic stage. In the UK, most patients are now screened because of an identifiable risk factor (previous intravenous drug use or blood transfusion) or because of abnormal liver biochemistry.

The mechanism by which HCV causes human disease is unclear. A very high proportion (80%) of acute infections go on to become chronic and the prognosis from chronic infection is very variable. Some infected people have normal liver histology,[16] which indicates that HCV is not directly cytopathic for hepatocytes. Immune mechanisms are again thought to be important in determining outcome.

Hepatitis C virus is an RNA virus. It is highly variable, with six major genotypes.[17] Genotypes are frequently geographically restricted, such as type 4 in the Middle East, or may vary with time

and mode of spread. This has been seen in Europe with genotype 1 occurring in older transfused individuals, with type 3 in younger drug users. There is some evidence that viral factors are important in the outcome of HCV infection. More severe fibrotic disease has been found in patients infected with genotype 1a or 1b than in those infected with other genotypes.[18] This is somewhat controversial as there are confounding factors, such as duration and mode of transmission, that make interpretation difficult.[19] The variability of the infecting HCV has also been postulated to affect outcome. The number of quasispecies present, a measure of genetic variability within a viral population, has been suggested as an important factor in evading the host immune response. Furthermore, quasispecies variability has been shown to be associated with increasing severity of liver disease, [20] whereas the number of quasispecies present in serum is higher in acute infection than in chronic infection.[21] More severe outcome appears to be correlated with selection of single species in the infecting HCV, which are presumably better adapted to survive in that particular immune environment.[22]

The level of viremia in a patient with HCV infection can be estimated using quantitative polymerase chain reaction (PCR) methods or branched chain DNA technologies, although these are somewhat less sensitive. High levels of viremia have been found to correlate with severity of liver disease.[23]

Evidence suggests that the host immune response is important in determining the outcome of HCV infection. There are HLA associations with viral clearance as evidenced by positive antibodies and negative tests for circulating viral genome (using PCR). In addition, patients with combined HCV and HIV infections and patients who were infected with HCV as a result of contaminated immunoglobulin given for hypogammaglobulinemia have more severe and more rapidly progressive liver disease.

PREVENTION

Hepatitis A

Primary prevention mechanisms are the avoidance of water contaminated by human urine or feces. As water purification has improved, the seroprevalence of HAV infection has fallen. In countries with a low seropositivity for HAV infection, protective immunization is recommended for certain groups at high risk (see Chapter 214). It should be remembered that the severity of the acute illness caused by HAV increases with age of exposure. Approximately 5% of those over the age of 65 years who are infected will develop fatal acute fulminant hepatitis.

Hepatitis B

The prevention of HBV infection is covered in Chapter 214 .

Hepatitis C

There is at present no effective vaccine against HCV infection. The difficulties in developing such a vaccine are numerous: the virus is highly variable, the mutation rate is high and the development of antibodies does not protect against reinfection with the same strain of HCV. The production of a clinically useful vaccine is likely to take many years.

Hepatitis D

No specific vaccine for HDV exists. In patients known to carry HBsAg, prevention is restricted to avoidance of risk factors. In populations at risk, the high level of effectiveness of HBV vaccination will also protect against HDV infection.

Hepatitis E

Prevention is restricted to avoidance of contaminated water. No vaccine is available.

CLINICAL FEATURES

Acute hepatitis

Anicteric disease

A large proportion of infections with any of the hepatitis viruses are asymptomatic or anicteric illnesses. Hepatitis A virus typically causes a minor illness in childhood, with more than 80% of infections being asymptomatic. In adult life infection is more likely to produce clinical symptoms, although only 30% of a cohort exposed to contaminated water experienced icteric illness.[2] Infections with HBV, HCV and HDV can also be asymptomatic. With HBV infection this again depends on the mode and time of transmission. Vertical transmission of infection from mother to child is almost always asymptomatic, although it produces chronic infection in the child. Transmission of HBV by other routes is much more likely to produce a symptomatic illness; about 30% of cases transmitted by intravenous drug use are icteric.

Clinically apparent acute hepatitis

Acute hepatitis presents with jaundice or elevated liver enzymes, usually preceded by a prodromal illness. The clinical features give little indication as to the likely etiologic agent. A history from patients who are suspected to have an acute hepatitis should be aimed at identification of specific risk factors for viral or other liver disease (Table 48.1).

Common symptoms in the preicteric phase include myalgia, nausea, vomiting, fatigue and malaise. There is often a change in the sense of smell or taste and right upper abdominal pain is common. Coryza, photophobia and headache are often seen and cough may be prominent in hepatitis A. Diarrhea with transient pale stools and dark urine may occur.

A serum sickness-like illness occurs in about 10% of patients who have acute HBV infection and in 5–10% of patients who have acute HCV infection. [24] This is characterized by an urticarial or maculopapular rash and arthralgia, typically affecting the wrist, knees, elbows and ankles. This illness is due to immune complex formation and rheumatoid factor is frequently positive. It is almost always self-limiting and usually settles rapidly after the onset of jaundice.

Viral hepatitis may produce other clinical or subclinical problems. Acute hepatitis B is rarely associated with clinical pancreatitis in the acute phase of the illness, although elevation of amylase is present in up to 30% of patients and autopsy studies in patients who have fulminant hepatitis B show histologic changes of pancreatitis in up to 50%. Myocarditis, pericarditis, pleural effusion, aplastic anemia, encephalitis and polyneuritis have all been reported.

Physical examination in the preicteric phase is usually normal although mild hepatomegaly (10%), splenomegaly (5%) and lymphadenopathy (5%) may be seen. Stigmata of chronic liver disease should not be present in patients who have an acute illness, and their detection suggests either that the episode causing presentation

is the direct result of chronic liver disease or that there has been an acute event superimposed on a background of chronic liver disease, as for example in HDV superinfection in a HBV carrier (Fig. 48.4).

TABLE 48-1 -- Important points in the history of a patient who has suspected viral hepatitis.

IMPORTANT POINTS IN THE HISTORY OF A PATIENT WHO HAS SUSPECTED VIRAL HEPATITIS
• Contacts with jaundiced patients
• Intravenous drug use
• History of blood transfusion
• Surgery or hospitalizations
• Family history of chronic liver disease
• Occupation

Figure 48-4 Facial stigmata of chronic liver disease. This woman presented with serologically proven acute hepatitis A virus infection. She has multiple stigmata of chronic liver disease including facial spider nevi and was shown to have pre-existing cirrhosis.

Biochemical confirmation of acute hepatic injury was seen with an elevated transaminase level which may reach 100 times normal.[25] No other biochemical test has been shown to be a better indicator of acute liver injury. There are a number of other laboratory tests that may be abnormal in patients who have acute viral hepatitis. Leukopenia is common, and in 10% of patients the white cell count may fall below 5000/mm^3 .[26] Both anemia and thrombocytopenia are described. Immunoglobulin levels may be nonspecifically elevated in viral hepatitis, with levels usually returning to normal within 2 weeks. In a small proportion of patients who have acute viral hepatitis, a profound cholestatic illness may occur. This is most frequently seen in patients who have hepatitis A and it may be prolonged, with occasional patients remaining jaundiced for up to 8 months.

Death from acute viral hepatitis is usually due to the development of fulminant hepatitis. This is usually defined as hepatic encephalopathy with an onset within 8 weeks of symptoms or within 2 weeks of onset of jaundice.[27] The risk of developing fulminant liver failure is generally low but there are groups with higher risks. Pregnant women with acute HEV infection have a risk of fulminant liver failure of around 15%, with a mortality of 5%.[28] The risk of developing fulminant liver failure in HAV infection increases with age [29] and with pre-existing liver disease.[30] Fulminant hepatitis B is seen in adult infection but it is relatively rare.

The primary clinical features of acute liver failure are encephalopathy and jaundice. Jaundice almost always precedes encephalopathy in acute liver failure, and the onset of confusion or drowsiness in a patient who has acute viral hepatitis is always a sinister development. The degree of the rise in transaminase values does not correlate with the risk of developing liver failure. Prolongation of coagulation is the biochemical hallmark of liver failure; it is caused by lack of synthesis of liver-derived clotting factors. Prolongation of the prothrombin time in acute hepatitis, even if the patient is clinically well without signs of encephalopathy, should be regarded as sinister and monitored closely. Hypoglycemia is seen only in fulminant liver disease, when it can be profound.

Chronic hepatitis

The agents that cause chronic hepatitis are HBV, HCV and HDV. Chronic hepatitis has been defined as abnormality of transaminase values persisting for more than 6 months. This has generally been a useful concept in patients who present with an acute illness. In clinical practice, the vast majority of patients will present with either an asymptomatic biochemical or serologic abnormality or the complications of cirrhosis, and it is reasonable to assume chronicity in these clinical settings at the time of initial presentation. Chronic viral hepatitis is characterized by the presence of inflammatory infiltrates in the liver associated with hepatocyte death.

The risk of developing chronic infection varies greatly with the virus implicated. Hepatitis A virus never causes chronic viremia or chronic liver disease. Hepatitis B virus causes chronic liver disease in a proportion of infected patients; this rate varies depending on the mode of transmission. Patients who are infected at or around the time of birth via a chronic carrier mother have infection rates of almost 100%, with the vast majority becoming chronic carriers of the virus and therefore at risk of long-term liver damage.[31] If HBV is acquired in later life, the risk of chronic infection falls considerably, with only 5% of such patients remaining HBsAg positive at 5 years.[32] The difference in the rate of chronic infection is probably related to the maturity of the host immune response.

Infection with HCV has, overall, the highest risk of chronicity. Posttransfusion studies indicate that at least 50% of patients with icteric disease develop chronically abnormal transaminase values, and most studies suggest that up to 80% of acutely infected people remain viremic.[33]

Hepatitis D virus can cause chronic liver damage, and there is evidence to suggest that the combination of HBV and HDV carries a particularly poor outlook.

Most patients who have chronic viral hepatitis either present with a complication of their viral liver disease or are detected by screening, either for viral serology or for abnormal biochemistry.

Symptoms

The majority of patients who have chronic viral hepatitis are asymptomatic and patients are often unaware of the infection. In HCV infection a number of symptoms are frequently reported by patients in the absence of severe liver disease. These include lethargy, inability to concentrate and pain over the liver. It is unclear if these symptoms are the direct result of the viremia or are related to depression as a result of the diagnosis. These symptoms, whatever their origin, contribute to a reduced quality of life for patients with hepatitis C compared to patients with chronic hepatitis B.[34] Other symptoms are due either to associated diseases affecting organs other than the liver or to end-stage liver disease.

Extrahepatic manifestations

Chronic hepatitis B can be associated with polyarteritis nodosa, with vasculitic rash, fever and polyarthralgia. Circulating HBsAg and anti-HBs complexes can be demonstrated, as can cryoproteins and HBsAg in blood vessel walls.[35] Cyclophosphamide appears to be effective treatment for HBV-associated vasculitis.

Glomerulonephritis is now known to occur with both HBV[36] and HCV infections.[37] This is a relatively rare association thought to be mediated by the deposition of immune complexes. There are reports of improvement of the renal lesion on treatment of the responsible virus.

Up to 60% of patients who have mixed essential cryoglobulinemia are anti-HCV positive;[38] the condition is again thought to be the result of immune complex formation and antigen-antibody deposition in the vasculature (Fig. 48.5). Successful therapy of the underlying hepatitis C may produce remission.

Figure 48-8 Computed tomography scan following lipiodol injection into the hepatic artery showing hepatocellular carcinoma in the cirrhotic liver of a hepatitis B virus-positive male. Lipiodol is selectively retained in the tumor.

Porphyria cutanea tarda is strongly associated with HCV infection, with up to 76% of Italian patients with porphyria cutanea tarda having antibodies to HCV.[39] Lichen planus is also associated with HCV infection.

Clinical signs

Patients who have decompensated cirrhosis caused by viral agents present with jaundice, encephalopathy, ascites or gastrointestinal bleeding as a result of portal hypertension (Fig. 48.6).

Cutaneous stigmata of chronic liver disease, spider nevi, leukonychia, gynecomastia, testicular atrophy and loss of body hair may be present. A late complication of chronic liver disease caused by HBV, HCV or HDV is hepatocellular carcinoma (Fig 48.7 , Fig 48.8).

Hepatocellular carcinoma may present as a sudden decompensation of previously stable chronic liver disease or as pain in the right upper quadrant of the abdomen, or there may be distant metastatic disease, with pulmonary or bone metastases being most common. Alphafetoprotein is often raised, although this is normal in up to 60% of small hepatomas.

All of these clinical signs occur late in the course of these viral infections and for most of the duration of infection no abnormal clinical signs will be present and the patient will be asymptomatic.

DIAGNOSIS

Acute hepatitis

Hepatitis A

Infection with HAV can be reliably diagnosed by the presence of anti-HAV IgM. This test has very high sensitivity and specificity.[40] Very occasional false-positive results can be seen in liver disease of other etiologies where very high levels of immunoglobulin are present but the clinical context usually makes this obvious.

Hepatitis B

Infection with HBV is usually characterized by the presence of HBsAg. In acute HBV infection the serology can be difficult to interpret. The reason that an acute hepatitis develops is the immune recognition of infected liver cells, which results in T cell-mediated hepatocyte killing. Active hepatocyte regeneration then occurs to replace those hepatocytes that have been lost. As well as a cell-mediated immune response, a humoral immune response develops and this is probably important in removing viral particles from the blood and thus preventing reinfection of hepatocytes. Because of the immune response attempting to eradicate HBV, at the time of presentation with acute hepatitis B, viral replication may already have ceased and the patient may be HBsAg positive, hepatitis B e antigen (HBeAg) negative, e antigen being a surrogate marker of HBV replication.

It is difficult in this situation to be certain that a patient's illness was due to acute hepatitis B and that the serology does not imply past infection unrelated to the current episode. To enable a clear diagnosis to be made, most reference centers now report the level of IgM antibody to HBcAg (IgM anti-core; Fig. 48.9). As core antigen does not appear at any time in serum, this implies an immune response against HBV within liver cells and has been shown to represent a sensitive and specific marker of acute HBV infection.[41]

Rarely, the immune response to HBV infection is sufficiently brisk that even HBsAg has been cleared from serum by the time of presentation with jaundice. This may be more frequent in patients who develop severe acute liver disease and has been reported in up to 5% of patients who have fulminant hepatitis in whom the diagnosis was made by an appropriate pattern of antibody response.

Diagnosing past HBV infection or establishing immunity to vaccine is easy serologically. If the virus is cleared after infection with HBV, antibodies to all viral antigens can be detected. The levels of most of these in blood, however, decline with time. This is particularly true of anti-HBsAg: after 1 year, most patients' level of antibody has fallen below the level of detection in most commercially available assays. Despite this low level, immunity is still sufficient to

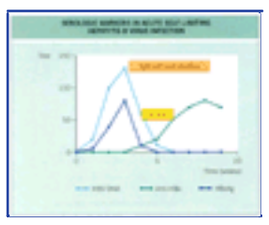

Figure 48-9 Serologic markers in acute self-limiting hepatitis B virus infection. HBV, hepatitis B virus; HBeAg, hepatitis B e antigen. Measurements in arbitrary units.

prevent reinfection. Natural immunity is proven by the presence of IgG antibodies to HBcAg. These are a highly reliable marker of past infection and remain at detectable levels for a long period. Vaccine-induced immunity is directed purely against HBsAg epitopes, and hence a vaccinated person will have detectable levels of anti-HBsAg but no anti-HBcAg.

Hepatitis C

Screening tests for HCV infection are enzyme-linked immunosorbent assay (ELISA) techniques that use recombinant viral antigens and patient's serum. Acute hepatitis C cannot be reliably diagnosed by antibody tests because these frequently do not become positive for up to 3 months (Fig. 48.10).

Hepatitis C virus used to be the cause of more than 90% of all posttransfusion hepatitis in Europe and North America[42] but acute HCV infection is now most commonly seen in intravenous drug users. Antibodies to HCV appear relatively late in the course of acute infection and therefore, if clinical suspicion is high and risk factors are present, testing of the patient's serum for HCV RNA is the only means of establishing the diagnosis (see Fig. 48.10). Identification of cases of acute HCV infection is important because there is strong evidence that early treatment with interferon-a may reduce the risk of chronic infection with HCV. The apparent rate of chronicity in untreated patients is approximately 80%; with interferon monotherapy given for 6 months, a recent study showed that more than 90% of treated patients with acute hepatitis C clear virus.[43]

Hepatitis D

As HDV requires the presence of HBsAg for infectivity, it occurs only in patients who are infected with HBV either previously (superinfection) or simultaneously (co-infection). Co-infection is usually relatively benign; the determining factor for severity of illness is the HBV infection. As this is usually self-limiting, with loss of HBsAg after a relatively short interval, chronic infection with HDV is rare (about 2%).

Superinfection with HDV, by contrast, is a much more severe disease. The presence of large amounts of HBsAg allows rapid replication of the HDV and establishment of both acute and chronic infection. Chronic infection is common in this setting because the continued production of HBsAg allows the delta agent to continue replication.

Diagnosis of delta hepatitis is not easy: the encapsulation of HDV by HBsAg masks much of the HDV antigenemia, and assays for the detection of delta RNA in serum are not widely available and are not always reliable. Conventional solid-phase immunoabsorbent tests for the detection of delta antigen in serum are only positive early in the infection, before the development of delta antibodies, which complex with antigen. Immunoblot assay is now more widely available and does not have the same drawback because it is independent of antidelta antibody. The IgG antidelta antigen antibody is not protective and elevated levels correlate with continued infection.[44]

A number of other viruses can cause hepatitis (Table 48.2). In the main, liver involvement is incidental and other features of the illness will suggest a diagnosis other than primary hepatitis. The exceptions are yellow fever, and disseminated herpes simplex and varicella-zoster infections in immunosuppressed patients, which in both cases may be associated with a severe hepatitis.

TABLE 48-2 -- Viral infections that may be associated with hepatitis.

VIRAL INFECTIONS THAT MAY BE ASSOCIATED WITH HEPATITIS	
Virus	**Comment**
EBV, CMV	Both these viruses cause an acute mononucleosis-type syndrome in the normal host. Mild elevations of the liver transaminases may be seen but are usually of little consequence
HSV, VZV, CMV	All may cause hepatitis in the immunosuppressed host as part of a disseminated infection. CMV is the least severe
Flaviviruses	Yellow fever causes severe hepatitis
Measles, rubella, rubeola, coxsackie B adenovirus	Mild hepatitis occurs occasionally

TABLE 48-3 -- Tests required in asymptomatic patients who have elevated transaminase levels.

TESTS REQUIRED IN ASYMPTOMATIC PATIENTS WHO HAVE ELEVATED TRANSAMINASE LEVELS

• Ferritin
• a_1 -antitrypsin phenotype (if indicated)
EBV, Epstein-Barr virus; CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

Chronic viral liver disease

Chronic viral liver disease may present with abnormal liver biochemistry, by serologic testing in at-risk groups without symptoms or as a result of the complications of cirrhosis. Abnormal liver biochemistry in viral hepatitis is usually a sustained elevation of transaminases. In contrast to the situation in acute infection, the rise in the transaminase values is modest, characteristically only two or three times the upper limit of normal. In HCV infection, the ?-glutamyl transpeptidase values are also often elevated. The degree of abnormality of transaminases has little relevance to the degree of underlying hepatic inflammation. This is particularly true of HCV infection, in which the transaminase values are often normal despite active liver inflammation.

Further investigation in patients who have a positive serologic test for a hepatotrophic virus is to exclude other concomitant liver disease and assess the severity of liver damage induced by the hepatotropic virus. The risk of development of serious liver pathology is increased in the presence of multiple pathologies. Table 48.3 shows the required baseline serologic tests required. In HCV infection, autoantibodies are frequently positive, antismooth muscle antibodies being detected in about 10% of patients and low-titer antinuclear antibodies in 15–20%. These autoantibodies do not appear to play a part in pathogenesis and would only alter management if a high titer were present with a raised IgG, suggesting a primary autoimmune hepatitis, in which interferon therapy may be contraindicated.

Chronic hepatitis B

The vast majority of patients who have hepatitis B will be HBsAg positive. There are viral mutants that do not produce HBsAg detectable by the usual serologic tests (Table 48.4), but these are very rare except in patients treated with interferon or after liver transplant.

The traditional classification of those individuals who have chronic hepatitis B has been based on the presence of HBeAg. All patients who have HBsAg can be regarded as infected but HBeAg has been regarded as a marker of infectivity. Hepatitis B e antigen is produced as a truncated version of core protein (Fig. 48.11).

In the wild-type virus, HBcAg and HBeAg are transcribed together using overlapping bases. Hence HBeAg is an indirect marker of viral replication. The exact function of HBeAg is unclear but it appears to be involved in the downregulation of the T-cell response to HBV infection and may play a pivotal role in the development of the long

• Hepatitis B DNA
• Hepatitis B IgM anticore

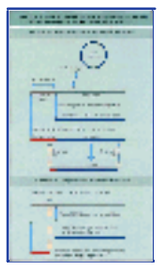

Figure 48-11 Production of hepatitis B core antigen and hepatitis B e antigen and the generation of e antigen-negative mutants. Hepatitis B virus (HBV) has a closed circular genome that contains insufficient bases to produce all its required proteins. It therefore uses different start points for transcription, enabling it to use the same base sequence to produce different proteins. Two important proteins, e antigen and core antigen, are produced by transcription of the same region with overlap; e antigen is produced from the core protein by cleavage at a specific site.

phase of relative immunologic tolerance seen in chronic HBV-infected carriers who acquire their infection in childhood. It has been shown that children infected with HBeAg-negative viral mutants do not have the immune tolerance that is almost universal in wild-type HBV transmission; most infected infants develop severe hepatic inflammation and cases of fulminant liver failure are described.

The discovery of HBeAg-negative mutant viruses has produced the need for a more specific marker of viral replication. The measurement of HBV DNA now provides direct detection of the circulating HBV genome.[45] This is the most sensitive measure of viral activity. There are two commonly used methods to estimate HBV DNA levels in serum: PCR-based techniques, which are very sensitive, and

branched chain DNA technology, which is rather cheaper to perform but less sensitive.

Patients who have persistence of HBsAg after 20 weeks of an acute episode can be assumed to have chronic carriage of the virus. Spontaneous loss of HBsAg after this time is unusual, being seen in only 1–2% of patients a year. Many people present with no obvious acute episode of hepatitis, and an apparently healthy person who is HBsAg positive can be regarded as chronically infected with HBV. The prognosis for that person is largely determined by the presence or absence of ongoing viral replication.

Chronic hepatitis C

Screening for HCV relies on antibody testing, with a second confirmatory test usually performed. Initial first-generation antibody assays were relatively unreliable with a high rate of false-positive results, but third- and fourth-generation ELISA-based tests are readily available and have high sensitivity and specificity. Confirmatory tests include radio-immunoblot assay (RIBA) and direct detection of viral RNA in peripheral blood using PCR. Initially there were major problems with the reliability of assays for detection of HCV RNA, with studies showing large variation in results between laboratories. This has been overcome to a large extent with the advent of commercially available kit systems for HCV RNA detection. These are reliable and sensitive. Hepatitis C virus RNA detection has largely replaced the use of RIBA testing in most centers. Detection of HCV RNA is regarded as the best test to determine infectivity and response to therapy. Hepatitis C antigen testing is now possible, and commercially available kit-based technology will make this test widely available. It has a very comparable specificity for the presence of HCV in blood to HCV RNA detection but is probably slightly less sensitive. Its major advantage is likely to be simplicity of assay and cost.

Patients presenting with detectable antibodies to HCV should be investigated (Table 48.5) to exclude other causes of chronic liver disease and to assess the severity of their HCV infection. Assessment of the severity of liver disease requires liver biopsy. Liver biopsy findings in hepatitis C are discussed later.

Chronic hepatitis D

Chronic infection with HDV has a high risk of producing severe liver disease. In the vast majority of cases of chronic infection, the HBV infection is nonreplicative as evidenced by HBeAg negativity and absence of HBV DNA.[46] This viral interference is seen in many combined viral infections (e.g. HBV and HCV infections) and it is rare to find patients with two replicating hepatotropic viruses. However, if the accompanying HBV is replicating, the prognosis is very poor with rapid progression to cirrhosis over as little as 2 years.[46]

Diagnosis of chronic HDV infection is usually by antibody testing in serum, where both IgM and IgG antidelta antigen antibodies are usually present in high titer, or by delta antigen staining on liver biopsy. Delta RNA testing is now more reliable and widely available

and is useful for monitoring therapy. For patients who have chronic infection, delta antigen staining in liver biopsy material remains the most definitive diagnostic test.[47]

MANAGEMENT (see Chapter 207)

Hepatitis B

Assessment of chronic hepatitis B virus infection

Any patient who has detectable levels of HBsAg is chronically infected. Assessment of a patient who has chronic HBV infection should include more detailed HBV serology, including measurement of HBV DNA levels. In patients who have no evidence of viral replication and normal liver enzyme levels and a normal liver ultrasound, liver biopsy is not usually required. Such patients have a very low risk of developing symptomatic liver disease or hepatocellular carcinoma. Reactivation of HBV replication has been described due to development of viral mutants which escape immune surveillance and patients who are HBsAg positive should be followed with yearly serology and liver enzyme estimations. The low risk of hepatocellular carcinoma does not justify screening in this group. In patients who have abnormal liver biochemistry (even without detectable HBV DNA) or an abnormal liver texture on ultrasound, a liver biopsy is probably required, because such patients may either have superinfection with HBV or have had ongoing replication of HBV in the past, sustaining substantial liver damage in the process. It is estimated that around 5% of patients in developed countries who have only HBsAg carriage at presentation will have a posthepatitic cirrhosis on liver biopsy. This finding is important because they are at risk of developing the complications of cirrhosis, including variceal bleeding and hepatocellular carcinoma.

Assessment of patients who have HBV replication is carried out by assessing the degree of liver inflammation and the stage of the underlying liver disease. Patients who are still in the tolerant phase of their infection usually have normal transaminase levels and high serum levels of HBV DNA (in excess of 10^8 copies per ml). As immune recognition increases, the HBV DNA levels fall, the degree of hepatic damage increases and the transaminases become abnormal. This is important in the selection of patients for therapy. Patients who have viral replication and abnormal transaminases should have a liver biopsy. The need for liver biopsy in a patient who has high levels of HBV DNA and repeatedly normal transaminases is less clear because it is very unlikely that the biopsy will show advanced liver disease or considerable inflammatory activity.

Therapy for hepatitis B

There are two licensed drug treatments for hepatitis B and a substantial number of new antiviral agents which are in either clinical trials or advanced stages of drug development. Although the agents used to treat hepatitis B vary considerably in their mode of action, the basic aim of treatment is the same: to stop viral replication. The concept of 'viral eradication' is not possible in hepatitis B; it is clear that viral DNA remains present in infected individuals over their lifetime. This is exemplified by reactivation of HBV in patients undergoing chemotherapy or other profound immunosuppression whose only marker of infection was antibodies to core antigen. It is, however, clear that almost all the major sequelae of infection with HBV are a consequence of active viral replication. This is clearly key for infectivity with major implications for others but is also required to generate liver cell damage. Individuals who remain HBsAg positive but have no ongoing viral replication are not at risk of developing significant hepatic fibrosis and consequently have a dramatically reduced risk of developing decompensated liver disease compared to those with ongoing viral replication. The only serious complication of HBV infection which is not entirely dependent on viral replication

---

TABLE 48-6 -- **Factors indicating the likelihood of response to interferon in chronic hepatitis B virus infection.**

FACTORS INDICATING THE LIKELIHOOD OF RESPONSE TO INTERFERON IN CHRONIC HEPATITIS B VIRUS INFECTION		
Factor	**High probability of response**	**Low probability of response**
Age	<50 years	>50 years
Sex	Female	Male
Hepatitis B DNA level	Low	High
Activity of liver inflammation	High	Low
Country of origin	Europe, North America, Australasia	Asia
Co-infection with HIV	Absent	Present
PCR, polymerase chain reaction.		

is cancer development where a risk remains, particularly in those with an established cirrhosis. Even there, the risk of developing hepatocellular carcinoma is substantially greater in patients where replication continues. Consideration of therapy is therefore only appropriate in patients where HBV is active as evidenced by detectable levels of HBV DNA. The choice of therapy is then determined by a number of factors: the stage of infection, the level of HBV DNA, the presence of mutant virus as the predominant strain (as evidenced by the presence or absence of e antigen), the degree of inflammatory liver disease and the degree of hepatic fibrosis.

Interferon therapy

Interferon-a was first shown to be effective for some patients who have HBV infection in the 1980s and it remains an effective therapy.[48] There are a number of commercially available variants of interferon-a, natural interferon, recombinant interferons and consensus interferons. In HBV infection there is little evidence that the type of interferon-a used has any substantial difference in effect or side-effect profile. Newer formulations of interferon-a, pegylated interferons, are now available. Clinical trials of these molecules in hepatitis B infection are being undertaken although there are few data available currently as to their effectiveness. They are more convenient for patients because of once rather than three times weekly administration. Trials are addressing their effectiveness as monotherapy but also in combination with other antiviral agents such as lamivudine. There are a number of factors that can help predict the likelihood of response to treatment with interferon-a and these aid selection of patients who have the best chance of response to therapy (Table 48.6).

TABLE 48-7 -- Common side-effects of interferon-a therapy for viral hepatitis.

COMMON SIDE-EFFECTS OF INTERFERON-a THERAPY FOR VIRAL HEPATITIS	
Side-effect	**Frequency (%)**
Flu-like syndrome	80
Depression	20
Local inflammation at injection sites	25
Hypothyroidism	10
Arthralgia or arthritis	10
Hair loss	10

Overall, the probability of response to interferon therapy in chronic hepatitis B is between 25% and 40%. A response to therapy is the cessation of viral replication; only a small number of patients lose all markers of infection with HBV and HBsAg usually remains in the serum. There is now good evidence that successful therapy with interferon, which renders the HBV nonreplicative, produces a sustained improvement in liver histology and a decrease in the risk of developing end-stage liver disease. The risk of developing hepatocellular carcinoma also appears to be reduced but it is not abolished in those who remain HBsAg positive. The likely reason why a number of patients with apparently successful responses to interferon therapy go on to develop significant liver disease is the emergence of mutant HBV strains which resume viral replication and hence liver cell injury.

Interferon therapy has a number of drawbacks: it is not effective in many patients, it is expensive and it has a large number of side effects (Table 48.7). In general, about 15% of patients on interferon therapy have no side-effects, 15% cannot tolerate therapy and the remaining 70% experience side effects but are able to continue therapy. Most patients are able to continue at work during therapy but many require substantial support. Depression can be a major problem and both suicide and admissions with acute psychosis are well described. Early use of antidepressants and close monitoring are essential, especially if there is a preceding history of

depression.

Treatment of hepatitis B in patients who have significant fibrotic liver disease is rewarding because they have a relatively high probability of response and have most to gain from cessation of viral replication. Many patients have a substantial improvement in liver function if viral replication is stopped, but treatment in such patients does carry an increased risk. Interferon therapy produces viral clearance, at least in part, by inducing immune-mediated killing of infected hepatocytes, and hence a transient hepatitis can cause severe decompensation requiring liver transplantation.

Week 20	+	+	+	+

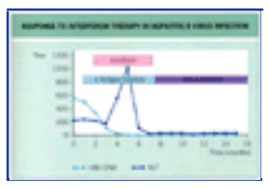

Figure 48-12 Response to interferon therapy in hepatitis B virus infection. HBV, hepatitis B virus; ALT, alanine transaminase. Measurements in arbitary units.

The optimal dose and duration of interferon for hepatitis B remain somewhat contentious, but most clinicians use 8,000,000–10,000,000 units three times a week for 4–6 months. It is likely that most treating clinicians will use pegulated interferons in the future, with doses based on body weight for the 12kDa molecule and a standard dose of 180µg for the 40kDa molecule. No comparative data exist as to their relative effectiveness. Monitoring therapy is intensive, and appropriate schedules are shown in Table 48.8 .

Patterns of response and special situations

The most frequent pattern of response to interferon-a is shown in Figure 48.12 . The HBV DNA level falls rapidly after initiation of interferon therapy. This is followed by a marked rise in transaminase values. This represents immune-mediated clearance of virus, and HBV DNA levels quickly fall to undetectable levels. This is then followed within a few weeks by seroconversion to HBeAg-negative, HBeAb-positive status with complete normalization of transaminases. This type of response is seen in 25% of treated patients. Hepatitis B surface antigen usually remains positive, with a small proportion of patients clearing all markers of viral infection either during interferon therapy (2%) or many months after it (6%). A further proportion of patients show a late seroconversion after therapy (Fig. 48.13).

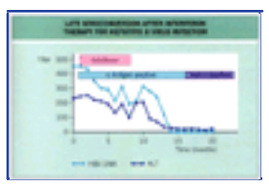

Figure 48-13 Late seroconversion after interferon therapy for hepatitis B virus infection. HBV, hepatitis B virus; ALT, alanine transaminase. Measurements in arbitary units.

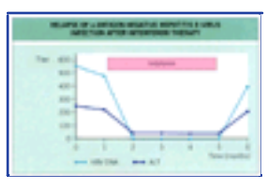

Figure 48-14 Relapse of eAg-negative hepatitis B virus after interferon therapy. HBV, hepatitis B virus; ALT, alanine transaminase. Measurements in arbitary units.

In such patients there is often an initial fall in HBV DNA levels but these remain detectable throughout therapy together with persistently abnormal transaminase values. After the end of treatment there is then a progressive fall in HBV DNA and normalization of transaminases. Seroconversion from HBeAg to anti-HBeAb follows after a few weeks or months of HBV DNA negativity. Such delayed responses to therapy occur in 10–15% of treated patients and this emphasizes the need to persevere with therapy once the decision to undertake treatment has been made.

There are a number of specific situations in which the above treatment protocols may change. In Greece and Italy, the proportion of patients with HBeAg-negative mutant virus infection is relatively high, and this situation is also encountered elsewhere. There is compelling evidence that, although such patients show a good rate of initial response to interferon with disappearance of HBV DNA from serum, they very frequently relapse after cessation of treatment (Fig. 48.14). There is now evidence that giving interferon therapy for longer in such patients may improve the rate of loss of viral replication. A regimen of 6,000,000 units three times a week for 24 months has been shown to produce a loss of viral replication in 30% of patients.[49]

Lamivudine therapy

Lamivudine, a nucleoside analogue, is a potent inhibitor of HBV DNA replication. Lamivudine has a good safety profile and has now been widely tested in patients who have chronic HBV infection. It was initially shown to produce a rapid fall in HBV DNA levels in short-term trials, mainly in post-transplant, recurrent HBV infection. In this setting, it produces marked improvement in liver function and histology and there is little doubt that this agent represents a major improvement in the therapy of hepatitis B.

Both in the posttransplant setting and when given in trials in patients who have chronic HBV in their own livers (Fig. 48.15), lamivudine has been shown to produce rapid inhibition of HBV DNA production, but this rapidly returns when therapy is stopped. With a 6-month period of therapy, 80% of patients who have chronic HBV became HBV DNA negative.[50] In about 14% of transplant patients a breakthrough was seen in which viral replication started again despite continuation of therapy. This phenomenon has also been seen in patients treated in the nontransplant setting with similar frequency (14% at 1 year),[51] and has been shown to be due to selection of a mutation in the YMDD locus of the HBV polymerase gene,[52] which allows viral replication in the presence of lamivudine.

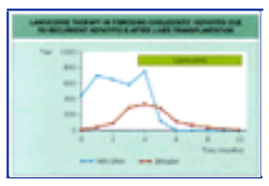

Figure 48-15 Lamivudine therapy in fibrosing cholestatic hepatitis due to recurrent hepatitis B after liver transplantation. HBV, hepatitis B virus. Measurements in arbitary units.

In longer term trials in patients of Asian origin, who have a relatively low probability of response to interferon therapy, almost all treated patients showed prompt inhibition of HBV DNA and, if therapy was continued for 12 months, a sustained inhibition of replication was seen in 35% with seroconversion to HBeAg negativity. This was associated with an improvement of inflammation and a reduction in progression of fibrosis on liver biopsy. Side-effects of treatment are generally mild. Breakthrough occurred in 6% of treated patients. A trial in Hong Kong looking at combination therapy with interferon and lamivudine failed to show any additional benefit from combining therapy, but this remains an area of ongoing study, particularly with the use of pegylated interferon and lamivudine. Lamivudine monotherapy, however, has an important role in the treatment of HBV, its main limitation being the development of viral resistance. Emergence of lamivudine-resistant HBV is increasingly common with prolonged treatment. Genotypic resistance is detectable in 14–32% of patients after 1 year and increases to 38%, 49% and 66% after 2, 3 and 4 years, respectively.[53] [54] The emergence of lamivudine-resistant HBV is not necessarily associated with phenotypic resistance, i.e. loss of clinical benefit. If this occurs, the decision whether to continue with lamivudine or stop treatment depends on the clinical setting. There is no doubt that lamivudine resistance can be associated with severe histological liver damage, particularly in the post-transplant setting. It is, however, clear that YMDD mutants of HBV are generally less replication competent than wild-type HBV, with lower levels of HBV DNA present in serum. This means that therapeutic benefit can continue even if viral replication returns.

The optimal duration of lamivudine therapy remains uncertain. For the majority of patients treated with lamivudine, inhibition of virus occurs with resumption on stopping therapy. In addition, the viral breakthrough means that a significant number of patients will still have active virus despite lamivudine. In patients treated with wild-type HBV, those with e antigen present in serum, the main aim of therapy once viral inhibition has been obtained is to see seroconversion to e antigen negative and e antibody positive. This switch is dependent on the immune recognition of HBV and if it occurs, usually represents an extension of host immunity and an immune environment where continued HBV replication will be either not present or present at much lower levels. If this occurs on therapy there is evidence that treatment with lamivudine can be stopped with a much reduced risk of the resumption of replication. Using available data therefore, approximately 35% of patients will have

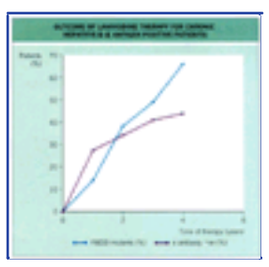

Figure 48-16 Outcome of lamivudine therapy for chronic hepatitis B (e antigen positive patients). e antigen seroconversion and the development of viral resistance both occur.

made this e seroconversion switch after a year of therapy and lamivudine can be stopped with continued monitoring (Fig. 48.16). There remains uncertainty as to the implications for an individual who has seroconverted to e antigen negativity but has also developed YMDD breakthrough and remains HBV DNA positive. In this situation, a trial period off therapy may be appropriate but monitoring will be required.

Factors predicting an initial response to lamivudine therapy (removing HBV DNA from serum initially) have been examined in large clinical trials. The most important predictors of initial response are the pre-treatment HBV DNA level and the degree of inflammatory response.[55] It is clear that patients in the 'immunotolerant' phase of their infection are those least likely to respond to lamivudine as they have very high levels of HBV DNA and minimal or no liver injury. Clearly this is the same group who will not respond to interferon therapy. This group are, however, not ill and can be safely monitored without therapy until the immune response changes. The only indication to try lamivudine in this context would be uncommon situations where the risk of transmission to others was high. The chances of removing viral replication in this group are, however, low.

The other clinical group where uncertainty remains about lamivudine therapy are those with significant liver disease. There is no doubt that in patients with decompensated cirrhosis and ongoing viral replication, lamivudine is effective at suppressing viral activity and that liver function recovers. The only issue is the potential for long-term viral breakthrough in this group which could preclude liver transplantation. This issue is likely to be resolved with the advent of alternative antiviral agents which can be effective in the pretransplant setting.

e Antigen-negative HBV and lamivudine

In Europe, up to 60% of all replicating hepatitis B infections now are in the late phase of infection, where initial inactivation of replication has occurred with later reactivation with so called precore mutant viruses which can presumably avoid the immune response. It is well

described that these mutants are generally much less responsive to therapy with interferon-a. Lamivudine has been shown to be effective at removing HBV DNA from serum and normalizing transaminases. Unfortunately this effect is not maintained in all patients, approximately 50% being HBV DNA positive again in 18 months. This virological breakthrough is progressive in terms of the level of HBV DNA and accompanied by the return of biochemical and histological hepatitis in the majority over time.[56] The management of precore mutant HBV therefore remains imperfect but lamivudine clearly has a role in patients with significant liver injury.

New therapies for HBV

There are a substantial number of new agents which have evidence of activity against HBV; most are nucleoside analogues. The best characterized is adefovir dipivoxil. Adefovir has been shown to produce a rapid decline in HBV DNA in the majority of treated patients and, unlike lamivudine, has shown little development of viral resistance in both wild-type and precore mutant HBV infection over a sustained period.[57] Histological improvement has been shown with this agent and it is a viable alternative for patients who have significant liver injury with lamivudine-resistant virus. Its safety profile is good but significant renal injury has been described with high doses. Entecavir and tenofovir are other agents with proven activity against HBV. Further studies are required to define their exact role (see Chapter 207). [58]

Treatment of HIV and HBV co-infection

With the advent of improved antiretroviral therapy, patients with HIV infection have good immune reconstitution and excellent long-term survival. Co-infection with hepatitis viruses is common and liver disease is now a leading cause of death in HIV-infected people. Hepatitis B infection in this group is challenging to manage. Many patients have been exposed to lamivudine as part of their antiretroviral therapy and have high levels of replication with lamivudine-resistant HBV. In this setting interferon has only a limited role, as the altered immune environment rarely allows clinical response to this agent. Adefovir dipivoxil is effective at reducing HBV DNA in lamivudine-resistant HBV in HIV-infected patients but there are few long-term outcome data (see also Chapter 125). [59]

Hepatitis C

Natural history of hepatitis C virus infection

In order to assess the need for treatment in a patient who has hepatitis C, it is important to have a clear understanding of the natural history of this infection and of the factors that may predispose to more severe outcome. In general, our knowledge is limited because of the relatively recent discovery of HCV. It is, however, clear that HCV-related liver disease is usually slowly progressive, taking many years to produce significant hepatic fibrosis. The most definitive studies to date suggest that the average time from infection to the development of cirrhosis is 33 years.[60] The rate of progression is, however, very variable with some 'rapid fibrosers' progressing to cirrhosis 11 years after infection and other 'slow fibrosers' who would take more than 40 years to progress to cirrhosis. The major factors associated with increased risk of progressive liver disease were age over 40 years at infection, high alcohol consumption and male sex (Table 48.9). Viral genotype may be important in progression but the data are controversial. This is illustrated by the epidemiology of HCV infection in Italy, which can be regarded as two separate outbreaks. The first outbreak, which involved HCV genotype 1, was spread by blood transfusion, infected older people and produced severe liver disease. The second, later outbreak was spread by intravenous drug use and was predominantly due to HCV genotype 3; it appeared to be associated with less severe liver disease. This emphasizes the difficulty of

extracting

TABLE 48-9 -- Factors influencing the progression of hepatitis C virus (HCV) infection.*

FACTORS INFLUENCING THE PROGRESSION OF HCV INFECTION	
Risk factor	**Time from infection to cirrhosis (years)**
Age >40 years	12
Age =40 years	35
Alcohol <50g/day	31
Alcohol >50g/day	24
Male	26
Female	36

** From Poynard et al. [60]*

single risk factors for progression of liver disease from epidemiologic studies because patients infected via transfusion are older as well as being infected by a different viral genotype.

In general, virologic factors have not proved as significant in predicting rates of progression; high viral load and genotype 1 have been proposed as markers of more serious liver disease but evidence that they are directly related to rapid progression of liver disease is lacking.

Management of the patient is usually based on the degree of liver damage as assessed by biopsy.

Liver biopsy

Assessing the need for therapy in hepatitis C is difficult. This is a disease which has a long natural history and an uncertain outcome. Liver biopsy is the only method of directly assessing the degree of inflammation in the liver and the stage of liver disease (fibrosis). All patients who are viremic with abnormal transminases need assessment by liver biopsy. There is a small group of patients who have documented viremia who have persistently normal transaminase levels. In this group, the incidence of serious disease on biopsy appears low.[61] However, the degree of elevation of alanine aminotransferase (ALT) in HCV infection is often minor and it fluctuates. Hence many patients with an initially normal ALT level will have abnormal values if they are followed carefully. In general it seems sensible to have liver biopsy evidence of the stage of disease in all viremic patients. Emerging therapies may alter this requirement. With the very high levels of cure seen with the latest therapies in patients infected with certain viral genotypes, the need for histology may lessen, particularly in young patients with no other risk factors for the development of severe fibrotic liver disease. Most treatment guidelines currently available still rely on assessment of liver histology.

Assessment of liver biopsies

There are two important features in the histologic assessment of hepatitis C. The first is disease stage (fibrosis); the second is the degree of necroinflammatory change. In order to improve the reproducibility of assessment there are a number of scoring systems that have been used to quantify viral hepatitis: the most widely used are the Knodell score[62] and a modification of this, the Ishak score.[63] These scores combine the two elements of assessment of chronic viral liver disease: fibrosis stage and inflammation. The difference between the Ishak and Knodell scores is that Ishak expanded the stage score to allow more discrimination of minor degrees of fibrosis.

Interferon-a therapy

The licensed treatment for hepatitis C is a combination of interferon-a and ribavirin. It is possible to predict response rates in patient populations, but wide variations are seen between patient groups.

Response to interferon-based therapy is defined by measurement of two parameters: serum transaminases and the detection of HCV RNA in serum. Many studies have also examined the effect of interferon therapy on the histologic progression of liver disease.

Interferon-a was first used to treat non-A, non-B hepatitis in the 1980s. Since the identification of HCV in 1989, a large amount of information has become available about the effectiveness of interferon therapy in HCV infection and its drawbacks. There is some evidence that the natural interferons may have slightly more antiviral effect than the recombinant interferons in HCV infection. This difference is, however, marginal at best and in practice there is little difference in effectiveness or side-effects with any of the commercially available variants. These 'standard' interferons have been superseded by the advent of pegylated molecules, which should now be regarded as the standard treatment for HCV infection when given in combination with ribavirin (see also Chapter 207).

Defining response to therapy

There are three potential responses to interferon-based therapy in patients who have HCV infection:

- no response in either biochemical or virologic markers (nonresponders);
- a suppression of HCV RNA and normalization of ALT on therapy but relapse after cessation of therapy (relapsers); or
- a disappearance of HCV RNA and normalization of ALT that is maintained after stopping therapy (sustained responders).

Overall, the chance of sustained response to interferon-a as monotherapy in HCV infection was approximately 20%.[64]

Ribavirin (1-b-D-ribofuranosyl-1H-1,2,4-triazole-3-carboxamide) is an oral nucleoside analogue which inhibits replication of a number of viruses. Initial studies of ribavirin in chronic HCV infection showed a lowering of transaminase levels but no effect on viral load when given as monotherapy. The effect on transaminases was also transient, returning to baseline values when therapy stopped. These initial data encouraged trials of combinations of interferon-a and ribavirin.

A landmark study in 1998[65] showed that combining standard interferon-a (3 million units three times per week) with ribavirin (1–1.2g per day on bodyweight) increased overall cure rates from around 20% to 35–40%. This study in the USA and a parallel study in Europe[66] also underlines the critical response factors and established the vital importance of hepatitis C genotype in the prediction of response to therapy. Genotype 1 or 4 infection is more difficult to

TABLE 48-10 -- 'Response factors' in interferon and ribavirin therapy for chronic hepatitis C.*

'RESPONSE FACTORS' IN INTERFERON AND RIBAVIRIN THERAPY FOR CHRONIC HEPATITIS C.			
Factor	**IFN+ribavirin 48 weeks**	**IFN+ribavirin 24 weeks**	**IFN alone 48 weeks**
Genotype 2 or 3	64%	64%	33%
Genotype 1 or 4	31%	18%	11%
HCV RNA $<2 \times 10^6$	47%	44%	31%
HCV RNA $>2 \times 10^6$	40%	28%	13%
Age <40	49%	41%	28%

Age >40	34%	26%	11%
Fibrosis — minor	46%	38%	21%
Fibrosis — major	33%	17%	10%
Female	45%	43%	24%
Male	41%	31%	16%
All percentages relate to sustained virological response.

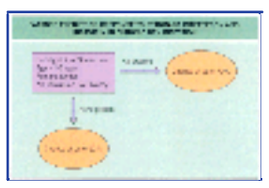

Figure 48-17 Factors predicting response to standard interferon and ribavirin therapy in chronic HCV infection.

treat and requires a longer duration of therapy to obtain its best results (Table 48.10). While genotype of virus remains the major determinant of response to therapy, other factors continue to have an influence (Fig. 48.17) and when planning duration of therapy should be taken into account. Ribavirin therapy does add to the toxicity of interferon. Ribavirin produces a hemolytic anemia in a substantial minority of patients treated. This effect is dose dependent and it is possible to keep patients on therapy by the use of dose reduction (Fig. 48.18). The mechanism of ribavarin's effect on hepatitis C remains unknown. It appears to act predominantly by immunomodulation, rather than as a direct antiviral effect. Its major action seems to be to prevent patients with relatively interferon-sensitive hepatitis C infection relapsing once initial viral clearance has occurred.

The combination of interferon and ribavirin was rapidly accepted as standard therapy. This has now been superseded by the advent of the pegylated interferons. Pegylation involves the attachment of an inert polyethylene glycol molecule to the active molecule, in this case interferon-a. The chemistry of pegylation is complex; there are many sites where the PEG chains can be attached and they have a variety of chain structures. There are two pegylated interferon-a molecules available and they do have substantial differences in their chemistry, if not in clinical effect. Interferon a-2a has been pegylated to form a 40kDa molecule whereas interferon-a-2b is pegylated into a 12kDa molecule. The difference in molecular size has two implications: the 40kDa molecule is excreted in bile and to a lesser extent renally, whereas the smaller molecule is cleared by the kidney. The 12kDa molecule is insoluble and is dispensed as powder for reconstitution whereas the larger is a liquid. Overall half-life in plasma is around 5–7 days with both molecules (Fig. 48.20).

Initial studies with these agents as monotherapy showed that effectiveness was enhanced compared to standard interferon monotherapy (Fig. 48.19).[67] One significant study with the 40kDa molecule showed sustained response rates of over 30% in patients with established cirrhosis (Fig. 48.20), [68] a dramatic change over previously published results. These studies also established that the fibrosis seen in patients with hepatitis C infection could reverse with successful therapy, underlining the fact that all patients with severe fibrotic liver disease should be considered for therapy.

The success with pegylated interferon monotherapy was followed by trials of combination therapy with pegylated interferon and ribavirin.[69] The only fully published data relate to the 12kDa pegylated interferon (Fig. 48.21). These data, using a year of therapy in all patient groups, showed that this combination had significant benefit for patients with genotype 1 infection and had no greater side effects

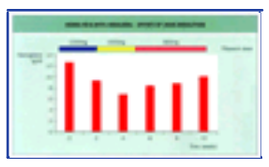

Figure 48-18 Hemolysis with ribavirin — effect of dose reduction.

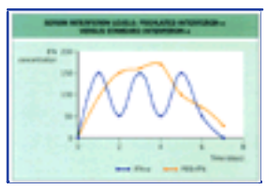

Figure 48-19 Serum interferon levels: pegylated interferon-a versus standard interferon-a.

for those with genotype 2 or 3 infection where effectiveness was similar. Hence with a better method of delivery for patients, this combination of treatments established the new standard of care and for the first time placed clinicians in a position to offer cure to more than 50% of infected patients. Trials of the 40kDa molecule have

Figure 48-20 PEG-interferons as monotherapy in interferon-naive patients with and without cirrhosis.

also been undertaken and results are available in abstract form only at present. The 40kDa molecule showed an overall sustained response rate of 57%, with a significant increment for both genotype 1 and genotype 2 or 3 infection. Results for the two differing interferons have been remarkably similar considering their different structure, with cure rates of 75% or more in genotype 2 or 3 infection and in excess of 40% in genotype 1 infection. The licence approved for the 12kDa molecule extrapolated from the previous interferon and ribavirin studies and gave 6 months therapy for patients with genotype 2 or 3 infection and 12 months for genotype 1 infection. Trials to confirm this are ongoing but most clinicians use these durations in clinical practice. The 40kDa molecule has been trialed in 6 versus 12 month settings and these data confirm that with this therapy there is no advantage for continuing therapy beyond 6 months in good response genotypes but that longer therapy produces worthwhile benefit in genotype 1 or 4 infection. Again these data are not yet fully published.

This great improvement in effectiveness of therapy has encouraged many patients to try treatment. The side-effect profile differs very little from standard interferon and ribavirin therapy, the only changes being a greater degree of injection site reactions. This remains a challenging therapy for patients to take. Compliance has been shown to be important; in an analysis of the 12kDa molecule with ribavirin, patients who were able to comply with therapy (by taking 80% of their medication for 80% of the time[70]) had better

Figure 48-21 Results or therapy with pegylated interferon and ribavirin compared to standard therapy. All based on 12 months' duration of therapy.

response rates than those who did not. Hence encouraging patients to complete the intended duration of therapy is important. This is somewhat easier in patients infected with genotype 2 or 3 infection as they have a high chance of cure with only a 6-month course of treatment required. It is more difficult for genotype 1 or 4-infected patients who have to have 12 months therapy to obtain the best result. About 15% of patients will be nonresponders to pegylated interferon and ribavirin; there is now good evidence to show that the results at week 12 of treatment are able to detect these individuals. The viral kinetics of responders show an initial very rapid decline in viral load, often complete in the first week or two of therapy. In a proportion, this initial decline slows and a second phase of more gradual decline starts. With both PEG-interferons, if the virus has not disappeared from serum at week 12, or at least declined by 2 logs from pretreatment samples, then the chance of a sustained response is almost nil (0% for the 12kDa molecule, 2% for the 40kDa molecule[71]). This allows patients who will not benefit from further therapy to be identified at the 3-month stage of treatment and therapy can be stopped. It also has the advantage of giving significant encouragement to patients who do make this cut-off; if they have responded at this stage their overall chance of cure rises.

Special patient populations

There are limited data as to the effectiveness of PEG-ribavirin in individuals co-infected with HIV. What information is available suggests that therapy with PEG and ribavirin is safe in patients on antiretroviral therapy and can be effective. Immune reconstitution seems important in response; if CD4 counts are normal response rates seem only slightly lower than non-HIV infected patients. Large trials in the USA and Europe are under way (see also Chapter 125 and Chapter 141).

In renal replacement therapy units or after renal transplantation, treatment is difficult. Ribavirin is renally excreted and effectively contraindicated in this setting. PEG interferon monotherapy can be given and has a reasonable chance of success prior to renal transplant but carries significant risks of rejection if used post transplant.

Hepatitis D

Delta virus infection is uncommon and the mainstay of therapy is to inactivate HBV replication in those with active co-infection. For patients with negative HBV DNA interferon-a therapy has been studied with only limited success. With standard interferon given at a dose of 3 million units three times per week, 29% will normalize ALT but most do not lose HDV RNA and relapse at the end of therapy. Higher dose treatment (9 million units three times per week) had a better biochemical and virological response but again most patients relapsed.[72] It is clear that if interferon therapy is given for delta infection a long duration of therapy is required, which few patients can tolerate. There is a case report of resolution of HDV replication after 12 years on interferon[73] but few patients will be so motivated. Studies of lamivudine[74] and famciclovir[75] have shown no benefit. There are as yet no trials of pegylated interferon in delta hepatitis.

Chapter 49 - Hepatobiliary Infection

Janice Main

LIVER ABSCESSES

PYOGENIC ABSCESS

Pathogenesis and pathology

Bacteria can reach the liver via the portal vein, the systemic circulation, the biliary tree, through the skin (following trauma or trans-hepatic procedures such as liver biopsy) or directly following perforation of a viscus with an ingested fish bone or other sharp object (Fig. 49.1).[1] Pyogenic liver abscesses are usually associated with biliary tree obstruction or gastrointestinal (GI) tract infection such as missed appendicitis, diverticulitis, perforated peptic ulcers, colonic carcinoma or following colonic surgery. The usual organisms are therefore from the GI tract or biliary tree. Liver abscesses are often polymicrobial with Enterobacteriaceae and enterococci predominating. *Streptococcus milleri* is increasingly seen in liver abscesses and staphylococci are not uncommon. *Actinomyces* spp.,[2] *Bartonellae henselae* [3] and *Capnocytophaga* [4] spp. are more unusual isolates from liver abscesses; in immunosuppressed persons infections by *Nocardia* spp.,[5] mycobacteria[6] and fungi such as *Aspergillus* spp. can cause abscess formation. Abscesses can be solitary or multiple and range in size from several centimetres in diameter to microabscesses identified histologically.

Clinical features

Pyogenic liver abscesses are classically seen in elderly patients with underlying GI disease. The patient may complain of right hypochondrial discomfort that is insidious in onset or may present more acutely with feverishness or an acute confusional state. Interventions such as transarterial embolization and percutaneous laser ablation of hepatocellular carcinoma can be complicated by liver abscess[7] and the diagnosis may be missed because fever and discomfort are not uncommon following the procedure. The differential diagnoses include cholecystitis and pyelonephritis.

Diagnosis

Abdominal ultrasound is the simplest way of making the diagnosis. Single or multiple abscesses may be present and the ultrasound may also help identify the original source of the sepsis, such as an obstructed biliary tree. Smaller abscesses not detected on ultrasound may be visible on computed tomography (CT) scanning,[8] which can also help determine the source of sepsis if this is not apparent on the ultrasound. Aspiration of the abscess yields useful microbiologic material and is an important part of therapy. Cytologic examination of smears from the abscess are important to exclude underlying and malignancy.

Blood cultures may also help with the microbiologic diagnosis. The white count is usually elevated and liver function tests may be deranged with elevation of alkaline phosphatase. The presence of a microcytic hyphochromic anemia in an elderly patient, for example, may point to an underlying colonic carcinoma. The patient should also be screened for diabetes and iron overload syndromes should be considered when *Yersinia* spp. are identified. [9]

Management

Drainage of the abscess is important and the favored approach is needle aspiration under ultrasound guidance. This may need to be repeated on several occasions, particularly if there are multiple lesions. Percutaneous catheter drainage is another approach, but is generally only practicable if there is one large and accessible abscess.

Abscesses are often polymicrobial and broad-spectrum intravenous antibiotics are generally recommended. If the abscesses are thought to have occurred as a result of biliary sepsis it is advisable to give antibiotics that achieve good concentrations in bile. Positive blood cultures and cultures from the abscess should help direct antimicrobial chemotherapy. The combination of gentamicin and amoxicillin-clavulanic acid or ticarcillin-clavulanic acid are useful regimens and should be given with metronidazole to broaden the anaerobic cover and if there is concern about possible amebic infection. Piperacillin-tazobactam and the carbapenems are also useful.

Although liver abscesses are more commonly seen in hospital practice the mortality rate has fallen considerably over the past 40 years[10] and this is attributed to advances in imaging and anti-microbial chemotherapy.

AMEBIC LIVER ABSCESS

Pathogenesis and pathology

Entamoeba histolytica reaches the liver via the portal vein and causes necrosis of the liver parenchyma. This is a complication in up to 10% of cases of amebic colitis.

The necrosis leads to liquefaction of the liver and the characteristic thick reddish brown pus, which is said to resemble anchovy sauce. On microscopy, hepatocytes, neutrophils and red blood cells are evident. Host factors can influence outcome. Secondary bacterial infection can occur and can complicate the clinical picture and cause confusion with pyogenic liver abscess.

Clinical features

Clinical features of amebic and pyogenic abscesses are compared in Table 49.1 . An amebic abscess can develop many years after travel to tropical areas and the long latency period has not been adequately explained. Cases have been described 30 years after the initial bowel infection. The patient may complain of right hypochondrial pain and fever. Lesions near the diaphragm can cause referred right shoulder discomfort. Low-grade fever may be present. More acute presentations with rigors have been reported. An abscess encroaching on the biliary tree may cause some biliary obstruction and mild jaundice, but deep jaundice is unusual. Right hypochondrial tenderness may be present and rarely a swelling may be evident in the epigastrium or right hypochondrium. There may be elevation of the right hemidiaphragm or a pleural effusion and therefore reduced expansion,

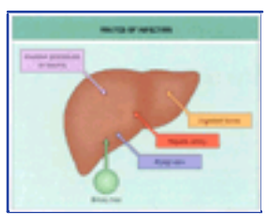

Figure 49-1 Routes of infection.

TABLE 49-1 -- Features of pyogenic and amebic liver abscess.

FEATURES OF PYOGENIC AND AMEBIC LIVER ABSCESS		
	Pyogenic	**Amebic**
Patients	Elderly, underlying gastrointestinal or biliary tract disease	Much more common in males than females
Imaging	Single or multiple abscesses	Solitary abscess right lobe
Pathogens	Polymicrobial, Enterobacteriaceae, enterococci	*Entamoeba histolytica*
Other tests	Blood cultures	Amebic immunofluorescent antibody test
Treatment	Broad-spectrum antimicrobials, aspiration	Metronidazole, diloxanide +/- aspiration

dullness to percussion and reduced air entry. Rarely an abscess can rupture within the lung or pericardium.

Diagnosis

An ultrasound examination will demonstrate the presence of an abscess, which is typically large and located in the right lobe of the liver. Smaller abscesses may be present. Abscesses can also be demonstrated on CT scanning or magnetic resonance imaging (MRI) of the liver. Aspiration may reveal the characteristics 'anchovy sauce' appearance, and although it is unusual to demonstrate amebae on microscopy, microscopy and culture are important to exclude a pyogenic liver abscess or secondary infection of an amebic abscess. A bleed into an underlying malignant lesion can mimic the symptoms of an amebic abscess. Cytology can demonstrate the presence of malignant cells and point to the diagnosis of an underlying metastatic lesion or primary hepatocellular carcinoma.

In patients presenting acutely it important to repeat the ultrasound a few days later if initially negative.

The chest radiograph may demonstrate elevation of the right hemidiaphragm or the presence of a pleural effusion.

The liver function tests may be normal, but there may be an elevation of the alkaline phosphatase and bilirubin and a large abscess can have a compressive effect on the intrahepatic bililary tree.

TABLE 49-2 -- Major causes of granulomatous liver disease.

MAJOR CAUSES OF GRANULOMATOUS LIVER DISEASE
Bacteria
Mycobacteria (*Mycobacterium tuberculosis, Mycobacterium avium-intracellulare, Mycobacterium leprae*)
Brucella spp.
Listeria spp.
Tropheryma whipplei
Yersinia spp.
Treponema pallidum
Viruses
Cytomegalovirus
Epstein-Barr virus
Hepatitis A and C viruses
Rickettsiae
Coxiella burnetii
Rickettsia conori, Rickettsia typhi
Protozoa
Leishmania spp.
Worms
Schistosoma spp.
Toxocara spp.
Fungi
Histoplasma spp.
Coccidioides spp.
Drugs
Primary liver disease (e.g. primary biliary cirrhosis)
Neoplasms (e.g. lymphoma)
Diseases of unknown cause (e.g. sarcoidosis, inflammatory bowel disease)

Treatment

Metronidazole followed by diloxanide to remove luminal cysts is the treatment of choice. In patients with large amebic abscesses aspiration with metronidazole hastens recovery,[11] but medical treatment alone is effective in over 90% of cases.[12] (See also Chapter 164 .)

DIFFUSE PARENCHYMAL INVOLVEMENT

The liver may be involved in many systemic infections. Viral infection has been described elsewhere (Chapter 48), but acute hepatitis has been described with several bacterial pathogens including meningococci, *Salmonella typhi*, *Listeria*, *Campylobacter*, *Borrelia* and *Brucella* spp.[13] [14] Septicemia and other causes of circulatory collapse can also cause hepatic ischemia, which can be associated with high transaminase values.[15] Infections account for many of the main causes of granulomatous liver disease (Table 49.2). Liver involvement and symptoms of liver disease can be a major part of the following infections:

MYCOBACTERIAL INFECTIONS

Tuberculosis of the liver

The liver is generally involved in miliary tuberculosis and the liver biopsy may help establish a diagnosis of tuberculosis in a patient with unexplained fever.

Pathology

Tuberculosis of the liver may present as an abscess[6] or more diffuse disease and liver biopsy may reveal nonspecific hepatitis or granulomatous

liver disease. Rarely tuberculomas may be present or enlarged intrabdominal lymph nodes can cause compression of the biliary tree and the patient presents with features of biliary tract obstruction.

Clinical features

Fever and weight loss are the usual symptoms. The patient may appear wasted. Hepatomegaly may be evident, but massive hepatomegaly is unusual. In severe tuberculosis infection the patient may present with liver failure.

Diagnosis

Elevated alkaline phosphatase levels are usually present and the albumin levels may be low if the disease has been longstanding. Anemia and elevation of the erythrocyte sedimentation rate and C-reactive protein are common. A chest radiograph is important to exclude active pulmonary disease, which is evident in a minority of cases.[16] The abdominal ultrasound may demonstrate intrabdominal lymphadenopathy or evidence of peritoneal involvement. Liver biopsy may be diagnostic, but caseating granulomas with acid-fast bacilli are demonstrable in less than 10% of cases. The appearances may be nonspecific and it is important to culture some of the liver biopsy material. It is hoped that rapid diagnostic methods such as polymerase chain reaction will facilitate diagnosis in the future.[17]

Management

Standard antimycobacterial therapy should be given (see Chapter 37 , Chapter 202). Liver function tests should be monitored as with standard therapy. As the patient improves the elevated alkaline phosphatase gradually returns to normal. Elevation in the transaminase level may be a sign of drug toxicity. Fever may persist for several weeks, but if the patient fails to improve then the possibilities of resistant *Mycobacterium tuberculosis* or atypical mycobacteria have to be considered.

Atypical mycobacteria

Atypical mycobacterial infection of the liver is usually seen in the setting of immunosuppression, particularly underlying HIV infection[18] or congenital immunodeficiency. Again culture of the biopsy material is important to establish the diagnosis, but the appearance of many organisms with poorly formed granulomas may be an important clue to atypical mycobacterial infection in an immunocompromised host.

SYPHILIS

The liver is involved with congenital, secondary and later stages of syphilis.

The standard screening tests usually confirm the diagnosis of congenital infection, but the diagnosis should also be considered in the setting of undiagnosed acute hepatitis in adults.[19] This is discussed in detail in Chapter 75 and Chapter 230 .

LEPTOSPIROSIS (see also Chapter 181)

Epidemiology

Several *Leptospira* species are associated with human disease, but *L. icterohaemorrhagiae* is specifically associated with Weil's disease. The main source of this pathogen is rat urine and it is therefore an occupational hazard for farm and sewage workers and those who use contaminated waters for recreational purposes such as rowing.

Pathology

The liver demonstrates cholestasis with swelling of hepatocytes, but very little necrosis. In classic Weil's disease renal disease is evident with acute tubular necrosis. There may be evidence of multifocal hemorrhage, particularly within skeletal and cardiac muscle.

Prevention

The use of protective clothing can help prevent occupational exposure and it has been recommended that sewage workers carry cards to remind clinicians of the possibility of leptospirosis should they become ill. Prophylactic antimicrobials such as doxycycline[20] have been suggested for those at risk of exposure through work or leisure activities such as canoeing, although this is not generally recommended.

Clinical features

The patient's occupation or leisure activities may point to the diagnosis.

In common with other spirochaetal infections there are several characteristic stages of the disease process. The severity varies from a minor influenza type illness to life-threatening multisystem failure. The incubation period ranges from two to 17 days.

The first (septicemic) stage is of a multisystem disease. It is abrupt in onset. Features may include:

- high fever,
- myalgia (often severe),

- abdominal pain,
- nausea,
- vomiting,
- severe headache and meningitis (CSF leukocytosis and an elevated protein level),
- pneumonitis,
- conjunctivitis,
- hepatomegaly,
- jaundice (said to be an ominous sign),
- bleeding (thought to be mainly related to capillary damage and leading to ecchymoses, gastrointestinal bleeding and on occasion intracerebral bleeding).

Urinalysis reveals proteinuria and bilirubinuria. The white count is usually elevated with mainly polymorphonuclear cells (it may be as high as 30,000/ml or 3×10^9 /l). Thrombocytopenia may be present. The liver function tests demonstrate elevated levels of bilirubin and alkaline phosphatase. In contrast to fulminant viral hepatitis the transaminase values may be normal or moderately elevated.

During the second stage or 'immune stage' the pyrexia generally resolves, but life-threatening disease may be evident. There may be signs of myocardial involvement with arrhythmias and nonspecific ECG changes. Blood tests confirm deteriorating liver function with evidence of muscle damage (elevated muscle enzymes). Worsening renal function is also a feature with elevations in the serum creatinine and proteinuria.

In the third (convalescent) stage a steady clinical and biochemical improvement occurs with resolution of the liver and renal failure and improved myocardial function. Minor relapses of symptoms can occur at this stage with further episodes of myalgia and spikes of fever.

Diagnosis

During the first phase of the disease leptospira may be found on examination of the blood film or grown from blood cultures. By the second phase the blood cultures are likely to be negative. Leptospira may be evident on urine microscopy, but the diagnosis is more likely to be made from the serologic tests for antileptospira antibodies, which are found in increasing titres in the convalescent stage of the disease.

At the time of the initial presentation, although the symptoms and jaundice may suggest a viral hepatitis, the high fever and leukocytosis

would be unusual for viral etiology, but similar hepatitic illnesses with or without renal failure have been described with hantaviruses.[21] [22]

Management

Most patients with leptospirosis are not seriously ill, but for those with Weil's disease full supportive care may be required with support and hemodialysis in an intensive care unit. High-dose intravenous penicillin is the treatment of choice, but the dose may need modification according to the renal function. A febrile reaction, similar to the Jarisch-Herxheimer reaction, can occur.

HELMINTHIC PARASITES OF THE LIVER

SCHISTOSOMIASIS (see also Chapter 167)

Schistosomal ova can reach the liver via the mesenteric veins and portal system. Liver involvement is particularly seen with *Schistosoma japonicum* and *Schistosoma mansoni*,, but can also occur with *Schistosoma haematobium*. In the early stages a granulomatous reaction is seen, but over years, if untreated, extensive collagen deposition can lead to portal fibrosis with the development of portal hypertension and splenomegaly (Fig. 49.2).

The diagnosis of schistosomal liver disease may only come to light when the patient presents with features of portal hypertension and, for example, has a variceal bleed.

Diagnosis

The diagnosis may be made from the serologic test — schistosomal enzyme-linked immunosorbent assay — or the histologic appearances of the granulomatous liver disease in the early stages and the fibrosis in the later stages. In the early stages a peripheral eosinophilia may be evident.

Management

Praziquantel is the treatment of choice. Patients should be warned that an influenza-like like illness can follow therapy. Supportive therapy is required for the patient with severe fibrosis and liver transplantation may be required in advanced cases.

HYDATID INFECTION (see also Chapter 169)

Hydatid cysts can follow infection with the *Echinococcus* tapeworm.

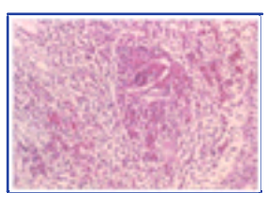

Figure 49-2 Schistosomiasis of the liver. A refractile schistosome ova is located in a portal tract and is associated with an eosinophil-rich granulomatous inflammatory reaction.

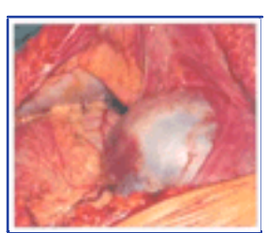

Figure 49-3 Hydatid disease. Hydatid cyst of the liver.

Epidemiology

The disease is widespread and man is typically infected by close contact with dogs which have become infected by the consumption of eggs from infected meat. Echinococcal infection is endemic in the main sheep farming areas of the world and is a particular concern throughout much of Europe, the Mediterranean littoral, Asia, South America and Kenya.

Pathology

The liver is the most frequent site for hydatid cysts (Fig. 49.3).

The ova enter the liver via the portal vein and lead to cyst formation within the liver parenchyma — classically involving the right lobe of the liver on the inferior surface. Rupture of a cyst, spontaneously or following trauma or surgical procedures, can lead to cardiovascular collapse. This is thought to be an inappropriate immune response to released hydatid antigens. Rupture of the cysts can also lead to infection into the biliary tree, the peritoneum, lungs and pleura.

Clinical features

Hydatid disease may be asymptomatic and liver cysts found incidentally on ultrasound examination, as calcified lesions on plain abdominal radiographs or at autopsy. Hepatomegaly may be present. The cyst may be diagnosed after ruptures or if secondary infection of the cyst occurs. Cysts can also be found within the brain, lungs, kidney and the heart (Fig. 49.4).

Diagnosis

The hydatid serology test is particularly useful although false-positive and -negative results can occur. A peripheral eosinophilia may be present. Several radiologic features can be helpful in making the diagnosis. Plain abdominal radiographs may reveal calcified

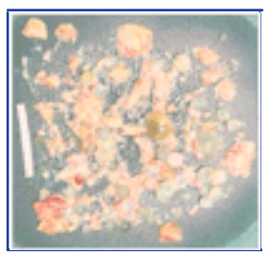

Figure 49-4 Hydatid disease. Hydatid 'daughter cysts'.

spherical structures within the liver. Ultrasound examination can often reveal several forms of the cysts, which can be single, multiple, thin- or thick-walled. CT scanning can detect smaller lesions and the presence of calcification. It may difficult to differentiate a single cystic lesion from a tumor. Biopsy or aspiration of the cysts may be dangerous in view of the risk of antigen leakage and immune response and should be performed only when there is appropriate backup to treat circulatory collapse and laryngeal edema.

Management

The management of hepatic hydatidosis remains controversial and many approaches have been tried. It is recognized that by itself antimicrobial therapy with albendazole, mebendazole or praziquantel is generally ineffective and should be combined with a drainage procedure. Percutaneous drainage has the advantage of avoiding major surgery, but in open surgical procedures peritoneal contamination is thought to be minimized by packing the surgical field with povidone-iodine swabs, decompressing the cysts by aspiration and then removing the cyst contents. Some surgeons advocate the use of injecting formalin or hypertonic saline into the cysts following decompression. In one study,[23] 50 patients with hepatic hydatidosis were randomized to receive either percutaneous aspiration and albendazole or cystectomy. Similar efficacies were demonstrated in both treatment groups, but the open surgical procedure was associated with greater morbidity. Puncture, aspiration and the use of alcohol and polidocanol as sclerosing agents are being increasingly used.[24]

ASCARIASIS

Rarely the large *Ascaris* roundworm can migrate up through the bile duct and cause biliary obstruction. More commonly the liver is involved as a result of ova invading the liver via the portal vein and setting up a localized granulomatous reaction.

Liver involvement is usually asymptomatic unless rare complications such as biliary obstruction, hemobilia or liver abscesses develop.

Worms within the biliary tree may show up as motile linear lesions on ultrasound or endoscopic retrograde cholangiopancreatography (ERCP).

TOXOCARA

Toxocariasis is a further cause of hepatic granulomas. The recommended therapy is thiabendazole.

LIVER FLUKES

Liver flukes are thought to invade the liver from the peritoneal cavity and migrate through the liver parenchyma to the biliary tree where an inflammatory reaction develops.

CLONORCHIS SINENSIS

Infection with *Clonorchis sinensis* is usually associated with the consumption of raw or undercooked fish in Asia. The flukes live within capillaries of the biliary tree and the inflammatory reaction can cause obstruction and encourage cholelithiasis. Cholangitis is a common complication and the ongoing inflammation and fibrotic reaction is thought to predispose the patient to the development of cholangiosarcoma.[25]

Diagnosis

Flukes may be evident on radiologic imaging such as percutaneous transhepatic cholangiography or ERCP. This diagnosis must be considered when atypical cholangiopathy is diagnosed in patients of eastern origin. The diagnosis is confirmed by finding the ova on stool microscopy.

Management

Praziquantel is the treatment of choice. Surgical or endoscopic approaches may be required to deal with associated cholelithiasis and biliary obstruction.

FASCIOLA HEPATICA

Infection with this common sheep fluke can follow consumption of contaminated watercress and is recorded throughout Europe, South America, the Caribbean, Africa and China.

Pathology

The picture is usually of biliary tract infection and obstruction, but hepatic granulomatous reactions can also occur.

Clinical features

In the early stages of infection the patient may complain of fever and right hypochondrial pain. Hepatomegaly may be present. The migration of the flukes within the biliary tree can lead to inflammatory and fibrotic reactions. Cholelithiasis can occur and the clinical picture may be of a bacterial cholangitis. In common with bacterial cholangitis the alkaline phosphatase may be elevated, but the presence of an eosinophilia should point to the possibility of a fluke infection.

Diagnosis

The diagnosis may be suggested by a history of watercress consumption and features of cholangitis and an eosinophilia. Praziquantel is the therapy of choice and surgical and endoscopic intervention may be required to deal with biliary tree obstruction.

PROTOZOAL INFECTIONS

LEISHMANIASIS (see also Chapter 172)

Visceral leishmaniasis or kala-azar can lead to massive hepatosplenomegaly.

Epidemiology

Leishmanial infection is transmitted by sandflies and is reported particularly around the Mediterranean basin, in South America and Asia.

Pathology

Host factors are thought to be important in determining the disease outcome following leishmanial infection. It is not known why some patients develop only localized lesions and others develop more serious systemic disease. Underlying HIV infection is associated with multisystem disease and reactivation of previous infections.[26]

Clinical features

The patient may present with fever or anemia. Massive hepatosplenomegaly may be present.

Diagnosis

The presence of organisms may be detected by bone marrow examination, liver biopsy or splenic aspiration. Hypergammaglobulinemia is often present. Serologic tests are often useful, but antibody tests may be negative in patients with HIV infection or other types of immunodeficiency.

Management

Therapy of leishmaniasis is somewhat limited by the toxicity of many of the antimicrobial agents. Antimonial compounds, for example, can

cause pancreatitis. Liposomal and other preparations of amphotericin are being increasingly used with success. In the setting of immunosuppression maintenance regimens are often required with regular administration of amphotericin B or intravenous pentamidine.

MALARIA

During acute malaria the parasitic load within the reticuloendothelial system and particularly the liver may be large and this may result in hepatic dysfunction. This is thought to predispose the patient with malaria to bacteremia. Mild elevation of the transaminase values may occur, but hyperbilirubinemia is mainly associated with the hemolysis of malaria rather than hepatic dysfunction.

TOXOPLASMA

Mild hepatitis or granulomatous liver disease has been reported with both primary and reactivation forms of toxoplasmosis infection.

FUNGAL INFECTIONS

The liver may be involved as part of a systemic fungal infection in a patient with candidemia.[27] Cryptococcal, histoplasmosis and pneumocystis infection of the liver are mainly seen in patients with HIV infection.

Aspergillus infection of the liver with abscess formation is mainly seen in patients with neutropenia as a result of chemotherapy.

BILIARY TREE INFECTIONS

ACUTE CHOLECYSTITIS

Pathology

Gallbladder infections are usually the results of gallstone formation and impaction within the cystic duct[28] with impaired biliary drainage leading to infection, edema and compressive effects on the local blood supply, which can cause gangrene of the gallbladder. Suppuration within the gallbladder can lead to bacteremia, septicemia, cholangitis and liver abscess formation. Acalculous cholecystitis can follow infection with *Salmonella* or *Campylobacter* spp. or can occur in acutely ill patients following major surgery or burns. In the setting of HIV infection, infection with *Salmonella* or *Campylobacter* spp. may be implicated or the gallbladder disease may be a feature of HIV cholangiopathy, [29] which is often associated with cytomegalovirus infection, cryptosporidiosis, microsporidiosis or lymphoma.

Clinical features

The patient may describe right hypochrondrial discomfort, which can occur in waves. Radiation to the right shoulder is common. Feverishness or rigors can occur and the patient may develop bacteremia and septicemia. Right hypochondrial tenderness is usually present and the gallbladder may be palpable in one third of cases. A degree of jaundice may be present depending on the extent of biliary tree obstruction.

Diagnosis

The diagnosis is usually made clinically, but ultrasound of the liver and gallbladder may demonstrate gallstones with thickening of the gallbladder wall or dilatation of the biliary tree in the presence of obstruction. Laboratory findings include an elevated white cell count, hyperbilirubinemia and elevated alkaline phosphatase. There may be modest elevations of the transaminase values. Impaired biliary drainage because of pancreatic carcinoma can also cause dilatation of the biliary tree and ERCP may be required to delineate the anatomy and to facilitate drainage if required. Magnetic resonance cholangiopancreatography (MRCP) is a helpful, noninvasive imaging technique useful in visualizing the biliary tract.[30]

Management

The priorities are to facilitate drainage of the biliary tree and to treat infection. Cholecystectomy, when performed by the open technique, has a high mortality and morbidity rate in patients with acute cholecystitis and the usual practice was for conservative management of the acute illness and elective cholecystectomy some weeks later. This, however, required two hospital admissions and the emergency readmission rate was high for these patients.[31] Laparascopic cholecystectomy is increasingly performed early in patients with acute cholecystitis[32] and appears successful, even when gangrenous cholecystitis[33] is present. For frail patients who are unfit for surgery ERCP can be both life-saving and diagnostic, with endoscopic removal of stones by sphincterotomy, basket or balloon removal and stent insertion. Where ERCP is not available or not technically feasible percutaneous biliary drainage can be performed.

Elective cholecystectomy can generally be performed subsequently, but emergency surgery may be required if the situation is complicated by a gangrenous gallbladder or poor response to antimicrobial therapy.[34]

Antimicrobial therapy is generally prescribed to cover Gram-negative bacilli, enterococci and anaerobes, although the importance of enterococcal infection is debated in this setting.[35] Piperacillin-tazobactam or ticarcillin-clavulanic acid are therefore useful. Aminoglycosides must be used carefully in this setting, particularly in the elderly because there is a high incidence of renal impairment in patients with biliary tree sepsis. Cephalosporins and quinolones do not adequately cover enterococcal infection. Antimicrobial prophylaxis is also advised for procedures involving an obstructed biliary system.

CHOLANGITIS

Pathology

Bacterial cholangitis generally results from infection of an obstructed biliary tree and is most commonly caused by gallstones obstructing the common bile duct.[36] Other predisposing causes include congenital biliary tract disorders, sclerosing cholangitis, HIV cholangiopathy and bile duct strictures.

Clinical features

The symptoms and signs are generally similar to acute cholecystitis, but the patient may have no history of abdominal pain and present with septicemia.

Diagnosis

Bacteremia has been reported in half the cases of cholangitis. Blood cultures are important investigations. The alkaline phosphatase and bilirubin are usually elevated. Ultrasound may show dilatation of the biliary tree with stones, but the bile duct is often difficult to visualize and other imaging techniques, such as endoscopic ultrasound and MRCP[37] may be required. ERCP is useful for diagnosis when the patient has been stabilized.

Management

As with cholecystitis the priorities are supportive care for the patient with the appropriate antimicrobial chemotherapy and drainage of the obstructed biliary system. The mortality rate when endoscopic sphincterotomy is used is lower [38] than with conventional surgical techniques.

CHRONIC CHOLECYSTITIS

Chronic cholecystitis is an unusual condition. Again gallstones are commonly seen. Chronic cholecystitis may be seen following infection with *Salmonella* or *Campylobacter* spp.

Management

Elective cholecystectomy is the treatment of choice. Laparoscopic cholecystectomy is increasingly used for gallstone disease and acalculous cholecystitis and is associated with lower morbidity and mortality rates.

Chapter 50 - Practice Points

50.a Management of an outbreak of gastroenteritis

Hilary Babcock

It is estimated that 76 million people contract food-borne illnesses annually in the USA. The incidence of the most common bacterial gastrointestinal infections has been decreasing steadily since 1996.[1] Outbreaks of gastroenteritis are still frequent, however, and can be both disruptive and disturbing to the community where they occur. This era of increasingly global mobility has stretched the definition of 'community' as well, so that the guests at a wedding in Smalltown, Ohio, who all contracted *Salmonella* from the chicken salad, might be found 3 days later all over the country and all over the globe.

Investigating these outbreaks serves several functions. First, investigations can suggest both short- and long-term control measures, preventing further cases from occurring during an ongoing outbreak and preventing further outbreaks in the future. Any members of the wedding party who took home left-over chicken salad can be prevented from sharing it with their family and the caterer can be better educated about handling raw chicken so that future weddings will not suffer the same aftermath. Second, outbreak investigations can identify new pathogens or provide new information about transmission, natural history and management of known pathogens. Third, the information generated in these investigations can be used by epidemiologists locally, nationally and internationally to monitor trends in specific infections over time and to guide changes in food handling regulations to improve public safety in the future.[2]

Common causes of food-borne outbreaks of gastroenteritis

Table 50a.1 and Table 50a.2 summarize the major causes of gastroenteritis outbreaks and provide clinical and epidemiologic information on each one. More detailed information on these diagnoses is available in Chapter 93 .

Identification of an outbreak

An 'outbreak' is defined as an increase in the incidence of a given disease or symptom complex clearly in excess of the usual rate. An outbreak may be brought to attention by clinicians noticing an unusually high number of patients with similar complaints, by laboratory workers noticing an unusually high number of isolates of a particular organism, or by members of the public noting an unusual number of cases of illness among friends or family (or the wedding party). The first goal of the outbreak investigation is to verify that an outbreak is occurring. This verification requires establishment of a prior baseline rate of illness or disease and confirmation that the purported cases all have the disease of interest. For example, laboratory contamination of multiple cultures with the same organism represents a different problem than an outbreak of clinical disease in the community. Co-ordination with local health departments, infection control specialists, infectious disease physicians and laboratory directors is crucial for these investigations.

Epidemiologic investigation

The first step in evaluating a verified outbreak is to generate case definitions. Multiple definitions may be necessary. A definite case, or laboratory confirmed case, is usually a person who has a clinically compatible symptom complex as well as laboratory-confirmed evidence of a specific disease. In cases of gastroenteritis, not all subjects may have undergone stool testing and not all microbes are easily identified. These subjects may be labeled clinical cases or probable cases. Once the source of the outbreak is identified, cases may also be divided into primary cases, acquired directly from the source, and secondary cases, acquired later from person-to-person transmission.

Once cases have been identified, an 'epi curve' can be generated with the date of onset of each case's symptoms. This exercise can help to determine the timing of the exposure and the incubation period of the infection. The shape of the curve will also help to determine the type of outbreak, by transmission pattern. Outbreaks can be divided into three types by source of exposure:

- ¦ Point source: exposure occurs once, at a single time and place, although possibly to multiple subjects. Example: contaminated chicken salad at a wedding reception (Fig. 50a.1);
- ¦ Common source: there is a single source of exposure but the source is available over a period of time. Example: a food handler who has hepatitis A prepares contaminated food at a restaurant. All subjects patronizing that restaurant while the food handler is working there will be exposed (Fig. 50a.2); and
- ¦ Person-to-person/propagative/ongoing transmission: after the initial exposure, infected subjects can pass on the infection to 'unexposed' subjects (Fig. 50a.3).

A combination of these types is also possible.

Determining the exposure source in an outbreak of gastroenteritis requires eliciting careful and detailed food histories from all affected subjects. The Centers for Disease Control and Prevention have on their web site an 'Outbreak Investigation Toolkit' that includes an

TABLE 50.a-1 -- Types of food poisoning.

TYPES OF FOOD POISONING			
Infection	**Incubation period**	**Major symptoms**	**Outbreak pattern**
Clostridium perfringens	18–36 hours	Watery diarrhea and colicky abdominal pain	1
Norwalk agent (small, round-structured viruses)	24–48 hours	Vomiting, diarrhea, myalgias, headache	1, 2, 3
Scombrotoxic poisoning	1–4 hours	Histamine poisoning (headache, flushing, urticaria, swelling, tingling lips)	1
Diarrhetic shellfish poisoning	<1 day	Acute diarrhea (severity proportional to dose of toxin)	1, 2
Paralytic shellfish poisoning	4–6 hours (?)	Bradycardia, parasthesia, muscle weakness	1, 2
Salmonellosis	18–36 hours	Diarrhea, vomiting	1, 2, 3
Bacillus cereus toxin (rapid)	1–6 hours	Nausea, precipitant vomiting	1, 2
Bacillus cereus toxin (late)	10–12 hours	Abdominal pain, profuse watery diarrhea, nausea	1, 2
Clostridium botulinum	24–48 hours	Cranial nerve palsy followed by general paralysis	1
Bean hemagglutinins	Minutes after ingestion	Severe vomiting, profuse diarrhea	1
Shigellosis	1–3 days	Fever prodrome, colic and diarrhea, occasional hyperpyrexia in children	2, 3

Escherichia coli 0157, verotoxin producing *E. coli* organisms	1–2 days (up to 5 days)	Brisk watery diarrhea, bloody stools, abdominal pain	1
Food-poisoning *Vibrio* spp.	5–92 hours	Watery diarrhea and colicky abdominal pain	1, 2
Yersinia enterocolitica	3–7 days	Mild-to-moderate gastroenteritis, aching abdominal pain	1, 2
Staphylococcal toxin	30 minutes to 6 hours	Nausea, precipitant vomiting	1
Campylobacter spp.	2–4 days (maximum 8–9 days)	Diarrhea, vomiting, abdominal pain, blood *per rectum*	1, 2, 3
Outbreak patterns: 1, point source; 2, common source; 3, person-to-person.			

TABLE 50.a-2 -- Complications of food poisoning.

COMPLICATIONS OF FOOD POISONING			
Infection	**Complications**	**Patients who have complications (%)**	**Isolation needed**
Bacillus cereus toxin (rapid)	Dehydration, occasional shock	Unusual	No
Bacillus cereus toxin (late)	No direct complications	-	No
Bean hemagglutinins	Dehydration, shock	Rare	No
Campylobacter spp.	Prolonged symptom, potential for relapse, bacteremia, focal sepsis, rarely Guillain-Barré syndrome	10–20% ill for >1 week, 5–10% relapse, bacteremia in <1%	Yes
Clostridium botulinum	Full requirement for respiratory support	50–80%	No
Clostridium perfringens	Dehydration, occasional shock	Elderly and compromised	Yes
Diarrhetic shellfish poisoning	No complications	-	No
Escherichia coli 0157, verotoxin producing *E. coli* organisms	Hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura	2–8%	Yes
Food-poisoning *Vibrio* spp.	No complications	-	Yes
Norwalk agent (small, round-structured viruses)	Not recorded	-	Yes
Paralytic shelfish poisoning	Death	Rare	No
Salmonellosis	Sepsis, reactive arthritis, distant focal collection, osteomyelitis in sickle cell disease, meningitis in infants	5% sepsis, 2% reactive arthritis	Yes
Scombrotoxic poisoning	Hypotensive crisis	<1%	No
Shigellosis	Osteomyelitis in sickle cell disease	Rare	Yes
Staphylococcal toxin	Shock, occasional death	<1%	No
Yersinia enterocolitica	Postinfectious arthritis, erythema nodosum	Arthritis 10–30%, erythema nodosum 30%	Yes

extensive 'Standard Foodborne Disease Outbreak Case Questionnaire' that can be very helpful (www.cdc.gov/ncidod/dbmd/outbreak/). Travel and event (e.g. weddings, parties) histories, as well as names of specific restaurants, should also be obtained when possible. If a specific etiologic agent is known or suspected, the incubation period of that pathogen can guide the timeframe for the food history.

In cases with a point source outbreak, any remaining food products should be collected and saved for possible testing. In common source outbreaks, where exposure may be ongoing, collecting

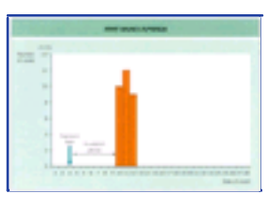

Figure 50.a-1 Point source outbreak.

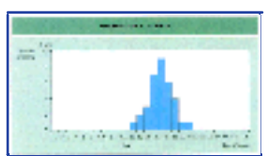

Figure 50.a-2 Common source outbreak.

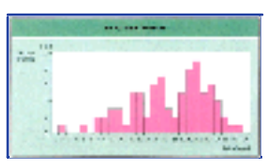

Figure 50.a-3 Propagative outbreak.

environmental and food samples from the suspected source location may confirm the etiology. Occasionally, the source of the infection can be confirmed with positive cultures from the incriminated food source. Negative cultures from food or other sources, however, should not be used to exclude potential sources as techniques of culture from disparate materials are not well standardized and may not be reliable. A positive source is not the end of the investigation either, as the infected food item may have been contaminated by a worker who has since prepared other items. Medical histories focused on compatible symptoms should be elicited from workers who prepared any implicated food items, if they are not already identified as cases.

From the elicited histories, multiple hypotheses may be made, evaluated and discarded. Comparison with unaffected individuals can be helpful in testing promising hypotheses. Often, histories are elicited from unaffected family members, work colleagues or guests of an event. From these histories a case-control study can be performed to analyze statistically the association of illness with specific exposures. Depending on the size of the outbreak and the number of cases and controls available, the case-control analysis may not have the power to demonstrate a statistically significant association. In those settings, other components of the analysis can be helpful in making a causal inference. These factors include the magnitude of the association, the temporal sequence of exposure and disease, any dose-response effect and the biological plausibility of the hypothesis.

Management of the outbreak

Management of the suspected source of the outbreak can be difficult. Witnessing new subjects becoming infected while information is being collected can be frustrating both to the investigators and to the public. However, announcing the inspection or closure of an individual food establishment or the recall of a food item can have profound legal and economic consequences. Management of the public announcement of any findings must also be handled carefully. Adequate but appropriate communication is necessary to ensure public health protection. A single designated media spokesperson is often helpful in the delivery of a coherent and co-ordinated message. Once the source is identified, prompt control measures must be instituted to prevent further exposures. In cases where the investigation reveals the potential for widespread effects, involvement of state and national agencies may be necessary. If the chicken salad at the wedding was contaminated by tarragon imported from another country, international co-operation may be required.

Practical arrangements for large scale outbreaks include ensuring adequate bed and staffing availability in local hospitals, emergency rooms and clinics; adequate communication of etiologic findings, presenting symptoms and clinical management suggestions to local clinicians; and co-ordination with state and local authorities.

Conclusions

Prior investigations of outbreaks of gastroenteritis have implicated a hepatitis-A-infected pastry chef who hand-glazed the pastry,[3] a food service worker infected with a Norwalk-like virus who prepared contaminated deli sandwiches,[4] cheese curds inadvertently made with unpasteurized milk contaminated with *Escherichia coli* 0157:H7,[5] a Komodo dragon at the zoo with *Salmonella* infection,[6] and lasagne contaminated with *Salmonella enteritidis*.[7] Each investigation is an opportunity to prevent further acute illnesses and to gather information helpful in preventing similar outbreaks in the future.

50.b Management of persistent postinfectious diarrhea in adults

Kok-Ann Gwee
Michael W McKendrick

Introduction

The presence of diarrhea beyond 2 weeks of a confirmed or presumed infectious exposure is a useful working definition of persistent diarrhea as this helps to exclude most common acute bacterial and viral infections, although protozoal infections may persist for longer. Patients who have persistent diarrhea who have recently returned from a tropical or developing country can also be considered as having postinfectious diarrhea.

Pathogenesis and clinical features

Postinfectious irritable bowel syndrome

In a prospective study, we found that 25% of previously healthy patients developed a diarrhea-predominant type of irritable bowel syndrome (IBS) (Table 50b.1) after an episode of acute infectious diarrhea. Psychologic disturbances such as anxiety and stressful recent life events were important predictors for the development of IBS. Other potential pathogenic factors are lactose malabsorption,

TABLE 50.b-1 -- Points to note in the history and physical examination of patients who have persistent diarrhea.

POINTS TO NOTE IN THE HISTORY AND PHYSICAL EXAMINATION OF PATIENTS WHO HAVE PERSISTENT DIARRHEA
• Onset of diarrhea in relation to confirmed or presumed infectious illness
• Travel to or residence in tropics or developing countries
• Weight loss
• Nature of the stools; frequency, consistency, estimated volume, steatorrhea
• Bowel symptoms suggesting irritable bowel syndrome: abdominal pain relieved by defecation, constipation, passage of mucus, feeling of incomplete evacuation, bloating
• Other abdominal symptoms: flatulence (suggesting giardiasis, lactose malabsorption), blood in the stool (suggesting colitis, dysentery)
• Risk factors for HIV if appropriate
• Examination for evidence of weight loss, anemia, malabsorption, abdominal masses, lymph nodes

TABLE 50.b-2 -- Organisms that may be involved in chronic diarrhea and their antibiotic treatment.

ORGANISMS THAT MAY BE INVOLVED IN CHRONIC DIARRHEA AND THEIR ANTIBIOTIC TREATMENT			
Organism		**Antibiotic**	**Suggested dosage**
Bacteria	*Shigella* spp.	Quinolones, e.g. ciprofloxacin, nonfloxacin	500mg q12h for 5 days
	Salmonella spp.		400mg q12h for 5 days
	Campylobacter spp.		
	Aeromonas spp.		
	Plesiomonas shigelloides		
	Spirochetes	Metronidazole	400mg q8h for 10 days
	Clostridium difficile toxin positive colitis	Metronidazole	400mg q8h for 10–14 days
		Vancomycin (oral)	125mg q6h for 10–14 days
		Cholestyramine	4g q8h for 10–14 days
Protozoa	*Giardia lamblia*	Metronidazole	2g q24h for 3 days
		Tinidazole	2g once daily for 1 day
	Entamoeba histolytica	Metronidazole	800mg q8h for 5 days
		Tinidazole	1g q12h for 3 days
	Cyclospora cayentensis	Trimethoprim-sulfamethoxazole	2 tablets q12h for 7 days
	Isospora belii	Trimethoprim-sulfamethoxazofe	2 tablets q6h for 14 days
	Blastocystis hominis	Metronidazole	800mg q8h for 10 days
Helminths	*Strongyloides stercoralis*	Thiabendazole	25mg/kg (maximum 1.5g) q12h for 3 days
		Albendazole	400mg q12h for 3 days (repeat at 3 weeks if required)
	Trichuris trichiura	Mebendazole	100mg q12h for 3 days
	Capillaria philippinensis	Mebendazole	100mg q6h for 20–30 days
	Mixed infection	Mebendazole	200mg q12h for 5 days
		Albendazole	400mg q24h for 3 days
Tropical sprue		Tetracycline plus	250mg q6h for 30 days (minimum)
		Folic acid	5mg q12h for 90 days

alterations in colonic motility and sensitivity, changes in the colonic microflora and bile acid malabsorption.

Inflammatory bowel disease

Some patients who have inflammatory bowel disease (IBD) in their initial presentation have a positive microbial finding. However, symptoms may persist or recur despite the eradication of the inciting organism. Commonly implicated pathogens are *Entamoeba histolytica, Shigella* spp., *Salmonella* spp., *Aeromonas* spp. and *Clostridium difficile*. Possible explanations for this association include bacterial infection added on to previously unrecognized IBD, and the precipitation of IBD by an

altered intestinal microflora or by an immunopathogenic effect of bacterial products of inflammation.

Human immunodeficiency virus-associated enteropathy

HIV-associated enteropathy may present with chronic diarrhea and significant weight loss or malabsorption. It is believed that in the majority of HIV-infected patients who have chronic diarrhea, a potential pathogen can be detected.

Postinfective malabsorption

Tropical sprue presents with chronic gastrointestinal symptoms and malabsorption following an acute diarrheal episode that is usually contracted in a tropical country (although it has also been described

in travelers to the Mediterranean area). Although a specific microbial agent has not been identified, the typical response to broad-spectrum antibiotics suggests an infectious pathogenesis. Intestinal infections with parasites, especially *Giardia lamblia*, may also present similarly.

Persistent intestinal infections

Occasionally infective colitis associated with *E. histolytica, Cryptosporidia, Campylobacter jejuni* or *Salmonella* spp. may persist beyond 6 weeks (Table 50b.2). The clinical spectrum of *G. lamblia* infection ranges from asymptomatic cyst excretion through chronic diarrhea with marked flatulence to intestinal malabsorption. *Cyclospora cayetanensis* is a newly recognized protozoal parasite that causes prolonged watery diarrhea in a characteristic relapsing cyclic pattern even in immunocompetent patients. Although cases of chronic diarrhea associated with *Blastocystis hominis, Aeromonas* spp. and *Plesiomonas shigelloides* have been reported, their pathogenic potential remains uncertain.

Diagnosis

Patients can be stratified to an appropriate level of testing on the basis of the points listed in Table 50b.1 .

Level 1 tests are:

- stool studies — microscopy, culture, ova, cysts and parasites, and tests for *C. difficile* toxin;
- blood studies — full blood count, erythrocyte sedimentation rate, biochemistry (electrolytes, protein, albumin, thyroid hormones) and studies for the detection of HIV antibodies; and
- sigmoidoscopy.

In a patient who has no history of travel to or residence in a tropical or developing country and no significant weight loss or blood in the stools, level 1 tests would usually be sufficient. To optimize the yield from stool examinations, three specimens, preferably when stools are loose, should be collected on separate days and processed rapidly. Sigmoidoscopy and rectal biopsy help to exclude colitis, although biopsies taken late in an infective colitis often show changes that are hard to distinguish from IBD. When there is doubt about the diagnosis, a follow-up biopsy 6–8 weeks later is helpful, as infective colitis usually reverts spontaneously to normal. In the absence of proctitis, a rectal biopsy can still provide an indication of mild but significant forms of proximal colitis. The decision to test further should be based on clinical indications and the results of the level 1 tests. For instance, in the presence of relevant exposure, or the finding of lymphopenia, the issue of testing for HIV should be addressed.

Level 2a tests are:

- a lactose hydrogen breath test or a 2-week trial of dietary exclusion; and
- selenium-75-labeled homotaurocholic acid test (SeHCAT) of bile malabsorption or trial of cholestyramine.

For patients whose presentation is consistent with IBS (see Table 50b.1), level 2a tests can be considered, depending on the clinical circumstances and the facilities available. Level 2b tests are:

- tests for malabsorption (serum folate, vitamin B12, iron and xylose absorption tests);
- endoscopy with small bowel biopsy or duodenal aspiration.

If there is a suspicion of malabsorption, evidence for this should be obtained as indicated for level 2b tests. Where there is positive evidence, and if stools are negative, further tests should be carried out to explain the malabsorption. Endoscopy with duodenal biopsy is preferred to duodenal aspiration. Histologic examination contributes to the diagnosis of conditions such as tropical and celiac sprue through the diagnosis of villous atrophy, as well as helps to isolate *Giardia* spp. trophozoites and other infectious and parasitic agents that reside on enterocytes. Duodenal aspiration was reported to add only 15% to the yield for giardiasis from three stool examinations.

Level 3 tests are:

- radiologic examinations (barium studies of the small and large bowel); and
- colonoscopy.

If the diagnosis remains uncertain, level 3 tests help to exclude Crohn's disease, colonic tumors, small intestinal diverticula (which may give rise to bacterial overgrowth) and intestinal lymphoma.

Management

If malabsorption or weight loss is present and a specific infective diagnosis can be made, the indication for antimicrobial therapy is clear. If the diagnosis remains uncertain after thorough investigation, a chemotherapeutic trial of metronidazole or tetracycline appears justified. In the presence of HIV, a persistent search for an enteric pathogen is important because it is recognized that a potentially treatable pathogen can often be detected. Nutritional supplements may occasionally be required.

Patients who have a positive stool isolate but no malabsorption, weight loss or dysenteric stools pose a therapeutic dilemma. Many of these patients are persistent excretors or carriers of the organism and are suffering from postinfectious IBS; antibiotic treatment will either not improve the diarrhea or will produce a temporary improvement, possibly as a non-specific effect of antibiotics on colonic flora. However, occasionally bacterial pathogens may give rise to protracted diarrhea and, as long as the pathogenic potential of an organism remains uncertain, a trial of antimicrobial chemotherapy can be justified. Repeated courses of antibiotics should not be pursued if the patient shows no improvement.

In patients who have postinfectious IBS, treatment with a lactose-free diet, loperamide, cholestyramine and low-dose tricyclic anti-depressant agents may be helpful.

50.c Infectious diarrhea and antibiotic treatment

Philip Bejon

Acute diarrhea kills 3–4 million per year; 4 billion cases of acute diarrhea occur yearly worldwide, generating 8 million consultations and 250,000 hospital admissions per year in the USA. The role of antibiotics is unclear. Randomized controlled trials compare outcomes for those with self-limiting albeit incapacitating colitis. Personal and economic benefits may result from antibiotic use, although serious morbidity and mortality from infective diarrhea are rare.

Treatment

Between 30% and 90% of traveler's diarrhea and community-acquired diarrhea in adults is bacterial. In children, most diarrheal episodes are viral and antibiotics are not indicated. The role of antibiotics in treating acute gastroenteritis has been the subject of numerous randomized trials and a Cochrane Review meta-analysis. Most of these patients would have been infected with enterotoxigenic (ETEC) or enteropathogenic (EPEC) *Escherichia coli*; these strains are not identified by routine stool culture. Significant clinical benefit from antibiotic use was described; there were more patients cured at 72 hours, reduced stool frequency and a shorter time to last unformed stool. Different antibiotics have been compared to placebo, but comparative data between antibiotics are not available. Data for tetracyclines, ampicillin and trimethoprim-sulfamethoxazole should be interpreted cautiously given the increase in reported resistance of enteric pathogens. Quinolone and macrolide treatments, ranging from single doses to 5 days, are effective. Minor antibiotic side effects were frequent. The rare occurrence of serious adverse events, such as rash, anaphylaxis, tendon rupture or reduced seizure threshold with quinolones must also be considered. Antibiotic use is felt to promote resistant organisms in the community; this contests an economic benefit to the 30–60% of overseas travelers who acquire diarrhea.

While bacterial diarrhea is unpleasant and inconvenient for most travelers, it is life threatening for undernourished children in the tropics. These children have a high incidence of *Campylobacter* and *Salmonella* infection. The immediate danger is dehydration, but recurrent bacterial infection is linked to small bowel enteropathy, malabsorption and undernutrition. EPEC is frequently isolated in association with persistent diarrhea. The limited trials undertaken have not prevented these complications with antibiotics and observational data link persistent diarrhea with prior antibiotic use during acute gastroenteritis.

Prophylaxis

Antibiotic prophylaxis against traveler's diarrhea has been examined in randomized controlled trials. Doxycycline and trimethoprim-sulfamethoxazole were effective in trials conducted 20 years ago. Resistance to these agents has since increased and recent trials now suggest limited efficacy. Quinolone susceptibility has largely been retained but there are limited safety data for long prophylactic courses and the optimal dose is unknown. It may be more appropriate to advise early self-treatment of diarrheal episodes.

Enteric fever

Patients with bloody or mucous stool, high fever or tenesmus have a 60–70% chance of *Campylobacter, Salmonella* or *Shigella* infection. *Salmonella* and *Shigella* species, the main causes of complicated colitis and bacteremia, retain predictable ciprofloxacin susceptibility. On initial presentation, typhoid fever may be in the differential diagnosis; ciprofloxacin is the drug of choice. Ceftriaxone has also been used in disseminated disease. Scoring systems based on clinical parameters and inflammatory markers have been shown to correlate with the isolation of pathogens in stool, but do not predict the risk of complications or the need for antibiotics.

Campylobacter and *Salmonella*

Campylobacter jejuni is isolated seven times more frequently than *Salmonella* or *Shigella*. Quinolone resistance is becoming more frequent in *Campylobacter* isolates (20–80%). Macrolides retain activity against *C. jejuni* and randomized trials demonstrate their utility. The length and severity of symptoms were reduced only when patients were treated early, before the stool culture results were available. However, most enteric pathogens (i.e. *Salmonella, Shigella, E. coli*) display intrinsic resistance to macrolides and macrolides were not demonstrably superior to quinolones, even where quinolone resistance is frequent.

By contrast, patients with either symptomatic or symptomless enteric *Salmonella* infection derive no benefit from antibiotics given in randomized controlled trials, even when treated early. Antibiotics were often associated with more prolonged carriage and weakly associated with risk of relapse. These trials do not provide data on the immunosuppressed, the elderly or neonates. Case control data suggest individuals with bacteremia have a high odds ratio for medical co-morbidity and HIV infection. Nevertheless, most of these individuals presented with disseminated disease rather than gastroenteritis alone. While empiric treatment targeting *Campylobacter* and *Salmonella* can be justified, initiating treatment after isolating organisms in stool cannot.

Hemolytic uremic syndrome

E. coli 0157 is a rare cause of bloody diarrhea. In 1–14% of infected children, the hemolytic uremic syndrome (HUS) results. Retrospective and prospective studies have associated antibiotic use with subsequent HUS. This may not be causal. HUS is associated with a high white cell count, early presentation and vomiting; these factors may influence antibiotic prescribing. Animal models of antibiotic-treated mice demonstrate harm from increased toxin production. However, HUS is less frequent in adults and less often linked to *E. coli* 0157. Waiting for stool culture before antibiotic use necessarily precludes benefit; the risks from antibiotic use remain unclear.

Protozoa

Protozoa account for up to 12% of travelers' diarrhea. Amebic colitis is rare, but the most serious; afebrile, insidious worsening of bloody diarrhea is characteristic. Empiric metronidazole may occasionally be necessary pending endoscopy. A trial of metronidazole or tinidazole may also be necessary when persistent diarrhea with steatorrhea suggests *Giardia*, since parasites are not always seen in stool.

Cryptosporidium (3% of all travelers' diarrhea) is not antibiotic responsive and early diagnosis by direct stool microscopy will avoid unnecessary treatment. It is persistent only in the immunocompromised. Cyclospora infection responded to trimethoprim-sulfamethoxazole in a single clinical trial. It is endemic in Nepal and Guatemala (3–8% of returning travelers with diarrhea) and acquired from imported raspberries in the USA. Since infection is self-limiting, rarely severe and amenable to rapid diagnosis by direct microscopy, empiric trimethoprim-sulfamethoxazole should not be necessary. Although the protozoan infections isospora and microsporidia may respond to trimethoprim-sulfamethoxazole and albendazole respectively, they are self-limiting infections in the immunocompetent and there are insufficient systematic data on incidence and treatment outcomes.

Clostridium difficile

Patients recently discharged from hospital or taking broad-spectrum antibiotics are more likely to have either antibiotic-related diarrhea or *Clostridium difficile*-related colitis than *Salmonella* or ETEC: if severe, metronidazole or oral vancomycin should be used empirically pending analysis for *C. difficile* toxin.

Cholera

The profuse watery diarrhea associated with *Vibrio cholerae* infection lasts 1–2 days less with doxycycline or single-dose ciprofloxacin. Fluid replacement requirements fall and stool carriage is reduced. Limited data suggest that the severity of secondary cases is attenuated by antibiotic prophylaxis for close contacts.

Conclusion

In conclusion, data show that antibiotics reduce the length of symptoms for those with acute gastroenteritis in the developed world, and either a quinolone or a macrolide may be considered. The personal and economic benefits must be balanced against antibiotic side effects and a potential impact on resistance patterns. Where antibiotics are given to those with a severe, febrile illness or where bacteremia or metastatic infection is suspected, quinolones or third-generation cephalosporins are active against the likely etiological agents. Evidence opposes antibiotic prescribing consequent on stool culture results.

Chapter 51 - Infective and Reactive Arthritis

Elie F Berbari
Douglas R Osmon
James M Steckelberg

INTRODUCTION

Infective arthritis is an inflammation of the joint space caused by invasion of micro-organisms. Hematogenous seeding of the joint is the most common mechanism of infection in native joints. The incidence of infective arthritis in adults caused by bacteria other than *Neisseria gonorrhoeae* is relatively low, but these infections can cause major morbidity as a result of pain, immobility and loss of joint function. Successful treatment requires prompt drainage of the joint, using multiple arthrocenteses or open arthrotomy, and prolonged antimicrobial therapy to achieve sterilization of the joint space as well as a satisfactory functional result. This chapter discusses infective arthritis in adults, with the major emphasis on bacterial infective arthritis. Viral and reactive arthritis are discussed briefly. Infective arthritis caused by *Borrelia burgdorferi* is discussed in Chapter 54 and mycobacterial arthritis in Chapter 37 .

BACTERIAL ARTHRITIS

EPIDEMIOLOGY

In 1998, according to the Centers for Disease Control and Prevention (CDC), there were an estimated 23,000 cases of pyogenic arthritis in the USA, or 8.4 cases per 100,000 person years; 61% of the patients were male and 39% were 65 years of age or older.[1] The mean duration of hospitalization of the 11,000 patients who had a primary diagnosis of pyogenic arthritis was 7.2 days. These data are in agreement with other published incidence rates of bacterial arthritis in the general population.[2] [3] Disseminated gonococcal infection with associated gonococcal infective arthritis is the leading cause of hospital admission due to infective arthritis in the USA, with an estimated incidence rate of 2.8 per 100,000 person years (Chapter 227). [4]

RISK FACTORS

Rheumatoid arthritis, diabetes mellitus, malignancy, old age and HIV infection, alone or through their treatment, suppress the immune system and, as such, are risk factors for acquiring bacterial arthritis.[5] [6] [7] [8] Novel therapies such as etanercept and infliximab, targeting tumor necrosis factor for the treatment of rheumatoid arthritis, have come into widespread clinical use. These agents have been shown to be implicated as a possible risk factor for severe polyarticular infectious complications in this patient population.[9] They have also been linked with an increased risk of mycobacterial infections, including tuberculosis.[10] Local abnormalities of host defenses caused by previous joint damage or surgery also predispose the joint to infection, as do situations that increase the risk of bacteremia, such as injection drug use, indwelling intravenous catheters and skin infection, and situations that allow direct inoculation of micro-organisms, such as intra-articular injection or arthroscopy. Recently, several cases of infective arthritis due to *Clostridium* spp. were reported to the CDC. All these cases underwent tissue allograft reconstruction surgery. Anaerobic cultures of the nonimplanted donor tissue yielded *Clostridium* spp. in selected cases. It is believed that the donor tissue was hematogenously seeded by bowel flora and that the aseptic processing techniques used for the implicated donor tissues did not eliminate spores of *Clostridium* spp.[11]

Disseminated gonococcal infection is more common among sexually active, menstruating women, although it can also occur during pregnancy and the peripartum period.[4] The male:female ratio is approximately 1:4. Often, the microbiologic etiology of infective arthritis can be predicted on the basis of the specific risk factor predisposing to infection (Table 51.1).[12]

PATHOGENESIS

Nongonococcal bacterial arthritis most often results from hematogenous seeding of the joint space as a result of bacteremia. Synovial tissue has a rich vascular supply but no basement membrane, factors that favor ingress of blood-borne organisms.[8] [12] The bacteremia can be primary or secondary to an infection elsewhere in the body (e.g. pneumonia, cellulitis) or to injection drug use.[5] An identifiable focus of infection can be found in approximately 50% of cases.[8] [13]

Direct inoculation of micro-organisms into the joint space due to trauma, arthrotomy, arthroscopy or diagnostic and therapeutic arthrocenteses is another mechanism of infection. The risk of septic arthritis after arthrocentesis has been reported to be 0.002–0.007%; after arthroscopy it is reported to be 0.04–0.4%.[14] Infection of the joint space as a result of contiguous soft tissue infection or periarticular osteomyelitis is much less common.

Once bacteria have entered the joint space there is ingress of polymorphonuclear leukocytes, which results in hydrolysis of proteoglycans and collagen through stimulation of locally synthesized cytokines and release of enzymes.[14] If left untreated, destruction of the articular cartilage eventually occurs, leading to irreversible joint damage.[15] [16] [17]

Staphylococcus aureus is the most common etiologic agent of infective arthritis in adults (Table 51.2).[8] [18] [19] [20] [21] In young, sexually active persons, *N. gonorrhoeae* is the predominant pathogen. Infection in patients who have rheumatoid arthritis is due to *S. aureus* in as many as 80% of patients. Group B streptococcal infection is more likely to occur in patients who have diabetes mellitus. Coagulase-negative staphylococci may cause infection following arthroscopy and other medical procedures, including intra-articular injections. Infective arthritis due to Gram-negative bacilli is more common in the elderly and in patients who have co-morbid illnesses.[22]

Anaerobic infection is uncommon except in the setting of septic arthritis occurring after human or animal bite injuries or diabetic foot infections. Among injection drug users, *Pseudomonas aeruginosa* and *S. aureus* are common pathogens.[23] [24] Hypogammaglobulinemia is a risk factor for infective arthritis due to *Mycoplasma* spp.[25]

PREVENTION

Prevention of infective arthritis is obviously preferable to treatment of established infection. Examples of efforts to decrease the incidence

TABLE 51-1 -- Epidemiologic and clinical features associated with specific etiologic agents of infective arthritis.*

EPIDEMIOLOGIC AND CLINICAL FEATURES ASSOCIATED WITH SPECIFIC ETIOLOGIC AGENTS OF INFECTIVE ARTHRITIS	
Clinical or epidemiologic setting	**Likely etiologic agent**
Bacteria	
Staphylococcus aureus	Rheumatoid arthritis, injection drug use, arthroscopy, arthrotomy, polyarticular arthritis
Coagulase-negative staphylococci	Arthroscopy, arthrotomy, foreign material
Neisseria gonorrhoeae	Young, sexually active, history of sexually transmitted disease or unsafe sex, menstruation, pregnancy, multiple skin lesions
Pseudomonas aeruginosa and other aerobic	Injection drug use, elderly
Gram-negative bacteria	
Anaerobes	Human and animal bites, orthopedic allograft infection with allograft without sporicidal sterilization, anaerobic infection elsewhere in body
Usual oral flora	Human and animal bites
Eikenella corrodens	Human bite
Pasteurella multocida	Cat or dog bite
Streptobacillus moniliformis	Rat bite
Neisseria meningitidis	Multiple purpuric lesions
Other	
Mycoplasma spp.	Common variable hypogammaglobulinemia
Borrelia burgdorferi	Resident in endemic area, known or suspected tick exposure, history of erythema chronicum migrans
Troypheryma whipplei	Other manifestations of Whipple's disease
Mycobacteria	

Mycobacterium tuberculosis	Positive tuberculin skin test, resident in country where disease is endemic, known exposure history
Mycobacterium marinum	Exposure to aquatic environment
Mycobacterium avium intracelulare	HIV, T-cell suppression
Mycobacterium leprae	Resident in country where disease is endemic
Fungi	
Sporothrix schenckii	History of trauma with exposure to colonized soil (e.g. sphagnum moss)
Candida	Prior known or suspected candidemia or culture-negative central infection, neutropenia
Aspergillus	Prior known or suspected invasive aspergillus infection, prolonged neutropenia
Blastomyces dermatididis	Resident in area where disease is endemic, exposure to beaver dams
Coccidiomyces immitis	Resident in area where disease is endemic

** Data from Smith and Piercy.*[12]

of infective arthritis include the promotion of public health measures to prevent the acquisition of *N. gonorrhoeae*, measures to decrease the incidence of animal bites, prophylactic foot care in patients who have diabetes mellitus and eradication of injection drug use. Rapid and effective treatment of antecedent infections that may cause joint infections, such as catheter-associated bacteremia due to *S. aureus* or skin and soft tissue infection in patients who

TABLE 51-2 -- Etiologic agents of nongonococcal bacterial arthritis in adults.[*]

ETIOLOGIC AGENTS OF NONGONOCOCCAL BACTERIAL ARTHRITIS IN ADULTS	
Micro-organisms	**Cases (%)**
Staphylococcus aureus	68
Streptococci (including ß-hemolytic streptococci, viridans group streptococci and *Streptococcus pneumoniae*)	20
Haemophilus influenzae	1
Aerobic Gram-negative bacilli	10
Polymicrobial and miscellaneous	1
Unknown	<1

** Data from Roberts and Mock.*[21]

have rheumatoid arthritis and diabetes mellitus, as well as the administration of vaccines against *Haemophilus influenzae* and *Streptococcus pneumoniae*, are also effective preventive measures.[26]

CLINICAL FEATURES

Nongonococcal infective arthritis

Nongonococcal infective arthritis is typically monoarticular and has an acute presentation. Patients complain of pain and limitation of motion in over 90% of cases.[12] In one study, fever was present in 78% of patients within 24 hours of hospitalization, although it was rarely above 102°F (39°C).[17] Chills were uncommon. Physical examination usually reveals a large effusion and a marked decrease in active and passive range of motion of the joint. However, these findings may be minimal or absent in those patients who have rheumatoid arthritis and they may be difficult to discern in infections of the hip or shoulder.

The knee is the most commonly involved native joint in adults. In a case series from the Netherlands, the percentage of cases involving a particular joint was as follows: knee 55%, ankle 10%, wrist 9%, shoulder 7%, hip 5%, elbow 5%, sternoclavicular joint 5%, sacroiliac joint 2% and foot joint 2%.[3] Sacroiliac or sternoclavicular joint infection is more common among injection drug users and may be difficult to diagnose. Polyarticular infection occurs in approximately 15% of patients and is often due to *S. aureus*.[27] Thus, a polyarticular presentation does not always imply the presence of gonococcal, viral, reactive or noninfectious arthritis. It is more common among patients who have rheumatoid arthritis, and patients receiving corticosteroid therapy.

The case-fatality rate for patients who have nongonococcal bacterial arthritis is estimated to be between 10% and 16%, and as many as 50% of patients who survive their infection have some degree of permanent loss of joint function. [8] [18] [19] [20] Morbidity and mortality is dependent on a number of factors, including age, presence of rheumatoid arthritis, infection in the hip or shoulder, duration of symptoms before treatment, the presence of polyarticular arthritis, persistently positive joint fluid cultures after appropriate therapy, the presence of bacteremia and the virulence of the infecting organism.[2] [8] [28] [29]

Gonococcal arthritis

Disseminated gonococcal infection presents with two distinct clinical entities.[4] Early after dissemination from mucosal surfaces such as the cervix or urethra the patient presents with bacteremia, fever, polyarthralgia, tenosynovitis (typically of the hands and fingers) and multiple maculopapular, pustular, vesicular or necrotic skin lesions. Asymmetric joint involvement is common. The knee, elbow, wrist, metacarpophalangeal and ankle joints are the most

commonly involved. This presentation accounts for 60% of patients who present with disseminated gonococcal disease, and it has been described as the dermatitis-arthritis syndrome. If left untreated, the patient will present later with monoarticular arthritis, usually without tenosynovitis or skin lesions. Co-infection with HIV often leads to infection of unusual joints and an aggressive course.[30]

The outcome of disseminated gonococcal infection is almost always excellent (see Chapter 227).

DIAGNOSIS

Although the history and physical examination can lead to a high index of suspicion for infection, a synovial fluid culture that yields a causative micro-organism is the only definitive method for diagnosing bacterial arthritis. Fever and rigors in the setting of an inflammatory arthritis have a low positive predictive value for bacterial arthritis and have been reported in crystal-induced arthropathy.[14] The erythrocyte sedimentation rate (ESR), C-reactive protein and leukocyte counts are elevated in the majority of cases, although again the positive predictive value of these tests in the setting of a monoarticular inflammatory arthritis is low. A rise in the ESR may help in the differential diagnosis of new joint pain and effusion in those patients who have rheumatoid arthritis.[12] [31] Blood cultures are positive in up to 70% of all patients with nongonococcal arthritis. [20] [27]

In disseminated gonococcal infection the majority of patients have an elevated ESR, and only 50% will have an abnormal leukocyte count. Anemia and abnormal liver function tests also may occur but these findings are usually transient. [4]

In approximately 80% of patients who have disseminated gonococcal arthritis there is a positive culture or *N. gonorrhoeae* DNA can be identified by polymerase chain reaction or ligase chain reaction in samples from the cervix, urethra, rectum, pharynx or urine. Skin lesions yield *N. gonorrhoeae* in 30% of cases and blood cultures in 5%.

The diagnostic procedure of choice for bacterial arthritis is an arthrocentesis. This should be done immediately once the diagnosis of joint infection is suspected so as not to delay appropriate medical or surgical therapy. If synovial fluid cannot be obtained by blind needle aspiration (e.g. in the case of hip joint infection), then aspiration

should be done with the help of a radiologist under fluoroscopic guidance. In selected cases, an open arthrotomy should be performed to make a definitive diagnosis.

Synovial fluid is often cloudy or purulent in appearance. The synovial fluid should be routinely examined for uric acid and calcium pyrophosphate crystals, and a leukocyte count and differential should be obtained on each specimen. The leukocyte count is usually greater than 50,000/mm^3 and often greater than 100,000/mm^3 , with more than 75% polymorphonuclear leukocytes. These findings can also be seen in patients who have inflammatory arthritis and crystal deposition arthritis. The sensitivity and specificity of a synovial fluid leukocyte count of more than 20,000/mm^3 for the presence of inflammatory arthritis have been estimated to be 84% and 84%.[32] For a differential count of more than 75% polymorphonuclear leukocytes the sensitivity and specificity are 75% and 92%. Although many clinicians order synovial fluid glucose and protein levels, the results of these tests have been shown to be less informative than the leukocyte count and differential.[32] The synovial fluid lactic acid and lactate dehydrogenase levels are often elevated in patients who have infective arthritis but elevation of these can be seen in other inflammatory joint disorders as well.[8]

Synovial fluid should be cultured for both aerobes and anaerobes and other organisms, depending on the clinical circumstances. A recent study performed at the Mayo Clinic showed superior performance for the BACTEC Peds Plus/F bottle over the conventional agar plate method for the detection of clinically significant micro-organisms from synovial fluid specimens.[33]

The synovial fluid culture will be positive in 90% of cases of nongonococcal arthritis, assuming that antibiotic therapy has not been started before the sample has been collected.[17] The Gram stain is positive in 50% of patients.[8]

In patients who have disseminated gonococcal infection, the synovial fluid cultures are positive in 25–30% of all patients and 50% of patients who present with monoarticular arthritis. The role of the polymerase chain reaction in detecting bacterial pathogens in patients who have infective arthritis has not yet been well defined, although the technique seems a promising tool for the detection of infectious arthritis due to *N. gonorrhoeae*, *Borrelia burgdorferi* and *Tropheryma whippleii*. [34] Polymerase chain reaction can help to distinguish disseminated gonococcal infection from other inflammatory arthropathies such as Reiter's syndrome.[35]

Synovial tissue cultures are indicated only for chronic infective arthritis when mycobacterial or fungal arthritis is suspected or when synovial fluid cultures cannot be obtained by less invasive techniques.

Periarticular soft tissue swelling is the most common abnormality seen on plain radiography in patients who have bacterial arthritis. Periarticular erosions and osteoporosis as well as joint space narrowing due to cartilage destruction do not occur for several weeks. Thus, plain radiographs are not usually helpful in making a diagnosis of bacterial arthritis. Occasionally, in longstanding infection, periarticular osteomyelitis will be visible on plain radiograph (Fig. 51.1). It is often difficult to distinguish infection from inflammatory arthritis using radiographic methods in the setting of rheumatoid arthritis, but the development of a rapid destructive arthritis in one or two joints suggests infection. Computerized tomography (CT) scans and magnetic resonance imaging (MRI) are more useful than plain radiographs for identifying concomitant periarticular osteomyelitis, soft tissue abscesses and joint effusions, but they are expensive and most often are not necessary (Fig. 51.2). Sacroiliac or sternoclavicular joint disease is optimally evaluated with these modalities as well as with radionuclide studies. Indium-111 scans may be useful for identifying relatively asymptomatic septic arthritis in immunocompromised patients who have one or more known septic joints and in whom there is a high index of suspicion for polyarticular infection.

In adults, the differential diagnosis for patients who have an acute onset of fever, chills and an inflammatory arthritis of one or more joints includes bacterial arthritis, gout, pseudogout, rheumatic fever, reactive arthritis and rheumatic illnesses such as rheumatoid arthritis and psoriatic arthritis. Gout and pseudogout are the most common

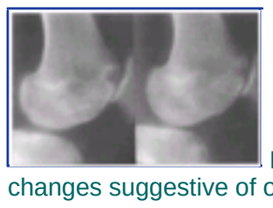

Figure 51-1 Tomogram of right knee of a patient who has *Staphylococcus aureus* septic arthritis and periarticular osteomyelitis. Note the mixed sclerosis and lytic changes suggestive of osteomyelitis.

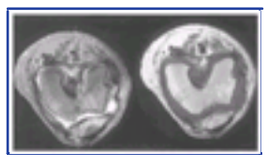

Figure 51-2 MRI scan of right knee of a patient who has *Staphylococcus aureus* septic arthritis. Note the soft tissue inflammation and a joint effusion.

noninfectious inflammatory arthritides that must be differentiated from bacterial arthritis.[8] They should be suspected when there is a history of previous episodes or there is chondrocalcinosis on plain film. Synovial fluid analysis using polarized light microscopy is the most useful diagnostic test for gout or pseudogout.

TABLE 51-3 -- Antibiotic therapy of infective arthritis in adults for selected bacterial micro-organisms.

ANTIBIOTIC THERAPY OF INFECTIVE ARTHRITIS IN ADULTS FOR SELECTED BACTERIAL MICRO-ORGANISMS			
Micro-organisms		**Antibiotic therapy**	**Alternative therapy**
Staphylococcus aureus	Methicillin-sensitive strains	Nafcillin or oxacillin 1.5–2.0g iv q4h	Vancomycin 15mg/kg iv q12h, not to exceed 2g in 24h unless serum levels are monitored
		or	
		Cefazolin (or other first-generation cephalosporins in equivalent dosages) 1 g iv q8h	
	Methicillin-resistant strains	Vancomycin 15mg/kg iv q12h, not to exceed 2g in 24h unless serum levels are monitored	Consult a specialist in infectious diseases
			Linezolid 600mg iv/po q12h
Penicillin-sensitive streptococci or pneumococci with an MIC=0.1 µg/ml		Aqueous crystalline penicillin G 20 × 10^6 U per 24h iv either continuously or in six equally divided doses	Vancomycin 15mg/kg iv q12h, not to exceed 2g in 24h unless serum levels are monitored
		or	
		Ceftriaxone 2g iv or im q24h	
		or	
		Cefazolin 1g iv q8h	
Enterococci or streptococci with an MIC =0.5µg/ml or nutritionally variant streptococci (all enterococci causing infection must be tested for antimicrobial susceptibility in order to select optimal therapy)		Aqueous crystalline penicillin G, 20 × 10^6 U per 24 iv either continuously or in six equally divided doses, plus gentamicin sulfate, 1 mg/kg iv or im q8h	Vancomycin 15mg/kg iv q12h, not to exceed 2g in 24h unless serum levels are monitored
		or	
		Ampicillin sodium 12g per 24h iv either continuously or in six equally divided doses	

Neisseria gonorrhoeae	Ceftriaxone 1g im or iv q24h for 24–48h after clinical improvement followed by	Ciprofloxacin 400mg iv q12h for 24–48h after clinical improvement
	Cefixime 400mg po q12h for 1 week	*or*
	or	Ofloxacin 400mg iv q12h for 24–48h after clinical improvement
	Ciprofloxacin 500mg po q12h for 1 week	
	or	*or*
	Ofloxacin 400mg po q12h for 1 week	Spectinomycin 2g im q12h for 24–48h after clinical improvement
		followed by
		Ciprofloxacin 500mg po q12h for 1 week
		or
		Ofloxacin 400mg po q12h po q12h for 1 week
Enterobacteriaceae	Ceftriaxone 2g iv q24h	Levofloxacin 500mg po q24h
	or	
Pseudomonas aeruginosa, Enterobacter spp.	Ciprofloxacin 750mg po q12h (based on in-vitro susceptibility)	
Dosages recommended are for patients who have normal renal function.		

The articular manifestations of rheumatic fever occur in approximately 75% of first episodes, last for several weeks and do not cause permanent joint damage. Typically, there is development of a migratory polyarthritis involving the knees, elbows, ankles and wrists that occurs within 1–5 weeks of the antecedent streptococcal pharyngitis. Joint symptoms can range from arthralgia without obvious physical findings to inflammatory arthritis indistinguishable from infective polyarthritis. Often more than six joints are affected. The diagnosis of rheumatic fever is dependent on satisfying the updated Jones criteria (see Chapter 225).[36]

Bacterial arthritis should be suspected in those patients at increased risk of infection. Fungal and mycobacterial infection is usually monoarticular but their presentation is usually over weeks to months instead of hours to days. Diseases that must be distinguished from disseminated gonococcal infection include viral and reactive arthritis, rheumatic fever and secondary syphilis.

MANAGEMENT

The keys to the management of infective arthritis are:

- drainage of the purulent synovial fluid;
- debridement of any concomitant periarticular osteomyelitis; and
- administration of appropriate parenteral antimicrobial therapy.

Experimental models of septic arthritis suggest that early drainage and antimicrobial therapy prevent cartilage destruction.[37] Local antimicrobial therapy is unnecessary and may cause a chemical synovitis.[8] Joint immobilization and elevation is useful for symptomatic relief of pain early in the course of the disease, but early active range of motion exercises are beneficial for ultimate functional outcome.

Synovial fluid drainage

The optimal method of drainage of an infected joint remains controversial, in part because no well-controlled randomized trials exist to guide therapy and because the therapy of each patient should be individualized.[38] Most adults who have septic arthritis have been managed with repeated joint aspirations instead of surgical debridement.[17] Patients who have disseminated gonococcal infection rarely require repeat joint aspirations, arthroscopy or arthrotomy.[4]

The use of arthroscopy has expanded in recent years because of the minimal morbidity of the procedure and the improved ability of arthroscopy to adequately drain purulent material from the joint compared with joint aspiration. [39] [40] [41] [42] [43] [44] A recent study by Smith *et al*[51] compared the efficacy of aspiration with arthroscopy in the therapy of septic arthritis in 61 children using a prospective randomized clinical trial. There was no statistical difference in the clinical outcome for the two treatment groups. Large multicenter, randomized trials are needed to further evaluate the comparative efficacy of these modalities.

Debridement

Recommended indications for surgical debridement have included effusions that fail to resolve with 7 days of conservative therapy and inability to adequately drain the infected joint by aspiration or arthroscopy either because of location (hip and shoulder) or loculations of pus[8] [12] (Fig. 51.3).

Antimicrobial therapy

Antimicrobial therapy should be administered as soon as the diagnosis is suspected and synovial fluid cultures obtained. Any delay in the administration of antimicrobial therapy may result in significant cartilage loss and functional limitation of the affected joint. To date there are no randomized studies to help guide the clinician in the antimicrobial therapy of septic arthritis. Initial antimicrobial therapy should be based on the results of the Gram stain and the specific clinical and epidemiologic setting. If no micro-organisms are seen on the Gram stain, empiric therapy for *S. aureus*, streptococci and gonococci (in young, sexually active adults) should be given. Antimicrobials with anaerobic activity should be added to this regimen if septic arthritis occurs after the use of an allograft.[11] Most experts

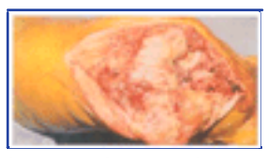

Figure 51-3 Intraoperative photograph of right knee of a patient who has ***Staphylococcus aureus*** **septic arthritis.** Note the damaged joint and dark brown, boggy and hyperemic synovium.

administer 2–4 weeks of intravenous antimicrobial therapy for the treatment of nongonococcal septic arthritis.[8] [12] In most cases this therapy can be administered on an outpatient basis after an initial period of hospitalization.

Suggested antimicrobials for specific pathogens causing infective arthritis are shown in Table 51.3 .

Oral antimicrobial therapy with an effective agent with excellent bioavailability, such as ciprofloxacin or linezolid, is also acceptable, particularly if compliance with oral therapy can be assured.

Current treatment guidelines for gonococcal septic arthritis recommend ceftriaxone as the initial drug of choice, followed by oral therapy with a cephalosporin or a quinolone after initial clinical improvement (see Table 51.3).

VIRAL ARTHRITIS

Arthritis is a common complication of infections with hepatitis viruses, parvovirus B19, rubella, HIV and alphaviruses, and is relatively rare with mumps virus, enteroviruses, adenoviruses and herpesviruses. The most common mechanism by which viruses cause arthritis is by invasion of the joint during the period of viremia. Other postulated mechanisms include immune complex deposition, insertion of the viral genome into the host DNA, thus promoting autoimmunity through an 'altered self,' and direct viral infection of the immune system, thus altering the immune response.[45] [46] [47] [48]

Typically, viral arthritis occurs during the prodromal stages of viral infection and is associated with a rash. Polyarticular involvement, including the small joints of the hands, is typical (Fig. 51.4). There is no specific pattern of joint involvement that is unique to a given viral etiology. Diagnosis is based on historic and clinical clues (Table 51.4) and diagnostic testing specific for each individual virus, the details of which are discussed in the relevant chapters. Viral arthritis is usually self-limited but may progress to a chronic arthropathy in certain instances. It is important that viral arthritis should be distinguished from rheumatic fever and the initial presentation of autoimmune disorders, including rheumatoid arthritis (Chapter 212 , Chapter 214 , Chapter 220 and Chapter 221).

Treatment is discussed in the chapters devoted to specific viruses. Prevention of viral arthritis is dependent on vaccination against the specific pathogen causing arthritis (e.g. mumps virus, rubella, hepatitis A virus, hepatitis B virus and varicella-zoster virus).

REACTIVE ARTHRITIS

Reactive arthritis describes the acute onset of an inflammatory arthritis soon after an infection elsewhere in the body in which micro-organisms cannot be cultured from the synovial fluid. However, genetic material may be found in the joint using molecular diagnostic techniques. Reiter's syndrome (the classic triad of arthritis, urethritis and conjunctivitis) is a common example of reactive arthritis. Many patients who develop reactive arthritis are HLA-B27-positive. The micro-organisms that have been associated with reactive arthritis are detailed in Table 51.5 .[49]

Typically, reactive arthritis begins several weeks after an antecedent infection. The initial clinical presentation is usually asymmetric oligoarticular arthritis without prominent constitutional symptoms. The syndrome also occurs without any identifiable symptom of infections, however, particularly in the case of *Chlamydia trachomatis*. In the case of Reiter's syndrome, extra-articular manifestations are also present.

Laboratory abnormalities are non-specific and include mild elevations in the leukocyte count, ESR and C-reactive protein. Radiographs usually show only soft tissue swelling in early disease, but juxta-articular osteoporosis and erosion may also be seen.

TABLE 51-4 -- Clinical or epidemiologic features of infective arthritis caused by selected viruses.*

CLINICAL OR EPIDEMIOLOGIC FEATURES OF INFECTIVE ARTHRITIS CAUSED BY SELECTED VIRUSES			
Viral agent	**Epidemiologic features**	**Clinical characteristics**	**Outcome**
Rubella (including rubella vaccine)	No prior vaccination; 51–61% of rubella cases; 0–14% of patients receiving vaccination. Less common with new vaccine.	Symmetric arthiritis of the metacarpal and proximal phalangeal joints, wrist, elbow, ankle, knee; onset variable in relationship to rash. May mimic rheumatoid arthritis. Post vaccination disease less symptomatic	Spontaneous resolution in days to weeks but may be chronic or recur.
	Ratio of women : men -9:1.		
Parvovirus B19	60% of adult cases, females > males.	Sudden severe polyarticular arthritis in small joints.	Spontaneous resolution most common. Chronic arthritis can occur
	May mimic rheumatoid arthritis	Child care providers or school teachers; unusual in children	
Hepatitis A	10–14% of cases of hepatitis A; typical risk factors for acquisition of hepatitis A	Often associated with rash	Resolves spontaneously
Hepatitis B	10–25% of cases of hepatitis B; typical risk factors for acquisition of hepatitis B	Severe arthritis of sudden onset, symmetric, polyarthritis involving hand and knee; morning stiffness is considerable; skin rash may be present including urticaria	May last 1–3 weeks. Typically resolves during the preicteric phase.
			Chronic arthritis may occur with chronic hepatitis B infection
Hepatitis C	Typical risk factors for acquisition of hepatitis C	Can occur with acute or chronic infection. Sudden onset; joint pain in hands, wrists and shoulders often greater than physical findings. May mimic rheumatoid arthritis. Distinct from cryoglobulinemia with hepatitis C	May resolve spontaneously. Has been reported to persist for months and recur
HIV	Typical HIV associated risk factors.	Most cases are monoarticular but monoarticular and polyarticular presentations occur. Distinct from Reiter's syndrome or psoriatic arthritis which also occur in HIV infected individuals. Occurs in multiple stages of HIV infection	Usually resolves in several weeks.
	Approximately 8% of HIV infected patients affected		May persist for months
Arthropod-borne alpha-virus infection		May occur in epidemics. May be associated with rash.	Spontaneous resolution is typical.
		Constitutional symptoms may be present.	Chronic arthritis is unusual except with Sindbis virus
Chikungunya	East Africa, India, South East Asia, Philippines		
O'nyong-nyong	East Africa		
Sindbis virus	Sweden, Finland, Russia		
Ross River agent	Australia, New Zealand, New Guinea		
Barmah Forest virus	Australia		

** Data from Smith and Piercy,[12] Siegel and Gall,[45] Veno et al,[52] Epinosa,[53] and Navdes.[54]*

TABLE 51-5 -- Micro-organisms associated with reactive arthritis.*

MICRO-ORGANISMS ASSOCIATED WITH REACTIVE ARTHRITIS
Definite association
Chlamydia trachomatis
Shigella flexneri
Salmonella enteritidis
Salmonella typhimurium
Yersinia enterocolitica
Yersinia pseudotuberculosis
Campylobacter jejuni

** Data from Hughes and Keat.[49]*

Reactive arthritis is normally a self-limited disease, but chronic arthritis and sacroiliitis can occur in up to 15–30% of patients. Treatment is with anti-inflammatory agents. The role of antibacterial therapy is controversial. Randomized trials evaluating the efficacy of antimicrobials in patients who have reactive arthritis have been limited by small numbers of patients. In one study there was a trend toward efficacy for acute reactive arthritis due to *Chlamydia* spp.[50] Prevention of infection is reliant on effective prevention and treatment of precipitating antecedent infections.

Chapter 52 - Acute and Chronic Osteomyelitis

Anthony R Berendt
Carl W Norden

EPIDEMIOLOGY

The character of osteomyelitis changed with the advent of antibiotics, evolving from a disease of high mortality to a disease with high morbidity. Certain trends are apparent. Bone and joint tuberculosis has become less common in the developed world, although the advent of HIV-related disease may bring about a reversal in that trend. An increasing number of chronic bone infections are now associated with trauma, surgery and joint replacement rather than being secondary to hematogenous spread.

The epidemiology of acute hematogenous osteomyelitis has been detailed.[1] The incidence is higher in males, it varies among geographic areas (Fig. 52.1) and, in some areas, classical acute hematogenous infection is in long-term decline.[2] The male-to-female ratio increases with age from 1.25 in the 0- to 4-year age group to 3.69 in the 13- to 19-year age group. There are substantially higher rates in Maori children from New Zealand and Aboriginal children from Western Australia compared both with white children living in the same areas and with children living in Europe. Although almost certainly socioeconomic in origin, these differences may also be influenced by host genetic factors.

There is less clear information on the epidemiology of chronic osteomyelitis, with the exception of diabetic foot infections.[3] There are an estimated 11 million people in the USA with diabetes; the majority of these have type 2 disease and hence are older adults. Some 3% of diabetic people develop a foot ulcer annually and 10–30% of patients with an ulcer will eventually need an amputation. Of all amputations in people with diabetes, 60% are preceded by an infected ulcer. Foot problems have been estimated to be responsible for 15% of the hospital admissions and 25% of the hospital bed usage among diabetic patients. The annual hospital costs for limb amputations that are related to diabetes amount to more than US$350 million.

PATHOGENESIS AND PATHOLOGY

Microbial factors

Adhesion is the initial event in the localization of infection. [4] The initial loose adhesion to bone is potentially reversible. However, if the solid phase offers a configuration that is acceptable to the receptors of the micro-organisms, a more permanent adhesion occurs. *Staphylococcus aureus* strains possess receptors for extracellular matrix components such as collagen, fibronectin, bone sialoprotein and osteopontin.[5] [6] It is unclear which are crucial for the genesis of osteomyelitis, with conflicting data on the role of the collagen receptor. The fibronectin-binding proteins appear to play a role in attachment to, and invasion of, endothelial cells, events that may be of relevance in the earliest stages of hematogenous seeding.[7] It is possible that trauma or injury may expose binding sites for strains of *S. aureus*.

Following adhesion, firm attachment and adherent growth occurs. For staphylococci and some Gram-negative organisms, synthesis of an exocellular polysaccharide (glycocalyx) produces a 'biofilm', within which bacteria can form microcolonies (Fig. 52.2 and Fig. 52.3). Adherent growth confers phenotypic resistance to antibiotics, probably as a result of changes in cellular metabolism, and the glycocalyx may confer protection against phagocytes and complement.[8]

Prostaglandins are potent bone resorption agents that enhance osteoclast activity and collagen synthesis. It was noted in studies of human bone, as well as in studies of experimental osteomyelitis in animals, that increased production of prostaglandin E2 (the most potent prostenoid in the resorption of bone) was present. [9] Cytokines, in particular tumor necrosis factor, are also potent stimulators of osteoclast action. Finally, it has been recognized that molecules released from a number of the pathogens that cause osteomyelitis are potent stimulators of bone resorption, via cytokine release from monocytes and by stimulation of osteoclast formation.[10]

Pathology

As in most organs, an insult to bone is followed by vascular and cellular responses. However, in bone this process is modified by the rigid nature of the bone, because the increased tissue pressure cannot be diffused into soft tissue. With increased intramedullary pressure, sinuses and capillaries are compressed in the marrow, producing infarction. At the infarction edge, there is reactive hyperemia, which is associated with increased osteoclastic activity. This in turn produces loss of bone and localized osteoporosis. An inflammatory process begins at the margin of the infarcted area and penetrates through the cortex into the subperiosteal area. Because there are few anchoring fibers in the periosteum of infants and children, the periosteum is readily stripped from the bone surface by the increased subperiosteal pressure. This can result in disruption of the periosteal blood supply to the cortex, and this leads to cortical bone infarction, bone death and sequestrum formation. (A sequestrum is a macroscopic piece of dead bone that is retained within the overall bone structure.) Stripping from underlying bone is an osteogenic stimulus to the periosteum, which responds by laying down new living bone. The end result is a shell of new bone around or above a dead segment, a response that preserves the mechanical strength of the bone, even though parts of it are now dead.

Classification systems for osteomyelitis

The most frequently used classification system is that of Waldvogel *et al.*[11] In this classification, infections are classified as hematogenous, secondary to a contiguous focus of infection or related to vascular insufficiency. For chronic long bone osteomyelitis, a second classification system, developed by Cierney and Mader,[12] combines four stages of anatomic disease and three categories of physiologic host (Fig. 52.4). This classification is useful for describing severity and location of infection and for planning treatment, and it is amenable to study. The three categories of host are:

- normal except for osteomyelitis
- systemic or local compromise, and
- treatment would be worse than the disease.

Causative agents of osteomyelitis

In acute hematogenous osteomyelitis in children, *S. aureus* accounts for more than half of the organisms isolated.[13] The next most frequent group of isolates are streptococci. In osteomyelitis or osteochondritis due to puncture wounds to the foot, *Pseudomonas aeruginosa* is isolated frequently and is associated with the wearing of sneakers. The organism is found in the sole of the sneaker and is presumably carried into the foot by the puncturing nail.[14] *Salmonella* spp., although an infrequent overall cause, are strongly associated with sickle cell disease. In diabetic patients with foot infections, *S. aureus*, *Staphylococcus epidermidis*, enterococci, other streptococci and *Corynebacterium* spp. are among the most frequent aerobic organisms that are isolated from bone. Anaerobic organisms are also frequently isolated, with *Peptostreptococcus* spp. being most common. Fungi, mycoplasma, mycobacteria, brucella, treponema, actinomycosis and parasites have also all been associated with osteomyelitis.

Pathogenesis of diabetic foot osteomyelitis

The pathogenesis of osteomyelitis in the diabetic foot is an important problem that merits additional consideration. Diabetic patients develop foot ulcers because of a combination of motor, sensory and autonomic neuropathy interacting with changes in the mechanical properties of the soft tissues of the foot. Motor neuropathy causes a high-arched foot with clawing of the toes, and this delivers excessive pressures to the metatarsal heads, the heel and the ends of the toes. Subluxation at the metatarsophalangeal joints not only brings the metatarsal head into a more prominent weight-bearing position but also causes the fibrous metatarsal pads to slip out from under the metatarsal heads. Sensory neuropathy reduces the response to pain, so that foreign bodies in the shoes are neglected, and clouds the recognition that it is time to change an ill-fitting pair of shoes or rest the feet. Autonomic neuropathy is associated with excessive fissuring and cracking from dry, poorly lubricated skin, an ideal portal of entry. Nonenzymatic glycosylation of collagen leads to cross-linking, with increased stiffness.

These factors together can readily lead to ulceration, which may lead down to a joint or bone. Loss of periosteum causes death of the superficial part of the cortex of the bone. Infection can track through the cortical bone into the medulla and spread rapidly up inside the long axis of the bone. Bone infarction and reaction to infection then proceeds just as in larger bones. Ischemia from peripheral vascular disease compounds the problem, as may diminished phagocyte function from poor glycemic control.

PREVENTION

There is no known effective method of preventing the development of acute hematogenous osteomyelitis. There is also no proven effective means of preventing the development of osteomyelitis secondary to bacterial seeding from an infected focus, such as an intravenous catheter. Even with rapid removal of the catheter and treatment for up to 6 weeks with an antimicrobial agent that is effective against the organism producing the bacteremia, osteomyelitis at a remote site has still been shown to develop on occasion.[15]

Antibiotic prophylaxis has been used successfully to prevent wound infections following surgery for noncompound hip fractures, and it has also been used successfully in the placement of total hip and knee prostheses.[16] The end point of these studies has been wound infections, but it is reasonable to presume that a certain number of patients who develop wound infections could go on to develop infection of the underlying bone and, therefore, antibiotic prophylaxis may play some role in preventing osteomyelitis. In trauma of long bones, aggressive debridement of contaminated and devitalized tissue, with appropriate stabilization and soft tissue cover, has been shown to reduce rates of infection.[17]

Prevention of diabetic foot osteomyelitis involves prevention of ulceration. Patients should have an annual review of their feet with reference to pulses, protective sensation, ulcers, callosities, evidence of infection, dermatophytosis and footwear. Those with a history of previous ulceration are at high risk of developing further ulcers and need more frequent review from a trained podiatrist. Ulceration must be promptly treated with the aim of healing the soft tissues to prevent the entry of new pathogens.

CLINICAL FEATURES

Acute hematogenous osteomyelitis

Early signs in children, particularly infants, are failure to move the affected extremity and pain on passive movement. These findings in an infant with an acute febrile illness should lead to suspicion of skeletal infection. Soft tissue changes of swelling, redness and heat occur late in osteomyelitis; if found early in the course of illness, one should suspect cellulitis. In older children, the diagnosis is often easier, but it may still be difficult to distinguish between bone and joint infection. Most radiographs do not show evidence of infection until at least 10–14 days after the onset, but they may show soft tissue changes.

In a large series, about 3% of children developed chronic infection as a complication.[13] However, most of these were associated with failure to treat adequately with antibiotics or with significant delays in treatment. Pathologic fractures are rare. If infection involves the growth plate, abnormal growth, resulting in either a shorter or longer limb, can occur. In young children, infection can track out of the focus in the metaphysis into the joint, because the joint capsule inserts distal to the growth plate. In general, the outcome of acute osteomyelitis in pediatric patients is good, as long as patients are seen within 7–10 days of the onset of illness and treatment is begun and continued for at least 3 weeks.

Subacute hematogenous osteomyelitis

Some studies suggest that, in temperate zones at least, an increasing proportion of cases present with longer, more insidious histories of pain of more than 2-week

duration, with minimal functional impairment and without systemic illness. The diagnosis of osteomyelitis is generally made when radiology shows a suspicious lytic lesion in the metaphysis, which biopsy shows to be infective. Cultures are usually negative, but the patient responds well to curettage of the lesion and antistaphylococcal antibiotics. One series of such cases represented 7% of all cases of osteomyelitis seen in the reporting hospital over a 9-year period.[18]

Chronic osteomyelitis in long bones

Chronic osteomyelitis in long bones usually occurs as a result of trauma; less frequently it occurs as a complication of acute hematogenous osteomyelitis. Patients usually report few systemic symptoms but are commonly troubled by persistent pain and drainage through sinus tracts. Following successful treatment, many patients comment on the dramatic improvement in overall physical well-being, and some patients gain weight. The fundamental problem is the prolonged persistence of viable pathogens. The process involves the consequences of continuing necrosis, such as sequestrum and sinus formation, versus repair with new bone formation and scar (Fig 52.5 and Fig 52.6).

Figure 52-5 Chronic osteomyelitis. The patient is a 30-year-old man who was born in Pakistan and who, as a child, had chronic osteomyelitis caused by *Staphylococcus aureus*. He is asymptomatic now except for occasional pain in the hip and a limp. The radiograph shows destruction of the femoral head and acetabulum, chronic changes in the femoral shaft and fusion of the right hip joint. *Courtesy of Dr Joseph Mammone.*

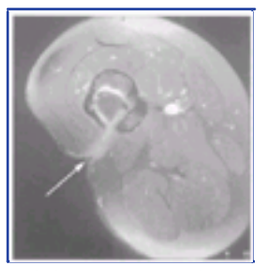

Figure 52-6 Chronic active osteomyelitis in the femur. This case of osteomyelitis was secondary to a fracture and open reduction and internal fixation 30 years before. This axial, contrast-enhanced, fat-suppressed T1-weighted MRI scan shows cortical thickening and a focal intraosseous fluid collection with an enhancing rim, communicating via a sinus tract to the surface of the thigh (arrow).

Potential complications of chronic osteomyelitis include septic arthritis if infection tracks into a joint, pathologic fracture, septicemia if a draining sinus becomes blocked and secondary amyloidosis, which is a rare occurrence (one series reported an incidence of about 1%).[19] A second rare complication, long recognized, is the development of squamous cell carcinoma in scar tissue. Again, the incidence is low (probably less than 1%) and those cases that have been reported occurred after an average of 27 years of osteomyelitis with drainage. The clinical features that are characteristic of malignancy include increased pain, increased drainage, odor and a mass. There was usually more radiographic evidence of bone destruction than is seen in patients with uncomplicated osteomyelitis.

Vertebral osteomyelitis

The most typical presentation of vertebral osteomyelitis is back pain. The pain is increased by loading the spine and relieved by rest. The degree of pain may seem out of proportion to the examination; it is unusually severe, and night pain is an important feature. In about 10% of patients, symptoms may be present for less than 1 week and

Figure 52-7 Vertebral osteomyelitis. A sagittal, contrast-enhanced convential spin echo MRI scan (T1-weighted) demonstrates a posteriorly located epidural abscess at the L4–L5 vertebral level with an enhancing rim and displacement of the nerve roots anteriorly. *Courtesy of Dr Joseph Mammone.*

the illness appears more severe with fever, night sweats and other systemic signs of infection. In such patients, blood cultures are usually positive. The majority have a subacute presentation with symptoms of back pain that are present for anywhere from 2 weeks to 2 years before diagnosis. Generally, only about half of the patients are febrile on initial evaluation.

The major complications of vertebral osteomyelitis are neurologic symptoms, caused by retropulsion of disc material, an inflammatory mass or an associated epidural abscess.[20] The classic clinical progression goes from spinal ache to root pain to weakness, followed by paralysis. Careful and repeated examination of patients with vertebral osteomyelitis is critical; if such symptoms begin, they should be investigated rapidly with radiologic studies, particularly magnetic resonance imaging (MRI; Fig 52.7 and Fig 52.8). Urgent surgical decompression is often needed.[21] Unfortunately, the neurologic complications of epidural abscess are not always reversible, so the goal of management should be detection at the earliest stage (Fig. 52.9).

Bone infections that underlie pressure sores

Patients with osteomyelitis beneath pressure sores are immobile, insensate at the pressure area or malnourished; they may be all of these things. Osteomyelitis presents as a failure of the patient to thrive, and a failure of the wound to heal, despite optimal nursing care and offloading of the sore.[22] There may be pain, but it is often not prominent. Systemic illness is ominous, implying the development of septicemia or the formation of an abscess. Depending on the degree of local sensory impairment and the location of the sore, underlying collections of pus can be very extensive. So too can be the extent of the wound, which may be deeply undermined and sloughy at presentation.

Special patient populations

Patients undergoing hemodialysis

In patients undergoing hemodialysis who present with bony pain or fractures, there must be a high index of suspicion of bone infections. Bone biopsy is necessary to make the diagnosis and to identify the infecting agent because the clinical signs, radiographic picture and symptoms can mimic those of renal osteodystrophy. [23] The usual infecting organisms are staphylococci (either *S. aureus* or *S. epidermidis*) or *P. aeruginosa*.

Figure 52-9 Vertebral osteomyelitis. A myelogram showing posterior compression of the spinal cord by an inflammatory mass. Note the involvement of adjacent vertebral endplates and the intervertebral disc. *Courtesy of Dr Joseph Mammone.*

Intravenous drug users

Although septic arthritis is more common than osteomyelitis in intravenous drug users, the diagnosis must be suspected if bone pain is present. Pain and tenderness are common. In general, the organisms isolated from bone are *S. aureus*, streptococci or *P. aeruginosa*; *P. aeruginosa* infection is presumably due to the use of nonsterile water for injecting drugs.

Osteomyelitis in the diabetic foot

Diabetic patients rarely manifest a fever with foot infections. Systemic illness indicates severe disease and at a local level, there is usually some accompanying necrosis, gangrene, fasciitis, severe

Figure 52-10 Osteomyelitis in a diabetic patient. Diabetic patient with osteomyelitis and destruction of proximal second phalanx and metatarsal as well as second metatarsal-phalangeal joint. *Courtesy of Dr Joseph Mammone.*

cellulitis or significant swelling of the foot indicating a deep abscess. Most patients appear well, although with some worsening of glycemic control. Despite neuropathy, there is often some pain to accompany an ulcer, with signs of soft tissue infection, purulence, erythema, swelling and local warmth. Depending on the depth and extent of the ulceration, bone, cartilage, joint capsule or tendon may be visible in the wound. Callosities indicate chronic excessive weight-loading on a particular area, and it is often beneath these that tissue breakdown occurs. Hemorrhage beneath a callosity is often associated with tissue breakdown or infection. Feet of this kind are often not properly evaluated during admission of the patient to a general hospital (Fig. 52.10).[24]

DIAGNOSIS

The diagnosis of osteomyelitis requires clinical suspicion, a consistent history and physical examination, and supportive laboratory studies (both radiographic and microbiologic). Certain conditions mimic osteomyelitis, and these differential diagnoses are reviewed briefly below.

Acute osteomyelitis

The diagnosis of acute hematogenous osteomyelitis is essentially a clinical one assisted by some of the studies discussed below. In the absence of a clear cause, limping or pain in an extremity should raise the suspicion of infection of bone. The sedimentation rate and C-reactive protein are frequently elevated in the presence of osteomyelitis (in 96% and 89% of cases, respectively), but normal values do not exclude the diagnosis.[25] Blood cultures are positive in just over 50% of cases. Plain radiographs may show soft tissue swelling but are otherwise usually normal because it takes anywhere from 10 to 14 days to destroy 50% of the bone (which is the amount of destruction required to show up as a lesion on conventional radiography).

Ultrasonography has been reported to be successful in detecting subperiosteal abscess in the presence of acute osteomyelitis; deep soft tissue swelling is the earliest sign of acute osteomyelitis, followed by periosteal elevation and a thin layer of periosteal fluid, which, in some cases, progresses to form a subperiosteal abscess.[26] [27] These later stages were marked by cortical erosion; this sign generally appears only in patients who have had symptoms for more than 1 week.

Technetium bone scans are exquisitely sensitive and are generally positive before lesions appear on radiograph; however, false-negative bone scans have been reported when the diagnosis of acute osteomyelitis has been confirmed by aspiration of pus.[28]

The ultimate diagnostic test in acute osteomyelitis is growth of the infecting pathogen in cultures of purulent material obtained by needle aspiration from the painful infected area. Complex tests such as indium-labelled white blood cell scan, computerized tomography (CT) scanning and MRI have little place in the management of acute hematogenous osteomyelitis unless for surgical planning or to confirm the diagnosis. In any even, treatment of the patient with suspected acute osteomyelitis must not wait for diagnostic imaging.

Chronic osteomyelitis

In contrast to acute osteomyelitis, investigation and diagnosis can generally precede antibiotic therapy. Given a clinical suspicion of chronic osteomyelitis, the clinician has a plethora of diagnostic studies to choose from. [28] Unfortunately, none is perfect (Table 52.1). An algorithm is offered for the approach to suspected osteomyelitis and its management (Fig. 52.11). In a nondiabetic patient, if the plain radiograph is positive for osteomyelitis, it is possible to proceed directly to bone biopsy for determination of the infecting organism and its antimicrobial susceptibility. The features of rapidly progressive,

TABLE 52-1 -- Tests for osteomyelitis.[*]

TESTS FOR OSTEOMYELITIS				
	Sensitivity (%)	**Specificity (%)**	**Positive predictive value (%)**	**Negative predictive value (%)**
Three-phase bone scan	95	33	53	90
Gallium scan	81	69	71	80

Indium-labeled white blood cell scan	88	85	86	87
MRI	95	88	93	92
Sensitivity, specificity, positive predictive values and negative predictive values of tests used to diagnose infection of bone.

Figure 52-11 Investigation and management of chronic osteomyelitis.

mixed destructive and reparative bone responses are highly distinctive. If the radiograph is normal and osteomyelitis is suspected, one may go directly to a three-phase bone scan, a labelled white cell scan or MRI. Indeed, MRI is particularly valuable in that it shows the extent of infection inside the bone, the presence of soft tissue abnormalities, including abscesses and sinus tracts, and erosions or breaches of the cortex. Its very high sensitivity and specificity have made it the imaging modality of choice in osteomyelitis,[29] although

its value is reduced in patients who have present or past metal work (because of signal void from implants or metallosis) and in patients with recent surgery, which causes marrow edema in its own right.

Ultimately, the procedure of choice is bone biopsy, often referred to as the gold standard for osteomyelitis. The test is easily done, but the rate of false-negative results have been reported in some series as being as high as 65%, probably because osteomyelitis has a patchy distribution in the bone. All specimens should be sent for both histology and microbiology. In one well-done study, in which 16 biopsy specimens demonstrated histologic evidence of osteomyelitis, only eight were also culture-positive.[30] In the same study, if either histology or culture was considered a positive criterion for osteomyelitis, the positive predictive value was 100% and the negative predictive value was 66%. Obviously, the larger the amount of bone sampled, the more biopsies taken and the better the imaging guidance, the more likely one is to get a positive biopsy. Finally, it should be noted that, in diagnosing osteomyelitis, sinus tract cultures have little value and correlate poorly with the organisms found in specimens taken in the operating room.[31] Therefore, the results of cultures of draining sinuses should not be relied on to identify the causative pathogen.

Bone infections underlying pressure sores

Confirming the diagnosis of osteomyelitis beneath a pressure sore can be difficult. Radiographic or nuclear imaging and soft tissue cultures can be abnormal in the area of a pressure sore and may suggest osteomyelitis when none is present. Such misdiagnosis can lead to prolonged and potentially toxic courses of antimicrobial agents.

A careful study of bone infections and pressure sores made several valuable points:[22]

- the diagnosis of underlying bone infection should be considered whenever a pressure sore does not heal;
- clinical evaluation of the depth of the sore or its duration is not helpful in determining whether bone infection is present;
- failure of the sore to close after pressure is removed is helpful in determining whether there is underlying osteomyelitis;
- nuclear scans are generally useful only if negative — the negative predictive value was high;
- Gram-negative bacilli, anaerobes and streptococci are most often cultured from infected bone; and
- bone biopsy histology and culture are the gold standard in diagnosing osteomyelitis — the procedure is rarely associated with complications. Biopsy must, however, be taken through uninvolved skin if done percutaneously, or after debridement of overlying tissue if at operation, to avoid culturing surface contaminants.

Osteomyelitis in the diabetic foot

In diabetic patients, the approach to diagnosing osteomyelitis in the foot (the usual site of the disease) is somewhat different. Conventional radiographs may be diagnostic if there is rapid progression of changes (e.g. over 2–3 weeks), but it can be extremely difficult to distinguish diabetic osteopathy from osteomyelitis. Because osteopathy will not respond to antimicrobial agents, this distinction is critical. Nuclear medicine scans are often difficult to interpret because there is soft tissue infection and it is difficult to localize infection to bone as opposed to the soft tissue (Fig. 52.12 and Fig. 52.13). One of the simplest tests is to take a steel probe and insert it into the ulcer; contact by the probe with bone has a high correlation with the presence of osteomyelitis. [32] If the probe does not hit bone, the negative predictive value of the test is not adequate to exclude osteomyelitis; in this instance, MRI should be used because it has an extremely high predictive value for osteomyelitis (Fig. 52.14). An algorithm for the diagnosis and management of osteomyelitis in the diabetic patient with infection of the foot is given in Figure 52.15 .

Figure 52-12 Twenty-four-hour bone scintigram of the hands. The patient is a 50-year-old diabetic with a draining ulcer at the top of the right thumb (arrow). A biopsy grew *Staphylococcus aureus*. There is intense uptake in distal first phalanx and in multiple neuropathic joints. *With permission from Jacobson AF, Harley J, Kipsky B, Pecoraro R. Diagnosis of osteomyelitis in the presence of soft tissue infection and radiologic evidence of osseous abnormalities. AJR Am J Roentgenol 1991;157:807–12.*

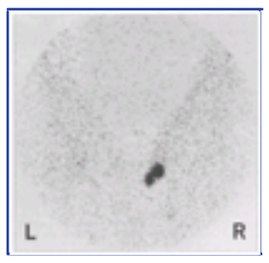

Figure 52-13 Leukocyte scintigram of the hands. This scan is from the same patient as the scan in Fig. 52.12 . Again there is intense uptake in distal first phalanx, but there is no accumulation of leukocytes in the multiple neuropathic joints. *With permission from Jacobson AF, Harley J, Kipsky B, Pecoraro R. Diagnosis of osteomyelitis in the presence of soft tissue infection and radiologic evidence of osseous abnormalities. AJR Am J Roentgenol 1991;157:807–12.*

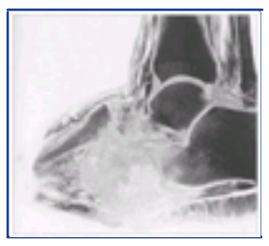

Figure 52-14 T1-weighted image of the foot. The scan reveals forefoot amputation and a normal signal in distal tibia, talus and posterior calcaneus. The interior portion of the calcaneus has edema. The remainder of the tarsal bones have been destroyed and replaced by a pale, heterogeneous inflammatory mass.

Differential diagnosis

Chronic recurrent multifocal osteomyelitis

Chronic recurrent multifocal osteomyelitis (CRMO) generally occurs in female children and presents a fascinating and bewildering spectrum of manifestations. [33] It is possible that a number of separate causes and conditions have been grouped together or that a single entity has a highly variable course. Patients present with pain and malaise, and they are found to have a bone lesion that is evidently chronic at presentation. Biopsy or exploration reveals sclerosis and some granulation tissue but very rarely any pus. Histology shows chronic inflammation including plasma cells (the condition has been called plasmacellular osteomyelitis), with no evidence of the bone tumor that is usually feared at first. Further radiographs or isotope scans may reveal multiple skeletal lesions, or these may develop over time as separate episodes. In contrast to the highly metaphyseal distribution of pyogenic osteomyelitis, the lesions are not only in the metaphysis but also in the clavicle, pelvis and spine (but in the vertebral body, not the disc space). Cultures are negative.

There may be an overlap with primary chronic osteomyelitis and chronic unifocal osteomyelitis. Both these terms describe osteomyelitis that has similar characteristics to CRMO but is only ever present at a single site. By adulthood some 50% of cases of CRMO also have an overlap with a syndrome called SAPHO (standing for synovitis, acne, pustulosis (psoriasis or palmoplantar pustolosis), hyperostosis and osteitis). More evident sacroiliitis, arthritis or spondylitis can develop over time. There is no link with HLA-B27, but a potential susceptibility gene exists on chromosome 18q21.3–18q22, analogous to a CMO gene in mice and identified in a human family study.[34] Management of these children is difficult because of persisting symptoms. Although the disease does not cause the rapid destruction and harm associated with pyogenic infection, 25–57% have been found to have persistent pain or flares at over 5 years and some children develop leg length inequality. Because antibiotics appear not to work, many therapies have been tried, including bisphosphonates. In some series, azithromycin has been shown to be helpful; it is not clear whether

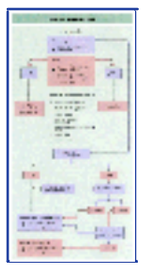

Figure 52-15 Diabetic foot infections. Algorithmic approach to diagnosis and management. *Adapted with permission from Lipsky et al.*[3]

this drug exerts an antimicrobial action or an anti-inflammatory action. Nonsteroidal anti-inflammatory drugs are often very helpful. It is important to remember the relatively good prognosis and to avoid giving repeated courses of antibiotics in the face of negative cultures.[35]

Histiocytosis X (eosinophilic granuloma)

Eosinophilic granulomas may present as one of several destructive foci within the skeleton, often without any constitutional indications of illness. The lesions generally respond to curettage or low-dose irradiation.

Gaucher's disease

Gaucher's disease is a hereditary metabolic disturbance in which cerebrosides accumulate in reticuloendothelial cells. The disease occurs mainly in Ashkenazi Jews. Constitutional symptoms include fatigue, weakness, weight loss, abdominal discomfort, hepatomegaly and splenomegaly. Bone symptoms include pain and limitation of motion, primarily of the hips and the knees. Vascular infarcts can mimic acute osteomyelitis; pathologic fractures may occur. The combination of necrosis of bone and subsequent repair produces a radio-graphic appearance similar to that of bone infection.

Ewing's sarcoma

A Ewing's sarcoma is rarely mistaken for osteomyelitis, although this error can occur, especially in locations with high prevalences of chronic osteomyelitis. [36] This emphasizes the importance of obtaining samples for histology and culture from suspicious lesions. More frequently, the biopsy of the suspected tumor is reported as infection, with no accompanying cultures.

MANAGEMENT

Acute hematogenous osteomyelitis

In the management of acute osteomyelitis, the experience of Nelson *et al.* is invaluable.[13] Optimal surgical management is controversial. In general, if frank pus is found in a diagnostic aspiration, surgical decompression is usually done. If the tap produces only bloody material, medical therapy will generally be sufficient. The choice of initial antibiotic agent can be guided by the results of Gram-stained specimens and modified if necessary after the results of culture are available. If the Gram stain is unrewarding, therapy must be empiric, based on the age of the patient and the most likely pathogen in that age group. The data obtained by Nelson *et al.* indicate that when patients are treated for a minimum of 3 weeks for infections caused by staphylococci or Gram-negative bacilli, the response is excellent and chronic osteomyelitis does not ensue. Longer periods of therapy may be necessary if the clinical response is slow or if the erythrocyte sedimentation rate remains elevated. Oral antibiotics may be given after a short course of parenteral therapy, provided that the patient and family are compliant, the drug is well absorbed and the organism is sensitive to the antibiotic.

Chronic osteomyelitis

The general principles of the treatment of chronic osteomyelitis are:

- to set realistic goals with the patient;
- to establish the microbiologic diagnosis and to stage the disease;
- to expect to need surgery to explore, to debride, to drain pus and to excise dead bone, sinus and scar tissue;
- to use antibiotics to support surgical management, according to the skill of the surgeon and the reliability of culture results and surgical excision;
- to preserve or restore physical function with further surgery if necessary; and
- to support the medical and psychologic state of the patient.

Multidisciplinary working with specialized surgical input is strongly recommended for success in chronic osteomyelitis. The condition is technically and emotionally demanding, although also enormously rewarding to treat.

Surgery

Surgery plays a major role in the management of osteomyelitis of long bones. The presence of dead bone or sequestra makes eradication of infection exceedingly

difficult because the dead bone is avascular and therefore poorly accessed by white cells or antibiotics. The goal of surgical management is to correct the underlying biology to the point where antibiotics can once again exert a useful effect. Staged procedures may be necessary (e.g. to perform bone grafting for defects) or segmental excisions, requiring stabilization with external fixators including circular frames (Ilizarov fixators). Bony reconstruction may require a free fibular transfer or bone transport. For complex wounds or areas with poor soft tissue cover, such as the front of the shin, collaboration with a plastic surgeon may be necessary to reconstruct the soft tissue defect that is left after bony debridement. The development of microvascular anastomosis allows muscle to be transferred with its vascular pedicle, thus providing a healthy soft tissue envelope to cover the operated bone.

Not all patients are suitable for surgery, either psychologically or because the procedure needed to treat their infection would create more morbidity than the infection. In such patients, the only option is long-term antibiotic use or intermittent antibiotic use to manage flares of activity. The condition is relapsing and remitting, and self-arrest is possible if a sequestrum is spontaneously discharged.

In vertebral osteomyelitis, surgery is generally not needed except for persistent pain, progressive deformity or neurologic compromise or to drain epidural or paravertebral abscesses. Scanning with MRI or CT is valuable in diagnosing epidural abscess, but clinical suspicion and careful observation of patients with vertebral osteomye-litis are critical to allow early detection by these sensitive imaging techniques.

Antimicrobial therapy

As noted above, establishment of an appropriate etiologic diagnosis either by bone biopsy or by blood cultures is critical to the management of osteomyelitis. Table 52.2 indicates our recommendations for antimicrobial therapy once the infecting organism has been identified.

The most common infecting organism is *S. aureus*. For methicillin-susceptible strains, treatment with nafcillin 2g q6h, flucloxacillin 2g q6h, cefazolin 1g q8h or clindamycin 600mg q6–8h parenterally for 4–6 weeks is appropriate therapy. Intravenous therapy may be administered at home; once daily ceftriaxone is effective. However, oral therapy, provided the drug is well absorbed and the organism is susceptible, has been shown to be highly effective following a short course of parenteral therapy. A few studies have suggested that an entire course of oral therapy will be as effective as parenteral therapy, but these studies have involved relatively few patients. A meta-analysis of all randomized antibiotic trials in bone and joint infection was unable to generate firm conclusions as to the best mode or choice of treatment.[37]

For osteomyelitis caused by methicillin-resistant strains of *S. aureus*, vancomycin remains the drug of choice. However, this agent has not always been effective, and rifampin (rifampicin) or rifampin plus gentamicin have been used in addition to vancomycin. Controlled studies are lacking in this area. For less common causes of osteomyelitis, including Gram-negative organisms, therapy is based on sensitivities of the infecting organism. Recommendations for duration of therapy for either Gram-negative or Gram-positive osteomyelitis are not based on controlled data, but we recommend a minimum of 4 weeks of therapy.

Quinolones have been used with increasing frequency in the treatment of chronic osteomyelitis. A total of seven randomized trials have been conducted, and despite methodologic issues, the overall view is that they are indistinguishable from conventional, ß-lactam-based therapy.[37] It is possible to draw certain conclusions regarding quinolones in osteomyelitis: [38] [39]

- the published success rate in osteomyelitis due to Enterobacteriaceae is sufficiently high (92%) to eliminate the need for further trials;
- for osteomyelitis caused by *P. aeruginosa* or *S. aureus*, success rates of 72% and 75% suggest a need for further comparative trials with larger sample sizes before quinolones can be recommended with confidence as sole treatment for these pathogens;

- development of resistance to quinolones has been observed with disturbing frequency among strains of *S. aureus*;
- the combination of rifampin and quinolones appears to offer promise; further studies are required in this area as well; and
- as newer quinolones with increased activity against Gram-positive organisms are developed, they may play an increasing role in the treatment of osteomyelitis due to *S. aureus*.

TABLE 52-2 -- Antimicrobial therapy for infections of bone.

ANTIMICROBIAL THERAPY FOR INFECTIONS OF BONE AND JOINTS		
	Antimicrobial agent of choice	
Organism	**Agent**	**Alternative agents**
Staphylococcus aureus (methicillin-sensitive)	Nafcillin or oxacillin 2g q6h iv	Cefazolin, vancomycin, clindamycin
Staphylococcus aureus (methicillin-resistant)	Vancomycin 1g q12h iv	Trimethoprim-sulfamethoxazole plus rifampin
Streptococcus pneumoniae	Penicillin G 5×10^6 U q6h iv*	Cefazolin, vancomycin, clindamycin
Group A ß-hemolytic streptococci	Penicillin G 5×10^6 U q8h iv	Cefazolin, vancomycin, clindamycin
Enterococci	Ampicillin 2g q4h iv†	Vancomycin
Haemophilus influenzae (ß-lactamase-negative)	Ampicillin 2g q4h iv	Trimethoprim-sulfamethoxazole, ceftriaxone
Haemophilus influenzae (ß-lactamase-positive)	Ceftriaxone 1g q12h iv	Trimethoprim-sulfamethoxazole
Klebsiella pneumoniae	Ceftriaxone 1g q12h iv	Ciprofloxacin, piperacillin, imipenem
Escherichia coli	Cefazolin 1g q8h iv	Ciprofloxacin, ceftriaxone, imipenem
Pseudomonas aeruginosa	Ciprofloxacin 400mg q12h iv or ceftazidime 1g q8h iv	Pipercillin plus aminoglycoside, aztreonam
Serratia marcescens	Ceftriaxone 1g q12h iv	Imipenem, trimethoprim-sulfamethoxazole, ciprofloxacin
Salmonella spp.	Depends on sensitivity test; choose between ampicillin, ceftriaxone, imipenem, ciprofloxacin	
Bacteroides spp.	Clindamycin 600mg q8h iv	Imipenem, metronidazole

* If susceptible or intermediate resistance. If high level resistance, use ceftriaxone 1g q24h or vancomycin 1g q12h.
† If susceptible. If ampicillin resistant but vancomycin susceptible, use vancomycin. If resistant to both, check susceptibility to tetracyclines, chloramphenicol or experimental agents.

The role of rifampin may not be confined to its usefulness in combination with vancomycin. Animal data support the view that rifampin is of particular value in killing staphylococci present as biofilms, and human experience in the area of orthopedic hardware suggests that combinations of fluoroquinolone and rifampin are effective in some cases. This combination has been reported as effective in diabetic foot infections and other combinations (e.g., trimethoprim-sulfamethoxazole (co-trimoxazole) plus rifampin, fusidic acid plus rifampin) have also been studied. A randomized trial of nafcillin with or without adjunctive rifampin did not show superiority. Further studies would be appropriate, because the addition of rifampin clearly increases the incidence of side-effects.

Local therapy

Among the potential complications of parenteral antibiotic therapy with high serum concentrations (particularly of aminoglycosides) are toxic reactions involving the kidneys, hearing and vestibular function. In theory, these potentially adverse effects of systemic antibiotic therapy can be avoided by releasing antibiotics locally into the wound in high concentrations through either antibiotic impregnated cement or antibiotic impregnated beads.[40] [41] There is considerable experience with this technique

in parts of continental Europe, and major published series have reported success rates comparable to those of systemic therapy. A multicenter randomized controlled trial to study this question was undertaken in the USA, but massive protocol violations made interpretation impossible.[42] A range of antibiotics can be incorporated into bone cement, including gentamicin, tobramycin, cefuroxime, erythromycin, vancomycin and fusidic acid. Antibiotics can be delivered via 'high-tech' resorbable polymers and by structural osseointegrative materials such as ceramics, or even via plaster of Paris, a 'low-tech' solution that merits further study for resource-poor areas of the world.

Hyperbaric oxygen therapy

Hyperbaric oxygenation (HBO) has frequently been proposed as a treatment modality or adjunct therapy for chronic osteomyelitis. Experimentally, there is evidence that increasing intramedullary oxygen tensions allows increased effectiveness of leukocytes in killing staphylococci. Increased oxygen tensions may also improve wound healing. Several open studies have reported improvement with the use of hyperbaric oxygen in patients with chronic osteomyelitis who were refractory to prior therapy. There is currently no compelling controlled clinical evidence to support the use of HBO, and it probably has little to add to the treatment of osteomyelitis when adequate debridement produces a well-vascularized wound. However, in patients in whom this condition is not met, HBO may be of some therapeutic value. A number of studies have been carried out in diabetic patients with infected ulcers, but these studies have been largely retrospective. A single randomized controlled trial showed only 3/35 patients treated with HBO needed amputation, whereas 11/33 patients treated with standard care did. The need for controlled studies in this area is obvious.[43]

Foot infections in diabetic patients

Treatment begins with evaluation of severity. The patient should be assessed for systemic compromise and admitted to hospital if this is present. The foot should be examined for the extent of infection. Uninfected ulcers and those with <2cm of erythema (mild infections) and involvement of the skin only can be treated on an outpatient basis. Moderate infections, with no systemic compromise, but with >2cm erythema and a degree of deeper involvement (early tendon, joint or bone) may be suitable for outpatient treatment or need hospitalization. Patients with gangrene, gross necrosis, fasciitis or major soft tissue loss with exposed bone should be admitted.

The next steps are to debride the ulcer to determine its extent, obtain microbiology (from the base of the debrided ulcer) and physically to debulk the ulcer of dead and infected material. This can usually be performed by a podiatrist in the clinic, but for severe cases a surgeon is required. An assessment of the healing ability of the wound must now be made, by checking the peripheral pulses with palpation or a Doppler probe. Ischemia, measured by Buerger's test, impalpable pulses, or an ankle-brachial pressure index of <0.6, should prompt urgent vascular review, because the combination of infection and ischemia has a high risk of culminating in amputation. Finally, for patients who are admitted, bedrest is essential. Outpatients should be advised to rest, and must be given shoes that offload the ulcer when walking.

Only when all these steps have been taken is it appropriate to consider antibiotic treatment.

Until culture results are available, therapy must be empiric, ensuring that *S. aureus* is covered. ß-Lactam agents, clindamycin or vancomycin are most frequently used. For methicillin-resistant *S. aureus*, rifampin has been added to vancomycin. New agents such as the prototype oxazolidinone, linezolid, which is effective against methicillin- and vancomycin-resistant organisms, are showing promise.

Mild infections can be treated for 2 weeks. Moderate infections should be treated for 2–4 weeks if there is no bone involvement. Severe infections may need ablative therapy to save the patient's life, and minimal therapy (48 hours) is needed if the amputation is through uninvolved skin and bone. For osteomyelitis, a minimum of 6 weeks is generally appropriate.

Surgical resection of infected bone may be helped by delineating the area of infection. In one series of 35 patients, 21 underwent surgical resection of infected bone. In 13 of these, the surgery was limited to the specific region of infection demonstrated by MRI. In all patients, the surgical margin encompassed the region of bone with abnormal MRI signal intensity, and there were no recurrences at the surgical margins with an average follow-up of 9 months.[44]

There are data to support the need for an aggressive surgical approach. Early surgical intervention has been shown to be associated with a lower rate of above-the-ankle amputation and a shorter duration of hospitalization than delayed or less aggressive surgical intervention.[45]

Against this must be set a number of retrospective series showing cure rates of diabetic foot osteomyelitis with antibiotics alone, with success rates of the order of 70–80%. It is difficult to compare between series because of varying methodologies and case definitions, but the overall trend is hard to dismiss. [46] [47] Recent studies have suggested that adjunctive treatment with GCSF (lenograstim) can reduce the complications associated with diabetic foot infections.[48] Further work is necessary to better define the precise role of GCSF in this setting.

Chapter 53 - Infections of Prosthetic Joints and Related Problems

Anthony R Berendt

INTRODUCTION

Infections of orthopedic devices are paradigms of device-related infection. Microbiological diagnosis is complicated by the important role of skin commensals as pathogens, but also as contaminants of diagnostic samples. Treatment requires a multidisciplinary approach that brings together the surgeon and the specialist in infection. Surgery is needed to remove infected foreign material and necrotic tissue, to restore skeletal integrity and soft tissue cover and, in some cases, to obtain diagnostic specimens. Antibiotics are essential — to prevent systemic illness and soft tissue involvement, to clear residual contamination after surgery or to suppress infection when further surgical intervention cannot be contemplated. The role of the infectious diseases specialist in prosthetic joint infection is therefore usually as a guide and supporter, helping the orthopedic surgeon to perform and interpret microbiologic tests appropriately and to choose and use antimicrobials rationally. This chapter therefore includes a strong emphasis on surgical management. Understanding the perspective of the orthopedic surgeon is crucial to arriving, through successful combined working, at the best plan for the individual patient.

EPIDEMIOLOGY

Reported infection rates for hip and knee replacements are approximately 0.5–3% and 1–2%, respectively.[1] [2] Most infection presents within the first 5 years of implantation, but all prosthetic joints are at a continuing low lifelong risk of infection. This risk probably rises if the joint begins to fail mechanically. Thus, rates of infection depend on the duration and diligence of follow-up and also on the criteria used for diagnosis. Lack of consensus definitions of prosthetic joint infection make such rates hard to compare between centers. Independent risk factors for infection, based on a large retrospective case-control study of hip and knee replacements,[2] are a history of superficial wound infection (OR, 35.9), a diagnosis of malignant disease (OR, 3.1), prior surgery on the replaced joint (OR, 2) and a National Nosocomial Infections Surveillance (NNIS) System patient risk index score of 1 (OR, 1.7). The latter is a composite score in which prolonged operation time (over 3 hours), wound status and an ASA score of >2 each contribute one point. Drainage of the postoperative wound at the fifth day or longer, and the presence of a hematoma, have both separately been shown to be independent risk factors for *superficial* wound infection (OR, 1.3 and 11.8 respectively).[3] In the same study, superficial wound infection was confirmed as a major risk factor for deep infection.

Rates of fracture-fixation infection vary widely depending on the site and the method of fixation adopted. Infection rates for closed fractures undergoing internal fixation by incisions through healthy soft tissue, for example, by intramedullary nailing, should be comparable to those of other 'clean' surgical procedures. Compound fractures are at higher risk, depending on the extent of environmental contamination, soft tissue injury and vascular injury.[4] In addition, delay in wound debridement and soft tissue closure leads to greatly increased infection rates.

PATHOGENESIS AND PATHOLOGY

Pathogenesis

Infection commences with the adhesion of bacteria to host tissues or biomaterials, either directly or via host plasma proteins, such as fibronectin, deposited on the biomaterial surface.[5] Bacteria express numerous structures to enhance adhesion, including proteinaceous cell wall associated adhesins and capsular polysaccharide adhesins. Furthermore, the surfaces of many bacteria are relatively hydrophobic, enhancing initial interactions mediated by van der Waals forces.

Adherent micro-organisms frequently produce exocellular polysaccharides that enmesh the bacteria. The resulting consortium of adherent bacteria is called a biofilm, which may be monomicrobial or polymicrobial. Compared with the same organisms cultured in liquid media, bacteria in biofilms are exceedingly difficult to kill with antibiotics or biocides or by host defenses. The possible mechanisms for this resistance include alterations in the growth rate of organisms within the biofilm and adherence-dependent differential gene expression. It does not appear to be due to impaired antibiotic access. Characterization of genes involved in coagulase-negative staphylococcal exopolysaccharide synthesis[6] indicates an essential role for a cluster denoted *icaABCD*, with a number of other genes involved in regulation and biofilm formation (reviewed in reference[7]). Biofilm formation is subject to phase variation, in part through integration and excision of insertion sequences close to regulatory genes. In human disease, the relationship between adherence to plastic or elaboration of exopolysaccharide and the clinical manifestations caused by isolates has been studied, with inconclusive results.

Host responses are impaired in the vicinity of biomaterials. This was dramatically demonstrated in the classic observations of Elek and Conen, who showed that the inoculum of *Staphylococcus aureus* required to cause a skin infection in human volunteers was reduced many-fold in the presence of a skin suture.[8] Neutrophils show defective phagocytosis, partly owing to the concentrations of metal ions or to the presence of monomeric or polymerized methacrylate (bone cement). In addition, bacterial exocellular polysaccharide may inhibit phagocytosis and other elements of the immune response,[9] though recent findings suggest that human leukocytes can interact with *Staphylococcus aureus* biofilms.[10]

Pathology

Once the organisms have established an association with the surface of the biomaterial, infection ensues with two major pathologic features:

- acute inflammation around the prosthetic material,
- activation of osteoclasts and recruitment of monocyte-derived bone-resorbing cells, leading to bone loss at the interface with the implant. This is probably in part due to inflammatory cytokines[11] and in part to direct triggering by bacterial antigens.[12]

The normally thin layer of poorly vascularized fibrous tissue between the host and the implant or its anchoring cement, generally termed

the 'membrane' by orthopedic surgeons, becomes markedly thickened and more vascular. Frank granulation tissue may be produced alongside the implant and eventually free pus is formed. In prosthetic joint infection, these processes exaggerate the pathologic mechanisms operating in aseptic loosening, in which a chronic inflammatory response is produced in response to wear particles derived from acrylic cement and polyethylene. This chronic inflammation, associated with mononuclear cells and giant cells, also leads to bone resorption (Fig. 53.1). A key feature of infection is thus the presence of an acute inflammatory infiltrate, but it may be superimposed on chronic inflammation (Fig. 53.2).[13]

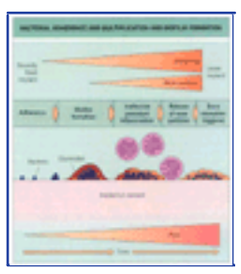

Figure 53-1 Bacterial adherence to the implant, bacterial multiplication on the surface and biofilm formation. An ineffective host response triggers bone resorption,

contributing to loosening, which is accelerated by wear particles and the host response to them.

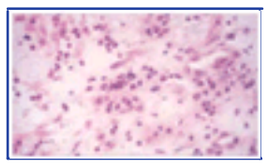

Figure 53-2 Histologic features of infection. Periprosthetic tissue from a clinically infected total hip replacement from which multiple specimens grew an indistinguishable organism. Numerous neutrophils are present in the tissue.

TABLE 53-1 -- Bacteria associated with infected implants presenting at different stages.

BACTERIA ASSOCIATED WITH INFECTED IMPLANTS PRESENTING AT DIFFERENT STAGES	
Early infection (up to 3 months)	*Staphylococcus aureus*
	Coagulase-negative staphylococci
	Aerobic Gram-negative rods
	ß-hemolytic streptococci
Delayed infection (4–12 months)	Coagulase-negative staphylococci
	Other skin commensals
	Staphylococcus aureus
Late infection, including hematogenous seeding (more than 12 months)	Coagulase-negative staphylococci
	Other skin commensals
	Staphylococcus aureus
	Aerobic Gram-negative rods
	Anaerobes
	Mycobacterium tuberculosis

Microbiology

Orthopedic implant infections are classified as early, delayed and late (Table 53.1). It can also be useful to distinguish between acute infections, which may arise early (postoperatively) or late (by hematogenous spread), and chronic ones, as this helps determine the management.

Early infections usually manifest as wound infections. They tend to be caused by higher grade pathogens able to exploit postoperative hematomas and breaches in the skin. *Staphylococcus aureus*, including methicillin-resistant strains, predominates. ß-Hemolytic streptococci and aerobic Gram-negative rods are also seen.

Delayed infections, in which pain and swelling develop in the context of a healed wound, are more often caused by coagulase-negative staphylococci and other skin commensals. This is presumably because, as lower virulence pathogens, they take longer to reach the critical number of organisms needed to produce clinical symptoms.

Late infections, which present more than 12 months postoperatively, are mostly caused by Gram-positive skin commensals that have been chronically infecting the prosthesis since implantation, but also include cases of hematogenous seeding with organisms capable of causing bacteremia.

Irrespective of the time of presentation, mixed infections are relatively common (accounting for approximately 20% of cases), with a variable proportion of aerobic Gram-negative rods, fastidious anaerobes and culture-negative cases. A very large number of individual organisms have been described as causes of prosthetic joint infection, including *Mycobacterium tuberculosis*, atypical mycobacteria, *Brucella* spp., *Listeria monoyctogenes, Campylobacter* spp., *Mycoplasma* spp and yeasts.

The high proportion of culture-negative cases in clinically suspected infected revisions (c.15%) is sometimes plausibly due to sampling error or prior antibiotic therapy, but there may also be fastidious organisms that cannot adapt to the conditions in the diagnostic laboratory. Furthermore, there is some evidence that sonication of implants leads to the release of bacteria from the prosthesis surface that can be cultured (yielding a high proportion of *Propionibacterium* spp.), detected visually with specific antisera or inferred from the presence of bacterial 16S ribosomal DNA identified by PCR.[14] The clinical spectrum of prosthetic joint infection and its microbiological causes may yet broaden.

PREVENTION

Prevention of all infections of orthopedic devices depends to a great extent on good surgical technique and operating room discipline. Ultraclean air in theaters reduces infection rates, as do prophylactic antibiotics. In most centers, one to three doses of a first- or second-generation cephalosporin are used; [15] where methicillin-resistant *Staph. aureus* is endemic, glycopeptide prophylaxis may be advised. Although there is clear evidence of the benefit of antibiotic prophylaxis, it is less clear as to whether a single dose will suffice, and whether intraoperative redosing is essential if the procedure is prolonged or accompanied by excessive blood loss, though many would advise this. Optimum prophylaxis specifically to prevent infection with methicillin-resistant organisms is also uncertain.

For joint replacement, specialized theater apparatus may also be used, including total body exhaust suits and the Charnley-Howarth sterile air enclosure, a plastic hood that excludes most of the operating theater environment from the vicinity of the surgical field. For prevention of fracture-fixation infection, energetic wound debridement and early soft tissue closure are essential, with initial stabilization by external fixation before proceeding to internal fixation once the soft tissues have recovered from the initial trauma. Free tissue transfer using muscle flaps allows debridement to be radical, removing all devitalized and contaminated tissue and replacing it with healthy tissue at the fracture site.

Late prophylaxis

The risk of hematogenous infection of prosthetic joints must be considered when planning procedures that are known to cause transient bacteremia. The risk is unclear, but the routine use of antibiotic prophylaxis for all procedures liable to cause bacteremia in all patients with prosthetic joints is probably not justified on risk-benefit or economic criteria. Patients at particular risk are likely to be those with newly implanted or loose prostheses and those with active infection elsewhere, including dental infection, and it may be reasonable to offer prophylaxis in these situations,[15] using protocols similar to those used for the prevention of infective endocarditis.

CLINICAL FEATURES

Orthopedic implant infections are almost always associated with pain, which may be mild at first but which usually becomes severe. 'Infection pain' is often distinguishable from other pains, even at the same site, but it does not have pathognomonic features. It is commonly present to some extent as soon as the infection is active. Even if presentation is delayed, many patients give a history that the implant was 'never right', that is, that it never became comfortable. Pain is due to inflammation but is also caused by loosening of the implant. This is characteristically 'start-up' pain, initially severe following rest (and therefore especially in the morning) but subsequently easing off with use of the joint. As loosening progresses, use of the joint or limb becomes increasingly painful at all times and night pain and unpredictable spasms develop.

Early infections are generally also associated with fever and marked inflammation in the operative wound. There may be purulent discharge (Fig. 53.3) or frank wound breakdown with skin necrosis when high-grade pathogens are involved. Rarely, sepsis results; this is also often a feature in hematogenous late infections. If infection

with less virulent pathogens presents early, the clinical features may be less florid, with a wound that continues to drain in a patient who is systemically well. In either case, inadequate treatment will lead to the formation of a sinus tract, which is also often seen with delayed and late infections (Fig. 53.4). It is not unusual for patients to give histories of recurrent wound infections, treated with repeated short courses of oral antibiotics because the underlying deep infection was

Figure 53-3 An acutely infected knee replacement. The site was washed out but the infection failed to resolve. At reoperation the implant was found to be loose and it needed to be removed. *Staphylococcus aureus* was grown from deep specimens.

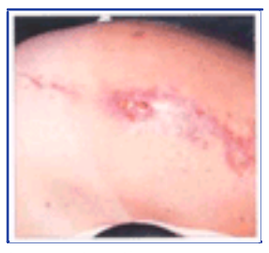

Figure 53-4 A sinus tract discharging from an infected total hip replacement. *Staphylococcus aureus* was grown from deep specimens. Note the Koebner phenomenon; this patient's psoriasis was probably a significant risk factor for infection.

not addressed. By the time such infections present to the specialist, the implant has usually loosened. A proportion of delayed and late infections simply present with rapid loosening and do not show any signs of local or systemic inflammation, although they do cause pain.

DIAGNOSIS

Diagnosis of infection requires clinical suspicion and appropriate investigation. When wounds develop purulence, spreading cellulitis, persistent erythema or persistent drainage (even with serosanguinous fluid), the implant should be considered infected until proved otherwise. Unless there are convincing alternative explanations, the same approach should be adopted for any implant that fails early or is persistently painful.

Early infections

The erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and white blood cell count are generally elevated. Blood cultures may demonstrate a bacteremia. Ultrasound of the implant may reveal a fluid collection or a hematoma; if so, this should be aspirated for microscopy and culture. If unexplained fever is present, aspiration of the joint space or the region of the fracture should be considered. Plain radiographs are of little value in early infection, but they serve as a useful baseline for subsequent change.

Of central importance in making the diagnosis is exploration, which should be performed before starting antibiotic therapy if the overall condition of the patient and the state of the soft tissues permit it. Infections presenting at this time interval, and acute late

infections, generally have a high microbial load and are readily diagnosed from microbiological specimens. It is nonetheless recommended that a number of independent samples (up to 5) are taken from around the joint at debridement, to maximize the definition of the infecting flora and to assist interpretation of the results if skin commensals are isolated.

Late infections

These are accompanied by systemic features only in the small minority of patients in whom bacteremia or abscess formation occurs. The white blood cell count, ESR and CRP may all be normal. Plain radiographs usually demonstrate loosening (Fig. 53.5). Additional features, such as periosteal reaction, cortical scalloping and endosteal erosion (with intramedullary implants), may be seen but their specificity for infection is unknown.

The clinical context is helpful in interpreting plain film changes, as infection is generally associated with early failure and with more rapid loosening. For prosthetic hips, arthrography combined with aspiration or capsular biopsy for microscopy and culture may be useful for determining the extent of loosening. Arthrography can detect loosening that is not apparent on the plain radiograph. Even if this is not seen the prosthesis is likely to be loose if pain is immediately relieved by the instillation of local anesthetic. More elaborate methods of imaging have been disappointing. Metal artefact renders CT scanning and MRI of little value except to evaluate periprosthetic

Figure 53-5 Implant loosening in late infection. (a) Radiograph of the infected hip shown in Figure 53.4 . There is an obvious radiolucent line at the bone-cement interface. This implant required revision. (b) Radiograph of a loose knee replacement, showing resorption of bone beneath the tibial component, a cause of instability. Coagulase-negative staphylococci were grown from multiple deep specimens.

soft tissue. Technetium bone scanning is sensitive but not specific and although indium-labeled white cells, gallium citrate, labeled immunoglobulins and even labeled antibiotic scans all have their proponents, there is no widely applicable and robust test with high sensitivity and specificity.[15] [16]

Molecular diagnosis, using the PCR or other molecular methods to detect bacterial DNA, offers the advantage of speed and potential sensitivity. Despite early studies that offer promise, it has not yet been validated as a practical diagnostic test.[17] Molecular methods would need to provide not only evidence of infection, but identification and antibiotic sensitivities, and this is likely to require considerable refinement.

Pathology has a useful role to play. In the absence of inflammatory joint disease, the presence of neutrophils is indicative of infection. Different authors have set different limits for an abnormal number of neutrophils, ranging from 10 to 1 cell per high power field, averaged over at least 10 fields. Often, however, the histologic changes are focal, with some specimens negative and others showing unequivocal acute inflammation. This variability, which was also observed in experimental studies of infected prosthetic joints in dogs, is probably due to infection with very low numbers of micro-organisms in a patchy distribution. Frozen sections can be used to make the diagnosis during surgery, again using as criteria the presence of neutrophils.[18] [19] [20] The specificity of the test is high and this makes it possible to identify at least some infected cases intraoperatively. The surgeon can then accordingly choose between one- and two-stage revision (see below).

If there is sinus tract drainage, the diagnosis of infection is effectively beyond doubt. However, because sinus tracts commonly acquire a complex mixed flora of both commensals and pathogens, including *Staph. aureus*, aerobic Gram-negative rods, enterococci and anaerobes, it has long been recognized that the predictive value of sinus tract cultures is poor. Such cultures should be discouraged except for the purpose of infection control in hospitals, where attempts are made to identify cases of methicillin-resistant *Staph. aureus*.

Aspiration for microscopy and culture is frequently performed, but published sensitivities and specificities vary widely. This may be explained by differences in techniques of aspiration, in sample handling and processing, and in the criteria used for the final diagnosis of infection when evaluating the test. With careful case selection, it was possible to achieve a sensitivity of 92% and a specificity of 97% in one study.[21] In general, specificity outperforms sensitivity, so the test is more useful at 'ruling in' infection than excluding it.

Definitive microbiologic diagnosis requires culture of periprosthetic tissue samples. For maximum diagnostic yield, deep specimens should be obtained from multiple

areas around the implant at debridement or excision and transported to the laboratory without delay. The surgeon must use separate instruments to prevent cross-contamination of samples and these should be processed in a laminar flow cabinet to avoid contamination in the laboratory. Enrichment cultures are essential. Unfortunately, published criteria for the diagnosis of infection based on operative samples are non-standardized (if stated at all), ranging from the isolation of organisms in four out of five or five out of six specimens to diagnosing infection on the basis of a single positive direct culture or on two or more positive enrichment cultures. [22] [23] [24] One prospective study of over 300 revision arthroplasties (known infected and predominantly believed uninfected) compared the results of culture with histology as the criterion standard for infection.[25] Using the strict protocols above, the sensitivity of a single sample from an infected patient was found to be approximately 60%. The false-positive rate for a single sample averaged 6%. Likelihood ratios were found to be

extremely high for the diagnosis of infection (positive histology) when three or more independent specimens of periprosthetic tissue yielded indistinguishable micro-organisms. The receiver-operator characteristic modeled from the data suggested that if five or six samples were sent a sensitivity of 91–95% and a specificity of 95–97% could be achieved (taking two or more samples positive with an indistinguishable organism as the cut-off). In agreement with other studies, the Gram stain was found to be of no value in diagnosing infection at revision arthroplasty.[25]

MANAGEMENT

Early infections of prosthetic joints

These should be considered to be emergencies, for two reasons:

- infection may lead to bacteremia or soft tissue loss or both;
- some cases of early infection have good long-term outcomes if aggressive debridement is combined with appropriate antibiotic therapy, whereas there is clear evidence that delay worsens outcome.[26] [27]

Hence, early infections (and the acute presentations of late infections) should be managed by urgent exploration, debridement of infected and devitalized tissue, and inspection of the prosthesis. If the implant is soundly fixed, salvage may be possible; if loose, the prosthesis should be removed. After specimens have been taken, intravenous broad-spectrum antibiotics should be given, active against methicillin-resistant staphylococci and aerobic Gram-negative rods. Antibiotic treatment can be rationalized according to culture results.

Many authors recommend treatment with intravenous antibiotics for 6 weeks. Outpatient parenteral antimicrobial therapy (OPAT) (see Chapter 191) may make this more acceptable to the patient and the surgeon and to health economists. Insertion of a central venous catheter (Hickman, Broviac or as a peripherally inserted line or PICC) allows assured long-term access for the outpatient and home setting. Once-daily dosing with ceftriaxone (for methicillin-sensitive organisms) or with teicoplanin (for methicillin-resistant Gram-positives) is particularly convenient. More frequent dosing or continuous infusion is possible, with a range of portable electrical or elastomeric devices available. It is essential that if such therapy is undertaken, there is a clear system of follow-up and patient support in place. A French study calculated that OPAT for 39 patients with osteomyelitis had saved $1,873,885 relative to conventional intravenous therapy.[28] The duration of therapy necessary to maximize the chance of salvage is unclear. There is anecdotal evidence that infection can be eradicated with finite courses of treatment in some cases but in others, prolonged suppression seems more appropriate rather than risking recurrence of infection.

An advance in this regard may be the recognition that combinations of a fluoroquinolone and rifampin (rifampicin) show excellent killing activity inside abscesses, inside cells and in experimental models of biofilms or infected foreign devices. This led to observational studies with ofloxacin and rifampin, or ciprofloxacin and rifampin, of a range of different infections of orthopedic hardware, including prosthetic joints.[29] [30] Subsequently a randomized controlled trial of ciprofloxacin and rifampin compared to ciprofloxacin alone showed that of 12 patients (with a range of orthopedic devices in situ) treated with combination therapy, all had cure of infection, whereas five of 12 failed in the placebo group. A further seven of nine patients who were randomized but dropped out of the trial subsequently took open label rifampicin combinations, and five of these were also cured.[31] Other regimens, including fusidic acid and rifampicin or high-dose trimethoprin-sulfamethoxazole, may also be effective with success rates of the order of 50%, according to sensitivity patterns.

In all cases, the key features associated with a good outcome appear to be:

- thorough debridement early after the onset of infection;
- infection with a sensitive organism (poorer outcomes occur with *Staph. aureus* and aerobic Gram-negative rods);
- the absence of a draining sinus; and
- a soundly fixed prosthesis.

If wound breakdown is a feature, implant salvage will also require the prompt restoration of soft tissue cover to prevent secondary colonization with other, more resistant flora. Plastic surgery may be necessary to cover large defects with free or rotational flaps, which obliterate the dead space generated by debridement and provide a mechanism for systemic antibiotics to reach to the site of infection.

In all situations of early infection, there is a need for randomized trials to address the question of whether long-term antibiotic therapy improves outcomes and, if it does, at what cost. Definitive identification of those patients who should proceed to immediate revision surgery would save patients and carers from the medical, psychological and financial costs of prolonged and ineffective attempts at salvage treatment.

Delayed and late infections of prosthetic joints

Excision arthroplasty

If the prosthesis is loose, revision surgery is usually needed. The simplest option is excision arthroplasty, which has a high cure rate provided that the debridement of cement and dead tissue is adequate. In the hip, where a Girdlestone's pseudarthrosis is the result, function is generally very much poorer than with a successfully reimplanted hip. However, it is an option in cases where attempted reconstruction is technically unrealistic or poses unacceptable risks of reinfection, other major morbidity or death. The affected leg is short, requiring a substantial shoe raise, the patient walks with a limp and at least one stick for life and function is particularly poor in patients of above average weight.

Excision arthroplasty alone is rarely employed for prosthetic knee infections because it leaves the knee flail and the limb unstable. An external brace is needed for ambulation and levels of discomfort are high. Nonetheless, in certain cases where limited demands are placed on the leg and poor bone stock makes reimplantation or fusion unlikely to succeed, this may still be preferable to an above-knee amputation.

One-stage revision

In one-stage procedures, the excision is followed by immediate reimplantation. Although systemic antibiotics may also be administered, in the largest published experiences of this method, great reliance was placed on a meticulous debridement and the use of gentamicin-impregnated bone cement. The high prevalence of gentamicin resistance among hospital-acquired coagulase-negative staphylococci has led to a decline in the popularity of this strategy.

It should, however, be noted that the benefits to the patient of a successful one-stage revision are enormous, making this a technique that would justify renewed efforts to improve its success. Published success rates vary, depending on both the skill of the surgeon and the completeness of the follow-up, but in the most reliable and largest series, approximately 80–85% of treated implants showed no signs of recurrence at 7 years.[32] [33]

One-stage revision can still be considered for patients for whom a staged procedure carries unacceptable anesthetic risks and there is prior knowledge of a highly sensitive pathogen. It is less successful if there are resistant organisms involved; furthermore, few surgeons would happily perform this operation in the presence of extensive bone loss, for which bone allografting is often used in reconstruction.

A retrospective review of patients referred to one center and managed with two-stage revision found that only four of 37 cases would have met accepted criteria for one-stage revision, and that preoperative definition of the pathogen was incomplete in 30% of cases.[34]

Two-stage revision

In two-stage revision, an excision arthroplasty is combined with intensive antibiotic treatment, often for 6–12 weeks, followed by reimplantation of a new prosthesis. Antibiotics may be administered systemically (intravenously or orally) or locally using antibiotic-impregnated cements. In the knee, some form of spacer is required to stop femur and tibia impacting.

Comparative studies between local or systemic routes of antibiotic administration are not available. Local delivery offers obvious advantages of convenience to patient and surgeon without the complications of systemic therapy, but it is necessary to know the infecting flora and antibiotic sensitivities in advance of the excision arthroplasty and this may necessitate an additional diagnostic procedure. Although again variable, the best results for two-stage revision of both hips and knees appear superior (90% success or greater) to one-stage revision, but these are in noncomparative, nonrandomized studies.[35]

One approach that is growing in popularity, especially in cases of severe bone loss from previous revisions, is to use some form of articulating spacer constructed with an outer surface composed entirely of antibiotic-loaded bone cement.[36] These can be fashioned intraoperatively and usually include both vancomycin and an aminoglycoside (gentamicin or tobramycin). Published results in specialist hands have been impressive.

Arthrodesis and amputation

The quality of bone stock at the distal femur and proximal tibia or the state of the soft tissues (including the extensor mechanism) may preclude an attempt at reimplantation of a functioning knee prosthesis. In these situations the options are external bracing (see above), a fusion or an above-knee amputation. In all series, a proportion of cases progress to these unsatisfactory outcomes and this proportion rises if the revision implant itself becomes infected.[37] Therefore, the risks should be discussed openly with all patients before knee revision surgery is embarked upon.

Suppressive therapy

For a small group of patients, the pursuit of radical cure and the surgery necessary to achieve it is inappropriate. This group includes the medically unfit patient in whom the risk of an anesthetic and an operation is unacceptable, patients with obvious infection (e.g. with sinus tract drainage or early infection) but a pain-free, mechanically sound implant, and patients in whom excision of a prosthesis would lead to an unreconstructable defect. Such cases may be suitable for long-term antibiotic suppression, particularly when infected with organisms that are sensitive to safe and well-tolerated antibiotics. In the majority of cases, revision will eventually be necessary.

Infections of fracture fixations and other orthopedic hardware

These pose related but different problems. Internal fixation devices are designed to stabilize the skeleton until mechanical strength is restored biologically by fracture healing or by the incorporation of bone graft. Infection may impair these processes, leading to nonunion, but mechanical instability also appears to play an important role in this. For the purposes of obtaining union or fusion, a stable but infected fracture (with implant retained) may be preferable to an unstable, uninfected fracture and it is definitely preferable to an unstable, infected fracture. Thus the goal of obtaining radical cure of infection may have to take second place to the need to allow the implant to perform its function (ideally with infection controlled), after which it may be removed and the infection treated definitively.

It follows that the key factor in management is whether or not union or fusion has occurred. Irrespective of the time of presentation, exploration and debridement should be carried out. If the fracture has not united but the implant is mechanically sound, the device can be retained, provided the organisms cultured are sensitive to a suitable antibiotic, the bone at the fracture or fusion site appears viable and soft tissue cover can be obtained. If the implant is loose or substantial amounts of dead bone are present, in which case fracture healing is unlikely, the implant should be removed and stability ensured, preferably with an external fixator. Once multiple samples have been obtained, an empiric antibiotic regimen can be commenced and refined according to results. Infections that are well established before the onset of suppression are liable to relapse once antibiotics are discontinued, whereas cure may sometimes be possible if very early infections are treated promptly. Elective implant removal and final debridement of poor-quality tissue once union has occurred have the advantage that the soft tissues (and the patient) are in an optimal state for the procedure while infection is suppressed. Oral suppression need not be stopped before removal of implants but samples should be sent for microbiology and histology. If organisms are cultured at the time of implant removal, antibiotic treatment as if for an osteomyelitis should be offered. As a minimum, 1 month of therapy should be given, even if the cultures are negative, while bone heals after the debridement. Implant removal is not always essential, though there is little information about late recurrence. This decision is best left to the surgeon and patient, who together must bear the risk of refracture, soft tissue breakdown or perioperative morbidity if the metalware is removed. The nature of the infecting organism is obviously an important factor in the risk-benefit equation. Intravenous therapy with a ß-lactam or glycopeptide, followed by oral therapy with bio-available drugs (depending on sensitivities) such as rifampicin with ciprofloxacin, doxycycline or fusidic acid, are standard regimens.

CONCLUSION

Infections of prosthetic joints and other orthopedic hardware continue to pose considerable challenges to the infectious diseases physician, just as they do to patients and surgeons. There is a pressing need to establish consensus definitions of infection that will allow comparison between separate studies and form a basis for multicenter trials. These can then address the challenge of finding the most cost-effective diagnostic and therapeutic strategies to benefit the relatively small, but hard-pressed group of patients beleaguered by these troublesome conditions.

Chapter 54 - Lyme Disease

Rekha Sivadas
Daniel W Rahn
Benjamin J Luft

HISTORY

Lyme borreliosis is caused by the tick-borne spirochete, *Borrelia burgdorferi* which is distributed throughout the Northern Hemisphere. The cutaneous manifestation, acrodermatitis chronica atrophicans (ACA) was first described in Germany by Buchwald. Afzelius subsequently described erythema migrans (EM) in Sweden. French physicians Garin and Bujadoux reported the first case of a neurologic manifestation, meningoradiculoneuritis.[1] [2] The disease was first treated with antibiotics in 1949 by Thyresson. In 1975, Steere and colleagues delineated the disease in the USA, while Burgdorfer isolated and cultivated the causative agent.[1] [2]

EPIDEMIOLOGY

Lyme disease is the commonest vector-borne disease in the USA [3] and occurs widely throughout Europe and Asia. [4] The infecting organism, *B. burgdorferi*, is maintained in and transmitted by ticks of the *Ixodes ricinus* complex, including *Ixodes scapularis* in north-east and north-central USA, *Ixodes pacificus* on the west coast of the USA, *Ixodes ricinus* in Europe, and *Ixodes persulcatus* in Asia (see Chapter 11).

In Europe, three genomospecies of the *B. burgdorferi* sensu lato complex are pathogenic, including *B. burgdorferi* sensu stricto, *Borrelia garinii*, and *Borrelia afzelii*. *Borrelia burgdoferi* is the only pathogenic species in North America. The relative distribution of these genomospecies from region to region throughout Europe and Asia may account for the relative variability of disease syndromes associated with Lyme disease. Additional borrelial species that have been identified are *Borrelia valaisiana* and *Borrelia lusitaniae*; although the role of the former in promoting human disease is not entirely clear, it has been detected by polymerase chain reaction (PCR) in skin biopsies of a few patients with EM and ACA. However, the organism has not yet been cultured from these lesions. [1] [5] [21]

Lyme disease is increasing in both incidence and recognition. The known endemic range is expanding, but the precise incidence and geographic spread are uncertain due to difficulties in diagnosis and disagreement regarding diagnostic criteria. A National Surveillance Case Definition was adopted in the USA in 1990 to establish uniform diagnostic criteria for surveillance (Table 54.1). Over 90% of cases in the USA have been reported by ten states in the north-east, upper midwest and Pacific coastal regions.[3] Even within these endemic states, the regional distribution is highly variable. The recent upsurge in cases in the USA may be explained by the reforestation of land used for farming a generation ago, creating environments suitable for deer (for *I. scapularis*, at least, deer are important for maintenance of the tick life cycle),[6] and outward migration of residential areas from cities into these rural areas.

Although cases have occurred at all ages, individuals who are active outdoors in spring and summer months are at greatest risk.[7] [8] In north-east and north-central USA, where *I. scapularis* is the primary vector, most cases begin in summer with the occurrence of EM. Those people who do not manifest this marker of disease onset may come to medical attention months later with one or more symptoms of disseminated disease.

The seasonal variation of onset in temperate climatic zones is explained by the ecology of the predominant tick vectors. Among the ixodid tick vectors, the life cycle and feeding habits of *I. scapularis* are best understood (Fig. 54.1 , Fig. 54.2). This tick has a three-stage life cycle (larva, nymph and adult) that spans 2 years. Larvae hatch from fertilized eggs in late spring and feed once for 2 or more days in midsummer. Preferred hosts include a broad range of small mammals. The next spring they molt into nymphs, and feed again for 3 or 4 days, with the same host range. After this second blood meal, the nymphs molt into adults. Adult *I. scapularis* has a narrower host range, with a preference for deer. Mating occurs on deer, and the female deposits her eggs and the cycle begins anew.[9]

In endemic areas, 30% or more of nymphs may be infected with *B. burgdorferi*; the rate of infection in adult ticks may be even higher, but infection rates in unfed larvae are less than 1%,[10] a pattern suggesting that ticks acquire *B. burgdorferi* from a reservoir host in the environment rather than from congenital transmission. The white-footed mouse, *Peromyscus leucopus*, is the primary reservoir host for *I. scapularis*.[11]

An enzootic cycle of infection is maintained through passage of *B. burgdorferi* back and forth between ticks and their hosts. Infected nymphal ticks transmit *B. burgdorferi* to mice, which serve as a reservoir from which uninfected larvae may acquire infecting organisms. In this manner, a high rate of infection can be maintained in the tick population once the organism, ticks, mice and deer are all present in the environment.

The establishment and maintenance of an enzootic cycle requires a competent reservoir host in addition to a tick vector. Variation in vector-host relationships provide the primary explanation for wide regional variation in the rate of infection in the tick population in California,[12] south-east USA[13] and north-east USA.

Lyme disease occurs when an infected tick (most often a nymph) feeds on a susceptible individual and transmits the causative spirochete.[8] As yet unknown factors influence the risk of developing Lyme disease after a bite by an infected tick. In published studies, the risk of developing Lyme disease after a bite by an infected tick has been less than the rate of infection in the tick vectors alone would predict. The low risk of transmission after a known tick bite may relate to the duration of tick attachment before removal.[14] [15] A tick attached for less than 24 hours has a low likelihood of transmitting *B. burgdorferi*.

Other modes of transmission have been postulated including transfusion of infected blood products[16] and biting flies, [17] [18] but evidence strongly favors ixodid ticks as the primary and, most likely, exclusive vector of Lyme disease. Congenital transmission has been reported,[19] [20] but the evidence regarding clinical disease resulting from transplacental transfer is inconclusive.

TABLE 54-1 -- Lyme disease: a summary of the US National Surveillance Case Definition.

LYME DISEASE: US NATIONAL SURVEILLANCE CASE DEFINITION	
Definition	A systemic, tick-borne disease with protean manifestations: dermatologic, rheumatologic, neurologic and cardiac abnormalities. The initial skin lesion, erythema migrans, is the best clinical marker (occurs in 60–80% of patients)
Case definition	1. Erythema migrans present *or*
	2. At least one late manifestation and laboratory confirmation of infection
General definitions	

1. Erythema migrans (EM)	• Skin lesion typically beginning as a red macute/papule and expanding over days or weeks to form a large round lesion, often with partial central clearing
	• A solitary lesion must measure at least 5cm; secondary lesions may also occur
	• An annular erythematous lesion developing within several hours of a tick bite represents a hypersensitivity reaction and does not qualify as erythema migrans
	• The expanding EM lesion is usually accompanied by other acute symptoms, particularly fatigue, fever, headache, mildly stiff neck, arthralgias and myalgias, which are typically intermittent
	• Diagnosis of EM must be made by a physician
	• Laboratory confirmation is recommended for patients with no known exposure
2. Late manifestations These include any of the opposite *when an alternative explanation is not found*	Musculoskeletal system
	• Recurrent, brief attacks (lasting weeks or months) of objective joint swelling in one or a few joints, sometimes followed by chronic arthritis in one or a few joints
	• Manifestations not considered to be criteria for diagnosis include chronic progressive arthritis not preceded by brief attacks, chronic symmetric polyarthritis, or arthralgias, myalgias or fibromyalgia syndromes alone
	Nervous system
	• Lymphocytic meningitis, cranial neuritis, particularly facial palsy (may be bilateral), radiculoneuropathy or, rarely, encephalomyelitis alone or in combination
	• Encephalomyelitis must be confirmed by evidence of antibody production against *Borrelia burgdorferi* in CSF, shown by a higher titer of antibody in the CSF than in serum
	• Headache, fatigue, paresthesia or mildly stiff neck alone are not accepted as criteria for neurologic involvement
	Cardiovascular system
	• Acute-onset, high-grade (2nd or 3rd degree) antrioventricular conduction defects that resolve in days to weeks and are sometimes associated with myocarditis
	• Palpitations, bradycardia, bundle-branch block or myocarditis alone are not accepted as criteria for cardiovascular involvement
3. Exposure	• Exposure to wooded, brushy or grassy areas (potential tick habitats) in an endemic county no more than 30 days before the onset of EM
	• A history of tick bite is not required
4. Endemic county	• A county in which at least two definite cases have been previously acquired or in which a tick vector has been shown to be infected with *B. burgdorferi*
5. Laboratory confirmation	• Isolation of the spirochete from tissue or body fluid *or*
	• Detection of diagnostic levels of IgM or IgG antibodies to the spirochete in the serum or the CSF *or*
	• Detection of an important change in antibody levels in paired acute and convalescent serum samples
	• States may separately determine the criteria for laboratory confirmation and diagnostic levels of antibody
	• Syphilis and other known biologic causes of false-positive serologic test results should be excluded, when laboratory confirmation is based on serologic testing alone

CLINICAL FEATURES

Although the most recognizable feature of Lyme disease is the skin condition EM, it is a complex systemic illness with protean clinical manifestations. Like syphilis, Lyme borreliosis is a 'great imitator'; its symptoms range from cutaneous to musculoskeletal, cardiac to neurologic. It is interesting to note the differences in manifestations between North American and European disease arising from the endemicity of particular genomospecies in those regions.[5] Variations in disease presentation within regions of Europe and Asia may be attributed to local endemicity of disease vectors (ticks) and reservoirs (deer, rodents) harboring specific borrelial genomospecies.[2] Just as these genomospecies produce a wide range of clinical manifestations, they also induce differing immunologic responses, rendering clinical and serologic diagnosis a formidable challenge. [21] Reported seropositivity depends upon the borrelial strain employed as antigen. Further confounding this diagnostic dilemma is the issue of coinfection with other tick-borne illnesses (i.e. ehrlichiosis and babesiosis).

Lyme disease, human granulocyte ehrlichiosis, and babesiosis not only share a common tick vector (*I. scapularis*), but may also be difficult to clinically distinguish due to overlap of clinical features. [22] However, despite similarities in presentation, each illness tends to influence and alter the natural course of the other. Therefore, recognition of the state of co-infection is crucial to guide choice of antibiotic therapy.

Localized early disease

Lyme disease begins with the appearance of a characteristic skin lesion, EM, at the site of a tick bite. (Fig. 54.3 Fig. 54.4 Fig. 54.5 Fig. 54.6). In approximately one-third of cases, however, this skin lesion is missed or absent and patients present with symptoms of disseminated disease.

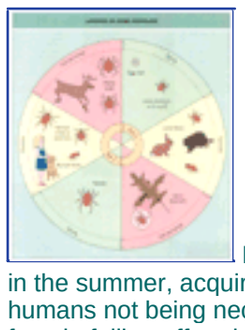

Figure 54-1 Life cycle of *Ixodes scapularis* (also known as *Ixodes dammini*). The life cycle spans 2 years. Eggs hatch in the spring; six-legged larvae develop and feed once in the summer, acquiring *Borrelia burgdorferi* from their preferred host, the white-footed mouse. Next spring, the larvae molt into eight-legged nymphs, which feed once; mice are the preferred host, humans not being necessary for the ticks' life cycle. The nymphs molt into adult male and female ticks; mating often occurs while the female feeds on a deer, and the male may remain on the deer, the female falling off and then laying eggs. Adapted, with permission, from an illustration by Nancy Lou Makris in Rahn and Malawista.[30]

Figure 54-2 *Ixodes scapularis.* Larva, nymph, adult male and adult female. *Courtesy of Pfizer Central Research.*

The interval between tick bite and appearance of EM varies from a few days to a month (median 7 days). The lesion begins as an erythematous papule and expands over several days to achieve a median diameter of 15cm; favored sites are the groin, buttock, popliteal fossa and axilla.

The lesions of EM are generally annular with a sharply demarcated outer border and an erythematous or bluish hue. They are warm to the touch, flat and minimally or non-tender. Lesions may show partial central clearing, but may also be indurated or even necrotic. This cutaneous lesion is the best clinical marker of Lyme disease.[8]

An annular erythema following a tick bite is insufficient evidence for a definitive diagnosis of Lyme disease, however, especially in nonendemic areas.

Early disseminated disease

Within several days of the appearance of EM, many patients develop evidence of dissemination of their infection by the appearance of prominent systemic symptoms, the occurrence of multiple secondary skin lesions, or both. Malaise, fatigue, lethargy, headache, fever and chills, arthralgia and myalgia are particularly common, each occurring in one-half or more of patients. Symptoms may fluctuate rapidly

Figure 54-4 Erythema migrans. A lesion with variation in color and a target-like appearance. The bite site is visible in the center. *Courtesy of Dr Steven Luger, Old Lyme, Connecticut, USA.*

Figure 54-5 Erythema migrans. A lesion with a dusky center, a common variant. *Courtesy of Dr Steven Luger.*

and vary from a flu-like syndrome to a meningitis-like illness from day to day.

Secondary skin lesions may occur anywhere on the body and resemble primary lesions but are usually smaller, show less expansion with time and lack indurated centers. These manifestations of early disseminated infection appear to be more common in the USA than in Europe and may reflect biologic differences in infecting organisms. Erythema migrans, secondary skin lesions and associated symptoms resolve, even without antibiotic therapy, a median of

Figure 54-6 Multiple erythema migrans lesions. Lateral (a) and posterior (b) views of the same patient with multiple erythematous macules of EM. Secondary lesions result from hematogenous spread. They may occur anywhere in the body. Secondary lesions are usually of uniform color and lack in duration. *Courtesy of Dr Steven Luger, Old Lyme, Connecticut, USA.*

28 days after onset, but recurrent crops of evanescent lesions may occur, and fatigue, intermittent musculoskeletal pain and headaches may persist for months.

Disseminated disease

After resolution of the signs and symptoms of early disease, some patients (20% in one series)[23] experience a long-lasting spontaneous remission, which may reflect cure. Most, however, subsequently develop other disease manifestations, with predominant involvement of the heart, nervous system and joints, although case reports have described involvement of multiple organs, including the liver,[24] subcutaneous tissue,[25] muscle,[26] eye structures[27] and spleen.[28] More than one organ system may be (and often is) affected simultaneously or sequentially in an individual patient.

Carditis

Fewer than 10% of patients with untreated early Lyme disease develop carditis, generally a few weeks to a few months after EM.[29] However, palpitations from an arrhythmia or unexplained syncope from high-degree atrioventricular block may be the presenting manifestation of Lyme disease.[30] The primary clinical manifestation of Lyme carditis is heart block, which may fluctuate from first-degree to

complete heart block over minutes to hours and generally resolves spontaneously in a few weeks or sooner, even in untreated patients.[31] Although temporary pacing is frequently required, permanent pacing is rarely needed. [30]

Much less commonly, congestive heart failure has been linked to Lyme disease. A case report suggested that Lyme carditis might be a cause of chronic dilated cardiomyopathy.[32] Endomyocardial biopsy and electrophysiologic testing have revealed direct spirochetal invasion of cardiac muscle and widespread abnormalities of cardiac conduction.[33]

Neurologic manifestations

Neurologic abnormalities were recognized as being associated with ixodid tick bites and EM in Europe many years before the initial description of Lyme disease in the USA.[7] [34] In the early series of Lyme disease cases described in the USA, frank neurologic abnormalities, including cranial neuropathy (particularly Bell's palsy), meningitis, radiculoneuropathy, myelopathy and encephalopathy, occurred in 15% of patients. Neurologic symptoms generally began a few weeks after EM (median 4 weeks), although some patients presented with neurologic manifestations alone.[8] [35]

Subtle neurologic complaints without objective deficits (headache, irritability, paresthesias, photophobia and lethargy) may accompany early disease dissemination and represent the mildest end of the spectrum of neurologic Lyme disease. Multiple neurologic abnormalities may coexist or occur sequentially. Peripheral nerve abnormalities may involve sensory and motor nerve roots, plexi and motor and sensory nerve fibers.[36] [37] [38] Meningitis and radiculoneuropathy often wax and wane for weeks to months but ultimately resolve spontaneously.

Borrelia burgdorferi has been isolated from the cerebrospinal fluid (CSF) of a patient whose only complaint was tinnitus,[39] and has been demonstrated by PCR in

patients with symptoms limited to headache, Bell's palsy or paresthesias, indicating that the symptoms associated with central nervous system (CNS) infection may be minimal. [40] The emergence of subtle neurologic manifestations years after onset of Lyme disease also supports the possibility of latent persistent infection in the CNS (see Late neurologic syndromes, below).

Rarely, cases of demyelinating encephalopathy mimicking multiple sclerosis have been reported.[41] [42]

Arthritis

Most people who have untreated Lyme disease develop arthritis. Brief, intermittent attacks of migratory musculoskeletal pain commonly begin while EM is present and may persist for months before the appearance of overt arthritis. Frank arthritis occurs in 60% of patients in the USA, at a median of 6 months after EM, but, as with other symptoms of disseminated disease, arthritis may be the presenting manifestation of Lyme disease.[43] Although the clinical expression varies, patients most often experience brief recurrent attacks of monoarticular or oligoarticular inflammatory arthritis involving large joints, particularly the knee.[23] [44] [45] Effusions may be massive (100ml or more), causing popliteal cysts, which may rupture and result in a pseudothrombophlebitis syndrome.

Attacks last a few days to a few weeks and over time (months to years) decrease in severity, frequency and duration.[23] Arthritis has been reported to be milder in children than in adults.[46] [47] Polyarthritis is decidedly uncommon. Synovitis becomes chronic in 20% of cases (see Chronic arthritis, below).

Late (persistent) disease

After the disseminated stage of Lyme disease during which multi-organ involvement occurs and symptoms are often changing and self-limited, inflammation may become chronic and persistent in some tissues. This has been been called 'late Lyme disease'. Late Lyme disease may involve the CNS, the joints and (particularly in Europe) the skin. Information is still emerging on this patient group. It is as yet unclear whether the clinical manifestations of late Lyme disease result from persistent infection in all cases.

Late neurologic syndromes

In Europe, radiculoneuritis is the predominant neurologic manifestation of *B. burgdorferi* infections in adults (as compared to the frequent occurrence of meningitis in children).[2]

Other reported CNS abnormalities include lymphocytic meningitis, peripheral neuropathy and cranial neuritis, collectively known as Garin-Bujadoux-Bannwarth (MPN-GBB) or Bannwarth's syndrome.[48] Garin and Bujadoux presented the first clinical description of such a disorder in 1922, 60 years before the disease itself became known as Lyme borreliosis.[2] Bannwarth's series of 26 patients in 1941 and 1944 with this constellation of findings led to the discovery of the link between this clinical entity and tick bite/EM.[2] Pfister and colleagues found that 73% of patients studied had a preceding arthropod bite or EM and that 73% developed radicular pain within the dermatomal distribution of the known area of an arthropod bite or EM.[48]

Both a mild, predominantly sensory, peripheral neuropathy and subtle encephalopathy may occur months to years after the onset of Lyme disease. [38] [49] [50] The diagnosis of encephalopathy hinges on the presence of cognitive deficits involving primarily short-term memory and concentration. Chronic fatigue, headaches and sleep disturbance may accompany these abnormalities, but these are not sufficient, without a documented neurologic deficit, to support the diagnosis of neurologic Lyme disease. Rarely, severe encephalomyelopathy has occurred with impairment of higher cortical function, seizures and spinal cord lesions.

Chronic neuropathy in patients with ACA has been described. The most common manifestations include peripheral neuropathy with sensory deficits in a patchy distribution.[51]

Chronic arthritis

Arthritis becomes chronic in 20% of patients who have untreated Lyme disease, resulting in a syndrome that is clinically indistinguishable from other forms of monoarticular or oligoarticular inflammatory arthritis. However, chronic Lyme arthritis is preceded by recurrent brief attacks of joint inflammation in most cases. The knee is by far the most commonly affected joint. Immunogenetic factors, particularly human leukocyte antigens (HLA-DR2 and DR4), may predict which people are at highest risk of developing chronic Lyme arthritis.[52] Even chronic Lyme arthritis may eventually remit spontaneously. Only a minority of patients develop radiographic evidence of erosions of cartilage or bone.[53] There have been no unequivocal cases of symmetric, peripheral, polyarticular, inflammatory arthritis with joint destruction resulting from Lyme disease. Differentiation from rheumatoid arthritis is rarely a problem.

Chronic skin involvement

Chronic skin involvement (acrodermatitis chronicum atrophicans) as a late manifestation of Lyme disease occurs primarily in Europe.[54] It usually occurs on the acral portion of an extremity and is characterized by violaceous discoloration and swelling of involved skin, often at a site where EM occurred years earlier. The lesion eventually becomes atrophic (Fig. 54.7). Other clinical manifestations include fibrotic nodules, ulnar bands, sensory disturbances, muscular weakness, myalgias, arthalgias and tenderness on impact over bony prominences.[51] In a study of 50 consecutive patients with ACM in Sweden, elevated antispirochetal antibody titers were found at indirect immunofluorescence and enzyme-linked immunosorbent assay (ELISA), and histologic biopsies demonstrated dermal lymphocytic infiltrates with plasma cells and telangiectasia.[51] Acrodermatitis

Figure 54-7 Acrodermatitis chronicum atrophicans. Typical inflammatory bluish-red lesions of acrodermatitis chronicum atrophicans. Lesions usually occur on acral portions of extremities. *Courtesy of Dr Eva Asbrink.*

chronica atrophicans is thought to result from local persistence of *B. burgdorferi*, which has been isolated from a lesion 10 years after onset. [55] Lichen sclerosis et atrophicus or morphea-like lesions have also been described.[54]

INVESTIGATIONS

It is often difficult to diagnose Lyme disease definitively because of the variation in clinical presentation and course, and because of the limitations of currently available diagnostic assays. The National Surveillance Case Definition of Lyme disease developed in the USA (see Table 54.1) requires either the presence of EM or a definite late manifestation of Lyme disease combined with laboratory confirmation of infection in a person who has had opportunity to be exposed to the causative agent. Definitive laboratory confirmation requires isolation of the causative organism from clinically involved tissue, but this is rarely achievable in clinical practice. Demonstration of specific serologic immune responsiveness against *B. burgdorferi* has been accepted as a substitute for bacteriologic isolation. Because the sensitivity and specificity of many tests has been poor,[56] [57] [58] Western blot confirmation of all positive and equivocal results is recommended.[59] The key to diagnosing Lyme disease rests with recognition of the characteristic clinical features of the illness. Laboratory testing should only be used for confirmation.

The laboratory abnormalities associated with early Lyme disease reflect the inflammatory nature of the illness. When the infection is localized to a single skin lesion, blood tests are typically normal. As the infection spreads, with development of systemic symptoms and secondary skin lesions, there may be a mild leukocytosis, anemia, elevation in the erythrocyte sedimentation rate, microscopic hematuria, elevation in liver enzymes and elevation in total serum IgM (which mirrors the specific IgM immune response).[8] These abnormalities resolve spontaneously when this phase of illness remits.

Subsequent localization of inflammation to specific target organs results in abnormalities of organ-specific tests. Patients who have carditis have fluctuating atrioventricular block and occasionally more generalized repolarization abnormalities, including ST-segment and T-wave changes on electrocardiography.[31] If carditis affects ventricular performance, the chest radiograph may reveal cardiomegaly, and cardiac ultrasonography and radionuclide ventriculography may reveal impaired

ventricular performance.

The laboratory hallmark of Lyme meningitis is a lymphocytic pleocytosis (generally a few to a few hundred cells)[37] in the CSF; the CSF protein may be elevated and, in protracted cases, the ratio of IgG to albumin may be elevated and oligoclonal bands may be present, reflecting the immunologic component of the inflammatory process within the CNS.[38]

Attacks of arthritis result in the accumulation of inflammatory joint fluid containing a few hundred to 50,000 white blood cells, mostly polymorphonuclear, elevation in protein and normal glucose.[45] Radiographs of affected joints most often show only soft tissue swelling, but when joint inflammation has persisted for many months, there may be pannus formation and erosions of underlying cartilage and bone.[53] Some patients develop enthesopathy with calcifications of tendon and ligament attachment sites.

Cognitive deficits associated with late neurologic involvement may be quantified by neuropsychologic testing, a very helpful modality in the formal assessment of cognitive complaints.[49] [50] A depressive overlay is often present, but findings should also reveal an organic encephalopathy primarily affecting short-term memory. Peripheral neuropathy and radiculoneuropathy cause abnormalities on electromyography and, less often, abnormalities of peripheral nerve conduction;[38] [50] sensory fibers are more frequently affected than motor fibers. Although these findings on tests of CNS and peripheral nervous system function are not specific for Lyme disease, abnormal findings indicate a definite disorder of the nervous system, and the combination of central and peripheral nerve abnormalities characteristic of Lyme disease is uncommon in other diseases.

Specific laboratory confirmation may be sought through either direct or indirect means. Efforts at direct confirmation have included culture of affected tissue, employing PCR on skin, urine, joint fluid, blood or CSF to amplify specific gene sequences unique to *B. burgdorferi*, and antigen testing of urine.[60] Although the causative organism has been cultured from affected skin,[55] [61] [62] blood, [63] [64] CSF[39] [61] and joint fluid,[65] the rarity with which it has been isolated limits the usefulness of culture. Polymerase chain reaction has been validated as a means of identifying the presence of *B. burgdorferi* both in vitro[66] and in tick vectors[67] using a variety of primers. Work on human tissues and fluids is in progress,[68] [69] [70] [71] [72] but PCR cannot be considered a routine diagnostic test for Lyme disease at present.

Detection of a specific immune response to *B. burgdorferi* remains the best means of confirming the diagnosis of Lyme disease. The first immune response in Lyme disease is mediated by T cells and is directed against a variety of epitopes.[73] [74] This T-cell response subsequently localizes preferentially to involved tissues. [73] [75] Unfortunately, tests to measure this response are not standardized, are technically demanding, require live cells and have varied in sensitivity and specificity.[76] For these reasons, measurement of the T-cell response cannot be recommended routinely for diagnosis.

The serologic response to *B. burgdorferi* has been well characterized (Fig. 54.8).[61] [77] Specific IgM antibody, directed initially primarily against the flagellae of the organism, is detectable a few weeks after disease onset. The response broadens to include additional antigens over time and peaks by 3–6 weeks. Generally IgM antibody falls to within the normal range by 6 months, but occasionally it may remain elevated for much longer. Specific IgG antibody is detectable a few weeks after IgM, but it may not peak until many months after disease onset. The IgG response is also initially directed primarily against flagellin and broadens with time to include an array of antigens on the outer surface of the organism.

Both immunofluorescence (IFA) and ELISA have been used to detect this antibody response; in general, ELISA is preferable because of better sensitivity, objectivity and reproducibility and because of its adaptability to automated systems. Serology results may be falsely positive or negative for various reasons, so the diagnosis of Lyme disease cannot be made by serologic test results alone. Immunofluorescence and ELISA may yield false-positive results

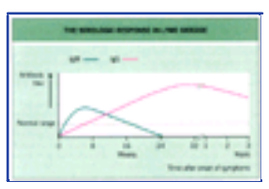

Figure 54-8 The usual serologic response in Lyme disease. Specific IgM becomes detectable 1–2 weeks after symptom onset and the appearance of erythema migrans. The later appearance of IgG is frequently concurrent with systemic manifestations. IgG is nearly always elevated with late disease. Typically, and even in untreated patients, IgM falls over 4–6 months; persistence for longer than this predicts later manifestations.

because of epitopes in the test antigen preparations that cross-react with other bacteria.[58] False-positive results may also occur in conditions associated with polyclonal B-cell activation. Specificity is increased by a two-step approach in which all positive or equivocal results are confirmed by Western immunoblotting. This two-step approach was recommended by participants in a national conference on serologic diagnosis of Lyme disease held in 1994 under the sponsorship of the Centers for Disease Control and Prevention.[59] A true positive ELISA is associated with immunoreactivity against polypeptides specific for *B. burgdorferi*, reactivity that is absent in the various conditions associated with false-positive ELISA results. The currently recommended criteria for a positive Western blot are given in Table 54.2 .

One special circumstance deserves mention. Antibiotic therapy administered early in the course of Lyme disease may result in a negative serology by curing the infection and eliminating antigen before systemic immune challenge. [78] One series indicated, however, that infection may persist after early antibiotic therapy despite persistently negative serologies. [74]

TABLE 54-2 -- Western blot criteria.

WESTERN BLOT CRITERIA
• All serum specimens found to be positive or equivocal by a sensitive enzyme immunoassay or immunofluorescent assay should be tested by a standardized Western blot procedure
• When Western immunoblot is used in the first 4 weeks of illness, both IgM and IgG procedures should be performed
• After the first 4 weeks of illness, IgG alone should be performed
• An IgM blot is considered positive if two of the following three bands are present: 24kDa (OspC), 39kDa (BmpA) and 41kDa (Fla)
• An IgG blot is considered positive if five of the following 10 bands are present: 18, 21 (OspC), 28, 30, 39 (BmpA), 41 (Fla), 45, 58, 66 and 93kDa
Recommendations of the Second National Conference on Serologic Diagnosis of Lyme Disease sponsored by the Centers for Disease Control and Prevention, the Association of State and Territorial Public Health Laboratory Directors and the Michigan Department of Health
Centers for Disease Control and Prevention Working Group recommendations for Western blot positivity. Osp, outer surface protein; Fla, flagella.

In a study of 17 patients with acute Lyme disease who received prompt treatment with oral antibiotics and subsequently developed 'chronic' illness, it was shown that none of them had diagnostic levels of antibodies to *B. burgdorferi* on either a standard ELISA or IFA.[74] On Western blot analysis, the level of immunoglobulin reactivity against *B. burgdorferi* was no greater than that of normal controls. These patients had a vigorous T-cell proliferative response to whole *B. burgdorferi* at levels similar to that of 18 patients with chronic Lyme disease with detectable antibodies. The T-cell response of both groups was greater than that of a control group. The investigators concluded that the presence of chronic Lyme disease cannot be excluded by the absence of antibodies against *B. burgdorferi* and that a specific T-cell response to *B. burgdorferi* is evidence of infection in seronegative patients with suggestive clinical parameters. [74]

This apparent dissociation between T-cell and B-cell immune responses may be attributed to the administration of antibiotics for ECM and therefore, the presence of low or undetectable levels of antiborrelia antibodies. Antibiotic therapy may have resulted in the elimination of most spirochetes at a critical early stage of the immune response, thereby hindering the development of a sustained B-cell response. [74] Persistent disease activity may result from harboring of *B. burgdorferi* in sites such as the CNS, which may not receive adequate concentrations of antibiotics to reach the minimum inhibitory concentrations (MICs) required against the majority of strains of *B. burgdorferi*. In support of this observation is the discovery of local production of antiborrelia antibody in the CNS in those suffering from neurologic symptoms of Lyme borreliosis in the absence of diagnostic serum antibodies levels. [79] [80] [81]

The concept of antigenic variation displayed by other borrelial species may represent an alternative explanation for the apparent absence of a specific antibody response in seronegative Lyme disease.[82] Classically, immunodominant 'variable major proteins' are replaced periodically by variant forms, enabling the organism to elude the host's antibody. Although *B. burgdorferi* does not precisely exhibit antigenic variation, antigenic diversity has been noted among strains found in humans,

animals, and ticks. These differences in strains must induce significant changes in antigenic profile to engender nonreactive Western blot assays.[82]

Although it may be challenging to diagnose definitively, Lyme disease is treatable with prompt and appropriate antibiotic therapy. Presently, chronic Lyme disease is a frequently used diagnosis, usually applied to patients with a constellation of symptoms including fatigue, arthralgias, aches, pains, memory disturbances, and impairment in concentration. Patients with persistent disease unresponsive to antibiotics have further compounded this clinical dilemma, creating anxiety and promoting phobias regarding the stigma of 'chronic' or lifelong disease. There is a lack of scientific medical literature to support the following misconceptions:

- antibiotics are often not curative in Lyme disease;
- long-term antibiotic therapy is always required;
- serologic tests are inaccurate yielding false-negative results; and
- the prognosis for patients who have Lyme disease is often poor.

To achieve an accurate diagnosis, one must elicit a history of EM with suggestive clinical features and ascertain a probable exposure in an endemic area. Serologic assays interpreted under these circumstances remain the best screening methods for exposure followed by confirmation with immunoblotting techniques. A lack of response to antibiotic therapy in presumed Lyme disease is most likely due to incorrect diagnosis, thereby warranting a continued search for the cause of illness.

These limitations notwithstanding, the greatest problem with serologic testing for Lyme disease results from interlaboratory variation. Standardization of procedures and performance as recommended by the Centers for Disease Control and Prevention is essential before

serologic response can be used reliably as a screening tool for Lyme disease. At best, serologic testing can only indicate immunologic exposure, not ongoing infection.

Measurement of immunoreactivity in CSF is a useful adjunct in the diagnosis of CNS Lyme disease.[83] [84] To have diagnostic value, a CSF index should be calculated comparing the ratios of specific antibody to total immunoglobulin in CSF and serum. A specific antibody response in CSF is not found uniformly in cases meeting other clinical criteria for CNS Lyme disease in the USA, but it is helpful if positive.

Until more specific serologic tests based on recombinant antigens are developed,[85] culture techniques are improved, or tests based on the PCR or antigen detection are available routinely, caution must be exercised in the use of diagnostic tests for Lyme disease. Serologic testing should be ordered only when the diagnosis is suspected from suggestive clinical data; in this circumstance, a positive serology and Western blot performed in a laboratory with high performance standards should be considered confirmatory of the diagnosis. As a corollary, a negative result should lead to serious doubt of the diagnosis. If testing is ordered indiscriminantly, many false-positive results must be expected, thus diminishing the predictive value of a positive test.

DIFFERENTIAL DIAGNOSIS

Erythema migrans is the classic skin lesion of Lyme disease and, in its typical appearance, can be confused with little else. However, atypical presentations may lead to confusion.[86] Not all annular erythemas associated with tick bites are indicative of Lyme disease, so particular caution must be exercised in nonendemic areas.[87] [88]

Lesions with indurated centers may be confused with cellulitis, and those with necrotic centers may look like spider bites, but EM lesions are generally minimally tender or nontender. Secondary skin lesions may be confused with erythema multiforme, but mucosal lesions do not occur and palms and soles are generally spared in Lyme disease. Secondary skin lesions may also have an urticarial appearance. The lesions of EM are generally nonpruritic, however, and other features of disseminated early Lyme disease aid in distinguishing it from a generalized allergic reaction or a systemic condition associated with generalized urticaria, such as the prodromal phase of hepatitis B.

An EM-like illness has recently been described in Missouri and North Carolina. The skin lesions in this illness are always single and are associated with *Amblyomma americanum*, a tick not known to transmit Lyme disease. Patients do not develop immunoreactivity against *B. burgdorferi*, and skin biopsy specimens have been negative for *B. burgdorferi* in culture and by PCR.[87] [88] The importance of this syndrome is that it demonstrates that EM-like skin lesions alone occurring in a patient in a nonendemic region are not sufficient to support a diagnosis of Lyme disease.

In later stages, Lyme disease may mimic a variety of cardiac, neurologic and arthritic disorders. Carditis can be confused with subacute bacterial endocarditis or acute rheumatic fever, but valvular lesions do not occur in Lyme disease. Blood cultures are negative.

The most helpful diagnostic feature of neurologic Lyme disease is the frequent simultaneous or sequential involvement of multiple levels of the CNS and peripheral nervous system. Bell's palsy caused by Lyme disease is indistinguishable from idiopathic Bell's palsy, but Lyme disease is one of very few causes of bilateral Bell's palsy (a helpful clue if present) and, by this stage of disease, patients are typically seropositive. Lyme meningitis presents a clinical picture similar to that of viral meningitis, but there is often an antecedent history of EM, the course is more protracted and Lyme meningitis is characterized by relapses and remissions. The peripheral neuropathy associated with chronic neurologic Lyme disease mimics other predominantly sensory neuropathies; a history of previous non-neurologic involvement is usually present, however. The rare patients who have demyelinating encephalopathy must be distinguished from patients who have multiple sclerosis; positive serology (particularly if present in CSF) combined with an exposure history is very helpful in this rare circumstance.

The typical patient with Lyme arthritis who has monoarticular inflammatory arthritis of a knee has a clinical appearance similar to that of reactive arthritis or septic arthritis. At initial presentation, bacterial infection must always be excluded. The pattern of brief, recurrent attacks is more common in Lyme disease than in either reactive or septic arthritis. Furthermore, patients who have Lyme arthritis are virtually always seropositive.

Patients who have chronic fatigue and non-specific symptoms (headaches, musculoskeletal pain, back pain, sleep disturbance and mood swings) have often been presumptively diagnosed as having Lyme disease with little or no substantiation of this diagnosis. The diagnosis of Lyme disease should not be made on the basis of non-specific complaints unsubstantiated by either objective neurologic deficits or inflammation of joints in a pattern known to be due to this illness, particularly if serologic confirmation is lacking. It is particularly important to differentiate fibromyalgia from chronic Lyme disease because the prognosis and response to therapy are quite different.[89]

PATHOGENESIS AND PATHOLOGY

Borrelia burgdorferi has been unequivocally established as being the cause of Lyme disease. Clinical isolates differ in their outer surface protein expression[90] [91] and genetic composition.[92] Three different genospecies have been described: *B. burgdorferi* itself, *B. garinii* and *B. afzelii*. All three genospecies have been isolated from patients who have Lyme disease and from ticks of the *I. ricinus* complex. There is some evidence that disease expression in humans may vary depending upon the genospecies of the infecting organism, but this is preliminary at present.

Unlike *Treponema pallidum*, *B. burgdorferi* can be grown in culture although a specialized medium is required. [61] [93] Serial passage in culture alters surface protein expression with loss of pathogenicity in mice,[92] but the specific factors conferring pathogenicity have not yet been identified. *Borrelia burgdorferi* can penetrate endothelial monolayers and survive intracellularly in cultured fibroblasts. [94] The implications for human infection of this intracellular persistence in vitro are unclear. Work in progress is providing insight into the mechanisms enabling the organism to cause persistent infection in humans despite a vigorous immune response.

Borrelia burgdorferi has been recovered from tissues or fluids of patients who have Lyme disease. It is most readily isolated by biopsy and culture of EM lesions,[62] but this is rarely indicated clinically. Later in the disease, organisms are scant in histologic sections[95] and have been recovered by culture only in research settings.

Borrelia burgdorferi is transmitted to the skin of the host by an infected tick. The organism may evade eradication through an initially delayed and ineffective immune response. It disseminates preferentially to certain target organs where it engenders an immunologically mediated inflammatory response, with tissue injury occurring as a result of the inflammatory response. Why this lesion becomes persistent in some people and whether live organisms persist in all cases of chronic disease remain to be elucidated.

An important question is how *B. burgdorferi* avoids destruction in the presence of the vigorous specific T- and B-cell responses that are

usually apparent within a few weeks of onset of disease. In humans, the early immune response is directed primarily against a flagellar antigen. Vaccine studies in mice have shown that specific antibodies against this antigen do not protect against subsequent infection. Vaccination with outer surface protein (Osp) A, an immunodominant surface antigen, to which antibodies appear much later in human disease, is protective.[96] It may be that, in human Lyme disease, *B. burgdorferi* is able to establish infection because of an ineffective initial immune response focused primarily against flagellae. Later, when the immune response broadens, infection may already be established and disease may be perpetuated through other mechanisms.

Immunogenetic studies have suggested that HLA-DR4 predisposes to the development of chronic Lyme arthritis and that DR4 is associated with a lack of response to antibiotics.[52] Patients who are HLA-DR4 positive and who have treatment-resistant Lyme arthritis have also been shown to have a strong immune response to an epitope on OspA that cross-reacts with human lymphocyte function antigen-1 (LFA-1), which may serve as an autoantigen.[97] This evidence suggests a possible autoimmune mechanism for chronic Lyme arthritis through a mechanism involving molecular mimicry between OspA and LFA-1 in HLA-DR4 positive individuals. No predictors of chronic neurologic disease have been described as yet.

A third potential mechanism through which organisms may evade antibiotic and immune-mediated destruction is by entering human cells.[94]

Histologic studies of affected tissues have provided evidence for immunologically mediated inflammation. Stains of EM lesions reveal a perivascular mononuclear infiltrate and fibrin deposition in the dermis, without epidermal changes except at the site of the bite.[43] Endomyocardial biopsies have revealed similar changes in the heart, with a focal perivascular infiltrate of mononuclear cells and fibrin deposition in both the endocardium and myocardium. [101] Biopsies of affected nerves, although few in number, have shown inflammatory infiltrates around endoneurial and perineurial vessels without vessel necrosis.[98] Both myelinated and unmyelinated fibers may be affected. Hematoxylin and eosin stains of synovium from arthritic joints have revealed synovial lining cell hyperplasia and hypertrophy, vascular proliferation and lymphocytic infiltration of the subsynovial areas. The intensity of the infiltrate varies, and fibrin deposition may be pronounced. Aggregates of T and B cells, often with lymphoid follicle formation, are common and may be concentrated in perivascular areas with obliteration of vessels but without vessel necrosis.[95] Levels of interleukin-1,[99] prostaglandin E_2 and collagenase[100] in joint fluid are elevated, similar to the situation in rheumatoid arthritis.

Spirochetes have been visualized in skin lesions,[61] heart tissue[32] [33] [101] and synovium,[95] but not in peripheral nerves, where it has been postulated that an autoimmune mechanism accounts for the inflammatory lesions.[102]

MANAGEMENT

The primary goals of therapy for Lyme disease are the control of inflammation and the eradication of the infection. Lyme disease is most responsive to antibiotic therapy early in the course of the disease. As with syphilis, some later disease manifestations do not seem to improve after administration of antibiotics.

Treatment regimens are based in part on data from controlled clinical trials and in part on clinical experience.[103] In-vitro antibiotic sensitivity testing does not reliably predict clinical response. Loose criteria for diagnosis accepted without critical review have led to widespread antibiotic use for presumptive Lyme disease in patients who almost certainly have other explanations for their symptoms. In one report, the leading reason for failure to respond to antibiotic therapy for Lyme disease was incorrect diagnosis.[104] In addition, the appropriate end-point of antibiotic therapy is often not clear because of the difficulty of proving when the infection has been eradicated and because of the common persistence of symptoms long after treatment. Current treatment recommendations (Table 54.3) represent a distillation of available evidence and will no doubt be refined in time.

Early localized or early disseminated disease

If antibiotic therapy is initiated early in the course of Lyme disease, EM typically resolves promptly and later stage disease is prevented.[105] [106] Early localized infection, limited to a single skin lesion, with mild or no systemic symptoms, is uniformly responsive to short-course oral antibiotic therapy with a number of agents. Of the antibiotics studied to date, amoxicillin (500mg q8h), doxycycline (100mg q12h) or cefuroxime axetil (500mg q12h) have been the most effective for this stage of disease.[107] [108] Although the optimal duration of therapy is unknown, most clinicians currently recommend 2–3 weeks for both early localized and early disseminated disease.

The appearance of systemic symptoms (fever, arthralgias, fatigue) and secondary skin lesions reflects dissemination of the organism beyond the site of inoculation. As long as no neurologic symptoms are present, 3 weeks of oral therapy is sufficient for this group of patients as well. In a recent study, 10% of patients with a single EM lesion and no systemic symptoms had a positive PCR on blood. This was interpreted as demonstrating that clinically silent blood-stream invasion may be relatively common early in the course of infection.[70]

Some experts have recommended the addition of probenecid to amoxicillin, but this combination has been associated with a relatively high frequency of rashes and is not known to be superior to amoxicillin alone. The pediatric dose range of amoxicillin is 30–40mg/kg per day in three divided doses. Herxheimer-like reactions, with intensification of fever and arthralgias, may occur shortly after initiation of therapy. If possible, doxycycline should be avoided in children under the age of 9 years and during pregnancy because of the possibility of staining of the teeth. Tetracyclines must be used with caution during summer in all patients because they may predispose the patient to sun-sensitive rashes or severe sunburn. Penicillin-allergic young children can be treated with cefuroxime or erythromycin, but results with macrolide antibiotics have been less satisfactory than those with penicillin, amoxicillin or tetracyclines.[105] Azithromycin has been studied systematically and found to be less effective than amoxicillin.[108]

Regardless of which agent is chosen, some patients experience a delayed resolution of systemic symptoms (headache, musculoskeletal pain, fatigue), which may persist as long as 3 months after completion of therapy. These symptoms usually resolve spontaneously and do not indicate continued infection requiring further antibiotic therapy.[106] A seemingly self-perpetuating fibromyalgia syndrome may develop as a sequel of Lyme disease; this too is unresponsive to antibiotic therapy.[109] The likelihood of delayed resolution of symptoms is greatest in patients who have prominent systemic symptoms or a delay in diagnosis before institution of antibiotics.[105]

Disseminated disease

With the possible exception of arthritis, which usually responds to oral therapy (see Arthritis, below), disseminated infection with target organ involvement other than skin should generally be treated with intravenous antibiotics. Carditis, meningitis, cranial neuropathy and radiculoneuropathy, and arthritis are discussed separately.

TABLE 54-3 -- Suggested antibiotic regimens for Lyme disease.

SUGGESTED ANTIBIOTIC REGIMENS FOR LYME DISEASE	
Early disease	• Doxycycline, 100mg po, q12h for 21 days, or
	• Amoxicillin (with or without probenecid) 500mg, q8h for 21 days, or
	• Erythromycin, 250–500mg po, q6h for 21 days, or
	• Azithromycin 500mg daily for 7 days, or
	• Cefuroxime axetil, 500mg po, q12h for 21 days
	Shorter courses (14 days) may suffice for localized early disease.
	Erythromycin and azithromycin less effective than other choices

Lyme arthritis	Initial treatment:
	• Doxycyline, 100mg po, q12h for 30 days, or
	• Amoxicillin and probenecid, 500mg each po, q6h for 30 days
	If initial treatment fails:
	• Penicillin G, 20 × 10^6 IU iv, daily in divided doses for 14 days, or
	• Ceftriaxone sodium, 2g iv, daily for 14 days
Neurologic manifestations	For facial nerve paralysis alone:
	• Doxycycline, 100mg po, q12h for 21–30 days, or
	• Amoxicillin, 500mg po, q8h for 21–30 days
Additional signs (e.g. Lyme meningitis, radiculopathy, encephalitis)	• Ceftriaxone, 2g iv, daily for 30 days, or
	• Penicillin G, 20 × 10^6 IU iv, daily in divided doses for 30 days
	Possible alternatives:
	• Cefotaxime sodium, 2g iv, q8h for 30 days, or
	• Doxycycline, 100mg po, q12h for 14–30 days, or
	• Chloramphenicol, 1g iv, q6h for 14–30 days
Lyme carditis	• Ceftriaxone, 2g iv, daily for 14 days, or
	• Penicillin G, 20 × 10^6 iv, daily in divided doses for 14 days
	Possible alternatives:
	• Doxycycline, 100mg po, q12h for 21 days, or
	• Amoxicillin, 500mg po, q8h for 21 days
During pregnancy	Localized, early disease:
	• Amoxicillin, 500mg po, q8h for 21 days
	Other manifestations:
	• Penicillin G, 20 × 10^6 IU iv, daily in divided doses for 14–30 days, or
	• Ceftriaxone, 2g, daily for 14–30 days

Carditis

Although carditis resolves spontaneously, observational data suggest that resolution of heart block may be hastened by treatment with salicylates, corticosteroids, oral penicillin, oral tetracyclines and intravenous ceftriaxone and penicillin.[31] [30] This response to either anti-inflammatory therapy or antibiotics suggests that the proximate cause of the heart block is the inflammatory reaction engendered by the Lyme spirochete rather than direct tissue destruction resulting from the infection. Control of the inflammatory response leads to resolution of clinical manifestations.

Heart block caused by carditis may progress suddenly, necessitating a temporary pacemaker, but permanent pacing is rarely necessary. Hospitalization with cardiac monitoring is prudent while antibiotic therapy is instituted. Although no comparative trials have been conducted, treatment with intravenous penicillin or a third-generation cephalosporin for a minimum of 2 weeks to eradicate systemic spirochetal infection is recommended. Salicylates or non-steroidal anti-inflammatory agents may hasten symptom resolution. Systemic corticosteroids may be dramatically effective in reversing heart block, but they may be best avoided during antibiotic therapy if possible.

Neurologic manifestations

Data on the treatment of neurologic manifestations are derived primarily from clinical experience. The tendency for spontaneous resolution of Bell's palsy, the fluctuating course of meningitis, the clinical variation of neurologic syndromes and the delayed emergence of the subtle deficits associated with late neurologic Lyme disease must all be considered in evaluating the clinical response to antibiotic therapy.[38] [50] [101] The emergence of chronic neurologic impairment years after remission of acute neurologic symptoms highlights the danger of complacency about the potential consequences of incomplete eradication of CNS infection.

Bell's palsy

Historically, Lyme facial palsy has been treated with oral antibiotics, whereas other neurologic syndromes have been treated intravenously. It is unclear whether this distinction is warranted. Facial palsy itself resolves completely or nearly completely in nearly all patients (121 of 122 patients in one series).[110] Patients who have facial palsy should undergo a careful neurologic evaluation, including a CSF examination. Cerebrospinal fluid invasion has been demonstrated by PCR in patients who have minimal CNS complaints and facial palsy, most of whom have clinically silent CSF pleocytosis.[40] [72] If facial palsy is the only clinical abnormality and CSF is normal, current practice is to administer oral antibiotics for 21–30 days, a practice that has resulted in favorable outcomes. Long-term follow-up of this group is important and, if CSF examination is not possible, the preferred course at present is to administer intravenous antibiotics.

Meningitis

Intravenous penicillin for 10 days has been shown in clinical trials to be effective treatment of meningitis. In one small series, intravenous ceftriaxone for 14 days was superior to a 10-day course of penicillin.[111] Most experts prefer a 30-day course of treatment, however, because of the occasional occurrence of late neurologic relapses after shorter courses of therapy. It is not necessary to document clearing of all CSF abnormalities before discontinuation of therapy because clearing of inflammation may lag behind bacteriologic cure. The co-occurrence of encephalopathy or encephalomyelopathy does not change this approach.

Radiculoneuropathy

Radiculoneuropathy is less clearly responsive to antibiotic therapy. Intravenous penicillin has not been shown to hasten resolution, and the response to ceftriaxone is unpredictable.[37] [38] Current practice is to administer intravenous antibiotic therapy, however, based on favorable long-term outcome with this approach and the belief that radiculoneuropathy is driven by systemic infection.

Resolution of neuropathy may be very gradual (taking place over months) and, with chronic involvement, this response may be incomplete. Doxycycline has been used orally and intravenously as an alternative to ceftriaxone or penicillin, but experience with this agent is limited.[112] One patient who had severe neurologic involvement, unresponsive to penicillin, responded favorably to chloramphenicol.[113]

Arthritis

Arthritis may respond to either oral[114] or parenteral[96] [103] [115] [116] antibiotic therapy, but antibiotic failures occur with either approach. Amoxicillin plus probenecid given orally for 4 weeks cures the majority of patients and those who fail oral therapy do not appear to respond to intravenous therapy. In a carefully carried out PCR study, no joint fluids were PCR-positive in patients who had received at least 8 weeks of antibiotic therapy. The optimal duration of therapy is unknown but an initial course for

4 weeks is recommended.

The role for parenteral therapy for Lyme arthritis is unclear. Patients who have concurrent neurologic involvement should receive intravenous treatment. In one randomized study, intramuscular benzathine penicillin given weekly for 3 weeks cured less than one half of patients, but intravenous penicillin for 10 days cured a higher percentage.[116] Ceftriaxone given for 14 days has been found to be more effective than 10 days of penicillin.[113] The primary reason for selection of intravenous therapy is concurrent neurologic involvement, in which case ceftriaxone or cefotaxine for 2–4 weeks are probably the agents of choice.

Resolution is commonly delayed, with synovitis persisting for months after completion of antibiotic therapy before eventually resolving. It has been suspected that administration of intra-articular corticosteroids during or before antibiotic therapy increases the risk of antibiotic failure, but a single intra-articular injection after completion of antibiotic therapy may hasten resolution. Patients who do not respond to a first course of therapy may respond to a repeat course, but there is no known rationale for a course of longer than 8 weeks. Adjunctive treatment measures should include evacuation of large effusions and limitation of weightbearing during acute attacks. Chronic inflammatory arthritis may occur through an autoimmune mechanism rather than as a result of persistent infection.

Late Lyme disease

Late Lyme disease, a designation reserved for those patients who have symptoms that persist for longer than 1 year, generally involves persistent inflammation in the CNS, joints or skin (ACA). Generally, patients who have ACA respond to oral penicillin. Late neurologic and arthritic involvement, however, are less predictably responsive. In one report, only one-half of patients who had late neurologic symptoms showed either resolution or sustained improvement after 6 months of follow-up after a 2-week course of ceftriaxone.[50] Those who did not respond, however, did not show progressive worsening. Long-term follow-up of this patient group is essential. In a European trial ceftriaxone and penicillin for 2 weeks were both effective for late neurologic involvement.[117]

Persistent arthritis after antibiotic therapy occurs most often in people who have HLA-DR4.[52] They are usually PCR negative and may be treated satisfactorily with arthroscopic synovectomy after failing to respond to either oral or intravenous antibiotics, suggesting that the pathogenesis of antibiotic-resistant arthritis may involve mechanisms other than persistent infection.[118] A recent study has provided strong evidence of an autoimmune mechanism for chronic Lyme arthritis.[97] Comparative trials of different antibiotics and varying durations of therapy are currently in progress for the treatment of late manifestations of Lyme disease, but there are no controlled data involving treatment periods longer than 4 weeks.

Pregnancy

Lyme disease acquired during pregnancy represents a special category because the health of the fetus must also be considered. Case reports have provided convincing evidence that *B. burgdorferi* can cross the placenta. Stillbirth[119] [120] and neonatal death[19] [20] have been attributed to *B. burgdorferi* transmitted from mother to fetus in utero, but the evidence to support this conclusion is still incomplete. The vast majority of pregnancies complicated by maternal Lyme disease have normal outcomes. *Borrelia burgdorferi* has not been linked statistically to congenital anomalies,[106] and no increased risk of an adverse outcome of pregnancy has been associated with asymptomatic seropositivity[121] or history of previous Lyme disease. It is appropriate to maintain a lower threshold for institution of aggressive antibiotic therapy for suspected Lyme disease during pregnancy, but women should be reassured that no cases of fetal Lyme disease have occurred with currently recommended antibiotic regimens.

PREVENTION

If possible, it is preferable to prevent Lyme disease by personal protection and the use of vaccine than to treat it. One obvious issue with regard to prevention is whether an individual with a known ixodid tick bite in a Lyme disease endemic area should be treated prophylactically with antibiotics. This question has been studied in a Lyme disease endemic area in Connecticut. A randomized, double-blind trial of amoxicillin therapy for tick bites[15] showed that, although the tick infection rate approached 15%, the risk of Lyme disease in untreated people was so low — 1.2% (95% CI 0.1–4.1%) — that prophylactic therapy (although probably effective) was not warranted. In a recent survey of pediatricians in an endemic area, 26% (70/267) routinely administered prophylactic antibiotics after tick bites.[122] Considerable controversy has arisen over this issue following a recent report by Nadelman *et al.*,[123] in which a single dose of oral doxycycline (200mg) within 72 hours after removal of an *I. scapularis* tick significantly reduced the incidence of Lyme disease (1/235 in the doxycycline group versus 8/247 in the placebo group). Many clinicians argue that this practice is unwarranted and may promote the development of antibiotic resistance.[124] [125] Prophylactic antibiotics may be cost effective in endemic regions if the risk of transmission following tick bites is greater than 0.01.[126] If the tick is preserved after it has been removed from its attachment site, a PCR for *B. burgdorferi* DNA can be done of the tick contents. This may allay fears of transmission risk and serve as a guide to preventative treatment in certain risk categories (e.g. pregnancy). Personal protection measures, including the wearing of protective

clothing, the use of insect repellent containing N,N-diethyl-metatoluamide (DEET) and the prompt removal of ticks, reduce the risk of Lyme disease.

Another area of active research involves efforts to develop a Lyme disease vaccine. A recombinant vaccine based on OspA, Lymerix, has been approved but was recently withdrawn from the market.[127] Efficacy was reported to be 79%[128] after three doses. New recombinant-based vaccines are under development; these are expected to have a broad range of specificity against the variants of *B. burgdorferi* distributed throughout the world.

Chapter 55 - Practice Points

55.a Fever and arthralgia

Nigar Kirmani

Introduction

Fever and arthralgia is a common clinical presentation of a variety of infectious and noninfectious entities. Clinicians need to be familiar with a broad differential diagnosis in order to differentiate active infection requiring antimicrobial therapy from a systemic inflammatory process that may require immunosuppressive therapy. Arthralgia may often progress to frank arthritis. The pattern of joint involvement and presenting signs and symptoms help categorize patients and are useful clues in establishing the diagnosis. Clinical presentations include:

- acute monoarticular arthritis,
- oligoarticular arthritis,
- polyarticular arthritis, and
- fever and arthralgia or arthritis with associated skin eruption.

Table 55a.1 lists the common etiologic agents in each category. Major causes of fever and arthralgia/arthritis and their diagnostic approach are listed in Table 55a.2 . Synovial fluid profiles of selected diseases are shown in Table 55a.3 . Infectious and reactive arthritis are reviewed in detail in Chapter 51 .

Diagnosis

The first and most important step in narrowing down the extensive differential diagnosis is a thorough history and physical examination. The severity and duration of symptoms, fever pattern, sexual history, immunization status, dietary, transfusion and travel history, along with occupation, animal or other exposures should be obtained. Past illnesses such as diarrhea, sexually transmitted disease or flu-like syndromes would suggest reactive arthritis as an immune-mediated sequel. A complete and thorough physical examination is essential with special attention to the joints, skin and mucous membranes. Fever with pain and swelling of a single joint should be considered septic arthritis until proven otherwise. Chronic monoarticular arthritis suggests mycobacterial or fungal infection. Splinter hemorrhages, Osler's nodes or other peripheral embolic phenomenon help in diagnosing bacterial endocarditis. Pustular skin lesions on the trunk or extremities are seen in disseminated gonococcal infection; erythema migrans (Lyme disease) and the 'slapped cheek' rash of erythema infectiosum are helpful clues, although adults with parvovirus B19 infection do not usually have rash. Schnitzler's syndrome is characterized by chronic urticaria, intermittent fever, arthralgia and lymphadenopathy. It is often confused with adult Still's disease, although high fever and an evanescent rash are seen in the latter. A malar or

TABLE 55.a-1 -- Causes of fever and arthralgia.

CAUSES OF FEVER AND ARTHRALGIA
Monoarticular arthritis
Septic arthritis
Tuberculosis
Fungal infections
Bacterial endocarditis
Calcium pyrophosphate dihydrate deposition disease (pseudogout, pseudorheumatoid arthritis)
Gout
Oligoarticular arthritis
Disseminated gonococcal infection
Brucellosis
Fungal infections
Histoplasmosis
Coccidioidomycosis
Sporotrichosis
Reactive arthritis
Salmonella spp. infection
Shigella spp. infection
Campylobacter spp. infection
Chlamydial infection
Lymphogranuloma venereum
Bacterial endocarditis
Rheumatic
Still's disease
Inflammatory bowel disease
Psoriatic arthritis
Ankylosing spondylitis
Paraneoplastic syndromes
Serum sickness
Sarcoidosis
Strongyloidiasis
Dracunculiasis
Polyarticular arthritis
Viral infections
Hepatitis B virus

Hepatitis C virus
HIV
Cytomegalovirus
Epstein-Barr virus
Arboviruses
Rheumatic fever
Rheumatoid arthritis
Relapsing fever
Whipple's disease
Giardiasis
Loa loa infection
Toxoplasmosis
Paraneoplastic syndromes
Atrial myxoma
Fluoroquinolone induced
Familial Mediterranean fever
Arthralgia or arthritis with skin eruption
Lyme disease
Disseminated gonococcal infection
Chronic meningococcemia
Syphilis
Rocky Mountain spotted fever
Rat-bite fever (streptobacillary form)
Murine typhus
Parvovirus
HIV
Rubella (natural or vaccine)
Dengue fever
Systemic lupus erythematosus
Mixed cryoglobulinemia
Schnitzler's syndrome

TABLE 55.a-2 -- Clinical findings and diagnostic strategies in selected diseases that cause fever and arthralgia.

CLINICAL FINDINGS AND DIAGNOSTIC STRATEGIES IN SELECTED DISEASES THAT CAUSE FEVER AND ARTHRALGIA			
Disease	**Etiologic agent(s)**	**Associated clinical findings**	**Diagnostic strategy**
Bacterial endocarditis	***Staphylococcus aureus,* coagulase-negative staphylococci, viridans streptococci, other organisms**	Cardiac murmur, splenomegaly, Osler's nodes, splinter hemorrhages, petechiae. Polyarthralgias, oligo- and monoarthritis and back pain are common musculoskeletal symptoms	Blood cultures, echocardiography
Lyme disease	***Borrelia burgdorferi***	History of tick exposure, erythema migrans, headache, myalgia, malaise, fatigue. Arthralgias in early disease, oligoarthritis in late disease	Acute disease: characteristic rash; chronic disease: serology, confirmed by Western blotting
Disseminated gonococcal infection	***Neisseria gonorrhoeae***	History of sexual exposure, pustular or necrotic skin lesions in acral and juxta-articular distribution, more common in women and associated with menses. Two forms of arthritis occur — migratory polyarthritis with skin lesions and oligoarticular arthritis	Confirmatory culture from urethra, endocervix, rectum, pharynx or involved joint; characteristically prompt resolution of symptoms with antibiotic therapy
Rheumatic fever	***Streptococcus pyogenes***	History of recent pharyngitis, cardiac murmur, erythema marginatum. Migratory polyarthritis involving large joints	Throat culture or streptococcal antigen assay; antistreptolysin O titer, anti-DNAse B, anti-hyaluronidase; Jones criteria
Parvovirus	**Parvovirus B19**	Erythema infectiosum ('slapped-cheek') or reticular recrudescent rash, mild-to-severe pancytopenia. Rash uncommon in adults	Parvovirus IgM and IgG antibody titers, PCR on blood
Reactive arthritis (Reiter's syndrome)	***Salmonella* spp., *Shigella* spp., *Yersinia* spp., *Campylobacter* spp., *Chlamydia* spp.**	History of diarrheal illness or previous sexually transmitted disease, conjunctivitis, urethritis, dactylitis, enthesopathy, oral ulceration. Sacroiliitis, sausage digits and tendinitis are seen	No specific diagnostic test, haplotyping for HLA-B27 provides supportive evidence for diagnosis
HIV-associated arthropathy	**HIV**	Arthralgia, which may occur at any stage of disease, including acute seroconversion, may be severe and refractory to analgesics ('painful articular syndrome'), increased susceptibility to other forms of arthritis such as Reiter's arthritis and psoriatic arthritis	Testing for HIV antibodies; in acute infection, HIV RNA testing by PCR
Rubella	**Rubella virus (wild-type and live-attenuated vaccine strains)**	Erythematous, macular rash, spreading from face to trunk, which may occur 2–4 weeks after vaccination, particularly in adults. Polyarthritis involving small joints of hands and other peripheral joints	Viral isolation from throat swab or blood, fourfold rise in IgG antibodies from acute to convalescent period
Hepatitis B	**Hepatitis B virus**	In acute infection, immune complex-mediated serum sickness associated with malaise, anorexia, maculopapular rash, urticaria preceding onset of jaundice by about 10 days; in chronic infection, mixed cryoglobulinemia with associated palpable purpura, urticaria, hepatosplenomegaly and glomerulonephritis	In acute infection, hepatitis B surface antigen, elevated hepatic enzymes and bilirubin; in chronic infection hepatitis B surface antigen, core antigen, antihepatitis B core antibody, antihepatitis B surface antibody

Septic arthritis	***Staphylococcus aureus,* streptococci**	History of pre-existing arthritis or injury, injection drug use is a risk factor. Usually monoarticular; may be polyarticular in patients with rheumatoid arthritis	Arthrocentesis revealing high white blood cell count with polymorphonuclear predominance; Gram stain and culture of synovial fluid
Brucellosis	***Brucella melitensis***	History of contact with livestock or ingestion of unpasteurized dairy products, typically a unilateral sacroiliitis	Culture of blood and synovial fluid, serologic testing (standard tube agglutinin test)
Crystal-induced arthritis	**Urate crystals (gout), calcium pyrophosphate dihydrate crystals (pseudogout)**	Tophi, first episode frequently involves the metatarsophalangeal joint of the first toe; recurrence generally polyarticular	Arthrocentesis with identification of crystals in the synovial fluid
Systematic lupus erythematosus		Malar rash, serositis, proteinuria, anemia, leukopenia, thrombocytopenia, seizures	LE cells, antinuclear antibodies, antibodies to dsDNA, Sm antigen
Still's disease		High fever, evanescent rash, lymphadenopathy	Leukocytosis, elevated ESR, negative rheumatologic serologies

discoid rash, along with fever and arthralgia are suggestive of systemic lupus erythematosus.

Initial investigations include a complete blood count and liver function tests. Diagnostic arthrocentesis is critical in distinguishing infectious from noninfectious arthritis. A Gram stain, culture, cell count with differential and examination for crystals should be performed. Antigen detection by PCR has been useful for fastidious organisms. In addition to blood, other sites (oropharynx, genital secretions, stool) may need to be cultured and skin lesions biopsied. Serum antibody titers (acute and convalescent) against specific viral and bacterial pathogens may establish a late diagnosis; saving a serum sample at the time of presentation is extremely useful. Rheumatoid factor, antinuclear

TABLE 55.a-3 -- Synovial fluid findings in selected diseases that cause fever and arthralgia.

SYNOVIAL FLUID FINDINGS IN SELECTED DISEASES THAT CAUSE FEVER AND ARTHRALGIA				
Group	**Color**	**Clarity**	**WBC/µl**	**PMN**
Normal	Colorless	Transparent	<200	<25%
Noninflammatory	Straw colored	Transparent	50–1000	<25%
Systemic lupus erythematosus (occasionally inflammatory)				
Osteo-arthritis (not associated with fever)				
Inflammatory	Yellow	Transparent	1000–50,000	>50%
Rheumatoid arthritis; rheumatic fever; reactive arthritis; viral arthritis; Lyme arthritis; bacterial endocarditis; gout (needle shaped, negative birefringent crystals); pseudogout (rhomboid, positive birefringent crystals)				
Septic	Yellow-green	Opaque	>50,000 (often >100,000)	>75%
Staphylococcus aureus (culture positive 90%)				
Neisseria gonorrhoeae (culture positive <50%)				

and other autoantibodies may help distinguish the rheumatic diseases. Radiologic studies are rarely necessary; CT scan and MRI are more helpful than plain X-rays.

Management

Identification of the underlying etiology is a critical first step. Empiric antibiotics should be avoided, unless the patient is critically ill. Repeated needle aspirations, arthroscopy or surgical drainage may be necessary for septic arthritis. Corticosteroids for presumptive rheumatologic disease should not be started until an infectious process has been ruled out.

55.b For how long should osteomyelitis be treated?

Andrew R Murry

Introduction

Bone infections vary considerably in their pathogenesis, microbiology and clinical presentation. They are usually classified as acquired by hematogenous or contiguous spread and as acute or chronic. The transition from acute to chronic evolves over a period of weeks to months. The antimicrobial treatment of osteomyelitis needs to be tailored to the characteristics of the individual infection.

Pathogenesis

Hematogenous osteomyelitis is most common in infants, children and the elderly. Bone involvement may become obvious during the acute illness or as recrudescent disease after the bacteremia has cleared. The preceding bacteremia may be inapparent, with osteomyelitis presenting as an isolated finding. Most cases of acute osteomyelitis in adults do not result from bacteremia, but are a consequence of contiguous spread from infected wounds, teeth, sinuses, ulcers, open fractures or implanted prosthetic devises. Early, vigorous antimicrobial treatment of acute bone infections reduces the risk of progression to chronicity. Chronic osteomyelitis is associated with devitalized bone, fibrosis, sinus tract formation and clinical recrudescence. Chronic infections are much more difficult to cure, particularly in the presence of diabetes mellitus, vascular disease or any condition that impairs host defenses.

Microbiology

The pathogens most associated with various types of osteomyelitis are shown in Table 55b.1 .

Clinical features

Acute infections may be associated with local symptoms and signs, including pain and local inflammation with or without fever, chills and other constitutional manifestations of infection. In those infections acquired by contiguous spread, the presence of bone involvement may be indeterminate by clinical criteria. Findings may be more vague in chronic infection, with only nonspecific pain and few constitutional symptoms. Vertebral osteomyelitis commonly presents with dull, constant back pain, spasm of the paravertebral muscles and tenderness over the involved vertebrae. Infected prosthetic joints may become painful or loosen. Sinus tracts may develop or increase their drainage.

Interventions

Plain radiographs of the suspected area can often confirm the presence of osteomyelitis, although abnormalities may not be apparent for about 2 weeks. Radiographs may be difficult to interpret when there are soft tissue infections, fractures or noninfectious skeletal diseases.

TABLE 55.b-1 -- Common pathogens in osteomyelitis.

COMMON PATHOGENS IN OSTEOMYELITIS			
Hematogenous spread	**Contiguous spread**		
	Acute skin and soft tissue infections	**Orofacial and dental infections**	**Diabetic foot and pressure sores**
Staphylococcus aureus	*Staphylococcus aureus*	*Streptococcus* spp.	*Staphylococcus aureus*
Streptococcus spp.	*Streptococcus agalactiae*	*Anaerobic cocci*	*Staphylococcus epidermidis*
Haemophilus influenzae[*]	*Streptococcus pyogenes*	*Fusobacterium* spp.	*Streptococcus* spp.
Enterobacteriaceae[†]		*Prevotella melaninogenicia*	*Enterobacteriaceae*
Staphylococcus epidermidis[‡] , [§]		*Pasteurella multocida*[‡]	*Pseudomonas aeruginosa*[*]
Candida spp.[§]		*Eikenella corrodens*[§]	*Enterococcus faecalis*
Pseudomonas aeruginosa[*]		*Actinomyces* spp.	Anaerobic cocci
Salmonella spp.[†]			*Bacteroides* spp.

*Infants and unimmunized children
†Elderly and neonates
‡Bone and joint prostheses
§Intravenous devices
‡‡Dog and cat bites
**Injection drug use and foot puncture wounds
§§Human bites
††Hemoglobinopathies
¶Young adults

Radionuclide scans, computed tomography or magnetic resonance imaging (MRI) can be helpful early in the disease. They do not need to be obtained routinely if treatment is initiated on the basis of clinical suspicion, and follow-up plain radiographs will be subsequently performed. Computed tomography and MRI are particularly useful when planning surgery.

A specific microbiologic diagnosis is most helpful in choosing antimicrobial therapy. Bone biopsy, although not through infected soft tissues, provides the most reliable specimen for microbiologic study. Although the results from cultures of sinus tracts, ulcers or wounds are somewhat unreliable, they may be useful for antibiotic selection if a single pathogen is consistently found or when a biopsy cannot be performed. Blood cultures should be obtained when appropriate.

Management

Acute osteomyelitis may be treated with antibiotics alone, but chronic infection often requires surgery to drain abscesses, resect fistulas, debride ulcers or necrotic devascularized bone, remove foreign bodies (including prostheses), manage dead space, provide stability or restore vascular supply, as well as for reconstruction. Optimization of host factors such as control of diabetes mellitus is also important.

Initial antimicrobial therapy is based on the known or probable pathogens as determined by the nature of the infection and the available culture and susceptibility test results. The antimicrobial agents most commonly used to treat osteomyelitis are shown in Table 55b.2 . Preferred drugs include the ß-lactams, clindamycin and the fluoroquinolones. Vancomycin, trimethoprim-sulfamethoxazole (co-trimoxazole) and metronidazole have more limited indications. Rifampin (rifampicin) may be used with a ß-lactam to treat staphylococcal infections, but there is more favorable experience using clindamycin alone. Aminoglycosides may be used with a ß-lactam for

Gram-negative infections, but they are toxic and ineffective when used alone. Macrolides and tetracyclines are not very effective and should be avoided. Linezolid has been used successfully in several case reports to treat osteomyelitis due to methicillin-resistant staphylococci and vancomycin-resistant enterococci.

Osteomyelitis has traditionally been treated with relatively high doses of intravenous antimicrobial agents for 4–6 weeks, although shorter courses of treatment have proven adequate in some children who have acute infection. Children who have acute infection caused by *Haemophilus influenzae*, *Neisseria* spp. or streptococci should be treated for at least 10–14 days and infections caused by *Staphylococcus aureus*, Enterobacteriaceae or *Pseudomonas aeruginosa* for at least 3 weeks.

For acute infections in adults and chronic infections in patients of any age, the recommended duration of treatment of 4–6 weeks should be considered a minimum unless the infected bone is completely removed by debridement. If this is accomplished, treatment can probably be abbreviated and, in patients undergoing amputation of an infected limb, treatment may be discontinued postoperatively if there is no residual soft tissue infection. For patients who have chronic, recalcitrant osteomyelitis that cannot be completely debrided, treatment with an appropriate agent for 3–12 months may be beneficial. Such infections may 'burn out' over a prolonged period of time with continued antimicrobial suppression. Antibiotic-impregnated beads or spacers can provide high antibiotic concentrations locally and may also be useful to manage dead space.

Prolonged intravenous treatment can be problematic because of hospitalization costs, the inconvenience and complications of long-term intravenous lines. The availability of highly active, predictably absorbed oral antimicrobial agents provide an alternative mode of therapy. The first experiences with oral therapy, usually a penicillin, cephalosporin or clindamycin, after about 5–10 days of initial intravenous therapy, were in children. Intravenous, and then oral, ampicillin-sulbactam was subsequently used successfully. Switching from intravenous to oral therapy has also been successfully accomplished in adults using those drugs or trimethoprim-sulfamethoxazole. Ciprofloxacin and other fluoroquinolones have been extensively used to treat skeletal infections successfully; however, the half-life of levofloxacin may be too short to rely on when treating osteomyelitis. Quinolones should not be used to treat methicillin-resistant staphylococci because resistance frequently develops during treatment.

When using oral treatment, either after an initial course of intravenous treatment or from the start, it is necessary to have a predictably

TABLE 55.b-2 -- Comparison of intravenous and oral antimicrobial regimens to treat osteomyelitis in adults.

COMPARISON OF INTRAVENOUS AND ORAL ANTIMICROBIAL REGIMENS TO TREAT OSTEOMYELITIS IN ADULTS						
INTRAVENOUS				**ORAL**		
Drug	**Dose**	**Approximate peak serum concentration (mg/l)**	**MIC (mg/l) for susceptible pathogens**	**Drug**	**Dose**	**Approximate peak serum concentration (mg/l)**
ß-lactams						
Penicillin G	1–2mU q4-6h	10–20 (U/ml)	=0.12	Penicillin V	500mg q6h	5

Linezolid††	600mg q12h	15	=2, =4	Linezolid††	600mg q12h	21
Vancomycin	1g q12h	40	=2	No oral equivalent available§§		

*MIC <0.12mg/l for most susceptible organisms; =8mg/l for *Enterococcus faecalis*
†MIC <2/1 mg/l for ßactamase-positive *Haemophilus influenzae*, <8/4mg/l for susceptible Enterobacteriaceae
§Cephalexin is fourfold less active than cefazolin against *Staphylococcus aureus*
‡Cefixime is for Gram-negative organisms only
**Avoid using for methicillin-resistant staphylococci
††Linezolid may be active against methicillin-resistant staphylococci and vancomycin-resistant enterococci, MIC <2mg/l for enterococci, <4mg/l for staphylococci
§§Trimethoprim-sulfamethoxazole, clindamycin may be active against methicillin-resistant staphylococci

absorbed drug that is highly active against the pathogen being treated. Although ß-lactams are often considered the preferred drugs for the treatment of skeletal infections, oral derivatives may not be predictably absorbed and do not yield serum concentrations as high as parenteral derivatives, even at high doses with probenecid. Serum concentrations after both intravenous and oral clindamycin far exceed those necessary to inhibit most staphylococci and streptococci. Serum concentrations of trimethoprim-sulfamethoxazole after intravenous and oral administration are virtually identical and far exceed those necessary to inhibit most staphylococci and Enterobacteriaceae. Careful studies have shown oral ciprofloxacin to be equivalent to intravenous ciprofloxacin and serum concentrations with either route of administration far exceed those needed to inhibit most Enterobacteriaceae and *P. aeruginosa*. The same appears true for most other quinolones. Serum concentrations of metronidazole after intravenous and oral administration are nearly equivalent and exceed those needed to inhibit most anaerobes. Finally, linezolid serum concentrations are equivalent using either intravenous or oral dosing making it an attractive option for treatment of multidrug-resistant staphylococci and enterococci.

Appropriate follow-up is necessary to evaluate adherence to the therapeutic regimen and to monitor for clinical improvement and radiographic healing. Determination of serum antibiotic concentrations or performing serum bactericidal tests may be helpful in drug regimens that might be marginal, but these tests are usually not necessary. Normalization of the erythrocyte sedimentation rate (ESR) is reassuring. If the ESR has fallen but not normalized, further treatment might be appropriate, and a persistently elevated ESR often predicts relapse within months of discontinuing antimicrobial agents.

55.c Management of chronic infection in prosthetic joints

Jonathan Cohen

Introduction

Joint replacement is one of the surgical success stories of recent years. Hips, knees, shoulders and elbows are all amenable to this approach. The major complication is infection, which occurs in less than 1–2% of cases. Acute infection of a prosthetic joint is unmistakable: there is pain, fever and physical signs of inflammation around the joint. A common and often more difficult problem is the patient who presents with features consistent with chronic prosthetic joint infection (PJI). Although there is no formal definition, chronic PJI typically presents 1–2 years after the placement of the prosthesis, although it may be much later.

TABLE 55.c-1 -- Microbial causes of prothestic joint infection.

MICROBIAL CAUSES OF PROSTHETIC JOINT INFECTION	
Pathogen	**Proportion of infected joints (%)**
Staphylococci	50
Coagulase-negative staphylococci	25
Staphylococcus aureus	25
Streptococci	20
Gram-negative aerobic bacilli	20
Anaerobes	10

TABLE 55.c-2 -- **Drugs for the treatment of prosthetic joint infections.** HAI, home antibiotic infusion.

DRUGS FOR THE TREATMENT OF PROSTHETIC JOINT INFECTIONS			
Antibiotic	**Spectrum**	**Preparation used**	**Comments**
Vancomycin	Gram-positive bacteria; used particularly for coagulase-negative staphylococci	Only as a parenteral agent	A single daily infusion is suitable for HAI therapy
			Nephrotoxic
Teicoplanin	Gram-positive bacteria; used particularly for coagulase-negative staphylococci	Only as a parenteral agent	Given as a single daily infusion is suitable for HAI therapy
	Do not assume that vancomycin and teicoplanin have interchangeable susceptibility patterns		Nephrotoxic potential
Isoxazolyl penicillins: nafcillin, flucloxacillin and related compounds	Gram-positive bacteria, particularly *Staphylococcus aureus*	Both oral and parenteral preparations	
	Most coagulase-negative staphylococci are resistant		
Fusidic acid (not available in USA)	*Staphylococcus aureus* and many strains of coagulase-negative staphylococci	Oral (intravenous also available)	Excellent record in bone infections, always used in combination with flucloxacillin
			Parenteral preparation has significant hepatotoxicity; avoid if at all possible
Clindamycin	*Staphylococcus aureus* and some strains of coagulase-negative staphylococci	Both oral and parenteral formulations	A large body of successful experience in bone and joint infections
	Has activity against some strains of anaerobic bacteria		Care in elderly people because of risk of antibiotic-associated colitis
Rifampin	*Staphylococcus aureus* and many strains of coagulase-negative staphylococci	Most useful as an oral agent	Little published experience in this setting, but widely used in tuberculosis
Cephalosporins	Broad activity which may include *Staphylococcus aureus* and many aerobic Gram-negative bacilli, depending on the particular agent chosen	Both oral and parenteral formulations	Most useful when the microbiology is unknown and it is necessary to treat empirically with broad-spectrum agents
	Not active against coagulase-negative staphylococci		Long-acting drugs such as ceftriaxone are useful for HAI
Ciprofloxacin (and other quinolones)	Wide activity including *Staphylococcus aureus* and many aerobic Gram-negative bacilli	Oral and parenteral formulations	Very valuable agents in mixed infections, known Gram-negative infection, patients with ß-lactam hyper sensitivity, or as second-line agents
	Not active against coagulase-positive staphylococci		
Trimethoprim-sulfamethoxazole	Broad spectrum includes many strains of *Staphylococcus aureus* and Gram-negative aerobic bacilli	Oral and parenteral formulations	Often forgotten; a useful reserve agent particularly in patients who have ß-lactam hypersensitivity
	Not active against coagulase-negative staphylococci		

Pathogenesis

Most PJIs are caused by exogenous infection by organisms that gain entry at the time of operation, and this is reflected in the type of organisms isolated from these cases (see Chapter 53), which are typically low-grade pathogens associated with skin contamination. However, prosthetic joints can become infected by the hematogenous route, and this is more common in late infections, more than 2 years after operation.

Microbiology

About 80% of infections are associated with a single organism, 10% are mixed infections and 10% are sterile. Gram-positive bacteria are the commonest isolates,

particularly coagulase-negative staphylococci (Table 55c.1). Infections may also be caused by anaerobic bacteria, typically peptococci and peptostreptococci, and by proprionobacteria.

Clinical features

The dominant complaint is of pain. It is usually aching in character, may be continuous or intermittent and is not necessarily of great severity. Local signs of inflammation are often absent, but there may be some erythema, induration or swelling. The finding of a sinus is very helpful; it may discharge very little material, and only intermittently. General systemic features of infection (fever, malaise, shaking chills) are very uncommon in chronic PJI.

The principal differential diagnosis is joint loosening without infection. Laboratory investigations are not very helpful (see below); only joint aspiration and isolation of the causative organism can establish the diagnosis.

Investigations

Establishing the microbiologic diagnosis is of great importance in managing these infections. Isolation of the causative organism will not only confirm the diagnosis of infection, but will also be crucial in guiding the choice of antimicrobial therapy. In this context, interpreting the microbiologic findings from a discharging sinus can present difficulties. While it may seem 'logical' to use this as a surrogate for direct joint aspiration (particularly as both the patient and the physician may be reluctant to do a further surgical procedure), there are pitfalls. The most obvious is that bacteria such as *Staphylococcus epidermidis* are common causes of PJI, but they are also common skin commensals and likely to be isolated from sinus swabs. On the other hand, isolation of *Staph. aureus*, *Proteus* spp. or *Pseudomonas* spp. from such a sinus is a very good indication of the likely cause of the underlying infection. A reasonable approach is to require:

- that the organism should be repeatedly isolated from the sinus; and
- that the organism is identical on each occasion by techniques such as antibiograms and, where appropriate, other more sophisticated forms of bacterial typing.

If there is any doubt, and in particular in cases where a patient presents after one failed course of therapy, joint aspiration should be carried out, ideally under computed tomography or ultrasound guidance. The laboratory should be forewarned, and anaerobic cultures should be included in the processing of the specimen. In the study by Tunney *et al.* (see Further reading, below) proprionobacteria were isolated from 60% of specimens submitted for investigation of possible PJI.

Measurement of C-reactive protein (CRP) is particularly helpful in gauging the response to treatment. It is nonspecific, but in my experience it is not significantly elevated in noninfected joints (even if they are loose and painful). Failure of the CRP to normalize is a reliable sign of persistent infection. Other investigations are less useful. The leukocyte count is rarely elevated in chronic PJI. Radiologic investigations have been particularly disappointing. Plain radiographs do not generally distinguish between infection and an uninfected loose joint. Scintigraphic investigations using gallium, technetium or indium are neither sensitive nor specific enough to be of real clinical value, particularly in the patient who has a low-grade, chronic infection. Ultrasound is useful for identifying collections that may be susceptible to surgical drainage, and it deserves further evaluation in chronic infections.

Management

Lasting cure almost always requires removal of all prosthetic material and extensive local debridement. The procedure of choice is a two-stage revision. First, the infected joint is removed and the patient is given 6 weeks of antimicrobial therapy based on the susceptibility pattern of the causative organism (Table 55c.2). In the second stage, a replacement joint is fitted. An alternative approach is a single-stage procedure involving removal of the infected prosthesis and immediate replacement with the new joint using antibiotic-impregnated bone cement.

A detailed discussion of the surgical aspects of the treatment can be found in orthopedic textbooks, but for the infectious diseases practitioner there are a number of difficult and unresolved questions.

Duration of antibiotic treatment

The advice to use 6 weeks of treatment is based on clinical experience rather than comparative clinical trials. A practical consequence of this is that the regimen chosen should either be available as oral agents, or else offered as part of a home-antibiotic treatment program. In a small number of cases in which further surgery is contraindicated, long-term suppressive therapy may be tried, although this is not generally recommended.

Choice of regimen

Despite the fact that a number of antibiotics have been used quite extensively in these infections, there are no good clinical trials that rigorously compare different regimens. For instance, there is no agreement as to whether one or two drugs should be used; many UK orthopedic surgeons favor the combination of flucloxacillin and fusidic acid, whereas in North America single-agent therapy is more common. Another issue is whether there is any merit in parenteral therapy; is high-dose oral therapy just as good?

In the absence of adequate data, the following recommendations are suggested, based on my experience; they will need modifying in the light of individual circumstances:

- for proven or presumed Gram-positive infection with coagulase-negative staphylococci, 6 weeks of parenteral vancomycin (or teicoplanin) plus oral rifampin (rifampicin);
- for proven or presumed *Staph. aureus* infection: 2 weeks of high-dose (2–4g/day) intravenous flucloxacillin (or nafcillin) plus oral fusidic acid (where available), followed by 4 weeks of oral therapy;
- for proven or presumed Gram-negative infection, 6 weeks of ciprofloxacin;
- for mixed infections or infections of uncertain etiology, the combination of vancomycin or rifampin plus ciprofloxacin is useful;
- reserve agent for Gram-positive infection: clindamycin; linezolid or quinupristin-dalfopristin are additional agents that may be useful but clinical experience in this setting is still very limited.
- reserve agent for Gram-negative infection: trimethoprim-sulfamethoxazole (co-trimoxazole).

Specific anti-anaerobic agents may be needed, depending on the microbiologic findings; penicillin, clindamycin and metronidazole are all useful for this purpose. The treatment of pseudomonal infections is particularly difficult; there may be benefit in adding gentamicin to ciprofloxacin, but the dangers of a long course of an aminoglycoside, particularly in the elderly, are such that this should only be done after very careful consideration.

Chapter 56 - Sepsis

William A Lynn

This chapter examines the pathophysiologic consequences of the systemic effects of infection. This is broadly referred to as sepsis and is a heterogeneous syndrome resulting from a complex interaction between host defenses and invading pathogens. In this chapter, I describe the pattern of disease seen in bacterial sepsis and detail a logical approach to therapy.

EPIDEMIOLOGY

Definition and nomenclature

For many years physicians recognized that infection could lead to generalized circulatory collapse and death. The association of bloodstream infection with severe systemic illness was generally referred to as septicemia, and in the 1960s the work of McCabe *et al.* described in detail, for the first time, the spectrum of disease associated with Gram-negative bacteremia, including septic shock.[1] [2] Although sepsis and septic shock are terms that most practitioners recognize, if asked to define bacteremia, sepsis, septicemia and septic shock a considerable range of views would emerge. Driven by the need to adopt a common currency of terms, Bone initiated a debate that continues to provoke discussion.[3] Bone suggested that 'sepsis' be used for the systemic response to infection according to specific clinical criteria. Furthermore, he recognized that an identical syndrome could occur with noninfective inflammatory stimuli. The American College of Chest Physicians and American Society of Critical Care Medicine (ACCP/ASCCM) accepted much of what Bone suggested and also introduced the term the systemic inflammatory response syndrome (SIRS) to define a common set of physiologic changes occurring in infected (sepsis) and noninfected patients.[4] SIRS has been criticized for being non-specific and encompassing too wide a range of disease processes.[5] Thus, although these concepts have helped to improve our understanding of the pathophysiology of sepsis, it is important to remember that all different infections may not behave the same way in all patients. A pragmatic approach to the terminology of sepsis is defined in Table 56.1 .

TABLE 56-1 -- Working definitions associated with sepsis and related disorders.

WORKING DEFINITIONS ASSOCIATED WITH SEPSIS AND RELATED DISORDERS	
Disorder	**Definition/signs**
Bacteremia	Bacteria present in the blood, as confirmed by culture. May be transient or associated with sepsis and organ failure.
Sepsis (identical to SIRS criteria minus evidence of infection)	Confirmed or clinical evidence of infection plus evidence of a systemic response manifested by two or more of the following:
	Temperature >100.4°F (38°C) or <96.8°F (36°C)
	Heart rate >90 beats/min
	Respiratory rate >20 breaths/min or arterial CO_2 tension <32mmHg (4.3kPa)
	WBC >12,000 cells/ml, <4000 cells/ml or >10% immature forms (bands)
Severe sepsis	Sepsis with associated organ dysfunction with one or more of the following:
	Hypotension
	Confusion
	Oliguria
	Hypoxia — not explained by primary respiratory disease
	Metabolic (lactic) acidosis
	Disseminated intravascular coagulation (DIC)
	Hepatic dysfunction — not explained by primary liver disease
Septic shock	Severe sepsis plus hypotension despite adequate fluid resuscitation
SIRS, systemic inflammatory response syndrome	
WBC, white blood count	

There is no single classification system that will satisfy the requirements of clinicians and researchers alike, but the current definitions can be used as a basis for recognizing patients who have sepsis and directing both therapies and clinical resources. These processes are best considered as a continuum, with localized inflammation at one end and a severe generalized inflammatory response leading to multiorgan failure at the other. Patients may present anywhere along this spectrum or alternatively may visibly progress from early sepsis, through severe sepsis, to refractory shock and death. The challenge for physicians is to recognize the onset of sepsis, identify those at high risk of complications and intervene early to try to prevent progression along this continuum, because once shock and organ failure are established the mortality rate remains high despite intensive therapy.

Incidence and prevalence of sepsis

Many host and environmental factors interact in the development of sepsis, making it a heterogeneous condition with varying rates in different patient populations. Sepsis is not a notifiable disease and estimates of the incidence of sepsis and SIRS have been further confounded by the failure of multicenter studies of novel therapeutic agents to include all patients fulfilling the definition of sepsis or SIRS. However, it is clear that sepsis is a major cause of hospital morbidity and death and has been increasing in prevalence over the past 30 years.[6] [7]

Community-acquired bacteremia is responsible for approximately 7–12/1000 hospital admissions. Angus and co-workers have performed the most comprehensive estimate of the epidemiology of sepsis in the USA.[8] Using existing data bases they analyzed discharge records of over six million patients from seven states in the USA during 1995 and extrapolated the results for the whole USA population. Data collected in this way should be viewed with some caution but the sheer size of this study demands attention. They estimated an annual incidence for severe sepsis of 3/1000 (2.26/100 hospital discharges) equivalent to 751,000 cases each year. Incidence rose from 0.2/1000 in childhood to 26/1000 over the age of 85 years. In terms of resources severe sepsis was estimated to cost around US$16 billion per year. In Holland Kieft *et al.* measured the attack rate for SIRS at 13.6/1000 and septic shock at 4.6/1000 hospital admissions. [9] An audit study of 61,874 admissions to intensive care units (ICUs) in England and Wales in 1999 indicated that 27.7% fulfilled criteria for severe sepsis during the first 24 hours following admission.[10] Once in the ICU the prevalence of SIRS is high, and in one study fully 68% of 3708 patients in intensive care fulfilled the criteria for SIRS at some time during their ICU stay.[11]

Morbidity and mortality rates

The mortality rate of SIRS and sepsis varies between countries and between different patient groups, possibly because of variations in

Figure 56-1 Potential risk factors leading to sepsis.

case definition, ICU facilities and patient populations. In an analysis of four large sepsis trials, 14-day mortality rate averaged 26% and 28-day mortality rate, 42%.[12] In

the Angus study cited above[8] overall mortality rate was 28.6%, equivalent to 215,000 deaths per annum in the USA. In this study mortality rate in childhood was around 10% rising to 38.4% in those over age 85 years.[8] Factors associated with early death include the number of organ systems involved, low arterial blood pH, shock and an unfavorable SAPS (Simplified Acute Physiology Score) or APACHE (Acute Physiology and Chronic Health Evaluation) score. Later deaths (within 28 days) are associated with the underlying disease process, pre-existing cardiac or liver disease, hypothermia, thrombocytopenia and multiple sources of infection. *Pseudomonas aeruginosa, Candida* spp. and mixed infections have a higher attributable mortality rate than other infectious agents.[13] Patients who have sepsis often have serious underlying medical or surgical problems that contribute to the mortality rate, but even when this is taken into account the attributable mortality rate from sepsis has still been measured as at least 25%. [13] Furthermore, a long-term follow-up of patients enrolled in the Veterans Affairs Co-Operative Study Of Corticosteroids In Systemic Sepsis performed in the early 1980s revealed a significant reduction in survival persisting for at least 5 years after the episode of severe sepsis.[14] Quality of life is also significantly impaired in survivors of sepsis.[15]

Risk factors for sepsis

Broadly speaking, risk factors for sepsis are those factors that weaken or breach host defenses, increasing the likelihood of bacterial invasion of otherwise sterile tissue as shown in Figure 56.1 . One of the most intriguing aspects of severe sepsis is why one individual will respond to a particular infection with devastating consequences of septic shock while another in apparently similar circumstances resolves the infection. It is apparent that there are numerous variations in our host response to all types of infecting organisms.

Figure 56-2 Positive blood cultures in severe sepsis. *Data from Bochud et al.* [42]

Genetic variations are known to be important in susceptibility to infection, but it is also clear that our genes may also hold the key to our vulnerability to severe sepsis.[16]

PATHOGENESIS AND PATHOLOGY

Etiologic agents of sepsis

Bacteria are the commonest underlying pathogens in patients presenting from the community and in hospital-acquired sepsis. McCabe *et al.*[1] identified Gram-negative bacteria as the predominant cause of septic shock in the early 1960s.[1] Over the past decade, however, there has been a shift in the etiology of nosocomial infections, with increased infection due to Gram-positive bacteria.[17] This is also reflected in the pattern of underlying infections in patients who have sepsis (Fig. 56.2). Staphylococci, *Escherichia coli* and enterococci remain the most commonly isolated pathogens.

Although it remains true that bacterial infections continue to be frequent, there has been a growing awareness that a wide range of nonbacterial pathogens may induce the pathologic responses necessary to lead to sepsis. This includes fungi (e.g. *Candida* spp.), rickettsia (e.g. *Rickettsia rickettsii* — Rocky Mountain spotted fever), protozoa (including *Plasmodium falciparum*) and certain viruses (e.g. those that cause dengue fever).

TABLE 56-2 -- Bacterial components involved in the pathogenesis of severe sepsis.

BACTERIAL COMPONENTS INVOLVED IN THE PATHOGENESIS OF SEVERE SEPSIS		
Category	**Source**	**Examples**
Structural cell wall constituent	Outer cell wall of all Gram-negative bacteria	Endotoxin (LPS, lipid A)
	Cell wall of all bacteria	Peptidoglycan
	Cell wall from Gram-positive bacteria	Lipoteichoic acid
Pore-forming exotoxins	*Staphylococcus aureus*	a-Hemolysin
	Streptococcus pyogenes	Streptolysin-O
	Escherichia coli	*E. coli* hemolysin
	Aeromonas spp.	Aerolysin
Superantigens	*Staphylococcus aureus*	Toxic shock syndrome toxin 1, enterotoxins A–F
	Streptococcus pyogenes	SPEA, SPEC, SMEZ
Enzymes	*Streptococcus pyogenes*	Interleukin-1ß convertase, proteases
	Clostridium perfringens	Phospholipase C
LPS, lipopolysaccharide		

As with other aspects of infectious diseases, the occurrence of sepsis is due to the combination of host and environmental factors. Thus the organisms responsible will vary geographically; for example, melioidosis due to *Burkholderia pseudomallei* is a common cause of community-acquired sepsis in South East Asia. Also there are large differences between specific patient groups, with certain pathogens occurring more frequently in vulnerable hosts, for example pneumococcal sepsis in asplenic patients.

Bacterial products involved in sepsis

Bacteria produce a variety of extracellular products (exotoxins) and endogenous cell wall products that have the capacity to induce proinflammatory responses in vitro that may culminate in sepsis in vivo (Table 56.2). Such products are released by bacteria during local or systemic infection and, in turn, may have local or distant proinflammatory effects. Thus, it is possible for a localized infection to induce the full inflammatory response leading to sepsis without the infecting organism itself actually disseminating. The most commonly recognized bacterial products are outlined in Table 56.2 (there are undoubtedly numerous others yet to be discovered or defined) and it is important to recognize that they may be additive or synergistic in their proinflammatory actions. For two bacterial toxins, namely endotoxin and toxic shock syndrome toxin 1 (TSST-1), considerable progress has been made in understanding their molecular and cellular interactions.

Cellular activation by endotoxin

The central role of endotoxin — lipopolysaccharide (LPS) — in the pathogenesis has been recognized for many years.[18] LPS is found only in Gram-negative bacteria, where it forms part of the outer leaflet of the bacterial cell wall (Fig. 56.3). It consists of a polysaccharide domain covalently bound to a unique diglucosamine-based phospholipid, lipid A, which is the key toxic moiety of LPS. Lipid A and LPS induce a wide range of both proinflammatory and counter-regulatory responses in vitro and in vivo. In human volunteers, administration of small amounts of endotoxin induces fever and release of cytokines including tumor necrosis factor (TNF)-a, interleukin (IL)-1 and IL-6.[19] That LPS alone can initiate severe sepsis in humans was reported in dramatic style in 1993 when a laboratory worker developed septic shock after deliberate self-administration of *Salmonella minnesota* endotoxin.[20]

So how does this lipid exert such widespread effects on a variety of cell types? The interaction of LPS with cells is complex, involving both serum LPS-binding proteins and cell-bound and soluble LPS

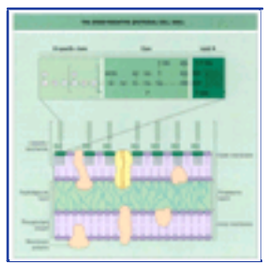

Figure 56-3 The Gram-negative bacterial cell wall. In the cell wall of a Gram-negative bacteria such as *Escherichia coli*, the inner membrane is composed of phospholipids and membrane proteins and is separated from the outer membrane by the periplasmic space and peptidoglycan. Lipopolysaccharide (expanded box) is found only in the outermost leaflet of the outer membrane with the lipid A moiety in the membrane and the polysaccharide (O) side chain directed outwards. Lipid A is highly conserved across Gram-negative bacteria and consists of a phosphorylated diglucosamine backbone decorated with six or seven acyl side chains. Dephosphorylation or deacylation of lipid A abrogates its toxicity. Lipid A is covalently linked to an inner core of sugar residues that is relatively well conserved across species and antibodies directed against the core may protect against challenge with heterologous Gram-negative bacilli. The core is followed by an outer polysaccharide chain, of repeating sugar residues, that varies between different of bacterial strains (O antigen). Antibodies directed against the O antigen will only protect against challenge with that individual bacterial strain. Gal, D-galactose; Glc, D-glucose; GlcNAc, *N*-acetyl-D-glucosamine; KDO, 3-deoxy-D-manno-octuylosonic acid; Hep, L-glycero-D-mannoheptose.

receptors.[21] [22] When released from bacteria, LPS interacts with serum proteins that may either enhance or negate its bioactivity. One of these, LPS-binding protein (LBP) binds LPS with high affinity and presents it to LPS acceptor molecules including CD14, a glycosphatidyl-inositol (GPI)-anchored protein on the surface of monocyte-macrophages and neutrophils as shown in Fig 56.4 . CD14 is also present in soluble form in human serum and can complex with LPS and LBP to activate cell-types that do not express surface CD14, such as endothelial cells. CD14 does not have a transmembrane domain and LPS passes from CD14 to one of the toll receptor family, namely TLR4, which has an intracellular signalling domain with homology to the IL-1 receptor.[23] Following receptor binding there is rapid activation of a number of second messenger pathways including mitogen activated protein (MAP) kinases leading to translocation of nuclear factor-kappa B (NF-?B) to the nucleus and activation of many genes. Several other LPS receptors have been identified including the leukocyte integrin CD11d/CD18, the macrophage scavenger receptor and most recently triggering receptor expressed on myeloid cells (TREM-1).[22] The inter-relationships of these different LPS response pathways and their relation to the cellular and physiologic processes in sepsis remain to be elucidated.

The toll receptor family are worthy of further comment regarding their role in responding to infection and the development of sepsis.[24] Toll receptors were first identified as important in the recognition of bacteria in *Drosophila* spp. Toll receptors are found in widely diverse organisms, including plants, animals and insects, where they play a key role in innate immunity. Thus far in man ten toll-like receptors (TLR) have been identified that bind bacterial, viral and fungal products as follows:

- TLR2: peptidoglycan, and lipoteichoic acid and some LPS,
- TLR3: dsRNA, (viruses)
- TLR4: LPS
- TLR5: flagellin
- TLR6: lipoteichoic acid
- TLR9: CpG (deoxycytidylate-phosphate-deoxyguanylate) unmethylated bacterial DNA.

The role of toll receptors and other arms of the innate immune response in host responses to infection is likely to provide further insights into the pathophysiology of severe sepsis.

Superantigens and toxic shock

Superantigenic bacterial toxins can cause profound hypotension, organ failure and inflammation.[25] It is postulated that strains of *Staphylococcus aureus* and *Streptococcus pyogenes* that are able to express these toxins (see Table 56.2) are the causal agents of staphylococcal and streptococcal toxic shock. The principle behind immune activation by superantigens is outlined in Figure 56.5 . Essentially, the bacterial toxin is capable of bypassing the normal highly antigen-specific mechanisms of T-cell activation by directly linking major histocompatability complex (MHC) II on antigen-presenting cells to the Vß subunit of the T-cell receptor. Whether an individual infected with a superantigen-producing organism develops toxic shock is complex, depending on the quantity of toxin produced, the presence or absence of neutralizing antitoxin antibodies and the composition of an individual's MHC molecules and T-cell repertoire of Vß subunits. The interaction of these factors was clearly demonstrated in outbreaks of staphylococcal toxic shock epidemiologically linked to tampon use in the USA in the 1970s. The use of a particular type of

Figure 56-4 CD14 and toll receptor pathway of cellular activation by bacterial lipopolysaccharide. Schematic representation of events at the inflammatory cell surface. Lipopolysaccharide (LPS), either free or as part of lipoprotein complexes, is bound by LPS-binding protein (LBP) in the fluid phase. The LPS-LBP complex binds to the cell surface receptor CD14 on neutrophils and macrophages. CD14 lacks an intracellular domain and acts as a co-receptor presenting LPS to toll-like receptor 4 (TLR4), leading in turn to activation of intracellular signalling and gene activation. MYD88, myeloid differentiation factor 88; NF?B, nuclear factor kappa B; I?B, inhibitor of kappa B; IRAK, interlkeukin 1 receptor-associated kinase; TRAF6, tumour necrosis factor receptor-associated factor 6; MAP3K, mitogen-activated protein 3-kinase

superabsorbent tampon allowed proliferation and increased toxin production by staphylococci in the vagina, leading to a marked increase in cases of menstruation-associated cases of toxic shock syndrome.[26]

Role of specific proinflammatory mediators in sepsis

As already alluded to, severe sepsis is the result of a complex interaction of environmental, microbial and genetic factors. Central to the development of shock and organ failure is the concept that severe sepsis is the end-result of an excess proinflammatory response to infection. Numerous mediators and inflammatory pathways have been described, some of which are depicted in Figures 56.6 and Table 56.3 . It is important to remember that any attempt to consider one mediator in isolation is a simplification and many of the proinflammatory mediators have additive or synergistic effects.

Cytokines

The evidence that proinflammatory cytokines such as TNF-a and IL-1 play a causative role in sepsis stems from several lines of research. First, IL-1 and TNF-a can induce features of septic shock in experimental animals, and inhibitors of these cytokines can prevent the onset of sepsis in these models. Furthermore, mice deficient in the genes encoding receptors for TNF-a are resistant to septic shock induced by endotoxin. Finally, these cytokines are elevated in human sepsis, and high levels of cytokines correlate with a poor outcome. TNF-a is released early in response to LPS challenge, and the cooperative effects of TNF-a, IL-1 and interferon (IFN)-? in producing inflammatory responses have made these three cytokines prime targets for experimental intervention in sepsis.[27]

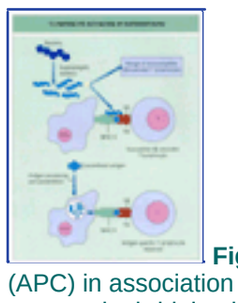

Figure 56-5 T-cell activation by superantigens. In the conventional response to bacterial antigens (bottom) the antigen is processed and presented by the antigen-presenting cell (APC) in association with MHC II. Only T cells with the correct antigen recognition site can then be activated (i.e. this is a highly antigen-specific process). Superantigens (top) are able to bypass this process by bridging between MHC II and the Vß subunit of the T-cell receptor. Thus the entire population of T cells expressing that particular Vß subunit can be activated; this can be up to 20% of the

total T-cell population. *Adapted from Sriskandan and Cohen. The pathogenesis of septic shock. J Infect 1995;30:201–6.*

Arachidonic acid metabolites

Thromboxane A_2 and prostaglandins are released via the cyclo-oxygenase pathway and leukotrienes through the action of lipoxygenases. LPS and other mediators can activate increased synthesis and release of cyclo-oxygenase and lipoxygenase products in sepsis.[28] Broadly speaking, prostaglandins (PGs), particularly PGE_1 and PGI_2 , have beneficial effects in sepsis by reducing procoagulant activity and improving tissue perfusion. Thromboxane and leukotrienes, however, are largely deleterious and have been particularly implicated in the pathogenesis of adult respiratory distress syndrome (ARDS). In the complicated setting of septic shock it is difficult to assess the contribution of individual arachidonic acid metabolites to the overall clinical picture.

Platelet-activating factor

Platelet-activating factor (PAF) is a potent phospholipid mediator produced by a variety of cell types — monocytes, neutrophils, platelets and endothelial cells — during severe sepsis. It enhances neutrophil chemotaxis, primes neutrophils for superoxide release and increases thromboxane synthesis in the lung. In animal models, infusion

TABLE 56-3 -- Important mediators in sepsis.

IMPORTANT MEDIATORS IN SEPSIS		
Target	**Proinflammatory mediators**	**Inhibitory or counter-regulatory mediators**
Monocyte/macrophage	TNF-a, IL-1, IL-8, IL-6, IL-12, IFN-?, tissue factor, prostanoids, leukotrienes, PAF, NO	IL-1ra, sTNFr, TGF-ß
Neutrophils	Integrin expression, superoxide production	BPI, CAP 57, defensins, acyloxyacylhydolase
Lymphocytes	IFN-?, IFN-ß, IL-2	IL-4, IL-10, sIL2r
Endothelia	Selectins, VCAM, ICAM, NO, tissue factor	TFPI
Platelets	Serotonin, prostanoids	PDGF
Coagulation pathway	Tissue factor, coagulation cascade leading to thrombin generation	TFPI, AT-III, PAI
Plasma components	Complement activation, bradykinin	Lipoprotein complexes, LBP, CRP

AT-III, anti-thrombin III	PAF, platelet-activating factor
BPI, bacterial/permeability-increasing protein	PAI, plasminogen activator inhibitor
CRP, C-reactive protein	PDGF, platelet-derived growth factor
ICAM, intercellular adhesion molecule	sIL-2r, soluble IL-2 receptor
IFN-?, interferon-?	sTNFr, soluble TNF receptor
IL, interleukin	TGF-ß, transforming growth factor ß
IL-1ra, interleukin-1 receptor antagonist	TNF-a, tumor necrosis factor a
LBP, lipopolysaccharide-binding protein	TFPI, tissue factor pathway inhibitor
NO, nitric oxide	VCAM, vascular cell adhesion molecule

Figure 56-6 Interaction of inflammatory pathways in severe sepsis. ARDS, adult respiratory distress syndrome; IFN-?, interferon-?; IL, interleukin; IL-1Ra, interleukin-1 receptor antagonist; LBP, LPS-binding protein; LPS, lipopolysaccharide; NO, nitric oxide; TGF-ß, transforming growth factor-ß; sTNFr, soluble TNF receptor.

of PAF leads to a sepsis-like state, and in particular can cause the pathophysiologic changes of ARDS. Increased levels of PAF can be detected in sepsis, and experimental strategies directed against PAF have been developed.[28]

Complement

The complement system exists to provide an immediate and non-specific host response to a variety of invading pathogens. Activation of complement leads to a proteolytic cascade resulting in the liberation of molecules that can act as opsonins, chemoattractants and also mediate bacterial lysis. LPS and other bacterial products activate complement by the alternative pathway. Massive local activation of complement during sepsis will fuel the inflammatory response by recruiting neutrophils, and through the activation of kinins and histamine will contribute to increased endothelial permeability and capillary leakage.[29] In addition, complement-mediated lysis of bacteria, by releasing endotoxin and other bacterial products, can exacerbate the septic response to infection.[30]

Coagulopathy

Widespread activation of the coagulation pathways leading to disseminated intravascular coagulation (DIC) is a serious consequence of severe sepsis.[31] Endotoxin and other bacterial products directly activate components of the coagulation system and also indirectly activate coagulation via activation of tissue factor on endothelial surfaces and release of kinins and proinflammatory cytokines. In addition to the direct effects of DIC, the widespread activation of coagulation factors and damage to the microvasculature further impairs endothelial function and exacerbates capillary leak. The development of coagulopathy and endothelial dysfunction is recognized as central to tissue damage and organ failure in severe sepsis.

Nitric oxide

Nitric oxide (NO) may be involved in the pathophysiology of sepsis through a number of mechanisms.[32] First, NO is a free radical and has the ability to kill phagocytosed organisms in rodents, although the importance of this action in humans is not clear. Second, NO is a potent vasodilator and a basal level of NO is required for the maintenance of normal arteriolar tone. Synthesis of NO is increased by a number of bacterial products, including LPS and cytokines. In particular, TNF-a, IL-1 and IFN-? appear to increase NO synthesis synergistically. Sepsis is characterized by widespread peripheral vasodilatation and loss of the normal regulation of tissue blood flow. There is considerable experimental evidence in animals to suggest that the vasodilatation in sepsis is mediated by increased NO levels. In humans, elevated urinary nitrite levels are found in sepsis/SIRS, implying increased NO synthesis.

Neutrophil-endothelial cell interactions

An early response to the local production of inflammatory mediators is the upregulation of adhesion molecules on endothelial cells and the release of chemokines that recruit neutrophils and other inflammatory cells to the site of infection. This is a key event in the successful containment of infection; for example, patients with leukocyte adhesion deficiency have neutrophils that cannot cross the endothelium and suffer from recurrent bacterial infection. Exposure of neutrophils to LPS and

some cytokines enhances the ability of neutrophils to release inflammatory molecules and primes neutrophils for the generation of oxygen radicals and proteolytic enzymes. These mechanisms enable neutrophils to survive longer in an inflammatory environment and to kill more bacteria, but excessive activation of endothelial adhesion may result in the migration of primed activated neutrophils into sites distant from infection. The ensuring tissue damage stimulates a vicious cycle of re-recruitment of inflammatory cells that may ultimately lead to organ damage and failure.

Endogenous anti-inflammatory mediators in sepsis

In addition to the large number of proinflammatory mediators induced during severe sepsis a growing number of counter-regulatory mediators have been discovered (Fig. 56.6 and Table 56.3). They have specific actions and may neutralize or detoxify bacterial products, block the synthesis or release of cytokines, or downregulate cell responses to inflammatory stimuli. Indeed, the notion that sepsis resulted from an uncontrolled pro-inflammatory 'storm' has given way to the recogition that later in the disease it is anti-inflammatory response that dominates. Indeed, some investigators believe that septic patients become effectively 'immunocompromised' and that immunostimulatory therapy is indicated.[33]

Interaction of mediators in sepsis

As already discussed there is no single central mediator, but rather a complex network of inflammatory responses to infection, which can in certain circumstances result in sepsis as depicted in Figure 56.6 . Once activated, these mediators induce further inflammatory responses in what has been referred to as the 'sepsis cascade', leading to tissue damage and eventually death. However, these same inflammatory processes trigger another complicated network of counter-regulatory or anti-inflammatory mediators, such as the IL receptor antagonist (IL-1ra) and soluble TNF receptors (sTNFr). Thus, it is the balance between these opposing mechanisms that will determine whether inflammation is successful in eliminating infection and then 'shutting down', or progressing so that healthy tissues become victims of 'friendly fire'. The complexity of this interaction can be seen by examining cytokine patterns in meningococcal disease. The risk of death in meningococcal disease is closely related to cytokine levels at presentation and those with the highest TNF-a levels do poorly. Thus one could hypothesize that people who produce less TNF-a have a survival advantage. However, an elegant study that examined whole blood responses measuring TNF-a (proinflammatory) and IL-10 (anti-inflammatory) release in response to meningococcal LPS in the relatives of survivors and nonsurvivors of meningococcal disease,[34] found that the relatives of survivors had a high TNF-a/IL10 ratio in comparison to the relatives on the nonsurvivors. Therefore maintaining a strong proinflammatory response appears to protect against overwhelming meningococcal infection.

Pathophysiologic events leading to organ failure in sepsis

How do the complicated and often confusing inflammatory responses outlined above lead to tissue damage and eventually multiorgan failure? At the cellular level, the end-result of the inflammatory process is cell death and there is increasing evidence that apoptosis is an important pathological event.[33] In the whole organism the key to organ damage lies in the breakdown of normal vascular homeostasis, leading to tissue hypoxia as described in Figure 56.7 . All organs may be affected, but clinically the most important are depressed myocardial function, alterations in the peripheral vasculature and failure of oxygen exchange in the lung.

Cardiac function

Initially when peripheral vasodilatation occurs in sepsis there is a compensatory rise in cardiac output (Table 56.4). However, the increase in cardiac output is often less than that predicted and it is recognized that most patients who have severe sepsis have impaired myocardial function. Cumulative evidence suggests that the impairment of myocardial contractility seen in sepsis is a consequence of circulating cytokines. TNF-a directly reduces myocyte contractility

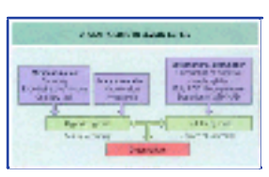

Figure 56-7 Organ failure in severe sepsis. Organ dysfunction and finally organ failure is the result of cellular hypoxia and acidosis. Hypoxia and acidosis result both from a failure of oxygen delivery due to disturbances in circulation and limitation of the cellular ability to use oxygen as a result of mitochondrial dysfunction.

TABLE 56-4 -- Hemodynamic changes in severe sepsis.

HEMODYNAMIC CHANGES IN SEVERE SEPSIS		
Parameter	**Normal range**	**Changes in severe sepsis**
Heart rate (HR)	72–88 beats/min	Sinus tachycardia
Mean arterial pressure (MAP)	70–105mmHg	Hypotension <60mmHg
Cardiac output (CO)	4–8L/min	Increased but not enough to compensate for low SVR
Systemic vascular resistance (SVR)	800–1500dyne/s/cm^2	Reduced (<600 if no pressor agents)
Oxygen delivery (DO_2)	520–720ml/min/m^2	Decreased
Oxygen consumption (VO_2)	100–180ml/min/m^2	Typically increased
CO = SV × HR, SVR = (MAP - CVP)/CO × 79.92		
Do_2 = CI × arterial oxygen × 10, Vo_2 = CI × (arterial - venous oxygen) × 10		
CI, cardiac index (CO/m^2 surface area); CVP, central venous pressure; SV, stroke volume.		

and induction of myocardial NO synthesis by cytokines also impairs myocardial function. Recent data suggest that elevated troponin levels occur in some patients with severe sepsis, indicating that direct myocardial damage may be a factor.[35]

Peripheral vasculature

The hallmark of severe sepsis is widespread peripheral vasodilatation, and, in refractory septic shock it may resist all attempts at pharmacologic intervention. As mentioned earlier, this is largely the consequence of increased NO production in response to cytokines. The most serious consequence of the vasodilatation is the loss of homeostatic regulation of tissue bloodflow. Thus, much of the circulating blood volume is shunted through capillary beds, bypassing deep tissues and reducing the opportunity for oxygen extraction. This in turn exacerbates tissue hypoxia and helps to drive the metabolic acidosis that is one of the prominent features of severe sepsis. Further local impairment of perfusion may occur as the result of aggregation of platelets and activation of coagulation in the microcirculation.

Respiratory failure

The lung is one of the most vulnerable organs in sepsis, and TNF-a, PAF, C5a, IL-8 and thromboxane appear to play prominent roles in the development of ARDS. The passage of neutrophils across the endothelium and subsequent degranulation in the lung interstitium leads to impairment of endothelial integrity and the accumulation of fluid and inflammatory cells in the alveolar spaces. Impaired gas exchange inevitably produces hypoxia, which further worsens the situation. The combination of hypoxia and increased pulmonary thromboxane synthesis increases pulmonary vascular resistance, in contrast to the fall in systemic vascular resistance. Thus the end-result of the pulmonary events in sepsis is the development of interstitial edema and pulmonary hypertension, the hallmarks of ARDS.

PREVENTION

The morbidity, mortality rate and hospital costs associated with sepsis demand that strenuous efforts must be made to reduce the incidence of this serious disease. These can be divided into three main areas:

¦ assiduous infection control for high risk patients;
¦ the use of prophylactic antibiotic therapies; and
¦ prompt recognition and treatment of infection

Details of infection control policies are outlined elsewhere (see Chapter 87), but it is worth re-emphasizing that many cases of sepsis are acquired in hospital, particularly in the ICU, and that nosocomial sepsis has a much higher mortality rate than community-acquired sepsis. It has been estimated that up to one-third of cases of nosocomial infections are preventable and a multidisciplinary approach to infection control can lead to significant reductions in ICU pneumonia and sepsis.

Antibiotic prophylaxis has a limited role in sepsis prevention, but it is important to recognize patients who have risk factors for developing sepsis, for example manipulation of the urinary tract in the presence of active infection, and to administer appropriate antimicrobial therapy. Principles of antibiotic prophylaxis are covered elsewhere (see Chapter 3).

Even where infection cannot be prevented it may still be possible to minimize the mortality rate associated with severe sepsis through the early recognition and management of patients. Intervening once refractory shock and multiorgan failure are established is simply too late for may patients.

CLINICAL FEATURES

A rigorous history, physical examination and directed investigations are essential to arrive at the correct diagnosis of any infectious disease. However, severe sepsis and shock is a medical emergency and therefore full assessment may have to be delayed until resuscitation and empiric antimicrobial therapy have been commenced. The aims of clinical evaluation are to establish the diagnosis of sepsis, estimate disease severity and prognosis, and elucidate the underlying cause. Although sepsis has many features common to most cases, the exact presentation will depend on the site of infection, the nature of the infecting organism, the host response and coexistent illness. Therefore, in the elderly and other immunocompromised groups the physical signs and some of the laboratory parameters that suggest sepsis may be absent; in this group it is important to consider sepsis in the differential diagnosis of any unexplained illness.

History and symptomatology

Symptoms that suggest the onset of sepsis are often nonspecific and include sweats, chills or rigors, breathlessness, nausea and vomiting or diarrhea, and headache. Confusion may be found in 10–30% of patients, especially the elderly.[36] There may be specific symptoms to suggest the underlying pathology, such as cough, dysuria or meningism, but in many cases there are no clues. Other important points to elicit that may give an indication of the diagnosis or help in choosing empiric therapy include recent travel, contact with animals, local infectious disease outbreaks, recent surgical procedures, indwelling prosthetic devices, previous antibiotics, underlying pathology and immunosuppressive illness or medication (see Fig 56.1). For the critically ill patient such details are often unavailable, and it may be helpful to speak to relatives or the patient's primary care physician.

Physical signs on examination

In its simplest form sepsis simply refers to the physiologic response to infection. With progression to severe sepsis and shock there is increasing evidence of organ dysfunction; the key physical signs and physiologic changes indicating this are encapsulated in Table 56.1 . Remember that sepsis is a dynamic evolving clinical picture and frequent evaluation and monitoring of the patient is essential.

The characteristic patient is febrile, tachypneic, tachycardic with warm peripheries and a bounding arterial pulse, hypotensive, disoriented

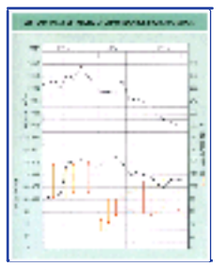

Figure 56-8 Systemic manifestations of Gram-negative bacterial sepsis. Observation chart of a 49-year-old woman admitted to hospital with a suspected drug fever. For the first 24 hours she was observed without antimicrobial chemotherapy and demonstrated a persistent fever and tachycardia (sepsis). At this point she suddenly became confused, hypotensive and oliguric indicating the development of severe sepsis. The underlying cause was an *Escherichia coli* bacteremia from an unsuspected urinary tract infection. She responded to fluid replacement and antibiotics and made a full recovery.

Figure 56-9 Toxic shock syndrome. A 30-year-old woman presented with a short history of fever, breathlessness, diarrhea and abdominal pain. She was pyrexial and hypotensive with a blanching macular rash noted on day 2. Blood cultures grew a Group A ß-hemolytic streptococcus. Laparotomy revealed 800ml of peritoneal pus with no intestinal perforation consistent with spontaneous bacterial peritonitis. She required ventilatory support plus inotropes to maintain blood pressure for 6 days and developed evidence of disseminated intravascular coagulation (DIC) and adult respiratory distress syndrome (ARDS). She made a gradual recovery complicated by an enterococcal urinary tract infection, finally leaving hospital 27 days after presentation. The group A streptococcal isolate from her blood was subsequently shown to release streptococcal mitogenic exotoxin Z (SMEZ) a potent superantigen. *Courtesy of P Gothard and S Sriskandan, Hammersmith Hospital, London.*

and oliguric. The observation chart of one such patient is shown in Figure 56.8 and the clinical course of another in Figure 56.9 . Some patients have a much more subtle presentation necessitating a high index of suspicion to recognize early disease. Although most patients are febrile, severe sepsis may present with hypothermia. A detailed physical examination is vital and it is important to examine the skin, all wounds and the fundi, and to perform full ear, nose and throat, and rectal and vaginal examinations because these sites are often overlooked and may hold valuable clues to the diagnosis (e.g. a retained vaginal tampon in the toxic shock syndrome). In the hospitalized patient and the ICU patient who develops sepsis, it is necessary to pay particular attention to indwelling intravenous and intra-arterial lines, insist on exposing and examining all wounds, and carefully review the pressure areas because these are frequently neglected sources of infection.

Occasionally, the physical examination will directly establish the diagnosis; helpful signs include the purpuric rash or peripheral gangrene of meningococcemia (Fig. 56.10a), peripheral emboli in endocarditis (Fig. 56.10b), the erythematous rash or desquamation in staphylococcal or streptococcal toxic shock (Figs. 56.11), ecthyma gangrenosum in patients who have neutropenia and *P. aeruginosa* bacteremia, or the retinal lesions of *Candida* endophthalmitis. Focal physical signs may help to identify the site of infection, for example renal angle tenderness, pulmonary consolidation, new cardiac murmur or finding an intra-abdominal mass, but in many cases the site of the infection remains uncertain.

If the patient is hypotensive, other causes of shock such as cardiac dysfunction (including myocardial infarction and cardiac tamponade), hypovolemia and redistributive shock from pancreatitis and physical injuries need to be considered. Invasive physiologic measurements are often used to distinguish between these (see below), but it is important to remember that the hypotension seen in sepsis is often multifactorial and sepsis may complicate or coexist with other causes of shock. Thus such invasive measurements must not be interpreted in isolation, but should be reviewed in the context of the whole clinical picture.

Figure 56-10 Cutaneous changes in meningococcal infection. (a) Petechial hemorrhages are the hallmark of meningococcal infection and may be found on the periphery or

as in this case the conjunctivae. (b) In severe disease the purpura may become confluent (purpura fulminans) and lead to severe digital gangrene. *Courtesy of J Cohen, Brighton.*

DIAGNOSIS

Laboratory investigations

Laboratory investigations can be broadly divided into those that help to confirm that the patient has sepsis and detect and follow complications such as organ failure, and those that establish the underlying cause.

Hematologic and biochemical evaluation in sepsis

Full blood count and blood film

Look for leukopenia or a neutrophil leukocytosis. The blood film may suggest bacterial infection with toxic granulation of neutrophils (increased band forms) even when the white cell count is within the normal range. Leukopenia at presentation is a poor prognostic sign. Low platelet count suggests DIC and evidence of microangiopathic hemolysis may be visible. In patients who have traveled to an endemic area, three separate thick and thin films for malaria parasites are required.

Coagulation screen

Look for evidence of DIC — prolonged prothrombin or activated partial thromboplastin time, low fibrinogen and elevated markers of fibrinolysis (fibrin degradation products or D-dimer levels).

Electrolytes and renal function

It is essential to monitor renal function closely. Elevated potassium may indicate rhabdomyolysis, which can occasionally complicate severe sepsis.

Liver function tests

Minor abnormalities are very common in patients who have bacteremia and sepsis, and do not necessarily signify a hepatic source of infection. Rises in bilirubin, alkaline phosphatase or transaminases of two to three times the normal level may be seen in up to 30–50% of patients.[37] These are generally transient and not of prognostic importance. More markedly abnormal liver function suggests the possibility of underlying hepatic or biliary tract infection, particularly if the pattern of liver enzymes suggests biliary obstruction. Progressively deteriorating liver function in patients who have sepsis suggests hepatocellular damage or acalculous cholecystitis, which may occur as complications of severe sepsis.

Plasma albumin

In patients who have severe sepsis an acute fall in albumin, to as low as 1.5–2.0g/dl (15–20g/l) over 24 hours, may occur as a result of widespread endothelial damage and capillary leakage of protein. In patients who have chronic underlying illness or prolonged infection, the albumin falls as a result of poor nutrition and a switch in hepatic metabolism towards acute-phase proteins.

C-reactive protein

C-reactive protein (CRP) is an acute-phase reactant that rises within a few hours of bacterial infection. High levels are detectable in patients who have septic shock although a raised CRP does not reliably distinguish septic from nonseptic causes of shock. Procalcitonin levels are also elevated in bacterial infections and may be a more sensitive marker than CRP and are preferred in some centers.

Blood glucose

Hypoglycemia or hyperglycemia may occur in severe sepsis. In patients who are diabetic, normalization of blood glucose is essential in helping to control the infection.

Plasma lactate

Plasma lactate is often increased three- to fivefold in severe sepsis (normal 1.0–2.5mmol/l) and relates to the degree of tissue hypoxia. Lactate estimations may be helpful in both confirming the diagnosis and in monitoring the response to therapy.

Arterial blood gases

Typically a respiratory alkalosis is seen early and metabolic acidosis late. The degree of acidosis is a marker of the severity of illness. The onset of hypoxia indicates severe disease and a high risk of ARDS. Measurement of venous and arterial oxygen content allows calculation of oxygen delivery and consumption (see below).

Other biochemical investigations

Amylase, creatinine phosphokinase, calcium and magnesium levels should be measured at baseline.

Endotoxin or cytokine levels

In some but not all studies plasma levels of endotoxin and cytokines such as TNF-a and IL-6 have correlated with outcome of Gramnegative sepsis. [38] [39] Variation in reported data along with technical difficulties in performing these assays in real time makes routine testing impractical at present.

Microbiologic investigations in sepsis

Ideally, cultures should be taken before initiating antibiotic therapy, but treatment is urgent and should not be unduly delayed.

Blood cultures are the most important microbiologic investigation. Two or three separate blood cultures (total 20–30ml of blood) should be inoculated into one of the standard commercial blood culture media. Culturing an inadequate volume of blood is the most common reason for not detecting bacteremia.[40] The bottles should be incubated aerobically and anaerobically at 98°F (37°C), preferably agitated, for 7 days. The development of automated blood culture analysis allows for more rapid

identification of positive cultures. Where there is a high risk of underlying fungal infection then specific fungal media may be helpful.

Sputum and urine microscopy and culture should be performed in all cases. All wounds should be swabbed and sterile body sites such as cerebrospinal fluid (CSF), joint or pleural fluid sampled as indicated. In cases in which toxic shock syndrome is suspected, wound, nose, throat and vaginal swabs should be taken. If staphylococci or streptococci are isolated in cases of toxic shock then the appropriate reference laboratories can assay the isolate for toxin production. Cultures should be repeated as directed by previous results and the condition of the patient.

Histopathologic changes in sepsis

Organ pathology in sepsis is due to the combined effects of hypoxia, impairment in tissue perfusion and severe acidosis. In the lung the changes are those of ARDS, with early findings of interstitial and alveolar edema, fibrosis developing at a later stage. The kidneys may show acute tubular necrosis that is generally reversible (Fig. 56.12). Hepatic changes are of an ischemic zonal necrosis and some cases may develop an acalculous cholecystitis. In the brain there may be areas of focal ischemia or hemorrhage. In severe cases of septic shock associated with *Neisseria meningitidis* infection there may be peripheral gangrene due to severe impairment of perfusion (see Fig. 56.10) and hemorrhage into the adrenal glands (Fig. 56.13). The gut is also affected by ischemia and may show mucosal ulcerations and areas of infarction.

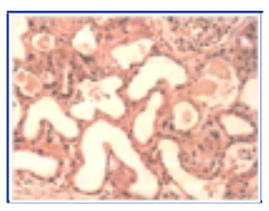

Figure 56-12 Acute tubular necrosis. The tubules are dilated with flattened epilithial cells, and contain debris; the glomerulus is not greatly affected. Hematoxylin and eosin. *With permission from Williams JD et al., Clinical Atlas of the Kidney. London: Mosby.*

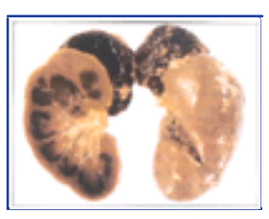

Figure 56-13 Acute hemorrhagic necrosis of the adrenal glands (Waterhouse-Friderichsen syndrome). Both adrenal glands of a child with meningococcal septicemia show hemorrhagic necrosis leading to acute adrenal failure. *With permission from Stevens A, Lowe J. Pathology. London: Mosby; 1995.*

Figure 56-14 Radiologic detection of occult foci of infection in severe sepsis. Plain abdominal radiograph in a diabetic with an *Escherichia coli* urinary tract infection and pyelonephritis who had developed hypotension and oliguria. The radiograph reveals gas around the kidney due to a perinephric abscess requiring urgent drainage.

Radiologic investigations

Chest radiography is necessary in all cases and may show signs of ARDS other studies may be indicated. Radiologic investigations can be of great help in identifying occult sites of infection (Fig 56.14), and close liaison with the diagnostic radiology department is vital. Ultrasound and computed tomography are particularly useful when trying to detect deep abscesses; in selected cases, nuclear medicine techniques may pinpoint the site of infection. Access to an interventional radiologist who can perform percutaneous sampling and drainage of sites of infection is invaluable.

MANAGEMENT

The mortality rate from sepsis and multiorgan failure remains high, but by early recognition and prompt therapeutic intervention patients can be prevented from progressing down this path. Guidelines on the management of severe sepsis and septic shock have been produced by the International Sepsis Forum.[41]

There are four therapeutic goals:

- to treat underlying infection;
- to preserve vital organ perfusion;
- to maintain tissue oxygenation; and
- to avoid complications.

Antibiotic chemotherapy

Studies of patients who have sepsis have identified the use of inappropriate empiric antibiotics (i.e. the infecting organisms were resistant to the antibiotics used) as being associated with a higher mortality rate.[42] In general it is accepted that the regimen used in severe sepsis should be bactericidal rather that bacteriostatic. There has been considerable debate regarding the use of monotherapy or combination therapy regimens in a number of infections, including sepsis. However, in studies in which appropriate empiric therapy has been employed it has been hard to demonstrate that any particular antibiotic or combination of antibiotics is superior. One exception may be in sepsis associated with necrotizing fasciitis due to streptococci where there are data to support the use of clindamycin in addition to penicillin.[25]

TABLE 56-5 -- Possible empiric antibiotic choice in severe sepsis.

POSSIBLE EMPIRIC ANTIBIOTIC CHOICE IN SEVERE SEPSIS	
Suspected site of infection	**Antibiotic**
Pneumonia	
Community-acquired	Cefotaxime + erythromycin
Hospital-acquired	Cefotaxime/ceftazidime alone or ureidopenicillin + aminoglycoside
Urinary tract	
Community-acquired	Amoxicillin + clavalunic acid (co-amoxiclav) or cefotaxime
Hospital-acquired	Ceftazidime alone or ureidopenicillin + aminoglycoside
Skin and soft tissue	
Community-acquired	Penicillin G (benzylpencillin) + nafcillin (flucloxacillin)
Hospital-acquired	Cefotaxime + nafcillin or cefotaxime + vancomycin
Intra-abdominal	Cefotaxime + metronidazole or ureidopenicillin + aminoglycoside or imipenem monotherapy
Biliary tract	Ureidopenicillin + aminoglycoside

Neutropenic	Ureidopenicillin + aminoglycoside or ceftazidime monotherapy

If the infecting organism has been identified and drug sensitivities determined, then the choice of antibiotics is comparatively easy. However, in most clinical situations empiric choice of appropriate antibiotic(s) is required. Table 56.5 provides a useful guide to antibiotic choice for the more common causes of sepsis, but it is not possible to recommend specific antibiotic regimens for all cases because of variations in infecting pathogens and antimicrobial resistance between hospitals. The decision regarding antibiotic choice should be made on the same principles as for any serious infection:

- clinical syndrome/likely microbiology;
- site of infection;
- risk of resistance based on local and national data;
- host factors including immunocompromise;
- comorbidities including organ function and drug allergy.

The antibiotic regimen should be reviewed every 24 hours in the light of the clinical situation and available microbiology data until the patient is clearly improving. There are few available data to give accurate guidance on the duration of therapy.

Antibiotic-induced endotoxin release.

Endotoxin is a major factor in the pathogenesis of shock due to Gram-negative bacteria. In experimental models, and some limited situations in humans, release of endotoxin from bacteria has been shown to increase the inflammatory response and different antibiotics vary in their capacity to induce endotoxin release from bacteria.[43] Thus, a school of thought has developed that antibiotics should be chosen on the basis of their potential to cause endotoxin release. However, beyond a handful of small studies there are few clinical data to support a major role for this hypothesis in severe sepsis. At present, antibiotics should be selected on the basis of efficacy for the specific clinical picture, rather than on the theoretic risk of endotoxin release.

Detection and removal of infected material

In addition to antimicrobial therapy it is essential to drain and remove all possible infective foci because these are often the cause

for treatment failure. Thus, abscesses should be drained, dead tissue resected and infected foreign material, such as an infected central venous catheter, removed. [44] The critically ill patient on intensive care may have repeated episodes of sepsis. Locating the underlying focus often requires considerable determination and patience and sometimes repeated discussions with surgical colleagues.

Supportive therapy

The central goal of supportive therapy is to try to maintain tissue oxygen delivery, a concept advanced by Shoemaker and others through the 1970s.[45] A full discussion of advanced techniques to preserve organ function in the critically ill patient is beyond the scope of this chapter, but the principles underpinning successful care are discussed here.[46] [47]

Ideally, patients who have sepsis should be closely monitored in an ICU or high-dependency unit. Indeed a review of 41 patients who had septic shock revealed an increased mortality rate when patients were managed outside an ICU, 70% versus 39%, even though the patients had less severe illness.[48] Minimal requirements for safe management include facilities for measurement of blood pressure, continuous cardiac monitoring, central venous pressure recording, rapid arterial blood gas analysis, continuous oxygen and facilities for assisted and mechanical ventilation or dialysis when required.

Invasive monitoring is useful in excluding other causes of shock such as hypovolemia and in directing supportive therapy. However, invasive monitoring is not a substitute for careful examination and assessment of the patient. Many factors such as cardiovascular disease, hypovolemia or inotropic drugs can confound such data; results must be interpreted in the context of the clinical situation. Normal values and the typical ranges for hemodynamic parameters in severe sepsis are given in Table 56.4 .

In the hemodynamic management of sepsis, the aim is to achieve sufficient arterial blood pressure for organ perfusion. This does not require normalization of blood pressure and generally can be achieved with a mean arterial pressure of 50–60mmHg. Sepsis is characterized by vasodilatation and widespread capillary leak and there is often significant depletion of intravascular volume, in which case correction of hypovolemia should be performed immediately. There is continuing debate about the ideal fluid replacement, and despite a number of systematic reviews this question is still unresolved.[49] Most clinicians use both colloid and crystalloid but avoid dextrans in sepsis because of an increased risk of bleeding. In practice, a balance must be kept between early aggressive fluid replacement, which is required to maintain tissue perfusion and organ function, and fluid overload, which may increase the risk of ARDS. Monitoring of central venous pressure and preferably pulmonary capillary wedge pressure is essential to achieve the correct balance. Pulmonary capillary wedge pressure measurements were routinely used but there has been some doubt over the safety and usefulness of pulmonary artery catheters in the critically ill patient.[50] As a result many ICUs have reduced their use of pulmonary catheters and monitor cardiac output and pulmonary artery pressure noninvasively. Blood transfusion is required in the event of hemorrhage or severe anemia (hemoglobin <9g/dl), but probably does not improve oxygen delivery in patients in whom hemoglobin is over 10g/dl.

If there is an inadequate response to volume replacement the use of inotropic/pressor agents is required. Impaired myocardial contractility responds to dobutamine (2–25µg/kg/min) or epinephrine (adrenaline, 2–8µg/min). However, it may be necessary to add pressor agents such as norepinephrine (noradrenaline, 2–8µg/min) or dopamine (2–25µg/kg/min) to raise peripheral resistance and increase blood pressure. No single regimen is effective for all patients and there is no consensus about the optimal combination or dosage of inotropic and pressor agents. Patients are best managed by repeated observation of response to different therapeutic measures.[47] Some patients develop resistance to catecholamines due to down-regulation of a and ß catecholamine receptors. Escalating concentrations of pressor agents are then needed to maintain blood pressure. In these patients low-dose corticosteroids may return catecholamine sensitivity. Vasopressin and terlipressin are also useful agents in this setting.

In established shock with multiorgan failure, poor perfusion and tissue oxygenation are the main factors. Patients require supplemental oxygen, and many need mechanical ventilation to maintain arterial oxygen saturation. Tissue hypoxia increases lactic acidosis, which further impairs cardiac and other functions. Experimental methods of extracorporeal oxygenation have been tried but none are in routine use.[51] Measurement of oxygen delivery (DO_2) and oxygen consumption (VO_2) (see Table 56.4) are employed in some ICUs to monitor the response to treatment. In severe sepsis VO_2 is increased and DO_2 is generally inadequate, which is often referred to as an 'oxygen debt'. If DO_2 and VO_2 are calculated then fluids, inotropes and oxygenation can be adjusted to attempt to achieve optimal oxygen delivery. Tissue hypoxia can also be measured directly using tonometry to follow gastric pH, by hepatic venous oxygen measurement and by muscle needle probes, but it is not clear whether routine use of these measurements will improve patient outcome.

The potential benefit of early aggressive supportive therapy is shown in a recent study by Rivers *et al.*[52] 263 patients with early sepsis seen in the emergency room were randomized to receive standard therapy or 'goal directed' therapy. Cardiac preload, afterload and contractility were actively managed to try and balance oxygen delivery with demand before admission to the ICU. The in-hospital mortality rate was reduced from 46.5% in the standard group to 30.5% in the goal-directed group ($p<0.009$). Further studies are required before these recommendations can be extended to other groups of septic patients.

Management of coagulopathy

Currently there is no universally accepted approach to the management of DIC in patients who have sepsis. For patients who have severe DIC, replacement of clotting factors with fresh frozen plasma or cryoprecipitate may be required to combat bleeding. However, it must be remembered that plasma also contains potentially pro-inflammatory components, such as complement, and that replacing the clotting factors may simply fuel the processes leading to DIC. Thus, patients should be treated with clotting factors not simply because of abnormal laboratory parameters but rather when there is a clear clinical indication.

Modulators of coagulation are protective in animal models of severe sepsis and some have entered human trials (Table 56.6). Of these recombinant activated protein C (rAPC) is most promising. In a phase III multicenter trial of rAPC versus placebo in 1690 patients with severe sepsis 28-day mortality rate was reduced from 30.8 to 24.7% ($p<0.005$). [53] This represents a relative reduction in risk of death of 19.4% and a number needed to treat to save one life of 16. Not surprisingly there was a

small but significant increase in serious bleeding in the active therapy group. On the basis of these results rAPC (drotrecogin alpha) was granted a limited product license for the treatment of severe sepsis in adults in the USA in early 2002. rAPC use is limited in most institutions to those with severe sepsis based on all of the following: a) known or suspected source of infection, b) evidence of a systemic response to infection and c) evidence of sepsis-related organ failure in two or more organ systems (using defination in Table 56.1). rAPC appears to have anti-inflammatory properties in addition to anticoagulant activity and the mechanism

TABLE 56-6 -- Adjunctive therapy for severe sepsis.

ADJUNCTIVE THERAPY FOR SEVERE SEPSIS	
Trial results	**Agents**
No benefit	Most anti-TNF monoclonal antibodies, soluble anti-TNF receptors, IL-1ra, pentoxyfylline
	Anti-LPS antibodies — ES, HA-1A
	Platelet factor antagonists, bradykinin antagonists, nonsteroidal anti-inflammatory drugs
	High-dose corticosteroids TFPI, AT-III
Possible benefit	Anti-LPS agents $rBPI_{21}$ in meningococcemia, E5331
	IVIG
	Anti-TNF MAb MAK 195f (Afelimomab)
	Plasma filtration, plasma exchange etc
Proven benefit	Insulin therapy
	rAPC
	Low-dose corticosteroids
AT-III, anti-thrombin III IL-1ra, interleukin-1 receptor antagonist IVIG, intravenous immunoglobulin LPS, lipopolysaccharide rAPC, recombinant activated protein C TFPI, tissue factor pathway inhibitor	
A multitude of approaches have been used to attempt to modify the course of sepsis and septic shock. The approaches listed above are those where sufficient human data are available to allow a judgment to be made.	

of protection in sepsis remains to be fully elucidated. The precise role for rAPC in patients with sepsis remains to be fully defined but it is likely that rAPC represents a major step towards effective immunotherapy.

Nutrition

Patients who have severe sepsis are extremely catabolic and it is very important to plan nutritional support and supplementation at an early stage. Unless there is a contraindication to oral feeding, nutrition should be given by the enteral route. Enteral feeding may help to protect the gut mucosa from ischemic damage in sepsis and to reduce bacterial translocation from the gut, which is thought to be involved in some episodes of sepsis. Parenteral nutrition increases the rate of secondary infections, particularly bacterial and fungal intravenous catheter infections, and so should be avoided if the gut is functional.

Corticosteroids in sepsis

There has been considerable controversy surrounding the use of corticosteroids in severe sepsis. In animal models pretreatment with corticosteroids protected against endotoxemia, and initial promising reports in humans lead to the widespread use of high-dose corticosteroids in sepsis. Subsequently two large multicenter trials failed to show benefit and meta-analyses of all suitable trials confirmed that the use of high-dose corticosteroids in sepsis is not of benefit and may potentially be deleterious by increasing rates of secondary infection.[54] However, impairment of the hypothalamic-pituitary-adrenal axis is seen in some patients with sepsis and is associated with a poor outcome. This has led to a re-evaluation of the role of lower-dose corticosteroid replacement therapy. Annane and colleagues have reported the results of a placebo-cntrolled randomized study of low-dose hydrocortisone and fludrocortisone in 300 patients with catecholamine-refractory septic shock.[55] 75% of patients in the active and placebo treatment groups were non-responders to synacthen. Beneficial effects of steroid replacement were confined to the synacthen non-responders with a significant reduction in pressor use (p=<0.001) and 28 day mortality (53% vs 63% P=<0.04). On the basis of this study it is reasonable to consider steroid replacement therapy in patients with catecholamine-resistant septic shock.

Intravenous immunoglobulin therapy

Intravenous immunoglobulin (IVIG) administration has been examined in bacterial sepsis with variable results.[56] In the case of toxic shock syndrome there is a rationale for the use of high-dose IVIG. Toxic shock is seen in persons with low levels of antitoxin antibodies and pooled IVIG contains neutralizing antibodies against a variety of superantigenic toxins. Experimental data and anecdotal reports would support the use of IVIG in this setting, but there are as yet no substantial clinical trials.[25]

Insulin therapy

As mentioned earlier assiduous control of the blood glucose level is essential in diabetic patients with severe sepsis. A recent study has suggested that insulin may be beneficial in nondiabetic adults with critical illness, including sepsis.[57] These are early data and should be viewed with caution, but if confirmed this approach could enter clinical practice.

Adjunctive therapy for sepsis

Despite all the therapies available, the mortality rate of established septic shock and organ failure remains high. The concept that organ damage in sepsis is the result of the host inflammatory response has lead to an enormous research effort to understand and intervene in this process. Many therapeutic strategies have been investigated in the laboratory setting and the past decade has seen large randomized clinical trials of some of the more promising agents. This has highlighted the difficulties inherent in performing interventional studies in sepsis and initial results have often been conflicting and disappointing. A full discussion of these approaches cannot be considered here but a brief summary of the current situation is given in Table 56.6 . The apparent success of rAPC and early results with other coagulation modulators suggests that this will be a fruitful therapeutic area. However, it must be stressed that attention to detail, good quality patient care and the early recognition and management serious infection can save many lives.

Chapter 57 - Infections of Vascular Devices

Christopher J Crnich
Dennis G Maki

INFECTIONS OF PERCUTANEOUS INTRAVASCULAR DEVICES

The use of percutaneous intravascular devices (IVDs) for the delivery of fluids, blood products and medicines as well as for hemodynamic monitoring has become an essential component of modern health care. Unfortunately, these devices are associated with a considerable and often underappreciated risk of bloodstream infection (BSI). Data from hospitals participating in the US National Nosocomial Infections Surveillance system suggest that the risk of primary BSI, most of which derive from central venous catheters (CVCs) of one form or another, ranges from 2.9 to 9.7 BSIs per 1000 CVC-days, depending on the type of medical unit,[1] and it is estimated that 250,000 to 500,000 IVD-related BSIs (IVDR BSIs) occur in the USA each year.[2] The prevention of IVDR BSI must be a high priority as studies have shown that these infections prolong hospitalization, increase health care expenditures to nearly US$40,000 for survivors[3] and, most importantly, are associated with significant attributable patient mortality. [2]

TABLE 57-1 -- Rates of bloodstream infection caused by the various types of devices used for vascular access.*

RATES OF BSI CAUSED BY THE VARIOUS TYPES OF DEVICES USED FOR VASCULAR ACCESS				
Catheter type	**Rates of device-related BSIs per 100 catheters**		**Rates of device-related BSIs per 1000 catheter days**	
	Pooled mean	**95% CI**	**Pooled mean**	**95% CI**
Peripheral venous cannulas				
Plastic catheters	0.2	0.1–0.3	0.6	0.3–1.2
Steel needles	0.4	0.0–2.3	1.6	0.0–9.1
Cutdowns	3.7	0.1–20.6	8.8	0.2–49.3
Arterial catheters used for hemodynamic monitoring	1.5	0.9–2.4	2.9	1.8–4.5
Central venous catheters				
Standard noncuffed, nonmedicated	3.3	3.3–4.0	2.3	2.0–2.4
Antibiotic coated	0.2	0.0–1.0	0.2	0.1–1.4
Control nonmedicated	4.4	3.5–5.5	—	—
Antiseptic-impregnated	3.1	2.4–3.9	2.9	2.3–3.7
Control nonmedicated	3.8	1.5–7.8	—	—
Peripherally inserted central catheters (PICCs)	1.2	0.5–2.2	0.4	0.2–0.7
Silver-impregnated cuffs	3.3	1.9–5.4	3.2	1.9–5.3
Tunneled but noncuffed	12.4	10.7–16.6	1.8	1.4–2.0
Pulmonary-artery catheters	1.9	1.1–2.5	5.5	3.2–12.4
Heparin-bonded	0.4	0.2–0.9	2.6	1.1–5.2
Hemodialysis catheters				
Noncuffed	16.2	13.5–18.3	2.8	2.3–3.1
Cuffed	6.3	4.2–9.2	1.1	0.7–1.6
Tunneled and cuffed central venous catheters	20.9	18.2–21.9	1.2	1.0–1.3
Subcutaneous central venous ports	5.1	4.0–6.3	0.2	0.1–0.2
Peripherally inserted central ports	0.0	0.0–2.8	0.0	0.0–0.1
Intra-aortic balloon counter-pulsation devices	1.9	0.9–3.6	5.5	2.5–10.5
Left ventricular assist devices	22.5	17.5–28.5	4.5	3.6–5.7
Based on 206 published prospective studies in which every device was evaluated for infection.

EPIDEMIOLOGY

A large variety of IVDs are employed in the care of hospitalized and, increasingly, nonhospitalized patients, including long-term devices for indefinite vascular access, which are used for total parenteral nutrition, outpatient antibiotic therapy or frequent drawing of blood. All IVDs carry some risk of causing BSI although the magnitude of risk varies by the type of device used (Table 57.1). Peripheral intravenous catheters, which typically remain in place for no more than 3–4 days, are associated with a very low risk, =0.2 BSIs per 1000 catheter-days.[4] In contrast, CVCs, which often remain in place for weeks, are associated with far higher rates of infection, in the range of 1.9–16.3 BSIs per 1000 CVC-days (see Table 57.1).[4] Surgically implanted IVDs, such as tunneled and cuffed Hickman or Groshong catheters as well as subcutaneous central venous ports, are associated with much lower rates of infection, in the range of 0.2–1.2 BSIs per 1000 IVD-days.[4] Contrary to popular belief, arterial catheters and peripherally inserted central catheters (PICCs) carry a considerable risk of infection (see Table 57.1) that may approach that seen with noncuffed and nontunneled CVCs. [4] The majority of

TABLE 57-2 -- Risk factors for intravascular device-related bloodstream infection.*

RISK FACTORS FOR IVDR BSI		
Risk factors (number of studies)		**Relative risk or odds ratio**

Patient characteristics	Underlying disease:	
	AIDS (2)	4.8
	Neutropenia (2)	1.0–15.1
	Gastrointestinal disease (1)	2.4
	Surgical service (1)	4.4
	Placement in intensive care unit or coronary care unit (3)	0.4–6.7
	Extended hospitalization (3)	1.0–6.7
	Other intravascular devices (2)	1.0–3.8
	Systemic antibiotics (3)	0.1–0.5
	Active infection at another site (2)	8.7–9.2
	High APACHE III score (1)	4.2
	Mechanical ventilation (1)	2.0–2.5
	Transplant patient (1)	2.6
Features of insertion	Difficult insertion (1)	5.4
	Maximal sterile barriers (1)	0.2
	Tunneling (2)	0.3–1.0
	Insertion over a guidewire (8)	1.0–3.3
	Insertion site:	
	Internal jugular vein (6)	1.0–3.3
	Subclavian vein (5)	0.4–1.0
	Femoral vein (2)	3.3–4.8
	Defatting insertion site (1)	1.0
	Use of multilumen catheter (8)	6.5
Catheter management	Routine change of iv set (2)	1.0
	1:2.0	61.5
	1:1.5	15.6
	1:1.2	4.0
	1:1	1.0
	Inappropriate catheter usage (1)	5.3
	Duration of catheterization >7 days (5)	1.0–8.7
	Colonization of catheter hub (3)	17.9–44.1
	Parenteral nutrition (2)	4.8

** Adapted from Safdar et al., 2002.*[69]

endemic nosocomial BSIs are primary, and most originate from an IVD, while a smaller number are secondary and stem from a local nonvascular site, such as ventilator-associated pneumonia or postsurgical site infection,

Whatever type of IVD is used, a variety of factors during IVD insertion and individual patient characteristics can have a profound impact on the risk for IVDR BSI (Table 57.2).

PATHOGENESIS

Micro-organisms that cause IVDR BSI may gain access to the blood-stream by a variety of routes (Fig. 57.1). A preponderance of evidence suggests that infections of short-term catheters (in place for less than 10 days) derive from cutaneous colonization of the insertion site, with centripetal migration along the extraluminal surface of the catheter. [3] Accumulating evidence suggests that long-term catheters (in place for 10 days or longer) most often become infected intraluminally, by micro-organisms that contaminate the hub or gain access to fluid infused through the catheter.[5] Less commonly, organisms may infect IVDs hematogenously, from remote sites of infection.[3] Outbreaks of IVDR BSI derive mainly from intrinsically or extrinsically contaminated infusate.[3]

An IVD is a foreign body that impairs local immune function and further provides an attractive surface to which micro-organisms can readily adhere to form a complex biofilm. After implantation, host proteins, including albumin, fibrinogen, fibrin, fibronectin and platelets, rapidly coat vascular catheters, providing an attractive surface for microbial adherence.[6]

Most micro-organisms that cause IVDR BSI produce large quantities of extracellular polysaccharide matrix (slime).[7] The combination of host proteins in intimate association with microcolonies of the infecting organism, embedded in exoglycocalyx, comprises a unique micro-ecosystem, the biofilm.[8] The extraordinary capacity of the biofilm to produce refractory infection has been demonstrated in studies showing that concentrations of a bactericidal antibiotic 100–1000 times those effective against the planktonic phase of the organism do not kill the micro-organisms within a biofilm.[9] Thus, although antimicrobial therapy is often effective in resolving the acute features of IVDR infection, such as local inflammation and fever, antimicrobial therapy alone rarely kills the indolent sessile organisms within the deepest layers of an implant-associated biofilm. This explains why it is usually necessary to remove an infected IVD to control the infection reliably.

MICROBIOLOGY

Figure 57.2 summarizes the microbial profile of IVDR BSI from 159 published prospective studies. [10] As might be expected, skin micro-organisms account for the largest proportion of IVDR BSIs.

PREVENTION

Considerable evidence has accumulated over the past two decades affirming the efficacy of specific infection control practices and novel technologies for reducing the risk of IVDR BSI. This information has been incorporated into the 2002 Centers for Disease Control and

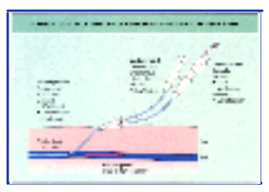

Figure 57-1 Potential sources of infection of a percutaneous intravascular device (IVD). These include contiguous skin flora, contamination of the catheter hub and lumen, contamination of infusate and hematogenous colonization of the IVD from distant, unrelated sites of infection. HCW, health care worker. *From Crnich and Maki.*[23]

Prevention Hospital Infection Control Practices Advisory Committee (HICPAC) Guideline for Prevention of Intravascular Catheter-Related Infections (Table 57.3).[11] With more consistent application of these guidelines, the incidence of CVC-related BSI in intensive care units in the USA has dropped by nearly 40% over the past decade.[12]

Given the pre-eminent role of skin micro-organisms in the pathogenesis of IVDR BSIs, it would seem that measures aimed at reducing the cutaneous microbial populations at the time of IVD insertion should have a great impact on the incidence of infection. Insertion of IVDs by trained and experienced staff, most reliably achieved with dedicated intravascular therapy teams, has been associated with greatly reduced rates of IVDR BSI.[13] However, if such personnel are unavailable, formal training programs for nurses and medical house officers can also reduce the risk of IVDR BSI.[14] Use of maximal barriers during insertion of CVCs, including sterile gloves, a sterile gown, a mask and a large sterile drape, has been shown to greatly cut the risk of IVDR BSI[15] and is considered mandatory for nonemergency insertion of all CVCs, including non-tunneled, noncuffed CVCs, pulmonary arterial catheters and hemodialysis catheters. Finally, multiple trials have shown that

Figure 57-2 Microbial profile of intravascular device-related bloodstream infection. Based on an analysis 159 published prospective studies, *from Maki et al.*[10]

chlorhexidine-based cutaneous antiseptics are associated with a 50% reduction in the risk of IVDR BSI compared with other cutaneous antiseptics, such as povidone-iodine or alcohol, making chlorhexidine the antiseptic of first choice when inserting an IVD.[16]

Although studies have shown that application of topical antibiotics such as mupirocin on the catheter insertion site can reduce the risk of CVC-related BSI, their use has been discouraged in the 2002 HICPAC Guideline because of the risk of emerging antibiotic resistance.[11]

The choice of the type of IVD, the location of its insertion and the duration of catheterization can also reduce the patient's risk of IVDR BSI:

- IVDs should have the minimum number of lumens needed for adequate access,
- CVCs are preferably inserted into the subclavian or internal jugular vein rather than the femoral vein, and
- the duration of IVD use should be limited to the absolute minimum.

Despite compliance with recommended guidelines, many centers continue to have high rates of IVDR BSI. Here, novel technology holds much promise (Table 57.4). Innovative technologies designed to reduce the risk of IVDR BSI have proved not only to be effective but also to reduce health care costs, both with short-term and long-term IVDs.

Studies of polyurethane dressings, which contain antiseptic, such as povidone-iodine or ionized silver, have been disappointing. However, on the basis of the demonstrated superiority of chlorhexidine for cutaneous disinfection of access sites, a novel chlorhexidine-impregnated sponge dressing has been developed that maintains a very high concentration of the antiseptic on the insertion site under the dressing. The largest study to date found that use of the chlorhexidine-impregnated sponge dressing was associated with a 60% reduction in catheter-related BSI (RR=0.37, p=0.01); there was no evidence of chlorhexidine resistance associated with use of the novel dressing.[17] Although there were no adverse side-effects associated with the use of this dressing in this trial in adults, a subsequent pediatric trial found that about 15% of low-birth-weight neonates developed local dermatotoxicity.[18]

Intravascular devices directly coated or impregnated with antimicrobials or antiseptics have been intensively studied over the past decade. A meta-analysis of prospective trials studying the most

TABLE 57-3 -- Guideline for the prevention of intravascular device-related bloodstream infection.*

GUIDELINE FOR THE PREVENTION OF IVDR BSI		
Recommendation		**Strength of evidence***
General measures	Educate all health care workers involved with IVD care and maintenance	IA
	Ensure adequate nursing staffing levels in intensive care units	IB
Surveillance	Monitor institutional IVD infection rates of IVD-related BSI	IA
	Express rates of CVC-related BSI per 1000 CVC-days	IB
At catheter insertion	Aseptic technique:	
	Hygienic hand care before insertion or manipulation of any IVD	IA
	Clean or sterile gloves during insertion and manipulation of noncentral IVDs	IC
	Maximal barrier precautions during insertion of CVCs: mask, cap, sterile gown, gloves, drapes	IA
	Dedicated IVD team strongly recommended	IA
	Cutaneous antisepsis: first choice, chlorhexidine; however, tincture of iodine, an iodophor or 70% alcohol are acceptable (no recommendations for use of chlorhexidine in infants less than 2 months, unresolved issue)	IA
	In adults, other than hemodialysis catheters (jugular site preference), use a subclavian site rather than a jugular or femoral site for CVC access (in pediatric patients, no recommendations for preferred site, unresolved issue)	IA
	Use of sutureless securement device	NR
	Sterile gauze or a semipermeable polyurethane dressing to cover site	IA
	No systemic or topical antibiotics at insertion	IA

Maintenance	Remove IVD as soon as no longer required	IA
	Monitor IVD site daily	IB
	Change dressing of CVC insertion site at least weekly	II
	Do not use topical antibiotic ointments	IA
	Change needleless iv systems at least as frequently as the administration set; replace caps no more frequently than every 3 days or per manufacturers' recommendations	II
	Complete lipid infusions within 12 hours	IB
	Replace administration sets no more frequently than every 72 hours. When lipid-containing admixtures or blood products are given, sets should be replaced every 24 hours; with propofol, every 6–12 hours	IA
	Replace peripheral IVs every 72–96 hours	IB
	Do not routinely replace CVCs or PICCs solely for prevention of infection	IB
	Do not remove CVCs or PICCs solely because of fever unless IVD infection is suspected but replace catheter if there is purulence at the exit site, especially if the patient is hemodynamically unstable and IVD-related BSI is suspected	II
Technology	Use antimicrobial-coated or antiseptic-impregnated CVC in adult patients if institutional rate of BSI is high despite consistent application of preventive measures and catheter likely to remain in place >5 days (no data or recommendations for pediatric patients)	IB
	Use chlorhexidine-impregnated sponge dressing for adolescent or adult patients with uncuffed CVCs or other catheters likely to remain in place >5 days (no recommendation for children, do not use in neonates <7 days old or gestational age <26 weeks)	NR
	Use prophylactic antibiotic lock solution *only* in patients with long-term IVDs who have continued to experience IVD-related BSIs despite consistent application of infection control practices	II

** Adapted from the Centers for Disease Control and Prevention. Guidelines for the prevention of intravascular catheter-related infections.*[11]

* IA, strongly recommended for implementation and supported by well-designed experimental, clinical or epidemiologic studies; IB, strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale; IC, required by state or federal regulations, rules or standards; II, suggested for implementation and supported by suggestive clinical or epidemiologic trials or a theoretical rationale — unresolved issue, an unresolved issue for which evidence is insufficient or no consensus regarding efficacy exists; NR, no recommendation for or against at this time.

widely used commercial CVC, the chlorhexidine-silver sulfadiazine catheter, found that use of the chlorhexidine-silver sulfadiazine CVC was associated with a 44% reduction in the rate of IVDR BSI (p=0.005).[19] Subsequent analyses estimated that US$59,000 could be saved and one patient death averted for every 300 such CVCs used.[20]

Comparably impressive results have been achieved with another CVC that is impregnated with minocycline and rifampin (rifampicin). In a large multicenter randomized trial, IVDR BSIs occurred in 5% of patients who received a nonmedicated CVC, compared with none of the patients who received a CVC impregnated with minocycline and

TABLE 57-4 -- Pooled analyses of prospective randomized clinical trials of novel technologies for prevention of intravascular device-related bloodstream infections with short-term and long-term devices.*

NOVEL TECHNOLOGIES FOR THE PREVENTION OF IVDR BSI WITH SHORT-TERM AND LONG-TERM DEVICES						
Technology		**Number of trials**	**Number of catheter-related bloodstream infections/number of central venous catheters studied**		**RR (95% CI)**	**p value**
			Technology	**Controls**

rifampin.[21] A subsequent study comparing the CVC impregnated with minocycline and rifampin to the chlorhexidine-silver sulfadiazine CVC found that CVCs impregnated with minocycline and rifampin were far less likely to be associated with IVDR BSI (p<0.002).[22] Although neither clinical trial found resistance to minocycline or rifampin among clinical isolates, concerns over the emergence of resistance has limited the wide use of this catheter. Other coatings, including active and passive silver iontophoresis, have also been developed;[23] however, their role at this time is limited by inadequate clinical studies.

Given the importance of hub contamination and intraluminal colonization in the genesis of IVDR BSI with long-term IVDs, intraluminal installation of an antibiotic or antiseptic solution has the potential to reduce the risk of BSI associated with these devices. Six randomized, prospective trials have examined a vancomycin-containing antibiotic lock solution for the prevention of IVDR BSI.[24] The largest of these trials found that use of a vancomycin or vancomycin-ciprofloxacin lock solution reduced the risk of IVDR BSI by nearly 80% (p=0.005).[25] Concern about the emergence of resistance with prophylactic antibiotic-containing lock solutions has limited their

acceptance to date. However, their use is considered acceptable in the HICPAC Guideline if a patient with an essential long-term IVD has continued to experience recurrent BSIs despite compliance with published infection control practices.[11]

CLINICAL FEATURES

Infection of an IVD represents a continuum, beginning with colonization of the extraluminal or intraluminal surface of the catheter, occasionally producing local infection manifested by erythema, pain and purulent drainage, and potentially culminating in BSI, attended by signs and symptoms of sepsis (Table 57.5). Colonization of short-term catheters precedes catheter-related BSI but, in the absence of signs of local infection or BSI, is of itself not an indication for initiating antimicrobial therapy. Similarly, with any IVD, a single positive blood culture drawn from the device, with negative peripheral blood cultures, most often represents contamination rather than true IVDR BSI. In contrast, local erythema, especially when accompanied by purulence at the insertion site, is normally an indication for antimicrobial therapy and mandates removal of the device. Local infection may occur in isolation or in combination with BSI; however, it must be noted that most IVDR BSIs in short-term devices occur in the absence of any signs of local infection. [26]

The majority of patients with IVDR BSI show signs of the sepsis syndrome, with fever, tachycardia, tachypnea or leukocytosis. However, these signs are not specific and are encountered with other types of infectious and noninfectious inflammatory conditions. Moreover, systemic signs of infection may be absent or minimal with IVDR BSIs caused by organisms of low pathogenicity, such as coagulase-negative staphylococci or *Corynebacterium* spp.[2] Despite the challenge of identifying the source of a patient's signs of sepsis, [27] several clinical, epidemiologic and microbiologic findings point strongly toward an IVD as the source of a septic episode (Table 57.6).[3] [28]

It is likely that any patient with an IVD who develops high-grade bacteremia or candidemia that persists after an infected catheter has been removed has an infected thrombus in the recently cannulated vein (Fig. 57.3); such a patient may even have developed secondary endocarditis or seeding to other distant sites. Fortunately, suppurative phlebitis of peripheral intravenous catheters is now rare and the syndrome of intravenous suppuration is predominantly a complication of CVCs, typically catheters that have been left in place for many days in vulnerable patients in the intensive care setting. The micro-organisms most frequently implicated in suppurative phlebitis or septic thrombosis are the same organisms that cause uncomplicated catheter-related septicemia: *Staphylococcus aureus*, nosocomial aerobic Gram-negative bacilli and, in recent years, *Candida* spp.[29]

DIAGNOSIS

Removal and culture of the IVD has historically been the gold standard for the diagnosis of IVDR BSI, particularly with short-term catheters.[3] [28] Studies have demonstrated the superiority of semiquantitative

TABLE 57-5 -- Proposed definitions for intravascular device-related colonization, local infection and bloodstream infection, which are based on microbiologic confirmation of the intravascular device as the source.‡

DEFINITIONS FOR IVDR COLONIZATION, LOCAL INFECTION AND BSI	
IVD colonization	(i) A positive semiquantitative* (or quantitative†) culture of the implanted portion or portions of the IVD; (ii) absence of signs of local or systemic infection
Local IVD infection	(i) A positive semiquantitative* (or quantitative†) culture of the removed IVD or a positive microscopic examination or culture of pus or thrombus from the cannulated vessel; (ii) clinical evidence of infection of the insertion site (i.e. erythema, induration or purulence) but; (iii) absence of systemic signs of infection and negative blood cultures, if done
IVD-related BSI	If the IVD is removed: (i) A positive semi-quantitative* (or quantitative†) culture of the IVD or a positive culture of the catheter hub or infusate (or positive microscopic examination or culture of pus or thrombus from the cannulated vessel) *and* one or more positive blood cultures, ideally percutaneously drawn, concordant for the same species, ideally by molecular subtyping methods; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI.
	If the IVD is retained: (i) If quantitative blood cultures are available, cultures drawn both from the IVD and a peripheral vein (or another IVD) are both positive and show a marked step-up in quantitative positivity (5-fold or greater) in the IVD-drawn culture; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI
	or
	(i) If automated monitoring of incubating blood cultures is available, blood cultures drawn concomitantly from the IVD *and* a peripheral vein (or another IVD) show both are positive, but the IVD-drawn blood culture turns positive more than 2 hours before the peripherally drawn culture; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI.

† Sonication culture of cannula segment(s) =10^3 cfu

or quantitative catheter tip culture methods for the diagnosis of IVDR BSI.[3] Using these techniques, catheter colonization is defined as recovery of more than 15 colony forming units (cfu) from a catheter segment using the semiquantitative roll-plate method[30] or more than 1000 cfu using a quantitative sonication method.[31] The diagnosis of IVDR BSI is completed when a colonized IVD is associated with concomitant BSI, with no other plausible source.[28]

Cultures of IVDs require their removal, a major problem in patients with long-term IVDs. Studies have shown that only 25–45% of episodes of sepsis in patients with long-term devices represent true IVDR BSI.[32] Thus, it would seem that in-situ methods for detecting IVDR BSI that do not require removal of the IVD would be of great value.

If a laboratory has available an automated quantitative system for culturing blood, quantitative blood cultures drawn through the IVD and concomitantly by venepuncture from a peripheral vein (or another IVD) can permit the diagnosis of IVDR bacteremia or fungemia to be made, with sensitivity and specificity in the range of 80–95%,[33] [34] without removal of the catheter, if empiric antimicrobial therapy has not yet been initiated. However, quantitative blood

TABLE 57-6 -- Clinical, epidemiologic and microbiologic features of intravascular device-related sepsis.‡

CLINICAL, EPIDEMIOLOGIC AND MICROBIOLOGIC FEATURES OF INTRAVASCULAR DEVICE-RELATED SEPSIS	
Non-specific features	**Suggestive of device-related etiology**
Fever	Patient unlikely candidate for sepsis (e.g. young, no underlying diseases)
Chills, shaking rigors*	
Hypotension, shock*	Source of sepsis inapparent, no identifiable local infection
Hyperventilation, respiratory failure	IVD in place, especially a CVC
Gastrointestinal*	Inflammation or purulence at insertion site
Abdominal pain	Abrupt onset, associated with shock
Vomiting	BSI caused by staphylococci (especially coagulase-negative staphylococci) or *Corynebacterium* spp., *Candida* spp., *Trichophyton* spp., *Fusarium* spp. or *Malassezia* spp.†

† Conversely, septicemia caused by streptococci, aerobic Gram-negative bacilli or anaerobes is unlikely to dervie from an intravascular device

cultures are labor intensive and expensive. The wide availability of automated radiometric blood culture systems, in which blood cultures are continuously monitored for microbial growth, has led to a clever application for the detection of IVDR BSI, the differential-time-to-positivity of blood cultures drawn through the IVD and concomitantly from a peripheral site. Positivity of a blood culture drawn from the IVD more than 2 hours before the culture drawn from a peripheral site turns positive has been shown to be highly predictive of IVDR BSI; in one study a sensitivity of 94% and specificity of 91% were reported. [35]

MANAGEMENT

Management of the device

Short-term intravascular devices

If a short-term vascular catheter is suspected of being infected because the patient has no obvious other source of infection to explain a fever, there is inflammation at the insertion site, or cryptogenic bacteremia or candidemia has been documented, blood cultures should be obtained and the catheter should be removed and cultured. Failure to remove an infected catheter puts the patient at risk of developing septic thrombophlebitis, septic thrombosis of a great central vein[36] [37] or even endocarditis. Continued access can always be established with a new catheter at a new site. A new catheter should never be placed in an old site over a guidewire if the first catheter is suspected of being infected, especially if there is purulence at the site.[38]

Long-term intravascular devices

Bloodstream infection originating from a cuffed and tunneled CVC does not automatically mandate removal of the device unless:

- there has been persistent exit site infection;
- the tunnel is obviously infected;
- there is evidence of complicating endocarditis, septic thrombosis or septic pulmonary embolism;
- the infecting pathogen is *S. aureus*, *Corynebacterium jeikeium*, a *Bacillus* sp., *Stenotrophomonas* spp., *Burkholderia cepacia*, any pseudomonal sp., a filamentous fungus or *Malassezia* spp. or a mycobacterium; or
- bacteremia or candidemia persists for more than 3 days despite adequate therapy.[39]

Further information on the management of an IVD in patients with suspected or confirmed IVDR BSI is covered in Chapter 61 .

Anti-infective therapy

If IVDR BSI is suspected (see Table 57.6), after cultures have been obtained, the combination of intravenous vancomycin (for resistant staphylococci) with a fluoroquinolone or cefepime or imipenem-meropenem (for multiresistant nosocomial Gram-negative bacilli) should prove effective against the pathogens most likely to be encountered.[39] Initial therapy should later be modified on the basis of the susceptibilities of the infecting organisms.

How long to treat IVDR BSI will be influenced by the infecting micro-organism and by whether the patient has underlying valvular heart disease, already has evidence of endocarditis or septic thrombosis, or shows evidence of metastatic infection. If endocarditis is suspected, transesophageal echocardiography offers superior sensitivity and discrimination for detecting vegetations.[40] In patients with high-grade bacteremia or fungemia but without clinical or echocardiographic evidence of endocarditis, septic thrombosis should be suspected. Central

TABLE 57-7 -- Rates of infection by location of arterial graft.*

RATES OF INFECTION BY LOCATION OF ARTERIAL GRAFT	
Location of arterial graft	**Rates of infection (%)**
Thoracic aorta	1.2–3.0
Aortoiliac	0.0–1.3
Aortofemoral	0.5–3.0
Femorofemoral	3.6–5.0
Femoropopliteal	1.0–4.6
Axillofemoral	5.3–6.0
Cervical	0.0–0.2

venous thrombosis can now be diagnosed by venography, ultrasonography, magnetic resonance imaging (MRI) or computerized tomography (CT).[3]

Most uncomplicated coagulase-negative staphylococcal infections can be cured with only 5–7 days of therapy[28] [41] and most infections caused by other micro-organisms can be adequately treated with 10–14 days of antimicrobial therapy,[28] as long as there are no complications related to the infection and the BSI clears within 72 hours of initiating therapy.

All patients with a IVDR BSI must be monitored closely for at least 6 weeks after completing therapy, especially if they have had high-grade bacteremia or candidemia, to detect late-appearing endocarditis, retinitis or other metastatic infection, such as vertebral osteomyelitis.

INFECTIONS OF ARTERIAL GRAFTS

Surgical replacement of occluded or aneurysmal arterial segments became feasible with the availability of synthetic polymeric grafts in the 1950s. Over 200,000 ateriovenous shunts and vascular bypass procedures are performed in the USA each year, most requiring the placement of a prosthetic arterial graft.[42] The most feared complication of arterial graft implantation is infection, which may result in limb loss or death. Diagnosis of infection of arterial grafts is often a formidable challenge for clinicians but is imperative to avert a catastrophic outcome.

EPIDEMIOLOGY

Most studies quantifying the risk of arterial graft infection have been retrospective and further limited by incomplete follow-up; however, it would appear the risk of infection following implantation of an arterial graft ranges from 1% to 6%.[43] Risk varies greatly by location of the arterial graft (Table 57.7): [43] [44]

- aortic grafts within the abdomen, 0.5–1.0%;
- aortofemoral bypass grafts, 1.5–2.0%; and
- infrainguinal grafts needed for revascularization, 2.2–6.0%.

The greater risk associated with arterial grafts below the inguinal ligament may be related to surgical disruption of lymphatics in the inguinal region, placement of the graft in a highly mobile area of the body so that wound closure is compromised, and an anatomic area associated with heavy cutaneous microbial colonization.

Arterial grafts used for hemodialysis appear to be at much higher risk of infection than grafts implanted for vascular bypass; rates of infection with synthetic grafts used for hemodialysis have ranged from 11% to 16%.[45]

Additional factors associated with an increased risk of arterial graft infection include operative times longer than 4 hours, advanced age, diabetes mellitus, malignancy, malnutrition, lower extremity infection at the time of surgery and reoperation.[43]

The 1-year survival in patients with aortic graft infection is only 58–77%,[46] and although survival is higher in patients with arterial grafts in the infrainguinal region — in the range of 75–90%[47] — infection of extremity grafts is associated with prohibitive risk of limb loss, ranging from 30% to 50%. [48] Approximately 20% of patients with prosthetic hemodialysis fistulas lose their graft because of infection,[49] [50] and bacteremia in this patient population is associated with greatly increased risk of death.[51]

PATHOGENESIS

Infections of arterial grafts occasionally occur in the early postoperative period (less than 1 month after surgery) but more commonly much later. Infections of arterial grafts involving the groin occur, on average, 3 months after implantation[52] whereas infections of aortic

grafts occur much later, with a delay to onset of 10–29 months.[53] [54] Infection in the early postoperative period is rare (<1%) and most often arises as a consequence of infection of groin or lower extremity wounds.[46]

Intraoperative cultures have shown that as many as 55% of arterial bypass grafts are contaminated by cutaneous or bowel micro-organisms at the time of implantation, suggesting that most arterial graft infections derive from intraoperative microbial contamination.[55] Graft infection as a result of contiguous spread from local wound infections can also occur and most commonly involves the graft segment immediately beneath the surgical incision.[56] Hematogenous contamination of the graft from a remote site of infection, such as pneumonia or an infected IVD, can also occur but, fortunately, appears to be rare.

Regardless of the route of infection, micro-organisms that adhere to the arterial graft surface are able to evade the effects of the host immune system and antimicrobial therapy by mechanisms analogous to those described above with infected IVDs. The implications are clear; once established, arterial graft infection is very difficult, if not impossible, to control without removal of the prosthetic material.

MICROBIOLOGY

Data from published series show that *S. aureus* is implicated in the majority (about 30%) of arterial graft infections; less commonly infection is caused by coagulase-negative staphylococci (about 12% of cases), enterococci (about 9%) and streptococci (about 5%) (Fig. 57.4). The Enterobacteriaceae, as a group, account for 25% of arterial graft infections and *Pseudomonas aeruginosa* is isolated in approximately 7% of cases. Approximately 10% of arterial graft infections are polymicrobial, and no organisms are recovered from 5% of patients with clinically overt signs of infection at the time of surgery. Early postoperative infections appear to be caused primarily by *S. aureus* and nosocomial Gram-negative bacilli; late infections appear to be caused by by organisms of lower virulence, such as coagulase-negative staphylococci. Enterobacteriaceae are recovered far more frequently from aortoilac graft infections whereas *S. aureus* and coagulase-negative staphylococci predominate in infections of aortofemoral and femorodistal arterial grafts (see Fig. 57.4).[43]

PREVENTION

The disastrous outcome associated with uncontrolled infection of a prosthetic arterial graft mandates an aggressive approach to prevention. If possible, the patient's nutritional and immune status should be optimized before elective surgery. Every attempt must be made to eradicate (or at least to control) active infections, especially infected skin ulcers or gangrenous toes; 55% of patients who develop arterial graft infections have had an identifiable focus of infection present before vascular surgery.[56] Although preoperative showering with chlorhexidine has been shown to produce significant reductions in cutaneous microbial counts,[57] its true value in vascular surgery remains to be defined.[58] Finally, hair removal at the prospective surgical site should be done as close to the surgery as possible, with depilatories or clipping rather than shaving.[57]

Vascular procedures are considered clean operations; however, the added risk with implantation of prosthetic materials justifies the use of perioperative antibiotic prophylaxis.[57] Perioperative use of cefazolin in 462 patients undergoing vascular surgery has been shown to be associated with a significantly lower risk of surgical site infection compared with placebo (0.9% vs 6.8%, RR=0.12, p=0.001); arterial graft infections occurred in the placebo group but none occurred in patients randomized to receive cefazolin.[59] Hasselgren *et al.* also confirmed the benefit of antistaphylococcal prophylaxis perioperatively and further showed that extending the duration of prophylaxis beyond 24 hours was of no added benefit.[60]

The increasing frequency of coagulase-negative staphylococcal infections of arterial grafts and rising rates of methicillin resistance of nosocomial *S. aureus* have raised the question of whether glycopeptides should become standard agents for perioperative prophylaxis in vascular and cardiothoracic surgery. One well-designed prospective randomized study of cardiothoracic and vascular surgical patients found a significantly lower rate of postoperative wound infection with vancomycin compared with either cefazolin or cefamandole.[61] However, at this time the routine use of glycopeptides in vascular surgery is not recognized by HICPAC.[57] Therefore, it is recommended that an antibiotic with antistaphylococcal activity, such as cefazolin or cefuroxime, should be given perioperatively for not more than 24 hours after vascular surgery; prophylactic use of glycopeptides should be limited to high-risk patients — such as those with a history of methicillin-resistant *S. aureus* colonization, heavy antibiotic use or chronic skin ulceration — and to hospitals with high rates of methicillin-resistant *S. aureus* infections of surgical sites.[57]

Figure 57-4 Microbial profile of infections of prosthetic arterial grafts by location of the implanted graft. *From Goëau-Brissonniere and Coggia.*[43]

Although in-vitro studies have shown that micro-organisms adhere to grafts made of polyethylene terephthalate more easily than to grafts made of polytetrafluoroethylene, [62] differences in rates of clinical infection have not been seen. However, there has understandably been much interest in developing graft materials that are intrinsically resistant to infection. A rifampin-bonded polyethylene terephthalate graft has been studied in animal models[43] with encouraging results, and it has been used with apparent success by surgeons for in-situ replacement of infected arterial grafts.[63]

CLINICAL FEATURES

The clinical manifestations of prosthetic arterial graft infection are heavily influenced by the location of the graft, the elapsed time since implantation and the organisms involved. Early postoperative infections and infrainguinal arterial graft infections typically present with local signs, such as cellulitis, wound dehiscence or cutaneous erosion over the graft, in combination with systemic signs of sepsis. [47] If not promptly recognized, infections caused by virulent organisms, such as *S. aureus*, can progress rapidly to false aneurysm formation and catastrophic hemorrhage. In contrast, local signs of infection are often absent with infections caused by coagulase-negative staphylococci and enterococci, and patients often feel well; the presence of graft thrombosis or delayed wound closure may be the only signs to suggest infection.

Aortic graft infections most often present late as unexplained bacteremia or fever, but they can also manifest themselves as catastrophic gastrointestinal hemorrhage from graft-enteric erosion or fistula formation. It is estimated that 35% of patients who develop infection of an aortic graft infection will show evidence of a graft-enteric fistula; however, not all present with massive gastrointestinal bleeding.[47] Bleeding seen in patients with graft-enteric fistulas often manifests itself as chronic, intermittent bleeding rather than as massive life-threatening hemorrhage. As a result, it is impossible to recognize graft-enteric fistula solely by presentation and this entity must be suspected in all patients with an aortic graft who present with gastrointestinal hemorrhage.

DIAGNOSIS

Laboratory abnormalities include leukocytosis and elevation of the erythrocyte sedimentation rate and C-reactive protein, which are non-specific and may only be borderline abnormal in infections caused by coagulase-negative staphylococci or enterococci. When arterial graft infection is suspected, two blood cultures should be obtained before empiric antimicrobial therapy is initiated. Cultures from open wounds, sinus tracts or exposed grafts may also be helpful. The presence of fluid about the graft segment is highly suggestive, but not diagnostic, of infection; within the first 1–2 months after surgery, fluid may represent normal postoperative changes or sterile lymphocele formation. Deep fluid collections should always be aspirated and can usually confirm infection caused by *S. aureus*, *P. aeruginosa* or Enterobacteriaceae but may fail to identify graft infections caused by coagulase-negative staphylococci or anaerobes or infections in patients who have received empiric antibiotic therapy before sampling.

Imaging techniques are very helpful in identifying arterial graft infection. With infrainguinal arterial grafts, ultrasonography may show the presence of perigraft fluid, pseudoaneurysm formation or graft thrombosis. Contrast CT has become the most useful imaging modality for investigating suspected graft infection, especially if an aortic graft is involved, and has shown sensitivity and specificity approaching 90% in published series.[44] The failure of an arterial graft to become incorporated into contiguous tissues, as indicated by the presence of air or fluid about the graft (Fig. 57.5), or the presence

Figure 57-5 Contrast computerized tomography of the pelvis demonstrating perigraft fluid in a patient with an infected left-sided aortoiliac graft (arrow).

of a pseudoaneurysm is highly suggestive of graft infection, especially if these findings are present more than 6–7 weeks after graft implantation.[64] Bowel wall thickening on abdominal CT, especially in the fourth duodenal segment, is suspicious for graft-enteric fistula and may even abrogate the need for endoscopic evaluation.

Magnetic resonance imaging has been reported to be more sensitive than CT for the diagnosis of arterial graft infection;[65] however, it must be noted that neither CT nor MRI can differentiate between infection or a sterile fluid collection, and at this time there are insufficient data to recommend routine the use of MRI for the evaluation of suspected arterial graft infections.

There has also been considerable interest in use of functional imaging studies, such as Gallium-67 citrate, indium-111-labeled leukocyte or IgG, or technetium-99m hexametazime-labeled leukocyte scintography.[66] These techniques are of little value in the early postoperative setting, because normal postoperative changes will result in a positive scan.[67] However, they may be of some use in difficult late postoperative cases.

MANAGEMENT

The treatment of suspected arterial graft infection must take into account the patient's acuity of illness and the options for preserving perfusion distal to the graft. If the patient is not critically ill and information about the causative micro-organism is lacking, an expedited diagnostic work-up utilizing one or more of the imaging modalities discussed above, blood and wound cultures and aspiration of deep fluid collections should be performed before empiric antimicrobial therapy is initiated. In patients who are floridly septic on presentation, empiric therapy should be initiated with drugs that cover nosocomial Gram-positive and Gram-negative pathogens; vancomycin combined with an antipseudomonal ß-lactam — cefepime, pipericillin-tazobactam, imipenem or meropenem — should provide adequate coverage. Antimicrobial therapy is usually initiated before surgery and continued for 4–6 weeks postoperatively, guided by the results of operative cultures and susceptibilities, the clinical response and normalization of C-reactive protein levels.

Although effective antimicrobial therapy is essential, surgical removal of the infected prosthetic graft material is the most important aspect of management. The exact surgical approach taken is dependent on the location of the graft, the extent of the infection and the options for preserving distal perfusion. Infection of an infrarenal aortic graft is best managed by total excision of the

infected area of the graft, followed by extra-anatomic revascularization, most commonly through a right axillobifemoral bypass. With this approach, overall operative mortality approaches 15% and rates of distal limb loss approach 20%, with a 3–10% risk of recurrent infection.[44] Extraanatomic bypass of the suprarenal aorta is not technically feasible and the only option in such cases is surgical debridement with in-situ placement of a fresh graft; operative mortality approaches 30% and rates of distal limb loss approach 15%, with recurrent infection seen in up to 20% of cases.[44] Newer surgical approaches that utilize graft excision with in-situ placement of human aortic allografts or antibiotic-bonded graft material or surgical debridement with retention of the original graft have been reported but remain investigational.

Infection of infrainguinal arterial grafts almost always requires complete surgical resection of the infected graft (or its involved segment) with in-situ replacement utilizing an autogenous vein graft or extra-anatomic bypass with a new prosthetic graft. Several groups have reported successful management of infrainguinal graft infection without removal of the graft by surgically debriding the wound and graft bed, followed by placement of a muscle flap.[68] Most of these reports have been from small series and were most successful in the early postoperative period.

Management of graft-enteric fistula must take into account the degree of intestinal bleeding and the stability of the patient. Patients who are hemodynamically stable and have shown only intermittent bleeding can be evaluated by contrast CT of the abdomen, followed, if negative, by an upper endoscopic study that visualizes the third and fourth segments of the duodenum. In contrast, immediate upper endoscopy in the operating room should be performed in patients who present with massive gastrointestinal bleeding. If CT or endoscopic findings suggest a graft-enteric fistula, immediate surgery is mandatory, with resection of the involved bowel and infected graft, followed by in-situ placement of a fresh graft, often with an omental wrap. Mortality in patients with graft-enteric fistulas approaches 40%, even with experienced surgeons; however, mortality is universal if the diagnosis is missed. [69]

Chapter 58 - Myocarditis and Pericarditis

W Garrett Nichols
G Ralph Corey

MYOCARDITIS

EPIDEMIOLOGY

The term myocarditis applies to a variety of disease states that produce inflammation of the myocardium. In its acute form, myocarditis ranges from an asymptomatic illness with reversible changes to fulminant myocardial necrosis and death. In its chronic form, lymphocytic infiltration of the myocardium may cause subacute deterioration of cardiac function; indeed, chronic myocarditis may predate the development of 'idiopathic' dilated cardiomyopathy (IDC). The possible association between viral myocarditis and IDC is intriguing and potentially important. Although frequently ascribed to inflammation caused by an infectious agent, myocarditis may also be seen in allergic reactions, drug reactions and in association with systemic inflammatory disease. A diagnosis of acute infectious myocarditis is suggested when unexplained heart failure or malignant arrhythmias occur in the setting of a systemic febrile illness or after symptoms of an upper respiratory tract infection.

The incidence of infectious myocarditis in the general population is unknown. In a prospective study of Finnish military recruits conducted over several years, a mean annual incidence of 0.02% was found.[1] The prevalence of clinically significant myocarditis is higher in children and young adults than in older adults, possibly due to different exposures to infectious agents and an absence of relevant immunity. Indeed, myocarditis is thought to be a major cause of sudden cardiac death in adults under the age of 40 years.[2] [3] [4] Within immunosuppressed patients, myocarditis is more prevalent, affecting approximately 50% of AIDS patients at autopsy.[5]

PATHOGENESIS AND PATHOLOGY

In myocarditis, damage to cardiac myocytes appears to involve one or more of four possible mechanisms:

- direct cytopathic effects of an infectious agent;
- cellular injury secondary to circulating exogenous or bacterial toxins;
- specific cell-mediated or humoral immunologic response to the inciting agent or induced neoantigens; and
- non-specific cellular injury caused by generalized inflammation.

Histologically, both myocyte necrosis and infiltration by inflammatory cells in the absence of ischemia are pathognomonic of the disease. The infiltrate may be composed of a variety of cell types, including neutrophils, lymphocytes, macrophages, plasma cells, eosinophils and/or giant cells (Fig. 58.1).

The pathologic abnormalities, location, severity and changes over time span a wide range depending on the etiologic agent and individual host response involved. Coxsackie virus, for example, appears to infect cardiac myocytes directly and can trigger either focal or widespread inflammatory infiltration and cellular necrosis. Infection with hepatitis B virus and varicella-zoster virus appears to involve vascular endothelium and thus can produce a different histologic pattern. The time after infection when tissue is obtained for analysis also greatly influences the histologic appearance. In acute enteroviral myocarditis, for example, few inflammatory cells may be seen, whereas cellular infiltrates are the hallmark of chronic enteroviral myocarditis. Analysis of endomyocardial biopsy specimens obtained during infection with different agents shows considerable overlap, however. Thus, an histologic diagnosis of myocarditis usually does not indicate the agent responsible.

Bacteria

Bacteria may cause myocarditis by a variety of mechanisms. Bacteremia caused by a wide variety of species may result in metastatic foci within the myocardium. Myocarditis has been noted in association with streptococcal and staphylococcal bacteremia, meningococcemia, bartonellosis, brucellosis, leptospirosis and Whipple's disease. However, the resulting myocardial dysfunction is only clinically significant in some patients who have overwhelming infections. In contrast, myocardial involvement in bacterial endocarditis is more common, and is often clinically significant. Bacteria (especially *Staphylococcus aureus*) may directly invade the myocardium from infected valves to cause abscesses, valvular failure and conduction abnormalities, or may embolize throughout the myocardium to cause global ventricular dysfunction. Cardiac infections caused by salmonellae are particularly serious; mural involvement responds poorly to antimicrobial agents and, without surgical therapy, mortality is 100%.

Bacterial toxin production can also be clinically significant. Subtle evidence of myocarditis can be detected in as many as two-thirds of patients who have diphtheria, with 10–25% of patients developing clinical cardiac dysfunction that is in direct proportion to the severity of the respiratory tract infection. [6] The virulence of *Corynebacterium diphtheriae* does not result from direct invasion of myocardium but from the effect of its potent exotoxin, which inhibits protein synthesis. Thus, evidence of cardiac toxicity may occur 1–2 weeks after the onset of diphtheria, often when the

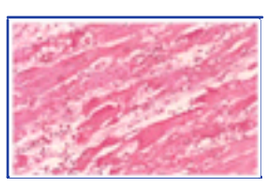

Figure 58-1 Acute viral myocarditis, with a characteristic mononuclear infiltrate.

oropharyngeal manifestations are improving. Patients who have electrocardiogram (ECG) changes of myocarditis have a mortality rate three to four times that of patients who have normal tracings, with atrioventricular nodal and left bundle branch block carrying a mortality rate of 60–90%.[7]

Finally, cardiac involvement (including myocarditis) occurs in up to 50% of cases of acute rheumatic fever (ARF). Pancarditis (e.g. endocarditis, myocarditis and pericarditis) in cases of ARF is likely the result of an over-exuberant host immune reaction to upper respiratory tract infection with rheumatogenic strains of group A streptococci. 'Molecular mimicry' (e.g. immunologic cross-reactivity to cardiac antigens elicited by streptococcal products) underlies the postulated pathogenesis of this disease, as investigators have failed to demonstrate the presence of streptococci within inflammatory cardiac lesions.

Spirochetes

Spirochetes such as *Borrelia burgdorferi*, the etiologic agent of Lyme disease, are important causes of myocarditis. The cardiac manifestations of Lyme disease may occur in an isolated manner, or coincident with other features such as erythema chronicum migrans or neurologic abnormalities. Within several weeks of infection, about 8% of patients will develop cardiac manifestations. [8] The most prevalent abnormality is fluctuating atrioventricular block, but some patients have evidence of more diffuse myopericardial involvement. Indeed, organisms have occasionally been demonstrated in endomyocardial biopsy tissue both pre-mortem[9] and at autopsy, [10] providing supportive evidence for direct spirochetal invasion. Myocardial involvement is common in cases of fatal leptospirosis (Weil's disease), where arrythmias or acute circulatory collapse may occur in conjunction with hepatorenal or central nervous system syndromes. At autopsy, myocardial inflammation, coronary arteritis and

aortitis are common findings.

Rickettsiae

Rickettsiae produce systemic vasculitis by endothelial invasion, which not infrequently involves the myocardium. Rocky Mountain spotted fever (caused by *Rickettsia rickettsii*) and scrub typhus

TABLE 58-1 -- Infectious causes of myocarditis.

INFECTIOUS CAUSES OF MYOCARDITIS			
Region	**Normal host**		**Immunocompromised host**
Developed world	**Common and/or important**	Viruses: Coxsackie viruses (A and B), echovirus, CMV, Epstein-Barr virus, human herpes virus-6, influenza viruses (A and B), adenovirus, parvovirus, hepatitis B virus, ?hepatitis C virus	Viruses: Human immunodeficiency virus (HIV), CMVV, EBV, varicella zoster virus (VZV), adenovirus, parvovirus
		Bacteria: diphtheria, Lyme disease, any organism associated with infective endocarditis	Fungi: Candidiasis, aspergillosis, crytococcosis
		Parasites: American trypanosomiasis, trichinosis	Parasites: toxoplasmosis, American trypanosomiasis
	Uncommon	Viruses: adenovirus, parvovirus, respiratory syncytial virus, hepatitis B virus, ?hepatitis C virus	Fungi: histoplasmosis, blastomycosis, coccidioidomycosis, zygomycosis
		Bacteria: staphylococci, streptococci, meningococci, salmonellae, listeria, clostridia, rickettsia, bartonellosis, ehrlichiosis	
Developing world		Viruses: poliovirus, mumps, rubella, arenaviruses, dengue, rabies, chikungunya, ebola virus, yellow fever	
		Bacteria: leptospirosis	
		Parasites: American trypanosomiasis, African trypanosomiasis	

(caused by *R. tsutsugamushi*) infections may cause transient cardiac dysfunction in severe illness, which invariably clears with disease resolution. *Coxiella burnetii* (the agent of Q fever) is a rare cause of myocarditis, but this may progress to heart failure and death. [11]

Parasites

Many parasites are known to cause chronic myocarditis and sustained myocardial dysfunction, primarily in the developing world. Chagas' disease (American trypanosomiasis), which is widely distributed in Central and South America, is caused by the protozoan *Trypanosoma cruzi*. The organism enters the human host via the bite of the reduviid bug. Rarely, patients develop fever, myalgias, hepatosplenomegaly and myocarditis during acute infection, when myocardial parasite are abundant. Far more common is the development of biventricular failure from chronic myocarditis, which occurs in 30% of infected individuals. In chronic Chagas' disease the heart is enlarged and microscopic evidence of focal mononuclear cell infiltrates is commonly found, despite the fact that parasites may be demonstrated in only a minority of patients. A history of residence in Central or South America should increase clinical suspicion for this pathogen.

Assessment of epidemiologic exposure is also essential for the diagnosis of *Trichinella spiralis*, an important parasite with worldwide distribution that has been linked to fatal myocarditis. Myocarditis generally develops in severe infections, in which the cardinal features of periorbital edema, myositis, fever and eosinophilia are present. Recent consumption of poorly cooked pork enhances the likelihood of this diagnosis. Other parasites and/or their ova, including ascaris, schistosomes and *Taenia solium*, may lodge in the myocardium during their systemic phase. The presence of eosinophilia in the context of acute heart failure should prompt a search for their presence, although eosinophilia is an important distinguishing factor for patients who have hypersensitivity myocarditis as well.

Viruses

Although any infectious agent may produce inflammation within the myocardium (Table 58.1), viruses are thought to cause the majority

of cases of acute infectious myocarditis in the Western world. Historically, outbreaks of mumps, influenza, measles, poliomyelitis and enterovirus-associated pleurodynia were commonly associated with classic findings of myocardial involvement. In the present era of widespread immunization, the enteroviruses (e.g. echovirus, Coxsackie A and Coxsackie B viruses) have been most commonly implicated in clinically significant myocarditis. As the amplification of viral genome by polymerase chain reaction (PCR) is increasingly applied to explore the role of viruses in myocarditis and dilated cardiomyopathy, other pathogens have also received attention. Recent molecular studies have alternatively implicated[12] or dismissed[13] adenovirus as a cause of myocarditis in the immunocompetent host. Given the high worldwide rates of chronic infection with hepatitis C virus (HCV), recent report of a link between HCV and dilated cardiomyopathy[14] [15] have stirred considerable interest but also controversy.[16] [17]

Until recently, evidence of a causal link between enterovirus infection and myocarditis was primarily circumstantial. For example, many individuals who have acute myocarditis present with flu-like symptoms; in one prospective study of patients who had biopsyproved myocarditis, over 50% had experienced an antecedent viral syndrome in the previous 3 months.[18] Observations of increased enteroviral antibody titers or a fall in convalescent titers have been offered as further evidence that enteroviruses are the causative agents. Unfortunately, these infections are common in the general population and it has been difficult temporally to associate serologic changes with changes in cardiac function. In one study it was found that 34% of patients who had IDC had Coxsackie virus B titers of 1:40, but the same incidence was found in control individuals.[19] However, if a cut-off antiviral titer of 1:1024 was used, 30% of patients who had IDC were abnormal as compared with 2% of control individuals.[20] Viral culture from myocardial biopsies has not been revealing.

Given the lack of confirmatory culture or serologic data, animal models of viral myocarditis have been constructed to demonstrate the pathogenicity of the enteroviruses. Murine models of myocarditis induced by Coxsackie B virus have been extensively studied and have shed light on the possible immunopathogenesis of infection. In this model, acute viral infection is characterized by viral attachment, myocyte penetration and subsequent viral replication, with resulting scattered foci of cellular necrosis. This initial phase terminates with viral clearance by mononuclear cells and the expression of proinflammatory cytokines, including tumor necrosis factor and interferon-?.[21] The chronic phase of infection is characterized by the presence of macrophages and T cells, not replicating virus, within myocardial tissue. Interestingly, depletion of T cells prevents the later stages of myocardial injury. Further cellular injury or scars do not form, although replicating virus persists within the myocardium after T-cell depletion.

These experiments highlight the importance of T cells in the perpetuation of myocardial injury. The antigens to which they are directed, however, remain unknown. Segments of the viral genome itself have not been shown to induce chronic immune activation. Rather, it appears that autoimmune reactivity to a novel tissue antigen induced by infection may be involved.[22] In addition, circulating autoantibodies against mitochondrial, contractile and adrenergic receptor proteins have recently been demonstrated in humans,[23] although their role in the pathogenesis of myocardial damage remains unclear. Finally, it is important to consider that the host genetic background may determine whether viral exposure results in a self-limited infection or chronic myocarditis. Indeed, asymptomatic relative of patients with cardiomyopathy often have echocardiographic evidence of ventricular dysfunction[24] or circulating autoantibodies against cardiac proteins.[25]

Although it is clear that direct injury to cardiac myocytes is important in many cases of neonatal myocarditis and some cases of acute myocarditis in adults, the studies noted above have led to the hypothesis that acute viral myocarditis more commonly predates chronic inflammation within the myocardium. The resulting chronic myocarditis may be the final common pathway to IDC, which accounts for 25% of cases of heart failure in the USA. Studies using molecular techniques suggest that 18–53% of patients who have myocarditis or IDC may have persistent enteroviral infection.[26] In a representative study, enteroviral RNA was detected in six out of 19 patients who had IDC; no RNA could be detected in a control group of 21 patients who had other cardiac disorders.[27] Histologic evidence of myocarditis and persistence of enteroviral genomic sequences, however, often appear as independent variables in many studies, and the findings correlate poorly with one another. A recent study using nested PCR demonstrated enteroviral sequences in only 7% of the patient sample; sequence analysis of the amplified products casts doubt on the true positivity of even these samples.[28] Moreover, the isolation of intact replicating virus from 'infected' tissue remains elusive, suggesting that any detected sequences are viral fragments that may merely be markers of previous infection. Whether these fragments result in antigenic persistence, forming a nidus for chronic autoimmunity, remains to be determined. Perhaps more importantly, the absence of replicating virus in most cases of myocarditis limits the potential application of

antiviral agents (see below).

Immunocompromised patients

Immunocompromised patients are subject to the same infections as the immunocompetent; however, their risk for clinically significant myocarditis is higher than in the general population, and they are uniquely at risk for opportunistic pathogens. In end-stage AIDS, as many as 10% of patients will have clinically significant cardiomyopathy.[29] In a study of 33 patients infected with HIV who underwent cardiac biopsy, specific DNA hybridization demonstrated HIV in five out of 33 patients and cytomegalovirus (CMV) in 16, suggesting that cardiotropic viral infections may be important in pathogenesis.[30] Although HIV itself has been cultured from heart tissue[31] and shown to be present by in-situ hybridisation,[32] it is only rarely present in cardiac myocytes in patients with demonstrable pathology. Thus, whether the virus itself causes heart failure, sets the stage for other cardiotropic pathogens, or is a correlate for the causative nutritional wasting present in late stage AIDS is unknown. In children with AIDS, myocarditis is perhaps even more common post-mortem than in adults, and may be associated with different pathogens; in one study, adenoviruses were detected in over 30% of hearts with histologic evidence of myocarditis.[33] Both *Cryptococcus* neoformans[34] and *Toxoplasma* gondii[35] are also important opportunistic causes of myocarditis in the setting of advanced HIV disease. Whether the use of highly active antiretroviral therapy has decreased the incidence of myocarditis remains to be determined.

Other disseminated fungal infections (such as disseminated candidiasis, aspergillosis and histoplasmosis) or viral infections such as herpes simplex virus or varicella-zoster virus may also present with myocarditis in the immunocompromised patient, but can usually be identified by associated findings. Cytomegalovirus is an important pathogen in solid organ and hematopoietic stem cell transplant recipients with myocarditis. In heart transplant recipients, CMV infection is a risk factor for a form of immune-mediated cardiac rejection that presents as accelaerated coronary atherosclerosis; importantly, prophylactic ganciclovir significantly reduces the incidence of this complication.[36] Finally, the role of CMV in myocarditis of immunocompetent patients is also intriguing; a recent study found intramyocyte CMV DNA in 14% of patients who had myocarditis but none was found in control individuals.[37]

TABLE 58-2 -- Noninfectious causes of myocarditis.

NONINFECTIOUS CAUSES OF MYOCARDITIS	
Connective tissue disorders	Systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis, dermatomyositis, polymyositis
Idiopathic inflammatory/infiltrative disorders	Kawasaki disease, sarcoidosis, giant cell myocarditis
Insect and arachnid stings	Wasp, scorpion, spider stings
Medications	Cocaine, ethanol, arsenic, cyclophosphamide, daunorubicin, adriamycin, sulfonamides, tetracycline, methyldopa
Post-irradiation myocarditis	
Peripartum myocarditis	
Pheochromocytoma	
Thrombotic thrombocytopenic purpura	
Thyrotoxicosis	

A wide variety of other diseases may cause myocardial inflammation. Important noninfectious causes of myocarditis are listed in Table 58.2 .

CLINICAL FEATURES

The clinical expression of acute myocarditis ranges from an asymptomatic state to rapidly progressive myocardial dysfunction and death. Complaints on presentation may include fever, fatigue, malaise, chest pain, dyspnea and palpitations; arthralgias and upper respiratory tract symptoms may be associated with viral myocarditis, but are non-specific. Chest pain may be vague, pleuritic (suggesting pericardial involvement) or angina-like. The majority of patients, however, have no precordial discomfort.

Physical examination may reveal tachycardia out of proportion to the height of fever or degree of heart failure. Cardiac auscultation may be unrevealing, or may demonstrate muffled heart sounds, extra beats, transient murmurs or loud ventricular gallops; friction rubs are uncommon and indicate pericardial involvement. In severe cases, signs of congestive heart failure (CHF) are present, and pansystolic apical pulses may be palpated.

The electrocardiographic manifestations of myocarditis are usually transient and occur far more frequently than clinical myocardial involvement. Indeed, mild aymptomatic myocardial involvement diagnosed by serial electrocardiographic changes was present in over 1% of military conscripts with acute viral syndromes. ST segment elevation and T wave inversions may be seen acutely, and reflect the focal nature of the myocardial inflammation. These changes usually return to normal within 2 months. Atrial and ventricular arrhythmias are common in severe cases. Atrioventricular nodal or intraventricular conduction defects denote involvement of the conduction system, and suggest more widespread disease or specific etiologies (e.g. Lyme carditis). Although usually transient and without sequelae, complete heart block may cause sudden death in these patients. Routine radiologic examination demonstrates cardiomegaly and pulmonary vascular congestion in severe cases.

DIAGNOSIS

The clinical diagnosis of myocarditis is often difficult, and requires a high index of suspicion. When unexplained heart failure or malignant arrhythmias occur in the setting of an acute febrile illness, the clinical diagnosis of infectious myocarditis is suggested. Heart failure of recent onset mandates that the physician first consider ischemic, valvular, primary pulmonary or congenital disease in the differential diagnosis. Other causes of acute myocardial dysfunction, such as rheumatologic disease, endocrinopathies, electrolyte disturbances and toxin exposure (e.g. ethanol, cocaine and heavy metals), must also be ruled out.

Electrocardiogram changes are important ancillary findings but, given the high incidence of non-specific ST segment and T wave changes seen in acute viral syndromes, they alone are often non-diagnostic. Similarly, laboratory abnormalities such as leukocytosis and an elevated erythrocyte sedimentation rate are also non-specific. Serum creatinine phosphokinase (CPK) elevations, on the other hand, do signify acute myocardial injury and thus are very important. Unfortunately, these elevations do not differentiate the cause of that injury (i.e. ischemic versus inflammatory). Myocardial enzyme release parallels myocyte necrosis, as in small-to-moderate myocardial infarctions. However, in contrast to ischemic necrosis, in which CPK levels return to normal within 72 hours, elevated CPK levels may persist for 6 days in myocarditis. [38] The CPK-MB is elevated in 70% of patients who have myocarditis and ST segment elevation on ECG, but is usually normal if only T wave changes are present. Although serum assays for troponin T (a cardiac contractile protein) offer greater specificity for myocardial damage and persist for 2–3 days longer than CPK-MB determinations, they also are not specific for myocarditis.

Echocardiography is a valuable tool in the initial evaluation of the patient and in follow-up. Echocardiograms in myocarditis commonly show variable degrees of cardiac dysfunction, often with striking focal wall motion abnormalities. Dyskinesia or akinesia is most often biventricular. Furthermore, the test may eliminate other anatomic causes of CHF and may demonstrate the presence of ventricular thrombi or pericardial effusions. Echocardiographic changes generally resolve within a few days in parallel with the clinical course; if progressive ventricular dysfunction is demonstrated, chronic myocarditis may be suggested.

Many other imaging modalities have been evaluated in acute myocarditis. Gallium scanning may demonstrate inflammation within the myocardium; the sensitivity and specificity of this test, however, is unknown. Indium-111 labeled antimyosin antibody scans have been shown to identify the degree of myocyte necrosis, but this finding does not help in determining the cause of this necrosis. Magnetic resonance imaging is sensitive to the alterations in the water content of tissue that occur in the inflammatory response. Although this modality has shown promise in children who have myocarditis,[39] it has not been formally evaluated in adults.

Despite advances in imaging techniques, the definitive diagnosis of myocarditis can only be made by endomyocardial biopsy. Because the inflammation involves both ventricles, a transvenous approach is generally employed in order to obtain a biopsy of the right ventricular septum. In experienced hands the procedure is relatively safe, although deaths have occurred. Biopsy studies in acute disease have generally been carried out in cases of fulminant myocarditis. Studies using serial biopsies have demonstrated findings similar to those seen in the murine model. In the majority of cases, histologic evidence of myocarditis has resolved 3–4 weeks after the onset of symptoms.[40] Late biopsy is thus unhelpful. Furthermore, because of the focal nature of the disease, many practitioners have recommended obtaining four or

five biopsies from different sites at initial catheterization. Repeat biopsies and/or left heart catheterization with biopsy have sometimes been necessary to establish the diagnosis firmly but increase the risk of complications such as ventricular wall rupture.

Disagreement among pathologists regarding interpretation of specimens has also been problematic. Recently, a working standard,

termed the Dallas criteria, was established; these guidelines are now used by the majority of investigators to define the disease.[40]

- Active myocarditis is defined as 'an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary heart disease'.
- Borderline myocarditis is present when infiltration is sparse, or when cardiac myocytes are infiltrated with leukocytes, but associated myocyte necrosis is not present; myocarditis cannot be diagnosed in the absence of inflammation.
- The absence of myocarditis indicates normal myocardium or pathologic changes of a noninflammatory nature (fibrosis, atrophy, hypertrophy).

The adoption of the Dallas criteria has led to 90% concordance among experienced pathologists. Application of the criteria in the Multicenter Treatment Trial for Myocarditis (MTT) suggests that the prevalence of 'active myocarditis' in patients who have recent onset (<12 months) CHF is approximately 10%;[41] a recent study demonstrated identical findings.[42] However, these patients are qualitatively different from those who have acute infectious myocarditis in which fever and acute ECG changes are present. They are best characterized as having IDC with myocardial inflammation.

The rationale for the development of the Dallas criteria was to identify patients prospectively who were likely or unlikely to benefit from immunosuppressive therapy. Given the results of the MTT (see below), many physicians have called into question the utility of the endomyocardial biopsy. In selected cases, however, the biopsy can provide valuable clinical data. Rarely, a biopsy will identify specific disease processes (i.e. toxoplasmosis, CMV, giant cell myocarditis, trichinosis, sarcoidosis) for which specific therapy is available or for which a prognosis can be given (i.e. Pompe's disease, amyloidosis). Because the prognosis in most cases of acute myocarditis is favorable (and an etiology is rarely discovered in cases of cardiomyopathy of gradual onset), we believe that the endomyocardial biopsy is unnecessary for the majority of patients with suspected myocarditis. Notable exceptions include transplant recipients and patients who have AIDS, for whom the discovery of a treatable etiology is more likely. In the setting of progresive clinical deterioration (such as arrhythmias or heart failure refractory to standard therapy) in which the diagnosis is unknown, endomyocardial biopsy should also be considered.

Thus, the approach for the immunocompetent patient who has acute myocarditis should focus on the management of CHF and its complications (see below). A thorough history (with attention to epidemiologic detail) and physical examination will unearth the majority of nonviral etiologies, in which signs and symptoms other than CHF frequently dominate the clinical picture. In the febrile patient, blood cultures should be obtained. Serologic testing for HIV should always be performed given the high prevalence of myocarditis in patients with AIDS; testing for Lyme's disease, Chagas' disease and autoimmune diseases should be performed in the appropriate clinical context. A complete blood count with differential should be performed to rule out eosinophilia (which may suggest parasitic infection or hypersensitivity myocarditis). Testing for CMV in blood (using assays such as pp65 antigenemia assay or PCR for CMV DNA) is unlikely to be helpful because CMV reactivation in the presence of unrelated acute febrile illnesses is relatively common. Athough enteroviruses are prominent pathogens, routine use of acute and convalescent enteroviral titers adds little to clinical management. Noninvasive testing for enteroviruses and adenoviruses by serum PCR is possible (although not widely available), but studies have not been performed to demonstrate that this information affects outcome. Perhaps future advances in virology and molecular biology coupled with targeted antiviral thrapy will provide more options for the diagnosis and treatment of myocarditis; for now, however, the majority of cases remain classified as 'idiopathic' and are treated expectantly.

MANAGEMENT

The natural history of acute infectious myocarditis is quite variable, although the majority of cases run a benign, self-limited course. Acute cardiac dysfunction does not predict chronic impairment, as most of these individuals demonstrate normalization of laboratory, echocardiographic and histologic parameters within 1 month of symptom onset. For this reason, supportive care in lieu of aggressive, invasive procedures is of primary importance.

General measures target CHF, arrhythmias and other derangements associated with myocarditis. Animal models have demonstrated that exercise during viral myocarditis is associated with higher mortality and more extensive histologic damage; thus, bed rest may be important. Conventional therapy has included oxygen, diuretics, digoxin and sodium restriction, as for any patient who has CHF. Most practitioners recommend anticoagulation for all patients who have documented intracardiac thrombi, and for those who have severely depressed myocardial function in order to prevent thromboembolic complications. In the murine model, early treatment with the angiotensin converting enzyme (ACE) inhibitor captopril decreased left ventricular mass and myocardial necrosis, suggesting benefits above and beyond afterload reduction. [43] Randomized trials in humans have yet to be conducted, although afterload reduction appears safe and effective in other settings. Rarely, fulminant heart failure requires the use of inotropic support, intra-aortic balloon pumps or ventricular assist devices as a bridge to the resumption of cardiac function. Unfortunately, there are no clinical or laboratory indicators to identify those patients who will spontaneously recover; indeed, patients who have fulminant myocarditis may have a better prognosis than those with acute, nonfulminant myocarditis. [44] For those who do not respond, cardiac transplantation is an option; however, patients who have myocarditis before transplantation have a significantly higher incidence of rejection and death in the first year.

As significant arrhythmias are probably associated with the majority of deaths in acute myocarditis, all hospitalized patients should be monitored on telemetry. Premature beats are common and do not require therapy. Supraventricular tachycardia, however, worsens heart failure and should be electrically converted. The use of antiarrhythmic agents for high-grade ventricular ectopy has not been studied. Care should be exercised with any antiarrhythmic agent (including digoxin, which has a low threshold for toxicity in these patients) but sustained ventricular arrhythmias may be cautiously treated, as in ischemic heart disease. Complete heart block is an indication for temporary venous pacing. The condition often resolves without a need for permanent pacemaker placement.

If a specific infection is identified (such as Lyme or staphylococcal carditis), antimicrobial therapy should be directed at the causative pathogen. As noted above, viruses are the likely cause of most cases of myocarditis, but patients who have putative viral myocarditis most commonly present after viral replication has ceased. Murine models of CMV-induced myocarditis confirm that ganciclovir or cidofovir improve outcomes in the acute (<24 hours) phase of infection, but are ineffective later.[45] Pleconaril is a novel compound that has antiviral activity against the enteroviruses (including Coxsackie viruses A and B) and thus has potential for treating the most common etiology of myocarditis. Clinical response was favorable in three-quarters of patients treated in one report, [46] but high rates of spontaneous recovery make conclusions speculative. Antiviral therapy with interferon-a for patients with enterovirus-induced myocarditis is also curently under study.[47]

Contrary to expectations, most studies of anti-inflammatory therapy and immunosuppression have not favorably influenced outcome. Nonsteroidal anti-inflammatory drugs (NSAIDs)[48] and ciclosporin[49] were associated with more severe histologic damage when used in the acute stage of murine viral myocarditis. For the most part, late stage immunosuppression has also been disappointing. In the MTT, the largest clinical trial of immunosuppressive therapy for myocarditis to date, 111 patients who had biopsy-proved myocarditis and CHF for less than 2 years were randomized to receive placebo or combination therapy with prednisone (prednisolone)/ciclosporin or prednisone/azathioprine. At 28 weeks, left ventricular ejection fraction improved in both groups from 0.25 to 0.34; there was no significant difference in mortality between the two groups at 1 year (20% in all patients) and 4.3 years (56%). Interestingly, markers of effective immune response were associated with a more favorable outcome.[50]

Intavenous immunoglobulin (IVIg) showed promise in early uncontrolled studies, but a recently conducted randomized trial of 62 patients with recent acute onset (<6 months) dilated cardiomyopathy showed no effect of IVIg when compared with placebo, even among the subgroup with histologic inflammation on biopsy.[51] However, a recently published study has opened the door for further studies on immunosuppression for myocarditis. The authors randomized 84 patients with evidence of HLA activation on endomyocardial biopsy to prednisone and azathioprine versus placebo. After 2 years, the primary end point of death, heart transplantation or readmission was not different between the two arms, but immunosuppressed patients had significantly higher ejection fractions and improvements in functional status when compared with placebo. [52] Interestingly, the Dallas criteria would have classified only 23% of the biopsies from these 84 patients with HLA unregulation as having either active or borderline myocarditis. Thus, it is quite possible that newer tests for inflammation will better identify subgroups appropriate for targeted therapy.

Ongoing studies of cytokine inhibitors such as Etanercept (which blocks tumor necrosis factor-a) in patients with CHF may provide additional options for treatment;[53] drugs that target other cytokines are likely to be tested in the future. Standardization of immunohistologic techniques to detect HLA activation in biopsy specimens, further studies on markers of immune activation, and the use of these markers to identify responsive subgroups of patients with CHF are needed before targeted immunosuppression (and the resulting revival of widespread endomyocardial biopsy) is again ready for primetime.

PERICARDITIS

EPIDEMIOLOGY

Interest in the pericardium dates to antiquity. The writings of Homer and Maximus relate the history of the 'hairy hearts of heroes' such as Aristomenes, the legendary Messinian warrior; his heart was cut out in battle and found to be 'stuffed with hair', probably the first recorded case of fibrinous pericarditis. Significant understanding of the etiology and pathophysiology followed, from Galen's first pericardial resection in the 2nd century AD to Lower's classic description of tamponade, constrictive pericarditis and pulsus paradoxus in the 17th century. Medical advances in antibiotic therapy, surgical technique, antineoplastic therapy and hemodialysis have substantially altered the spectrum and prognosis of pericardial disease in the 20th century. Imaging modalities have also made a significant impact; since the advent of echocardiography in 1955, pericardial effusions are now readily diagnosed. The etiologic determination of pericardial disease, however, remains difficult. Timely, directed therapy depends in large part on the diligence of the clinician.

The incidence of pericardial inflammation detected in several autopsy series ranges from 2–6%, whereas pericarditis is diagnosed clinically in only about 1 out of 1000 hospital admissions. The relative frequency of each etiologic process depends upon the clinical setting. Thus, viral or idiopathic pericarditis often presents in the outpatient clinic, whereas malignant or uremic effusions are more frequently seen in referral centers.

PATHOGENESIS AND PATHOLOGY

The human pericardium forms a strong, flask-shaped sac that encloses the heart and the origins of the great vessels. It is composed of a fibrous outer layer and an inner serous membrane formed by a single layer of mesothelial cells. This membrane is attached to the surface of the heart to form the visceral pericardium; it reflects upon itself, lining the inside of the collagen-based fibrous layer to form the parietal pericardium. The visceral pericardium continuously produces a clear pericardial fluid, which serves as a lubricant; it is also the source of excess fluid in disease states. The human pericardium normally contains up to 50ml of this fluid, which drains via the thoracic and right lymphatic duct into the central circulation.

Pericardial effusion may develop in response to pericardial injury (as in pericarditis) or may be secondary to other processes that alter the secretion and drainage of pericardial fluid. The pathologic changes seen in acute pericarditis are those of non-specific inflammation with cellular infiltration, fibrin deposition and the outpouring of pericardial fluid. These changes may resolve spontaneously over time, or may organize with fibrous adhesions between the epicardium and visceral pericardium, the visceral and parietal pericardium, or the pericardium and adjacent sternum and pleura (Fig. 58.2). Thus, inflammation, fluid exudation, and fibrin organization account for the cardinal manifestations of pericarditis: chest pain, pericardial effusion, and constriction.

The causes of this pericardial inflammation are numerous, including both infectious (Table 58.3) and noninfectious (Table 58.4) etiologies.

Noninfectious agents

The three most prevalent noninfectious causes of pericardial disease are malignancies, uremia and connective tissue disorders.

Figure 58-2 Heart at autopsy of a patient who had acute suppurative pericarditis. The parietal pericardium has been stripped from the specimen, revealing a 'bread and butter' appearance.

TABLE 58-3 -- Infectious causes of pericarditis.

INFECTIOUS CAUSES OF PERICARDITIS
Viruses
Cytomegalovirus
Herpes simplex virus
Coxsackie A virus
Coxsackie B virus
Echovirus
Adenovirus
Influenza
Mumps
Varicella-zoster virus
Epstein-Barr virus
HIV
Bacteria
Streptococcus pneumoniae
Streptococcus spp.
Staphylococcus aureus
Neisseria meningitidis
Listeria monocytogenes
Haemophilus influenzae
Francisella tularensis
Brucella melitensis
Enteric Gram-negative rods
Actinomyces spp.
Nocardia asteroides

Legionella pneumophila
Tropheryma whippelii
Salmonella spp.
Campylobacter spp.
Rickettsial/Q fever
Mycobacteria
Mycobacterium tuberculosis
Mycobacterium chelonae
Mycobacterium avium complex
Spirochetes
Borrelia burgdorferi
Mycoplasma
Mycoplasma pneumoniae
Ureaplasma urealyticum
Mycoplasma hominis
Fungi
Histoplasma capsulatum
Coccidioides immitis
Cryptococcus neoformans
Blastomyces dermatiditis
Candida spp.
Aspergillus fumigatus
Parasites
Toxoplasma gondii
Entamoeba histolytica
Echinococcus granulosus
Schistosoma spp.

TABLE 58-4 -- Noninfectious causes of pericarditis.

NONINFECTIOUS CAUSES OF PERICARDITIS
Idiopathic
Connective tissue disorders
Acute rheumatic fever, systemic lupus erythematosus, rheumatoid arthritis, scleroderma, mixed connective tissue disease, Wegener's granulomatosis, polyarteritis nodosa, temporal arteritis
Metabolic
Uremia, hypothyroidism
Malignancies
Lung cancer, breast cancer, leukemia, lymphoma, melanoma, others
Acute myocardial infarction
Post-myocardial infarction syndrome (Dressler syndrome)
Dissecting aortic aneurysm
Traumatic
Chest trauma, post-surgical hemopericardium, pacemaker insertion, cardiac catheterization, esophageal rupture, pancreatic-pericardial fistula
Post-irradiation
Idiopathic infiltrative/inflammatory disorders
Sarcoidosis, amyloidosis, inflammatory bowel disease, Behçet's disease, FMF
Medications
Procainamide, hydralazine, isoniazid, phenylbutazone, dantrolene, doxorubicin, dilantin, methysergide, minoxidil
FMF, familial Mediterranean fever.

¦ Neoplasms may cause pericarditis or effusions by direct involvement of the pericardium (in which malignant cells are usually demonstrated within pericardial fluid) or by obstruction of the pericardial lymphatic drainage (with resulting 'benign' effusions).
¦ Uremic pericarditis, which affects up to 20% of patients on chronic hemodialysis, is characterized by the appearance of a shaggy, fibrinous exudate without cellular infiltration.
¦ Collagen vascular diseases (most commonly systemic lupus erythematosus and rheumatoid arthritis) are notable for their propensity to involve the pericardium; immune complex deposition is thought to be primary in the pathogenesis of pericardial disease.

Infectious agents

A variety of microbes have been reported to cause pericarditis. Chief among these are viruses, which can produce a clinical syndrome of myopericarditis, but often other infectious agents are also implicated.

Viruses

Coxsackie virus and echovirus type 8 have been most commonly identified. As is the case for myocarditis, these viruses have only rarely been isolated from pericardial fluid or tissue; as such, evidence for viral causation of pericardial inflammation is primarily based upon isolation of virus from other sites, such as stool, by demonstration of a four-fold rise in serum antibody titers and, more recently, by PCR. Historic evidence, however, favors a viral etiology for the majority of community-acquired 'idiopathic' pericarditis. For example, epidemic pleurodynia (Bornholm disease), caused by Coxsackie virus infection, has long been noted to be epidemiologically associated with outbreaks of self-limited pericarditis. In addition, most cases of idiopathic pericarditis seem to cluster in the spring and autumn, coincident with outbreaks of enteroviral infections.

Many other viruses have been associated with pericarditis (see Table 58.3). For example, CMV has been pathologically confirmed as a cause of pericardial disease in

the immunocompetent patient who has the CMV mononucleosis syndrome. One series reported five cases of culture-proved CMV infection in patients who had large pericardial effusions. In four of these CMV cases, the patients were not immunosuppressed at the time of diagnosis. [54] In addition, CMV may be a common pathogen in HIV-infected patients. Herpes simplex pericarditis has also been documented both in patients who have AIDS and in patients who have uremia. Most recently, PCR testing has found evidence of adenovirus, enterovirus, CMV in pericardial fluid and tissue from patients with acute pericarditis.[55]

Bacteria and other infectious agents

Bacteria may cause pericarditis by a number of different mechanisms. Hematogenous seeding of the pericardium may occur during the course of bacteremia caused by a variety of organisms. In the pre-antibiotic era, most cases of purulent pericarditis were seen as complications of bacteremia or pneumonia. Today, extension of infection from a contiguous focus within the chest is seen as a postoperative or post-traumatic complication. Subdiaphragmatic abscesses may also cause pericardial infection by direct extension. Highly invasive bacterial infections within the heart, such as acute staphylococcal endocarditis, may erode into the pericardium from a perivalvular abscess to cause purulent pericarditis. Pericardial effusions in patients who have subacute infective endocarditis provide another mechanism by which bacterial infection can lead to pericardial disease. Pathologic changes in the pericardium are caused by immune complex deposition, resulting in sterile exudates. Although common, these effusions are not correlated with prognosis, and most resolve without specific therapy.

The microbiology of bacterial pericarditis continues to evolve (see Table 58.3). Before antibiotics, uncontrolled pneumococcal, streptococcal or staphylococcal pulmonary infections were most frequently implicated. Streptococci and staphylococci remain important pathogens today (particularly in traumatic and post-thoracotomy pericarditis), with Gram-negative bacilli, atypical bacteria and *Candida* also assuming important roles. Pericardial involvement has also been documented in the course of such illnesses as tularemia, brucellosis, salmonellosis, legionellosis, meningococcal disease and Q fever.[56] In children, bacteria cause proportionately more cases of pericarditis than is the case in adults; *Staphylococcus aureus* and *Haemophilus influenzae* are the most common etiologic agents.

Pericarditis caused by *Mycoplasma* spp. deserves special mention. Although pericarditis has been recognized in the course of *Mycoplasma* disease since 1944, culture of the organism has proved difficult. Therefore, autoimmune phenomena have been invoked to explain the association. Recently *Mycoplasma pneumoniae*, *M. hominis* and *Ureaplasma urealyticum* were isolated from culture of pericardial fluid and/or tissue in five patients who had large pericardial effusions.[57] Treatment with doxycycline after drainage of the effusions resulted in complete resolution in all five cases. Pericarditis caused by *Mycoplasma* spp. is thus more common than previously recognized, and fluid obtained for culture should always be analyzed for the presence of these organisms.

Mycobacteria continue to be important causes of acute pericarditis, pericardial effusion and constrictive pericarditis, particularly in developing countries. The incidence of tuberculous pericarditis among patients who have pulmonary tuberculosis ranges from 1–8%.[58] In Transkei, South Africa, tuberculous pericarditis with secondary constriction is the second most common cause of 'heart failure' after rheumatic disease.[59]

Histoplasma capsulatum is the most common cause of fungal pericarditis; in large outbreaks, pericarditis was noted in 6% of patients who had symptomatic histoplasmosis. It most commonly develops as a noninfectious inflammatory response that resolves spontaneously without therapy. Occasionally, seeding of the pericardium occurs in the course of disseminated infection. In contrast, pericarditis has only rarely been reported in cases of severe coccidioidomycosis.

In the severely immunosuppressed or post-thoracotomy patient, infection caused by *Candida* spp., *Aspergillus fumigatus* or *Cryptococcus neoformans* has occasionally resulted from either fungemia or direct inoculation.

Pericarditis in AIDS

In contrast to other immunocompromised states, pericardial disease in patients who have AIDS is quite common. Effusions are frequently noted in end-stage AIDS (occurring in 16–40% of patients) and are associated with a poor prognosis. Etiologies include a variety of pathogens (including viruses, bacteria, fungi and mycobacteria), although in the majority of cases no causative agent can be defined. Malignant effusions secondary to lymphomatous involvement of the pericardium have also been noted. Furthermore, although extrapericardial disease suggested specific infectious or malignant etiologies in 55% of patients who had pericardial effusions in one trial, these assumptions proved incorrect for all those in whom pericardiocentesis was performed.[60]

CLINICAL FEATURES

Acute pericarditis is most often recognized by its chief presenting manifestation: chest pain. The pain is usually precordial or retrosternal, often with radiation to the trapezius ridge or neck; it is exacerbated by lying supine, coughing or deep inspiration, with relief upon sitting upright or forward. The patient's discomfort may be caused by inflammation of the adjacent pleura, accounting for the pleuritic component that often accompanies the pain. This pain is distinguished from the pain of myocardial ischemia by its quality, its duration (pain may last for days without therapy) and the absence of associated factors (i.e. pain is unchanged with exertion or rest). Patients may also report that splinting reduces the pleuritic discomfort.

A pericardial friction rub is the pathognomonic physical finding of acute pericarditis. Characterized as scratchy or grating, it is best appreciated along the left sternal border with respirations suspended and the patient leaning forward. The classic friction rub has three components, corresponding to atrial systole, ventricular systole and the rapid ventricular filling phase of early diastole, although one or more of these phases are usually absent. Of note, the friction rub frequently waxes and wanes in intensity and may disappear altogether with the accumulation of fluid within the pericardial sac. The pericardial rub may again become prominent in tamponade, in which the pericardium rubs against the adjacent pleura.

Pericardial effusions range from the asymptomatic to those causing cardiac tamponade. The rate of fluid accumulation is a major determinant in physiologic manifestations. When the effusion develops slowly, the pericardium may stretch to accumulate as much as 2 liters of fluid. The normal pericardium, however, can accommodate the rapid accumulation of only 100–200ml of fluid before signs and symptoms of tamponade develop. Patients may then complain of dyspnea or a dull retrosternal ache, and examination will reveal jugular venous distension, the most common physical finding in acute tamponade. A fall of 10mmHg or more in systolic blood pressure during inspiration (the pulsus paradoxus) is recognized as a hallmark of critical cardiac tamponade, although it may be absent if hypotension is already present.

Enlargement of the cardiac silhouette on routine radiography does not usually occur until at least 250ml of fluid have accumulated in the pericardial space. Other findings on chest radiogram, such as a 'water bottle' heart (Fig. 58.3) or a prominent fat stripe sign, are found only in large pericardial effusions; their absence does not rule out the presence of a hemodynamically significant effusion. Chest radiograms may also provide etiologic clues for pericardial disease, such as pneumonic infiltrates or mediastinal adenopathy.

Electrocardiographic changes in acute pericarditis imply inflammation of the pericardium. Thus, in uremic or neoplastic pericardial

Figure 58-3 Cardiomegaly in a patient who has pericarditis. The presence of a 'water-bottle' heart on this plain film suggests a large pericardial effusion.

Figure 58-4 Electrocardiogram of a patient who has early acute pericarditis. Note the presence of diffuse ST segment elevation and PR depression in the inferolateral leads

(arrows). 25mm/s; 10.0mm/mV; F–W 0.05–100.

effusions, characteristic ECG changes are often absent. Cardiac arrhythmias are uncharacteristic in isolated pericardial disease; their presence implies myocardial involvement. The ECG typically evolves through four stages during acute pericarditis.

¦ Diffuse ST-segment elevation (usually concave up) with reciprocal ST depression in aVR and V1 accompanies the onset of chest pain and is virtually diagnostic of pericarditis; these findings are present in 50% of patients who have acute pericarditis. [61] PR depression in the inferolateral leads is frequently seen in this stage (Fig. 58.4).
¦ ST and PR segments normalize, typically several days later.
¦ Diffuse T wave inversions develop, generally after ST segments become isoelectric.
¦ Electrocardiograph changes normalize; long-term inversion of T waves suggests 'chronic' pericarditis.

Elevated CPK and troponin I levels are common in cases of acute pericarditis. Whether this signifies clinically relevant myocardial changes has not been adequately evaluated.

DIAGNOSIS

A number of studies have established the utility of using a stepped approach.[62] One study prospectively evaluated 231 consecutive patients who had acute pericardial disease of unknown cause.[63] Pericardiocentesis was performed in patients who had tamponade, suspicion of purulent pericarditis or symptoms and/or effusion persisting for more than 1 week after initiation of NSAID therapy. Pericardial biopsy was undertaken if clinical activity persisted at 3 weeks and the etiology was unknown. Despite this extensive evaluation, a specific diagnosis was confirmed in only 32 patients: neoplasia in 13, tuberculosis in nine, rheumatic disease in four, purulent pericarditis in two, toxoplasmosis in two and viral pericarditis in two. Diagnostic yield was substantial when pericardiocentesis or biopsy were performed to relieve tamponade, but poor when used solely for diagnostic purposes. Over a mean follow-up of 31 months, no patient diagnosed with idiopathic pericarditis and treated with NSAIDs showed signs of recurrent or chronic pericardial disease.

Because of the recent interest in subxiphoid pericardial biopsy and drainage of pericardial effusions, we recently undertook a prospective nonrandomized trial of all patients who had large pericardial effusions hospitalized at our institution. These patients underwent a similar stepped preoperative approach, with subsequent subxiphoid pericardial biopsy and drainage of their effusions.[64] Diligent handling and extensive microbiologic analysis (including cultures for aerobic and anaerobic bacteria, viruses, chlamydiae, mycoplasmas, fungi and mycobacteria) of pericardial fluid and tissue allowed specific diagnoses to be established in 53 out of 57 patients, confirming prior reports of high diagnostic yield when stepped algorithms are used for large effusions. More than one-third of the patients had malignancy or a history of irradiation to the thorax for malignancy. Infections (mostly viral), collagen-vascular disease and uremia were also frequently implicated (Table 58.5). Unexpected

pathogens included CMV in three patients, herpes simplex virus 1 in one, *M. pneumoniae* in two, *Mycobacterium avium* complex in one, and *Mycobacterium chelonei* (see Table 58.3) in one patient. No patient showed evidence of Coxsackie A or B viral infection. Comparison of this study with two other important series shows a significant variation in etiologies as a result of different populations, diagnostic strategies and investigator interests (i.e. infectious disease specialist versus cardiologist).

A comparison of diagnostic yield between pericardial fluid and biopsy demonstrated that fluid analysis was far more sensitive for malignancy; tissue provided additional information only in infected patients in whom fluid was not available for analysis. Previous studies demonstrated similar utility of pericardial fluid analysis; in a retrospective study of 93 cases of malignant effusion with both pericardial fluid and tissue analysis, cytology was correct in 87 cases (diagnostic accuracy 94%) with 100% specificity.[66]

In summary, acute pericarditis is most often viral or idiopathic in etiology; as such, invasive work-ups are usually not necessary. For the patient who has large effusions, tamponade, or presentation suggestive of purulent pericarditis, early and aggressive intervention will often yield diagnostic and therapeutic rewards.

As noted previously, a wide variety of infectious and noninfectious agents can cause acute pericarditis and/or pericardial effusions (Table 58.6). For the patient presenting with acute chest pain, initial evaluation should focus on identifying conditions that may be rapidly fatal. Thus, myocardial infarction, aortic dissection, purulent pericarditis and cardiac tamponade should be systematically ruled out. An appropriate work-up includes a thorough history and physical examination, ECG and chest X-ray (to rule out intrathoracic malignancy, tuberculosis or a widened mediastinum suggestive of aortic dissection) and routine laboratory studies including complete blood counts, serum chemistries, serial CPK with MB fraction determination, thyroid function tests, rheumatoid factor and antinuclear antibodies; blood cultures should be obtained for the febrile patient. Due to the serious consequences of untreated tuberculous pericarditis, a tuberculin skin test with appropriate controls should be placed as well.

For the majority of individuals, a specific etiology will not be apparent, and a diagnosis of acute viral or idiopathic pericarditis will be made. Because either entity typically follows a brief and benign course, a full diagnostic evaluation is not appropriate. The confirmation of a particular viral agent is not necessary, as serologic titers and/or viral cultures are quite non-specific, the work-up is costly and a retrospective diagnosis is usually not helpful in management. Because

?, no distinction between acute idiopathic pericarditis and idiopathic chronic pericardial effusion.			

* Acute idiopathic pericarditis.

significant pericardial effusions may accumulate even in idiopathic disease, however, all patients should be carefully evaluated for their presence; hemodynamic compromise on physical examination, cardiac enlargement on chest radiography, or significant effusions on echocardiography necessitate rapid intervention. For patients who have large effusions, and for those in whom another diagnosis is suggested, a more thorough work-up often includes pericardial drainage with or without pericardial biopsy.

As noted above, noninvasive diagnosis of pericardial disease in patients who have AIDS is extremely difficult. Because specific etiologic diagnosis often has important treatment ramifications, pericardial effusions in these patients should be managed on an individualized basis, with invasive diagnostic testing employed in those whose baseline health would benefit from aggressive therapeutic measures.

Echocardiography has largely replaced other methods for the detection of pericardial fluid. With experience, operators can detect as little as 20ml of excess fluid posterior to the left ventricle. Echocardiography can also provide ancillary data in assessing the patient who has an effusion. Increased respiratory flow variation across the mitral valve with Doppler echocardiography is characteristic of cardiac tamponade. In addition, other etiologies of myocardial dysfunction such as left and right ventricular infarction can be ruled out. Finally, the echocardiogram can direct attempts at pericardiocentesis by identifying the location of pericardial fluid.

Computed tomography (CT) scans of the chest are primarily helpful in the diagnosis of pericardial thickening. Significant effusions are also readily demonstrated (Fig. 58.5). In addition, CT scans are more sensitive for the demonstration of small parenchymal nodules and mediastinal lymphadenopathy than is conventional radiography, and thus have clinical utility in the diagnosis of malignant pericarditis. Similarly, magnetic resonance imaging may be useful in the non-invasive characterization of pericardial fluid as well as pericardial thickness.

Cardiac catheterization is reserved for patients in whom pericardial constriction is believed to play a role in symptomatology. In those who have chest pain of undetermined etiology, catheterization is also useful for ruling out myocardial ischemia as a confounding diagnosis.

MANAGEMENT

Nearly all patients who have acute pericarditis should be hospitalized for relief of symptoms, diagnostic evaluation and observation for complications. Specific medical therapy is tailored to the cause of pericarditis.

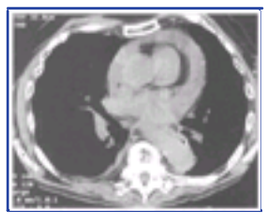

Figure 58-5 Chest CT of a patient who has a large crescent-shaped pericardial effusion.

Aspirin, at doses of 2–6g/day, or other NSAIDs are effective in reducing symptoms of pericarditis, and are the agents of choice for idiopathic or viral pericarditis. Corticosteroids should be reserved for symptomatic nonresponders. Prednisone, however, is the drug of choice in pericarditis associated with connective tissue disease.

Idiopathic or viral pericarditis generally follows a benign, self-limited course but the occasional patient will present with recurrent pericardial pain. Treatment for recurrences generally begins with NSAIDs; corticosteroids have been used successfully for NSAID-resistant cases. Colchicine has shown promise as a steroid-sparing agent in a number of small trials.[69] Pericardiectomy for recurrent pericarditis should be reserved for those who fail medical therapy. Interestingly, only one-third of patients will respond.[70]

Targeted intravenous antibiotics and surgical drainage of the pericardium remain the mainstays of therapy for purulent pericarditis. Pericardiocentesis urgently performed for the critically ill patient does not obviate the need for complete drainage and irrigation; fluid may re-accumulate rapidly, and sequelae such as constriction may develop in hours. There is no rationale for intrapericardial antibiotic administration, as pericardial penetration of antibiotic is excellent.

Tuberculous pericarditis remains a diagnostic and therapeutic challenge. Clinical features are non-specific, the disease course is confusing and laboratory evaluation is often nondiagnostic, particularly in low prevalence settings and in patients who have localized disease. For example, although large effusions are more likely to be tuberculous, up to 50% of tuberculous effusions resolve spontaneously despite ongoing tissue infection. The tuberculin skin test may be negative in up to 30% of patients as a result of cutaneous anergy yet may be positive in the patient who has acute idiopathic pericarditis and benign natural history. Suggestive, but not diagnostic, findings include a recent history of pulmonary tuberculosis, a positive sputum smear or culture, or a high pericardial fluid adenosine deaminase level (>45units/l). [71] Even granulomatous inflammation of the pericardium is not diagnostic, as this may be demonstrated in pericardial disease from other causes, such as histoplasmosis, sarcoidosis and rheumatoid arthritis. Additionally, a negative biopsy of the pericardium does not rule out tuberculous pericarditis, as removal of the entire pericardium may be necessary to demonstrate clear-cut evidence of tuberculosis.[72]

Definitive diagnosis rests upon the demonstration of the tubercle bacillus in pericardial fluid and/or tissue. However, the need for early therapy demands that treatment often be undertaken based upon a presumptive diagnosis. Initial treatment should consist of four drugs including isoniazid and rifampin (rifampicin) until sensitivities are known. The use of concomitant prednisone (at doses of 60mg/day initially) to reduce pericardial inflammation is supported by two large controlled trials in Transkei, South Africa. Clinical improvement occurred more rapidly, 2-year mortality was lower (4 versus 11) and pericardiectomy was required less often (21% versus 30%) compared with those treated with four-drug therapy alone.[73] These data also highlight the incidence of constrictive complications in this disease. Complete pericardiectomy is advocated for those who have recurrent effusions or cardiac compression with constrictive physiology after 4–6 weeks of oral therapy. Such early pericardiectomy is associated with a good outcome; mortality is substantially higher in patients who undergo pericardiectomy at the late stage of calcific pericardial constriction.[74] A recent review highlights these issues and the controversies that still remain.[75]

Chapter 59 - Endocarditis and Endarteritis

Philippe Moreillon

INTRODUCTION

This chapter reviews infective endocarditis (IE) and other endovascular infections in the context of their evolving epidemiology, diagnostic tools and therapeutic strategies. These diseases were invariably lethal in the pre-antibiotic era. Fifty years ago, the introduction of penicillin followed by other antibiotics revolutionized the treatment and prognosis of IE. More recently, developments in clinical micro-biology and the availability of improved imaging techniques, especially transthoracic and transesophageal echocardiography, have led to new, more accurate diagnostic criteria. [1] [2] In industrialized countries, despite improvements in health care and the sharp decrease in the incidence of chronic rheumatic heart disease, IE has not disappeared and has even increased in some populations.[1] [3] [4] [5] [6] [7] New at-risk groups have emerged, including intravenous drug users, elderly people who have sclerotic cardiac valves and patients who have intravascular prostheses.

EPIDEMIOLOGY

Studies of the epidemiology of IE have been hampered by several factors: IE is a relatively rare disease, it is not officially a reportable disease and a precise case definition is lacking. This lack of a precise case definition is an important problem because it may be difficult to make a clinical diagnosis of IE with certainty. Therefore, many former studies were based on autopsy series. Fortunately, newer diagnostic criteria now allow a better assessment of IE in live patients.[1] [2]

Overall, the incidence of IE ranges between 2 and 6 per 100,000 population per year.[3] [4] [5] [6] [7] Recent series report a predominance in males, with a male:female ratio of approximately 2:1. Infective endocarditis has not disappeared in the modern era; it may even be increasing, according to recent reports from Europe and the USA. Moreover, its morta-lity remains high, and ranges between 20% and 30% in spite of aggressive antimicrobial treatment combined or not with surgical valve replacement.[3] [4] [5] [6]

The risk factors and the infecting micro-organisms have both changed over time. Chronic rheumatic heart disease, which was a prime risk factor in up to 75% of cases in the pre-antibiotic era,[8] is now rare in industrialized countries.[9] Classic pathogens such as pneumococci and gonococci have become uncommon, whereas there is an increasing number of cases due to *Staphylococcus aureus* and *Staphylococcus epidermidis*.[4] [5] [6] [7] These micro-organisms occur frequently in the newer risk groups of intravenous drug users, elderly people and patients who have prosthetic valves or pacemakers.

Infective endocarditis is commonly classified in four categories, which are discussed below:

- native value IE;
- prosthetic valve IE;
- IE in intravenous drug users; and
- nosocomial IE.

Native valve infective endocarditis

Risk factors for native valve IE include congenital heart disease and acquired abnormalities such as chronic rheumatic heart disease and degenerative heart disease. People who have cardiac abnormalities that result in high-to-low pressure gradients are at greater risk of infection. Turbulent blood flow may provoke damage or peeling of the endothelium and formation of vegetation. Circulating bacteria tend to adhere on the low-pressure side of such Venturi-like systems. These observations explain why left-sided valves and left-to-right ventricular or arterial shunts are the most common sites of IE.

Congenital heart disease

Congenital heart disease is a lifelong risk factor. It is a major risk factor in children, in whom it accounts for 30–40% of IE.[9] It is a less frequent risk factor in adults but still represents about 5% of cases. [10] This includes all of the cardiac abnormalities associated with turbulent blood flow. Tetralogy of Fallot carries the highest risk for IE, followed by bicuspid aortic valve, coarctation of the aorta and ventricular septal defect. In contrast, secundum atrial septum defects rarely put the patient at risk, probably because they result in a low-pressure shunt.

Surgical or medical closure of a patent ductus arteriosus usually eliminates the risk of endovascular infection. However, surgical correction does not exclude the risk of IE in patients suffering major congenital heart disease such as tetralogy of Fallot.[10] Importantly, the type of surgical correction may influence the risk of subsequent infection in this situation. In a long-term survey involving 1142 patient-years of observation, IE occurred in 23% of patients treated with anastomotic operations but in only 9% of patients treated with pulmonary valvulotomy or infundibular resection or both.[11] Because vascular anastomoses are likely to generate turbulent blood flow, this observation underlines the importance of hydrodynamic disturbances in promoting endovascular infections.

Rheumatic heart disease

Rheumatic heart disease was the most frequent acquired cardiac anomaly leading to IE in the pre-antibiotic era. In one series, the frequency of chronic rheumatic heart disease in patients who had developed IE decreased from approximately 22% between 1933 and 1952 to less than 1% between 1963 and 1972.[8] Although the prevalence of the disease has decreased to less than 10 per 100,000 population per year in industrialized countries, it remains the predisposing factor of IE in up to 50% of cases in some developing countries. Moreover, recent clusters of rheumatic heart disease are occasionally described in the USA, suggesting a possible resurgence of the disease. Thus, rheumatic heart disease remains an important risk factor for IE.

Mitral valve prolapse

Mitral valve prolapse is a relatively common condition, affecting 2–4% of the population. It has recently been shown to be inherited in an autosomal-dominant manner and linked to a region in chromosome 16p.[12] Patients who have valve regurgitation have a

10- to 100-fold increased risk of IE.[13] The risk of IE may be especially important in children and in patients over the age or 50 years.[14] Interestingly, mitral valve prolapse is associated with body leanness, lower blood pressure and lower prevalence of diabetes mellitus in Native Americans. Thus, the inherited valve alteration is ironically associated with some cardiovascular protective parameters and represents a Darwinian paradox.[15]

Degenerative valve lesions

Degenerative valve lesions are present in up to 25% of patients aged over 40 years and in 50% of patients over age 60 years who have IE.[16] Degenerative valve lesions leading to senile aortic stenosis or mitral regurgitation are frequent in patients aged over 70 years. Elderly people should be carefully examined for clinical

evidence of valve dysfunction.

Prosthetic valve infective endocarditis

Prosthetic valve endocarditis occurs in 1–5% of cases, or 0.3–0.6% per patient-year.[17] [18] The issue of whether mechanical or bioprosthetic valves are more prone to infection remains unresolved.[17] Prosthetic valve endocarditis is usually classified as either early infection or late infection, depending on whether the symptoms of infection occur within 60 days after surgery or later. The risk of endocarditis peaks during the 2 months after valve implantation; thus, infection probably results from perioperative contamination. Early prosthetic valve endocarditis is often due to *S. epidermidis* and less frequently to *S. aureus*. These organisms are commonly found on the skin and are frequently introduced into the heart or bloodstream during or soon after surgery.

Progressive endothelialization of the prosthetic material over 2–6 months eventually reduces the susceptibility of the implanted valve to infection. This is reflected in a change in the predominant pathogens over time. *Staphylococcus epidermidis* causes prosthetic valve endocarditis most often during the first year after a valve implantation; later, this organism is replaced by streptococci and sometimes by Gram-negative bacteria of the so-called HACEK group, including *Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens* and

TABLE 59-1 -- Microbiology of infective endocarditis in the general population and in specific at-risk groups.£

MICROBIOLOGY OF IE IN THE GENERAL POPULATION AND IN SPECIFIC AT-RISK GROUPS				
Pathogens	**No. of episodes (% of total)**			
	Native valve	**Intravenous drug abusers**	**Prosthetic valve**	
			Early	**Late**
Staphylococci	124 (44)	60 (69)	10 (66)	33 (45)
Staphylococcus aureus	106 (38)	60 (69)	3 (21)	15 (20)

£ *Data from Watanakunakorn and Burkert[3] , Sandre and Shafran[4] and Bouza et al.[5]*
* Including 9 *Streptococcus agalactiae*, *6 S. bovis*, *3 S. pneumoniae*, *2 S. pyogenes*, 1 group G streptococcus, and 1 *Abiotrophia* spp.
† Mostly (>80%) represented by *Enterococcus faecalis*.
‡ Includes *Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens* and *Kingella kingae*.
§ Includes 4 *Escherichia coli, 2 Corynebacterium* spp., *2 Proteus mirabilis,* 1 *Mycobacterium tuberculosis* and 1 *Bacteroides fragilis*.

Kingella kingae.[6] Patients who have a prosthetic valve implanted during active IE also have a greater risk (up to seven times) of subsequent prosthetic valve endocarditis than patients undergoing elective valve replacement, although the infection may be due to a different organism.

Infective endocarditis in intravenous drug users

Intravenous drug users constitute a special risk group of relatively young people, with a median age varying between 30 and 40 years.[7] Men are more often affected than women. The prevalence of intravenous drug users among patients who have IE depends on the study population, representing up to 40% of cases of IE in San Francisco but less than 1% in Olmsted County, Minnesota, USA. [19] The tricuspid valve is infected in more that 50% of cases, followed by the aortic valve in 25% and the mitral valve in 20%, with mixed right-sided and left-sided IE in a few cases.[7] It has been suggested that repeated injections of impure drugs and particulate material might produce microtrauma to the tricuspid leaflets, thus facilitating microbial colonization and infection. However, 20–40% of intravenous drug users suffering IE have pre-existing cardiac lesions, often caused by previous valve infection. The responsible bacteria often originate from the skin, which explains the predominance of *S. aureus* infections (Table 59.1), but streptococci and other micro-organisms are also encountered; some pathogens, such as *Pseudomonas aeruginosa* and fungi, may produce severe forms of IE. Infection with HIV is not itself a risk factor for IE, except in rare cases caused by *Bartonella* spp. Nevertheless, the mortality of IE is higher in patients who have AIDS, especially in advanced cases, than in other patients.[20]

Nosocomial infective endocarditis

The incidence of nosocomial IE is increasing. In a recent series it accounted for 22% of 109 cases overall and 16% of cases excluding early prosthetic valve endocarditis in cardiac surgery patients.[5] Many patients had debilitating underlying conditions but fewer than 50% had obvious cardiac predisposing factors. In most circumstances a potential source of bacteremia could be identified, such as the presence of intravenous lines or invasive procedures. [5] [21] Pathogens usually originated from the skin or the urinary tract, staphylococci

and enterococci being the most common. In one study, up to 13% of nosocomial *S. aureus* bacteremia was responsible for subsequent IE.[22] However, other organisms may be encountered, including Gram-negative bacteria and fungi. Right-sided IE is increasingly recognized in association with central venous lines, pulmonary artery catheters and pacemakers. Possible right-sided IE was reported in 5% of bone marrow transplant recipients who had central venous catheters.

Thus, nosocomial IE must not be underestimated. Any procedures that produce transient bacteremia represent some degree of risk in hospitalized patients, especially when the circulating organism is *S. aureus*. [22] Such considerations are important because the mortality of nosocomial IE is greater than 50%.[5] [21]

PATHOGENESIS, PATHOLOGY AND INFECTING MICRO-ORGANISMS

The key issues in the pathogenesis of IE, discussed below, are:

- the predisposing host factors;
- the characteristics of the infecting micro-organisms;
- the role of transient bacteremia; and
- the inability of the immune system to eradicate micro-organisms once they are located on the endocardium.

Predisposing host factors

The importance of host factors is indicated by the fact that IE most often develops on pre-existing lesions of the layer of endothelial cells covering the valve or endovascular surfaces. Normally, this endothelium is resistant to colonization by circulating bacteria, but damage to this delicate protective layer increases susceptibility to bacterial colonization by several orders of magnitude (Fig. 59.1). Exposure of the underlying extracellular matrix proteins and the local production of

tissue factors trigger the deposition of platelets and fibrin as a normal host response initiating the healing process. Such a platelet-fibrin meshwork, referred to as nonbacterial thrombotic endocarditis (NBTE), is a favorable nidus for bacterial colonization during transient bacteremias.[23]

Endothelial damage may occur in several ways. Congenital cardiac abnormalities may cause turbulent blood flow, which in turn may provoke peeling of the endothelium. Valve scarring and calcification following rheumatic carditis or in the sclerotic valves of elderly patients result in endothelial lesions. Extrinsic intervention, such as

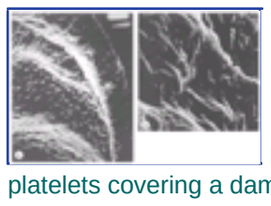

Figure 59-1 Scanning electron microscopy of a rabbit aortic valve leaflet. (a) A normal valve, covered by a monolayer of endothelial cells. (b) The meshwork of fibrin and platelets covering a damaged valve. Mechanical lesions of the valve were created by inserting a catheter through the right aortic carotid and across the aortic valve.

prosthetic valve replacement or indwelling electrodes or catheters, also promote endothelial lesions. Recently, the presence of *Chlamydia pneumoniae* or cytomegalovirus in endovascular locations has been linked to arteriosclerosis. [24] Whether these organisms also promote endothelial lesions that promote IE remains to be demonstrated.

Characteristics of the micro-organisms

The pathogenesis of IE was recently reviewed.[25] The organisms most frequently responsible for IE are also those that have the greatest ability to adhere to and colonize damaged values. Together, *S. aureus*, *Streptococcus* spp. and enterococci are responsible for more than 80% of all cases of IE (see Table 59.1). Infective endocarditis pathogens possess several surface ligands that mediate attachment to extracellular matrix proteins of the host. These proteins are abundant in the milieu of endothelial lesions. Such bacterial adhesins are collectively referred to as MSCRAMMs, for 'microbial surface component reacting with adhesive matrix molecules'.

In *S. aureus*, fibrinogen-binding proteins — also called clumping factors — and fibronectin-binding proteins are involved in valve colonization and infection.[26] Figure 59.2 presents a likely scenario in the case of IE due to this organism. The role of other *S. aureus* MSCRAMMs is currently being investigated. In streptococci, several adhesins as well as platelet-activating factors and exopolysaccharides seem to be involved in bacterial adherence to NBTE. This abundance of surface adhesins makes IE pathogens particularly prone to colonize damaged valve tissues.

Although bacterial colonization of pre-existing NBTE is a leading mechanism for establishment of IE, direct invasion of endothelial cells may also occur under certain circumstances. A few cases of IE are due to intracellular pathogens such as *Coxiella burnetii* (the agent of Q fever), *Chlamydia* spp., *Legionella* spp. and *Bartonella* spp.[27] Infection by these pathogens may occur by direct or indirect invasion of the cardiac endothelium. Direct invasion of endothelial cells has been demonstrated in vitro with *S. aureus* (reviewed by Moreillon *et al.*[25]). During inflammation, endothelial cells may express a variety of molecules, including integrins of the $ß_1$ family (very late antigen, VLA) that bind fibronectin. Endothelial-bound fibronectin may be a privileged ligand for pathogens expressing fibronectin-binding proteins, including *S. aureus*. Moreover, bridging endothelial cells and *S. aureus* via fibronectin triggers bacterial internalization by the host cell. Thus, local inflammation due to

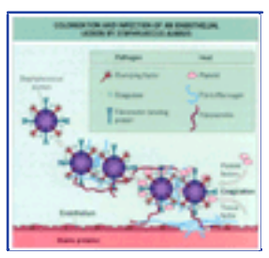

Figure 59-2 Colonization and infection of an endothelial lesion by *Staphylococcus aureus*. Exposure of the subendothelial matrix triggers the deposition of platelet-fibrin clots and other plasma-soluble and matrix proteins, including fibrinogen, fibrin, fibronectin and thrombospondin. Triggering of the coagulation cascade is also mediated by tissue factor, which contributes to platelet activation and the constitution of a nonbacterial thrombotic vegetation. *Staphylococcus aureus* is equipped with a wealth of surface determinants that may promote binding and colonization of nonbacterial thrombotic vegetations. The best known of these are fibrinogen-binding protein (or clumping factor), fibronectin-binding protein and coagulase. These factors are likely to mediate direct and/or indirect attachment to vascular lesions and promote infection.

degenerative lesions, arteriosclerosis or as yet undetermined conditions may promote fibronectin deposition on the endothelial surface and further infection. These events may be important in the pathogenesis of infection due to facultative or strict intracellular bacteria.

The role of transient bacteremia

Infective endocarditis has been modeled in rats and rabbits with catheter-induced valve lesions. These experiments have allowed the determination of a hierarchy of the infectivity of the various pathogens. Bacterial adherence is a critical factor and the magnitude and duration of the bacteremia after inoculation are also important determinants (reviewed by Moreillon *et al.* [25]).

Medical and surgical procedures in nonsterile anatomic sites may provoke transient invasion of the bloodstream with bacteria from the local flora. Such bacteremia is usually low-grade and of short duration (e.g. 1–100cfu/ml of blood for less than 10 minutes in the case of dental extraction). Depending on the characteristics of the circulating bacteria, even these transient bacteremias may put patients who have pre-existing cardiac lesions at greater risk of developing IE. In the case of dental procedures, postextraction bacteremia is more important in patients suffering from gingivitis than in individuals who have a healthy gingivodental status. This was simulated in rats with catheter-induced aortic NBTE.[28] Animals suffering from gingivitis were at a much greater risk of postextraction endocarditis than those with healthy gingivae. Most interestingly, although all the rats developed polymicrobial bacteremias during a dental procedure, only two types of organism — group G streptococci and *S. aureus* — colonized the valves to cause IE. This correlates with the ability of these bacteria to attach to NBTE.[29]

Transient bacteremias occur spontaneously during chewing, toothbrushing and other normal activities. These spontaneous bacteremias provide the likely explanation for the fact that most cases of IE are not preceded by medical or surgical procedures. Moreover, because streptococci are normal inhabitants of the mouth, spontaneous bacteremias arising from the mouth during chewing may explain why these bacteria are a predominant cause of IE. Thus, proper prophylactic measures during specific medical interventions will only marginally affect the overall frequency of IE.[30] Simple prevention strategies such as good dental hygiene provide the best method of prophylaxis in this context.

The role of host defenses

Infective endocarditis is most often due to Gram-positive organisms, and rarely to Gram-negative bacteria (see Table 59.1). The reason for this is probably multifactorial. Differences in bacterial adherence to NBTE may be one explanation. However, differences in the susceptibility of Gram-positive and Gram-negative bacteria to serum-induced killing may also account for these variations. The C5b–C9 membrane-attack complex of complement kills Gram-negative bacteria by perforating their outer membrane. In contrast, complement does not kill Gram-positive bacteria. They lack an outer membrane and their plasma membrane is protected from the membrane-attack complex of complement by the surrounding peptidoglycan.

The importance of serum was demonstrated in experimental IE induced by serum-susceptible *Escherichia coli*.[31] These organisms were spontaneously cleared from the vegetations even after infection with very large inocula. Nevertheless, some Gram-negative bacteria may carry thick capsules or other modifications of their outer membrane that help them resist complement-induced killing. An important subgroup of cases of IE are caused by Gram-negative bacteria, including micro-organisms of the HACEK group, as well as *P. aeruginosa* in intravenous drug users.[32]

Although Gram-positive bacteria are resistant to complement, they may be the target of another non-specific immune factor, namely the platelet microbicidal proteins (PMPs).[33] These are peptides produced by activated thrombocytes that kill bacteria by a mechanism that is as yet incompletely understood. Indirect evidence for the protective role of PMPs in IE came from experiments in which thrombocytopenic rabbits demonstrated greater bacterial densities in their vegetations than rabbits with normal platelet counts. Likewise, micro-organisms recovered from patients who had IE were consistently resistant to PMP-induced killing, whereas similar bacteria recovered from patients who had other types of infection were susceptible to PMP.[34] Therefore platelets, which are a major component of the vegetations, may be key

players in the non-specific defense against IE.

Humoral and cellular immunity seem to play only a limited role in defense against IE. Recent immunization studies in experimental endocarditis gave contradictory results. Immunization of rats against the streptococcal MSCRAMM FimA conferred cross-protection against IE due to several *viridans* group streptococci.[35] In contrast, immunization of rabbits against the enterococcal aggregation substance (AS) failed to protect the animals against experimental IE.[36] In this case, specific antibodies arising from vaccination could not appropriately penetrate inside the vegetation in vivo. Administration of granulocyte colony-stimulating factor did not influence the course of infection either.[37] Infective endocarditis is not noticeably more frequent in immunocompromised patients than in those who have no immune defects. In established infection, bacteria are clustered in amorphous platelet-fibrin clots (the vegetations), permitting little access to professional phagocytes to remove the bacteria (Fig. 59.3). This explains why successful treatment of IE relies primarily on the ability of antibiotics rather than host defenses to kill bacteria in situ in the vegetation. Figure 59.4 presents the

Figure 59-3 Microscopic appearance of a vegetation from a patient suffering mitral valve infective endocarditis due to *Streptococcus sanguis.* The purple area represents clusters of streptococci packed within a fibrin-platelet meshwork. Professional phagocytes are essentially absent from the lesion.

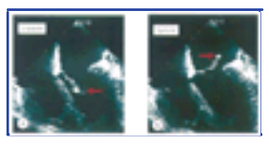

Figure 59-4 Transesophageal echocardiography of a mitral valve infective endocarditis. (a) Mass attached to anterior leaflet. (b) Prolapse of the leaflet due to rupture of chordae tendinae. Arrows indicate a large pediculated vegetation, which oscillates from the left ventricle to the left atrium during systole. *Courtesy of Dr X Jeanrenaud.*

echocardiographic picture of this very vegetation, which occurred in the context of a mitral valve endocarditis with a large, oscillating valve lesion.

PREVENTION

Because of its severity, it is generally agreed that IE should be prevented whenever possible. Choice of appropriate prophylactic measures requires:

- identification of patients at risk;
- determination of the procedures or circumstances that may result in bacteremias;
- choice of an appropriate antimicrobial regimen; and
- balancing of the known risks against the possible benefits of intervention.

In many countries, recommendations for prophylaxis have been established, based on underlying cardiac conditions and distinguishing between high-risk and low-risk situations depending on the anatomic defects and the medical or dental procedure in question (Table 59.2).[38] [39]

The practice of IE prophylaxis is not based on the results of randomized studies because these would require too many patients and raise difficult ethical issues. Therefore, antibiotic regimens used in humans are based upon their proven efficacy in animal models of IE. In contrast to therapy, successful prophylaxis does not require bactericidal antibiotics. The key factor is the period of time during which serum levels of antibiotics remain above the minimum inhibitory concentration (MIC) for the circulating pathogen. For amoxicillin, this optimal duration is 10 hours or more.[40] Therefore, prophylactic antibiotics are given in large single doses or in repeated doses, or both, in order to ensure the prolonged presence of the drug in the serum.

Antibiotics are chosen in relation to the most probable pathogens circulating in the blood during a given procedure (Table 59.3). For oropharyngeal manipulation, antibiotic prophylaxis should be aimed at streptococci. For gastrointestinal or urogenital manipulations, it should be aimed at enterococci. Indeed, although gastrointestinal procedures are more likely to produce Gram-negative bacteremia, these organisms are rarely responsible for IE. For drainage of skin or other infected lesions, antibiotic prophylaxis should be aimed at the most likely infecting organism present in the lesion and, as a minimum, it should cover staphylococci. It is noteworthy that, during dental manipulation, the risk of bacteremia correlates with the status of dental hygiene; patients who have healthy gums are at lower risk than those who have severe gingivitis. In cases of severe gingivitis, the local application of an antiseptic wash using chlorhexidine may be a useful additional measure.

CLINICAL FEATURES

Infective endocarditis may follow an acute or subacute course. The general clinical features (Table 59.4) are not usually specific.

Acute infective endocarditis

Acute IE is most frequently caused by *S. aureus*, followed by enterococci and certain streptococci, such as *Streptococcus milleri*. Infective endocarditis caused by *S. aureus* and other primary invasive pathogens can be devastating. Bacterial production of proteases and other exoproteins contributes to rapid destruction of valve leaflets and the development of abscesses located in the valve ring and the myocardium. Myocarditis and pericardial effusions are frequent. Patients are prostrate and have a high fever. Hypotension and shock may occur, caused both by the septic state and by cardiac failure. Cardiac vegetations may vary from a few millimeters in diameter to more than 1cm. Large vegetations are frequent in acute staphylococcal and fungal IE (Fig. 59.5) and are more likely to detach and give rise to septic emboli. Complications in peripheral organs mainly result from embolic lesions; these may include skin abscesses and retinal emboli (Fig. 59.6) and cerebral abscesses and splenic lesions (Fig. 59.7).

Major indications for urgent valve replacement include refractory cardiac failure due to valve destruction and persistent sepsis related to myocardial abscesses. A defect in atrioventricular conduction is often an early sign of septal invasion by a contiguous valve ring abscess, which usually requires urgent surgery.

Subacute infective endocarditis

Subacute IE is not usually due to *S. aureus* but it may be caused by any of the organisms listed in Table 59.1 . The course of subacute IE can mimic chronic wasting diseases. The duration between an identifiable event producing bacteremia (e.g. a dental procedure) and the diagnosis of IE can vary from a few days to 5 weeks or more. Fever is almost always present (see Table 59.4). Physical signs reflect the existence of cardiac or peripheral complications. These

TABLE 59-2 -- Pre-existing conditions associated with an increased risk of developing endocarditis.[*]

PRE-EXISTING CONDITIONS ASSOCIATED WITH AN INCREASED RISK OF DEVELOPING ENDOCARDITIS
Endocarditis prophylaxis recommended
High-risk patients
• Prosthetic cardiac valves, including bioprosthetic and homograft valves

• Previous infectious endocarditis
• Complex cyanotic congenital heart disease
• Surgically constructed systemic pulmonary shunts or conduits
• Other congenital cardiac malformations (except for those specified in the next column)
Moderate-risk patients
• Other congenital cardiac malformations (except for those specified in the next column)
• Acquired valve dysfunction (including rheumatic heart disease)
• Hypertrophic cardiomyopathy
• Mitral valve prolapse with valve regurgitation and/or thickened valve leaflets
Endocarditis prophylaxis not recommended
Patients who have identical risk to the general population
• Isolated secundum atrial septal defect
• Surgical repair of septal defect (atrial or ventricular)
• Surgical or medical repair of ductus arteriosus
• Previous coronary artery bypass
• Mitral valve prolapse without valve regurgitation
• Functional heart murmur
• Previous Kawasaki disease without valve dysfunction
• Previous rheumatic fever without valve dysfunction
• Cardiac pacemaker (intravascular or epicardial) and implanted defibrillator

** Adapted from recommendations in Europe[38] and the USA.[39]*

include a new or changing heart murmur and evidence of embolic events.

Immunologic stimulation during subacute IE causes hyperproduction of gammaglobulin. Rheumatoid factor is present in up to 50% of patients after 6 weeks of subacute infection; its level decreases after effective treatment. Immune phenomena may be the cause of petechiae, splinter hemorrhages, Osler nodes and Roth spots, arthritis and glomerulonephritis. Osler nodes are small and painful nodular lesions on the pads of the fingers or toes or on the thenar or hypothenar eminences (Fig. 59.8). They are caused by an allergic vasculitis. Although classic, they are not pathognomonic of subacute IE. Roth spots are rounded retinal hemorrhages with a white center. Focal or diffuse glomerulonephritis is present in most of the cases. Because these phenomena follow stimulation of the immune system, they are less common in acute IE.

Vascular complications

Embolic lesions result from vegetation fragments breaking off the valve and lodging in arteries serving peripheral organs. Other types of vascular manifestation are the consequence of immune-related vasculitis. Mycotic aneurysms are found in up to 15% of cases and are especially common in staphylococcal IE. They may arise either from direct invasion of the arterial wall by the infecting organisms, from septic embolization of the vasa vasorum or from the deposition of immune complexes that trigger local inflammation and weakening of the arterial wall. Mycotic aneurysms tend to be located at the bifurcation points of vessels. They may either heal during antibiotic therapy or become clinically evident later, even months after the clinical cure of the disease. Therefore, the true incidence of mycotic aneurysms during IE is probably underestimated. In right-sided IE, embolization occurs in the pulmonary circulation and gives rise to pulmonary infiltrates and lung abscesses.

Neurologic complications

Neurologic manifestations occur in up to 40% of cases.[3] [5] [41] However, because patients who have no neurologic symptoms do not undergo specific investigations, the true incidence of neurologic events during IE may be underestimated. Anatomic alterations include cerebral infarction, arteritis, abscesses, mycotic aneurysms, intracerebral or subarachnoid hemorrhage, encephalomalacia, cerebritis and menin-gitis. Such complications occur most often in staphylococcal or streptococcal IE but they are not restricted to IE caused by these pathogens. The frequency of stroke is similar between native valve and prosthetic valve IE.[41] [42] However, the frequency of both vegetations and stroke is significantly greater in patients who have mitral valve IE than in patients who have aortic valve IE.[5] [42]

Controlling the infection is essential. Embolization sharply decreases within 1–2 weeks of effective therapy.[43] [44] Recurrent embolization may necessitate urgent valve replacement. This decision is difficult because anticoagulation during extracorporeal circulation and after valve replacement puts the patients at increased risk of secondary intracerebral hemorrhage. Therefore, the tendency is often to postpone emergency surgery and wait for the patient to stabilize. On the other hand, ongoing studies suggest that earlier intervention, within the first 72 hours of stroke, may be beneficial in selected patients.[45] The best approach to these challenging issues needs continuing investigation.

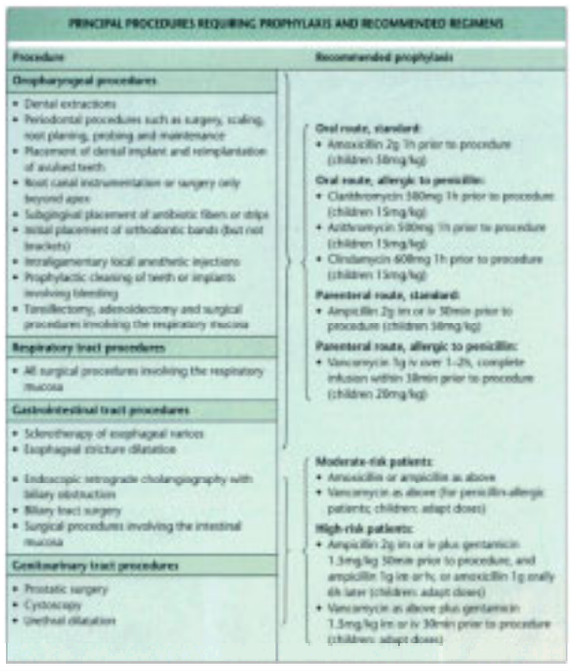
DIAGNOSIS

Whether acute or subacute, IE may result in life-threatening complications. Therefore, precise clinical and microbiologic diagnosis is mandatory in order to guide therapy. In theory, IE combines both persistent bacteremia and anatomic lesions of the valves. However, blood cultures may remain negative in up to 10% of cases (Table 59.1 and Table 59.5). Clinical and microbiologic diagnosis of IE is difficult in such blood-culture-negative cases, or when changes in the valve status cannot be assessed owing to lack of information on preexisting cardiac lesions.[1] [2]

The Duke criteria

In 1994 new diagnostic criteria based on both microbiologic data and echocardiographic imaging of cardiac vegetations were proposed.[1]

TABLE 59-3 -- Principal procedures requiring prophylaxis and recommended regimens.*



** Adapted from recommendations in Europe[38] and the USA.[39]*

Today, nearly all patients suspected of having IE should undergo at least one echocardiographic evaluation, including transesophageal echo in selected cases. These criteria, which are referred to as the Duke criteria, were validated in several studies worldwide. Recently, they were refined to more accurately detect patients who have IE in the case of negative blood cultures and *S. aureus* bacteremia (Table 59.6).[2]

Blood cultures

Blood cultures are of primary importance because they reveal the infecting organism and thus guide antibiotic therapy. For the main etiologic agents, the first two blood cultures will be positive in more than 90% of cases. However, certain micro-organisms may be difficult to isolate. Variables affecting isolation include the volume of blood cultured, the number of blood cultures obtained before antimicrobial therapy is started, the type of micro-organism involved and the techniques of blood culture.

The volume of blood cultured is critical because persistent bacteremia in IE is often low-level, representing only 1–100 bacteria/ml of blood. For each culture, 8–12ml of venous blood should be drawn with careful antiseptic precautions and distributed into a two-bottle system for incubation. Blood for culture should be drawn on two or three separate occasions over a 24-hour period. If possible, the interval between each culture should be at least 30–60 minutes.

Culture-negative infective endocarditis

Special attention must be given to culture-negative IE. Such cases are often associated with antibiotic consumption within the previous 2 weeks. In such patients it may be necessary to obtain additional blood cultures and to use media supplemented with ß-lactamase when appropriate. However, culture-negative IE may also be due to fastidious organisms or to intracellular pathogens that are not easily detected by standard culture conditions. The issue is important because these organisms often require alternate diagnostic procedures and respond to different therapies.

Infective endocarditis due to rare and fastidious organisms was recently reviewed.[27] Table 59.5 lists the principal organisms of this group and proposed diagnostic procedures and therapies. Since such cases are rare, most therapeutic recommendations are based on limited experience, including case reports and small series. Therefore, any of these conditions requires special case-by-case attention from the care giver.

Microbiologic cultures

Bacteria of the HACEK group are usually detected after prolonged (more than 1 week) incubation of the blood cultures. In contrast, *Abiotrophia* spp. grow well in blood but fail to grow when subcultured on conventional agar media. These so-called deficient bacteria do grow as satellite colonies if the plates are streaked with *S. aureus*, or if the growth medium is enriched with vitamin B6. One of these methods

TABLE 59-4 -- Clinical features of infective endocarditis in the general population and in specific at-risk groups.[*]

CLINICAL FEATURES OF IE IN THE GENERAL POPULATION AND IN SPECIFIC AT-RISK GROUPS

* *Data from Watanakunakorn and Burkert[3] and Sandre and Shafran.[4]*
*As reported by Sandre and Shafran.[4]
† As reported by Watanakunakorn and Burkert.[3]

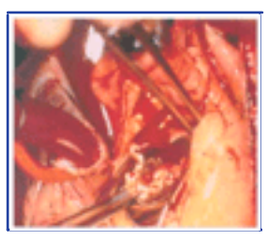

Figure 59-5 Aortic valve of a patient undergoing emergency valve replacement for acute endocarditis caused by *Staphylococcus aureus.* In this patient, emergency valve replacement was mandatory because of multiple embolizations and acute heart failure. Here, the aorta has been opened and the valve is viewed from its upper side. The lower tweezers are holding a valve leaflet covered with vegetations. Next to the upper tweezers, a portion of a cuspid with a normal appearance can be distinguished.

should be applied when bacteria are observed microscopically in blood cultures but fail to grow on the subculture plates.

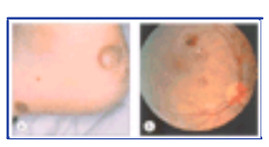

Figure 59-6 Skin lesions (Janeway spots) on the foot (a) and septic emboli of the retina (b), the results of peripheral emboli in acute endocarditis caused by *Staphylococcus aureus.* These occurred in the patient described in Figure 59.5 and were present on admission to hospital.

Brucella spp, *Bartonella* spp., *Legionella* spp. and *Mycobacteria* spp. are rare causes of IE that require special culture techniques. Serologic tests may help define both culture strategies and other diagnostic procedures. Tissue cell cultures may be performed in specialized laboratories for the detection of strict or facultative intracellular bacteria. These include *C. burnetii*, *Chlamydia* spp., *Legionella* spp. and *Bartonella* spp.

If the patient undergoes surgery it is of utmost importance to obtain valve samples for both cultures and other microbiologic tests. The presence of large numbers of bacteria in the vegetation increases the chance of positive culture and/or identification of the pathogen by other means. The importance of cultures cannot be emphasized enough, because they fulfill both diagnostic and therapeutic purposes, and in particular allow testing for antimicrobial susceptibility.

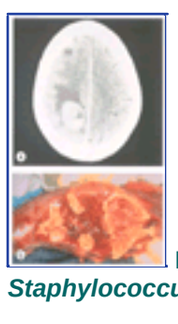

Figure 59-7 A cerebral abscess (a) and multiple abscesses and ischemic necroses of the spleen (b), the result of peripheral emboli in acute endocarditis cause by *Staphylococcus aureus.* Again these occurred in the patient described in Figure 59.5 ; they developed after admission to hospital.

TABLE 59-5 -- Rare causes of infective endocarditis associated with negative blood cultures.*

RARE CAUSES OF IE ASSOCIATED WITH NEGATIVE BLOOD CULTURES		
Pathogen	**Diagnostic procedure**	**Proposed therapy**
Brucella spp.	Blood cultures	Doxycycline plus rifampin or trimethoprim-sulfamethoxazole (treatment for >3 months*
	Serology	
	Culture, immunohistology and PCR of surgical material	
Coxiella burnetii (agent of Q fever)	Serology: IgG phase 1 > 1/800	Doxycycline plus hydroxychloroquine†
	Tissue culture, immunohistology and PCR of surgical material	Doxycycline plus quinolone (>18 months treatment)
Bartonella spp.	Blood cultures	ß-lactams or doxycycline plus aminoglycoside‡ (>6 weeks treatment)
	Serology	
	Culture, immunohistology and PCR of surgical material	
Chlamydia spp.	Serology§	Doxycycline
	Culture, immunohistology and PCR of surgical material	Newer fluoroquinolones¶ (long-term treatment, optimal duration unknown)
Mycoplasma spp.	Serology	Doxycycline
	Culture, immunohistology and PCR of surgical material.	Newer fluoroquinolones¶ (>12 weeks treatment)
Legionella spp.	Blood cultures	Macrolide plus rifampin
	Serology	Newer fluoroquinolones¶ (>6 months treatment)
	Culture, immunohistology and PCR of surgical material.	
Tropheryma whippelii (agent of Whipple's disease)	Histology and PCR of surgical material	Trimethoprim-sulfamethoxazole*
		ß-lactam plus aminoglycoside (long-term treatment, optimal duration unknown)
Because of the lack of large series on IE due to these pathogens, optimal treatment duration is mostly unknown. Treatment durations in the table are indicative and are based on selected case reports.		

* *Adapted from Brouqui and Raoult.[27]*
* According to Hadjinikolaou *et al.*[46]
† Doxycycline 100mg po q12h and hydroxychloroquine 200mg po q8h (hydroxychloroquine levels in the serum were monitored) was significantly superior to doxycycline.[47]
‡ Several therapeutic regimens were reported, including aminopenicillins and cephalosporins combined with aminoglycosides, doxycycline, vancomycin and quinolones (reviewed in Brouqui and Raoult[27]).
§ Beware of serologic cross-reaction with the more common IE pathogen *Bartonella* spp.
¶ Newer fluoroquinolones are more potent than ciprofloxacin against intracellular pathogens such as *Mycoplasma* spp., *Legionella* spp. and *Chlamydia* spp.
** Treatment of Whipple IE remains highly empiric. Successes were reported with long-term (>1 year) trimethoprim-sulfamethoxazole therapy. Gamma interferon plays a protective role in intracellular infections. It was proposed as adjuvant therapy in Whipple's disease.[50]

Histology

A number of special stains may help guide the etiologic diagnosis. Important techniques include Gram stain for Gram-positive and Gram-negative bacteria, periodic acid-Schiff stain for Whipple's disease, Giemsa and Warthin-Starry stains for numerous bacteria, including *Bartonella* spp., Ziehl-Neelsen stain for *Mycobacteria* spp, and Gimenez stain for *C. burnetii* and *Legionella* spp. While not strictly diagnostic, these techniques help to delineate more specific etiologic procedures, including cultures, immunohistology and molecular assessment.

Polymerase chain reaction amplification

Polymerase chain reaction (PCR) amplification of the 16S ribosomal RNA gene has become a critical method for bacterial diagnosis in tissue samples. It has been successfully applied to IE surgical material,[48]

Figure 59-8 Osler node on the thumb during subacute endocarditis. This was a rounded, tender, inflamed mass about 5mm in diameter.

TABLE 59-6 -- Modified Duke criteria for diagnosis of infective endocarditis.*

MODIFIED DUKE CRITERIA FOR DIAGNOSIS OF INFECTIVE ENDOCARDITIS	
Definition terminology used in the criteria	
Major criteria	
1. Blood culture	Positive blood cultures (>2/2) with typical IE micro-organisms (*viridans* streptococci, *Streptococcus bovis*, HACEK group or community-acquired *Staphylococcus aureus* or enterococci in the absence of primary focus)
	Persistently positive blood cultures defined as two culture sets drawn >12h apart, or three or the majority of four culture sets with the first and last separated at least by 1h
	Single positive culture for *Coxiella burnetii* or anti-phase I antibody titer >1:800
2. Endocardial involvement	New valve regurgitation
	Positive echocardiogram for IE (transesophageal echo recommended in patients who have prosthetic valves and patients rated as 'possible' IE by clinical criteria) defined as:
	(i) oscillating intracardiac mass in the valve or supporting structure, *or* in the path of regurgitant jets, *or* on implanted material, in the absence of an alternative anatomic explanation, *or*
	(ii) abscess, *or*
	(iii) new partial dehiscence of prosthetic valve
Minor criteria	
1. Predisposing cardiac condition or intravenous drug use	
2. Fever: >100.4°F (>38°C)	
3. Vascular phenomena: arterial emboli, mycotic aneurysms, petechiae, Janeway lesions	
4. Immunologic phenomena: glomerulonephritis, Osler nodes. Roth spots, rheumatoid factor	
5. Microbiology: positive blood cultures, but not meeting major criteria, serologic evidence of active infection with plausible micro-organisms	
Diagnosis	
Definite	
• Pathology or bacteriology of vegetations, *or*	
• 2 major criteria, *or*	
• 1 major and 3 minor criteria, *or*	
• 5 minor criteria	
Possible	
• 1 major and 1 minor criterion, *or*	
• 3 minor criteria	
Rejected	
• Firm alternative diagnosis, *or*	
• Resolution of IE syndrome after <4 days of antibiotic therapy, *or*	
• No pathologic evidence at surgery or autopsy after <4 days of antibiotic therapy	
• Does not meet criteria mentioned above	

** Adapted with modifications from Durack et al. [1] and Li et al. [2]*

including cutaneous biopsies of peripheral septic emboli (personal experience). Polymerase chain reaction is invaluable to detect poorly cultivable or noncultivable bacteria such as *Tropheryma whippelii*.[50] Figure 59.9 depicts a case of culture-negative aortic valve IE necessitating valve replacement. *Tropheryma whippelii* was identified by histology and PCR amplification of the surgical material. Undiagnosed culture-negative IE is a genuine problem because unusual pathogens may not respond to empiric ß-lactam and aminoglycoside therapy.

Serology

Serologic tests are included in both the original and modified Duke criteria.[1] [2] Common tests include the agglutination test for *Brucella melitensis*, indirect fluorescence for *Legionella pneumophila*, enzyme-linked immunosorbent assay (ELISA) for *Mycoplasma pneumoniae*, and complement fixation, ELISA and indirect immunofluorescence for *Chlamydia* spp. Of note, cross-reaction may occur between *Bartonella* spp. and *Chlamydia* spp. Since culture-proven IE due to *Chlamydia* spp. is notoriously rare, *Bartonella* should be suspected in the case of positive *Chlamydia* serology. This point is important because antimicrobial therapy differs (see Table

59.5).

Other tests

Although many laboratory findings may be abnormal, most of them are non-specific. The erythrocyte sedimentation rate and the

Figure 59-9 Blood culture-negative aortic valve endocarditis caused by *Tropheryma whippelii* in a 48-year-old patient. The patient was admitted to hospital for acute abdominal pain. Abdominal surgery revealed an ischemic necrosis of the transverse colon, presumably due to arterial embolization. An echocardiogram revealed exuberant vegetations on the aortic valve. All blood cultures were negative. Emergency valve replacement was performed for cardiac insufficiency. *Tropheryma whippelii* infection was identified by histology and by using broad-spectrum PCR amplification of the surgical material. The patient was treated with long-term (>1 year) trimethoprim-sulfamethoxazole (see Table 59.5). *With permission from Bugon and Moreillon.*[49]

C-reactive protein are elevated in 90–100% of cases. Acute IE may be accompanied by high or low leukocyte counts with increased polymorphonuclear cells and immature forms, as well as other blood and chemistry abnormalities related to active infection. In subacute IE, non-specific laboratory findings accompanying chronic infection are common but not universal. These findings include mild anemia with low serum iron concentration and low iron-binding capacity and thrombocytosis, as well as leukocytosis, hypergammaglobulinemia and the presence of circulating immune complexes. Urinalysis often reveals proteinuria and microscopic hematuria. Although none of these tests can prove the diagnosis of IE, their return to normal values during treatment is an indirect marker of therapeutic success.

MANAGEMENT

Successful treatment of IE relies primarily on antibiotic therapy. Combined medical and surgical treatment is needed in up to one-third of cases. Both experimental and clinical studies have indicated the importance of using bactericidal drugs in order to cure IE. For instance, 2 weeks penicillin treatment for streptococcal IE was insufficient to prevent relapses, whereas 2 weeks of the synergistic combination of penicillin plus an aminoglycoside successfully cured patients. Combination of bactericidal drugs is even more important against enterococcal IE, where the association of ß-lactams

TABLE 59-7 -- Suggested treatment for native valve endocarditis due to streptococci, enterococci and HACEK micro-organisms.‡

SUGGESTED TREATMENT FOR NATIVE VALVE ENDOCARDITIS DUE TO STREPTOCOCCI, ENTEROCOCCI AND HACEK MICRO-ORGANISMS			
Antibiotic	**Dosage and route**	**Duration (weeks)**	**Comments**
Penicillin-susceptible *viridans* streptococci and *Streptococcus bovis*			
Penicillin G Ceftriaxone*	6 × 2–3 million units/day iv	4	Preferred in patients older than 65 years or who have impaired renal function
	1 × 2g/day iv or im	4	
Penicillin G with gentamicin	6 × 2–8 million units/day iv	2	Studies suggest that gentamicin once daily might be adequate
	3 × 1mg/kg/day iv or im	2	
Ceftriaxone* with netilmicin	1 × 2g/day day iv or im	2	
	1 × 4mg/kg/day iv	2	
Vancomycin	2 × 15mg/kg/day iv	4	Recommended for ß-lactam-allergic patients
Intermediate penicillin-resistant (MIC 0.1–1mg/l) *viridans* streptococci and *S. bovis*			
Penicillin G with gentamicin	6 × 3 million units/day iv	4	Studies suggest that gentamicin once daily might be adequate
	3 × 1mg/kg/day iv or im	2	
Vancomycin	2 × 15mg/kg/day iv	4	Recommended againist highly resistant strains
***Enterococcus* spp.†**			
Penicillin G with gentamicin	6 × 3–5 million units/day iv	4–6	6-weeks therapy recommended for patients who have had symptoms >3 months
	3 × 1mg/kg/day iv or im	4–6	
Ampicillin with gentamicin	6 × 2g/day iv	4–6	Studies suggest that gentamicin once daily might be adequate
	3 × 1mg/kg/day iv or im	4–6	
Vancomycin with gentamicin	2 × 15mg/kg/day iv	4–6	Monitor drug serum levels and renal function
	3 × 1mg/kg/day iv or im	4–6	
Micro-organisms of the HACEK group			
Ceftriaxone*	1 × 2g/day day iv or im	4	
Ampicillin with gentamicin	6 × 2g/day iv	4	Studies suggest that gentamicin once daily might be adequate
	3 × 1mg/kg/day iv or im	4	

‡ *Adapted from Wilson et al.,*[52] *Francioli et al.*[53] *and Heldman et al.*[54]
* Preferred for outpatient treatment.
† Treatment of endocarditis due to vancomycin-resistant enterococci requires a careful assessment of susceptibility to alternative antibiotics, including the new streptogramin combination quinupristin-dalfopristin.

and aminoglycosides is mandatory to ensure treatment success.

Therapeutic schemes recommended for the most common pathogens are presented in Table 59.7 and Table 59.8 .[51] [52] [53] High concentrations of antibiotic in the serum are desirable to ensure penetration into vegetations. Moreover, prolonged treatment is mandatory to kill dormant bacteria clustered in the infected foci (see Fig. 59.3). Therefore, although outpatient and oral therapy has been proposed in specific conditions, [54] [55] prolonged parenteral therapy is usually recommended.

The choice of an optimal therapeutic regimen is based on antibiotic susceptibility testing. The MICs of the principal drugs for the infecting pathogens should be determined. More sophisticated tests, such as minimum bactericidal concentration (MBC) or serum inhibitory and bactericidal concentrations during drug therapy, are not usually needed, although they may be useful when the therapeutic response is inadequate. In such cases, it is important to exclude other causes of treatment failure, such as inadequate antibiotic administration, antibiotic resistance or the presence of a surgically removable focus.

Resistant pathogens and culture-negative IE may fail to respond to standard therapy. The three most problematic organisms in this respect are penicillin-resistant streptococci, methicillin-resistant staphylococci and multiple-drug-resistant enterococci. The organisms responsible for culture-negative IE are listed in Table 59.5 and are also described below.

TABLE 59-8 -- Suggested treatment for native valve and prosthetic valve endocarditis due to staphylococci.[†]

SUGGESTED TREATMENT FOR NATIVE VALVE AND PROSTHETIC VALVE ENDOCARDITIS DUE TO STAPHYLOCOCCI			
Antibiotic	**Dosage and route**	**Duration (weeks)**	**Comments**
Native valves			
Methicillin-susceptible staphylococci			
Flucloxacillin, or oxacillin, or nafcillin with gentamicin (optional)	6 × 2g/day iv	4–6	The benefit of adding gentamicin has not been demonstrated
	3 × 1mg/kg/day iv or im	3–5 days	
Cefazolin (or other first generation cephalosporins) with gentamicin (optional)	3 × 2g/day iv	4–6	Alternative for patients allergic to penicillins (not in case of immediate type penicillin hypersensitivity)
	3 × 1mg/kg/day iv or im	3–5 days	
Vancomycin	2 × 15mg/kg/day iv	4–6	Recommended for ß-lactam-allergic patients
Methicillin-resistant staphylococci			
Vancomycin	2 × 15mg/kg/day iv	4–6	Recommended for ß-lactam-allergic patients
Prosthetic valves			
Methicillin-susceptible staphylococci[*]			
Flucloxacillin, or oxacillin, or nafcillin with rifampin and gentamicin	6 × 2g/day iv	=6	Rifampin increases the hepatic metabolism of numerous of drugs, including warfarin
	3 × 300mg/day po	=6	
	3 × 1mg/kg/day iv or im	2	
Vancomycin with rifampin and gentamicin	2 × 15mg/kg/day iv	=6	Recommended for ß-lactam allergic patients
	3 × 300mg/day po	=6	
	3 × 1mg/kg/day iv or im	2	
Methicillin-resistant staphylococci			
Vancomycin with rifampin and gentamicin	2 × 15mg/kg/day iv	=6	
	3 × 300mg/day po	=6	
	3 × 1mg/kg/day iv or im	2	

† *Adapted with modifications from Francioli et al.*[53]

* Rifampin plays a special role in prosthetic device infection, because it helps kill bacteria attached to foreign material. Rifampin should never be used alone, because it selects for resistance at a high frequency (ca. 10–6).

Penicillin-resistant streptococci

Streptococci are becoming increasingly resistant to penicillin and other ß-lactams, owing to a decreased affinity of their membrane-bound penicillin-binding proteins (PBPs). Penicillin-resistant streptococci are classified as having either intermediate resistance (MIC 0.1–1mg/l) or high resistance (MIC >1mg/l).

Intermediately resistant streptococci may respond to standard therapy because the drug concentrations in the serum produced by intravenous ß-lactams are up to one or two orders of magnitude greater than the MIC for these bacteria (see Table 59.7). For instance, peak serum levels of penicillin G, amoxicillin or ceftriaxone are of the order of 100mg/l, as compared with the MICs of these drugs, which vary between 0.1mg/l and 1mg/l. Nevertheless, a ß-lactam should preferably be combined with an aminoglycoside in such situations.

Against highly resistant streptococci, on the other hand, alternative drugs must be considered. These include vancomycin, to which streptococci are still largely susceptible. In the future, newer quinolones with activity against Gram-positive bacteria, injectable streptogramins such as the quinupristin-dalfopristin combination, or newer oxazolidinones (linezolid) may prove useful.

Methicillin-resistant staphylococci

Staphylococci resistant to methicillin carry a new, low-affinity PBP called PBP2A. This protein allows cell wall assembly when normal PBPs are blocked by ß-lactams. PBP2A confers cross-resistance to most ß-lactam drugs. In addition, methicillin-resistant staphylococci are usually resistant to most other drugs, leaving only vancomycin to treat severe infections.

Vancomycin resistance has emerged among many strains of enterococci, and can be transferred experimentally to *S. aureus* via a transposable genetic element. Moreover, both *S. aureus* and coagulase-negative staphylococci with intermediate resistance to vancomycin have recently emerged in Japan and in the USA. The mechanism of resistance in these bacteria is different from that in enterococci, being mediated by chromosomal mutations affecting synthesis of the cell wall.[56]

Treatment of infections caused by vancomycin-resistant staphylococci will require new drugs. At the present time, few alternatives are available besides older ß-lactams with relatively good affinity for PBP2A, quinupristin-dalfopristin and oxazolidinones. Importantly, such organisms are most likely to be resistant to the newer quinolones.

Multiple-drug-resistant enterococci

These organisms are of major concern because they have become resistant to most available drugs, including vancomycin. Today, treatment of such organisms often relies on the combination of multiple drugs and the use of experimental antibiotics. Treatment of such infections requires precise determination of antibiotic susceptibilities,

testing for bactericidal activity and sometimes determination of serum inhibitory and bactericidal titers and monitoring of drug levels in the serum. Importantly, although aminoglycoside resistance is usually present, these antibiotics may still be synergistic with cell-wall inhibitors provided that the MIC for the aminoglycosides is 1000mg/l or less. Depending on the mechanism of resistance, streptomycin is worth testing because it may be active against enterococci that are resistant to other aminoglycosides.

Culture-negative endocarditis

Treatment of IE due to rare pathogens are summarized in Table 59.5 . Infective endocarditis due to *Brucella* spp. responds to prolonged (<3 months) treat- ment with doxycycline (100–200mg q12h) plus trimethoprim-sulfamethoxazole (960mg q12h) or rifampin (300–600mg/day) combined or not with streptomycin (16mg/kg/day) and surgery. Associated surgery may be required.[46] Cure is evaluated by antibody levels returning to less than 1:160.

Infective endocarditis due to *C. burnetii* is often treated with a combination of doxycycline plus a fluoroquinolone given for up to 3 years. However, recurrences are common. Recently, a regimen of doxycycline combined with hydroxychloroquine appeared more effective.[47] The proposition was based on in-vitro bactericidal tests performed in tissues cultures. Intracellular *C. burnetii* is poorly killed by tetracyclines in the acidic phagolysosomal environment. Hydroxychloroquine increases the phagolysosomal pH (from 4.7 to 5.8) and improves tetracycline-induced bacterial killing. Treatment success was assessed by the evolution of the serology. Patients are considered cured when the anti-phase I antigen IgG titer is less than 1:800 and IgM and IgA titers are less than 1:50.[47]

Infective endocarditis due to *Bartonella* spp. should be suspected in homeless at-risk patients. In a review of 48 *Bartonella* IE cases, patients were treated with a variety of regimens including primarily ß-lactams (amoxicillin and ceftriaxone) combined with aminoglycosides (netilmicin or gentamicin) for at least 2 weeks, or ß-lactams combined with other drugs (e.g. doxycycline) for a total of more than 6 weeks.[57] Importantly, more than 90% of these patients underwent surgical valve replacement, emphasizing the importance of an aggressive approach in such cases.

Optimum treatment of IE due to *Chlamydia* spp., *Mycoplasma* spp. and *Legionella* spp. is unknown. These organisms are highly susceptible to newer fluoroquinolones in vitro. Therefore, these drugs should probably be part of the therapeutic regimen.

Infective endocarditis due to *T. whippelii* is very rare. In non-IE Whipple's disease, trimethoprim-sulfamethoxazole (960mg q12h) given for more than 1 year seems the safest alternative.[50] Some authors also recommend sequential treatment, starting with penicillin plus streptomycin or ceftriaxone plus gentamicin, for 2–6 weeks, followed by long-term trimethoprim-sulfamethoxazole therapy. A recent review of 35 cases of Whipple IE supports this approach.[58] Moreover, it also suggests that surgical valve replacement might be a prerequisite for successful therapy (see Fig. 59.9).

In the absence of any positive microbiologic information the therapeutic approach to culture-negative IE must balance disease severity, risk factors for specific micro-organisms and the selection of a regimen that is likely to be effective against most of the likely pathogens.

In patients who have mild uncomplicated subacute IE, it may be appropriate to await the results of blood culture before initiating therapy. However, in acute fulminating disease, especially if occurring on a background of drug addiction, staphylococcal endocarditis is likely and must be treated promptly. A penicillinase-resistant penicillin (flucloxacillin, oxacillin or nafcillin) intravenously in high dosage (2g q4h), or a first-generation cephalosporin (intravenous cefazolin 2g q8h) in combination with intravenous gentamicin (1mg/kg q8h) or intramuscular streptomycin (0.5g q12h) is an appropriate choice pending culture results.

For the truly culture-negative patient, a regimen directed at the HACEK group, enterococci and non-viridans streptococci is appropriate. Intravenous penicillin 2–3 million units q4h (or intravenous ampicillin 2g q4h) combined with intravenous gentamicin (1mg/kg q8h) is recommended. A cephalosporin, such as intravenous ceftriaxone 2g q24h, may be substituted in patients who are allergic to penicillin. Vancomycin should be reserved for the truly ß-lactamintolerant patient, or where a resistant pathogen is suspected.

Treatment of culture-negative endocarditis should be continued for a total of 6 weeks, although, if the features are those of right-sided endocarditis complicating drug addiction, then the aminoglycoside may be discontinued after 2 weeks while continuing the other agents in full dosage.

Surgery

The leading indications for surgery are:

- ¦ refractory cardiac failure caused by valvular insufficiency;
- ¦ persistent sepsis caused by a surgically removable focus or a valvular ring or myocardial abscess; and
- ¦ persistent life-threatening embolization.

The decision of when to operate on an unstable patient is difficult and requires a multidisciplinary assessment of the situation.

ENDARTERITIS AND MYCOTIC ANEURYSMS

Endarteritis is the inflammation of the arterial wall. The term mycotic aneurysm was coined by Osler to define a nonsyphilitic aneurysm resulting from infective endarteritis. Arterial infection may result from:

- microembolization of bacteria in the vasa vasorum;
- hematogenous seeding of the arterial intima or of thrombi lining atherosclerotic plaques during bacteremia;
- extension from contiguous infected foci; or
- arterial trauma with direct bacterial contamination.

The first two mechanisms are most important during IE. Other risk factors include pre-existing endarterial lesions (e.g. congenital malformations such as patent ductus arteriosus and aortic coarctation, atherosclerosis of large vessels, vascular prosthesis and sometimes depressed host immunity due to diabetes, cirrhosis or corticosteroid therapy). Infected aneurysms represent 2.6% of all aneurysms, with a male:female ratio of about 3:1.[59]

MICROBIAL PATHOGENS AND CLINICAL MANIFESTATIONS

In the context of IE, the pathogens of endarteritis follow the pattern shown in Table 59.1 . In the absence of IE, on the other hand, Gram-negative bacteria are found more frequently. *Salmonella* spp., *E. coli* and other enterobacteria are isolated in more than 50% of cases of abdominal aortitis.[59] *Salmonella choleraesuis* and *Salmonella typhimurium* seem to have a particular tropism for atherosclerotic arteries. It was proposed that all patients over 50 years of age who develop *Salmonella* bacteremia should undergo abdominal imaging to detect possible aortic lesions. *Staphylococcus aureus* is the organism most often associated with extra-abdominal lesions and infections of vascular prosthesis, and it has been reported in about 30% of endarteritis overall. Other pathogens, including fungi, are occasionally reported.

Signs and symptoms depend on the anatomic site of the disease. Local signs include pain, erythema, manifestations due to compression of contiguous organs, and distal ischemia or embolization. Fever and leukocytosis are almost always present.

DIAGNOSIS AND MANAGEMENT

Diagnosis requires a high degree of clinical suspicion. Microbiologic documentation is essential. Blood cultures and cultures of surgical specimens should be performed, if possible before starting antibiotic treatment. Otherwise, special culture media should be used by the laboratory to inactivate antimicrobial drugs present within the samples. Ultrasonography, computerized tomography, magnetic resonance imaging and gallium- or indium-labeled leukocyte scans are helpful to delineate the lesions. None of these techniques will distinguish between sterile and infected fluids; however, they may guide more invasive diagnostic procedures such as percutaneous needle aspiration of the affected area.

Appropriate antibiotic therapy and surgical resection of the infected vessel with extensive local debridement is mandatory. The material should be carefully examined by both the pathologist and the microbiologist. Whenever possible, autologous vascular graft and bypass in uninfected tissue should be performed in order to decrease the risk of re-infection. Antibiotics should be given for at least 4–6 weeks. Certain situations are so complicated that therapeutic strategies must be adapted for each particular case. Sometimes, patients are kept on antibiotics for much longer periods of time, even for life. Despite antibiotic treatment, the morbidity of vascular infections remains high. Infections of arteries in the lower extrem-ities result in amputation in as many as 20% of cases.[60] Moreover, the mortality rate of patients who have infected aneurysms that are diagnosed late may exceed 70%.[61]

Chapter 60 - Rheumatic Fever

Jonathan R Carapetis

Rheumatic fever is an autoimmune sequel to group A streptococcus infection and is characterized by damage to heart valves, brain, joints and/or skin and, less commonly, heart muscle, pericardium or lungs. All of these tissues eventually recover from the acute inflammation, with the exception of heart valves, which may be left with long-term or permanent damage. This is known as rheumatic heart disease, which remains the most common acquired heart disease of childhood in the world.

EPIDEMIOLOGY

Rheumatic fever is a disease of poverty. During the 1900s it became uncommon in industrialized countries but increasingly recognized in developing countries, which may represent an increasing incidence or better detection of cases. Most of the reduction in industrialized countries occurred prior to the availability of antibiotics[1] and is attributed to the effects of improved living conditions and hygiene infrastructure.

During the year 2000, there were estimated to be 2.5 million people in the world with congestive heart failure caused by rheumatic heart disease during 1994; of 340,000 deaths each year, only 6% occur in established market economies. [2] Others have estimated that about 12 million people suffered from either rheumatic fever or rheumatic heart disease.[3] The incidence of acute rheumatic fever is not well documented; the highest reported incidence was 508 per 100,000 children aged 5–14 years between 1987 and 1996, in the Aboriginal population of northern Australia.[4]

Approximately 50% of people with acute rheumatic fever will develop chronic heart valve damage. Rheumatic heart disease affects over 2% of all northern Australian Aboriginals[4] and is also common in the Pacific Island nations. Other regions with confirmed rheumatic heart disease prevalence >2 per 1000 include sub-Saharan Africa, the Indian subcontinent, Vietnam, Middle Eastern countries and some poorer countries in Latin America.[5] [6]

The prevalence of rheumatic heart disease is very low (usually <0.5 per 1000) in virtually all industrialized countries and is falling in many emerging market economies.[7] Since the 1980s, some areas of the United States have experienced outbreaks of acute rheumatic fever, thought to be due to the emergence of virulent group A streptococci belonging to M serotypes 1, 3 and 18.[8] [9]

First episodes of acute rheumatic fever occur most commonly in children aged between 5 and 15 years and are virtually unheard of in the first two years of life. First episodes may occur in adulthood, but are rare over the age of 35 years. Recurrent episodes also tend to occur in the 5–15 year age group but more frequently occur in adulthood, including some cases up the age of 60 years. [10] Although males and females were equally affected in most early studies, females now outnumber males in developing countries, particularly in rheumatic heart disease prevalence surveys (with ratios ranging between 1.3 and 2 to 1).

PATHOGENESIS

Acute rheumatic fever results from infection of a susceptible host with a 'rheumatogenic' group A streptococcus, leading to an abnormally vigorous, tissue-specific immune response. The exact nature of each of these components has yet to be unraveled but the recent development of improved animal models of rheumatic carditis is likely to be informative.

Immune response

Molecular mimicry — the presence of epitopes in human tissue that are immunologically similar to group A streptococcal antigens — is thought to be responsible for the autoimmune response. Epitopes cross-reacting with group A streptococcal antigens have been identified in human myosin, tropomyosin, keratin, actin, laminin, vimentin and *N*-acetylglucosamine. The cross-reactive epitopes in group A streptococci have been found in the cell wall and streptococcal membranes and in the A, B and C repeat regions of the surface M protein.[11] [12]

Antibodies reactive with both group A streptococci and human heart tissues in the sera of rheumatic fever patients have suggested that a humoral autoimmune response may mediate the tissue damage.[13] The subsequent finding that markers of cell-mediated immune responses were dramatically elevated early in acute rheumatic fever raised the possibility that T-cell activation may be critical and that humoral responses were secondary to antigens released from already damaged tissues. This has been supported by the identification of cytotoxic lymphocytes in the blood of rheumatic fever patients and the findings that M protein can stimulate cytotoxic lymphocytes, M5 protein contains T and B cell epitopes, T cells isolated from heart valve tissue of rheumatic fever patients previously infected with M serotype 5 organisms respond to several M5 peptides, and CD4 and CD8 T cells extravasate into rheumatic valves through the surface valvular endothelium.[11] [14] Finally, recent studies have demonstrated cross-reactive monoclonal antibodies cytotoxic for heart cells in culture, in the presence of complement. [15]

Host factors

There is an inherited susceptibility to rheumatic fever: there is weak concordance in monozygotic twins and inheritance may be autosomal recessive with limited penetrance.[16] [17] During outbreaks of group A streptococcal pharyngitis in US military camps during the 1950s and 1960s, up to 3% of recruits developed acute rheumatic fever.[18] More recent data suggest that approximately 3–6% of any population is likely to be susceptible to rheumatic fever and that this proportion does not vary substantially between populations.[4]

There has been little consistency in the association of HLA type with rheumatic fever. Using molecular techniques, HLA DRB1*0701 and DQA1*0201 alleles and DRB1*0701-DQA1*0201 and DRB1*13-DQA1*0501-3-DQB1*0301 haplotypes were associated with rheumatic heart disease in an Egyptian population, whereas the DQA1*0103 and DQB1*0603 alleles were found less commonly in rheumatic heart disease, suggesting that they may confer protection.[19]

In most populations in which it has been studied, the B-cell alloantigen, D8/17, is expressed in a high proportion of B cells in patients with rheumatic heart disease or a history of rheumatic fever, a moderate proportion of B cells in first-degree family

members of rheumatic fever patients and a low proportion of B cells in control subjects. [20] This suggests that D8/17 may be a marker of inherited susceptibility. Researchers in northern India have identified different B-cell alloantigens that appear to identify rheumatic fever patients in that population. [21]

Organism factors

Certain M serotypes of group A streptococci have been associated with rheumatic fever — particularly serotypes 1, 3, 5, 6, 14, 18, 19, 24, 27 and 29.[22] However, not all strains belonging to these serotypes cause rheumatic fever it therefore seems likely that the potential to cause rheumatic fever is not serotype specific and that any group A streptococcal strain could acquire this potential.

Group A streptococci associated with rheumatic fever have been characterized as class I, based on amino acid sequences within the C repeat region of the M protein (as opposed to class II organisms, which have been associated with poststreptococcal glomerulonephritis).[23] An alternative classification system, in which strains are separated into patterns (labeled a through e) based on the arrangement of genes within the *emm* region of the streptococcal chromosome, concluded that strains associated with rheumatic fever and/or throat infection came from patterns a, b or c, whereas strains associated with skin infection came from pattern d (pattern e strains had no particular tissue or disease association).[24] However, most of the initial studies associating class I or pattern a–c organisms with rheumatic fever came from populations with relatively low endemicity of rheumatic fever or primary group A streptococcal infections. Subsequent studies in Aboriginal Australian, Saudi and Thai populations have failed to confirm any strong association of certain groups or types of group A streptococci with rheumatic fever.[25] [26]

Other issues in pathogenesis

Classic studies from the first half of the 20th century established that acute rheumatic fever always followed a symptomatic or asymptomatic group A streptococcal infection of the upper respiratory tract.[27] This has been challenged in recent years.[28] In tropical developing countries where there is a high prevalence of pyoderma, group A streptococci originating in skin infections may have the potential to cause acute rheumatic fever, either de novo or by subsequently infecting the throat. An alternative hypothesis is that rheumatic fever may sometimes follow infection with group C or G streptococci, which may have acquired 'rheumatogenic' factors by horizontal

TABLE 60-1 -- Recommended doses of antibiotics to prevent rheumatic fever.

RECOMMENDED DOSES OF ANTIBIOTICS TO PREVENT RHEUMATIC FEVER					
Indication and antibiotic	**Route**	**Dose in children (=27kg)**	**Dose in adolescents and adults**	**Frequency**	**Duration**
Options for treatment of GAS tonsillitis/pharyngitis ('primary prophylaxis')					
Phenoxymethyl penicillin (penicillin V)	Oral	250mg	500mg	Twice daily	10 days
Benzathine penicillin G	IM	450mg (600,000U)	900mg (1,200,000U)	NA	Single dose
Erythromycin*	Oral	20mg/kg (max 250mg)	250mg	Twice daily	10 days
Options for prevention of rheumatic fever recurrences ('secondary prophylaxis')					
Benzathine penicillin G	IM	900mg (1,200,000U)	900mg (1,200,000U)	Every 4 weeks†	5 yrs since last episode or age 21 yrs (whichever is longer).
Phenoxymethyl penicillin (penicillin V)	Oral	250mg	250mg	Twice daily	To age 40yrs or for life if heart disease present (see text for details)
Erythromycin**	Oral	250mg	250mg	Twice daily	
IM, intramuscular; NA, not applicable; GAS, group A streptococcal					
Doses as recommended by the American Heart Association [32]					

* Erythromycin should only be used if patient is allergic to penicillin
† If possible, doses every 3 weeks provide superior protection

transmission from group A streptococci.[29] Both hypotheses have yet to be proved.

PREVENTION

Primary prevention

Primary prophylaxis — antibiotic treatment of group A streptococcal upper respiratory tract infection — has been the cornerstone of primary prevention since the mid-1900s. If commenced within 9 days of the onset of symptoms, oral or intramuscular penicillin treatment will usually prevent the subsequent development of rheumatic fever (see Table 60.1 for doses of antibiotics).[30] [31] Alternative regimens using shorter courses of macrolides or oral cephalosporins are effective in treating pharyngitis, but have not yet been proven to prevent rheumatic fever. Their increased cost and broader antimicrobial spectrum argue against their use as first-line agents.[32]

In populations with high rates of acute rheumatic fever, primary antibiotic prophylaxis is important. However, in settings where rheumatic fever is now rare, it is argued that the benefits of antibiotic treatment of group A streptococcal pharyngitis (prevention of rheumatic fever and suppurative sequelae and abbreviating symptoms) do not outweigh the cost, inconvenience, adverse reactions and potential for induction of resistance in other organisms.[33]

In developing countries, although the diagnosis and treatment of pharyngitis must remain priorities, primary prophylaxis has not been proven to substantially reduce the incidence of acute rheumatic fever. In recent studies, at least two-thirds of acute rheumatic fever cases have not been preceded by a sore throat, and therefore would not be preventable even if facilities were available to diagnose and treat group A streptococcal pharyngitis. This has heightened the importance of developing new approaches to primary prevention, whether based around reducing streptococcal transmission by improving housing and hygiene or combining sore throat treatment with skin disease control in tropical countries. The most effective control programs have combined secondary prevention, primary prophylaxis, control of skin infections and wider education of health staff and the community. [34]

A type-specific group A streptococcal vaccine targeting the *N* terminal region of multiple M serotypes is currently in human trials.[35] However, the potential effectiveness of this vaccine in developing countries, where new serotypes emerge rapidly, has been questioned.

Other vaccines in development contain epitopes conserved among all group A streptococci. [36]

While primary prevention remains a dilemma in developing countries, there is no doubt that secondary prophylaxis is feasible and cost effective.[7] Secondary prophylaxis (Table 60.1) is the long-term administration of antibiotics to those with previous acute rheumatic fever or rheumatic heart disease, to prevent rheumatic fever recurrences and the subsequent development, or worsening, of rheumatic heart disease. Benzathine penicillin G is the best option. Its effectiveness is optimal when administered every 3 weeks, although 4-weekly or even monthly dosing is acceptable. Oral penicillin is almost as effective as benzathine penicillin G, provided that adherence can be assured. Penicillin-allergic patients should be offered erythromycin.

The duration of prophylaxis is determined by the risk of recurrent rheumatic fever (which is greatest in the 5 years following the previous attack) and the potential consequences of a recurrence (which are most dangerous in patients with established valvular disease). The minimum duration is 5 years after the last attack or until age 21 years, whichever is longer. If at that time the patient has residual valvular disease, prophylaxis should continue for a minimum of 10 years or until age 40 years, whichever is longer. Patients with severe valvular disease, or any who have had valve surgery, should receive prophylaxis for life.[32]

In regions with high prevalence rates of rheumatic heart disease, it is recommended that a formal control program be established.[3] [37] This requires national commitment (including budgetary), a full-time co-ordinator, a multi disciplinary steering committee and a centralized register of patients. The priorities are case-finding and surveillance, co-ordinating secondary prophylaxis and ensuring good clinical care and follow-up of patients. Resources should be allocated to educational activities and primary prevention once the initial priority activities are in place.

CLINICAL FEATURES

The onset of rheumatic fever symptoms always follows a latent period after the preceding group A streptococcal infection. This latent period is usually 1–5 weeks (mean about 3 weeks) but may be shorter in recurrences or up to 6 months before the onset of chorea.[38] The preceding streptococcal infection is asymptomatic in about two-thirds of cases.

Although patients with acute rheumatic fever may have any or all of the following clinical features, the most common major manifestations are polyarthritis (found in 50–75% of cases) and carditis (40–60%). The most common combination of presenting clinical features in most countries is fever and polyarthritis, with or without a murmur of mitral regurgitation.

Carditis

Acute rheumatic fever may affect the pericardium (often asymptomatic, and sometimes with a pericardial rub and/or small effusion), the myocardium (usually detected only on echocardiography, and rarely contributing to cardiac failure) or the endocardium (the most common and important). Initially, cardiac valves become friable, inflamed and regurgitant, but with time become thickened, scarred, shortened and stenotic. Their function can be further affected by thickening and shortening of the chordae tendinae. The mitral and/or aortic valves are most commonly affected; pulmonary or tricuspid valve disease is rare and usually secondary to increased pulmonary pressures resulting from left-sided valve disease.

The most common clinical manifestation of carditis is a pansystolic murmur of mitral regurgitation, with or without a low-pitched mid-diastolic (Carey-Coombs) murmur.[7] Aortic valve disease may occur alone or accompany mitral valve disease. In general, younger patients

Figure 60-1 (a) Chest radiograph of a 15-year-old boy who had multiple recurrences of acute rheumatic fever, showing gross cardiac enlargement and failure. He had mitral regurgitation and stenosis, and aortic regurgitation and stenosis. He died 2 days after this radiograph was taken, of intractable cardiac failure. (b) Postmortem cardiac examination of the same boy, showing thickened, shortened mitral valve cusps with calcific vegetation and thickened chordae tendinae. *(Photographs kindly provided by Professor Bart Currie, Darwin, NT, Australia.)*

with carditis more commonly have pure mitral and/or aortic regurgitation, but in late adolescence and adulthood, stenotic or mixed regurgitant/stenotic lesions become more common (Fig. 60.1). Rarely, mitral stenosis occurs in younger children.

Rheumatic involvement of the myocardium, manifest by the pathognomonic 'Aschoff body' may disrupt the electrical conduction,

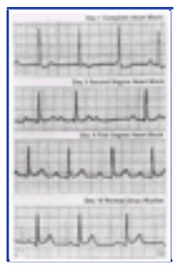

Figure 60-2 Electrocardiographic changes in a young adult with acute rheumatic fever, showing evolution over 18 days from complete heart block to second-degree (Wenckebach) block to first-degree block and then to normal sinus rhythm. *(Reproduced with permission from Bishop W, Currie B, Carapetis J, Kilburn C. A subtle presentation of acute rheumatic fever in remote northern Australia. Aus NZ J Med 1996;26:241–2.)*

leading to prolongation of the P–R interval (Fig. 60.2). Some healthy people have this finding, but a prolonged P–R interval that resolves over days to weeks may be a useful diagnostic feature in cases with atypical clinical features.

Joint manifestations

Rheumatic polyarthritis produces painful red, hot and swollen joints which may contain purulent (but sterile) effusions. The arthritis is asymmetrical and classically migratory, affecting large joints, most commonly knees, ankles, wrists or elbows. Usually, only one or two joints are affected at one time and each may be involved for just a few hours or up to one or two days. The arthritis is very responsive to nonsteroidal anti-inflammatory medication. Should joint symptoms and signs persist more than one to two days after starting high-dose salicylates, the diagnosis should be questioned.

Sometimes, the joint manifestations are milder. Arthritis may affect only a single joint or arthralgia only may occur.[10] As with polyarthritis,

Figure 60-3 Erythema marginatum on the trunk of an 8-year-old Caucasian boy. The pen mark shows the location of the rash approximately 60 minutes previously. *(Photograph kindly provided by Associate Professor Mike South, Royal Children's Hospital, Melbourne, Australia.)*

polyarthralgia is usually asymmetrical, affects large joints and rapidly responds to nonsteroidal anti-inflammatory medication.

Chorea

This intriguing manifestation was named by the English physician Thomas Sydenham, who in 1686 initially called it St Vitus' Dance. Depending on the population, it is present in <10% to >30% of cases of rheumatic fever. Chorea may follow a latent period of up to 6 months following group A streptococcal infection, commonly occurs in the absence of other manifestations and is predominantly found in females (almost never occurring in postpubertal males). The choreiform movements most frequently affect the arms and face (particularly the tongue, which may dart around when protruded), but may be more generalized or asymmetrical. The classic signs include rhythmic squeezing when grasping the examiner's fingers ('milk-maid's grip'), flexion of the wrists and extension of the fingers when the hands are extended ('spooning') and out-turning of the arms and palms when held above the head (the 'pronator sign'). Chorea worsens with anxiety or purposeful movements, but always disappears during sleep. It is commonly associated with emotional lability, personality changes or obsessive-compulsive behaviors. The choreiform movements eventually disappear, usually within 6 weeks, and almost always within 6 months (although individual cases lasting up to 3 years have been described).

Erythema marginatum and subcutaneous nodules

Both manifestations are uncommon (<2% of cases). Erythema marginatum is rarely detected in dark-skinned people. It is a pink, serpiginous rash with a well-defined edge, which begins as a macule and expands with central clearing (Fig. 60.3). Multiple lesions can affect the trunk and sometimes the limbs (but rarely the face) and seem to move before the examiner's eyes. They usually appear early in the acute phase, but may recur for weeks or even months after the other symptoms have subsided: this does not signify ongoing rheumatic inflammation.

Subcutaneous nodules usually appear 2–3 weeks after the onset of rheumatic fever, last from days to 3 weeks and are commonly associated with severe carditis. They are painless, firm subcutaneous lumps between 0.5 and 2cm in diameter and found mainly over extensor surfaces or bony protuberances, particularly the hands, feet, occiput and back.

Fever

With the exception of chorea, most manifestations of acute rheumatic fever are accompanied by fever. Although the peak temperature is commonly >102.2°F (39°C), lower-grade temperatures are not uncommon. The fever, like arthritis or arthralgia, is very responsive to salicylate therapy.

Elevated acute-phase reactants

The C-reactive protein (CRP) and the erythrocyte sedimentation rate (ESR) are usually dramatically elevated in the acute phase of rheumatic fever, except in chorea when they are commonly normal. The CRP often returns to normal more rapidly than the ESR. The peripheral white blood cell count may also be moderately elevated, although this is a less sensitive marker of rheumatic inflammation.

Other less common clinical features

Infrequently, the presenting complaint of acute rheumatic fever may be severe, central abdominal pain, which responds quickly to anti-inflammatory medication. Epistaxis was prominent in early descriptions of rheumatic fever, but has not been common in recent studies. 'Rheumatic pneumonia' refers to pulmonary infiltrates that

may be found in patients with acute carditis. Mild elevations of liver transaminases, microscopic hematuria, pyuria or proteinuria are found occasionally, but are non-specific and usually not severe.

Other associated poststreptococcal syndromes

Poststreptococcal reactive arthritis has a shorter incubation period after streptococcal infection than rheumatic fever, sometimes follows non-group A ß-hemolytic streptococcal infection, often affects small joints and is less responsive to anti-inflammatory medication. Because of the lack of cardiac involvement, these patients are said not to require secondary prophylaxis. However, this diagnosis should be considered with caution in populations with high rates of rheumatic fever, as some cases have subsequently developed carditis. Even in populations with low rates of rheumatic fever, patients diagnosed with poststreptococcal reactive arthritis should receive secondary prophylaxis for at least one year; it can then be discontinued if there is no evidence of carditis.

Some basal ganglia disorders other than chorea have also been associated with group A streptococcal infections. PANDAS (Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal) infections describes a constellation that may include tic disorders, Tourette's syndrome and obsessive-compulsive symptoms. Unlike rheumatic chorea, patients with PANDAS appear not to be at risk of developing carditis. These patients, and some children with autism, may have high proportions of circulating B cells expressing D8/17 antigen. It is not yet clear whether these syndromes are linked with acute rheumatic fever.

DIAGNOSIS

There is no definitive diagnostic test for acute rheumatic fever. In 1944, the American physician T Duckett Jones developed a set of diagnostic criteria. The clinical features were divided into those that were critical to the diagnosis ('major manifestations') and those that were less specific ('minor manifestations'). The 1992 updated Jones criteria (Table 60.2) for the first time specified that the criteria apply only to the initial diagnosis of acute rheumatic fever.[39] At least two major, or one major and two minor, manifestations are needed, in addition to evidence of a recent group A streptococcal infection to make the diagnosis. Recurrences may be diagnosed based only on the presence of a single major or multiple minor manifestations (together with evidence of recent group A streptococcal infection), provided that other diagnoses have been excluded. There are two exceptions: rheumatic chorea may be diagnosed in the absence of

TABLE 60-2 -- The Jones criteria for guidance in the diagnosis of the initial attack of acute rheumatic fever, updated 1992.*

THE JONES CRITERIA FOR GUIDANCE IN THE DIAGNOSIS OF THE INITIAL ATTACK OF ACUTE RHEUMATIC FEVER, UPDATED 1992	
Major manifestations	**Minor manifestations**
Carditis	Fever
Polyarthritis	Arthralgia
Chorea	Elevated acute-phase reactants
Subcutaneous nodules	Prolonged PR interval
Erythema marginatum	
Plus	
Supporting evidence of a recent group A streptococcal infection	
• Positive throat culture or rapid antigen test	
• Elevated or increasing streptococcal antibody titer	
The presence of two major or one major and two minor manifestations, plus evidence of a preceding group A streptococcal infection, indicates a high likelihood of acute rheumatic fever	

** Reprinted with permission from reference.[39]*

any other manifestations or evidence of a preceding streptococcal infection; and low-grade carditis may occur as a delayed presentation, after streptococcal antibody titers have returned to normal.

In experienced hands, Doppler echocardiography may help to confirm the diagnosis, by revealing subclinical valvular regurgitation or the characteristic appearance of affected valve leaflets.[8] However, echocardiographic criteria have not yet been standardized and the ability to distinguish acute carditis from previous rheumatic valve damage is not always definitive.[40]

A preceding group A streptococcal infection may be demonstrated either by a positive throat swab culture or rapid antigen test, or positive antistreptococcal serology. The serological tests most commonly used are antistreptolysin O, anti-DNase B and antihyaluronidase. At least one of any two of these tests will be positive following >90% of group A streptococcal infections. Serology is of limited value in regions with high prevalence rates of streptococcal impetigo, where children may have positive antistreptococcal titers most of the time.

The diagnosis of acute rheumatic fever may be difficult because of the nonspecific nature of many of the clinical features and the wide range of differential diagnoses, particularly of children presenting with fever and polyarthritis. Some possible differential diagnoses are listed in Table 60.3 .

MANAGEMENT

The main aims of management in acute rheumatic fever are to confirm the diagnosis, treat cardiac failure, shorten the duration of symptoms and ensure that ongoing secondary prophylaxis and clinical follow-up are assured. There is no evidence that treatment in the acute phase alters the likelihood or severity of long-term cardiac valvular damage.[41] Hospital admission is recommended for all cases, to ensure that relevant investigations are performed, provide adequate medical treatment, commence educational activities for the patient and family and ensure that a follow-up program (secondary prophylaxis, inclusion on rheumatic fever registers, etc.) is set in place.

Investigations

Initial investigations should include a throat swab and culture (or rapid streptococcal antigen test), streptococcal serology assays (at least two of antistreptolysin O, anti-DNase B or antihyaluronidase, if available), ESR, CRP, white blood cell count, electrocardiogram, chest X-ray and, if available, echocardiogram. Additional investigations may

TABLE 60-3 -- Differential diagnoses of the three most common major manifestations of acute rheumatic fever.*

DIFFERENTIAL DIAGNOSES OF THE THREE MOST COMMON MAJOR MANIFESTATIONS OF ACUTE RHEUMATIC FEVER.			
	Polyarthritis	**Carditis**	**Chorea**

Differential diagnoses	Connective tissue disease	Innocent murmur	Systemic lupus erythematosus
	Immune complex disease	Mitral valve prolapse	Drug reaction
	Septic arthritis (including gonococcal)	Congenital heart disease	Wilson's disease
	Viral arthropathy	Infective endocarditis	Tic disorder
	Reactive arthropathy	Hypertrophic cardiomyopathy	Choreo-athetoid cerebral palsy
	Lyme disease	Myocarditis: viral or idiopathic	Encephalitis
	Sickle cell anemia	Pericarditis: viral or idiopathic	Huntington's chorea
	Infective endocarditis		Intracranial tumor
	Leukemia or lymphoma

be necessary to exclude alternative diagnoses, including blood cultures for endocarditis, antiviral serology and autoimmune markers for arthritis, and testing for systemic lupus erythematosus, Wilson's disease or acute drug ingestion in the case of chorea.

Bed rest

It is no longer recommended that all patients with acute rheumatic fever should routinely rest in bed for at least 4 weeks. Instead, as soon as the patient can walk, and provided that cardiac failure is controlled, bed rest can be relaxed.

Antimicrobial treatment

Although in most cases the causative group A streptococcal strain can no longer be isolated by the time rheumatic fever symptoms start, all patients should receive antibiotics to treat any possible ongoing streptococcal infection. The recommended regimens are listed in Table 60.1 . Intravenous penicillin is not required.

Anti-inflammatory medication

Although anti-inflammatory medication is used for most cases of acute rheumatic fever, there is no evidence that it alters the short- or long-term outcome.[41] In cases where the diagnosis is unclear, withholding anti-inflammatory medications for hours or even a day or two may allow the characteristic features (e.g. migratory polyarthritis) to appear. In these cases, pain can be controlled with codeine. Once the diagnosis is confirmed, patients with arthritis, arthralgia or fever may be treated with aspirin at a dose of 80–100mg/kg/day (4–8g/day in adults) in 4–5 divided doses for 2 weeks, reducing then to 60–70mg/kg/day for a further 2–4 weeks. The response to salicylate treatment is almost always dramatic: joint symptoms and fever resolve within 1 or 2 days. Sometimes nausea and vomiting occur with the initial high doses. In such cases, the dose can be reduced for 1–2 days and then gradually increased to treatment doses. If available, salicylate levels can be monitored if there are symptoms of toxicity. Arthritis or arthralgia may recur up to 3 weeks after cessation of salicylate therapy, sometimes accompanied by a raised CRP or ESR. In such cases a brief further course of salicylates will control symptoms. Although there are no data to compare salicylates with other nonsteroidal anti-inflammatory medications, good symptomatic responses to naproxen (10–20mg/kg/day) have been reported. [42]

Corticosteroids

A meta-analysis failed to confirm a long-term beneficial effect of corticosteroids in acute rheumatic carditis.[41] Although they have no proven benefit, most clinicians use steroids to treat acute rheumatic carditis associated with cardiac failure or more severe cases of rheumatic pericarditis. Oral prednisone or prednisolone is most commonly used at doses of 1–2mg/kg/day (max 80mg/day), tapering after 2 or 3 weeks. Intravenous methylprednisolone may be used in life-threatening carditis.

Management of cardiac failure

Diuretics, angiotensin-converting enzyme inhibitors (particularly in the presence of aortic regurgitation) and fluid restriction are the mainstays of treatment of cardiac failure due to rheumatic carditis.[43] Digoxin is mainly used when cardiac failure co-exists with atrial fibrillation. Cardiac failure in rheumatic carditis is due almost exclusively to valvular disease rather than myocardial dysfunction and is most common when recurrent carditis damages a previously affected valve. Rarely, life-threatening cardiac failure may necessitate urgent valve surgery during the acute inflammatory phase.

Valve surgery is more often required for chronic rheumatic heart disease. In recent years, there has been a tendency to undertake valve repair rather than replacement or to use homografts or xenografts rather than mechanical prostheses. These procedures avoid the need for anticoagulation, which is frequently associated with thromboembolic complications. There is an increasing tendency to identify candidates for valve surgery early in the illness, because valve repair is difficult when valves are extensively damaged, and preoperative left ventricular dysfunction and/or pulmonary hypertension are the most important negative prognostic factors. Ideally, a cardiologist should review all patients with rheumatic heart disease shortly after diagnosis. Surgery should be considered for patients with aortic or mitral stenosis, cardiac failure, left ventricular enlargement, evidence of pulmonary hypertension, tricuspid regurgitation or atrial fibrillation.

Treatment of chorea

Milder cases of chorea require no treatment. However, chorea that impairs normal daily activities, or that causes embarrassment or discomfort to the patient, may require intervention. Haloperidol, carbamazepine and diazepam have all been reported to be effective. Other medications sometimes used are chlorpromazine, sodium valproate and pimozide. The associated anxiety, emotional lability and behavioral abnormalities may require low-dose minor tranquilizers or even behavioral therapy. Salicylates and steroids have no role in treating chorea.

Immunomodulatory treatment

Because of the autoimmune nature of acute rheumatic fever, it has been postulated that immunomodulatory treatments may be beneficial. Small studies of intravenous immunoglobulin have suggested benefit in accelerating recovery from chorea, but have not demonstrated

reduced incidence of long-term valve disease in nonchorea acute rheumatic fever. [44] However, this and other similar treatments have not yet been properly assessed in large controlled trials.

Prognosis and follow-up

Acute rheumatic fever will resolve spontaneously, usually within 12 weeks, if left untreated. With treatment, most cases can be discharged from hospital within 2 weeks.

The likelihood of developing rheumatic heart disease relates to the severity of acute carditis and the number of episodes of recurrent acute rheumatic fever.[45] Overall, 30–50% of all people with acute rheumatic fever will eventually develop rheumatic heart disease, increasing to >70% in patients with severe carditis at the first episode or in those who have had at least one recurrence. Approximately 75% of recurrences occur within 2 years of the previous acute episode and >90% within 5 years. The reasons for this are unclear but probably related to immune sensitization that wanes with time following the acute attack. Although the clinical features of recurrent episodes tend to mirror those present at earlier episodes, this is not always the case and patients with no evidence of carditis initially may develop it with recurrences. [10]

Therefore, regardless of the clinical features of the initial episode, the priorities of long-term management are to ensure adherence to secondary prophylaxis, treat cardiac failure (including considering early surgical intervention if necessary) and educate about the need to treat streptococcal upper respiratory or skin infections. Angiotensin-converting enzyme inhibitors may delay the need for operation in asymptomatic patients with chronic aortic regurgitation. Regular echocardiography is

often useful to follow the progress of valve disease, especially where follow-up may be irregular or when communication or cultural differences make clinical assessment difficult. All patients with rheumatic valvular disease should receive antibiotic prophylaxis at the time of dental or surgical procedures (with a nonpenicillin antibiotic such as clindamycin if the patient is receiving penicillin secondary prophylaxis — see Chapter 59 on infective endocarditis). If heart failure is present, pneumococcal and influenza immunization should be offered.

If possible, all patients with carditis should be reviewed by their primary medical practitioner at least every 6 months, by a specialist (pediatrician, physician or cardiologist) every 1–2 years, by a dentist every year and have echocardiography every 1–2 years. These arrangements should be tailored to the requirements of each patient and according to local resources. Patients without clinical evidence of carditis may have less frequent specialist reviews and should not require echocardiography after the initial acute rheumatic fever diagnosis.

Chapter 61 - Practice Points

61.a Role of white cell scans for deep-seated sepsis

Verka Beric

Introduction

White blood cell scans are used to locate areas of pyogenic infection or acute inflammation.

The neutrophil is the active component of the radiolabeled leukocyte preparation used during the scan. Lymphocytes play no part in the investigation as they are damaged by radioactive labeling; similarly, monocytes fail to respond to the labeling technique. In pyogenic infections, neutrophils are mobilized from their resting positions, along the margins of blood vessels, in order to migrate specifically to inflamed tissues. This migratory activity is most vigorous during the acute illness and it is this phenomenon that is exploited by the white cell scan. White cell scans have, however, a limited role in the investigation of chronic sepsis and inflammation, in which neutrophil migratory activity is reduced. Unless secondary pyogenic infection exists, a negative result is seen in viral, mycobacterial, fungal and parasitic infections because of the relative lack of neutrophil activity.

Technique

Mixed leukocytes from the patient and labeled in vitro with a chelated radioactive gamma-emitting isotope. Indium-111-oxine (^{111}In-oxine) remains the gold standard radiopharmaceutical used for labeling purposes but technetium-99m-hexamethylpropylene amine oxime (^{99m}Tc-HMPAO) is now preferred in certain clinical situations. The labeled leukocytes are then injected intravenously. The sites within the body to which the radioactive neutrophils migrate are detected by imaging the distribution of the isotope with a gamma camera. Sites of focal infection and acute inflammation appear as areas of abnormally increased isotope uptake.

The normal physiologic distribution of ^{111}In-oxine immediately after injection is the blood pool, lungs, liver and spleen, with activity decreasing over time. ^{99m}Tc-HMPAO has a similar distribution but has the disadvantage of additional renal and intestinal clearance. Renal, bladder, gallbladder and bowel activity may be seen within the first hour and are usually seen by 4 hours.

Despite the above limitation, ^{99m}Tc-HMPAO is less costly, more readily available, imparts a lower radioactive dose to the patient and yet provides images of better quality than ^{111}In-oxine. The relatively short half-life of ^{99m}Tc-HMPAO means that sensitivity is near maximal at 60 minutes. Indeed, the study may be completed by 2–4 hours, thus allowing abdominal imaging to be performed before signs of bowel clearance occur. By virtue of its longer half-life,^{111}In-oxine usually requires a 24-hour image for maximal sensitivity, which in turn becomes advantageous in situations in which the rate of neutrophil migration and turnover is reduced. With both agents, in order to limit errors in interpretation, serial images are acquired at approximately 1 hour, 3 hours and 24 hours. Despite such precautions, false-positive and false-negative results may be found in certain clinical conditions (Table 61a.1).

The decision to use the white cell scan and the choice between using technetium-99m and indium-111 for a particular clinical situation are both confusing and controversial issues. Suggested guidelines based upon current use and literature are outlined below.

Abdominal sepsis

The white cell scan is the next investigation of choice for the patient who has suspected abdominal or pelvic sepsis after an inconclusive ultrasound or computerized tomography scan.

Despite the normal physiologic uptake of ^{99m}Tc-HMPAO in the bowel, it is the preferred agent for imaging the abdomen in most situations, particularly when rapid diagnosis is required. Indeed, the main clinical role of^{99m}Tc-HMPAO in some centers is to detect acute relapses of inflammatory bowel diseases such as ulcerative colitis and Crohn's disease.

For the diagnosis of abdominal abscesses that communicate with bowel (typically seen in diverticular disease, Crohn's disease and as a result of pancreatitis), ^{111}In-oxine is preferred for its lack of physiologic bowel excretion. Early images demonstrate focal abscess activity that declines with time as the abscess decompresses and discharges into the bowel. As a result, the isotope is first detected within the bowel lumen on the 24-hour image.

^{111}In-oxine is also preferred for the diagnosis of abscesses close to the liver and spleen, where they may be obscured by the intense physiologic uptake of these organs on early images. The abscess is identified by its increase in activity with sequential images over 24 hours, whereas the activity in the liver and spleen either reduces or remains constant during this period.

Thoracic sepsis

The white cell scan has no place in the routine investigation of pulmonary sepsis. It is usually negative for lobar pneumonia. Rarely, the white cell scan is used to determine the degree of inflammatory activity present in cavities thought to represent pulmonary abscesses or in a region of lung known to be bronchiectatic.

White cell scans are almost always negative for bacterial endocarditis and valvular vegetations. The investigation is only justified in these cases when pyrexia develops with associated positive blood

TABLE 61.a-1 -- False-negative and false-positive white cell scan results.

FALSE-NEGATIVE AND FALSE-POSITIVE WHITE CELL SCAN RESULTS
False-negative results
Chronic low-grade infection
Parasitic, fungal, mycobacterial and viral infections
Encapsulated nonpyogenic abscess
Acute vertebral osteomyelitis
Intrahepatic or intrasplenic abscess
Abnormal neutrophil function caused by chemotherapy or corticosteroid use
Appropriate antibiotic use
False-positive results

Drug-induced pneumonitis
Graft-versus-host disease
Inflammatory bowel disease
Hematoma and gastrointestinal hemorrhage
Pseudoaneurysm
Swallowed labeled leukocytes from oropharynx, esophagus or lungs
Surgical wounds, enterostomy or catheter sites

cultures, thereby raising suspicion of septic emboli or metastatic abscesses.

Musculoskeletal and soft tissue infection

Acute osteomyelitis has traditionally been diagnosed with the combination of a technetium-99m-methylene diphosphonate (^{99m} Tc-MDP) bone scan and plain radiography. The ^{111} In-oxine white cell scan is preferred for suspected acute relapses of chronic osteomyelitis or suspected prosthetic joint infection where plain radiography and the bone scan may appear abnormal, even in the absence of acute infection. In this situation, a map of the normal physiologic marrow uptake of neutrophils must be obtained in order to differentiate the areas of abnormal inflammatory uptake seen with the white cell scan. Normal marrow uptake is depicted by the 1-hour ^{111} In-oxine image or by a separate ^{99m} Tc-colloid scan.

Similarly, the combination of a ^{99m} Tc-MDP bone scan with a ^{111} In-oxine white cell scan may be used to determine whether soft tissue infection, such as a diabetic foot ulcer, has extended to involve the underlying bone. The scans are acquired simultaneously and superimposed to determine the precise anatomic relationship between focal neutrophil activity and the 'bone map' provided by the bone scan. Neutrophil activity overlying the bone scan image is taken to represent osteomyelitis. The combination of scans is required because the bone scan alone may be abnormal in the absence of osteomyelitis because of the effects of local hyperemia from the soft tissue infection.

Prosthetic vascular graft infection is associated with high morbidity and mortality rates if delay in diagnosis occurs. A high index of suspicion is required because the only indication may be a low-grade fever, although aortofemoral or iliofemoral graft infections may additionally present with groin pain or local soft tissue infection. White cell scans are particularly useful for demonstrating the extent of infection along the graft and for imaging abdominal grafts. ^{111} In-oxine is the preferred agent for detecting chronic graft infections.

Undiagnosed fever

In this situation, the white cell scan is used simply to locate the pathology causing the fever so that a diagnosis may be made with more conventional means. Determining the characteristics of the undiagnosed fever and using the white cell scan only if appropriate may optimize the yield of positive results.

A true 'fever of unknown origin' is defined as a fever of at least 3 weeks' duration where at least 1 week of in-hospital investigation has failed to reach a diagnosis. Most causes of fever of unknown origin are due to nonpyogenic infection, malignancy or connective tissue disease. Pyogenic infection is seen in only 10–20% of cases.

Any infection associated with an occult fever is likely to be subacute or chronic with reduced neutrophil migration, and the ^{111} In-oxine white cell scan is therefore preferred for its superior 24-hour images.

Neutropenic patients and HIV-positive patients may have fever and infection without localizing signs. Because the low neutrophil count will produce a suboptimal result with the white cell scan, fresh cross-matched donor leukocytes may be used instead and are often preferred in HIV-positive patients in order to avoid risk of contamination of staff handling the blood.

Discussion

The role of the white cell scan in deep-seated sepsis may be solely to localize or to confirm the presence of a pyogenic infection. A specific diagnosis is often regarded as a bonus. It is important to realize that this investigation may not be the most appropriate in chronic and nonpyogenic infections such as fever of unknown origin, sarcoidosis, tuberculosis and *Pneumocystis carinii* pneumonia. In these situations, more general inflammatory markers, such as gallium-67 and the newer agents, ^{99m} Tc- or ^{111} In-labeled human polyclonal immunoglobulin, may be more suitable. Further, other imaging modalities may be more appropriate in certain clinical situations; for example, magnetic resonance imaging in musculoskeletal infections. Advice from an imaging specialist should be sought in all but the most straightforward cases.

61.b Should all infected intravascular devices be removed?

Christopher J Crnich
Dennis G Maki

Case presentation

A 63-year-old woman patient in the intensive care unit (ICU) was admitted 5 days previously following a motor vehicle accident in which she sustained blunt chest trauma leaving her with a lung contusion and flail chest, mandating intubation and prolonged mechanical ventilatory support. Underlying co-morbidities include hypertension and non-insulin-dependent diabetes mellitus. Upon admission to the ICU, an arterial line and triple-lumen central venous catheter (CVC) were placed in the right radial artery and right internal jugular vein, respectively. The patient has been doing well, but has now developed fever of 102°F (38.6°C), associated with tachycardia and hypotension.

Discussion

How should patients with fever and an intravascular device be evaluated?

Intravascular devices (IVDs) in their many forms are essential to modern health care. Unfortunately, their use is associated with an often-underappreciated risk for IVD-related bloodstream infection (IVDR BSI). The majority of endemic nosocomial BSIs are primary, most of which originate from an IVD, while a smaller number are secondary BSIs and stem from a local nonvascular site, such as ventilator-associated pneumonia or postsurgical site infection. Prospective studies of IVDs show that every type of IVD carries some risk of causing BSI. It can be seen that when this risk is expressed per 1000 IVD days, the relative risk of IVDR BSI with standard noncuffed, nontunneled CVCs and hemodialysis catheters is approximately 2.3 and 2.8 BSIs per 1000 IVD days, respectively, whereas the risk with cuffed and tunneled CVCs (1.2/1000 IVD days) and subcutaneous central venous ports (0.2/1000 IVD days) is considerably lower. It should be noted that, contrary to popular belief, peripherally inserted central venous catheters (PICCs) (2.1/1000 IVD days) and arterial catheters (3.7/1000 IVD days) have a risk of IVDR BSI that approaches that seen with standard noncuffed CVCs.

Micro-organisms that cause IVDR BSI must first adhere to the intraluminal or extraluminal surface of the IVD before infection of the bloodstream can occur. With short-term IVDs (in place <10 days) — peripheral intravenous catheters, arterial catheters and noncuffed, nontunneled CVCs — most device-related BSIs are of cutaneous origin, from the insertion site, and primarily gain access extraluminally. In contrast, contamination of the catheter hub and lumen appears to be the predominant mode of BSI with long-term, permanent IVDs (in place >10 days), such as cuffed Hickman- and Broviac-type catheters, cuffed hemodialysis CVCs, subcutaneous central venous ports and PICCs.

Recent evidence-based guidelines provide the best current information on the evaluation of the ICU patient with fever or other signs of sepsis. Before any decision regarding initiation of antimicrobial therapy or removal of an IVD, the patient must be thoroughly examined to identify all plausible sites of infection, including ventilator-associated pneumonia, catheter-associated urinary tract infection, surgical site infection or antibiotic-associated colitis, as well as line sepsis. Although bacteriuria is extremely common in hospitalized patients with a urinary catheter, it is rarely the cause of fever or sepsis. The presence of inflammation or purulence at the catheter insertion site is now rare in patients with IVDR BSIs caused by short-term, noncuffed vascular catheters; however, the presence of purulence is highly suggestive of IVD-related infection.

Removal and culture of the IVD has historically been the gold standard for the diagnosis of IVDR BSI, particularly with short-term catheters. Studies have demonstrated the superiority of semiquantitative or quantitative catheter tip culture methods for the diagnosis of IVDR BSI. The diagnosis of IVDR BSI is completed when a colonized IVD is associated with concomitant BSI, with no other plausible source.

Cultures of IVDs obviously require their removal, which is a major problem in patients with long-term IVDs. If a laboratory has available an automated quantitative system for culturing blood, quantitative blood cultures drawn through the IVD and concomitantly by venipuncture from a peripheral vein (or another IVD) can permit the diagnosis of IVDR bacteremia or fungemia to be made with sensitivity and specificity in the range of 80–95%. The wide availability of automated radiometric blood culture systems, in which blood cultures are continuously monitored for microbial growth, has led to a clever application of this system for the detection of IVDR BSI: the differential-time-to-positivity (DTP) of blood cultures drawn through the IVD and concomitantly from a peripheral site. Detection of positivity in a blood culture drawn from the IVD more than 2 hours before positivity of the culture drawn from a peripheral site has been shown to be highly predictive of IVDR BSI in one study with long-term catheters, yielding an overall sensitivity of 94% and specificity of 91%.

Further assessment includes review of radiographic studies and, especially, Gram-stain and culture of sputum aspirated from the endotracheal tube, and cultures of urine and blood. It is ill-advised to routinely remove an IVD or start anti-infective drugs for suspected or presumed infection in the critically ill patient without first obtaining blood cultures, with at least one being drawn from a peripheral vein by percutaneous venipuncture.

What, if any, antimicrobials should be started in patients with suspected IVDR BSI?

Once the initial basic examination has been completed and cultures have been obtained, empiric antimicrobial therapy based on the most likely source of infection may be initiated. If an IVD is suspected as the source of sepsis — purulence is present at the insertion site or, more likely, no other plausible source of sepsis can be found — the combination of intravenous vancomycin (for staphylococci resistant to methicillin) and a fluoroquinolone, cefepime or imipenem/meropenem (for multiresistant nosocomial Gram-negative bacilli) should prove effective against the bacterial pathogens most likely to be encountered. Initial therapy can then be modified based on the microbiologic identification and susceptibility of the infecting organisms.

It should be emphasized that bacterial growth on culture of a vascular catheter or in a blood culture drawn from a retained device, with negative blood cultures drawn from a peripheral vein, is rarely an indication for initiation of antimicrobial therapy, especially if the culture is positive for coagulase-negative staphylococci. In the absence of local or systemic signs of infection, an isolated positive catheter culture usually reflects colonization of the device rather than true infection.

Does the type of catheter in place influence whether the IVD should be removed?

Short-term vascular catheters, such as noncuffed and nontunneled CVCs, arterial lines and noncuffed and nontunneled hemodialysis catheters, while essential for vascular access in critically ill patients,

are easily removed and can always be replaced with minimal additional risk to the patient. If a short-term, noncuffed CVC or arterial catheter is suspected of being infected because the patient has no obvious other source of infection to explain sepsis, there is inflammation at the insertion site or cryptogenic staphylococcal bacteremia or candidemia has been documented, blood cultures should be obtained and the catheter should be removed and cultured (Table 61b.1). Failure to remove an infected catheter puts the patient at risk of developing septic thrombophlebitis with peripheral intravenous catheters, septic thrombosis of a great central vein with CVCs, or even endocarditis. Continued access, if necessary, can always be established with a new catheter inserted in a new site. A new catheter should never be placed in an old site over a guidewire if the first catheter is suspected of being infected, especially if there is purulence at the site.

In contrast, suspected infection of long-term CVCs, such as cuffed and tunneled Hickman-like catheters and subcutaneous central venous ports, does not automatically mandate removal of the device (see Table 61b.1). These devices provide essential vascular access for patients who require total parenteral nutrition or chemotherapy, and

TABLE 61.b-1 -- Algorithm for diagnosis and management of line sepsis with intravascular devices.*

ALGORITHM FOR DIAGNOSIS AND MANAGEMENT OF LINE SEPSIS WITH IVDs
Examine the patient thoroughly, to identify unrelated sources of infection
Carefully examine all catheter insertion sites; Gram stain and culture any expressible purulence
Obtain two 10–15ml cultures:
• If standard (nonquantitative) blood cultures, draw one by percutaneous peripheral venipuncture and one through the suspect IVD
• If quantitative blood culture techniques are available (e.g. the Isolator system), catheter-drawn cultures can enhance the diagnostic specificity of blood culturing in the diagnosis of line sepsis. However, a peripheral percutaneous quantitative blood culture must be drawn concomitantly
Option regarding a peripheral intravenous or arterial catheter: remove and culture catheter
Options regarding a short-term CVC:
• Purulence at insertion site or no purulence, but patient floridly septic, without obvious source:
Remove and culture catheter
Gram stain purulence
Re-establish access at new site
• No purulence, patient not floridly septic:
Leave catheter in place, pending results of blood cultures
or
Remove and culture catheter, re-establish needed access at new site
Options regarding surgically implanted, cuffed Hickman-type catheters
• Remove at outset if:
Infecting organism known to be *Staphylococcus aureus, Bacillus* spp., *Corynebacterium jeikeium, Mycobacterium* spp. or filamentous fungus
Refractory or progressive exit site infection, despite antimicrobial therapy, especially with *Pseudomonas aeruginosa*
Tunnel infected
Evidence of septic thrombosis of cannulated central vein or septic pulmonary emboli
Evidence of endocarditis
• Remove later on if:
Any of the above become manifest
BSI persists =3 days, despite iv antimicrobial therapy through catheter
Options regarding surgically implanted subcutaneous central ports (e.g., Portacath):
• Cellulitis without documented bacteremia: begin antimicrobial therapy, withhold removing port
• Aspirate from port shows organisms on Gram stain or heavy growth in quantitative culture, or documented port-related bacteremia: remove port
Decision on whether to begin antimicrobial therapy, before culture results available, are based on clinical assessment or Gram stain of exit site or the blood drawn from a long-term IVD
With no microbiologic data to guide antimicrobial selection in a septic patient with suspected line sepsis, consider iv vancomycin and ciprofloxacin, cefepime, or imipenem/meropenem

** Adapted from Maki (2002).*

replacement of these devices is associated with considerably more risk and expense than with short-term IVDs.

What are the absolute indications for removal of an IVD, regardless of the type?

As summarized in Table 61b.1 , even long-term IVDs, despite their value, must be removed when:

¦ there has been persistent exit site infection;
¦ the tunnel is obviously infected;
¦ there is evidence of complicating endocarditis, septic thrombosis or septic pulmonary emboli;
¦ the infecting pathogen is *Staphylococcus aureus*, *Corynebacterium jeikeium*, a *Bacillus* sp., *Stenotrophomonas* spp., *Burkholderia cepacia*, any pseudomonal species, a filamentous fungus or *Malassezia* spp. or a mycobacterial species; or
¦ bacteremia or candidemia persists for more than 3 days despite adequate therapy.[4]

Staphylococcus aureus and *Candida* spp. are particularly virulent causative organisms of IVDR BSI.

How should IVD-related infections with Staphylococcus aureus and Candida spp. be managed?

Intravascular device-related BSI caused by *S. aureus* must always prompt removal of the IVD, even if signs of bacteremia have resolved following antimicrobial therapy because of the significant risk of infectious endocarditis (IE) or other metastatic infection if bacteremia recurs.

Historically, high rates of associated IE and late complications led to a universal policy of 4–6 weeks of antimicrobial therapy for all patients with *S. aureus* bacteremia. Earlier diagnosis and bactericidal therapy of nosocomial *S. aureus* in recent years has been associated with lower rates of IE and metastatic complications, prompting suggestions that short-course therapy (i.e. 14 days) is effective and safe for many cases of IVDR *S. aureus* bacteremia as long as the patient defervesces within 72 hours and there is no evidence of metastatic infection. In a study using transesophageal echocardiography (TEE) in 103 hospitalized patients with *S. aureus* bacteremia, 69 related to an IVD, Fowler *et al.* (1997) found a surprisingly high incidence of endocarditis, 23% with IVDR *S. aureus* BSI. In a more recent report, these authors have reported that the routine use of TEE with IVDR *S. aureus* BSI as a means to stratify patients into short-course or long-course therapy is cost-effective. However, at this time there are no prospective studies to affirm this approach. Until more data are available, short-course therapy for IVDR *S. aureus* bacteremia therapy should be approached with caution and employed only when the TEE is unequivocally negative and the patient has defervesced quickly — within 72 hours of removing the IVD and starting anti-infective therapy.

Likewise, all patients with IVDR candidemia should be treated, even if the patient becomes afebrile and blood cultures spontaneously revert to negative following removal of the catheter without antifungal therapy. Several studies have reported successful treatment of IVD BSI due to *Candida* spp. without IVD removal with prolonged courses of amphotericin B administered through the catheter; however, this is in contrast to the results of other prospective studies that have found an increased duration of candidemia and mortality rate in patients who retain their infected IVD. Until this issue is clarified by prospective randomized studies most episodes of candidemia caused by an infected IVD mandate early removal of the IVD. Intravascular device-related candidemia that responds rapidly to

TABLE 61.b-2 -- Formulations of various antibiotic-containing lock solutions published in the medical literature.*

FORMULATIONS OF VARIOUS ANTIBIOTIC-CONTAINING LOCK SOLUTIONS PUBLISHED IN THE MEDICAL LITERATURE

Drug	Dosage	Dwell time	Duration of therapy	Stability with heparin solutions
Vancomycin	1–5mg/ml	8–24 hours	7–15 days	10–100 units/ml has been shown to be safe when co-administered with low-dose vancomycin (1–5mg/ml)
				High dose vancomycin (83mg/ml) has been used successfully without co-administration of heparin
Teicoplanin	100–150mg/ml	24 hours	5–9 days	10 units/ml
Gentamicin	1–13mg/ml	8–72 hours	5–21 days	Gentamicin precipitates rapidly in heparin solutions when gentamicin doses of 5mg/ml are used
				A single study has reported the stability of 1 mg/ml of gentamicin in solutions with heparin concentrations as high as 2500 units/ml
Amikacin	1.5–2mg/ml	12–24 hours	6–27 days	Most studies have not addressed the issue of stability of amikacin with heparin
				A single study using amikacin concentrations as high as 40mg/ml reported no drug precipitation in heparin (100 units/ml) although formal stability studies were not performed

** Adapted, in part, from Berrington and Gould (2001).*

removal of the catheter and institution of intravenous amphotericin B can be reliably treated with a daily dose of 0.3–0.5mg/kg and a total dose of 3–5mg/kg. Fluconazole (400mg/day) has been shown to be as effective as amphotericin B in randomized trials in non-neutropenic patients, and has further been shown to be comparable to amphotericin B in observational studies of neutropenic patients with *Candida* IVDR BSI, but should not be used with IVDR BSIs associated with septic thrombosis and high-grade candidemia or, obviously, with infections caused by fluconazole-resistant organisms, such as *Candida krusei* and *Candida glabrata*. Although data on the use of caspofungin are limited, at least one study has demonstrated its equivalency to amphotericin B deoxycholate in 186 candidemic patients, and its use may be considered in cases where fluconazole resistance is likely or other antifungals are contraindicated.

Are there any proven methods that improve the chances of retaining a long-term IVD?

Studies using 7–21 days of antibiotics infused through the infected line, primarily with BSIs caused by coagulase-negative staphylococci, have shown success rates of 60–91% without catheter removal although there was considerable variability in the clinical response, depending on the infecting micro-organism; with coagulase-negative staphylococcal BSIs, the risk of recurrent bacteremia has been approximately 20%.

In small, uncontrolled clinical trials of antibiotic lock therapy (ALT), usually in conjunction with systemic antibiotic therapy, cure rates of infected IVDs in excess of 90% have been reported. The vast majority of IVDs reported in these studies were infected with coagulase-negative staphylococci and enteric Gram-negative bacilli and therefore, at this time, ALT cannot be recommended for the routine management of long-term IVDs infected by *S. aureus*, *Bacillus* spp., *Corynebacterium jeikeium*, *Stenotrophomonas* spp., *B. cepacia*, all pseudomonas species, fungi or mycobacterial species.

Antibiotic lock therapy is reasonable for the salvage of long-term IVDs infected with coagulase-negative staphylococci or enteric Gram-negative bacilli although commercially available standard lock solutions do not exist. Table 61b.2 lists the types of lock solutions that have been studied most extensively, although lack of data limits recommending one solution over another. Obviously, if IVDR BSI recurs after an attempt to salvage the IVD with ALT, the device should be removed.

Chapter 62 - Vaginitis, Vulvitis, Cervicitis and Cutaneous Vulval Lesions

Jack D Sobel

VAGINITIS

Vaginal symptoms are extremely common, and vaginal discharge is among the 25 most common reasons for consulting physicians in private office practice in the USA. Vaginitis is found in more than one-quarter of women attending sexually transmitted disease (STD) clinics. Not all women with vaginal symptoms have vaginitis; approximately 40% of women with vaginal symptoms will have some type of vaginitis (Table 62.1).

EPIDEMIOLOGY

Bacterial vaginosis is the most common cause of vaginitis in women of child-bearing age. It has been diagnosed in 17–19% of women seeking gynecologic care in family practice or student health care settings.[1] The prevalence increases considerably in symptomatic women attending STD clinics, reaching 24–37%. Bacterial vaginosis has been observed in 16–29% of pregnant women. *Gardnerella vaginalis* has been found in 10–31% of virgin adolescent girls, but is found significantly more frequently among sexually active women, reaching a prevalence of 50–60% in some at-risk populations.

Evaluation of epidemiologic factors has revealed few clues of the cause of bacterial vaginosis. Use of the intrauterine device and douching was found to be more common in women with bacterial vaginosis. Bacterial vaginosis is significantly more common among African-American and sexually active women including lesbians.

PATHOGENESIS AND PATHOLOGY

Bacterial vaginosis is the result of massive overgrowth of mixed flora, including peptostreptococci, *Bacteriodes* spp., *G. vaginalis*, *Mobiluncus* spp., and genital mycoplasma.[2] There is little inflammation, and the disorder represents a disturbance of the vaginal microbial ecosystem rather than a true infection of tissues. The overgrowth of mixed flora is associated with a loss of the normal *Lactobacillus* spp. dominated vaginal flora. No single bacterial species is responsible for bacterial vaginosis. Experimental studies in human volunteers and studies in animals indicate that inoculation of the vagina with individual species of bacteria associated with bacterial vaginosis (e.g. *G. vaginalis*), rarely results in bacterial vaginosis. In support of the role of sexual transmission is the higher prevalence of bacterial vaginosis among sexually active young women than among sexually inexperienced women, and the observation that bacterial vaginosis-associated micro-organisms are more frequently isolated from the urethras of male partners of females with bacterial vaginosis.[1]

The cause of the overgrowth of anaerobes, *Gardnerella*, *Mycoplasma* and *Mobiluncus* spp. is unknown. Theories include increased substrate availability, increased pH and loss of the restraining effects of the predominant *Lactobacillus* spp. flora. It has been reported that normal women are colonized by hydrogen peroxide-producing strains of lactobacilli, whereas women with bacterial vaginosis have reduced population numbers of lactobacilli, and the species present lack the

TABLE 62-1 -- Causes of vaginitis in adult women.

CAUSES OF VAGINITIS IN ADULT WOMEN	
Common infectious vaginitis	Bacterial vaginosis (40–50%)
	Vulvovaginal candidiasis (20–25%)
	Trichomonal vaginitis (15–20%)
Uncommon infectious vaginitis	Atrophic vaginitis with secondary bacterial infection
	Foreign body with secondary infection
	Desquamative inflammatory vaginitis (clindamycin responsive)
	Streptococcal vaginitis (group A)
	Ulcerative vaginitis associated with *Staphylococcus aureus* and toxic shock syndrome
	Idiopathic vulvovaginal ulceration associated with HIV
Noninfectious vaginitis	Chemical/irritant
	Allergic, hypersensitivity and contact dermatitis (lichen simplex)
	Traumatic
	Atrophic vaginitis
	Postpuerperal atrophic vaginitis
	Desquamative inflammatory vaginitis (corticosteroid responsive)
	Erosive lichen planus
	Collagen vascular disease, Behçet's syndrome, pemphigus syndromes
	Idiopathic

ability to produce hydrogen peroxide.[3] The hydrogen peroxide produced by lactobacilli may inhibit the pathogens associated with bacterial vaginosis, either directly by the toxicity of hydrogen peroxide, or as a result of the production of hydrogen peroxide-halide complex in the presence of natural cervical peroxidase.

Accompanying the bacterial overgrowth in bacterial vaginosis is the increased production of amines by anaerobes, facilitated by microbial decarboxylases. Volatile amines in the presence of increased vaginal pH produce the typical fishy odor, which is also produced when 10% potassium hydroxide is added to vaginal secretions. Trimethylamine is the dominant abnormal amine in bacterial vaginosis. It is likely that bacterial polyamines together with the organic acids found in the vagina in bacterial vaginosis (acetic and succinic acid) are cytotoxic, resulting in exfoliation of vaginal epithelial cells and creating the vaginal discharge. *Gardnerella vaginalis* attaches avidly to exfoliated epithelial cells, especially at the alkaline pH found in bacterial vaginosis. The adherence of *Gardnerella* organisms results in the formation of the pathognomonic clue cells.

PREVENTION

Because the pathogenesis of bacterial vaginosis is obscure, preventive measures have not been forthcoming. Although not typically sexually transmitted, barrier contraception may reduce occurrence and avoiding douching is recommended.

CLINICAL FEATURES

As many as 50% of women with bacterial vaginosis may be asymptomatic. An abnormal malodorous vaginal discharge, often described as fishy, that is infrequently profuse and often appears after unprotected coitus, is usually described. Pruritus, dysuria and dyspareunia are rare. Examination reveals a nonviscous, grayish-white adherent discharge.

Bacterial vaginosis has been considered to be largely of nuisance value only. There is now considerable evidence of serious obstetric and gynecologic complications of bacterial vaginosis, including asymptomatic bacterial vaginosis diagnosed by Gram stain. Obstetric complications include chorioamnionitis, pre-term labor, prematurity and postpartum fever.[4] Gynecologic sequelae are postabortion fever, posthysterectomy fever, cuff infection and chronic mast cell endometritis. A more recent association is reported between untreated bacterial vaginosis and cervical inflammation and low-grade dysplasia.[5] Bacterial vaginosis is a risk factor for HIV infection.[6]

DIAGNOSIS

Signs and symptoms are unreliable in the diagnosis of bacterial vaginosis (Table 62.2). The clinical diagnosis can reliably be made in the presence of at least three of the following objective criteria:

- adherent, white, nonfloccular homogeneous discharge;
- positive amine test, with release of fishy odor on addition of 10% potassium hydroxide to vaginal secretions;
- vaginal pH >4.5; and
- presence of clue cells on light microscopy.

TABLE 62-2 -- Diagnostic features of infectious vaginitis.

DIAGNOSTIC FEATURES OF INFECTIOUS VAGINITIS					
		Normal	***Candida* vaginitis**	**Bacterial vaginosis**	***Trichomonas* vaginitis**
Symptoms		None or physiologic leukorrhea	Vulvar pruritus, soreness, increased discharge, dysuria, dyspareunia	Malodorous moderate discharge	Profuse purulent discharge, offensive odor, pruritus, and dyspareunia
Discharge	Amount	Variable, scant to moderate	Scant to moderate	Moderate	Profuse
	Color	Clear or white	White	White/gray	Yellow
	Consistency	Floccular nonhomogeneous	Clumped but variable	Homogeneous, uniformly coating walls	Homogeneous
	'Bubbles'	Absent	Absent	Present	Present
	Appearance of vulva and vagina	Normal	Introital and vulvar erythema, edema and occasional pustules, vaginal erythema	No inflammation	Erythema and swelling of vulvar and vaginal epithelium (strawberry cervix)
	pH of vaginal fluid	<4.5	<4.5	>4.7	5.0–6.0
	Amine test (10% potassium hydroxide)	Negative	Negative	Positive	Occasionally present
	Saline microscopy	Normal epithelial cell, lactobacilli predominate	Normal flora, blastospores (yeast) 40–50% pseudohyphae	Clue cells, coccobacillary flora predominate, absence of leukocytes, motile curved rods	PMNs + + +, motile trichomonads (80–90%), no clue cells, abnormal flora
10% potassium hydroxide microscopy		Negative	Positive (60–90%)	Negative (except in mixed infections)	Negative

These features are simple and reliable, and tests for them are easy to perform. The presence of clue cells is the single most reliable predictor of bacterial vaginosis. Clue cells are exfoliated vaginal squamous epithelial cells covered with *G. vaginalis*, giving the cells a granular or stippled appearance with characteristic loss of clear cell borders. Of observed epithelial cells, diagnostic significance is indicated by 20% clue cells. Occasionally, clue cells covered exclusively by curved Gram-negative rods belonging to *Mobiluncus* spp. can be demonstrated. The offensive fishy odor may be apparent during the physical examination or may become apparent only during the amine test. Gram strain of vaginal secretions is extremely valuable in diagnosis, with a sensitivity of 93% and specificity of 70%.

Although cultures for *G. vaginalis* are positive in almost all cases of bacterial vaginosis, *G. vaginalis* may be detected in 50–60% of women who do not meet the diagnostic criteria for bacterial vaginosis. Accordingly, vaginal culture has no part in the diagnosis of bacterial vaginosis. DNA probes for *G. vaginalis* are both sensitive (95%) and specific (99%), but have not been accepted by practitioners because of costs and lack of insurance reimbursement.

MANAGEMENT

Poor efficacy has been observed with triple sulfa creams, erythromycin, tetracycline, acetic acid gel and povidone-iodine vaginal douches.[7]

Only moderate cure rates have been obtained with ampicillin (mean 66%) and amoxicillin. The most successful oral therapy remains metronidazole. Most studies using multiple divided dose regimens of 800–1200mg/day for 1 week achieved clinical cure rates in excess of 90% immediately, and of approximately 80% at 4 weeks. Although single-dose therapy with 2g metronidazole achieves comparable immediate clinical response rates, higher recurrence rates have been reported. The beneficial effect of metronidazole

results predominantly from its anti-anaerobic activity and because *G. vaginalis* is susceptible to the hydroxymetabolites of metronidazole. Although *Mycoplasma hominis* is resistant to metronidazole, the organisms are usually not detected at follow-up visits of successfully treated patients. Similarly, *Mobiluncus curtisii* is resistant to metronidazole but usually disappears after therapy.

Topical therapy with 2% clindamycin cream once daily for 7 days, clindamycin ovules for 3 days or metronidazole gel 0.75% administered daily for 5 days have been shown to be as effective as oral metronidazole, without any of the side effects of the latter.[7]

In the past, asymptomatic bacterial vaginosis was not treated, especially because patients often improve spontaneously over several months. However, the growing evidence linking asymptomatic bacterial vaginosis with numerous obstetric and gynecologic upper tract complications has caused reassessment of this policy, especially with additional convenient topical therapies.[4] [8] Asymptomatic bacterial vaginosis should be treated before pregnancy, in women with cervical abnormalities and before elective gynecologic surgery. Routine screening for and treatment of asymptomatic bacterial vaginosis in pregnancy remains controversial, pending the outcome of studies proving that therapy of bacterial vaginosis reduces pre-term delivery and prematurity.[9]

Despite indirect evidence of sexual transmission, no study has documented reduced recurrent rates of bacterial vaginosis in women whose partners have been treated with a variety of regimens, including metronidazole. Accordingly, most clinicians do not routinely treat male partners.

After therapy with oral metronidazole, approximately 30% of patients initially responding experience recurrence of symptoms within 3 months.[1] Reasons for recurrnece are unclear, including the possibility of re-infection, but recurrence more likely reflects vaginal relapse, with failure to eradicate the offending organisms and re-establish the normal protective *Lactobacillus* spp. dominant vaginal flora. Management of bacterial vaginosis relapse includes oral or vaginal metronidazole, or topical

clindamycin, usually prescribed for 14 days. Maintenance antibiotic regimens have been disappointing and new experimental approaches include exogenous *Lactobacillus* spp. recolonization using selected bacteria-containing suppositories.

TRICHOMONIASIS

EPIDEMIOLOGY

Studies estimate that 2–3 million American women contract trichomoniasis annually, with a worldwide distribution of approximately 180 million annual cases.[1] The prevalence of trichomoniasis correlates with the overall level of sexual activity of the specific group of women under study, being diagnosed in about 5% of women in family planning clinics, in 13–25% of women attending gynecology clinics, in 50–75% of prostitutes and in 7–35% of women in STD clinics. In many industrialized countries, recent surveys indicate a decline in the incidence of trichomoniasis.

PATHOGENESIS AND PATHOLOGY

Sexual transmission is the dominant method of introduction of *Trichomonas vaginalis* into the vagina.[1] *Trichomonas vaginalis* was identified in the urethra of 70% of men who had had sexual contact with infected women within the previous 48 hours. There is also a high prevalence of gonorrhea in women with trichomoniasis, and both of these are significantly associated with use of nonbarrier methods of contraception.

Recurrent trichomoniasis is common and is indicative of lack of significant protective immunity. Nevertheless, an immune response to *Trichomonas* spp. does develop, as indicated by low titers of serum antibody, but this is insufficient for diagnostic serology. Antitrichomonal IgA has been detected in vaginal secretions, but a protective role is not defined.

Delayed hypersensitivity in natural infection can also be demonstrated. The predominant host defense response is provided by the numerous polymorphonuclear leukocytes (PMNs), which respond to chemotactic substances released by trichomonads and are capable of killing *T. vaginalis* without ingesting trichomonads. *Trichomonas vaginalis* destroys epithelial cells by direct cell contact and cytotoxicity. The urethra and Skeene's glands are infected in the majority of patients, and organisms are occasionally isolated from bladder urine.

PREVENTION

Sexual transmission of trichomonads is efficiently prevented by use of barrier contraception. Spermicidal agents such as nonoxynol-9 also reduce transmission. Re-infection of women is common, hence the mandatory requirement of treatment, preferably simultaneously, of all sexual partners with metronidazole.

CLINICAL FEATURES

Infection with *Trichomonas* spp. in women ranges from an asymptomatic carrier state to severe acute inflammatory disease. [10] [11] Vaginal discharge is reported by 50–75% of women diagnosed with trichomoniasis; however, the discharge is not always described as malodorous. Pruritus occurs in 25–50% of patients and is often severe. Other infrequent symptoms include dyspareunia, dysuria and, rarely, frequency of micturition. Lower abdominal pain occurs in fewer than 10% of patients and should alert the physician to the possibility of concomitant salpingitis caused by other organisms. Symptoms of acute trichomoniasis often appear during or immediately after menstruation. Although controversial, the incubation period has been estimated to range from 3 to 28 days.

Physical findings represent a spectrum depending on the severity of disease. Vulvar findings may be absent, but are typically characterized in severe cases by diffuse vulvar erythema (10–33%), edema and a copious, profuse and malodorous vaginal discharge, which is often described as being yellow-green and frothy, but is frequently grayish-white.[11] Frothiness is seen in a minority of patients and is more commonly seen in bacterial vaginosis.

The vaginal walls are erythematous and in severe cases may be granular in appearance. Punctate hemorrhages (colpitis macularis) of the cervix may result in a strawberry-like appearance that, although apparent to the naked eye in only 1–2% of patients, is present in 45% of cases on colposcopy.[11]

The clinical course of trichomoniasis in pregnancy is identical to that seen in the nonpregnant state, and when untreated it is associated with premature rupture of membranes and prematurity. Trichomoniasis is reported to facilitate HIV transmission.

DIAGNOSIS

None of the clinical features of vaginitis caused by *Trichomonas* spp. are sufficiently specific to allow a diagnosis of trichomonal infection based on signs and symptoms alone (see Table 62.2).[10] Definitive diagnosis requires the demonstration of the organism. Vaginal pH is markedly elevated, almost always above 5.0, and not infrequently 6.0. On saline microscopy, an increase in number of PMNs is almost invariably present. The ovoid parasites are slightly larger than PMNs and are best recognized by their motility. The wet mount is positive in only 40–80% of cases (low sensitivity). Gram stain is of little value because of its inability to differentiate PMNs from nonmotile trichomonads, and use of Giemsa, acridine orange and other stains

has no advantage over saline preparations. Although trichomonads are often seen on Papanicolaou smears, this method has a sensitivity of only 60–70% when compared with saline preparation microscopy, and false-positive results are not infrequently reported.

Several equivalent culture medium methods are available, and growth is usually detected within 48 hours. Culture is now recognized as the most sensitive method for detecting the presence of trichomonads (95% sensitivity) and should be considered in patients with vaginitis in whom an elevated pH, PMN excess, absence of motile trichomonads and clue cells are found. Several new rapid diagnostic kits using DNA probes are under investigation.

MANAGEMENT

Therapy consists of administering the 5-nitroimidazole group of drugs — metronidazole, tinidazole and ornidazole, — which are all of similar efficacy.[7] Oral therapy as opposed to topical vaginal therapy is preferred because of the frequency of infection of the urethra and periurethral glands, which provide sources for endogenous recurrence.

Treatment consists of oral metronidazole, 500mg q12h for 7 days, which has a cure rate of 95%. Comparable results have been obtained with a single oral dose of 2g metronidazole, achieving cure rates of 82–88%. The latter cure rate increases to greater than 90% when sexual partners are treated simultaneously. The advantages of single-dose therapy include better patient compliance, lower total dose, shorter period of alcohol avoidance and possibly decreased incidence of subsequent vaginitis caused by *Candida* spp. A disadvantage of single-dose therapy is the need to insist on simultaneous treatment of sexual partners.

The 5-nitroimidazoles are not in themselves trichomonacidal, but low-redox proteins reduce the nitro group, resulting in the formation of highly cytotoxic products within the organisms. Aerobic conditions interfere with this reduction process and decrease the antianaerobic activity of the 5-nitroimdazoles. Most strains of *T. vaginalis* are highly susceptible to metronidazole, with minimum inhibitory concentrations (MICs) of 1mg/l.

Patients not responding to an initial course often respond to an additional standard course of 7-day therapy. Some patients are refractory to repeated courses of therapy even when compliance is assured and sexual partners are known to have been treated. If re-infection is excluded, these rare patients may have strains of *T. vaginalis* that are resistant to metronidazole, which can be confirmed in vitro. Increased doses of metronidazole and longer duration of therapy are necessary to cure these refractory patients. The patients should be given maximal tolerated dosages of oral metronidazole of 2–4g/day for 10–14 days. Rarely, intravenous metronidazole, in dosages as high as 2–4g/day, may be necessary, with careful monitoring for drug toxicity. Considerable success has been observed in treating resistant infections with oral tinidazole; however, the drug is not readily available and the optimal dose to be used is unknown.[12] Most investigators use high-dose

tinidazole 1–4g/day for 14 days.[12] Rare patients not responding to nitroimidazoles can be treated with topical paramomycin.

Side-effects of metronidazole include an unpleasant or metallic taste. Other common side-effects include nausea (10%), transient neutropenia (7.5%) and a disulfiram-like effect when alcohol is ingested. Caution should be taken when 5-nitroimidazoles are used in patients taking warfarin. Long-term and high-dose therapy increase the risk of neutropenia and peripheral neuropathy. In experimental studies, metronidazole has been shown to be mutagenic for certain bacteria, indicating a carcinogenic potential, although cohort studies have not established an increase in cancer morbidity. Thus, the risk to humans of short-term low-dose metronidazole treatment is extremely small. Superinfection with *Candida* spp. is by no means uncommon.

Treatment of trichomoniasis in pregnancy is unsatisfactory.[7] Metronidazole readily crosses the placenta, and because of concern for teratogenicity some consider it prudent to avoid its use in the first trimester of pregnancy. More recently investigators have become more comfortable with the use of metronidazole throughout pregnancy. Topical clotrimazole and povidone-iodine jelly offer minimal benefit.

VULVOVAGINAL CANDIDIASIS

EPIDEMIOLOGY

Data from the UK reveal a sharp increase in the incidence in vulvovaginal candidiasis (VVC). In the USA, *Candida* spp. are now the second commonest cause of vaginal infections.[13] [14]

It is estimated that 75% of women experience at least one episode of VVC during their child-bearing years, and approximately 40–50% experience a second attack. A small subpopulation of women of undetermined magnitude, probably less than 5% of adult females, suffers from repeated, recurrent, often intractable episodes of *Candida* vaginitis.[14]

Point-prevalence studies indicate that *Candida* spp. may be isolated from the genital tract of approximately 20% of asymptomatic, healthy women of child-bearing age. The natural history of asymptomatic colonization is unknown, although animal and human studies suggest that vaginal carriage continues for several months and perhaps years. Several factors are associated with increased rates of asymptomatic vaginal colonization with *Candida* spp., including pregnancy (30–40%), use of oral contraceptives, uncontrolled diabetes mellitus and frequency of visits to STD clinics (Table 62.3). The rarity of isolation of *Candida* spp. in premenarchal girls, the lower prevalence of *Candida* vaginitis after menopause and the possible association with hormone replacement therapy emphasize the hormonal dependence of VVC.

PATHOGENESIS AND PATHOLOGY

The organism

Between 85 and 90% of yeast isolated from the vagina are *Candida albicans* strains. The remainder are other species, the commonest of which are *Candida glabrata* and *Candida tropicalis*. Non-*albicans Candida* spp. are capable of inducing vaginitis and are often more resistant to conventional therapy. Recent surveys indicate an increase in VVC caused by non-*albicans Candida* spp., particularly *C. glabrata*. [14] [15]

TABLE 62-3 -- Host factors associated with asymptomatic vaginal colonization by *Candida* and with *C andida* vaginitis.

HOST FACTORS ASSOCIATED WITH INCREASED ASYMPTOMATIC VAGINAL COLONIZATION BY *CANDIDA* AND WITH *CANDIDA* VAGINITIS	
Genetic	
Blood group antigen/secretor status	
Acquired	
Biologic	Pregnancy
	Uncontrolled diabetes mellitus
	Corticosteroids/immunosuppressive therapy
	Antimicrobial therapy (systemic, topical)
	HIV infection
Behavioral (sexual)	Oral contraceptives
	Intrauterine device/contraceptive sponge
	Nonoxynol-9 spermicide
	Receptive oral-genital sex
	Coital frequency (?)

Germination of *Candida spp.* enhances colonization and facilitates tissue invasion. Factors that enhance or facilitate germination (e.g. estrogen therapy and pregnancy) tend to precipitate symptomatic vaginitis, whereas measures that inhibit germination (e.g. bacterial flora and local mucosal cell-mediated immunity) may prevent acute vaginitis in women who are asymptomatic carriers of yeast.

Candida organisms gain access to the vaginal lumen and secretions predominantly from the adjacent perianal area. This finding is borne out by epidemiologic typing studies. *Candida* vaginitis is seen predominantly in women of child-bearing age, and only in the minority of cases can a precipitating factor be identified to explain the transformation from asymptomatic carriage to symptomatic vaginitis in individual patients.

Host factors

Host factors associated with increased asymptomatic vaginal colonization by *Candida* spp. and with *Candida* vaginitis are outlined in Table 62.3 . During pregnancy, the vagina is more susceptible to vaginal infection, resulting in higher incidences of vaginal colonization, vaginitis and lower cure rates. The clinical attack rate is maximal in the third trimester, and symptomatic recurrences are also more common throughout pregnancy. The high levels of reproductive hormones result in a higher glycogen content in the vaginal environment, which provides an excellent carbon source for growth and germination of *Candida* spp. A more common mechanism is where estrogens enhance vaginal epithelial cell avidity for *Candida* spp. adherence, and a yeast cytosol receptor or binding system for female reproductive hormones has been documented. These hormones also enhance yeast mycelial formation. Several studies have shown increased VVC associated with oral contraceptive use[16] and uncontrolled diabetes mellitus. Glucose tolerance tests have been recommended for women with recurrent VVC; however, the yield is low, and testing is not justified in otherwise healthy premenopausal women.

Symptomatic VVC is frequently observed during or after courses of systemic antibiotics. Although no antimicrobial agent is free of this complication, broad-spectrum antibiotics, such as tetracycline, and ß-lactams are mainly responsible, and are thought to act by eliminating the normal protective vaginal bacterial flora. The natural flora provides a colonization resistance mechanism and prevents germination of *Candida* spp. The provider of this protective function has been singled out to be *Lactobacillus* spp.[17] *Lactobacillus-Candida* interaction includes competition for nutrients, steric interference with adherence of *Candida* spp. and elaboration of bacteriocins that inhibit yeast proliferation and germination.

Other factors that contribute to an increased incidence of *Candida* vaginitis include the use of tight, poorly ventilated clothing and nylon underclothing, which increase perineal moisture and temperature.

Candida spp. may cause cell damage and resulting inflammation by direct hyphal invasion of epithelial tissue. It is possible that proteases and other hydrolytic enzymes facilitate cell penetration with resultant inflammation, mucosal swelling, erythema and exfoliation of vaginal epithelial cells, The characteristic nonhomogeneous vaginal discharge consists of a conglomerate of hyphal elements and exfoliated nonviable epithelial cells with few PMNs. *Candida* spp. may also induce symptoms by hypersensitivity or allergic reactions, particularly in women with idiopathic recurrent VVC (see Noninfectious vaginitis and vulvitis, below).[18]

Oral and vaginal thrush correlate well with depressed cell-mediated immunity in debilitated or immunosuppressed patients.[18] This is particularly evident in patients who have chronic mucocutaneous candidiasis and AIDS.

Pathogenesis of recurrent and chronic *Candida* vaginitis

Careful evaluation of women with recurrent vaginitis usually fails to reveal any precipitating or causal mechanism.[14] In the past, investigators attributed frequent episodes to repeated fungal reinoculation of the vagina from a persistent intestinal source or to sexual transmission.[19]

The intestinal theory is based on the report of recovery of *Candida* spp. on rectal culture in almost 100% of women with VVC. Typing of simultaneously obtained vaginal and rectal isolates almost invariably reveals identical strains. This theory has been criticized in the past few years because of lower concordance between rectal and vaginal cultures in patients with recurrent VVC. Moreover, long-term therapy with oral nonabsorbable nystatin is not effective in preventing recurrences.

Although sexual transmission of *Candida* organisms occurs via vaginal intercourse and orogenital contact, the role of sexual reintroduction of yeast as a cause for recurrent VVC is doubtful. Recurrent VVC frequently occurs in celibate women and only a minority of male partners of women who have recurrent VVC are colonized with *Candida* spp. Although most studies aimed at treating male partners have not reduced the frequency of recurrent episodes of vaginitis, reduction was achieved in recurrent VVC by treating colonized male partners.[19]

Vaginal relapse implies that incomplete eradication or clearance of *Candida* spp. from the vagina occurs after antimycotic therapy. Organisms persist in small numbers in the vagina and result in continued carriage of the organisms, and when host environmental conditions permit, the colonizing organisms increase in number and undergo mycelial transformation, resulting in a new clinical episode.

Whether recurrence is caused by vaginal re-infection or relapse, women with recurrent VVC differ from those with infrequent episodes in their inability to tolerate small numbers of *Candida* organisms re-introduced or persisting in the vagina. On the basis of typing of organisms, women with recurrent and infrequent infection have the same distribution frequency of *Candida* strains as women without symptoms.

Host factors responsible for frequent episodes are not clearly delineated, and more than one mechanism may be operative. There is no evidence of complement, phagocytic cells or immunoglobulin deficiency in these patients. Recurrent VVC is rarely caused by drug resistance.[20]

Current theories about the pathogenesis of recurrent VVC include qualitative and quantitative deficiency in the normal protective vaginal bacterial flora and an acquired, often transient antigen-specific deficiency in T-cell function that similarly permits unchecked yeast proliferation.[18] [21] Another theory is that of an acquired acute hypersensitivity reaction to *Candida* antigen, which is accompanied by elevated vaginal titers of *Candida* antigen-specific IgE. This theory has a clinical basis in that patients with recurrent VVC often present with severe vulvar manifestations (rash, erythema, swelling and pruritus) with minimal exudative vaginal changes, little discharge and lower numbers of organisms. Allergic responses to *Candida* spp. have been reported to involve the male genitalia immediately after coitus with a woman infected with *Candida* spp. and are characterized by the acute onset of erythema, edema, severe pruritus and irritation of the penis. As yet, only a minority of women with recurrent VVC have been shown to have elevated *Candida*-specific vaginal IgE. Limited studies using *Candida* antigen desensitization have been found to be helpful in reducing the frequency of recurrent episodes of vaginitis.

Women who are HIV seropositive have higher vaginal colonization rates than seronegative women, but the attack rate of symptomatic VVC appears similar. Reports of chronic, severe recurrent VVC are largely unsubstantiated. Recurrent VVC in the absence of other risk factors for HIV is not an indication for HIV testing. [14]

PREVENTION

In women with confirmed recurrent VVC linked to frequent courses of systemic antibiotics, prophylactic antimycotics are justified. A useful regimen is fluconazole 100mg once weekly for the duration of antibiotic therapy. No other dietary or alternative method has stood the test of time in preventing VVC. In women prone to VVC, avoiding use of oral contraceptives, intrauterine devices and the contraceptive sponge is prudent.

CLINICAL FEATURES

The most frequent symptom of VVC is vulvar pruritus because vaginal discharge is not invariably present and is frequently minimal.[14] Although described as typically cottage cheese-like in character, the discharge may vary from watery to homogeneously thick. Vaginal soreness, irritation, vulvar burning, dyspareunia and external dysuria are commonly present. Odor, if present, is minimal and nonoffensive. Examination frequently reveals erythema and swelling of the labia and vulva (Fig. 62.1), often with discrete pustulopapular peripheral lesions and linear fissures (Fig. 62.2). The cervix is normal and vaginal mucosal erythema with adherent whitish discharge is present. Characteristically, symptoms are exacerbated in the week before the onset of menses, with some relief with the onset of menstrual flow.

Figure 62-1 Typical *Candida* vulvovaginitis with bilateral symmetric erythema and edema of vestibule and labia.

Figure 62-2 Severe *Candida* vulvovaginitis with bilateral painful fissure formation in the vulva.

DIAGNOSIS

The relative lack of specificity of symptoms and signs precludes a diagnosis that is based only on history and physical examination. Most patients with symptomatic VVC may be readily diagnosed on the basis of simple microscopic examination of vaginal secretions. A wet mount or saline preparation has a sensitivity of 40–60%. The 10% potassium hydroxide preparation is more sensitive in diagnosing the presence of germinated yeast. A normal vaginal pH (4.0–4.5) is found in *Candida* vaginitis, and the finding of a pH in excess of 4.5 should suggest the possibility of bacterial vaginosis, trichomoniasis or a mixed infection.[14]

Although routine fungal cultures are unnecessary, vaginal culture should be performed in the presence of negative microscopy. The Papanicolaou smear is unreliable, being positive in only about 25% of cases. There is no reliable serologic technique for the diagnosis of *Candida* vaginitis.

MANAGEMENT

Topical agents for acute *Candida* vaginitis

Antimycotics are available for local use as creams, vaginal tablets, suppositories and coated tampons (Table 62.4) There is little to suggest that the formulation of the topical antimycotic influences clinical efficacy.[20] Extensive vulvar inflammation dictates local vulvar application of cream.

The average mycologic cure rate of 7- and 14-day courses of nystatin is 75–80%. Azoles appear to achieve slightly higher clinical mycologic cure rates than the polyenes (nystatin): 85–90%. Although many studies have compared the clinical efficacies of the various azoles, there is little evidence that any one azole agent is superior to others.[22] Topical azoles are remarkably free of local and systemic side-effects; nevertheless, the initial application of topical agents is not infrequently accompanied by local burning and discomfort.

TABLE 62-4 -- Therapy for vaginal candidiasis — topical agents.[*]

THERAPY FOR VAGINAL CANDIDASIS		
Topical Agents		
Drug	**Formulation**	**Dosage regimen**
* Butoconazole	2% cream	5g/day for 3 days
* Clotrimazole	1% cream	5g/day for 7–14 days
	100mg vaginal tablets	1 tablet/day for 7 days
	100mg vaginal tablets	2 tablets/day for 3 days
	500mg vaginal tablets	1 tablet, single dose
* Miconazole	2% cream	5g/day for 7 days
	100mg vaginal suppository	1 suppository/day for 7 days
	200mg vaginal suppository	1 suppository/day for 3 days
	1200mg vaginal suppository	1 suppository, single dose
Econazole	150mg vaginal tablet	1 tablet/day for 3 days
Fenticonazole	2% cream	5g/day for 7 days
* Tioconazole	2% cream	5g/day for 3 days
	6.5% cream	5g, single dose
Terconazole	0.4% cream	5g/day for 7 days
	0.8% cream	5g/day for 3 days
	80mg vaginal suppository	80mg/day for 3 days
Nystatin	100,000U vaginal tablets	1 tablet/day for 14 days

* Drugs available over the counter, without prescription.

Systematic agents for acute *Canadida* vaginitis

There has been a major trend toward shorter treatment courses with progressively higher antifungal doses, culminating in highly effective single-dose topical regimens. Although short-course regimens are effective for mild and moderate vaginitis, cure rates for severe and complicated vaginitis are lower.

Oral systemic azoles available for the treatment of VVC include ketoconazole 400mg q12h for 5 days, itraconazole 200mg/day for 3 days (or q12h single-day regimen) and, finally, fluconazole 150mg single-dose.[23] All the oral regimens achieve clinical cure rates in excess of 80%; however, only fluconazole is approved for use in the USA. Oral regimens are generally preferred by women because of convenience and lack of local side-effects. None of the systemic regimens should be prescribed during pregnancy and the potential for systemic side-effects and toxicity exists. In particular, hepatotoxicity with ketoconazole precludes its widespread use in VVC.[22]

Vulvovaginal candidiasis is classified as uncomplicated or complicated on the basis of the likelihood of achieving clinical and mycologic cure with short-course therapy (Table 62.5). Uncomplicated VVC represents by far the most common form of vaginitis seen, is caused by highly sensitive *C. albicans* and, provided that the severity is mild to moderate, patients respond well to all topical or oral antimycotics, including single-dose therapy. In contrast, patients who have complicated VVC have a relatively resistant organism, a host factor or a severity of infection that dictates more intensive and prolonged therapy lasting 7–14 days. Most non-*albicans Candida* infections respond to conventional topical or oral antifungals provided they are administered for sufficient duration. However, vaginitis caused by *C. glabrata* often fails to respond to azoles and may require treatment with vaginal capsules of boric acid 600mg/day for 14 days. [24] Patients with severe vulvovaginitis require more prolonged systemic or topical therapy. The former can be provided by a second dose of fluconazole 150mg, 72 hours after the first dose.[25]

Treatment of recurrent vulvovaginal candidiasis

The management of women who have recurrent VVC aims at control rather than cure. The clinician should first confirm the diagnosis of recurrent VVC. Uncontrolled diabetes mellitus must be controlled and use of corticosteroids or other immunosuppressive agents should be discontinued where possible. Unfortunately, in the majority of women with recurrent VVC, no underlying or predisposing factor can be identified. Recurrent VVC requires long-term maintenance with a suppressive prophylactic regimen. Because of the chronicity of therapy, the convenience of oral treatment is apparent, and the best suppressive prophylaxis has been achieved with weekly oral fluconazole at a dosage of 150mg. An effective topical prophylactic regimen consists of weekly vaginal suppositories of clotrimazole 500mg.[14] [22]

ATROPHIC VAGINITIS

Clinically significant atrophic vaginitis is quite rare, and the majority of women with mild-to-moderate atrophy are asymptomatic. Because of reduced endogenous estrogen, the epithelium becomes thin and lacking in glycogen, which contributes to a reduction in lactic acid production and an increase in vaginal pH. This change in the environment encourages the overgrowth of nonacidophilic coliform organisms and the disappearance of *Lactobacillus* spp. Despite these major but usually gradual changes, symptoms are mostly absent, especially in the absence of coitus.

With advanced atrophy, symptoms include vaginal soreness, dyspareunia and occasional spotting or discharge. Burning is a frequent complaint and is often precipitated by intercourse. The vaginal mucosa is thin, with diffuse redness, occasional petechiae or ecchymoses with few or no vaginal folds. Vulvar atrophy may also be

TABLE 62-5 -- Classification of vulvovaginal candidiasis.

CLASSIFICATION OF VULVOVAGINAL CANDIDIASIS	
Uncomplicated	**Complicated**
Candida albicans	Non-*albicans Candida* spp.
	Resistant *Candida albicans* (rare)
+	or
Infrequent episodes	History of recurrent vulvovaginal candidiasis
+	or
Mild-to-moderate vaginitis	Severe vulvovaginal candidiasis
+	or
Normal host	Abnormal host, for example, uncontrolled diabetes, pregnancy, immunocompromised

apparent and discharge may be serosanguinous, thick or watery, and the pH of the vaginal secretions ranges from 5.5 to 7.0. The wet smear frequently shows increased number of PMNs associated with small, round epithelial cells. The latter parabasal cells represent immature squamous cells that have not been exposed to sufficient estrogen. The *Lactobacillus* spp.-dominated flora is replaced by mixed flora of Gram-negative rods. Bacteriologic cultures in these patients are unnecessary, and can be misleading.

The treatment of atrophic vaginitis consists primarily of topical vaginal estrogen. Nightly use of half or all the contents of an applicator for 1–2 weeks is usually sufficient to alleviate the atrophic vaginitis.

NONINFECTIOUS VAGINITIS AND VULVITIS

Women frequently present with acute or chronic vulvovaginal symptoms caused by noninfectious etiologies. Symptoms are indistinguishable from those of infectious syndromes, but are most commonly confused with those of acute *Candida* vaginitis, including pruritus, irritation, burning, soreness and variable discharge.

Noninfectious causes include irritants [physical (e.g. minipads) or chemical (e.g. spermicides, betadyne, topical antimycotics, soaps and perfumes, topical 5-fluorouracil)] and allergens, which are responsible for immunologic acute and chronic hypersensitivity reactions, including contact dermatitis (e.g. latex condoms, antimycotic creams). An enormous list of topical factors responsible for local inflammatory reactions and symptoms exists and many more have yet to be defined. Depending on the site of contact, symptoms may be vaginal or vulvar. Included in this category are systemic dermatoses that may present in the vulva (e.g. psoriasis, Fig. 62.3) or vulva-specific dermatosis (e.g. lichen sclerosus).

A noninfectious mechanism may coexist with or follow an infectious process, and should be considered when the three common infectious causes and hormone deficiency are excluded and in the presence of a normal vaginal pH, normal saline and potassium hydroxide microscopy, and, ultimately, a negative yeast culture. Unfortunately, given the anticipated 20% colonization rates in normal asymptomatic women, occasionally a positive yeast culture in a symptomatic patient reflects the presence of an innocent bystander and not the cause of the vulvovaginal symptoms. The only logical way of establishing the role of *Candida* spp. in this context is to treat with an oral antifungal agent and assess the clinical response.

Once a local chemical irritant or allergic reaction is suspected, a detailed inquiry into possible causal factors is essential. Offending agents or behaviors should be eliminated wherever possible, including

Figure 62-3 Vulvar psoriasis resulting in pruritus vulva and misdiagnosed as *Candida vulvovaginitis.*

avoiding chemical irritants and allergens (e.g. soaps, detergents). The immediate management of severe vulvovaginal symptoms of noninfectious etiology should not rely on topical corticosteroids, which are rarely the solution and frequently high-potency corticosteroid creams cause intense burning. Local relief measures include sodium bicarbonate sitz baths and oral antihistamines.

A syndrome of hyperacidity of the vagina causing overgrowth of lactobacilli has been described but not confirmed. A rebound increase in population numbers of lactobacilli is thought to occur after completion of topical antimycotics and is alleged to suppress population numbers of healthy resident flora. The proposed syndrome of cytolytic vaginosis is characterized by vulvovaginal burning, irritation, soreness and dyspareunia, and is usually incorrectly diagnosed as VVC. The finding of large numbers of lactobacilli on wet count and low pH, together with extensive squamous epithelial cell cytolysis is said to confirm the diagnosis. Recommended therapy for cytolytic vaginosis is daily alkaline douching using sodium bicarbonate to elevate the low vaginal pH and suppress growth of lactobacilli.

VULVITIS

Most of the important infectious and noninfectious causes of vulvitis have been described in the section on vaginitis. Human papillomavirus and genital herpes are described in Chapter 77 and Chapter 76 , respectively. Bacterial vulvitis due to streptococci, anaerobes and Gram-negative rods occurs infrequently and should be diagnosed by clinical features and bacterial culture. Specific antimicrobial treatment is indicated for patients with the diagnosis of bacterial vulvitis. Occasionally a Bartholin's abscess creates a painful swelling in the vulva. This can be due to *N. gonorrhoeae* or to a variety of pathogens, particularly Gram-positive organisms. A Bartholin's cyst infection should be treated with appropriate antibiotics and occasionally may require drainage. Other causes of vestibulitis or vulvitis include lichen sclerosus, erosive lichen planus and theoretically any cause of dermatosis or dermatitis such as psoriasis (see Fig. 62.3), eczema and pemphigus.

CERVICITIS

EPIDEMIOLOGY

The presence of a purulent exudate in the cervical os has been highly associated with cervical infection with *Chlamydia trachomatis, N. gonorrhoeae*, herpes simplex virus and cytomegalovirus. Infection with *T. vaginalis* correlates with colpitis macularis and inflammatory changes of the ectocervix.[26] [27] Not infrequently, mucopurulent endocervitis or ectocervicitis are seen in the absence of these pathogens, indicating that additional, as yet unrecognized causes exist. A role for disruption of vaginal flora, specifically overgrowth of anaerobes in causing cervical inflammation has been proposed. Rare causes of cervicitis include *Mycobacterium tuberculosis* and *Actinomyces israelii*, the latter almost invariably in the presence of intrauterine devices. Although the most important and prevalent infection of the cervix is undoubtedly human papillomavirus, this virus does not cause cervicitis and is discussed in Chapter 216 .

The prevalence of genital chlamydial infection ranges from 8 to 40%.[28] Risk factors include young age, unmarried status, lower socioeconomic conditions, number and recent change of sexual partner, ectopy, oral contraceptive use and concurrent gonococcal infection; the latter may reactivate latent chlamydial infection and increases shedding of chlamydia from the endocervix.[28] Risk factors for gonococcal mucopurulent cervicitis are identical to those of *Chlamydia* spp. but also include urban dwelling, prostitution, illicit drug use and minority racial status. Up to 60% of women with *N. gonorrhoeae* have co-infection with chlamydia.[28] Herpetic cervicitis is rare in the absence of genital lesions and is most commonly associated with first episode, primary disease with an 80% viral isolation rate.[27] Cytomegalovirus is thought to be responsible for approximately 5% of cases of cervicitis, is usually asymptomatic and when it is isolated from cervical secretions, the detection may not imply a causal relationship with present pathology.

CLINICAL FEATURES

Cervicitis is frequently asymptomatic and is detected on routine pelvic examination. Alternatively cervical inflammation is recognized because of signs and symptoms of concomitant infection (e.g. vaginal trichomoniasis, genital herpes or salpingitis). Mucopurulent cervicitis may result in a purulent vaginal discharge in its own right. Accordingly cervical speculum evaluation should be an essential part of vaginal examination in women with an abnormal discharge. Mucopurulent endocervicitis results in swelling and erythema of the zone of ectopy associated with friability, contact bleeding, spotting and a yellow or a green endocervical exudate. The purulent discharge is best appreciated by obtaining an endocervical swab specimen and observing the latter against a white background.

Trichomoniasis is associated with ectocervical squamous epithelial mucosal inflammation giving the cervix a 'strawberry' appearance due to microscopic focal patchy petechiae (colpitis macularis) in 5–20% of patients.[11] Primary herpes cervicitis may be associated with severe necrosis that is reminiscent of cervical cancer. Most commonly, primary herpetic cervicitis is characterized by increased surface vascularity, and micro- and macro-ulcerations with and without necrotic areas. Asymptomatic shedding of herpesvirus occurs in the absence of cervical lesions.

DIAGNOSIS

Mucopurulent cervicitis is confirmed when a Gram-stained specimen of green or yellow endocervical exudate reveals more than 30 PMNs per high power field. Microscopic examination of cervical mucus from a patient with mucopurulent endocervicitis reveals an overabundance of inflammatory cells, obliterating the background ferning pattern. A similar excess of inflammatory cells can be found in a Papanicolaou smear. These two microscopic studies are not reliable in identifying the underlying cause of mucopurulent cervicitis. For a diagnosis of *C. trachomatis* cervicitis, culture techniques to identify the obligate intraparasites served as the gold standard in the past.

Now the development of the more widely available enzyme-linked immunosorbent assay antigen detection tests has been replaced by the highly sensitive DNA amplification techniques, particularly ligase chain reaction, allowing diagnosis not only from cervical specimens, but also by screening urine specimens. Gram stain of cervical mucus may reveal intracellular Gram-negative diplococci, but has low sensitivity and specificity in the diagnosis of gonococcal cervicitis. Diagnosis relies mainly upon culture of the endocervix using a modified Thayer-Martin medium; however, diagnostic methodologies now include use of DNA probes, especially for screening purposes, given the high sensitivity of these newer techniques.

Although Papanicolaou smears in herpetic cervicitis are useful in revealing multinucleated giant cells, viral culture and fluorescein-conjugated monoclonal antibodies are the mainstay of clinical diagnosis; polymerase chain reaction is used for monitoring asymptomatic viral shedding in a research context.

The clinical differentiation of the various causes of cervicitis is not possible, but requires the aforementioned diagnostic tests, recognizing that frequently more than one etiologic agent may be present simultaneously because many of the pathogens share risk factors and behavior. The most important diagnostic problem is that of overdiagnosis of cervicitis. All too frequently physiologic changes in the appearance of the cervix, in spite of the use of colposcopy, are interpreted as reflecting pathologic cervicitis. Regrettably, after failed attempts to identify pathogenic micro-organisms, patients are needlessly treated with cervical ablative techniques. Cervical ectopy is often mistaken for cervicitis with eversion of endocervical columnar cells, and is commonly seen in women on oral contraceptives.[29] Other physiologic changes related to childbirth and dilatation of the cervical canal are mistakenly diagnosed as cervicitis. Equally important is the failure to recognize that a friable, abnormal cervix may reflect dysplasia and neoplasia. If the Papanicolaou smear reports inflammatory cells with or without atypia, the presence of atypical squamous cells of undetermined significance (ASCUS) should be considered in the differential diagnosis between a benign change in reaction to a stimulus and a low-grade squamous intraepithelial lesion. Accordingly, women with a Papanicolaou smear showing ASCUS should have their smears repeated. Persistence of an ASCUS smear should prompt colposcopy.

MANAGEMENT

Antimicrobial regimens for infectious cervicitis are provided in the chapters on gonorrhea and chlamydial infections and pelvic inflammatory disease (see Chapter 63 , Chapter 74 and Chapter 236).

Chapter 63 - Infections of the Female Pelvis Including Septic Abortion

Gina Dallabetta
Munkolenkole C Kamenga
Mary Lyn Field

Infections of the female pelvis constitute a diverse group. This chapter considers three groups of infections: pelvic inflammatory disease (PID), postpartum and postabortal infections (including postpartum endometritis and cesarean section, episiotomy infections and postabortion sepsis) and postsurgical gynecologic infections.

PELVIC INFLAMMATORY DISEASE

EPIDEMIOLOGY

Pelvic inflammatory disease refers to an acute clinical syndrome that results when vaginal or cervical organisms ascend into the upper structures of the female reproductive tract unrelated to pregnancy or surgery.[1] [2] The term PID includes the following: endometritis, parametritis, salpingitis, oophoritis, pelvic peritonitis, tubo-ovarian abscess, periappendicitis, perihepatitis (Fitz-Hugh-Curtis syndrome) and perisplenitis.

Pelvic inflammatory disease and sexually transmitted diseases (STDs) share many of the same risk factors and, in the USA, 40–80% of PID is attributed to STDs. Bacterial vaginosis may be an antecedent vaginal condition. [3] The identified risk factors for PID include younger age, unmarried status, lower socioeconomic status, sexual behavior (number of sexual partners, age of sexual debut, rate of acquiring new partners), substance abuse, poor health care behavior (treatment-seeking and compliance with treatment instructions), douching and intrauterine device insertion.[1] [4] In studies from the USA and Europe, about three-quarters of women who had PID were under 25 years of age, and about one-half had never been pregnant.[2] Oral contraceptive users tend to have clinically and laparoscopically milder infection than do nonusers and oral contraceptives appear to protect against chlamydial PID.[5]

PATHOGENESIS AND PATHOLOGY

The vast majority of PID cases result from a direct canalicular spread of organisms from the endocervix to the mucosa of the endometrium and fallopian tubes, although the precise mechanisms are poorly understood. Postinfectious scarring (e.g. intratubal adhesions, tubal occlusion, peritubal scarring and damaged fimbrial ostia) results in the long-term sequelae of PID.

Occurrence of PID is described only among sexually active women and its risk is associated with the numbers of sexual partners and the frequency of sexual acts among women with only one sexual partner. Multiple organisms have been implicated as etiologic agents of PID (Table 63.1). The rates of isolation of these organisms are variable. They may vary with geographic region, duration of infection and the site of sampling (i.e. cervix, fallopian tubes or endometrium). The most commonly recovered organisms are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, followed by other aerobic and anaerobic bacteria associated with bacterial vaginosis (e.g. *Gardnerella vaginalis*, *Mycoplasma hominis*, *Prevotella bivia*, and *Porphyromonas*, *Prevotella* and *Peptostreptococcus* spp.). *Mycoplasma genitalium* may also be an important etiological agent of PID but further studies are necessary. Rates of isolation of 10–20% in the upper genital tract and as high as 85% (5–27% in studies from Europe versus 44–70% in those from North America) in the lower genital tract have been reported for *N. gonorrhoeae*. For *C. trachomatis*, rates of 1.2–31% in the upper genital tract and 31% in the lower genital tract have been reported.[2] [3] [6] It is estimated that between 10% and 40% of women who have untreated gonococcal or chlamydial cervical infection will develop acute upper tract infection. However, PID is a polymicrobial infection, even in the setting of gonococcal or chlamydial cervicitis. It has been suggested that, in many cases of PID, STD organisms initiate the inflammation of the tubal mucosa and this process facilitates the invasion of the mucosa by organisms endogenous to the lower genital tract.[2]

PREVENTION

Prevention is directed at reducing a woman's risk of acquiring an STD, and the detection and treatment of lower genital tract infections. A recent study showed that women screened and treated for asymptomatic chlamydial infection were nearly 60% less likely than unscreened women to develop PID.[7] Prompt and correct treatment of upper tract infections will ameliorate some of the long-term sequelae.

CLINICAL FEATURES

The most common clinical complaint in a woman who has PID is bilateral lower abdominal or pelvic pain. Gonococcal PID tends to have an abrupt, fulminant presentation within 1 week of the onset of menses. Chlamydial PID is characterized by a subacute course with mild symptoms, often described as a dull pain. It is not unusual for a woman who has chlamydial PID to be unaware of her infection and to present as a contact of a male with urethritis, with right upper quadrant pain or with other genitourinary complaints such as dyspareunia, dysuria, dysmenorrhea, menorrhagia or abnormal vaginal discharge. Chlamydial PID represents the diagnostic challenge, as uterine and adnexal tenderness may be very mild. The clinician should be alert to adnexal masses or fullness as the major signs of chlamydial infection. Women who have HIV infection and PID may present with more clinically severe disease.[8]

These traditional clinical signs and symptoms of PID, however, are neither sensitive nor specific for the syndrome. Laparoscopy confirms salpingitis in 45–89% of women who have clinical PID. Of women who have acute clinical PID, 6–45% have normal fallopian tubes and 5–33% have other conditions, including ectopic pregnancy, appendicitis, hemorrhagic ovarian cysts, endometritis, pelvic adhesions and torsion of an adnexal structure.[6] [9] False-negative clinical diagnoses for PID range from 16% to 47%.[9] The diagnoses prior to laparoscopy in women who have laparoscopically confirmed PID included ectopic pregnancy, ovarian cyst, hemorrhagic ovarian cyst, endometriosis, fibroids, ovarian tumor, appendicitis, pyelonephritis and uncertain diagnosis. The common complications and sequelae of PID include

TABLE 63-1 -- Common etiologic agents of pelvic inflammatory disease.

COMMON ETIOLOGIC AGENTS OF PID	
Aerobic bacteria	*Neisseria gonorrhoeae*
	Chlamydia trachomatis
	Gardnerella vaginalis
	Escherichia coli
	Streptococcus spp.
	Haemophilus influenzae
Anaerobic bacteria	*Bacteroides* spp.
	Peptostreptococcus spp.
	Peptococcus spp.
	Prevotella spp.
	Porphyromonas spp.
Mycoplasmas	*Mycoplasma hominis*
	Mycoplasma genitalium

ectopic pregnancy, tubal infertility, recurrent PID, chronic abdominal pain, tubo-ovarian abscesses and pelvic adhesions. A woman's risk of ectopic pregnancy increases seven- to 10-fold after an episode of PID.

The number of episodes of PID, the woman's age and the severity of tubal inflammation determined at laparoscopy influences the fertility prognosis of PID (Table 63.2). It appears that PID caused by chlamydial infection may result in more infertility than PID caused by gonococcal infection. Recurrent pelvic infections will develop in up to one-third of women who have had PID. Chronic abdominal pain lasting more than 6 months occurs in 15–18% of women after PID. Pyosalpinx, tubo-ovarian abscesses and pelvic adhesions occur in 15–20% of women who have had PID and often require surgical intervention. Mortality from acute PID is rare. The most

common cause of death from PID is a ruptured tubo-ovarian abscess with subsequent peritonitis. The mortality rate from this complication of PID is 6–8%.

DIAGNOSIS

The clinical diagnosis of PID is imprecise. Laparoscopy can be used to obtain a more accurate diagnosis but is neither readily available in most cases nor justifiable in clinically mild disease.

Women who have lower abdominal tenderness, adnexal tenderness and cervical motion tenderness — the Centers for Disease Control minimum criteria — should be treated for PID if there is no other diagnosis that should be considered. [10] One analysis on a large number of women enrolled in a clinical trial showed that lower abdominal tenderness alone was the most sensitive of the physical

TABLE 63-2 -- Prevalence of post-infection tubal dysfunction (tubal factor infertility or ectopic pregnancy) infertility after pelvic inflammatory disease.*

PREVALENCE OF POSTINFECTION TUBAL DYSFUNCTION (TUBAL FACTOR INFERTILITY OR ECTOPIC PREGNANCY) INFERTILITY AFTER PID			
No. PID episodes	**Total patients**	**No. with tubal dysfunction**	**%**	**Relative risk**
0	448	10	2.2	1.0
1	1015	140	13.8	6.3
Mild	320	13	4.1	1.0
Moderate	459	45	9.8	2.4
Severe	236	82	34.7	8.5
<25 years	783	94	12	1.0
25–35 years	232	46	19.8	1.8

>3	69	45	65.2	29.6

** Data from Weström and Eschenbach.[2]*

findings.[11] Additional tests to document an inflammatory and infectious process in the lower genital tract should be used to increase the sensitivity of the clinical signs.

A ratio of more than one white blood cell to epithelial cell on vaginal wet mount or an endocervical Gram stain, obtained after cleaning the ectocervix, showing Gram-negative intracellular diplococci or 30 or more polymorphonuclear leukocytes per 1000× field is highly supportive of the diagnosis of PID in women with appropriate clinical criteria. Tests (culture or antigen) for the detection of *N. gonorrhoeae* and *C. trachomatis* are useful in supporting the diagnosis but not in the decision to start therapy. A pregnancy test should be done. Erythrocyte sedimentation rate, C-reactive protein and complete white blood cell count may also be useful. Pelvic and endovaginal ultrasound can detect findings consistent with severe PID, including tubo-ovarian abscesses, dilated fallopian tubes and cul-de-sac fluid. Ultrasound is less useful in mild or atypical clinical presentations. Computerized tomography (CT) has the same limitations as ultrasound. However, in severe cases of PID with atypical ultrasound findings CT can be useful.[12] For example, spiral CT scanning optimizes identification of small air bubbles that are specific for abscess.[13]

Endometrial biopsy documenting endometrial neutrophils or plasma cells confirms the diagnosis but requires at least 24 hours for processing. Purulent material from the peritoneal cavity obtained by culdocentesis, a painful procedure, may support the diagnosis of PID but may also occur with other intra-abdominal infections, such as appendicitis. Laparoscopy is the gold standard for the diagnosis and staging of acute PID. The minimum criteria for visual confirmation of PID include hyperemia of the tubal surface, edema of the tubal wall and a sticky exudate on the tubal surface and from the fimbriated end when patent.[14]

MANAGEMENT

Management of a patient who has PID includes therapy, education, careful follow-up and partner management. The goal is to cure the patient, prevent recurrences and, ultimately, to preserve fertility. Empiric treatment should be instituted as soon as the diagnosis is suspected. Based on the polymicrobial nature of PID, therapy must provide broad-spectrum coverage. Several antimicrobial regimens have proved to be highly effective in achieving clinical cure of PID but there are few data on the efficacy of recommended or tested regimens on preventing the late sequelae.[15] Studies from the pre-antibiotic era documented infertility rates after PID of 60–70%, indicating that prompt institution of antimicrobial therapy does influence the fertility outcome.[2]

Pelvic inflammatory disease should always be treated with at least two antibiotics for at least 10–14 days (Table 63.3). The combination

TABLE 63-3 -- Recommended treatment of pelvic inflammatory disease.*

RECOMMENDED TREATMENT OF PID		
Oral treatment		
Regimen A		Ofloxacin 400mg po q12h for 14 days
	Plus	Metronidazole 500mg po q12h for 14 days
Regimen B	Either	Ceftriaxone 250mg im, or
		Cefoxitin 2g im plus probenecid 1g po in a single dose concurrently, or
		Other parenteral third-generation cephalosporin (e.g. ceftizoxime or cefotaxime)
	Plus	Doxycycline 100mg po q12h for 14 days
	Plus	Metronidazole 500mg po q12h for 7 days
Parenteral treatment		
Regimen A	Either	Cefotetan 2g iv q12h, or
		Cefoxitin 2g iv q6h
	Plus	Doxycycline 100mg iv or po q12h
This regimen should be continued for 48 hours after substantial clinical improvement. Doxycycline 100mg po q12h should then be administered for a total of 14 days.		
Regimen B		Clindamycin 900mg iv q8h
	Plus	Gentamicin loading dose iv or im (2mg/kg body weight) followed by a maintenance dose of 1.5mg/kg
	Followed by either	Doxycycline 100mg po q12h, or
		Clindamycin 450mg po q6h
This regimen should be continued for 48 hours after substantial clinical improvement. Doxycycline 100mg po q12h or clindamycin 450mg orally q6h should then be administered for a total of 14 days.		

** Data from Centers for Disease Control and Prevention.[10]*

regimen of an extended-spectrum parenteral cephalosporin plus doxycycline provides good coverage for all potential pathogens, including ß-lactamase-producing strains. There are no data on the use of oral cephalosporins for the treatment of PID. An alternative parenteral inpatient regimen is the combination of clindamycin plus an aminoglycoside. Although this combination provides coverage against gonococcal and chlamydial infections, it is inferior to the cephalosporin-doxycycline combination for these pathogens. The combination of ofloxacin and clindamycin or metronidazole also provides excellent coverage.

Many experts recommend that all PID patients should be hospitalized to receive optimal therapy, although this is not always possible. Hospitalization is recommended for women whose tolerance or compliance with outpatient regimens is uncertain, or who have factors that complicate treatment, severe illness or an uncertain diagnosis (Table 63.4).

Supportive therapy includes hydration, bedrest in the semi-Fowler position to localize the infection to the pelvis, pelvic rest and pain relief. Intrauterine devices should be removed. The patient should abstain from sexual intercourse until test-of-cure studies and resolution of signs and symptoms. All sexual partners in the previous 30 days should be evaluated and presumptively treated for gonococcal and chlamydial infection. Explicit and clear patient education cannot be overemphasized in the treatment of PID, especially in the context of outpatient management.

The incidence of ascending infection among pregnant women who have intact membranes is unknown but is believed to be rare.[16] However, given the high-risk of miscarriage and pre-term delivery associated with PID, pregnant women who have PID must be hospitalized and given parenteral antibiotic therapy.[10]

Women who have tubo-ovarian abscesses should be hospitalized and begun on broad-spectrum antibiotics (aminoglycoside plus clindamycin or metronidazole). The vast majority of abscesses with a diameter of 4–6cm respond to antibiotics alone, whereas only 40% of those that are 10cm or larger respond to medical therapy alone.[17] Increasing abscess size or failure to defervesce 72 hours after administration of antibiotics suggests medical failure and requires surgical intervention (e.g. percutaneous or transvaginal drainage under sonographic guidance, laparoscopic drainage or laparotomy). Leaking or ruptured abscesses require immediate laparotomy after stabilization of the patient. Extensive surgery such as complete hysterectomy is rarely indicated except in life-threatening complications such as extensive necrotic myometrium.

POSTPARTUM ENDOMETRITIS AND CESAREAN SECTION

EPIDEMIOLOGY

Postpartum endometritis, an infection of the uterus, is the most common cause of maternal postpartum fever and includes the

TABLE 63-4 -- Recommendations for hospitalizing patients who have pelvic inflammatory disease

RECOMMENDATIONS FOR HOSPITALIZING PATIENTS WHO HAVE PID	
Uncertain tolerance or compliance with outpatient regimen	Adolescents
	Substance abusers
	Nausea and vomiting
	Follow-up at 72 hours after starting antibiotic treatment is problematic
Complicating factors	Pregnancy
	HIV infection or other immunosuppressive condition
	Intrauterine device use
	Suspected pelvic or tubo-ovarian abscess
	Recent history of intrauterine instrumentation
Severe illness	Temperature over 101°F (38.3°C)
	White blood cell count greater than 15,000/ml
	Peritoneal signs
	Septic
Uncertain diagnosis	Failure to respond clinically to outpatient treatment
	Inability to exclude surgical emergencies (ectopic pregnancy, appendicitis)

inflammatory conditions of endometritis, endomyometritis and endoparametritis. It can be categorized into early infection (i.e. onset within 48 hours of delivery) and late infection (i.e. onset 2 days to 2 weeks after delivery). The most significant risk factor for postpartum endometritis is cesarean section. The incidence of postpartum endometritis after vaginal delivery is 2–5% whereas the rate after cesarean section ranges from 20% to 55%.[18] Postpartum upper tract infections following vaginal delivery are about 10 times more common in developing countries than in developed countries as a result of unclean delivery practice, traditional birth practices and the high prevalence of STDs in some populations. [19]

PATHOGENESIS AND PATHOLOGY

Early postpartum endometritis usually is associated with nonelective cesarean section and is probably the result of direct uterine contamination by organisms in the amniotic cavity. This is in direct contrast to women who develop late postpartum endometritis, who usually deliver vaginally. The timing of these late infections suggests an ascending infection similar to the mechanisms for PID. Wound infections after cesarean section appear to be a result of a direct contamination of the wound by organisms in the endometrium at the time of surgery.

Postpartum endometritis is a mixed aerobic-anaerobic infection (Table 63.5). *Ureaplasma urealyticum* and *Mycoplasma hominis* have also been isolated from the endometrium and blood but their clinical significance is not clear. *Chlamydia trachomatis* is associated with the late form of postpartum endometritis.[20] Group A ß-hemolytic streptococcal endometritis is rare and clustered cases are probably related to a common source, often a care-giver. Herpes simplex endometritis has also been reported.[21] Bacteremia occurs in 10–20% of patients and most common blood isolates are group B streptococci, *Gardnerella vaginalis* and *Peptostreptococcus* spp.[22]

PREVENTION

The timely diagnosis and treatment of lower tract syndromes during pregnancy, especially bacterial vaginosis, would prevent some postpartum endometritis. Prophylactic antibiotic use for patients requiring a nonelective cesarean section after labor or rupture of membranes of any duration greatly reduces the incidence of post-cesarean endometritis.[18] [23]

TABLE 63-5 -- Common endogenous micro-organisms identified as potential etiologic agents in postoperative pelvic infections

COMMON ENDOGENOUS MICRO-ORGANISMS IDENTIFIED AS POTENTIAL ETIOLOGIC AGENTS IN POSTOPERATIVE PELVIC INFECTIONS	
Aerobic bacteria	*Streptococcus* spp.
	Enterococcus faecalis
	Staphylococcus aureus
	Staphylococcus epidemidis
	Escherichia coli
	Klebsiella pneumoniae
	Gardnerella vaginalis
Anaerobic bacteria	*Bacteroides* spp.
	Peptostreptococcus spp.
	Prevotella bivia
	Prevotella disiens
	Fusobacterium spp.
Mycoplasmas	*Mycoplasma hominis*
	Ureaplasma urealyticum

CLINICAL FEATURES

Risk factors for postpartum endometritis include duration of labor, length of time membranes remain ruptured, presence of STDs, presence of bacterial vaginosis, the number of vaginal examinations, the use of internal fetal monitoring and socioeconomic status.[22] [24] [25]

Postpartum endometritis should be suspected in any woman who develops significant fever (oral temperature 101.3°F (38.5°C) or higher in the first 24 hours after delivery or 100.4°F (38°C) or higher for at least 4 consecutive hours, 24 hours or more after delivery). The diagnosis of postpartum endometritis can be made on the basis of clinical features of fever and when signs on physical examination suggest an endometrial inflammatory process including abdominal pain, uterine tenderness, foul lochia, increased uterine bleeding and uterine subinvolution. Late-onset endometritis tends to have a mild, subacute clinical presentation.

Acute complications of postpartum endometritis include pelvic abscess and puerperal ovarian vein thrombophlebitis. Puerperal ovarian vein thrombophlebitis is an acute thrombosis of one or both ovarian veins postpartum, is usually associated with postpartum endometritis with an onset of 2–4 days after delivery, and can be associated with septic pulmonary emboli. The reported incidence is 1 in 2000 deliveries.[26] Chronic complications and sequelae result from postinfectious scarring.

DIAGNOSIS

Blood cultures should be obtained from all patients before starting therapy. Tests for the detection of cervical infection with *N. gonorrhoeae* and *C. trachomatis* should be obtained from all women at risk of STDs (in women failing initial therapy). Quantitative endometrial cultures obtained using a triple lumen catheter, which minimizes contamination, provides useful information. A complete white blood cell count should be done. If an adnexal mass is felt on examination, then ultrasound or CT can be used to confirm the diagnosis.

MANAGEMENT

Postpartum endometritis is commonly treated parenterally with a broad-spectrum antibiotic regimen with activity against *Bacteroides fragilis* and other penicillin-resistant anaerobic bacteria, including the second generation cephalosporins (cefoxitin or cefotetan) or the extended-spectrum penicillins (ticarcillin-clavulanate or sulbactam-ampicillin).[25] The combination of aminoglycoside plus clindamycin remains an appropriate regimen. [26] Once-daily administration of aminoglycosides appears to be effective and safe in the treatment of endometritis. Women should continue to receive parenteral therapy until fever has resolved, uterine tenderness and abdominal pain are gone, and white blood cell count has normalized. Subsequent oral antibiotic therapy with erythromycin or doxycycline need only be given to women who have documented chlamydial infection for a total of 10–14 days. Reasons for failure to respond to antimicrobial therapy include inappropriate antibiotics (enterococcal infection or resistant anaerobic infection), pelvic or wound abscess, or ovarian vein thrombophlebitis. When postpartum septic pelvic thrombophlebitis is suspected heparin should be given.[27] Late postpartum endometritis can be managed in the same way as PID (see Table 63.3).

EPISIOTOMY INFECTIONS

EPIDEMIOLOGY

Episiotomy infections are rare. The rate of infection of episiotomies is 0.1% overall but increases to 1–2% of episiotomies complicated

by third- or fourth-degree extensions. Episiotomy infections, however, can have severe and even fatal consequences.

PATHOGENESIS AND PATHOLOGY

Episiotomy infections have been classified into four categories based on the depth of infection in the soft tissue: simple infection, superficial fascial infection, superficial fascial necrosis and myonecrosis.[28]

Bacteria implicated in episiotomy infections include skin pathogens, streptococci and staphylococci, and bacteria associated with vaginal flora, Enterobacteriaceae and anaerobic bacteria, including *B. fragilis. Clostridium perfringens* and *C. sordellii* are likely if myonecrosis is present.

PREVENTION

Treatment standards should be introduced that reduce the liberal or routine use of episiotomies, as they appear to increase the risk of third- and fourth-degree tears. In the USA between 1980 and 1998 there was an overall decline of 39% in the use of episiotomy.[29]

CLINICAL FEATURES

The simple wound infection is a local infection limited to incision site in the skin and the superficial fascia. Clinically there is edema and erythema only along the incision. A superficial fascial infection involves two layers of the superficial fascia and resembles a cellulitis with erythema, edema and pain. This superficial infection is indistinguishable on the basis of skin appearance from an early superficial fascial infection with necrosis (necrotizing fasciitis). Necrotizing fasciitis involves all layers of the superficial fascia (and may involve the deep fascia). Skin anesthesia may precede the skin breakdown, because of nerve involvement. As nutrient vessels are occluded the skin may turn dusky and develop bullae and then frank necrosis. Subcutaneous gas may be present with the mixed infection. These patients often have evidence of marked toxicity out of proportion to the clinical findings. In myonecrosis, pain is often the dominant feature. Patients are extremely toxic, restless and confused or disoriented.

DIAGNOSIS

Prompt diagnosis is of paramount importance because necrotizing fasciitis and myonecrosis are rapidly progressive. Frozen section examination of full-depth biopsy specimens has been helpful in the diagnosis of necrotizing faciitis. [30] However, surgical exploration is warranted if necrotizing fasciitis or myonecrosis is suspected.

MANAGEMENT

Management of a simple episiotomy wound infection includes opening of the incision and exploration to ensure that there is no accumulated blood or a rectovaginal opening. Any superficial fascial infection should be managed with broad-spectrum antibiotic coverage (e.g. ampicillin/gentamicin/metronidazole or ampicillin/gentamicin/clindamycin) and observed closely. Surgical exploration should be undertaken if:

- erythema and edema extend beyond the incision site;
- there is no improvement in 24–48 hours after the start of antibiotics or if the patient deteriorates; or
- the patient has severe systemic manifestations.

In the case of necrotizing fasciitis the superficial fascia will separate easily from the deep fascia with a probe or finger (this does not occur in healthy tissue), the incisions will be bloodless and the exudate will be serosanguineous rather than purulent. Surgical debridement of all necrotic and pale tissue should be performed promptly and broad-spectrum antibiotic therapy should be instituted. The wound should be left open after debridement. A second-look procedure is often necessary after 24 hours.

Myonecrosis is an extremely rare event that is usually caused by *C. perfringens* or *C. sordellii* but may result from an extension of necrotizing fasciitis through the deep fascia to the muscle. Therapy includes high-dose penicillin and urgent surgical debridement. Hyperbaric oxygen therapy remains controversial and should be considered only as an adjunctive therapy.

POSTABORTION SEPSIS

EPIDEMIOLOGY

Postabortion sepsis is an ascending infection of the female pelvis after spontaneous or induced abortion. Inflammatory conditions associated with infectious complications of abortion are similar to those for PID but can be complicated by retained, poorly perfused tissue and uterine or bowel trauma. The mortality from abortion in developed countries is low (an estimated 0.6 per 100,000 cases), and abortion accounts for only 5% of all maternal mortality in the USA. Infection is the major cause when mortality does result from abortion complications. In a review of 107 deaths caused by abortion in the USA between 1975 and 1977, 33% were caused by sepsis.[31] In developing countries the World Health Organization estimates that illegal abortion accounts for 25–50% of the 500,000 maternal deaths that occur each year.

PATHOGENESIS AND PATHOLOGY

The bacteria associated with postabortion sepsis are similar to those associated with PID. However, the potential of direct uterine or bowel injury and retention of the products of conception after an abortion may result in injured and poorly vascularized tissue and an enlarged spectrum of enteric organisms, including *C. perfringens*. In developing countries, tetanus is a cause of mortality after abortion.

PREVENTION

Prevention measures include providing effective and acceptable contraception and appropriate medical management of abortion. Prophylaxis for cervical and vaginal infections before voluntary termination of pregnancy has been suggested as a preventive measure but there are few data to support this practice. Prompt diagnosis and effective treatment of endometritis after the procedure is extremely important as delayed treatment is a common feature in cases of death from septic abortion.

CLINICAL FEATURES

The diagnosis of septic abortion should be considered in any woman who has a temperature of 100.4°F (38°C) or higher on two occasions more than 24 hours after an abortion and in any woman of reproductive age who presents with fever, abdominal pain and bleeding. Additionally, details of the procedure, including microbiologic studies and pathology of the aborted tissues, should be obtained. Physical examination findings typically include uterine tenderness, foul or purulent cervical discharge and products of conception at the cervical os. In more severe infections the patient may be hypotensive or in shock. The presence of cervical or vaginal lacerations should be assessed. Women who have clostridial infection may have severe disseminated intravascular hemolysis.

Acute complications are seen in advanced stages of the disease process and include the respiratory distress syndrome, septic shock, renal failure, abscess formation, septic pelvic vein thrombophlebitis and septic emboli, and disseminated intravascular coagulopathy; death may also occur. The chronic complications are similar to those of PID and include infertility, chronic pelvic pain and ectopic pregnancy.

DIAGNOSIS

Except for women who have mild, early, uncomplicated postabortion endometritis, all women should have blood and cervical cultures as well as a complete white blood cell count and urinalysis. Upright and flat abdominal and pelvic radiographs should be done to assess the presence of air in the abdominal cavity, dilated bowel and gas in the uterus. Pelvic ultrasound can determine the presence of retained tissue and other fluid collections, and the disruption of the myometrium by fluid or gas. Computerized tomography is useful in assessing the entire abdomen. Laparoscopy can be used to examine the uterus for perforation but is suboptimal for a detailed examination of the bowel.[32]

MANAGEMENT

Any woman who has an incomplete or failed abortion or retained clotted or liquid blood (hematometra) should undergo immediate re-evacuation.[33] This tissue serves as a nidus for infection. The recommended treatment of PID (see Table 63.3) is appropriate for a woman who has early, uncomplicated postabortion infection limited to the endometrial cavity. The patient should be evaluated 48 hours after institution of therapy. If fever or pain persist then the patient should be hospitalized and evaluated as above.

Women who have more severe illness should be hospitalized and begun on broad-spectrum antibiotics such as ampicillin, gentamicin and clindamycin. If clostridial infection is suspected, high-dose penicillin therapy should be used. These patients should be monitored closely and aggressively evaluated for uterine perforation and bowel injury. Laparotomy with possible hysterectomy should be performed if there is failure to respond to uterine evacuation and medical therapy, uterine perforation with necrotic myometrium or suspected bowel injury, pelvic and adnexal abscesses, or clostridial myometritis. Indications for a total hysterectomy with removal of adnexae include a discolored, woody appearance of the uterus and adnexae, clostridial sepsis, pelvic tissue crepitation and gas in the uterine wall on radiographs.

POSTOPERATIVE GYNECOLOGIC INFECTIONS

EPIDEMIOLOGY

Hysterectomy is the most frequently performed elective surgical procedure among women of reproductive age in the USA.[34] The spectrum of postoperative infections after hysterectomy include vaginal cuff cellulitis, pelvic cellulitis, vaginal cuff abscess, phlegmon, pelvic abscess and wound infections.[23] Rates of infection after abdominal hysterectomy without antibiotic prophylaxis ranged from 11% to 38% and from 4% to 8% with antibiotic prophylaxis. For vaginal hysterectomies without antibiotic prophylaxis infection rates varied between 12% and 64% and with prophylaxis between 0% and 10%.[35] Risk factors for postoperative infection include duration of surgery, younger age, lower socioeconomic status and the presence of bacterial vaginosis.

PATHOGENESIS AND PATHOLOGY

Bacterial contamination of the operative site with flora of the lower reproductive tract occurs at the vaginal incision. The exposure in a vaginal hysterectomy occurs from the initial vaginal incision throughout the procedure and the exposure in an abdominal hysterectomy occurs near the end of the procedure. Hospitalization itself, regardless of whether antimicrobial prophylaxis is given, changes the vaginal flora, resulting in an increase in colony counts of *Escherichia coli*, *Enterococcus faecalis* and *Bacteroides* spp. and a decline in *Staphylococcus epidermidis* and *Streptococcus* and *Peptostreptococcus* spp.

Postoperative infections involve a mix of aerobic and anaerobic bacteria from the lower reproductive tract (see Table 63.5). *Bacteroides fragilis* and *Fusobacterium* spp. are more common in infections than when they are found in normal vaginal flora.

PREVENTION

Patients undergoing elective hysterectomy should be screened and, if necessary, treated for bacterial vaginosis several weeks before surgery. Preoperative single-dose antibiotic prophylaxis substantially reduces the rate of postoperative febrile morbidity in these procedures.[23] [35]

CLINICAL FEATURES

Postoperative fever itself does not indicate infection but should prompt the clinician to evaluate the patient for one. In pelvic cellulitis symptoms usually occur 2–3 days after surgery and include fever (temperature over 100.4°F (38°C)) and complaints of increasing abdominal and pelvic pain that may not be symmetric.[36] Parametrial tenderness without palpable mass is found on bimanual examination. Histologic vaginal cuff cellulitis will develop in all women postoperatively as part of the normal healing process and most cases resolve without antibiotic therapy. Women who have more severe cellulitis will complain of increasing central or lower abdominal pain, increasing vaginal discharge or low grade fever, usually within the first 2 weeks postoperatively. Bimanual pelvic examination may show only mild suprapubic tenderness to deep palpation without masses. Speculum examination will show a tender, indurated, hyperemic vaginal surgical margin. In a vaginal cuff abscess patients typically have fever 2–3 days postoperatively and may report vaginal fullness. On examination a tender, palpable collection will be found above the vaginal surgical margin. A phlegmon would be diagnosed if a tender mass were felt in one or both parametrial areas and if no abscess could be identified on radiographic studies. Pelvic abscesses are a late postoperative complication that present many weeks after surgery and most have a palpable mass in the pelvis. Wound infections are characterized by pain, marginal cellulitis and purulent exudate.

Septic pelvic vein thrombophlebitis and osteomyelitis pubis are both rare complications of gynecologic surgery.

DIAGNOSIS

Microbiologic cultures obtained from drained abscesses are useful in guiding therapy. Cultures of the vaginal cuff are likely to be contaminated with vaginal flora. Abdominal and pelvic ultrasound and CT scans are useful to confirm the presence of a fluid collection when pelvic abscesses are suspected.

MANAGEMENT

Patients who have pelvic cellulitis should be treated with a broad-spectrum parenteral antibiotic regimen, such as a second-generation cephalosporin (cefoxitin or cefotetan), extended-spectrum penicillin (ticarcillin-clavulanate or sulbactam-ampicillin), or an aminoglycoside plus clindamycin, for 24–36 hours after the patient becomes

afebrile. Cuff abscesses should be managed similarly and the abscess should be drained. Vaginal cuff cellulitis can be managed on an outpatient basis with oral antibiotics such as amoxicillin-clavulanic acid, but patients should have a follow-up evaluation 72 hours after starting therapy. Medical therapy that covers Gram-negative aerobes and Gram-negative anaerobes (aminoglycoside-clindamycin or aminoglycoside-metronidazole) is often successful in treating postoperative pelvic abscesses that are inaccessible to drainage. Patients who fail to respond to medical therapy alone (no defervescence in 72 hours or enlarging abscess) will require laparotomy and drainage, or excision. Abscesses accessible from a cutaneous surface should be drained. Patients should be treated with parenteral antibiotics until all signs and symptoms have resolved. Some clinicians give post-discharge outpatient treatment with metronidazole and amoxicillin for a week after discharge in those patients who responded to medical management. All patients who have pelvic abscesses should be re-evaluated 2 weeks after discharge to ensure no recurrence of the abscess has occurred.

Chapter 64 - Complications of Pregnancy: Maternal Perspectives

Marleen Temmerman

EPIDEMIOLOGY

Medical progress, such as effective antibiotics and vaccines, in combination with improved living conditions has modified the sequelae of infections, yet infectious morbidity in pregnancy remains a serious problem.

Any acute or chronic infection may occur before conception, during pregnancy or during the puerperium and may have serious consequences for the mother, the fetus and the neonate. Some micro-organisms are known to cause congenital infections and are discussed in Chapter 65 . Others primarily influence the health of pregnant women and are described below.

The problem of maternal infections during pregnancy is addressed with emphasis on organ systems, including genitourinary tract infections, respiratory tract infections, gastrointestinal infections, puerperal sepsis, wound infection, mastitis, thrombophlebitis, endocarditis and meningitis. The infectious etiology of pre-term birth, premature pre-term rupture of membranes (pPROM) and chorioamnionitis deserves special attention. In addition, the implications of specific infections, including malaria, listeriosis, Lyme disease, varicella-zoster, HIV and other sexually transmitted diseases (STDs), are summarized in Table 64.1 and Table 64.2 .

The topic of infections in pregnancy is too wide to summarize in a single chapter. The interested reader will find excellent reviews by Sweet and Gibbs, Ledger, Hurley and Lamont.[1] [2] [3] [4]

Incidence and prevalence

Genital micro-organisms, particularly sexually transmitted organisms, are important in poor pregnancy outcome, including pre-term birth, pPROM, spontaneous abortion, perinatal morbidity and mortality, and maternal infections.[5] [6] [7] [8] [9] [10] [11] [12] Recent publications confirm the role of *Neisseria gonorrhoeae* in low birth-weight and in spontaneous abortion, of bacterial vaginosis in pre-term birth, and of genital mycoplasmas in pPROM and in postpartum febrile infections in women and neonates. Bacterial vaginosis has received renewed attention because of its role in pre-term delivery and because it is possibly prone to interventions. The prevalence of bacterial vaginosis varies between 15% and 25%. Group B streptococci (GBS), which are known to be a risk factor for neonatal infections and pre-term birth, also contribute to spontaneous abortion. The reported rates of GBS colonization in the genital tract range from 5% to 40%, with an average transmission rate to the neonate of 60%. The rates of early-onset GBS infection in the neonate, especially in pre-term and low-birth-weight babies, can be as high as 3 in 1000.

Prevalence rates of HIV in pregnant women are increasing all over the world but have reached endemic proportions in developing countries, where over 25% of pregnant women in some urban areas are HIV-seropositive. The impact of maternal HIV infection on pregnancy outcome is still debated but most data from large studies of pregnant women who do not use drugs show an increased risk of adverse obstetric outcome, including abortion, prematurity, low birth-weight and stillbirth, with perinatal HIV transmission rates of 15–40%.

Urinary tract infections (UTIs) are the most common infections in pregnancy, with or without clinical signs or symptoms. Asymptomatic bacteriuria is found in 4–7% of pregnant women, of whom 25–30% will develop pyelonephritis later in pregnancy.

Upper respiratory tract infections are common but of limited consequence for mother and child. In contrast, pneumonia is a serious illness for a pregnant woman.

Gastrointestinal infections caused by viruses are usually mild with no harm to the pregnancy and no need for specific medication. Meningitis is rare except for areas in which HIV and cryptococcal meningitis are endemic. Bacterial endocarditis is also uncommon and incidence rates vary from 1 in 4000 to 1 in 16,000 deliveries.

Febrile illness at delivery is uncommon in uncomplicated term pregnancies. Common underlying causes are chorioamnionitis, pyelonephritis, influenza and listeriosis.

The overall incidence of postpartum infections varies between 1% and 10%, depending on the definitions used, particularly for mastitis and postpartum endometritis. Postpartum infections consist of genital tract infections, puerperal mastitis, pelvic thrombophlebitis, UTIs, wound infections, complications of anesthesia and other infectious complications.

Genital tract infections of the uterus are the most common cause of puerperal infection and are categorized as endometritis, endomyometritis or endoparametritis depending on the extent of the infection. Wound and episiotomy infections occur frequently. After cesarean section wound infection defined as erythema, positive discharge and/or positive wound cultures varies between 5% and 10%, with emergency cases at higher risk of infection.

Septic thrombophlebitis is a rare complication of pregnancy with reported incidence rates of 1 in 2000 deliveries. The incidence of puerperal mastitis is estimated at around 1% in lactating women. Most have a mild disease.

Burden of disease, morbidity and mortality

In the general population the attributable risk of infections for adverse pregnancy outcome depends on the prevalence rates of infections in the population as well as on the socioeconomic and cultural factors that influence health, health behavior and health-seeking behavior. All infections that manifest with fever increase the risk of pre-term birth because of the release of pyrogens that increase myometrial activity.

Intra-amniotic infection diagnosed on clinical criteria occurs in 1–5% of pregnancies, with or without ruptured membranes. Consequences are pre-term birth, pPROM and postpartum and neonatal infections. The mother and the fetus are put at risk with pPROM, as it is associated with pre-term birth and frequent infectious morbidity. Ascending infections, either the cause or the result of pPROM, may lead to intra-amniotic infection, chorio-amnionitis, placentitis and fetal infections, including pneumonia and bacteremia.

The impact of asymptomatic UTI on pregnancy complications such as hypertension, anemia and poor obstetric outcome remains

TABLE 64-1 -- Implications of specific infections on pregnancy.

IMPLICATIONS OF SPECIFIC INFECTIONS ON PREGNANCY			
	Impact on mother and child	**Prevention**	**Management**

Malaria	More frequent, more severe in pregnancy, especially in nonimmune women; increased risk of hypoglycemia in the mother	Chemoprophylaxis in travelers to endemic areas	Prompt treatment with chloroquine or quinine according to resistance patterns
		If no *Plasmodium falciparum* resistance, chloroquine phosphate 500mg/week po	
	LBW, IUGR, pre-term birth, abortion and stillbirth increased	In case of resistance proguanil 200mg/day + chloroquine 500mg/week po	Similar treatment regimens to those in nonpregnant women
	Congenital malaria (fever, hepatosplenomegaly, jaundice, anemia)	Avoid exposure	
Listeriosis	Mild maternal infection, but increased susceptibility	Early diagnosis in any febrile illness in pregnancy, cervical and blood cultures for *Listeria monocytogenes*	Ampicillin 2g q6h iv + gentamicin 2mg/kg q8h for 1 week
	Serious impact on the fetus: amnionitis, pre-term birth, septic abortion, stillbirth, fatality rate 3–50%	Avoid implicated foods (e.g. unpasteurized cheese)	
Lyme disease	Erythema migrans in the mother, risk of transmission unknown, probably low	Protective clothes in tick-infected areas (rural forest); remove ticks	Early treatment with amoxicillin 500mg q6h po for 10–30 days or ceftriaxone 2g iv for 14 days
	Pre-term birth, stillbirth, syndactyle, cortical blindness, rash		
Varicella-zoster	Rare in adults, fever, malaise followed by rash, 20% risk of varicella pneumonia	IgG testing if exposed	In cases of pneumonia: admission, respiratory support, aciclovir 10–15mg/kg for 7 days
	Risk of abortion, stillbirth	If no IgG: varicella-zoster immunoglobulin 125 units/10kg, max 625 units im, <96h after exposure	Ultrasound assessment of the fetus
	Congenital varicella (limb hypoplasia, cortical atrophy, retardation, IUGR, cutaneous scars, microphthalmia)		
Measles	Increased maternal mortality secondary to pneumonia	Passive immunization in susceptible exposed women with pooled immunoglobulins 0.25ml/kg within 6 days of exposure	Symptomatic
	Risk of prematurity		
	Developmental abnormalities (e.g. congenital heart disease, cleft lip, cerebral leukodystrophy and cyclopia have been reported)	Avoid measles vaccine in pregnancy	
Group B streptococci	Sepsis in 1–3/1000 neonates, high mortality rates	No consensus	Penicillin G 5 million units iv followed by 2.5 million units q4h until delivery or ampicillin 2g followed by 1g q4h until delivery
		Antenatal case detection and treatment, or intrapartum treatment of women at risk?	

LBW, low birth weight; IUGR, intrauterine growth retardation

TABLE 64-2 -- Implications of some sexually transmitted diseases on pregnancy.

IMPLICATIONS OF SOME STDs ON PREGNANCY			
	Impact on mother and child	**Prevention**	**Management**
Neisseria gonorrhoeae	Ophthalmia nenatorum, pre-term delivery, puerperal infections	Silver nitrate 1% or tetracycline eye ointment	Spectinomycin 2g im, ceftriaxone 250mg im, or standard antimicrobial treatment
Chlamydia trachomatis	Ophthalmia neonatorum, puerperal infections, pre-term delivery	Tetracycline eye ointment	Erythromycin 500mg for 4–7 days
Bacterial vaginosis	Risk of pre-term birth	Case detection and treatment is still under study	Metronidazole 250mg q8h for 3–7 days or erythromycin base 333mg q8h for 3–14 days
Trichomonas vaginalis	Risk of pre-term birth	Case detection and treatment no proven effect	Metronidazole 2g single dose
Condylomata acuminatum	Risk of respiratory papillomatoses 1/80–1/1500	Case detection and treatment	Topical trichloroacetic acid (85%)/surgery
Herpes simplex	Neonatal herpes 50% in mother with primary herpes at delivery	History from pregnant woman, careful inspection of the genital tract on the day of delivery	In case of active lesions, cesarean section or vaginal delivery under aciclovir 200–400mg q8h (under study)
HIV	Transmission in 25–45%	Antiretroviral therapy according to the most recent guidelines	Avoid long labor, rupture of membranes <4h
	Risk of abortion, pre-term delivery, puerperal infections	Elective Cesarean section	Treat with antiretroviral therapy according to the most recent guidelines
		No breast-feeding	

controversial. In contrast, ascending UTIs clearly play a role in the etiology of pre-term delivery and neonatal death.

Lower respiratory tract infections, meningitis and bacterial endocarditis are all life-threatening conditions for the mother and should be treated without delay.

Although postpartum infections are seldom life-threatening, sepsis remains an important cause of maternal death worldwide. Maternal mortality rates of 1–5 per 100,000 live births are registered in the Western world, whereas 100–600 per 100,000 pregnant or childbearing women in developing countries die as a consequence of reproduction. In addition, for every woman who dies in childbirth another 30 women suffer from injuries, infections and disabilities. Overall, 25% of maternal mortality is considered to be caused by infections and this number can be lowered substantially by better health services and prompt treatment.

A number of reports estimating the role of infections in maternal death are summarized in Table 64.3 . Few etiologic studies have been carried out in developing countries but the role of infections is likely to be more important. My own personal observations from Nairobi, Kenya indicate that infections play a role in up to 40% of mothers dying in childbirth. The silent tragedy of maternal death should receive more attention from the international community, and also from the research world, because a substantial proportion of maternal deaths as a result of infections, bleeding and eclampsia are avoidable and interventions have to be tested to lower this unacceptable consequence of giving birth.

Postpartum genital infections may lead to chronic pain and discomfort, bleeding irregularities and infertility caused by ascending infections. Wound infections may increase pain and discomfort and prolong hospital stay. Pelvic vein thrombophlebitis may lead to serious complications such as septic pulmonary emboli.

Risk factors

Poverty is the most important risk factor for maternal infections during pregnancy. Poor women are more susceptible to malnutrition, infections, including STDs, less

adequate sanitary conditions and lower access to preventive and curative health care than those who are financially better off.

Risk factors for UTI in pregnancy include sexual activity, older age, history of UTIs, lower socioeconomic status, diabetes mellitus, sickle-cell disease and specific bacterial factors such as the serotype and the virulence determinants of the micro-organisms.

Risk factors for lower respiratory disease include low socioeconomic status and HIV infection, particularly for infections with *Streptococcus pneumoniae*. Bacterial endocarditis has been reported more often in urban settings and among drug users.

Risk factors for puerperal genital infections include socioeconomic variables, anemia, STD, obstetric factors such as length of rupture of membranes, pre-term delivery, Cesarean section and number of vaginal examinations. Puerperal fever caused by group A ß-hemolytic streptococci, once one of the most striking examples of iatrogenic

TABLE 64-3 -- Cases of maternal death from infections.[*]

CASES OF MATERNAL DEATH FROM INFECTIONS		
	Date of study	**%**
Michigan	1950–1971	23
Iowa	1926–1980	56
	1950–1980	16
South Carolina	1970–1984	14
Oklahoma	1950–1979	7

* *Data from Sweet and Gibbs.*[1]

infections in the 19th century, is a rare event in modern obstetrics, although sporadic outbreaks have been reported. A toxic-shock-like syndrome can occur caused by the release of pyrogenic exotoxins from streptococcal isolates (see Chapter 56).

Factors known to increase the risk for wound infections are age, obesity, bacterial contamination, operating time and duration of preoperative hospitalization, emergency procedures, number of vaginal examinations, duration of internal fetal monitoring, length of labor and underlying maternal disease. Puerperal mastitis can be related to poor nursing techniques and lack of strict hygiene measures.

PATHOGENESIS AND PATHOLOGY

Pathogenesis

The pathogenesis of most infections is similar in pregnant and nonpregnant women except for possible alterations in the immune system as noted below. Of specific interest is the role of infectious agents in the onset of labor or, more importantly, of pre-term labor. Although the exact mechanism of the onset of labor is still part of the human parturition puzzle, there is convincing evidence for the role of prostaglandins in the initiation of parturition. Arachidonic acid, one of the precursors of prostaglandins, is made available for prostaglandin synthesis by the enzyme phospholipase A_2 . This enzyme, produced by many micro-organisms but especially by anaerobes, might be one of the mechanisms of pre-term initiation of labor. Micro-organisms can stimulate the release of cytokines, such as interleukins and tumor necrosis factor, that stimulate prostaglandin precursors, thus leading to uterine contractions.

In theory, the amniotic cavity is sterile, protected by the placental membranes, with the cervical mucus serving as an effective barrier preventing micro-organisms from entering the uterine cavity. With the onset of labor and the rupture of membranes, bacteria may ascend and result in an amniotic infection. Pathogens may also gain access to the amniotic cavity through intact membranes or after invasive procedures such as amniocentesis, chorion villus sampling, umbilical blood sampling and cervical cerclage.

Urinary tract infections are caused by organisms that are part of the normal fecal flora, with *Escherichia coli* responsible for 80–90% of infections. Others are facultative Gram-negative bacteria, including *Klebsiella*, *Proteus*, *Enterobacter* and *Pseudomonas* spp., and Grampositive bacteria such as staphylococci and GBS. Symptomatic UTIs are more frequent in pregnancy for several reasons, including decreased ureteric muscle tone and activity, dilatation of the ureter and renal pelvis because of the progesterone effect, and mechanical obstruction caused by an enlarging uterus, changes of the bladder and alterations in the properties of urine during pregnancy. Bacteriuria is of concern because of the increased risk of pyelonephritis associated with pre-term labor caused by pyrogens, ureteric contractions leading to reflex myometrial contractions, the release of bacterial enzymes that may weaken the membranes and bacterial products that stimulate prostaglandin synthesis.

The most common organisms causing pneumonia in pregnant women are *S. pneumoniae*, *Haemophilus influenzae*, group A ß-hemolytic streptococci and coagulase-positive streptococci.

Postpartum endometritis seems to be a mixed infection with aerobic and anaerobic bacteria from the genital tract. Sexually transmitted diseases, including *Chlamydia trachomatis* and *N. gonorrhoeae*, are important risk factors for ascending infections. Cesarean section is the single most important predisposing factor for pelvic infection. Wound infections are determined by the surgical techniques used, the amount of bacterial contamination and the resistance of the patient. An adequate blood supply is necessary to avoid acidosis in the wound. Organisms involved are *Streptococcus faecalis*, *E. coli*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Proteus* spp.

and anaerobes. Predisposing factors for septic pelvic thrombophlebitis include changes in coagulation factors, alterations in the vein wall and stasis of blood flow.

In most cases of mastitis, *S. aureus* is the responsible organism, although *S. epidermidis* and viridans streptococci may also be isolated. Sporadic mastitis, usually the result of poor nursing technique, manifests as a cellulitis of the breast, primarily involving the interlobular connective tissue, to which the pathogens gain entry via a cracked or fissured nipple. In epidemic mastitis, however, infection occurs via the ductal system and spreads throughout the entire breast, resulting in mammary adenitis.

Immunity

The normal course of pregnancy is associated with a variety of changes in humoral and cellular immunity, such as a loss in $CD4^+$ cells and other alterations in T-cell subsets.[13] [14] [15] [16] Reports on T-cell subsets during pregnancy have been conflicting. Some studies have found a progressive fall in the $CD4^+$ count throughout pregnancy, from a mean of 950 cells/ml before 18 weeks to 720 cells/ml at term. Others have either reported a U-shaped $CD4^+$ cell count profile during pregnancy, with a minimum at approximately 32 weeks of gestation (CD4 of 30% and a $CD4^+$ count of 876 cells/ml), or have found stable CD4 levels and CD4:CD8 ratios during pregnancy with a rise (rebound) afterwards. Such differences may be attributable to different methodology (manual fluorescence microscopy versus automated flow cytometry), to differences in study populations or to the fact that blood was taken at different times during pregnancy. The altered immune status of pregnant women may also alter the response of the host to infectious agents.

Despite conflicting laboratory data, most studies agree that the humoral immune response in pregnancy is similar to that in nonpregnant women but that the cellular immune response is diminished. Mortality rates of, for example, pneumococcal pneumonia, malaria or influenza have been found to be higher in pregnant than in nonpregnant women.

PREVENTION

Elimination of poverty and improvement of antenatal and obstetrical care in deprived groups of society are primary strategies to prevent adverse pregnancy outcome.

The challenge of identifying women at risk of adverse obstetric outcome is still a subject of intensive research. Early markers of infection-related preterm birth are needed to identify a subset of women at risk for preterm delivery who could benefit from antimicrobial therapy. The finding of mucopurulent cervicitis defined by more than 30 polymorphonuclear cells per high-power field has been identified as a predictor of poor pregnancy outcome.[17] Elevated reproductive tract phospholipase A_2 concentrations were detected in pregnant women colonized with bacterial vaginosis, *Trichomonas vaginalis* or *C. trachomatis*.[18] Phospholipase A_2 is an enzyme that leads to prostaglandin synthesis and is important in the physiology of human parturition. Cervicovaginal interleukin-6 and elevated fetal fibronectin concentrations have been associated with preterm birth but their predictive value remains to be determined.[19]

Case detection and treatment of genitourinary infections is recommended in pregnant women who note an abnormal discharge. Screening for genitourinary pathogens with a potential negative impact on pregnancy outcome such as bacterial vaginosis, trichomoniasis, GBS, gonorrhea, Chlamydia and others, depends on the prevalence of infectious agents in the population, the expected outcome of the intervention, and the available resources. Recent intervention studies have provided convincing evidence of the benefit of identifying and treating bacterial vaginosis in pregnancy in women at high risk for pre-term birth.[8] [9] However, the practice of routine screening for bacterial vaginosis in asymptomatic women at low risk for pre-term delivery cannot be justified by current evidence from the literature.

Screening for GBS in pregnant women is still a subject of debate. Between 10% and 30% of pregnant women are colonized with GBS, an important source of perinatal morbidity and mortality. Recently, the Centers for Disease Control and Prevention issued recommendations for the active prevention of GBS, which have been adopted by the American College of Obstetricians and Gynecologists.[20] A strategy based on late prenatal cultures, followed by intrapartum treatment with penicillin or other broad-spectrum antibiotics is recommended. Others argue that routine antimicrobial treatment with a broad-spectrum antibiotic is optimal for pregnant women at high risk of adverse pregnancy outcome in order to reduce the incidence of infectious complications such as pre-term birth, neonatal infections and maternal infectious morbidity.[21] Risk may be based solely on laboratory findings or on clinical and obstetric factors (bad obstetric history, clinical signs and symptoms). However, many questions remain unanswered, especially the benefit of screening and treating low-risk groups and the ideal antimicrobial regimen. The existing evidence is hampered by methodologic weaknesses such as small numbers, use of combinations of antibiotics and differences in populations studied. Although practice guidelines have been established it is essential to prove that the costs and the benefits associated with screening and treating genital infections in pregnant women outweigh the potential risks and effects. Only prospective, randomized and blinded clinical trials with large study populations can determine the effect of antimicrobial therapy on infectious morbidity and mortality in pregnancy.

Intercourse during pregnancy has been implicated as a risk factor for pre-term birth. This could be because of the effect of STDs or because of increased myometrial activity and cervical ripening caused by the prostaglandins in sperm. After correcting for STDs, there is little evidence of a causal relation between sexual intercourse and pre-term birth. Randomized trials of condom use versus unprotected sex in high-risk groups for poor pregnancy outcome have not been carried out to date.

Detection and treatment of maternal bacteriuria in early pregnancy, preferably around 16 weeks, can reduce the risk of pyelonephritis, pre-term delivery and neonatal mortality.

Routine examination of stools for pathogens is not useful in pregnant women, except in populations that have high rates of anemia and malnutrition.

Prevention of puerperal infections is a major concern in obstetrics. Antenatal detection and treatment of STDs and hygienic standards during delivery decrease the risk for puerperal infection. The indications for cervical cerclage have to be carefully weighed against the risks, and antibiotic prophylaxis should be given. Active management of labor, including shorter labor, fewer vaginal examinations and reduced cesarean section rates, help to prevent genital infections. Antibiotic prophylaxis in cases of long, complicated or operative deliveries is effective, although resistance is a limiting factor.

Mastitis can be prevented through good nursing technique, including strict hygienic measures.

CLINICAL FEATURES

Infections in pregnancy can be asymptomatic but usually manifest with symptoms similar to those in nonpregnant individuals.[1] [2] [3] [4] The course of the infection may be worse because of alterations in immune response and because of the potential hazards for the outcome of pregnancy and the well-being of the fetus.

The clinical diagnosis of intra-amniotic infection is based upon fever, uterine tenderness, fetal tachycardia, leukocytosis and elevated C-reactive protein, with or without ruptured membranes.

Urinary tract infections are the most common infectious complications of pregnancy and can be asymptomatic or manifest with signs of cystitis such as frequency, urgency and dysuria. Fever, flank pain and chills occur with ascending UTIs.

Lower respiratory tract infections manifest with cough, fever and chest pain.

Gastrointestinal infections appear as diarrhea and are usually self-limiting and without complications. If the diarrhea persists beyond 24 hours, a stool specimen should be obtained for culture. Acute appendicitis can be a diagnostic dilemma as the clinical presentations differ from those seen in nonpregnant women because of the large uterus and the altered immune response. Appendicitis may manifest as upper right quadrant pain with nausea and vomiting, without leukocytosis or fever, and should be differentiated from acute cholecystitis and amebic liver diseases.

Meningitis should be considered in every patient with headache, malaise, nausea, vomiting and fever. The diagnosis of bacterial endocarditis in pregnant women should be considered in any febrile, lethargic patient with no signs of localizing infection. Cutaneous lesions and heart murmurs should be sought. Blood cultures are required for diagnosis.

Diagnostic criteria for postpartum endometritis include fever, uterine and/or adnexal tenderness, purulent or foul lochia and leukocytosis in the absence of other signs of infection within the first 5 days after delivery. Late postpartum endometritis may occur weeks after delivery. Retention of placental products has to be excluded.

Early wound infection starts usually within 48 hours postpartum and manifests with fever and cellulitis or edema of the wound. Early wound infection is often caused by group A or group B streptococci, or *Clostridium perfringens*. In clostridial infection, wound cellulitis is associated with a watery discharge and a bronze appearance of the skin. Late-onset wound infections occur about 4–8 days after surgery, and manifest with fever and an erythematous, draining wound.

Early recognition of life-threatening complications such as necrotizing fasciitis is crucial. Cutaneous findings can be minimal and include cellulitis, edema and sometimes crepitations. However, the patient may be critically ill and require prompt treatment. A surgical exploration of the wound may be necessary to make the diagnosis.

Puerperal mastitis occurs with breast engorgement and milk stasis, often in the second or third week after delivery. The onset of sporadic mastitis is rather sudden, with breast tenderness, chills, fever, malaise and headache mimicking a flu-like syndrome. The breast may show foci of local infection characterized by erythema, tenderness and warmth. The development of a breast abscess is rare in lactating women.

Patients with ovarian vein thrombophlebitis, which is more frequently present on the right, usually have distinct clinical findings. They present with fever and lower abdominal pain, and on examination are acutely ill with tachycardia and tachypnea and may be in respiratory distress. Abdominal examination usually shows direct tenderness, guarding and a tender abdominal mass. Pelvic pain thrombophlebitis without pulmonary emboli manifests less dramatically and has a more rapid response to therapy. These patients are more often not as critically ill, and just have fever and tachycardia.

DIAGNOSIS

Most infections that manifest with clinical signs and symptoms do not give rise to diagnostic difficulties, as they are related to specific infections of the urinary or reproductive tract, or to common infections in the community. Outlining a complete scheme of investigations is beyond the scope of this chapter, but a summary of the most important diagnostic leads and laboratory tests is presented in Table 64.4 . (See also Chapter 135).

TABLE 64-4 -- Clinical and laboratory criteria in the diagnosis of infection in pregnancy.

CLINICAL AND LABORATORY CRITERIA IN THE DIAGNOSIS OF INFECTION IN PREGNANCY	
History	Signs, symptoms, onset, specific localization, additional signs such as pain, rash, uterine tenderness, leakage of amniotic fluid, exposure to infections, pets, occupation, hobbies, travel, place of residence, history of infections
Clinical examination	Auscultation of heart and lungs, assessment of the uterus and cervix, examination of the breasts, detection of masses, enlargement of spleen, liver, lymph nodes, signs of thrombophlebitis
Laboratory tests	White blood cell count and differential, C-reactive protein, serum enzymes, blood smears, blood cultures, throat and vaginal swabs, specific antibodies, urine culture

Rapid and inexpensive tests for the early detection of intraamniotic infection in patients in pre-term labor, including amniotic fluid Gram stain, leukocyte esterase, amniotic fluid glucose concentration and the Limulus amebocyte lysate assay for endotoxin, have been tested in women admitted with pPROM or pre-term birth. The greatest sensitivity for predicting infection was demonstrated by a low glucose level in amniotic fluid but none of the tests had sufficient accuracy to allow clinical decisions.[21] [22] For women with cervical dilatation in the mid-trimester of pregnancy, amniocentesis to determine the microbiologic characteristics of the amniotic cavity should be considered before placing a cerclage because of the poor prognosis in women with microbial invasion of the amniotic cavity.

The diagnosis of UTI is based on quantitative cultures with more than 100,000cfu/ml clear-voided urine (midstream) in asymptomatic patients, or more than 100cfu/ml in symptomatic patients. Direct suprapubic bladder aspiration is a better technique for obtaining uncontaminated urine but is less readily accepted by patients and/or physicians. To avoid screening all pregnant women with expensive and time-consuming urine cultures, rapid screening tests such as leukocyte esterase dipstick, microscopy for pyuria, nitrite tests and enzymatic screening tests have been developed. The rapid enzymatic test seems to be a reliable alternative to culture screening with a sensitivity of 100%, a specificity of 81% and a negative predictive value of 100%.[23]

The key to the care of lower respiratory tract infections is an early diagnosis, with careful clinical evaluation and examination, if possible, of a sputum sample and a blood culture. One should not hesitate to take a chest radiograph, as well as an arterial Po_2 in pregnant women if a serious lower respiratory tract infection is suspected. In patients with meningitis, a spinal tap with Gram stain, culture and chemical analysis of the cerebrospinal fluid is usually indicated.

Postpartum endometritis is a clinical diagnosis supplemented by a cervical swab for aerobic culture to identify pathogens that may require additional measures besides the antibacterial therapy. Isolation of group A streptococci should lead to isolation of the patient whereas that of GBS should prompt further action in relation to the neonate. Culturing techniques of the endometrium with double- and triple-lumen devices have been hampered by vaginal and cervical contamination and are not used routinely.

The diagnosis of early wound infection is made clinically and confirmed by a Gram stain. Gram-positive rods are highly suggestive of clostridia, and Gram-positive cocci indicate the presence of group A streptococci or *S. aureus*.

The diagnosis of mastitis is a clinical diagnosis. Mammography and ultrasound can be useful in the early diagnosis of an abscess and

to differentiate infection from a breast malignancy. However, this technique is rarely used because of pain and discomfort to the patient.

Pelvic vein thrombophlebitis is a difficult clinical diagnosis often confused with acute appendicitis, torsion of an adnexa, urolithiasis, pyelonephritis, leiomyoma and pelvic abscess. In case of clinical suspicion of a pelvic vein thrombophlebitis, additional examinations such as venography, computerized axial tomography and sonography have to be performed.

MANAGEMENT

A number of interventions with proven value in the management of morbidity related to infection during pregnancy are discussed. The serologic screening and subsequent management of viral infections, including rubella, toxoplasmosis, cytomegalovirus, HIV and others, is discussed in Chapter 65 .

Although the initiating mechanism of labor, and particularly preterm labor, is unknown, the potential role of inflammation is clear. Consequently, attempts to prolong gestation and improve pregnancy outcome using antimicrobials have been made. A number of prospective, randomized clinical trials with antibiotics have been reviewed. Most authors agree that treatment of pre-term labor with antibiotic therapy can prolong gestation but the impact on neonatal morbidity and mortality has not been demonstrated. Antibiotics in women with pPROM seem to prolong the interval to delivery and neonatal outcome.[24] [25] [26] [27] [28] The reason for the continuing controversy might be that infection is the underlying cause of pre-term birth in only a fraction of women, the subset that may benefit from antimicrobial therapy. Hence, improved diagnostic methods are needed to identify those patients who will gain from antibiotics.

As bacteriuria predisposes the pregnant woman to pyelonephritis with potential hazards for mother and fetus, screening and management in pregnancy is justified. Antimicrobial treatment options of UTIs include 3-day courses of amoxicillin 500mg q8h, nitrofurantoin 100mg q6h, cephalexin 500mg q6h, or trimethoprim-sulfamethoxazole 160/800mg q12h. The last regimen should be avoided in the third trimester because sulfonamides cross the placenta and compete with bilirubin in the fetus. Trimethoprim is a folate antagonist and should be combined with folinic acid if given in high doses. In view of the high rate of recurrence of bacteriuria in pregnancy, suppressive therapy is recommended until 2 weeks postpartum in women with recurrent UTIs. Pregnant women with acute pyelonephritis require admission for parenteral administration of antibiotics and careful monitoring.

Penicillin is the drug of choice in women with lower respiratory tract infections caused by pneumococci. The fever may cause premature contractions. Because of possible cardiopulmonary complications, ß-mimetic tocolytic drugs should be avoided or, if necessary, administered with caution.

Treatment of gastrointestinal infections is usually not necessary during pregnancy except when the problems persist and interfere with the mother's health. Metronidazole should be prescribed for *Entamoeba histolytica* infection. Pregnant women with acute appendicitis should undergo surgical exploration by the obstetrician together with the surgeon, and antibiotics should be prescribed.

Treatment of postpartum genital infection includes appropriate antibiotics with good anaerobic coverage. After Cesarean section the desired results have been obtained with a combination of clindamycin and gentamicin. Newer antibiotics such as the monobactams may replace gentamicin in combination with clindamycin, and the newer cephalosporins with a wide spectrum of activity are increasingly used. Intravenous antibiotics should be continued for 24–48 hours after the patient has become afebrile, and can be stopped without changing to oral antibiotics unless a staphylococcal infection is present. The treatment of early wound infections may require excision of the necrotic tissue and aggressive antibiotic treatment with a cephalosporin or clindamycin. In late-onset (after 5 days) wound infection incision of the wound and drainage is required. If the patient does not become afebrile after 24 hours, antibiotics should be prescribed. Open wounds can be allowed to close spontaneously by granulation after wound debridement and packing. Surgical closure of Cesarean section has been shown to be successful and requires less healing time. The procedure may be carried out under general or local anesthesia, and antibiotic prophylaxis is generally used. Episiotomy incisions should not be resutured but given time to heal by granulation, unless the sphincter muscle or the rectal mucosa is involved. In rare complications such as necrotizing fasciitis or clostridial gas gangrene, treatment must be aggressive, including high doses of broad-spectrum antibiotics and extensive drainage and debridement.

Therapy of mastitis includes continuation of lactation and treatment with a penicillinase-resistant penicillin or a cephalosporin, given orally except in the case of a severely sick patient. Ice packs, breast support, analgesics and regular emptying of the infected breast may help to prevent abscesses. In case of abscess formation, surgical incision and drainage should be performed.

Treatment of pelvic vein thrombophlebitis includes broad-spectrum antibiotics, heparin for 7–10 days intravenously, followed by long-term anticoagulation with oral anticoagulants. Surgery, including bilateral ovarian vein and inferior vena cava ligation, may be required for patients who do not respond to treatment. Hysterectomy is seldom required.

Antibiotics in pregnancy

Antibiotics are frequently used during pregnancy. Several studies have shown that 25–40% of pregnant women take antibiotics, mainly in the second trimester, while the incidence of antibiotic intake is around 5% in the first trimester. Administration of a drug to a pregnant woman presents a unique problem. The pharmacologic

mechanisms must be well considered, and the fetus must always be kept in mind. Most drugs or chemical substances taken during pregnancy can cross the placenta to some extent throughout pregnancy, but the fetus is at highest risk during the first 3 months of gestation.

Risk factors have been assigned to all level of risk that a drug poses to the fetus (A, B, C, D and X). The definitions used for the risk factors, described by Briggs *et al.*,[29] are summarized below.

¦ Category A: Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.
¦ Category B: Either animal-reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal-reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
¦ Category C: Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women, or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
¦ Category D: There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g. the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).

¦ Category X: Studies in animals or human begins have demonstrated fetal abnormalities or there is evidence of fetal risk based on human experience or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

TABLE 64-5 -- Risk factor assignments for antibiotics in pregnancy.*

RISK FACTOR ASSIGNMENTS FOR ANTIBIOTICS IN PREGNANCY			
Agent		**Category**	**Potential toxicity**
1	Penicillin	B	
2	Cephalosporin	B_M	
3	Monobactam	B_M	
4.1	Aminoglycoside/group 1	C*	Fetal ototoxicity, maternal oto- and nephrotoxicity
4.2	Aminoglycoside/group 2 (spectinomycin)	B	
5	Chloramphenicol	C	Gray syndrome (cardiovascular collapse in babies) when given near term
6	Tetracycline	D	Adverse effects on fetal teeth and bones, congenital defects, maternal liver toxicity
7.1	Macrolide: erythromycin	B	! Estolate salt form can induce maternal hepatotoxicity
7.2	Other macrolides	$C\text{-}C_M$	
8	Clindamycin	B	
9	Fluoroquinolone	C_M	
10.1	Sulfonamides	B*	No teratogenic effect, to be avoided near term because of potential toxicity to the newborn (kernicterus)
10.2	Trimethoprim sulphamethoxazole	C_M	Megaloblastic anemia, folate activity

** The classification of commonly used antibiotics as set out by Briggs et al.[29]*

Many older drugs have not been given a letter by their manufacturers, and the risk factor assignments were made by Briggs *et al.*[29] In cases where the manufacturer has rated the product in its professional literature, the risk factor is shown with a subscript (e.g. C_M). Risk markers with an asterisk are drugs that present different risks for the fetus. The classification of the most commonly used antibiotics are summarized in Table 64.5 .[29]

CONCLUSIONS

Infectious diseases are important risk factors for maternal and neonatal morbidity and mortality and can be detected early with improved outcomes or prevented entirely. Maternal mortality due to infections is an unbearable tragedy and must be addressed by improved access to modern obstetric care for all pregnant women. This care must be affordable, even in resource-limited countries, and should be a priority for governments and international agencies.

Preventing pre-term birth is a global issue, including industrialized countries. A substantial portion of pre-term births can be prevented with improvements in the detection and management of infections during pregnancy. Further research is required to identify women and babies at risk, and to develop preventive, diagnostic and management strategies to enhance care with maximal benefits at minimal costs and adverse effects.

Chapter 65 - Implications for the Fetus of Maternal Infections in Pregnancy

E Lee Ford-Jones
Greg Ryan

The nature of congenital infections is changing rapidly with new opportunities to link pathogens to untoward events through advances in molecular technology (e.g. polymerase chain reaction (PCR)) and wider availability of intrauterine diagnostic testing (e.g. maternal serum a-fetoprotein screening, ultrasound, amniocentesis, fetal blood sampling). Congenital infection in pregnancy may come to clinical attention through:

- a history of maternal risk factors,
- known exposure,
- documented acute maternal infection,
- laboratory screening,
- detection of fetal abnormalities on clinical examination or ultrasonography,
- suggestive findings in the neonate, and
- suggestive findings in the child.

Depending on the scenario, one or a range of infections must be considered in the differential diagnosis.

Fortunately, the vast majority of maternal infections have no effect on the fetus, either because there is no transmission to the intrauterine site or because the fetal infection is asymptomatic. Fear and poor understanding of risk on the part of the parents or physician can lead to unnecessary termination of pregnancy.

EPIDEMIOLOGY

Although many micro-organisms are known to cause congenital (intrauterine) infection (Table 65.1),[1] only more common agents are discussed (see below). A brief summary of infections transmitted primarily at the time of delivery is given at the end of the chapter.

Because the use of appropriate diagnostic testing is highly variable and because many of these diseases are not reportable to public health departments, there are few data on incidence. Actual rates are highly variable and depend on the presence of specific risk factors; estimates are provided in Table 65.2 .

Geography

There is considerable geographic variation in risk of exposure. Although some variation is related directly to the presence of the pathogen (e.g. *Plasmodium* spp., *Trypanosoma cruzi*), in others it may be related to other practices (e.g. breast-feeding). Maternal toxoplasmosis exposure reflects culinary practices, including handling and ingestion of fresh raw meat.[3]

Other factors associated with infection

Annual seroconversion rates to cytomegalovirus (CMV) for health care workers, usually in the range of 2–4%, are generally lower than rates in day care workers or susceptible parents of children in day care (12–45%). [4] Syphilis in pregnancy generally affects women who are young, unmarried, of low socio-economic status and who receive inadequate prenatal care. Factors associated with maternal—fetal infection are summarized in Table 65.3 .

PATHOGENESIS AND PATHOLOGY

Infections occurring in the neonate may be acquired in the following ways:

- transplacentally in utero (congenital or intrauterine) by direct blood flow to the amniotic fluid or from the genital tract via the cervical amniotic route, during pregnancy or just before delivery. The placenta can be infected and even act as a repository for pathogen growth;
- at the time of birth (perinatal) through vaginal secretions and blood; and
- after birth but during the neonatal period (postnatal), from the mother, her breast milk or other sources.

Adverse effects include abortion, stillbirth, premature delivery, physical defects, intrauterine growth restriction (e.g. rubella, enterovirus, herpes simplex virus (HSV)) and postnatal persistence of infection (e.g. rubella, CMV, HSV). Association of these findings, particularly early gestational loss, with particular pathogens has been hampered by the lack of availability of molecular diagnostic testing of macerated and hydrolyzed fetal tissues.

General associations of the following sites of infection, with adverse effects, exist:

- embryo: malformations, spontaneous abortion;
- fetus: stillbirth, neurologic sequelae; and
- placenta: preterm birth, stillbirth and neonatal death.

Factors affecting fetal disease

Pathogen

The greater virulence of some microbes in the fetus and infant is probably caused by the hematogenous route of exposure and inoculum size, as well as by the status of the immune response derived from the infant and passively derived maternal antibody and postnatally, immunocompetent cells in colostrum and breast milk.[5] Primary mechanisms of damage include cell death, abnormalities of cell growth (mitotic inhibition), direct cytoxic effect (chromosomal injury, cell necrosis) and secondary inflammatory responses.

Certain organisms have a propensity for certain stages of organogenesis. Rubella virus inhibits cell growth and thus causes structural damage. Enterovirus, CMV, toxoplasma and HSV may also be associated with intrauterine growth restriction. The inflammatory response to HSV infection leads to intrauterine infection rather than any particular developmental anomalies. There is a receptor for parvovirus B19 on the red blood cell (p antigen), with the result that at the time of the rapid increase in erythrocyte numbers during the second trimester, anemia and hydrops occur. Postnatal persistence of infection and some further damage can occur with rubella, CMV, HSV and varicella-zoster virus (VZV) infections.

Maternal immunity

Before conception

Usually maternal antibody in the immunocompetent host is protective to the fetus. Exceptions include viruses with known latency,

TABLE 65-1 -- Infectious agents known to cause congenital infection.*

INFECTIOUS AGENTS KNOWN TO CAUSE CONGENITAL INFECTION

Viruses	Herpesviruses: cytomegalovirus, herpes simplex virus, varicella-zoster virus
	Parvovirus B19
	Rubella virus
	Measles virus
	Enteroviruses: Coxsackie B virus, echovirus, poliovirus
	HIV-1 and HIV-2
	Lymphocytic choriomeningitis virus
	Hepatitis B virus
	Vaccinia
	Smallpox
	Adenovirus
	Western equine encephalomyelitis virus
	Venezuelan equine encephalomyelitis virus
	Human herpesvirus 6
	West Nile virus
Bacteria	*Treponema pallidum*
	Mycobacterium tuberculosis
	Listeria monocytogenes
	Campylobacter fetus
	Salmonella typhi
	Borrelia burgdorferi
	Brucella sp.
	Coxiella burnetti
Protozoa	*Toxoplasma gondii*
	Plasmodium spp.
	Trypanosoma cruzi
Fungus	Coccidioidomycosis

** Adapted with permission from Guerina.[1]*

TABLE 65-2 -- General rates of selected congenital and perinatal infections.

GENERAL RATES OF SELECTED CONGENITAL AND PERINATAL INFECTIONS	
Infection	**Rate/live births**
Group B streptococcus	1–5/1000
Cytomegalovirus	2–24/1000 (10–20% have disease)[4]
HSV (intrauterine)	1–2/200,000
HSV (perinatal)	1/2000–5000 USA; 1/33,000 UK[2]
Toxoplasma	0.1–3.5/1000
Syphilis	0.05–6.1/1000 (varies with definition)
Rubella	0.02/1000

such as CMV and occasionally HSV, and rarely rubella, for which maternal immunity has waned, and untreated *Treponema pallidum*.

The rate of intrauterine transmission is about 40% after primary maternal CMV infection, with approximately 15% of affected infants ultimately developing clinically significant disease during childhood. Of the 10% of infants symptomatic at birth, 90% of survivors will have significant neurologic sequelae, including hearing

TABLE 65-3 -- Factors associated with maternal-fetal infection.

FACTORS ASSOCIATED WITH MATERNAL-FETAL INFECTION	
Association	**Pathogen**
Seasonality (in North America)	Parvovirus B19 (winter, spring)
	Rubella (winter, spring)
	Enterovirus (summer, autumn)
Handling/ingestion of uncooked, previously unfrozen meat	*Toxoplasma gondii*
Children:	
Day care	CMV, parvovirus
School	Parvovirus
Household	CMV, parvovirus
Exposure in travel to certain geographic regions	*Toxoplasma gondii*, *Mycobacterium tuberculosis*, *Plasmodium* spp., *Trypanosoma cruzi*, *Borrelia burgdorferi*, hepatitis B virus, *Brucella* sp.
	West Nile virus
Kitten/cat feces within 21 days of primary infection (handling animals, kitty litter, gardening)	*Toxoplasma gondii*
Number of sexual partners, sex industry worker/partner, illicit drug use	*Treponema pallidum*, herpes simplex virus, hepatitis B virus
Sexually active adolescents	CMV, herpes simplex virus, hepatitis B virus
Unimmunized (e.g. immigrant from developing world; World Health Organization Expanded Program of Immunization does not include rubella)	Rubella
Other incompletely immunized	All of measles, mumps, tetanus, diphtheria, poliomyelitis, hepatitis B, varicella

loss in 30–65%. Approximately 1% of previously seropositive women also transmit CMV in utero but there are no laboratory markers to identify those at greatest risk.

Symptomatic congenital CMV infection with long-term neurologic complications can thus occur after a nonprimary or recurrent maternal infection, probably due to reinfection with a different strain of CMV.[6]

Immunosuppressive disorders and immunosuppressive therapy will also alter the risk of fetal disease (e.g. HIV-1 infection facilitates the transmission of toxoplasma).

During pregnancy and before delivery

The length of time before conception during which infection may occur without causing later fetal damage is not known. In the immunocompetent mother, it is advisable to have an interval of 7–9 months between *Toxoplasma gondii* acquisition and conception. Over 50% of infants born to mothers with primary or secondary syphilis will have congenital infection, decreasing to 40% with early latent syphilis and 10% with late latent infection.[7] Although the risk of intrauterine syphilis increases during gestation and is particularly high in late pregnancy, it can occur at any time during pregnancy.

In some infections the mother may develop immunity to an infection, but the fetus is delivered before transplacental transmission of this protection. Essentially the infant experiences a massive viremia, but with cutting of the umbilical cord is left without protection. For example, the risk of acquiring maternal varicella in the 5 days

before delivery is associated with a 30% risk of congenital infection in the neonate.

Placenta

Placental infection is more common than fetal infection for a variety of infections, including rubella, malaria and tuberculosis. This may be because of specific placental immunologic defense, antimicrobial properties (e.g. interferon production), placental phagocytic capacity or a non-specific physical barrier function. In early gestation, the small developing placenta effectively excludes most pathogens. As the placenta matures, with expansion of the maternal-fetal interface, this barrier becomes more porous, rendering transplacental transmission more likely. Placental dysfunction may also be associated with hypoxia, fever, toxins, thrombosis and placentitis, and result in fetal injury or death indirectly.[5]

Stage of fetal gestation

Fetal disease may result from many pathogens at any time during gestation. In general, however, transplacental transmission (via umbilical blood flow or direct spread to the amniotic fluid) is less likely early in gestation, but the results of infection, if it occurs, are more likely to be severe. The deficiencies in immune function of the young fetus both in humoral and in cellular function contribute to tissue damage, organ dysfunction and teratogenicity. Detectable IgM is rarely produced before 20–24 weeks of gestation. Certain pathogens are associated with producing particular effects at certain stages of cell development. For example, maternal rubella infection in pregnancy after 16 weeks is not associated with defects. [8]

Congenital varicella syndrome occurs almost exclusively before 20 weeks of gestation; in seven studies of varicella infection in pregnancy, 14 out of 1063 babies had congenital anomalies (1.3%); a higher risk (2–9%) appears to occur between 13 and 20 weeks.[9] After 20 weeks of gestation, early childhood zoster is almost exclusively the presenting finding, occurring after maternal infections between 17 and 24 weeks in 0.8% of cases and after infection

TABLE 65-4 -- Summary of preventive antenatal strategies.

SUMMARY OF PREVENTIVE ANTENATAL STRATEGIES				
Pathogen	**Education/immunization**	**Routine screen**	**Selective screen**	**Maternal-fetal intervention**
CMV	Yes		Day care workers (pre-pregnancy only)	Handwashing after handling respiratory secretions and urine
HIV/AIDS	Yes	Yes	If high risk, third trimester delivery	Antiretroviral therapy, serologic follow-up
Parvovirus B19		Exposure, epidemic		Intrauterine transfusion(s)
Rubella	Yes	Yes	Exposure	If susceptible, postpartum immunization before discharge
VZV	Yes	Recommended by some experts	Exposure	If susceptible, some experts recommend varicella-zoster immune globulin =96 hours after exposure
Treponema pallidum	Yes	Yes	If high risk, third trimester delivery	Penicillin, HIV testing, monthly serologic follow-up
Toxoplasma gondii	Yes	Only if recommended by regional authority	If ingestion of raw, previously unfrozen meat; handling of kitten or litter	Spiramycin or pyrimethamine/sulfadiazine/folinic acid with monitoring

between 25 and 36 weeks in 1.7%.[10] While transmission of toxoplasmosis occurs in only about 15% of first trimester infections, severe disease occurs in about 40% of infected infants. In the third trimester the reverse is true, with 60% transmission, but the disease is generally milder or asymptomatic.

PREVENTION

Prevention of maternal infection in pregnancy requires a combination of approaches: education, immunization, screening and intervention (Table 65.4).

Prenatal prevention through immunization and education

Certain preventive efforts should antecede pregnancy, including documentation of rubella immunity and preventive education regarding optimal food handling practices (i.e. toxoplasma, enteric bacterial pathogens, *Listeria* spp.). All women should also be immune to measles, mumps, tetanus, diphtheria, poliomyelitis, hepatitis B and varicella, either by natural infection or by vaccination. Influenza and pneumococcal immunization are recommended for women who are at high risk of infection. Immune globulin or specific immune globulin may be indicated on exposure to measles, hepatitis A or B virus, tetanus, varicella or rabies and, in the case of certain travel, to poliomyelitis, yellow fever, typhoid and hepatitis B virus.[11] Although inactivated vaccines are generally considered safe, some physicians wait until after the first trimester to administer them. Live viral or bacterial vaccines should be avoided during pregnancy. However, the risk of congenital rubella syndrome after administration of vaccine to a pregnant woman is very low.

The efficacy of education regarding toxoplasmosis has been demonstrated. All women who are planning pregnancy should be given general information.

- ¦ Ensure complete adult immunization, including hepatitis B and ideally varicella.
- ¦ Ensure that you are immune to rubella by blood test. If you are not, you require immunization.
- ¦ Follow simple procedures to reduce the risk of infection with *Toxoplasma* spp. (Table 65.5).[1]
- ¦ Minimize the risk of other food-borne infections (Table 65.6).
- ¦ If you are exposed to erythema infectiosum (fifth disease, human parvovirus B19), chickenpox or shingles, or whooping cough (pertussis) during pregnancy, inform your physician promptly.
- ¦ If your partner is diagnosed with an infection other than a cold or flu, inform your physician.
- ¦ There is currently no effective strategy to prevent the complications of CMV or enterovirus during pregnancy. Although women who regularly handle the respiratory secretions or diapers of young children may wish to be tested for CMV immunity before pregnancy, the only current preventive strategy for susceptible women is good hygiene when they are with young children in their home or in the group child care environment.
- ¦ Symptoms of genital herpes may occur years after the original infection; it is usually the first infection, which may occur without any symptoms (asymptomatic primary), that affects the infant; such infections are rare.
- ¦ In pregnancy, your doctor routinely tests for rubella immunity, hepatitis B virus, HIV/AIDS and syphilis infection.

TABLE 65-5 -- Measures to reduce the risk of infection with *Toxoplasma* spp.

MEASURES TO REDUCE THE RISK OF INFECTION WITH *TOXOPLASMA* SPP.	
Source of infection	**Preventive measure**
Meat	Avoid eating undercooked meat in pregnancy; previously frozen meat is free of toxoplasma
	Wash hands thoroughly after handling; keep cooking utensils thoroughly cleaned
Cats	Avoid contact with materials potentially contaminated with cat excrement
	Avoid kitty litter boxes; infectious toxoplasma may be present if in use more than 24 hours
	Disinfect with boiling water for 5 minutes; avoid aerosolization
	(Even indoor cats may be in contact with mice and fresh, raw meats)
Vegetables	Wash raw fruit and vegetables thoroughly before eating; wash hands after handling
Gardening	Wear gloves

TABLE 65-6 -- Measures to reduce the risk of food-borne infections other than *Toxoplasma*.

MEASURES TO REDUCE THE RISK OF FOOD-BORNE INFECTIONS OTHER THAN *TOXOPLASMA*
• Wash hands thoroughly before eating and before and after food preparation
• Use separate or thoroughly cleaned surfaces for foods to be served raw and cooked
• Avoid unpasteurized milk or cheese
• Avoid soft cheese (e.g. Brie, Camembert)
• Reheat leftovers and pre-cooked foods until piping hot
• Wash and scrub raw vegetables before eating
• Use foods before the expiry date

Screening for infection during pregnancy

Rubella screening in pregnancy alerts the physician to which mothers require postpartum immunization. Also, if the susceptible woman has known exposure or disease, the physician can confirm acute infection through study of a second serum sample. Antenatal screening for syphilis is cost-effective at an incidence as low as 5 in 100,000 population.[12] Hepatitis B virus screening allows for preventive management of the infant of the hepatitis B surface antigen (HBsAg)-positive mother.

The interpretation of other serology in pregnancy in the absence of seroconversion is fraught with difficulty as the acuity of the infection often cannot be determined. A woman at high risk of CMV infection (e.g. a day care worker) would therefore be advised to establish her immune status before pregnancy. The general value of antenatal screening for CMV is debatable.[13]

Screening for toxoplasma requires testing each trimester to document seroconversion and to allow for prompt treatment before transplacental transmission has occurred. *Toxoplasma*-specific IgM antibody persists for more than a year in about one-third of infections. Screening may be worthwhile if the incidence of primary maternal infection exceeds 1.1 per 1000. Practitioner-based testing for acute toxoplasmosis in the absence of a community-based program should be discouraged in countries where screening and treatment are not routine.

Clinical and ultrasound findings

Clinical and ultrasound findings may provide an additional opportunity to make diagnoses in the fetus.

Maternal illness

Rash in pregnancy requires exclusion of syphilis, rubella, parvovirus B19 and enterovirus infection. Arthritis occurs with parvovirus B19 infection as well as with rubella. In the presence of acute mononucleosis-like symptoms of fatigue and lymphadenopathy, Epstein-Barr virus, CMV, *Toxoplasma* and HIV infection must be considered.

Fetal ultrasonography

Ultrasound findings of in-utero infection are provided in Clinical Features, below. For toxoplasmosis identified ultrasonographically, maternal antimicrobial therapy with spiramycin before 18 weeks of gestation or pyrimethamine and sulfadiazine thereafter may reduce the severity of disease. In nonresolving fetal hydrops caused by parvovirus B19 infection, intrauterine transfusion may be used to treat severe fetal anemia.

CLINICAL FEATURES

Fetal

The features of in-utero infections are summarized in Table 65.7 . Some fetal abnormalities detected on antenatal ultrasonography may be caused by infection. However, no ultrasonographic findings are pathognomonic for a particular agent.[14] [15] Postnatal follow-up of infants, including ophthalmologic examination, cranial neuroimaging (i.e. computerized tomography (CT) and magnetic resonance imaging (MRI) and head growth and developmental progress over at least the first 2 years of life, is important in identifying affected infants, particularly with CMV and *Toxoplasma* infections. Ophthalmologic examination and cranial neuroimaging studies are abnormal in 40–50% of apparently normal but *Toxoplasma*-infected infants at birth.[16]

Prematurity and low birth weight

Routine investigation of these infants for congenital infection only rarely yields positive results. Prematurity is typical of congenital

TABLE 65-7 -- Clinical features of in-utero infection.

CLINICAL FEATURES OF IN-UTERO INFECTION	
General	Intrauterine growth retardation: all etiologies
	Hydrops fetalis: parvovirus B19, CMV, syphilis, *Toxoplasma*, HSV, Coxsackie B3 virus[14]
	Placentamegaly: CMV, syphilis

Head and neck	Hydrocephalus: CMV, *Toxoplasma*, enterovirus, varicella
	Microcephalus: CMV, *Toxoplasma*, rubella, varicella, HSV
	Intracranial calcifications: CMV, *Toxoplasma*, HSV, rubella, HIV, parovirus, West Nile virus, lymphocytic choriomeningitis virus
Heart	Congestive heart failure: parvovirus B19, syphilis, CMV, *Toxoplasma*
	Pericardial effusion: parvovirus B19, syphilis, CMV, *Toxoplasma*
	Cardiac defects: rubella, parvovirus B19, mumps (not proved)
	Myocarditis: enterovirus
	Calcification of the pericardium and lungs: varicella
Lungs	Pleural effusion: parvovirus B19, syphilis, CMV, *Toxoplasma*
	Pulmonary hypoplasia: CMV
Abdomen	Hepatosplenomegaly: CMV, rubella, *Toxoplasma*, HSV, syphilis, enterovirus, parvovirus B19
	Hypoechogenic bowel: CMV, *Toxoplasma* [15]
	Hepatic calcifications: CMV, *Toxoplasma*
	Meconium peritonitis: CMV, *Toxoplasma*
	Ascites: parvovirus B19, CMV, *Toxoplasma*, syphilis
Extremities	Limb reduction, restriction: VZV

syphilis and common in perinatal HSV infection. Intrauterine growth retardation occurs with rubella, CMV infections, toxoplasmosis and, occasionally, enteroviral infection.

Spontaneous abortion and stillbirth

Pregnancy loss has been associated with infection with CMV, enterovirus, HSV, HIV, parvovirus B19, rubella, *T. pallidum* and *T. gondii*. Fetal loss occurring with any maternal viral infection requires comprehensive pathologic and microbiologic evaluation to determine the role of the infection in pathogenesis.

Syndromes of congenital infection

General

The majority of infected infants have no symptoms at birth although some will develop sequelae later in childhood (Table 65.8). The clinical findings in congenital infection are summarized in Table 65.9 .

Sepsis-like illness

Herpes simplex virus acquired just before delivery or intrapartum may present as a perinatal syndrome, often without skin lesions, and resemble neonatal sepsis or pneumonitis. An early laboratory clue is abnormal liver enzymes. Shock, coagulopathy, fulminant hepatitis and, often, skin lesions follow. Congenital tuberculosis can also present in this way.

Hepatitis

Enterovirus, HSV and *Toxoplasma* can cause overwhelming acute neonatal liver failure in the first week of life. Other infections, including CMV[20] and parvovirus B19, [21] can also present with hepatic findings.

Central nervous system

Central nervous system (CNS) involvement may occur with all of the congenital infections (as well as with perinatally acquired HSV and enteroviral infections), although initial findings may be very subtle. Occult findings in congenital neurosyphilis have led to general recommendations that neurosyphilis be assumed with any cerebrospinal fluid (CSF) abnormality.[22] With newer molecular techniques, CNS involvement may be better recognized (i.e. PCR detection of CMV DNA in the CSF). Clinical findings may be preceded by ophthalmologic and neuroimaging findings. Central nervous system involvement in congenital toxoplasmosis may be manifest only on neuroimaging at birth.[14] As opposed to the poorer prognosis of cranial calcifications in CMV infection, the cranial calcifications of toxoplasmosis may disappear during therapy in infancy or persist, with normal cognitive development.

Cardiac

Rubella infection causes structural defects including patent ductus arteriosus; parvovirus B19 may cause intrauterine congestive heart failure with resulting prenatal closure of the foramen ovale and Epstein's anomaly, and occasionally acute and chronic lymphocytic myocarditis.[23] Viral myocarditis is characteristically caused by Coxsackie B virus or other enteroviruses.

Ophthalmologic

Ophthalmologic abnormalities are seen in a variety of congenital infections (see Table 65.9). [5]

Deafness

Deafness is a common sequela of CMV and rubella infection, as well as of untreated *Toxoplasma* and syphilis infections. One-third of sensorineural hearing loss is caused by congenital CMV infection. Of rubella-infected infants, 80% or more may have deafness, often as the only significant consequence. Given the progressive nature of impairment, serial hearing evaluations to age 6–9 years are recommended for CMV-infected infants.

Specific infections

While characteristic presentations by etiologic agents are described below, it should be recognized that isolated and apparently uncharacteristic findings do occur (e.g. unilateral chorioretinitis following intrauterine HSV or esophagitis with CMV).

Cytomegalovirus

Up to 10% of CMV-infected infants will have typical findings of petechiae, hepatosplenomegaly, jaundice, microcephaly, inguinal hernia in males, chorioretinitis or other, atypical findings. Symptomatic infants are at high risk of significant neurologic and developmental dysfunction, particularly if abnormalities are noted on cranial CT or chorioretinitis exists.[24] Cerebral calcifications tend to be periventricular. Most children with an abnormal newborn CT scan (90%) develop at least one neurologic sequela as compared with 29% of those with a normal study, making a cranial CT scan a good predictor of an adverse neurodevelopmental outcome. Normal development at 12 months of age makes subsequent neurodevelopmental or intellectual impairment unlikely. Infants with asymptomatic infection have a 5–15% risk of hearing loss, mental retardation, motor spasticity and microcephaly evolving in the early years. While rates of hearing loss in symptomatic and asymptomatically infected infants are approximately 40% and 7%, respectively, in both the loss may be late in onset, fluctuating and progressive, necessitating follow-up (see Deafness above).

Enteroviruses (Coxsackie viruses, echovirus)

Although high rates of maternal infection in pregnancy (up to 25%) have been reported, disease is limited to case reports or series of

TABLE 65-8 -- Ratio of neonatal infection to neonatal and postnatal symptoms.

RATIO OF NEONATAL INFECTION TO NEONATAL AND POSTNATAL SYMPTOMS			
Micro-organism	**Infected fetuses/neonates with clinical manifestations (%)**	**Additional percentage with late-onset manifestations**	**Late-onset manifestations**
CMV	10%	5–15%	At =2 years sensorineural hearing loss, microcephaly, motor defects, mental retardation, chorioretinitis, dental defects
			>2 years hearing loss
Rubella	First 16 weeks, decreasing from 90% to 24%	>20%	Hearing loss, visual defects, multiple endocrinopathies, panencephalitis
Treponema pallidum	30%[17] (30–40% stillborn)	Unknown	Hearing loss, visual defects; abnormal dentition, bones and joints, CNS
Toxoplasma gondii	Severe organ damage in 20% of infants of untreated mothers and in 2% in treated mothers	Subclinical infection in 41% of infants of untreated mothers and in 17% in treated mothers	>85% have chorioretinitis

infected infants with a variety of entities including growth retardation, CNS malformations, blueberry muffin rash, hepatic necrosis, myocarditis or pericarditis.

Herpes simplex virus

Intrauterine HSV infection is characterized by the triad of skin vesicles or scarring, eye lesions and microcephaly or hydranencephaly. It may follow primary or recurrent, symptomatic or asymptomatic, HSV-1 or HSV-2 maternal infection at any stage of gestation. Acquisition just before delivery can lead to disease identical to that acquired at delivery, except that it occurs within the first 48 hours of life. The presence of even a single vesicle should prompt ophthalmologic examination and cranial imaging.

Parvovirus B19

The spectrum of infection in the fetus and neonate continues to expand and includes spontaneous abortion, nonimmune hydrops fetalis, stillbirth, congenital liver damage (portal fibrosis), transfusion-dependent congenital anemia, neutropenia and thrombocytopenia, prenatal closure of the foramen ovale and a syndrome of anemia, blueberry muffin rash and hepatomegaly.

The vast majority of maternal infections, both symptomatic and asymptomatic, are followed by delivery of a healthy term infant, perhaps in most cases because the fetus is not infected. Whereas the exact rate of loss in early and late pregnancy remains to be determined, there appears to be an excess loss in the second trimester. Studies of pregnant women with confirmed parvovirus infection have found a low rate of hydrops of 0–1.6%.

Rubella

The clinical features of congenital rubella syndrome (CRS) can be divided into the categories of transient, in newborns and infants; permanent, at birth or during the first year of life; and delayed, occurring in 10–20% of patients, usually in the second decade of life. In rare cases, reinfection with maternal rubella has resulted in CRS.

Varicella-zoster virus

The congenital varicella syndrome (or fetal varicella-zoster syndrome, better reflecting the pathogenesis), including cicatricial skin scars, eye abnormalities including microphthalmia, hypoplastic limbs, and autonomic nervous system damage causing gastroesophageal reflux with or without CNS abnormalities, occurs almost exclusively with maternal varicella infection acquired before 20 weeks of gestation. Cases have been reported at 26–28 weeks of gestation. Generally, after 20 weeks manifestations include skin scars, as with postnatal VZV infection, and childhood shingles. Only rarely has this syndrome been reported after gestational zoster. Subclinical maternal VZV infection is now recognized as a cause of neurologic symptoms and signs in children without other manifestations of congenital varicella syndrome, including dermatologic findings, suggesting the damage done by intrauterine varicella is underestimated. If the CNS is relatively spared, a good long-term outcome can occur.

Treponema pallidum

Most commonly physicians are required to investigate the asymptomatic infant whose mother had positive serologic testing for syphilis. Of the diverse findings, bone lesions are the most frequently encountered abnormality, occurring in 20% of symptom-free infected infants. Cerebrospinal fluid examination is required and some experts believe that minimal abnormalities in the CSF should be considered to indicate neurosyphilis. These include leukocyte counts of 5/mm^3 or more and protein concentrations of 100mg/dl or greater.[25]

Toxoplasma gondii

The diversity of findings may be classified according to timing of symptomatology as:

- symptomatic neonatal disease;
- disease in the first months of life, usually with neurologic and ophthalmologic findings;
- sequela of previously undiagnosed infection (i.e. chorioretinitis later in childhood); and
- subclinical disease.

Of asymptomatic infected infants, half will have abnormalities on cranial imaging or ophthalmologic examination. Among 23,000 mothers and infants in the Collaborative Perinatal Project, infants of IgG *Toxoplasma* antibody-positive mothers had a 2-fold increase in hearing loss, a 60% increase in the incidence of microcephaly and a 30% increase in the occurrence of low intelligence quotient (<70). [26]

Other

Intrauterine adenovirus infection has been associated with fetal myocarditis, pneumonia and encephalitis. Measles infection in pregnancy increases the risk of prematurity in the first 2 weeks after rash.

TABLE 65-9 -- Clinical findings in congenital infection.[5] [19]

CLINICAL FINDINGS IN CONGENITAL INFECTION	
Prematurity	Syphilis, HSV
Intrauterine growth retardation	All etiologies including tuberculosis
Anemia with hydrops	Parvovirus B19, syphilis, CMV, *Toxoplasma*
Bone lesions	Syphilis, rubella
Cerebral calcification	*Toxoplasma* (widely distributed)
	CMV and HSV (usually periventricular)
	Parvovirus B19, rubella, HIV, WNV, LCM
Congenital heart disease	Rubella, parvovirus B19, mumps (not proved)
Hepatosplenomegaly	CMV, rubella, *Toxoplasma*, HSV, syphilis, enterovirus, parvovirus B19
Hydrocephalus	*Toxoplasma*, CMV, syphilis, possibly enterovirus
Hydrops, ascites, pleural effusions	Parvovirus B19, CMV, *Toxoplasma*, syphilis
Jaundice	CMV, *Toxoplasma*, rubella, HSV, syphilis, enterovirus
Limb paralysis with atrophy and cicatrices	Varicella
Maculopapular exanthem	Syphilis, measles, rubella, enterovirus
Microcephaly	CMV, *Toxoplasma*, rubella, varicella, HSV
Ocular findings (see below)	CMV, *Toxoplasma*, rubella, HSV, syphilis, enterovirus, parvovirus B19
Progressive hepatic failure and clotting abnormalities	Echovirus, Coxsackie B virus, enterovirus, HSV, *Toxoplasma*
Pseudoparalysis	Syphilis
Purpura (usually appears on first day)	CMV, *Toxoplasma*, syphilis, rubella, HSV, enterovirus, parvovirus B19[18]
Vesicles	HSV, syphilis, varicella, CMV, parvovirus B19, enterovirus
Cataracts	Rubella, HSV, VZV, parvovirus B19, *Toxoplasma*, syphilis
Chorioretinitis	HSV, VZV, rubella, CMV, *Toxoplasma*,
Optic atrophy	HSV, VZV, rubella, CMV, *Toxoplasma*, syphilis
Microphthalmia	Rubella, HSV, parvovirus B19, *Toxoplasma*, CMV, varicella
Coloboma	CMV
Keratoconjunctivitis	HSV
Pigment retinopathy	Rubella
Glaucoma	Rubella, toxoplasmosis, syphilis
Iritis	HSV, rubella, syphilis
Anophthalmia	CMV
Peter's anomaly	CMV
Horner syndrome	VZV

DIAGNOSIS

Diagnosis of fetal infection

Attribution of adverse outcome to a particular micro-organism in early fetal life is problematic and frequently requires molecular diagnostic testing (e.g. DNA detection by PCR). Detection of micro-organism specific IgM is hampered not only by the testing method but also by the failure of the fetus to reliably produce IgM-specific antibody before 22–24 weeks. Fetal infection may follow maternal infection by at least 4–6 weeks, providing false reassurance if

TABLE 65-10 -- Laboratory evidence of clinically significant maternal infection.

LABORATORY EVIDENCE OF CLINICALLY SIGNIFICANT MATERNAL INFECTION		
Micro-organism	**Detection by culture, PCR (site)**	**Serology**
CMV	Infrequently blood/serum	Seroconversion
		Possibly CMV IgM capture enzyme-linked immunosorbent assay
Enterovirus	Yes (stool, throat, other)	Seroconversion
HSV	Yes (vesicle)	Seroconversion
		Research laboratory required to differentiate between HSV-1 and HSV-2
Parvovirus B19	Yes (blood)	Seroconversion
		Parvovirus B19-specific IgM
Rubella		Seroconversion
		Rubella-specific IgM
VZV	Yes (vesicle)	Seroconversion
Treponema pallidum	Yes (lesion, dark field)	VDRL/rapid plasma reagin =1/8 and positive treponemal test
Toxoplasma gondii		Seroconversion
		Toxoplasma-specific IgM with confirmatory timing of infection in reference laboratory

fetal diagnosis, through direct detection or antibody production, is attempted too soon after maternal infection.

Antenatal diagnosis of fetal infection requires a multidisciplinary approach to exclude noninfectious causes and to obtain maternal-fetal studies. Follow-up of the infant at birth and in the ensuing few months is also required to determine the presence, extent and damage, if any, resulting from the infection.[27]

In the absence of fetal disease, the prenatal diagnosis of fetal infection is not warranted because the predictive values of positive and negative results cannot be used as a basis for management decisions.[28] For example, in contrast to the prenatal diagnosis of genetic diseases for which the outcome is reasonably certain, most infants with congenital CMV infection are asymptomatic and do not suffer sequelae.

Maternal testing

Many maternal infections are asymptomatic and all infections, symptomatic or otherwise, can pose a risk to the fetus. Laboratory tests are listed in Table 65.10 . Routine broad screening of a single serum is unlikely to be helpful and is rarely indicated. The diagnosis of a primary CMV infection can be made by demonstration of seroconversion of CMV-specific IgG antibodies from negative to positive, but not by boosting of a titer, as this may occur with recurrent infection. Differentiation of the serofast state from inadequately treated syphilis is difficult. A serofast patient usually has a titer of =1:4; although titers can be as high as 1:8,[29] caution in interpretation is essential.

Maternal symptoms and their likelihood

Although fetal disease follows both symptomatic and asymptomatic maternal infection and maternal infections are frequently asymptomatic, the following symptoms should suggest a search for micro-organisms: flu or an acute mononucleosis syndrome-like illness (CMV, *Toxoplasma*, HIV) and arthritis or rash (parvovirus B19, rubella, *T. pallidum*).

Fetal testing

Detection of the micro-organism by culture or DNA by PCR amplification and product detection in amniotic fluid or fetal blood is promising, but should generally not be undertaken in the absence of fetal abnormalities because of the uncertain sensitivity and specificity. After week 18 of gestation, and at least 4 weeks after maternal infection, PCR testing of the amniotic fluid will detect 97% of toxoplasmosis-infected fetuses.[30] Fetuses infected with CMV are likely to have positive amniotic fluid cultures after 20–22 weeks of gestation because fetal kidney infection is common. Other sites such as effusions may also be cultured and tested by PCR; there are case reports of positive enteroviral cultures.[31]

Other indirect evidence of infection may be obtained through hematologic and biochemical profiles, including hepatic enzymes and, in the future, through study of lymphocyte subclass populations and cytokine production.

Neonatal testing

In evaluating the neonate with suspected congenital infection at birth, it is necessary to:

- review the maternal history including serologic screening (Table 65.10 and Table 65.11);
- review ultrasonography undertaken in pregnancy (Table 65.7);
- evaluate the infant (Table 65.9 and Table 65.12);
- attempt detection of the pathogen in the neonate; and
- undertake judicious maternal and infant serologic testing pertinent to the most likely diagnoses.

Detection of the micro-organism in the neonate

The best evidence for infection with CMV, enterovirus, HSV, parvovirus B19, rubella, syphilis and *Toxoplasma* comes from detection of the agent in the neonate (see below).

Maternal and infant testing pertinent to the most likely diagnoses

Diagnostic tests are summarized in Table 65.13 . Over- and under-diagnosis of congenital infection has arisen as a result of failure to:

- submit maternal serology for documentation of a source of infection;
- detect the organism in the infant through culture (or newer methods of antigen detection);
- sequentially test the infant serologically; and
- appreciate the enormous rate of false-positive and false-negative test results obtained through IgM-specific testing and use of cord blood.

False-negative IgM tests in infants are very common (e.g. only 25% of infants with clinical manifestations of intrauterine infection had VZ IgM).[10] An exception is the rubella-specific IgM test, which is highly sensitive and specific. Parvovirus-specific IgM is frequently negative when virus is detected by PCR.

Serologic documentation of maternal infection and acute and follow-up serology of the infant over the first months or year of life can be diagnostic, albeit not sufficiently quickly to facilitate decisions about therapy. Passively transferred antibody will disappear in the first 6–12 months, whereas antibody persists or rises in the infected infant. Follow-up serology is more complicated in the case of congenital CMV as infection may also be acquired at birth or postnatally through breast milk or other contact.

Cord blood is not acceptable for specific antibody testing for syphilis, *Toxoplasma* or CMV because of false-positive and false-negative results. Total cord IgM levels may be falsely elevated through contamination by maternal blood. Cases of congenital syphilis have been reported in which both mothers' and neonates' titers were negative at birth but the infants subsequently developed clinical syphilis at 3–14 weeks of age with strongly positive titers.[32]

TABLE 65-11 -- Maternal history relevant to congenital infections.

MATERNAL HISTORY RELEVANT TO CONGENITAL INFECTIONS
Woman's history
Underlying illness and medications
Previous history of sexually transmitted disease (HSV, syphilis, chlamydia, gonorrhea, HIV)
Drug or alcohol use, current and previous
Travel during pregnancy (consider culinary practices and other factors in region traveled)
Occupation
• Working with children wearing diapers or who have disabilities (CMV)
• Working with elementary school children (parvovirus, rubella)
• Working with animals or raw meat products (*Toxoplasma*)
• Working in the sex trade industry (HIV, syphilis, tuberculosis, hepatitis B virus, hepatitis C virus).
Household exposure to young children (CMV)
During her pregnancy
• Has she eaten raw meat or tasted it while cooking? (toxoplasmosis)
• Has she consumed unwashed vegetables? (food-borne pathogens, *Toxoplasma*)
• Has she changed kitty litter without wearing gloves? (*Toxoplasma*)
• Has she worked in soil/garden without wearing gloves? (*Toxoplasma*)
• Has she had any illness she might not have mentioned until now?

• Cold sore? (HSV)
• Dysuria, burning, itching? (HSV)
• Profound fatigue? (CMV, *Toxoplasma*, HIV)
• Swollen glands? (CMV, *Toxoplasma*, HIV)
• Arthritis? (rubella, parvovirus B19)
• Rash? (rubella, parvovirus B19, syphilis, enterovirus)
Has her husband/partner had any particular illness?
• Skin sores anywhere? (HSV, syphilis, HIV)
Routine serologic testing
HBsAg, rubella-specific antibody, syphilis serology (VDRL, rapid plasma reagin)
• First trimester
• If high risk, repeat third trimester, delivery
Antenatal care
• If absent, see Table 65.18

The futility of a single serologic (syphilis, toxoplasmosis, other agents, rubella, CMV, herpesvirus (STORCH)) screen is well known and a more directed approach is required. In preference to a single serum (STORCH titer), every effort should be made to recover the organism from the neonate and follow-up maternal and infant blood (Table 65.14).

Definitions of selected congenital infections

Because of delayed onset and/or recognition of signs of infection as well as the varied availability of diagnostic tests, definitions have been developed that take into consideration the likelihood of infection (Table 65.15).

MANAGEMENT

General

A thorough understanding of the consequences of infection in pregnancy is required to counsel parents regarding risks to the fetus and possible courses of action.

Selected maternal infections should be followed by ultrasonography to identify adverse effects. Antenatal diagnosis is generally attempted only if fetal abnormalities are present. After delivery, additional information

TABLE 65-12 -- Evaluation of the neonate with suspected congenital infection.

EVALUATION OF NEONATE WITH SUSPECTED CONGENITAL INFECTION	
Clinical	Physical examination (gestational age, height, weight, head circumference) to identify prematurity, intrauterine growth retardation, microcephaly
	Measure liver/spleen size
	Ophthalmologic examination (pediatric expert)
Laboratory	Complete blood count and smear
	Platelet count
	Liver transminase levels
	Bilirubin level, direct and indirect
	CSF examination (cells, protein, with pertinent antibody, detection; see Table 65.13)
	Laboratory testing (detection of agent, maternal and infant (not cord)) serology
	Immunoglobulin determinations
	Hold pretransfusion blood for possible additional tests
Other	Cranial CT scan with enhancement
	Long-bone radiographs (if syphilis or rubella likely)
	Placental pathology
	Audiology assessment
	Multidisciplinary follow-up

about contagiousness, breast-feeding and risk of transmission in subsequent pregnancies should be conveyed. Comprehensive long-term pediatric follow-up is required to identify and manage the spectrum of cognitive, motor, visual, hearing and other impairments that may be imparted by some of these infections.

Specific infections

Cytomegalovirus

Neurologic outcome cannot be reliably predicted until the infant is 2 or 3 years of age, during which head growth is monitored and achievement of developmental milestones is documented. Infants with abnormal cranial imaging are more likely to have cognitive and other deficits on follow-up.[24] Progression of existing retinal lesions or delayed development of chorioretinitis during childhood has been reported in about 20% of children, whereas hearing loss will evolve in about 30% of children, as late as school age. Children with asymptomatic congenital CMV infection show no differences in IQ score or other neuropsychologic test performance as compared with uninfected children.[33] [34]

The highly variable, unpredictable course of congenital CMV infection makes randomized controlled trials of therapy such as ganciclovir imperative before their widespread use. Infants with CNS disease at birth have already sustained enormous damage. Theoretically, therapy might be of some use because infection is active at birth and damage appears to continue for up to 2.5 years.[35] In a phase 3 randomly controlled trial, ganciclovir therapy (6mg/kg/dose twice daily for 6 weeks) protected infants from hearing deterioration beyond 1 year. Transient effects on growth and resolution of transaminase elevation were also seen. Approximately two-thirds developed neutropenia with half requiring dose reduction. Prevention through vaccination is urgently needed.

Herpes simplex virus

As intrauterine infection is rare, infected women should be assured that maternal infection is common but that fetal infection is unusual.

Parvovirus B19

After maternal exposure and documented infection, serial ultrasonography for 1–14 weeks will identify the hydropic fetus. For the fetus with nonimmune hydrops fetalis and a low hematocrit and reticulocyte count, one or more intravascular fetal transfusions of packed erythrocytes, until marrow aplasia resolves, have been used with good results. Hydropic fetuses with an intermediate hemoglobin and a high reticulocyte count, in whom the process is resolving spontaneously, need not be transfused and show no sequelae. The management of the neonate who has sustained red cell aplasia through a 'hit and run' effect of the virus on the bone marrow may respond to immunoglobulin and corticosteroids. There is no medical indication for termination of the pregnancy complicated by parvovirus B19 infection.[36]

Rubella

Infected infants should be considered infectious for the first year of life unless repeated nasopharyngeal and urine cultures are negative. Long-term follow-up will identify progressive hearing loss and visual deterioration, endocrinopathies and subacute sclerosing panencephalitis.

Treponema pallidum

All infected women should receive penicillin therapy appropriate to their stage of disease to minimize or eliminate the risk of transmission to the fetus. If serology has been positive for less than 1 year, the patient may be treated with intramuscular benzathine penicillin G 2.4 million units intramuscularly as a single dose. If the patient has been seropositive for 1 year or more, then benzathine penicillin G 2.4 million units in a single dose weekly for 3 successive weeks is required. Maternal CSF examination (protein, cell count, CSF-venereal disease research laboratory (VDRL) is required only if neurosyphilis is suspected; it is not routinely required in patients with infectious syphilis if the neurologic examination is negative. Retreatment during pregnancy is unnecessary if titers followed monthly continue to fall. In the presence of penicillin allergy, desensitization is the preferred management; any other therapy will necessitate treatment of the infant after birth. All women with positive serology require HIV testing and testing of their recent sexual contacts, as well as repeat testing in the third trimester and at birth. Cord blood should not be used for rapid plasma reagin/VDRL testing as it may be falsely negative or positive.[37] Long bone radiographs and usually CSF examination are required.

Indications for treatment include:

- ¦ symptomatic disease;
- ¦ inadequate maternal treatment (i.e. not documented, inadequate or unknown), use of a drug other than penicillin and treatment within 4 weeks of delivery (or last trimester, according to some experts) or poorly documented response to treatment;
- ¦ uncertain follow-up; and
- ¦ secondary or latent syphilis in the mother within 1 year of delivery.

Therapy with aqueous crystalline penicillin G 100,000–150,000IU/kg (given every 8–12 hours) intravenously for 10–14 days is recommended. After the second week of life, or with confirmed neurosyphilis or severe disease, aqueous penicillin 200,000–250,000U/kg per day may be used.[22] A preliminary study suggests that selected asymptomatic infants may be treated with intramuscular benzathine penicillin 50,000U/kg once, provided that there are no signs of congenital syphilis on physical examination, CSF cell count is normal and CSF-VDRL is negative, and radiographic studies of the long bones of the lower extremities, platelet counts and liver function tests are normal.[38] Follow-up of all infants is required up to 1 year or beyond to ensure that the appropriate falls in titers have occurred and

TABLE 65-13 -- Laboratory investigation and follow-up of neonate with suspected congenital infection.

LABORATORY INVESTIGATION AND FOLLOW-UP OF NEONATE WITH SUSPECTED CONGENITAL INFECTION			
Infection	**Mother at birth**	**Neonatal (not cord blood)**	**Follow-up of infant**
CMV	Antibody	Virus detection in urine, saliva, blood leukocytes, CSF	Repeated antibody testing to 6–12 months; passive maternal antibody disappears at 4–9 months; negative infant and maternal antibody rules out infection, although intrapartum cervical and postpartum breast milk transmission is common
		IgM capture enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay	
		Antibody	
Enterovirus	Virus detection in stool, throat, blood, of mother of infant with suspected congenital enteroviral infection	Virus detection in stool, throat, CSF, nose, blood, other	Selective testing of paired infant and maternal sera appropriate to infant, maternal or community isolates
	Bank serum	Bank birth and 2nd serum at 2–4 weeks	
HSV	Antibody	Virus detection in skin vesicles, throat, CSF, urine, nose, conjunctiva, rectal swab	Repeated antibody testing to 6–12 months (cannot differentiate between type 1 and type 2 viruses)
		Antibody	Negative infant and maternal antibody rules out infection
Parvovirus	IgM and IgG antibody	Detection of DNA (e.g. by PCR) in blood, bone marrow	Repeated antibody testing to 6–12 months
B19	Detection of DNA (e.g. by PCR) in blood	Parvovirus-specific IgM	Infected infants and their mothers may lack IgM antibody
Rubella	Rubella-specific IgG and IgM antibody	Rubella-specific IgM antibody	Repeated antibody testing to 6–12 months
		Virus detection in urine, nasopharynx, CSF, blood	Negative infant antibody at 6–12 months usually rules out infection
		CSF rubella-specific IgM antibody	
VZV	Antibody	Virus detection in skin lesions	Antibody testing 6–12 months postnatally
		Antibody	Intrauterine infection commonly manifest only as persistent antibody and childhood zoster
Toxoplasma gondii	*Toxoplasma*-specific IgM and IgG antibody	Reference laboratory testing of *Toxoplasma*-specific:	Repeated antibody testing to 6–12 months
	To determine acuity of infection in IgM positive mother, need reference laboratory testing	IgM-ISAGA, DS-IgM-ELISA, IgE-ELISA, IgA-ELISA	Negative infant antibody at 6–12 months usually rules out congenital infection
		or	
	Seroconversion or 4-fold rise in *Toxoplasma*-specific IgG in pregnancy	Blood culture (*Toxoplasma*-specific IgM falsely positive and negative)	
		Culture and histopathology of the placenta	

Treponema pallidum	Quantitative VDRL, rapid plasma reagin (RPR)	Detection of treponemes in nasal secretions, skin lesions, etc. by dark-field examination	Repeated quantitative VDRL and treponemal antibody testing to 12–15 months
	Treponemal antibody (e.g. fluorescent treponemal antibody absorption)	Quantitative VDRL, RPR	No test at birth can differentiate between the asymptomatic infected and uninfected neonate
	If positive, maternal HIV status	Serum treponemal antibody (e.g. fluorescent treponemal antibody absorbed (FTA) test)	Passively transferred antibody disappears at 6 months (VDRL, RPR) and 12–15 months (treponemal)

that treatment or retreatment is not required. Nontreponemal antibody titers, followed at 1, 2, 4 and 6 months, should be nonreactive at 6 months. At 12–15 months treponemal titers, if negative, rule out infection.

Toxoplasma gondii

If acutely infected women can be identified and treated in pregnancy through organization of a regional system of screening, there is evidence that the outcome is improved. Despite a large number of studies undertaken over the past 30 years, however, antenatal treatment of women with presumed toxoplasmosis remains controversial.[39]

Although maternal spiramycin therapy reduces the rate of transmission to the fetus, the combination of pyrimethamine and sulfadiazine is required once infection is established to improve fetal outcome. The regimen currently recommended for treatment in North America is given in Table 65.16 . (See also Chapter 66.b)

In the absence of antenatal diagnosis and fetal therapy,[40] the results of a 1-year course of therapy in infants in whom therapy was initiated within 2.5 months of birth have been reported in the Chicago Collaborative Treatment Trial.[41] Developmental, audiologic and visual performance was adequate for normal function in 75% of treated children with a follow-up of 33 months. The single most important predictor of poor outcome was hydrocephalus. Evidence of hydrocephalus must be actively sought and the condition managed aggressively. When infants are not treated, late sequelae after subclinical disease include active chorioretinitis in 85%, including some cases of blindness or impaired vision, developmental delay in 20–75% and moderate hearing loss in 10–30%.

TABLE 65-14 -- Appropriate specimens to diagnose congenital infection.[19]

APPROPRIATE SPECIMENS TO DIAGNOSE CONGENITAL INFECTION		
Specimen	**Tests**	**Interpretation**
Urine	Viral culture/detection (CMV, HSV, rubella)	Urine for CMV must be obtained at =2 weeks of age
		Positive is diagnostic
Throat swab	Viral culture (CMV, HSV, rubella, enteroviruses)	Positive is diagnostic
Blood	Agent detection (CMV, parvovirus B19)	Positive is diagnostic
Neonatal serum (single specimen)	Rubella-specific IgM	Positive is diagnostic, although determination of status at 10–12 months is confirmatory
Sequential neonatal, infant sera over 6–12 months	All	Passive maternal antibody in uninfected infant disappears at 4–9 months for CMV (unless peri-, postnatal transmission); 8 months for *Toxoplasma gondii*; 6 months VDRL, rapid plasma reagin; 12–15 months (treponemal)
		Positive specific antibody at 8–12 months suggests congenital toxoplasmosis, parvovirus B19, rubella, VZV infection
Single maternal serum at delivery	*Toxoplasma*-specific IgM	If IgM-specific antibody positive, reference laboratory testing of maternal, infant sera and placenta
Serology of both mother and infant	All	Negative maternal serology rules out source of infection
		Serial infant serology identifies passive maternal antibody (titers fall) and active infection (titers remain the same, rise over months)
CSF culture, detection	Detection of CMV, enteroviruses, HSV, *Toxoplasma* (reference laboratory), parvovirus B19	Positive is diagnostic
	Rubella-specific IgM antibody	
	VDRL (non-bloody tap)	
Skin lesions culture, detection	If active/vesiculated at birth: herpes, enteroviruses, VZV	Positive is diagnostic
	Syphilis dark-field	
Nasopharyngeal secretions	Syphilis dark-field	Positive is diagnostic
Stool cultures	Enteroviruses	Positive is diagnostic
Placenta	Variable	May be supportive of specific pathogen

Perinatal infections

These occur as a result of ascending infection and premature rupture of the membranes or through intrapartum transmission. Their management and prevention are summarized in Table 65.17 .

Specific infections

Enterovirus

Enteroviruses are among the commonest pathogens encountered by the newborn in the first months of life. The most common symptoms are undifferentiated fever and aseptic meningitis. Pleconaril is currently being studied in a National Institutes of Health-sponsored trial and should be considered in cases of severe hepatitis or sepsis.[42] Given the likelihood that an infected infant has received no passive maternal antibody, high-dose intravenous immune globulin may be reasonable in the acutely ill infant, although efficacy has not been demonstrated.

Herpes simplex virus

Because it is the primary infection, rather than recurrent infection in pregnancy, that is a risk to the fetus, transmission cannot be eliminated despite the best obstetric care. Primary infection is characterized by cervical infection in 80% of cases, protracted shedding for a mean of 11 days and a 33% risk of transmission to the newborn if shedding occurs at delivery. Conversely, in recurrent infection, there is only a 13% risk of cervical shedding, 2–4 days of shedding and a 3% risk of transmission if

there is shedding at delivery.

Neither a positive nor a negative clinical history will predict the neonatal risk for HSV infection. Of women with no previous history of genital HSV, 0.2% will have positive genital cultures at delivery.[43] Because viral shedding at the time of delivery cannot be predicted by third trimester cultures, screening is not recommended.

Women with recurrent disease should be reassured. With a risk of asymptomatic shedding of about 2% and a transmission rate of less than 5%, the risk of neonatal infection in this situation is about 1 in 2000 births. Cesarian section is generally recommended for women with active lesions at birth or a clinical primary infection during pregnancy, particularly in the last half of gestation; infection may occur in spite of Cesarian section. Fetal scalp monitors should be avoided. Viral cultures should be obtained from the maternal cervix at birth. Infant cultures (i.e. urine, mouth, nasopharynx, stool/rectum) should be obtained at 24 hours and the child carefully observed for symptoms of neonatal HSV requiring therapy.

Herpes simplex virus commonly presents without skin lesions as neonatal sepsis or pneumonitis, with one of the earliest clues being abnormal liver enzymes. Shock, coagulopathy, fulminant hepatitis and skin lesions follow. Prematurity is extremely common, occurring in one-quarter of infected infants. Infected infants may have progressive deterioration over the first year, especially with a history of multiple episodes of recurrent skin lesions in the first 6 months. Central nervous sytem relapse is common and involvement of the CNS, not initially evident, may occur. Initial evaluation of all infants with

TABLE 65-15 -- Definitions of selected congenital infections.

DEFINITIONS OF SELECTED CONGENITAL INFECTIONS		
CMV	Confirmed	Detection of CMV in the first 2–3 weeks of life from urine, throat or other sources in newborn with one or more of:
		• Small for gestational age
		• Hematologic findings (petechiae, purpura, splenomegaly, jaundice at birth)
		• Neurologic findings (microcephaly, chorioretinitis, neurologic abnormality, intracranial calcifications, hearing impairment)
		• Laboratory findings (direct hyperbilirubinemia >3mg/dl), thrombocytopenia (platelet count <75,000/ml), liver function abnormality (alanine aminotransferase >100mg/dl)
	Possible	As for Confirmed, except viral detection only after 3 weeks of age and other diseases ruled out
HSV	Congenital	Detection of HSV within 24 hours of birth or stable positive titer over 3 months in infants with one or more of skin, eye and brain lesions
	Perinatal	Detection of HSV after 24 hours and in first 6 weeks of life further characterized by clinical and laboratory findings as one of:
		• Disseminated
		• CNS
		• Skin, eye, mouth disease (with negative CSF pcv)
Rubella	Confirmed	Defects of congenital rubella syndrome present and one or more of:
		• Virus detected
		• Positive rubella-specific IgM antibody
		• Positive infant serology after disappearance of passively transferred maternal antibodies at 3–12 months
	Compatible	Insufficient laboratory data for confirmation of diagnosis but any two complications from (a) or one from (a) and one from (b):
		(a) Cataracts or congenital glaucoma, congenital heart disease, hearing loss, pigmentary retinopathy
		(b) Purpura, splenomegaly, jaundice, radiolucent bone disease, meningoencephalitis, microcephaly, mental retardation
	Possible	Presence of some compatible clinical findings, but insufficient criteria for either the Confirmed or Compatible categories
Syphilis	Confirmed	Identification of *Treponema pallidum* in nasal or skin lesions
	Presumptive	One or more of:
		• Infant born to mother with untreated or inadequately treated syphilis
		• Treated with drug other than penicillin and/or
		• <30 days to 3 months before delivery
		• Infant has reactive treponemal test with findings of one or more of abnormal physical examination, long bone radiographs, CSF (including reactive CSF-VDRL and/or a leukocyte count of 20ml or greater or a protein concentration of 100mg/dl or greater), 4-fold higher VDRL than mother has
		• Infant has documented 4-fold rise in titers and positive treponemal test
		• Infant has reactive treponemal test that does not revert by 12–15 months
Toxoplasma gondii	Confirmed	• *Toxoplasma*-specific IgM (or if available, Sabin-Feldman Dye test >300IU) in maternal sera with infant findings of chorioretinitis, cerebral calcifications or hydrocephalus in the absence of CMV infection
		• Positive antibody in infant at 8–10 months (after disappearance of passively transferred maternal antibody) with or without clinical findings
	Compatible	• Chorioretinitis with positive *Toxoplasma*-specific antibody after 8–10 months of age
		• Cerebral calcifications and/or hydrocephalus with positive *Toxoplasma*-specific antibody after 8–10 months of age in the absence of CMV infection
Parvovirus B19		Detection of parvovirus B19 by:
		• Direct electron microscopy or nucleic acid in blood and/or tissue obtained within the first 3 weeks of life in the presence of fetal or neonatal findings of hydrops and anemia
		• Parvovirus B19-specific IgM in the first 3 weeks or persistent IgG beyond 3–12 months with either documented maternal infection or fetal/neonatal findings of hydrops/anemia or cranial calcification
Varicella		One or more of:
		• Anomalies of congenital varicella syndrome (skin, eye, limb, neurologic)
		• Acute varicella at birth with viral detection
		• Herpes zoster in the first year of life with viral detection
		• VZV-specific IgM at birth, persistent IgG to 12 months or detection of specific lymphocyte transformation in response to VZV virus antigen

suspected or confirmed HSV infection must include CSF PCR to detect subclinical CNS disease. The role of long-term oral antiviral therapy in infected infants is under study.

Empiric therapy may be indicated for the infant who is unwell, especially if liver function tests are abnormal, if surface cultures are positive after 48 hours, if the CSF is

abnormal, if there has been prolonged

TABLE 65-16 -- **Treatment of toxoplasmosis in the fetus and infant.**[*]

TREATMENT OF TOXOPLASMOSIS IN THE FETUS AND INFANT			
Manifestation of disease	**Medication**	**Dosage**	**Duration of therapy**
In pregnant women with acute toxoplasmosis	Spiramycin	1g every q8h without food	Until fetal infection documented or excluded at 18–20 weeks; if documented, in alternate months with pyrimethamine, leukovorin and sulfadiazine until term (France)
If fetal infection confirmed after week 17 of gestation or if maternal infection acquired in last few weeks of gestation	Pyrimethamine and	Loading dose: 100mg/day in two divided doses for 2 days then 50mg/day	Until term (leukovorin is continued 1 week after pyrimethamine is discontinued)
	Sulfadiazine	Loading dose: 75mg/kg per day in two divided doses (maximum 4g/day) for 2 days then 100mg/kg per day in two divided doses (maximum 4g/day)	
	Leukovorin (folinic acid)	10–20mg/day	
Congenital *Toxoplasma* infection in the infant	Pyrimethamine and	Loading dose: 2mg/kg per day for 2 days, then 1mg/kg per day for 2–6 months, then this dose every Monday, Wednesday and Friday	1 year
	Sulfadiazine and	100mg/kg per day in two divided doses	1 year
	Leukovorin	10mg 3 times a week	1 year
	Corticosteroids (prednisolone) have been used when CSF protein is =1g/dl and when active chorioretinitis threatens vision	1mg/kg per day in two divided doses	Until resolution of elevated (=1g/dl) CSF protein level or active chorioretinitis that threatens vision

TABLE 65-17 -- Preventive strategies and intrapartum management.

PREVENTIVE STRATEGIES AND INTRAPARTUM MANAGEMENT			
Micro-organism	**Clinical situation**	**Preventive management**	**Comment**
Enterovirus	Active maternal enteroviral infection (i.e. fever, abdominal pain) at delivery	Attempt to defer delivery	May allow transmission of antibody
Hepatitis B virus	Maternal HBsAg status unknown	Neonatal immunization	Many experts recommend universal neonatal immunization
HSV	Maternal lesions at delivery	Active observation of neonate for signs of infection	See detailed guidelines
			Cesarian section for active lesions or primary infection in (late) pregnancy
HIV-1	HIV-positive mother	Single or combination antiviral therapy of infant	Antenatal delivery screening and therapy is advisable
Rubella	High risk, no antenatal care, no serology at delivery	Postpartum immunization of susceptible mother before hospital discharge	Failure to immunize prior to discharge has resulted in subsequent infected neonates
VZV	Maternal lesion within 1 week before or after delivery	Varicella-zoster immune globulin ± aciclovir therapy of neonate	Post-partum immunisation of mothers known to be susceptible
Treponema pallidum	High risk, no antenatal care, no serology at delivery	Evaluation and possible therapy with follow-up of neonate	In high-risk women repeat screen in third trimester, delivery

longed rupture of the membranes or if maternal primary infection has occurred near birth.

Aciclovir therapy is prescribed at a dose of 60mg/kg per day intravenously q8h for 14–21 days.[44] While mortality is certainly reduced, morbidity remains significant. The progression of cutaneous to CNS disease can be halted by antiviral therapy in the majority of cases. Emergence of resistant organisms has been reported. Isolation of the infant with lesions is required.

Varicella-zoster virus

A neonate whose mother has developed varicella 5 days before delivery to 48 hours after delivery should receive a dose of 125U (1.25ml or 1 vial) of zoster immune globulin as soon as possible. These infants carry a 30% risk of infection without the protection of passive maternal antibody and a 30% mortality rate without antiviral therapy. Aciclovir at a dose of 1500mg/m^2 per day is used to treat symptomatic neonates,[45] with dose adjustments for liver and renal failure or prematurity.[46]
Separation of an infected and contagious mother from the child may be advisable. Isolation of the exposed hospitalized infant is required.

HIV

Over 600,000 infants worldwide are infected with HIV from their mothers each year. There is evidence for both early and late

in-utero transmission. Fetal diagnostic testing may result in iatrogenic infection of the fetus and is generally contraindicated. Elective Caesarian section can reduce the risk of transmission by half but is not yet a realistic option for poor countries. Breast-feeding is a major contributing factor in mother-to-child transmission in Africa. Prevention of transmission is achievable through antiretroviral therapy including antenatal oral zidovudine, intrapartum intravenous zidovudine and 6 weeks of oral zidovudine in the babies (see Chapter 135). Shorter courses of lamivudine with zidovudine and nevirapine alone are effective in settings where such drugs are affordable and breast-feeding is not undertaken, although antiviral resistance, particularly with nevirapine, is concerning. Transmission rates reach 35% when there is no intervention and are below 5% when antiretroviral treatment and appropriate care are available. Routine use of zidovudine in pregnancy has reduced transmission rates in the USA by between a half and two-thirds to less than 5%. A similar pattern has been seen in Europe, where the rate of transmission has fallen from 15.5% in 1994 to 2.6% after 1998. Implementing programs to prevent mother-to-child transmission has been difficult and slow in poor countries. Non-breast-fed infants of infected mothers can be accurately diagnosed by 3 months of age (see Chapter 136).[47] Future research should focus on prevention of postpartum infection and operational issues. Studies in Africa have shown a 3-fold to 4-fold increased risk of death in children whose mothers have died in the first year of life.

Hepatitis B virus

In four studies of over 33,000 pregnant women in North America, a prevalence of HBsAg carriage of 0.8% was documented; 52% of women acknowledged no known risk factors. The risk of perinatal infection is greater if the maternal infection was acquired in the third trimester (80–90% versus less than 10% in the first trimester). If HBsAg positivity is accompanied by e-antigen positivity, the neonate is both more likely to become infected (70–90% versus 20–25%) and more likely to become a chronic carrier (85% versus 5%). The strongest predictor of transmission may be maternal hepatitis B virus DNA load.

Infants of carrier mothers should receive 0.5ml hepatitis B immune globulin within 12 hours of birth and either 5mg of the Merck hepatitis B vaccine (Recombivax HB) or 10mg of the SmithKline Beecham hepatitis B vaccine (Engerix-B). The second dose of vaccine is given at 1–2 months of age and the third dose at 6 months of age. Infants born to mothers of unknown status should receive either 5mg of Recombivax HB or 10mg of Engerix-B. The second dose of vaccine is given at 1–2 months of age and the third dose at 6 months of age.

Hepatitis C virus

In 20 studies the risk of perinatal transmission of hepatitis C virus was 14%, being 21% in infants born to HIV-infected mothers (65 out of 309), 10% in infants born to HIV-negative mothers (50 out of 495), 14% in those born to hepatitis C virus RNA-positive mothers and 2% in those born to hepatitis C virus RNA-negative mothers (Delages G, personal communication).

Group B streptococcus

Of the 10–35% of women asymptomatically carrying group B streptococcus, 50% of their infants will be colonized on their skin and mucous membranes. Of those colonized, 1–2% will develop early-onset disease. Two alternative approaches (i.e., screening, risk factor identification) to the prevention of group B streptococcal disease have been developed in the USA with a 70% reduction in

TABLE 65-18 -- Women with limited or no antenatal care.

WOMEN WITH LIMITED OR NO ANTENATAL CARE	
Mother	• Genital examination for findings suggestive of sexually transmitted diseases
	• Cultures for *Chlamydia trachomatis*, *N. gonorrhoeae*
	• Serologic testing for HBsAg, hepatitis C virus, HIV, syphilis (nontreponemal and treponemal testing), rubella
	• Adequate follow-up
Infant	• Prophylactic eye care
	• Serologic testing for HBsAg, hepatitis C virus, HIV, syphilis (nontreponemal and treponemal testing)
	• First dose of hepatitis B vaccine
	• Adequate follow-up

the incidence of early-onset disease.[48] According to the more effective screening-based approach, all pregnant women should be screened at 35–37 weeks' gestation for anogenital group B streptococcus colonization. Intrapartum antibiotics are offered to all culture-positive women, regardless of risk factors. If the results of cultures are not known at the time of labor, intrapartum antibiotics are used in the presence of risk factors, which include the following: less than 37 weeks' gestation; more than 18 hours of membrane rupture; and temperature higher than 100.4°F (38°C). Also, infants born to women with a previously infected infant and women with group B streptococcus bacteriuria during pregnancy or postpartum GBS sepsis are treated with intrapartum antibiotics (see Chapter 66.c). In geographic regions with differing epidemiologic data, this approach is not appropriate.

Absence of antenatal care

For women in whom there has been inadequate antenatal care, detection of infection is required at delivery, as summarized in Table 65.18 .

Breast-feeding

Breast-feeding during an active infection

Contaminated milk has been implicated in neonatal infection with *Staphylococcus aureus*, group B streptococci, *Mycobacterium* spp. and possibly *Salmonella* spp.

Although viral contamination of milk by rubella, HSV, hepatitis B virus and CMV has been reported, serious sequelae have not generally occurred. Mothers with herpetic lesions on their breasts should refrain from breast-feeding. They should cover other active lesions and wash their hands before breast-feeding.

Breast-feeding is estimated to confer an additional risk of 14% over transmission of HIV-1 in utero or at delivery (see Chapter 135).[47]

Breast-feeding and drug therapy

The American Academy of Pediatrics recommends that breast-feeding be discontinued while a nursing mother is being treated with metronidazole and warns about the use of nitrofurantoin and sulfa drugs, which can cause hemolysis in glucose-6-phosphatase-deficient infants.[49] Although it would be unusual for an effective maternal medication to be contraindicated because of risks to the infant through breast milk, physicians should be aware of information specific to agents being used. Frequent feeding exposes the infant to more drug than feeding at 4-hour intervals. Mothers can be encouraged to avoid frequent feedings to reduce drug exposure and the consequent changes in the infant's gastrointestinal flora and risk of oropharyngeal candidiasis.

Chapter 66 - Practice Points

66.a Management of an HIV-positive pregnant woman who has a positive VDRL test from an area endemic for *Treponema* infection

Juan C Salazar
Justin D Radolf

Introduction

The dual epidemics of venereal syphilis (*Treponema pallidum* subsp. *pallidum*) and HIV are responsible for increasing tolls of morbidity and mortality among pregnant women and their offspring. Syphilis and HIV infection are closely interrelated. As sexually transmitted diseases, each poses a risk for the other, and there is now substantial evidence that genital ulcerative diseases, including syphilitic chancres, facilitate the bidirectional transmission of HIV-1. Although a simple screening test for syphilis and effective antibiotics are available, the disease remains uncontrolled in resource-scarce regions where antenatal testing and treatment are not always accessible. Moreover, in many of these countries, the endemic (i.e. nonvenereal) treponematoses yaws, endemic syphilis and pinta, caused by *T. pallidum* subsp. *pertenue*, *T. pallidum* subsp. *endemicum* and *T. carateum*, respectively, have not only not been eliminated but are resurging in some places because of the breakdown of once successful control programs. In the pregnant female, regardless of HIV infection status, untreated syphilis poses a grave risk to the fetus or neonate on top of whatever morbidity, acute or chronic, it may inflict upon the mother. The possibility of infection with a nonvenereal treponematosis in such individuals poses a further diagnostic challenge inasmuch as it is impossible to distinguish these infections from venereal syphilis using currently available serologic tests. Health care professionals managing patients residing in or emigrating from areas endemic for the nonvenereal treponematoses need to be aware of the clinical and epidemiologic features that distinguish these diseases from venereal syphilis. They also need to know how HIV co-infection may influence the management and outcome of syphilis in pregnant women and their offspring (Table 66a.1).

Clinical features

A detailed discussion of the clinical features of the treponematoses is beyond the scope of this commentary (see Chapter 75 , Chapter 156 and Chapter 230); the salient clinical features of these diseases, however, are summarized in Table 66a.1 . Treponemal infections are divided into early (i.e. primary, secondary and early latent) and late (i.e. late latent and tertiary) stages. Early lesions, as well as blood and exudative body fluids, are infectious. Primary lesions of venereal syphilis (chancres) occur usually in the anogenital area of sexually active individuals; a substantially greater proportion of heterosexual men present with genital ulcers than women and gay men. By contrast, acquisition of nonvenereal treponematoses occurs earlier in life, usually in childhood, with primary lesions often occurring on an extremity. Although anecdotal reports indicate that syphilis manifestations in HIV-infected patients may be florid and/or predispose to central nervous system complications, the manifestations of syphilis in most HIV-infected patients appear to be essentially the same as in HIV-uninfected patients. No studies are available on the impact of HIV infection on the course or severity of the nonvenereal treponematoses. With both venereal and nonvenereal treponematoses, mucocutaneous lesions are the most common form of secondary disease; extracutaneous manifestations, occasionally severe, can occur in secondary syphilis (nonvenereal as well as venereal) and yaws. The gummatous lesions of late yaws can be extremely destructive. Venereal syphilis is the only treponematosis that involves the central nervous system or that causes congenital infection.

Serodiagnostic tests

Visualization of spirochetes in lesion exudate by darkfield examination is the definitive method for diagnosing primary treponemal infection. A presumptive diagnosis is possible with the use of nontreponemal and treponemal serologic tests. The nontreponemal tests (NTTs), represented by the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test, detect antibodies to a defined mixture of cardiolipin, lecithin and cholesterol. These tests have traditionally been designated as 'nontreponemal' based upon the belief that lipoidal antigens of host origin induce the antibodies being detected. Nontreponemal tests are used to screen for syphilis because they are easy to perform and have reasonably high sensitivity. Because they are titratable and usually decline in parallel with disease activity, they are also used to monitor the response to therapy. Falsely reactive NTTs are usually of low titer (<1:8) and may occur in a variety of conditions (see Chapter 75). Although pregnancy

TABLE 66.a-1 -- Overview of treponemal infections.

OVERVIEW OF TREPONEMAL INFECTIONS						
Disease	**Organism**	**Endemic areas**	**Primary lesion**	**Secondary lesions**	**Tertiary lesions**	**Congenital infection**
Venereal syphilis	*Treponema pallidum* subsp. *pallidum*	Worldwide	Chancre, usually in anogenital region	Mucocutaneous lesions (condyloma lata, papules, macules or maculopapules)	Gummas, including	Yes
				Visceral involvement	CNS	
				Central nervous system (CNS) involvement (usually) aseptic meningitis)	Carditis/aortitis	
					Neurosyphilis (meningovascular, tabes, paresis)	
Yaws	*Treponema pallidum* subsp. *pertenue*	Rural areas of Africa, Central and South America, the Caribbean, equatorial islands of South East Asia and remote parts of India and Thailand	Papule	Diffuse papules, papillomas and ulcers	Destructive gummas of skin and bone	No
			Papilloma	Osteitis		
			Ulcer, usually on an extremity	Dactylitis		
Pinta	*Treponema carateum*	Underdeveloped rural areas of Mexico and northern South America	Erythematous papule, usually on an extremity	Scaly papules	Areas of altered skin pigmentation	No
				Areas of altered skin pigmentation	Hyperkeratosis	
Endemic bejel	*Treponema pallidum* subsp. *endemicum*	West Africa, small foci in Zimbawe, Botswana, Arabian peninsula and central Australia	Oral mucosal ulcer	Oral and pharyngeal ulcers	Gummas of skin, bone and joints	No
				Mucous patches		
				Condyloma lata		
				Periostitis		

is a recognized cause of a falsely reactive NTT, one must exercise great caution in labelling a reactive NTT in a pregnant patient as a false-positive result.

The second type of serodiagnostic test, represented by the fluorescent treponemal antibody-absorption test and the microhemagglutination *T. pallidum* treponemal tests (MHA-TP), detects antibodies directed against *T. pallidum* antigens and hence is designated as 'treponemal'. Treponemal tests are used to confirm that reactivity in a NTT is indeed due to syphilitic infection. Because they are more difficult and expensive to perform than NTTs, treponemal tests may not always be available in underdeveloped countries. Molecularly based efforts to design serodiagnostic tests capable of distinguishing venereal syphilis from the nonvenereal treponematoses, principally yaws, have thus far been unsuccessful. It is hoped that the availability of the genomic sequence for *T. pallidum* and, eventually, those of other pathogenic treponemes may enable investigators to identify polymorphisms that can be exploited for developing disease-specific serodiagnostic or polymerase chain reaction (PCR)-based tests.

Both treponemal and nontreponemal serologic tests are generally reliable for the diagnosis and management of syphilis in patients co-infected with HIV. However, HIV-infected syphilis patients may on occasion show higher than expected NTT titers, false-negative treponemal or nontreponemal tests, or delayed seroreactivity. When serologic tests and clinical syndromes suggestive of early syphilis do not correspond, alternative tests such as biopsy of suspicious lesions should be performed. When available, lesions also can be analyzed by PCR for the presence of *T. pallidum* DNA. As with serologic tests, the PCR tests in widespread usage cannot distinguish between the pathogenic treponemes.

Syphilis testing during pregnancy

It is estimated that, of all pregnant women who have untreated syphilis, only 20% will both carry the fetus to term and deliver a normal child. Complications include stillbirth (30%), neonatal death (10%) and mental handicap (40%). Because of the seriousness of these complications, pregnant women should be screened serologically for syphilis early in pregnancy. For communities and populations

TABLE 66.a-2 -- Treatment of syphilis during pregnancy in HIV-infected women.

TREATMENT OF SYPHILIS DURING PREGNANCY IN HIV-INFECTED WOMEN	
Primary or secondary syphilis	Benzathine penicillin G 2.4 megaunits im (single dose)
Early latent syphilis	Benzathine penicillin G 2.4 megaunits im (single dose)
Late latent syphilis or latent syphilis of unknown duration	Benzathine penicillin G 7.2 megaunits in three doses each of 2.4 megaunits im at 1-week intervals
Tertiary syphilis	Benzathine penicillin G 7.2 megaunits in three doses each of 2.4 megaunits im at 1- week intervals
Neurosyphilis	Aqueous crystallin penicillin G 18–24 megaunits a day administered as 3–4 megaunits iv q4h for 10–14 days

in which the prevalence of syphilis is high or for patients at high risk, serologic testing should be performed twice during the first trimester, at 28 weeks gestation and at delivery. Pregnant women who are seropositive but who lack clinical manifestations should be considered to be infected unless an adequate treatment history is clearly documented and sequential serologic antibody titers have declined appropriately. Given the inability of serodiagnostic tests to distinguish between venereal and nonvenereal treponematoses, syphilis should be the presumed diagnosis in asymptomatic, seropositive patients unless a diagnosis of nonvenereal treponematosis can be established unequivocally (see Table 66a.1).

Treatment

Penicillin is the antimicrobial of choice in the treatment of syphilis during pregnancy (Table 66a.2). Treatment during pregnancy should consist of the penicillin regimen appropriate for the stage of syphilis. Some specialists recommend a second dose of benzathine penicillin

2.4 million units intramuscularly, 1 week after the initial dose. The present consensus is that alternative regimens are potentially too harmful to the fetus (e.g. tetracycline), lack efficacy because of the inability of the drug to cross the placenta (e.g. erythromycin) or are insufficiently studied (e.g. ceftriaxone). The current Centers for Disease Control and Prevention guidelines remind the practitioner of the importance of evaluating the HIV-infected patient both clinically and serologically for treatment failure. This is accomplished by blood draws at 3, 6, 9, 12 and 24 months after the course of therapy has been finished. The guidelines go on to suggest considering cerebrospinal fluid examination approximately 6 months after treatment, emphasizing that this is of unproven benefit. The treatment regimens for nonvenereal treponematoses are the same as those used for the comparable stage of venereal syphilis.

Because penicillin is clearly the preferred treatment, penicillin skin testing is recommended for reportedly penicillin-allergic pregnant women who have syphilis. If the penicillin allergy is confirmed, desensitization can be accomplished using incremental doses of oral penicillin V over 4–6 hours. A Jarisch-Herxheimer reaction, which presents with fever, headache and myalgia, can occur within hours of initiation of penicillin therapy in early syphilis. Women treated for syphilis during the second half of pregnancy may also experience self-limiting uterine contractions, decreased fetal activity and fetal heart rate abnormalities after penicillin treatment, but premature labor or fetal distress is rare. Women should be warned of the symptoms of the Jarisch-Herxheimer reaction and be instructed to use acetaminophen (paracetamol) to control these symptoms and to self-monitor uterine and fetal activity during the first 48 hours after penicillin therapy. In the second half of pregnancy, management and counseling may be facilitated by a fetal ultrasound but this should not delay therapy. Ultrasound signs of fetal syphilis (hepatomegaly, hydrops fetalis) indicate a greater risk to fetal health; such cases should be managed in consultation with specialists in high-risk obstetrics.

66.b Treatment of a positive *Toxoplasma* titer in pregnancy

William R Bowie

Introduction

Clinically recognized toxoplasmosis is infrequent, but serologic evidence of toxoplasmosis is common. In immunologically competent people, even symptomatic toxoplasmosis is usually of minimal clinical significance. The exception is when symptomatic or asymptomatic infection is acquired just before or during pregnancy. *Toxoplasma gondi*ı readily crosses the placenta to infect the fetus, with immense clinical and financial implications. It is estimated that in North America, approximately one pregnancy in 1000 is affected, with higher reported rates in Europe. Although definitive proof is lacking, because early treatment of the mother has been thought to decrease the risk of infection of the fetus and diminish the sequelae in infected fetuses, appropriate management of the mother is essential.

Because most infected women are either asymptomatic or have non-specific and transient symptoms, the diagnosis is rarely made clinically. Rather, the health care provider and the woman are typically faced with a positive serologic test without clear information on when the infection was acquired. 'Positive' serology with routine tests does not reliably determine the acuteness of infection, which is what determines the management. Inappropriate response may result in unwarranted psychologic distress, unnecessary evaluations and treatments, and even unnecessary termination of pregnancy. At least in the USA, a recent study of obstetricians and gynecologists revealed that few were aware that 'positive' IgM antibody did not necessarily indicate acute infection, or that the US Food and Drug Administration had sent out an advisory about this problem with serologic tests for toxoplasmosis.

Pathogenesis

The definitive hosts of *T. gondii* are felines, and people are infected by direct or indirect contact with oocysts excreted by cats. Oocysts, spread for example in cat litter or soil or sand contaminated by cat feces, are highly infective. When ingested by animals or humans, they ultimately result in cysts in tissues. These also infect humans when uncooked or inadequately cooked meat containing viable cysts are ingested. Rarely, humans can also be infected by blood transfusions (see Chapter 65 and Chapter 245).

During acute infection of humans, toxoplasmosis is disseminated widely. Infection acquired immediately before conception or during pregnancy carries with it the risk of spread to the fetus. The risk of transmission is lowest in the first trimester (10–15%), but the consequences then are the most devastating (severe disease or death). By the second trimester, there is 25–40% transmission, with usually nonfatal sequelae. By the third trimester, over 60% of fetuses are infected, with typically mild or asymptomatic manifestations.

The classic triad of clinical features in severely infected infants who survive includes hydrocephalus, intracranial calcifications and chorioretinitis. Asymptomatically infected infants are typically not recognized at birth, but many if not most are thought to be at risk of subsequently developing chorioretinitis, hearing loss or subtle neurologic manifestations.

The economic impact of congenital toxoplasmosis is substantial, and screening programs to detect infection in pregnancy or at birth have been considered. In the USA, routine screening for toxoplasmosis in pregnancy is rarely recommended, but in some other countries screening is repeated serially in pregnancy, particularly in France.

Investigation

The focus of this Practice Point is on immunocompetent pregnant women who have had a 'positive' test for antibody to *T. gondii*. This will usually have been performed as a screening test rather than a diagnostic one. Depending on the laboratory, this will be either a positive IgG titer, or possibly a positive titer for both IgG and IgM.

Unless timing was fortuitous, even with repetition titers are likely to be stable rather than rising or falling.

Difficulties in interpretation of serologic results

There are several substantial problems in the interpretation of results.

- First, there are problems with sensitivity, and more frequently specificity of many of the commercially available tests.
- Second, potential markers of acuteness of infection, such as IgM and IgA, may persist long after the risk of transmission to the fetus ends, so that although positive IgM and IgA results may be true-positive results, they do not by themselves establish acuteness of infection. Thus, when the IgM is reported as being 'positive', it can be a false positive (with the rate of false positives dependent on the test and the laboratory), a true positive indicative of recent infection or a true positive but simply reflecting persistence of IgM antibody.
- Third, history and physical examination only rarely aid in the ascertainment of determination of the acuteness of infection.

*Negative anti-*Toxoplasma gondii *IgG and IgM*

Unless it is very early in infection, negative anti-*Toxoplasma gondi*ı IgG and IgM indicates absence of previous infection. Women with such results are susceptible to infection. Primary prevention messages should be strongly reinforced. Subsequent repeat testing is required if one wishes to exclude infection later on in the pregnancy.

IgG titer only available, and is positive

An IgM test should be requested on the same or a new serum specimen because a single positive IgG titer provides no information about acuteness of infection. The presence of IgG antibody with a negative IgM antibody excludes recent infection. If performed early in pregnancy, no further investigation is required for toxoplasmosis. If performed late in pregnancy, there is an outside possibility that acute infection may have arisen in pregnancy, with subsequent disappearance of IgM. Because of long-term persistence of IgM this is unlikely, but if there is any clinical concern of toxoplasmosis then the infant should be screened at birth.

Initial negative IgG titer with positive or equivocal IgM titer

When the IgG titer is negative, it is highly likely that the IgM titer is falsely positive. However, because the woman could be in the process of seroconverting, testing should be repeated in parallel on a second sample that is collected approximately 3 weeks after the first. If the IgG titer remains negative, then the result is probably falsely positive. Unless there are other features suggesting active infection, no further investigation is needed. Recent acquisition of infection is strongly suggested if the IgG titer becomes positive or there is a significant increase in the IgM titer.

Initial or subsequent positive IgG titer, and IgM titer is positive

Unless there is seroconversion or a significant increase in titers, interpretation at this stage is much more difficult because this information by itself does not establish acuteness of infection. This requires further clinical assessment and serologic and other studies in the mother and potentially in the fetus.

History and examination of the mother

Although symptoms are usually absent or so non-specific as to be unhelpful, a careful history and examination might detect symptoms that provide a clue to the onset of the disease. Most helpful would be development of lymphadenopathy, typically involving one node or a few nodes. A physical examination should be performed, looking in particular for abnormal lymphadenopathy and ocular disease.

Serologic studies in the mother

Pregnant women are often screened for a variety of processes (e.g. rubella, HIV), and this serum might have been stored. If available, prior stored serum should be tested for antibody to *T. gondii*. The results may be very helpful in determining the chronicity of infection.

Additional testing is required on available or newly acquired serum. If repeat testing on specimens run in parallel (that is, testing is performed on all specimens at the same time) shows or has shown seroconversion or a 4-fold or greater rise, then infection is acute. Usually titers are stable, and further testing is required in specialized or reference laboratories. A battery of tests is usually performed to assess acuteness of infection. Results should be interpreted in consultation with the reference laboratory. The two tests most often employed to assess acuteness of infection are IgG avidity and differential agglutination testing, but numerous other tests may be used by reference laboratories. If these additional results are consistent with acute infection or if they do not exclude acute infection, the woman should be managed as below.

Management

Studies diagnostic of or consistent with acute infection in pregnancy or immediately before conception

Management is in part determined by the time when infection was acquired. If results are consistent with infection immediately before or just after conception, the risk of delivering an infected baby is low. Either the fetus is not infected or if the fetus is infected it is likely to abort. When infection occurs later, the risk of having a viable but affected infant is much greater.

The mother should immediately be started on treatment (see below) for the duration of pregnancy and the fetus should be assessed by ultrasound. Amniocentesis for polymerase chain reaction (PCR) should be strongly considered.

Fetal ultrasound may show features consistent with infection, especially increased size of the ventricles. Negative studies do not exclude fetal involvement and studies may need to be performed serially.

With or without fetal abnormalities, amniocentesis should be considered at 18 weeks or later. If performed, as a minimum the amniotic fluid should be tested by PCR. Reference laboratories may do additional testing on amniotic fluid, such as mouse or cell culture inoculation. Although PCR can be falsely positive or falsely negative, if it is positive treatment of the mother should be switched to pyrimethamine and sulfadiazine.

Some authorities also sample fetal blood to detect the parasite or a fetal immunologic response, but PCR on amniotic fluid is probably safer.

Treatment of the mother

Initial treatment is with spiramycin 1g orally q8h. Spiramycin reduces the incidence and severity of fetal infection, but when the fetus is known to be infected, pyrimethamine and sulfonamides are more active than spiramycin. Hence, ultrasound or amniotic fluid findings suggestive of fetal involvement should prompt a change of treatment to pyrimethamine and a sulfonamide. A variety of dosage regimens have been used, but currently suggested is pyrimethamine 25mg/day and sulfadiazine 2g orally q12h, with supplemental folinic acid 5mg/day. When treatment of the mother is initiated, it should be continued for the duration of the pregnancy.

Spiramycin is a macrolide with possible adverse reactions including nausea, vomiting, anorexia and diarrhea. Sulfadiazine has typical adverse reactions associated with sulfonamides, including concerns of kernicterus. The major adverse reaction to pyrimethamine is dose-related bone marrow suppression. To assess hematologic abnormalities, testing is recommended at least once weekly to detect anemia, leukopenia and thrombocytopenia.

Although other drugs have been used to treat toxoplasmosis, there is minimal experience with them in the context of pregnancy and fetal infection.

Termination of pregnancy

Many women with 'positive' serology for toxoplasmosis have had inappropriate termination of pregnancy. Positive IgG and IgM serology is not of itself an indication for termination. Most of these women will not have infected fetuses, but even if the fetus is infected, with appropriate long-term treatment the infants often do well. Termination should only be considered when there is documented evidence of fetal involvement, especially if infection was acquired early in the first trimester. However, even most of these infants who survive have done well with treatment of the mother followed by treatment of the infant.

Initial management of the infant at birth

If there is any question about the possibility of fetal acquisition of toxoplasmosis, the infant should be evaluated, including by one or a series of serologic tests. If clinical, serologic or other testing suggests congenital toxoplasmosis, the infant should be treated for 1 year. On this treatment, even infants who have clinically apparent manifestations such as intracranial calcifications, meningitis or chorioretinitis are highly likely to have a favorable outcome.

HIV infection and toxoplasmosis in pregnancy

In contrast to immunocompetent women, women who have HIV infection whose antibody to *T. gondii* is IgG positive and IgM negative are at risk of transmitting HIV to the fetus. Appropriate management is unclear. Important variables probably include the degree of immunosuppression, concurrent *Pneumocystis carinii* prophylaxis with trimethroprim-sulfamethoxazole (co-trimoxazole), *Mycobacterium avium-intracellulare* treatment or prophylaxis with macrolides, *T. gondii* treatment or suppression, and infection acquired in pregnancy. Acute infection with *T. gondii* in pregnancy should be managed aggressively, probably with pyrimethamine and sulfadiazine, whether or not there is objective evidence of fetal involvement (see Chapter 134).

Other considerations

Pregnant women who have possible or proven toxoplasmosis are likely to feel guilty that they did something that put their fetus at risk. It is prudent for women who are or might be pregnant to avoid direct or indirect contact with cats or raw or inadequately cooked meat. However, most people with toxoplasmosis are totally unaware of when or how they became infected. Care should be taken to avoid adding guilt to the stress that women who have 'positive' serology undergo.

66.C A pregnant patient with a previous pregnancy complicated by group B streptococcal disease in the infant

Upton Allen

Introduction

The group B streptococcus (GBS, *Streptococcus agalactiae*) remains an important cause of invasive disease in neonates and pregnant women. Among neonates, premature infants are at greatest risk of an adverse outcome from GBS infection. These premature infants account for 25% of the cases of GBS disease among neonates. In these infants, the disease manifests itself as an early-onset form (<7 days after birth) and a late-onset form (=7 days after birth). Disease among infants usually presents as bacteremia, pneumonia and meningitis. However, they may experience other syndromes, including soft tissue and bone infection. The mortality rate ranges from 5% to 10% and from 2% to 6% for early-onset and late-onset disease, respectively. However, higher mortality rates have been documented in pre-term and low-birth-weight infants. Improvements in survival rates in recent years have been attributed to advances in neonatal care.

Epidemiology

The organism colonizes the gastrointestinal tract of humans, with the genitourinary tract being the most common site for secondary spread. Colonization rates vary widely among different ethnic groups, geographic areas and age groups. These rates generally indicate that 10–30% of pregnant women have vaginal or rectal colonization with GBS. Approximately 1–2% of all infants born to colonized women develop early-onset GBS disease. Data from a multistate population-based study in the USA indicate that early-onset disease accounts for about 80% of neonatal GBS disease.

The incidence of early-onset disease is higher in babies born to women less than 20 years of age and in those who are of black race in the USA. Intrapartum risk factors include premature onset of labor (<37 weeks gestation), prolonged rupture of membranes (=18 hours) and intrapartum fever (<100.4°F/38°C). Additional risk factors include heavy vaginal colonization with GBS, previous

delivery of an infant who had GBS disease and the presence of low maternal levels of anti-GBS capsular antibody. Women who have GBS bacteriuria are at an increased risk of delivering an infected baby who has early-onset disease. This is related in part to the fact that women who have GBS bacteriuria are usually heavily colonized with GBS. Bacteriuria caused by GBS is associated with an increased risk of pre-term labor.

Microbiology

Group B streptococci are represented by several serotypes, including Ia, Ib, II, III, V–VIII. All serotypes may cause disease in humans but serotype III is the main cause of early-onset meningitis as well as of late-onset GBS disease among neonates.

In the determination of the GBS carrier status of a pregnant woman, culture techniques that maximize the recovery of GBS are essential. The optimal method for GBS screening involves collection of a single vaginal-anorectal swab or two separate swabs from the vagina and rectum. Swabs should be placed in a transport medium if the bacteriology laboratory is off-site and subcultured on to selective broth medium. After overnight incubation, the specimen is subcultured on to solid blood agar. Slide agglutination tests or other tests used to detect GBS antigen may be used to enable specific identification of GBS.

Prevention

Although research is being carried out to develop vaccines that could be administered to pregnant women to prevent GBS disease in neonates, this modality has not yet evolved as a preventive strategy. However, chemoprophylaxis has evolved as a useful preventive strategy. In this regard, because the majority of newborns who have GBS disease acquire infection in utero, the administration of antibiotics to neonates (postnatal prophylaxis) will not prevent the majority of GBS disease. Intrapartum chemoprophylaxis (administration of antibiotic during labor) has the potential of preventing neonatal as well as maternal GBS disease.

Guidelines on intrapartum chemoprophylaxis have been established by various groups. However, it should be noted that some countries do not have specific recommendations for prophylaxis against GBS disease. Guidelines are based on the collective evidence showing a beneficial effect of intrapartum prophylaxis in preventing early-onset GBS sepsis. The most widely accepted recommendations are those proposed by the US Centers for Disease Control and Prevention. Based on these recommendations, the following summary points can be made.

- ¦ Obstetric practitioners, in conjunction with supporting laboratories and labor and delivery facilities, should adopt a strategy for the prevention of early-onset GBS disease.
- ¦ Intrapartum chemoprophylaxis is recommended for women with GBS bacteriuria. Such women are usually heavily colonized with GBS. Women who have symptomatic or asymptomatic GBS urinary tract infections in pregnancy should be managed according to curent standards of care for urinary tract infections in pregnancy.
- ¦ Women who have previously given birth to an infant who had GBS disease should receive intrapartum chemoprophylaxis; prenatal screening is not necessary for these women.

In 1996, it was suggested that two approaches were appropriate for prevention of GBS disease, pending the availability of additional data: a screening-based and a risk-factor-based approach. As shown in Table 66c.1 , in the screening-based strategy, in which women are cultured at 35–37 weeks gestation and intrapartum antimicrobial prophylaxis is offered to those who have pre-term deliveries and all GBS carriers, theoretical modelling suggested that an estimated 86% of GBS disease could be prevented. The trade-off was that proportionately more women would have received antibiotics (26.7%) compared with a risk-factor-based approach (18.3%). Currently, revised

TABLE 66.C-1 -- Estimated impact of group B streptococcal prevention strategies.*

ESTIMATED IMPACT OF GROUP B STREPTOCOCCAL PREVENTION STRATEGIES.		
Strategy	**Early onset GBS disease prevented (%)**	**Deliveries receiving IAP (%)**
Recommended screening-based strategy: culture at 35–37 weeks; IAP for pre-term deliveries and all GBS carriers	86.0	26.7
Recommended risk-factor-based strategy: no prenatal cultures; IAP for all women who have intrapartum risk factors	68.8	18.3
Previous strategy recommended by the American Academy of Pediatrics: culture at 26–28 weeks; IAP for GBS carriers who develop risk factors	50.7	3.4
Boyer and Gotoff (1985) found that the proportion of deliveries among women who had positive prenatal cultures and who went on to develop intrapartum risk factors was 4.6%. IAP, intrapartum antimicrobial prophylaxis.		

** The figures are derived from the Centers for Disease Control and Prevention (1996) and Rouse et al. (1994).*

guidelines suggest that the former strategy is more effective and should be preferred. In order to put these revised guidelines in context, the 1996 guidelines are briefly summarized.

Screening-based approach

All pregnant women should be screened at 35–37 weeks gestation for anogenital GBS colonization. Patients should be informed of the screening results and of the potential benefits and risks of intrapartum antimicrobial prophylaxis for GBS carriers. Information systems should be developed and monitored to ensure that prenatal culture results are available at the time and place of delivery. Intrapartum prophylaxis should be offered to all pregnant women identified as GBS carriers by culture at 35–37 weeks gestation.

If the result of GBS culture is not known at the time of labor, intrapartum antimicrobial prophylaxis should be administered if one of the following risk factors is present:

- <37 weeks gestation;
- duration of membranes ruptured =18 hours; or
- body temperature =100.4°F (=38°C).

Culture techniques that maximize the likelihood of GBS recovery should be used. Because lower vaginal and rectal cultures are recommended, cultures should not be collected by speculum examination.

Laboratories should report results to both the anticipated site of delivery and the health care provider who ordered the test. Ideally, laboratories that perform GBS cultures will ensure that clinicians have continuous access to culture results

Risk-factor-based approach

A prophylaxis strategy based on the presence of intrapartum risk factors alone (e.g. <37 weeks gestation, duration of membrane rupture =18 hours or temperature =100.4°F/38°C) was considered as an acceptable alternative. However, in the revised guidelines below, the risk-factor-based approach is now considered to be inferior to the screening-based approach.

Women who have previously delivered a GBS-affected newborn and those who have GBS bacteriuria in pregnancy quality for prophylaxis regardless of their colonization status.

Revision of group B streptococcus prophylaxis guidelines, 2002

Data generated in the USA have suggested that the theoretical models are correct in indicating that the screening-based strategy is more effective than the risk-factor-based strategy. The revised recommendations suggest that all pregnant women should be screened at 35–37 weeks gestation for vaginorectal colonization. At the time of labor or rupture of membranes, intrapartum antimicrobial prophylaxis should be offered to all women identified as GBS carriers. If the results of cultures are not known at the time of labor, the risk-factor-based strategy becomes the default option.

If the results of GBS culture are not available and women present with onset of labour or rupture of membranes prior to 37 weeks gestation with a substantial risk of preterm delivery, intrapartum prophylaxis should be provided pending culture results.

As with previous guidelines, prophylaxis is recommended for women with GBS bacteriuria and those who have previously delivered an infant with invasive GBS disease, regardless of colonization status. Thus, screening at 35–37 weeks is not necessary for these women.

Figure 66.C-1 Management of neonates whose mothers received IAP. The flow chart summarizes the management of neonates born to mothers who have received IAP for early-onset GBS-disease (2002 revision). Full diagnostic evaluation includes full blood count and differential white cell count, blood culture and chest radiograph. A lumbar puncture is performed at the discretion of the clinician. Limited evaluation includes full blood count and differential white cell count plus blood culture. The duration of IAP stated applies only to penicillin, ampicillin and cefazolin prophylaxis.

Women who are colonized and have a planned cesarean section prior to rupture of membranes and the onset of labor do not warrant routine prophylaxis. These women are felt to be at an extremely low risk of delivering an infant who has early-onset GBS.

The recommendations for the prevention of GBS disease are accompanied by a suggested approach to the management of neonates born to mothers who have received intrapartum antimicrobial prophylaxis (Fig. 66c.1). This approach is based on the gestation age of the neonate, the presence or absence of symptoms and signs of sepsis and whether sufficient time has elapsed between intrapartum antimicrobial prophylaxis and delivery. Antibiotics must be administered at least 4 hours prior to delivery to allow for adequate antibiotic levels in amniotic fluid.

Management of a pregnant woman with a previous affected newborn

A woman who has lost an infant as a result of GBS disease requires the usual understanding and support given to any woman who has lost an infant during the neonatal period. Intrapartum prophylaxis is recommended regardless of screening cultures because of the previous delivery of a baby who had GBS disease. Routine vaginal-rectal screening for GBS is not necessary in this setting. However, it would be appropriate to obtain urine cultures at different antenatal visits to determine whether GBS bacteriuria is present.

Penicillin G (5 megaunits intravenously initially followed by 2.5 megaunits intravenously q4h) should be given until delivery. Ampicillin (2g intravenously initially and then 1g intravenously q4h until delivery) is an acceptable alternative. Penicillin G is preferred because it has a narrow spectrum and is thus potentially less likely to select out resistant bacteria. Women who are allergic to penicillin should receive clindamycin or erythromycin if they are considered to be at high risk of anaphylaxis. If they are thought to be at low-risk for anaphylaxis, cefazolin is recommended. Vancomycin should be reserved in women who are penicillin-allergic, but are unable to receive clindamycin due to drug resistance (Table 66c.2).

Group B streptococci are associated with various complications during pregnancy. These include septic abortion, urinary tract infections, chorioamnionitis, wound infection and endometritis. Although intrapartum antimicrobial prophylaxis may have a beneficial effect on endometritis, an assessment is necessary in the immediate postpartum period in order to guide further antibiotic therapy directed at the mother.

The newborn infant of a mother who has received intrapartum prophylaxis requires a special management approach. The approach outlined in Figure 66c.1 may be used as a guide to the management of neonate. However, if the infant is believed to have invasive GBS disease, the following apply.

- Penicillin G or ampicillin plus an aminoglycoside is the initial treatment. Penicillin G may be given alone when GBS is proved to

be the etiologic agent and clinical and microbiologic responses have been documented.
- In cases of meningitis, a second lumbar puncture at 24 hours after the start of treatment is recommended by some experts; this may have prognostic significance.
- Bacteremia without a defined focus should be treated for a minimum of 10 days.
- Uncomplicated meningitis should be treated for 14–21 days (longer periods of treatment are needed in infants who have complicated courses).

¦ Osteomyelitis should be treated for a minimum of 4 weeks.
¦ There is a high incidence of co-infection among twins, and the twin of an index case should be observed or evaluated for sepsis as clinically indicated.

TABLE 66.C-2 -- Alternative antibiotic regimens for intrapartum antimicrobial prophylaxis.

ALTERNATIVE ANTIBIOTIC REGIMENS FOR INTRAPARTUM ANTIMICROBIAL PROPHYLAXIS	
Drugs	**Doses**
Penicillin	5 megaunits iv load, then 2.5 megaunits iv q4h
Ampicillin	2g iv load, then 1g iv q4h
Cefazolin	2g iv load, then 1g iv q8h
Clindamycin	900mg iv q8h
Erythromycin	500mg iv q6h
Vancomycin	2g iv load, then 1g iv q12h

66.d Managing the pregnant woman exposed to or developing varicella

Barbara Law

Definition of the problem

The lifetime risk of becoming infected with varicella-zoster virus (VZV) is 95%. From 80% to 95% of infections occur before the age of 15 years with the highest rates among toddlers and primary school children. In temperate climates maternal chickenpox occurs 0.6–3 times per 1000 pregnancies giving rise to potentially serious consequences for both the mother and infant including:

- severe maternal disease complicated by potentially fatal pneumonitis;
- intrauterine infection resulting in fetal death, a characteristic fetal varicella syndrome or premature onset of labour; and
- if maternal infection onsets during the week before or after delivery, then severe, potentially fatal, neonatal infection.

These outcomes are preventable through the appropriate and timely use of immunoprophylaxis and antiviral therapy. The window for action is narrow, however, and it is essential to know who is at risk for infection and to manage both exposures and infection rapidly and appropriately.

A safe and effective live attenuated vaccine to prevent varicella is available in many countries and in the USA and Canada is recommended for universal use in childhood. Vaccine is also recommended for susceptible nonpregnant women of childbearing age provided they avoid pregnancy for 1 month following each dose of vaccine. In the USA, where vaccine coverage has been increasing steadily since 1996, significant reductions in the frequency of varicella are being observed. Nevertheless, chickenpox is still ubiquitous in the world community and women of childbearing age, especially those with young children at home, are likely to be exposed, giving rise to scenarios such as the one outlined below.

Perhaps because it is so frequent, nearly everyone, lay public and medical experts alike, has an opinion about the relative severity of disease in children versus adults. One of the more strongly held perceptions is that chickenpox is usually severe in adults and that pregnant women are particularly predisposed to a complicated course with pneumonia and high case fatality rates. Such beliefs stem from the inherent bias toward severity for data derived from hospitalized patients. Population-based data and prospective outpatient cohort studies suggest a different picture. Symptomatic pneumonia occurs in 3–10% of adults with chickenpox and the observed prevalence among pregnant women has been 3.4–5.2%. Most recover uneventfully with appropriate treatment. Risk factors for a more severe course include smoking and the presence of over 100 vesicles at the time of presentation. Nevertheless, while disease is mild to moderate in most cases, the mortality rate during pregnancy may be as high as 2–3% and thus appropriate and timely management of both exposures and proven infection is essential.

The risk to the fetus is also low but definite. The congenital varicella syndrome, of which the most notable and unique features are cutaneous cicatricial scarring (70%) and limb hypoplasia (50%), affects 1% of fetuses exposed during the first 20 weeks of gestation. The greatest risk, 2%, follows exposure between 13 and 20 weeks of gestation. From 20 weeks of gestation until just before delivery the risk of intrauterine infection rises, reaching 60% by the last month of the third trimester, but fetal infection is usually asymptomatic. In 0.8–1.7% of exposed infants, a mild case of herpes zoster occurs in infancy or early childhood. Of great concern, however, is when maternal rash onsets during the interval of 5 days before to 2 days after parturition. Their infants are exposed to the virus with no or minimal

ameliorating transplacental antibody transfer. From 30% to 60% will develop clinical infection and in the absence of appropriate management up to 30% may die.

Typical case

First consultation

During a routine prenatal visit at 28 weeks of gestation, a healthy 25-year-old pregnant with her second child mentions that her 3-year-old son broke out with chickenpox that morning. She cannot remember ever having had chickenpox as a child. She was known to be rubella immune from serology done during her first pregnancy but has never been tested for varicella. What is the appropriate management of this scenario?

Second consultation

Two weeks later the same patient calls to cancel her scheduled appointment because she is feverish, feels miserable and is very concerned that she is developing chickenpox. She decided against getting the immunoglobulin you recommended because it was a human blood product and she feared it might be contaminated. You suggest that she stays home but to call you back if she develops a rash similar to the one her son had, anytime over the next few days. Two days later she calls to confirm that she broke out in a rash overnight and is now feeling a bit short of breath. You arrange to see her at the local emergency department where appropriate isolation precautions can

Figure 66.d-1 Managing exposure to varicella during pregnancy.

be arranged. Physical examination confirms chickenpox based on the rash appearance. There are no other abnormalities, but because of her dyspnea you request a chest radiograph, which is normal. What treatment, if any, would you recommend at this point?

Third consultation

The next day the patient calls to say that her water has broken and she is in active labor. Ten hours later a 2000g infant girl is born by spontaneous vaginal delivery. The infant is transferred to the intermediate intensive care nursery where the attending staff judge her to be a normal premature infant of 30 weeks' gestation and in no acute distress. What is the appropriate management for the infant at this time?

Diagnosis

First consultation: establish varicella-zoster virus immune status

Blood should be drawn immediately for serum VZV antibody. Results should be available within 24 hours, leaving time for appropriate prophylaxis. Routinely available testing methods, usually by enzyme-linked immunosorbent assay (ELISA) or latex agglutination, are sufficiently sensitive to detect immunity. Ideally, all women should be screened for a history of varicella at the first opportunity during routine prenatal care. Chickenpox is still so prevalent and the course so typical that a personal history of typical infection is considered valid proof of immunity. For all others immunity should be

tested by serology. Among individuals with a negative or uncertain history of past chickenpox, 70–90% will be immune by currently available tests. Management of VZV exposures during pregnancy is relatively straightforward if the maternal immune status is known (Fig. 66d.1). To be effective varicella-zoster immunoglobulin (VZIG) prophylaxis must be given within 96 hours of the exposure. This window of opportunity is often compromised during last minute attempts, when more often than not, serology cannot be arranged, as at weekends and holidays.

Second consultation: confirm and determine severity of chickenpox

Chickenpox is usually a clinical diagnosis based on the characteristic pruritic papulovesicular rash with different lesion stages (macule, papule, vesicle, pustule, scab) present in the same area of involved skin. The presence of scalp lesions is especially characteristic of chickenpox. Onset of the rash during the usual incubation period (10–21 days) following a known exposure to chickenpox adds to the diagnostic certainty. Laboratory tests in individuals with known chickenpox should not be carried out to rule out suspected complications in the absence of specific symptoms or signs. Mild elevations of hepatic transaminases occur in 50% or more of adults but are transient in nature and do not predict a worse course. Mild thrombocytopenia (95,000 to <150,000) of no clinical consequence may be present in up to 25% of adults. Chest radiographs should be reserved for adults with dyspnea or other clinical evidence of respiratory distress because diagnosis based on radiographic changes alone can overestimate the incidence of pneumonia by a factor of 8. In the case above dyspnea was an appropriate indication to obtain a chest radiograph. The normal result was not unexpected based on a prospective

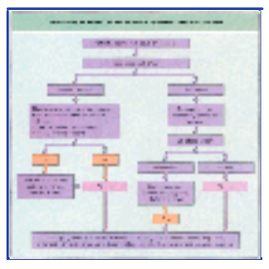

Figure 66.d-2 Managing chickenpox in the immunocompetent pregnant woman.

study by Harger *et al.* (2002) of 329 pregnant women with chicken-pox. Of 86 (26%) women with dyspnea, chest radiographs were normal in 68 (80%).

Management options

First consultation: varicella-zoster virus exposure

Figure 66d.1 presents an algorithm for management of VZV exposures during pregnancy. In this case serology revealed susceptibility to VZV, and VZIG should have been given as soon as possible after results were known. The likelihood of infection following household exposure to VZV is 80% or more. Varicella-zoster immunoglobulin is safe and significantly lessens the severity of maternal varicella. Steps in the manufacture of VZIG ensure the absence of risk of transmission of known blood-borne pathogens. Prevention of fetal infection is not guaranteed and this point should be made clear as part of counseling regarding the risks of infection.

Second consultation: varicella-zoster virus infection

Figure 66d.2 presents an algorithm for the management of VZV infection during pregnancy. Oral aciclovir may speed symptom and rash resolution if given within 24–48 hours of rash onset, but it is not routinely recommended for pregnant women with chickenpox because the risks to the fetus and mother are not clearly known. An ongoing registry of use in pregnancy, however, does suggest it is safe and can be considered in selected situations where the risk of pneumonia is high, as is true among smokers. Intravenous aciclovir is indicated for individuals with symptomatic pneumonia or other evidence of severe varicella. The earlier in the course of infection that treatment is started the better the outcome. Prior receipt of VZIG does not alter this recommendation although severe infection is much less likely to occur.

Third consultation: perinatal infant exposure to varicella-zoster virus

This infant is at risk of severe neonatal varicella because she was born within 4 days of the onset of maternal rash. She should be given VZIG at the earliest possible time after birth, preferably on the first day of life. Even with VZIG chickenpox is likely to occur and could be severe; thus, intravenous aciclovir should be started at the first sign of a vesicular rash.

Strict isolation precautions are required for the mother until her rash is completely crusted. Decisions regarding isolation of the infant are complex and should be made on a per case basis with input from neonatalogy, infectious disease, infection control and the parents.

Conclusions

Varicella is a treatable, and more importantly preventable viral infection. Evidence suggests that there is a great deal of room for improvement in the management of VZV exposures and infections during pregnancy. Screening for maternal immunity is simple but not routinely practiced. Prophylaxis with VZIG is available and effective but too often not used. Live varicella vaccine, contraindicated in pregnancy, has been mistakenly given to exposed pregnant women instead of VZIG. Intravenous aciclovir is live-saving for serious infection, but needs to be started promptly for maximum effect.

Establishing a woman's varicella immune status should be a routine part of early prenatal care. For the majority of individuals who do not remember having had chickenpox but are immune when tested, a great deal of needless anxiety can be avoided in the event of an exposure to chickenpox while pregnant. For the few individuals who are susceptible, advance knowledge is the key to appropriate management.

Chapter 67 - Cystitis and Urethral Syndromes

Stephen T Chambers

Urinary tract infections (UTIs) are the second most common infectious cause for consultation and prescription of antibiotics among family physicians and are a common cause of morbidity in institutional care. Most infections are limited to the lower urinary tract but may cause pyelonephritis and bacteremia. The global incidence is estimated to be 2–3%, or at least 150 million cases per annum, costing billions of dollars annually.[1] Most cases of cystitis are uncomplicated and respond readily to antimicrobial treatment, but complicated infections, associated with anatomic or functional abnormalities, have an increased risk of therapeutic failure.

ACUTE CYSTITIS

EPIDEMIOLOGY

In the first 3 months of life UTIs are about three times more common in males than females, but thereafter infections occur more frequently in females. The prevalence of bacteriuria in preschool- and school-aged girls is 30 times higher than that in boys; 5–6% of girls will have had at least one episode of bacteriuria during their school-age years. Thereafter the prevalence of significant bacteriuria among females increases at about 1% per decade (Table 67.1). Men have low rates of bacteriuria until advanced age when rates rise dramatically.[2]

Among college women more that two-thirds of acute episodes may be attributable to intercourse.[3] Asymptomatic bacteriuria during childhood confers a risk of symptomatic UTI about the time women become sexually active. Other risk factors in this group include use of a diaphragm and spermicide. Less is known about the relationship between intercourse and UTI in older age groups, but previous symptomatic UTI is a risk factor for subsequent infections in both groups, with at least 20% of women developing a further infection within 6 months of the first.

In pregnancy asymptomatic bacteriuria occurs in 4–7% of women predisposing them to developing acute pyelonephritis (15–40% of cases) during the third trimester or in the puerperium. Up to 20% of such patients have significant abnormalities of the urinary tract. Bacteriuria of pregnancy has also been associated with increased risk of pre-eclampsia, lowered fetal birth weight, prematurity and increased perinatal mortality rates.[4]

In males UTI is associated with abnormalities of the urinary tract. In men with AIDS the risk is increased with a lowered $CD4^+$ count.[5]

In the elderly, both concurrent disease of the urinary tract and other medical conditions contribute to the high prevalence of UTI (Table 67.2). Instrumentation is associated with an increased risk of infection of 1% of ambulatory patients and 5–10% of hospitalized patients.

PATHOGENESIS

Infecting organisms

In uncomplicated cystitis more than 95% of infections are caused by a single organism. The most common pathogen is *Escherichia coli* (80–90% of cases) and *Staphylococcus saprophyticus* accounts for 10–20% of cases in young women during late summer and autumn (Table 67.3).[6] A small number of serotypes of *E. coli* account for most UTIs and some may be clonal.[7]

Complicated infections and infections among the institutionalized elderly may be polymicrobial (30% of cases), particularly when stones are present. [8] There is an increased incidence of resistant Gram-negative, *Pseudomonas aeruginosa* and yeast infections in this group. Urease-producing organisms *(Proteus, Providencia* and *Morganella* spp.) are of concern because urease leads to the conversion of urea to ammonia, an increase in the pH of urine, precipitation of struvite crystals ($MgNH_4PO_4.6H_20$), and stone formation.

Mechanisms

Cystitis is almost always caused by ascending infection, although *Staphylococcus aureus* may infect the urine from the bloodstream. The increased susceptibility of women to UTI is probably related to the shorter distance between the anus and urethral orifice, shorter length of urethra and the absence of the antibacterial barrier provided by prostatic fluid in males. In other respects the pathogenesis is similar in men and women and depends on a series of complex, interdependent host-parasite interactions that enable colonization of the periurethral area from the bowel, ascent of organisms into the bladder, growth in urine, tissue invasion and immune response (Fig. 67.1).

Colonization

The region between the anus and urethra is normally colonized by specialized flora. Lactobacilli, particularly hydrogen peroxide producing strains, inhibit colonization with enteric organisms. Spermicides (nonoxynol-9), diaphragms, estrogen deficiency and antibiotics (particularly ß-lactams) may cause a reduction in the number or concentration of these organisms and increase colonization by enteric organisms.[9]

Some women with recurrent UTI have an increased susceptibility to colonization of the periurethral zone with enteric organisms that persists between episodes.[10] *Escherichia coli* adheres more to vaginal epithelial cells from these patients than from controls. Nonsecretors of histo-blood group antigens (Lewis blood group [Le(a+b-)] and recessive [Le(a-b-)] phenotypes) are at greater risk of recurrent UTI.[11] Likewise, bowel carriage of *E. coli* possessing DNA sequences for P fimbriae, is more common among patients with the P blood group.[12]

Ascent

Bacteria normally enter the bladder by ascending along the mucosal sheath. This may be introduced mechanically by instrumentation or sexual activity. The mechanisms are poorly understood but include Brownian motion augmented by motile flagella.

Fimbriae: role in mucosal adherence and inflammation

Symptomatic bacteriuria is highly correlated with the presence of bacteria that mediate attachment to uroepithelial cells. Type I (mannose-sensitive) fimbriae are important in initiating colonization

TABLE 67-1 -- Prevalence of bacteriuria in different age groups.

PREVALENCE OF BACTERIURIA IN DIFFERENT AGE GROUPS		
	Group	**Prevalence (%)**
Females	Schoolgirls	1.2
	Sexually active young women	2–4
	Women	
	>60 years	6–8
	70 years	5–10
	80 years	20
	Institutionalized elderly	30–50

Males	Childhood to middle age	<1
	Men	
	60–65	1–3
	>80 years	>10
	Institutionalized elderly	20–30

TABLE 67-2 -- Risk factors for lower urinary tract infection.

RISK FACTORS FOR LOWER URINARY TRACT INFECTION			
Young adults	Women	Past history of UTI	Parity
		Sexual intercourse	Diabetes (women)
		Diaphragm use	Primary biliary cirrhosis
		Spermicide	Sickle cell anemia (pregnancy)
			Instrumentation
	Men	Lack of circumcision	Homosexual activity
		AIDS	
Elderly people	Women	Loss of estrogen effect	Abnormalities of urinary tract
		Incomplete emptying of bladder	Rectoceles
			Urethroceles
			Bladder diverticula
	Men	Strictures	Prostatic disease
		Instrumentation	Benign enlargement
			Calculi
			Loss of bactericidal secretions
	Both sexes	Neurologic disease	
		Alzheimer's disease	Cerebrovascular disease
		Parkinson's disease	

of the bladder, but are not expressed subsequently following phase variation of the organisms. This may prevent binding to Tamm-Horsfall protein and IgA, and decrease recognition by phagocytic cells, which possess type I receptors.[13] Type II fimbrial attachment (mannose-resistant) is mediated by P fimbriae (Gal-Gal), which are associated with pyelonephritis, and attach to a variety of receptors associated with the globose series of glycolipids, including Gal-Gal and Globo A structures. [14] Attachment of bacteria to the mucosa and cell wall components, such as lipid A, activate an inflammatory response, including production of tumor necrosis factor (TNF) and interleukin (IL)-2, IL-6 and IL-8, and attraction of inflammatory cells.

In contrast, asymptomatic bacteriuria is usually caused by organisms that neither possess fimbriae nor excite an inflammatory response unless tissue invasion occurs. The molecular mechanism by which they reach the bladder and maintain colonization is unknown.[15]

TABLE 67-3 -- Organisms associated with urinary tract infections.

ORGANISMS ASSOCIATED WITH URINARY TRACT INFECTIONS		
Common organisms	*Escherichia coli*	
	Staphylococcus saprophyticus	
Less common organisms	*Klebsiella* spp.	*Pseudomonas aeruginosa*

	Morganella spp.	Yeasts
	Citrobacter spp.	*Corynebacterium urealyticum*
	Group B streptococcus	
	Group D streptococcus	
	Enterococci	
Rare infections	*Haemophilus influenzae*	*Salmonella* spp.
	Mycobacterium tuberculosis	*Shigella* spp.
	Anaerobes	Adenovirus (type 11)
Unproven causes	*Gardnerella vaginalis*	
	Ureaplasma urealyticum	
	Mycoplasma hominis	

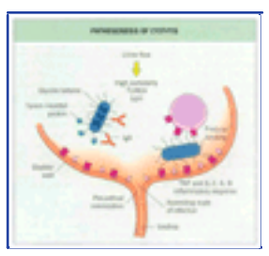

Figure 67-1 Pathogenesis of cystitis. Factors favoring bacterial persistence and infection include bacterial binding to bladder mucosa (fimbriae), and high bacterial growth rates despite high osmolarity and urea concentrations and low pH. Factors favoring bacterial elimination include high urine flow rate, high voiding frequency, bactericidal effects of bladder mucosa, secreted proteins that bind to fimbrial adhesins and the inflammatory response. IL, interleukin; TNF, tumor necrosis factor.

Urodynamics

Normal structure and function of the urinary tract promotes elimination bacteria from the urinary tract because voiding eliminates free organisms and the bladder mucosa is bactericidal to many organisms on contact. Similarly adequate urine flow promotes removal of bacteria from the upper urinary tracts. These defense mechanisms are potentially compromised by low urine flow rate,

infrequent voiding, residual bladder urine and reflux of urine.[16] Neurologic disease, diabetes, debility, and anatomic changes impair bacterial clearance by these mechanisms, particularly in the elderly.

Growth in bladder urine

Growth in urine is essential for invasion of the urinary tract. Gonococci, anaerobes and urethral commensals are inhibited whereas uropathogens grow well in urine. Extremes of pH (<5.5 and >7.5), high tonicity, high urea concentrations and dietary-derived weak organic acids have some inhibitory effects on growth. Bacteria derive protection from the inhibitory effects of high osmotic forces by the intracellular accumulation of osmolytes normally present in urine (e.g. glycine betaine). The osmolytes also counteract the toxicity of urea and low pH by stabilizing macromolecular structures.[17] Osmotic pressure also has a significant influence on the expression of fimbriae genes, but the importance of this is uncertain. Cranberry juice has a slight antibacterial effect due aromatization of quinic acid to benzoic acid by enteric bacteria and subsequent conversion to hippuric acid in the liver.

Immune response

Locally produced urinary antibodies produced in response to febrile UTI (monomeric and dimeric IgA and IgG) decrease adherence by interference with adhesion receptors and agglutination of bacteria. Hyperimmunization can protect animals against experimental UTI.[18]

PREVENTION

Normal urinary tract

Women who suffer recurrent or closely spaced symptomatic UTIs suffer considerable morbidity and anxiety. When no cause is found, advice is often given to empty their bladder completely, maintain a high fluid intake and to void after intercourse, but there is little evidence to support these measures. Application of antiseptic cream (e.g. 0.5% cetrimide) to the urethral oriface may prevent infections. Women who use a diaphragm and spermicide should consider alternative methods of contraception. Postmenopausal women with recurrent UTI have been shown to benefit from the application of estriol vaginal cream (0.5mg/day for 2 weeks then twice weekly). [19]

If these measures fail, chemoprophylaxis should be considered (Table 67.4). Low-dose antibiotics are effective if taken nightly three times weekly or after intercourse.[20] Efficacy continues for up to 5 years. Nitrofurantoin is an excellent agent because it does not alter the fecal flora, and resistance during treatment is rare. Self-initiated therapy is effective in selected groups and should be reserved for those who are not at risk of sexually transmitted infections (STIs) or pregnancy and who do not have significant co-morbid condition.[21] See Figure 67.3 for a treatment algorithm.

TABLE 67-4 -- Drug regimens for prophylactic therapy administered as a single dose at night.

DRUG REGIMENS FOR PROPHYLACTIC THERAPY ADMINISTERED AS A SINGLE DOSE AT NIGHT	
Drug	**Dose**
Nitrofurantoin	50mg
Trimethoprim	100mg
Trimethoprim-sulfamethoxazole (co-trimoxazole)	480mg
Norfloxacin	200mg
Cephalexin	125mg
Hexamine hippurate	1.0g

Abnormal urinary tract

Any lesions in the urinary tract should be corrected if possible. Urologic referral is essential. Large residual volumes and high pressure may require intermittent self-catheterization. Low-dose chemoprophylaxis is often effective.

Vaccine

There is no vaccine currently available, although there has been interest in the development of vaccines directed against type I and type II pili. These are more likely to be useful for the prevention of pyelonephritis than for the prevention of cystitis, but anatomic and functional abnormalities may limit their applicability.

CLINICAL FEATURES

Symptomatic infection

The dominant complaint in cystitis is usually painful micturition (dysuria), which may be associated with frequency, urgency, strangury, initial and terminal hematuria, suprapubic discomfort and voiding small amounts of turbid urine. Low-grade fever may occur, but is usually absent. Pyuria or hematuria are almost always present. Elderly patients usually have similar symptoms but occasionally present with incontinence or smelly urine, or in men, epididymo-orchitis.[22]

Dysuria caused by bacterial cystitis should be distinguished from that caused by vulvitis and urethritis (see Chapter 62). In vulvitis there is often labial discomfort as the stream of urine is passed. Genital herpes and candidiasis are common causes. In urethritis there may be a history of a new sex partner, urethral discharge, mucopurulent cervicitis or bartholinitis. *Chlamydia trachomatis,* and *Neisseria gonorrhoeae* are the usual causes.

Dysuria caused by chronic conditions such as interstitial cystitis and *Mycobacterium tuberculosis* infection may cause initial confusion but usually persists following attempts at treatment.

Asymptomatic bacteriuria

Asymptomatic bacteriuria is very common in elderly patients. It is poorly correlated with fatigue, poor appetite and urinary incontinence. Similarly, symptoms such as frequency, dysuria and hesitancy, which may be caused by infection are common and nonspecific and often fail to respond to treatment of coexisting bacteriuria. [23] Asymptomatic UTIs have been shown to increase morbidity in pregnancy but not in the elderly.

DIAGNOSIS

The diagnosis of UTI can only be proven by culture of an adequately collected urine sample. This is essential in all suspected cases in males, infants and children. A presumptive diagnosis can be made in sexually active women in the presence of typical clinical features together with the presence of pyuria if sexually transmitted infections are unlikely.

Pyuria

The preferred method for assessment of pyuria is microscopic examination of uncentrifuged fresh urine using a hemocytometer, although counts per microscopic field are reasonably reliable in the clinical laboratory. Urine from adult patients who have symptomatic UTI almost always (>96%) contains more than 10 leukocytes/ml.

Pyuria occurs less frequently in asymptomatic bacteriuria of pregnancy (50% positive) and the elderly (90% positive).

Pyuria alone is not a reliable predictor of infection. Specimens from women with vaginitis often contain white cells and there are many other causes of inflammation within the urinary tract (Table 67.5)

Urine dipsticks using esterase provide a simple inexpensive method for detecting pyuria. A positive test indicates a minimum of eight white blood cells per high power field and has a sensitivity of

TABLE 67-5 -- Conditions associated with pyuria but without culturable bacteria using standard bacterial isolation techniques.

CONDITIONS ASSOCIATED WITH PYURIA BUT WITHOUT CULTURABLE BACTERIA USING STANDARD BACTERIAL ISOLATION TECHNIQUES	
Recent treatment of UTI	
Organism not culturable on usual bacterial media	Adenovirus
	Anaerobes
	Chlamydia trachomatis
	Fungal infections
	Herpes simplex
	Leptospirosis
	Myobacterium tuberculosis
	Neisseria gonorrhoeae
Noninfectious causes	Cyclophosphamide therapy
	Foreign bodies
	Glomerulonephritis
	Interstitial cystitis
	Neoplasms
	Stones
	Transplant rejection
	Trauma
	Tubulointerstitial disease
	Vaginal contamination

88–95% and specificity of 94–98% compared with the counting chamber method. The presence of blood, rifampin (rifampicin), nitrofurantoin, bilirubin and ascorbic acid may result in a false-negative test, whereas trichomonads, imipenem and amoxicillin-clavulanate may give a false-positive test.[24]

Detection of bacteria

The presence of bacteria on microscopy of urine correlates well with culture results. Experienced laboratories can reliably detect 10^8 organisms per liter in unstained specimens. The nitrite test is reliable for detecting Gram-negative bacilli in first morning urines but not other specimens because prolonged incubation in the bladder is required to allow reduction of nitrate to nitrite.

Midstream urine specimens

The simplest method for obtaining urine for quantitative culture is to collect a clean midstream specimen. This minimizes the confounding effects of contamination from the first few milliliters of urine.

The sensitivity and specificity of quantitative culture for diagnosis of UTI is dependent on the presence of symptoms and pyuria:

- in asymptomatic women, a single count of 10^4 –10^5 /ml has a 95% chance of representing contamination;[25]
- in symptomatic women with pyuria (>10 white blood cells/ml) a single count of more than 10^5 /ml has a very high specificity (>99%) but a low sensitivity (51%) for UTI.[26]

Routine application of this criterion would fail to diagnose one-third of women with a UTI (Table 67.6).

Specimens from males are less likely to be contaminated and lower counts (>10^3 /ml) are highly predictive of infection. Grampositive bacteria and yeasts in urine tend to be associated with lower counts than Gram-negative bacilli.

In practice specimens are often poorly collected and delays in processing without refrigeration allow bacterial multiplication. In the

TABLE 67-6 -- Value of quantitative urine culture in diagnosis of UTI with Gram-negative bacilli in women.

VALUE OF QUANTITATIVE URINE CULTURE IN DIAGNOSIS OF URINARY TRACT INFECTION WITH GRAM-NEGATIVE BACILLI IN WOMEN				
	Number of specimens	**Organisms/ml of urine**	**Sensitivity (%)**	**Specificity (%)**
Asymptomatic women	two	>10^5	>95	>80
Symptomatic women with pyuria	one	>10^5	51	99
	one	>10^3	80	90
	one	>10^2	95	85

presence of symptoms and pyuria, a bacterial count greater than 10^3 /ml is a reasonable criterion for significant bacteriuria in routine laboratories, bearing in mind that this represents ten organisms on a plate if a 0.01ml loop is used. Others argue that over 10^4 /ml is more realistic. False-negative results can occur in the presence of obstruction, antimicrobial agents and, possibly, diuresis.

Suprapubic aspiration

Suprapubic aspiration of urine from a distended bladder is an efficient means of diagnosis. Any bacteria identified can be regarded as significant because the technique avoids contamination. In most infected specimens bacteria can be seen microscopically, and so treatment can be started promptly. Provided the patient has a full bladder it is safe and acceptable.

Catheter specimens

Catheterization specifically for a urine culture may be justifiable if the patient is unable to co-operate to obtain an uncontaminated sample or to hold urine in the bladder for a suprapubic aspiration. Catheterization rarely leads to false-positive results, but may introduce bacteria into the bladder. Straight plastic catheter or Alexa bag techniques are satisfactory.

Imaging of the urinary tract

All men, children and infants need investigations of the urinary tract if they have a UTI regardless of the clinical features at presentation. This is not cost-effective in women unless there is some evidence of an unusual clinical pattern,[27] such as urinary infection as a child, treatment failure and persistent microscopic hematuria or pyuria at follow-up. An ultrasound examination including postmicturition bladder volumes plus a plain abdominal radiograph, including the kidneys, ureters and bladder, or an intravenous urogram, are adequate in most instances. Cystoscopy rarely yields useful information in women with acute cystitis.

MANAGEMENT

Untreated 50–70% of lower UTIs will clear spontaneously although symptoms may persist for many months. Thus the goal of treatment is to eradicate the infection, and to reduce morbidity caused by relapse or recurrence with minimum toxicity, inconvenience and distress for the patient. The cornerstone of management is effective antimicrobial therapy (Table 67.7). Drinking large amounts of fluids may decrease bacterial counts and improve symptoms, but adds little to effective antimicrobial therapy. Likewise alkalinizing agents may decrease symptoms, but do not influence bacterial eradication.

Follow-up visits at 7–14 days after completion of therapy give the opportunity to obtain urine cultures and discuss the importance of

TABLE 67-7 -- Drug treatment regimens for a 3-day course of oral therapy for bacterial cystitis.

DRUG TREATMENT REGIMENS FOR A 3-DAY COURSE OF ORAL THERAPY FOR BACTERIAL CYSTITIS	
Drug	**Dose**
Trimethoprim	300mg q24h
Trimethoprim-sulfamethoxazole (co-trimoxazole)	960mg q12h
Ciprofloxacin	250mg q12h
Fleroxacin	400mg q24h
Lomefloxacin	400mg q24h
Nalidixic acid	500mg q8h
Norfloxacin	400mg q12h
Amoxicillin	250mg q8h
Amoxicillin/clavulanate	500/125mg q12h
Cephalexin	250mg q8h
Cephradine	250mg q8h
Pivmecillinam	200mg q8h

Figure 67-2 Treatment of uncomplicated cystitis in a nonpregnant woman.

the diagnosis. It is essential to relieve anxiety about sexual activity and perceived long-term consequences, and to discuss advice offered by the family and the popular press.

Acute uncomplicated bacterial cystitis

Short-course therapy has now become the standard for treatment in clinical practice for most treatment regimens.[28] Short-course therapy is contraindicated in complicated infections. Advantages of short-course therapy include better compliance, lower cost, fewer side-effects and decreased likelihood of the emergence of resistant strains. A treatment algorithm is given in Figure 67.2 .

Three-day therapy

A 3-day regimen has become the recommended approach for many clinicians because it provides the advantages of short-course therapy and has a slightly higher success rate than single-dose therapy, particularly in older women.[29] It is appreciated by patients because it may take several days for symptoms to abate. Three days of trimethoprim-sulfamethoxazole (TMP-SMX) (co-trimoxazole), trimethoprim alone, the quinolones or pivmecillinam are as effective as longer courses with fewer side-effects. ß-lactams as a group are less effective than trimethoprim, TMP-SMX or the quinolones. There is insufficient evidence to recommend nitrofurantoin for 3 days rather than 7 days

Single-dose therapy

Single-dose therapy is essentially 1 day of treatment given in a single dose that produces inhibitory concentrations of antibiotic over a 12–24-hour period. It is most suitable for cystitis in sexually active women and for younger patients who have normal urinary tracts and a short history (<7 days) (Table 67.8).

Amoxicillin is less effective than either TMP-SMX or trimethoprim alone and is no longer recommended in single-dose regimens. Fluoroquinolones are very effective, although they may be less effective against *S. saprophyticus* than Gram-negative bacilli. Fosfomycin trometamol is marketed specifically as single-dose therapy and is highly effective but is relatively expensive.

Those who fail to respond to single-dose therapy have an increased risk of abnormalities within the urinary tract.[30]

Therapeutic agents

Both TMP-SMX and trimethoprim (TMP) alone are highly effective, but as sulfonamides have occasional severe side-effects, especially in the elderly, TMP is preferred. There is no evidence that the combination with sulfamethoxazole prevents the emergence of resistance.

The fluoroquinolones have essentially superseded nalidixic acid and oxolinic acid. All these agents are extremely active and effective against most pathogens, including many hospital pathogens. Norfloxacin is usually the most inexpensive fluoroquinolone for the treatment of cystitis in some countries.

Nitrofurantoin is ineffective against *Proteus mirabilis*. The side-effects of nausea and vomiting can be minimized by treating with 50mg q8h without loss of efficacy, rather than 100mg q6h.

Mecillinam has been widely used in Scandinavia without apparent resistance problems developing in Gram-negative organisms. In-vitro studies show resistance in Gram-positive organisms, but clinical studies show that there is a high cure rate for *S. saprophyticus*,

TABLE 67-8 -- Suggested drug treatment regimens for single-dose therapy.

SUGGESTED DRUG TREATMENT REGIMENS FOR SINGLE-DOSE THERAPY	
Drug	**Dose**
Trimethoprim	600mg
Trimethoprim-sulfamethoxazole (co-trimoxazole)	1.92g
Ciprofloxacin	500mg
Fleroxacin	400mg
Norfloxacin	800mg
Fosfomycin trometamol	3g

presumably because of the very high concentrations achieved in the urine.

Amoxicillin is the treatment of choice for treating *Streptococcus faecalis,* but increasing resistance has limited its usefulness against other uropathogens. Combinations of ß-lactams with ß-lactamase inhibitors may be effective, but there is a high rate of diarrhea. Cephalosporins such as cephalexin, cephradine and cefaclor are useful, particularly in renal failure.

Choice of initial therapeutic agent

Trimethoprim and TMP-SMX have been regarded as the agents of first choice but are less appropriate if resistance rates in *E. coli* and other Gram-negative organisms exceed 10–20%, and the quinolones offer an alternative choice. In-vitro resistance reduces the clinical success of TMP-SMX from 95 to 60% and bacterial eradication from 93 to 50%. Thus the expected clinical and bacterial success rates for Gram-negative infections will be 92 and 89%, respectively, for a 10% resistance rate, and 88 and 84%, respectively, for a 20% resistance rate. [31] The net effect on success from intention to treat will be smaller, because Gram-positive uropathogens remain susceptible to TMP or TMP-SMX.

The decision to change policy may be made more difficult because reliable estimates of resistance rates in the local setting are often lacking. Resistance rates reported by clinical laboratories may be misleading because isolates from patients who have failed therapy or are at a high risk of resistance are over-represented. [32] Using

Figure 67-3 Treatment of recurrent bacterial cystitis in a nonpregnant woman.

quinolones as a first choice may be a short-term solution because resistance to these agents, although currently low, is increasing worldwide and has reached 23% in Spain and 18% in Bangladesh.

Where resistance to TMP-SMX is a potential problem a reasonable approach is to use it unless the patient has risk factors for TMP-SMX resistance. These include previous infection with TMP-SMX-resistant organisms, recent use of TMP-SMX or another antimicrobial agent, recent hospitalization or recurrent UTI in the past year. Alternatives include fluoroquinolones (3 days), nitrofurantoin (5–7 days), pivampicillin (3 days) and fosfomycin (single dose).

Recurrent infections

The major problem with uncomplicated acute cystitis is recurrence. About one-half of adult women will have another infection within 1 year, many within 3 months. Recurrence rates vary (0.3–7.6 episodes per year) and may occur in clusters. With treatment of each episode 20–30% will cease having recurrences. [33] If episodes are closely spaced, self-administered therapy, preferably after obtaining a urine specimen, postcoital therapy or prophylaxis can be considered. Self-initiated therapy should be reserved for those who are not at risk of STIs or pregnancy, and do not have significant co-morbid conditions.[21] A treatment algorithm is given in Figure 67.3 .

Complicated infections

Patients who fail short-course treatment often have abnormalities of the urinary tract (e.g. stones, diverticula, strictures, chronic bacterial

Figure 67-4 Treatment of asymptomatic bacteriuria in pregnancy.

TABLE 67-9 -- Possible toxicities of antimicrobial agents in pregnancy.

POSSIBLE TOXICITIES OF ANTIMICROBIAL AGENTS IN PREGNANCY	
Agent	**Toxicity**
Trimethoprim sulfonamides	Antifolate activity and megaloblastic anemia
Sulfonamides (protein bound)	Kemicterus of newborn

Sulfonamides/nitrofurantoin	Hemolytic anemia in glucose-6-phosphate dehydrogenase deficiency
Tetracycline	Fatty liver/hepatic necrosis in mother, stained teeth in baby
Fluoroquinolones	Not approved

prostatitis). These should be corrected where possible and infection treated with more prolonged courses of therapy of 10–14 days.

Urinary tract infections in pregnancy

The risks of symptomatic infection and pyelonephritis during the third trimester of pregnancy in mothers and prematurity in infants can be prevented by early detection and eradication of asymptomatic bacteriuria. In the first instance single-dose or a 3-day course of therapy are appropriate (Fig. 67.4). If relapse or re-infection occurs then the patients should be re-treated. At that stage the simplest strategy is to institute prophylaxis (e.g. nitrofurantoin 50mg at night), although some prefer close surveillance with repeated cultures and prompt treatment of each episode. All such patients need evaluation of the urinary tract with ultrasonography and a plain abdominal radiograph after delivery.

There is probably no absolute contraindication to any antimicrobial agent during pregnancy, but caution is urged with some agents.[34] The antifolate activity of trimethoprim and TMP-SMX is minimal in short courses and probably safe between 16 and 30 weeks of gestation (Table 67.9).

Males

Lower UTI in males may be complicated by infection of prostatic fluid, even if there is no clinical prostatitis.[35] For this reason there is reluctance to treat men with short regimens and studies of single-dose therapy in elderly men have been disappointing.[36] Long-term suppressive therapy may be helpful for frequent recurrences.

Asymptomatic bacteriuria

Asymptomatic bacteriuria is often best left untreated except in pregnancy. In elderly patients it is extremely common and there is no convincing evidence that treatment benefits the patient either in terms of recurrent symptomatic episodes or mortality rate. Antimicrobial therapy is associated with adverse effects, the potential for development of resistant strains, and financial cost.

Invasive procedures

Asymptomatic bacteriuria should be treated if a patient is to undergo an invasive procedure of the genitourinary tract. Mucosal trauma may cause postprocedural bacteremia, and occasionally septic shock and death. The antimicrobial agent should be selected on the basis of the sensitivity of the infecting organism. [37] Likewise, it is prudent to treat any urinary infections before the insertion of permanent indwelling devices, particularly prosthetic joints.

Treatment in the presence of renal failure

If treatment is truly indicated, drugs that achieve adequate urine concentrations in the presence of renal failure should be used. The best levels may be achieved with penicillins and cephalosporins. Trimethoprim and fluoroquinolones will probably achieve adequate concentrations, whereas nitrofurantoin, sulfamethoxazole and doxycycline are present in very low concentrations when creatinine clearance falls below about 0.16ml/s.

Infections with *Candida* spp.

Infections with *Candida* spp. may occur either from hematogenous spread or via the ascending route. There is an increased risk in those with diabetes, prolonged antimicrobial therapy and instrumentation of the urinary tract. The natural history has not been well-defined, but most infections are asymptomatic, limited to the lower urinary tract and may resolve in otherwise normal patients. Occasionally pyelonephritis, papillary necrosis or bezoars occur, especially in patients who have diabetes mellitus, obstructive uropathy or renal transplantation. Those at increased risk should be treated, but it is less clear for other patients. The treatment of choice for those without a catheter is oral fluconazole (50–100mg/day), although some species such as *Candida krusei* may be resistant.[38] A single dose of intravenous amphotericin B (0.3mg/kg) is usually effective, presumably because of prolonged renal excretion. Oral flucytosine and alteration of urinary pH are ineffective. If a catheter is present, bladder washouts with amphotericin B may be used, but are of questionable efficacy.

URETHRAL SYNDROMES

PATHOGENESIS AND CLINICAL FEATURES

Following the introduction of quantitative bacterial counts, about half of women with acute symptoms of cystitis did not have significant — $>10^5$ colony forming units (cfu)/ml — bacteriuria. These women were said to have acute urethral syndrome or dysuria-pyuria syndrome. Many women with acute urethral syndrome have periurethral colonization with uropathogenic organisms and low numbers of *E. coli, S. saprophyticus* and enteric Gram-negative organisms present in their urine. Furthermore many such patients responded to antibiotic therapy, suggesting that this was essentially a UTI. These patients probably have urethritis with little infection of the bladder and the diagnosis may be missed because of the low numbers of organisms present.

There remains a group with similar symptoms who do not have a low-count bacteriuria. It is possible that symptoms are caused by infection confined to the proximal urethra, especially if there is pyuria, but it is very difficult to diagnose. Various agents, including organisms that commonly cause UTIs (especially in women who suffer recurrent UTI), *Ureaplasma urealyticum, C. trachomatis* are possible pathogens. Multiple other causes have been suggested, including infection of the female paraurethral glands, lactobacilli, chemicals (e.g. bubble baths and deodorants), trauma and psychologic factors, but none have been proven.

MANAGEMENT

Management of the urethral syndrome is difficult. A pelvic examination should be carried out to exclude herpes simplex, gonorrhea and vaginitis. The symptoms usually settle in a few days, although some patients appear to benefit from a high fluid intake. Antimicrobial therapy may be helpful if pyuria is present, presumably reflecting bacterial urethritis or chlamydial infection. Antibiotics useful for treatment of UTI are often prescribed in the first instance. If these fail, doxycycline (100mg q12h) for 10 days may be effective.[39]

Chapter 68 - Prostatitis, Epididymitis and Orchitis

Kurt G Naber
Wolfgang Weidner

PROSTATITIS

The diagnosis of prostatitis syndrome refers to a variety of inflammatory and noninflammatory conditions probably not always affecting the prostatic gland itself. In 1978 a classification system[1] was developed to differentiate inflammatory from noninflammatory entities and was much used in the past. However, many aspects of chronic prostatic symptoms remained enigmatic. In 1999 a consensus conference at the National Institute of Diabetes, Digestive and Kidney Diseases (NIDDK) of the National Institutes of Health developed a new classification system[2] [3] based on the clinical presentation of the patients, the presence or absence of leukocytes in the expressed prostatic secretion (EPS) or voided bladder urine after prostatic massage (VB_3), and the presence and absence of bacteria in the EPS or VB_3 . In addition, the inflammatory conditions are categorized into symptomatic and asymptomatic presentations identifying patients who are incidentally diagnosed from biopsies, evaluations for fertility disorders or routine examinations. The term chronic pelvic pain syndrome (CPPS) was chosen, because it has not been scientifically demonstrated either that CPPS is primarily a disease of the prostate or that it is an inflammatory process.[2] [3] Table 68.1 illustrates the most recent NIH concensus.

EPIDEMIOLOGY

Definition and nomenclature

Acute prostatitis is an acute febrile illness that may be characterized by intense pain in the perineum and rectum, fever, voiding difficulties,

TABLE 68-1 -- The National Institutes of Health consensus classification of prostatitis syndromes.

NIH CONSENSUS CLASSIFICATION OF PROSTATITIS SYNDROMES			
Category	**Characteristic clinical features**	**Bacteriuria**	**Inflammation***
I. Acute bacterial	Acute urinary tract infection (UTI)	+	+
II. Chronic bacterial	Recurrent UTI caused by the same organism	+	+
III. Chronic prostatitis chronic pelvic pain syndrome	Primarily pain complaints, but also voiding complaints and sexual dysfunction		
A. Inflammatory subtype†		-	+
B. Noninflammatory subtype‡		-	-
IV. Asymptomatic	Diagnosed during evaluation of other genitourinary complaints	-	+

* Objective evidence of an inflammatory response in EPS, postprostate massage urine or semen or by histology.
† formerly termed 'nonbacterial prostatitis'.
‡ Formerly termed 'prostatodynia'.

systemic symptoms of sepsis and a tender, swollen prostate on rectal examination. The chronic prostatitis syndromes (bacterial, nonbacterial and prostatodynia, or CPPS) cause symptoms that cannot be differentiated from each other (Table 68.2). In patients who have signs of inflammation, leukocytes (neutrophils, macrophages) are present in EPS or VB_3 . Pathogens must be present in EPS or VB_3 for a conclusive diagnosis of chronic bacterial prostatitis (CBP).[4] In noninflammatory CPPS (prostatodynia) no signs of inflammation are detectable. In asymptomatic inflammatory prostatitis detected either by prostatic histology or by the presence of leukocytes in seminal fluid or in prostate secretion during evaluation for other disorders, the patients have no subjective symptoms (see Table 68.1).

Incidence and prevalence

Because of classification difficulties, few data are available to determine the incidence of prostatitis. Acute prostatitis is infrequent, with a probable incidence of fewer than 1 in 1000 adult men per year. However, prostatic symptoms are common. In the USA approximately 30% of men between 20 and 50 years of age experience 'prostatitis-like' symptoms[5] and these symptoms are responsible for about 25% of physician office visits by men for genitourinary complaints.[5] Prostatitis is the most common urologic diagnosis in men under 50 years of age and the third most common urologic diagnosis in men over 50 years of age.[6] It has been demonstrated that a diagnosis of chronic prostatitis can have a quality of life impact similar to a diagnosis of angina or Crohn's disease.[7] Thus, prostatitis is a major health care issue, perhaps as important as the other two major prostatic diseases, namely benign hyperplasia and carcinoma.[8]

TABLE 68-2 -- Symptoms in patients with the chronic prostatitis syndromes.

SYMPTOMS IN PATIENTS WITH THE CHRONIC PROSTATITIS SYNDROMES	
Urethral symptoms	• Burning in the urethra during voiding
	• Discharge
	• Difficult urination
	• Stranguria
	• Frequency
	• Nocturia
	• Prostatorrhea
	• Leukocytospermia

Prostatic symptoms	• Pressure behind public bone
	• Perineal pressure tension in testes and epididymes
	• Inguinal pain
	• Anorectal dysesthesia
	• Diffuse anogenital syndromes
	• Lower abdominal discomfort
Sexual dysfunction	• Loss of libido
	• Erectile dysfunction
	• Ejaculatory dysfunction
	• Pain during or after orgasm
Other symptoms	• Myalgia
	• Headache
	• Fatigue

The term prostatitis implies inflammation, but only 5–10% of patients who have this diagnosis actually have a proven bacterial infection.[5] [9] The rest do not have 'significant' prostatic fluid bacterial counts. About half of these men have inflammatory CPPS/nonbacterial prostatitis (NBP) with an elevated leukocyte count in prostatic fluid.[4] [5] [9] [10] [11] [12] [13] [14] The rest are categorized as having noninflammatory CPPS/prostadynia. This is a diagnosis of exclusion and in most cases it cannot be proved that the symptoms arise from the prostate.

Risk factors

Urinary tract infections (UTIs) are the major underlying determinant of both acute bacterial prostatitis (ABP) and CBP. Strains of *Escherichia coli* responsible for both ABP and CBP appear to have similar urovirulence determinants to the *E. coli* strains that cause pyelonephritis. [15] Prostatic calculi can account for recurrences of CBP.[4] Bacterial micro-colonies enclosed within biofilms inside prostatic acini and ducts can be a foci for bacterial persistence. [12] Inflammatory CPPS/NBP may be due to intraprostatic reflux of urine causing inflammation.[16] Other presumed and unproven causes of inflammatory CPPS/NBP are immunologic reactions to spermatozoa and migration of sexually transmitted organisms from the urethra.

CLINICAL FEATURES

Diagnosis

Acute bacterial prostatitis is diagnosed by its clinical presentation. [14] It presents as an acute febrile illness with irritative and obstructive voiding symptoms. Prostatic massage is contraindicated and the diagnosis depends upon:

- urine and blood cultures;
- a gentle examination of the prostate that demonstrates acute inflammation; and
- a urinalysis, which usually demonstrates pyuria.

Prostatic abscess may occur in patients who have acute prostatitis. This diagnosis is made by clinical examination and transrectal ultrasonography. Focal hypoechoic zones with irregular internal echoes, septations and indirect borders with the surrounding parenchyma are typical patterns. The abscess may be distinct or more diffuse. Prostatic abscesses are usually due to the same uropathogens that are responsible for ABP, although a variety of anaerobes and fungi are implicated sporadically. Systemic mycoses, particularly *Cryptococcus neoformans, Blastomyces dermatitidis, Coccidioides immitis* or *Histoplasma capsulatum*, can involve the prostate gland and produce prostatic abscesses. *Candida albicans* can also cause prostatic abscesses.

Chronic bacterial prostatitis is a less precise diagnosis (see Table 68.2). Patients presenting with prostatic complaints should have a prostatic massage to localize the infection. The method of choice is the Meares and Stamey localization technique (Fig. 68.1).[17] Increased numbers of neutrophils and fat-laden macrophages are typical cytologic signs in the EPS. Although increased numbers of leukocytes may be found in EPS, it is generally accepted that over 10 neutrophils/high-power field indicates prostatitis.[14] [15] In patients for whom an EPS cannot be obtained increased numbers of neutrophils in the urine after prostatic massage (VB_3) is an indication of prostatitis if first voided urine (VB_1) and midstream urine (VB_2) do not contain these cells. In patients who have CBP, bacterial pathogens will be present in the EPS or VB_3 in larger numbers, usually a 10-fold higher concentration than in the VB_1 [14] [15] The exact technique for localizing infection with the Meares and Stamey technique is outlined in Figure 68.1 and should be followed carefully.[17]

The role of *Chlamydia trachomatis and Ureaplasma urealyticum* in bacterial prostatitis is uncertain and there are no widely accepted criteria for defining prostatitis due to these or other infrequently isolated pathogens (Table 68.3).[18] [19] [20]

Ejaculate analysis is sometimes recommended in men who have CBP to obtain further information but studies of seminal fluid are mostly unhelpful. A proportion of men who have CBP have bacteriospermia (>10^3 cfu/ml) and the organisms present are usually identical to those in the EPS.[21] Biochemical analysis of EPS has been used as an additional diagnostic criterion for CBP but these observations have not been shown to be sufficiently sensitive or specific to add to the diagnosis (Fig. 68.2).[14] [15] The pH is usually increased (>7.8) in the EPS from patients who have CBP.

Biopsy under ultrasonographic guidance, particularly if nodules are present, is used for histology and culture.[4] [10] [22] Inflammatory findings in the prostate are usually non-specific and the primary indication for biopsy is to exclude prostatic cancer.

Evaluation of bladder emptying by flow rate measurements and ultrasonography can be useful in patients who have voiding disturbances.[22] On occasion this diagnostic work-up should include a voiding cystourethrogram. Urodynamic changes are present in about one-third of patients who have CBP. In the presence of abnormal flow rate measurements, further studies should be performed to differentiate between functional and anatomic changes.

Urethrocystoscopy may reveal visible inflammatory changes in the posterior urethra. Prostatic sonography may demonstrate prostatic calculi (Fig. 68.3). Prostatic calculi may serve as nidi for pathogens and lead to CBP, but they are common and increase with age, and their role remains controversial. Figure 68.4 outlines the diagnostic investigation of patients who present with possible prostatitis.

Nonbacterial prostatitis is a less specific diagnosis. These patients have inflammatory cells in the EPS with negative cultures from both the EPS and VB_3 . Although numerous investigators have attempted to demonstrate that NBP is due to difficult-to-culture pathogens such as *C. trachomatis* or genital mycoplasmas, there is no consensus that these organisms cause NBP.[18] [23] [24] As a result, this diagnosis is currently poorly defined and is presumed to be caused by unknown etiologic and pathogenetic processes. This entity is classified as inflammatory CPPS according to the new definition of the NIDDK.[2] [3]

Figure 68-1 Meares and Stamey[17] localization technique to diagnose chronic bacterial prostatistis. Prostate secretion can be more readily obtained if the patient has not

ejaculated for approximately 3–5 days before the examination.

TABLE 68-3 -- Prostatitis infections by unconventional fastidious pathogens.

PROSTATITIS INFECTIONS BY UNCONVENTIONAL FASTIDIOUS PATHOGENS		
Species	**Clinical features**	**Comment**
Haemophilus influenzae		Single case reports
Neisseria gonorrhoeae	Associated with history of gonococcal urethritis	Decreasing due to effective antibiotic treatment
Mycobacterium tuberculosis	Urogenital manifestation	Associated with HIV infection
Anaerobes	Prostatic abscesses	
Candida spp.	In immunocompromised patients with indwelling urinary catheters	
Coccidioides immitis, Blastomyces dermatitidis, Histoplasma capsulatum	Disseminated disease	Associated with HIV infection
Trichomonas vaginalis	Chronic inflammation	May be associated with urethritis

TABLE 68-4 -- Dissociation constants of fluoroquinolones.[28]

DISSOCIATION CONSTANTS OF FLUOROQUINOLONES [28]		
Quinolone	**Pk_{a1}**	**Pk_{a2}**
Ciprofloxacin	6.1	8.7
Enoxacin	6.3	8.7
Fleroxacin	5.5	8.1
Gatifloxacin	6.0	9.2
Lomefloxacin	5.8	9.3
Norfloxacin	6.3	8.4
Ofloxacin*	6.1	8.2
Pefloxacin	6.3	7.6
Sparfloxacin	6.3	8.8

* The disassociation constants of levofloxacin are similar.

MANAGEMENT

Treatment varies according to the severity of the patient's presenting symptoms and the probable etiologic agent. Antimicrobial treatment should be initiated immediately in patients who have acute bacterial prostatitis after blood and urine cultures have been obtained. Prostatic massage is contraindicated. Parenteral treatment with a fluoroquinolone or a ß-lactam with an aminoglycoside are all appropriate initial regimens. After initial improvement, a switch to an oral regimen, a fluoroquinolone, is appropriate and should be prescribed for at least 4 weeks.

Patients who have possible CBP require investigation for evidence of inflammation and an etiologic agent. Selection of an appropriate antimicrobial agent that has optimal pharmacokinetics for prostatic secretion and tissue is important. [25] Antibacterial diffusion into prostate secretion depends upon the lipid solubility, molecular size and pKa of the agent.[25] For example, trimethoprim, a weak base with a pKa of 7.4, penetrates well into vacid prostatic secretion. However, because the pH of prostatic fluid in patients who have CBP is often alkaline, concentrations in prostatic secretion may be inadequate. [26] [27] In contrast, the fluoroquinolones exist as zwitterions with a pKa in acid and alkaline milieus [28] (Table 68.4). This allows prostatic fluid levels that compare favorably with plasma levels, with ratios ranging from 0.12 to 1.02 (Table 68.5).[29] [30] [31] [32] The concentration of some fluoroquinolones in the alkaline seminal fluid may even exceed that in plasma (Table 68.5).[29] [30] [31] [32] Other studies have examined fluoroquinolone concentrations in prostatic tissue obtained at transurethral resection and they appear to be consistently at or above corresponding plasma concentrations.[31] Macrolides also penetrate into prostatic and seminal fluids very well.[25] [33]

Although it remains unproven, considerable evidence suggests that bacteria in prostatic tissue survive in a milieu protected by biofilms. Antimicrobial agents, particularly the fluoroquinolones and the macrolides, that penetrate through biofilm may be preferred drugs. Most studies in patients who have CBP have not been well controlled and have been variably designed.[31] [34] As a result, comparison is difficult. Duration of therapy has ranged from 14 to 150 days and follow-up investigation has not been standardized. An EPS should be obtained from all patients at 4–8 weeks and at 6 months after treatment to ensure that the pathogens have been eradicated.[34] Overall, it appears that 60–80% of patients who have *Escherichia coli* and other Enterobacteriaceae can be cured with a 4–6-week course of therapy (

Table 68.6). [35] [36] [37] [38] [39] [40] [41] [42] [43] However, prostatitis due to *Pseudomonas aeruginosa* or enterococci often fails to respond to treatment.

Eradication of pathogens (bacteriologic cure) in patients who have chronic bacterial prostatitis. Only studies are listed in which the diagnosis was derived from application of the Meares and Stamey technique and a follow-up of at least 6 months was available							

Chronic bacterial prostatitis can be a relapsing illness and recurrent episodes are best managed by either continuous low-dose suppressive therapy with an effective regimen such as fluoroquinolone, intermittent treatment whenever symptoms recur, or efforts to resect infected prostatic tissue, particularly prostatic calculi, in order to effect a surgical cure.[5] The latter is rarely successful and should only be carried out with very specific indications.

A prostatic abscess may require drainage in addition to antimicrobial treatment. Occasionally, anaerobes or mixed infections may be responsible for the abscess. Cultures should always be obtained and, if fungal infection is suspected, the laboratory should be informed. Most treatment regimens should include an agent effective against anaerobes. Prostatic abscesses can be drained through the urethra, the perineum and occasionally the rectum.

Inflammatory CPPS/NBP is managed empirically and no regimen has proved to be routinely successful. Occasionally, patients appear to have a very specific response to antimicrobial therapy and, whenever this occurs, a prolongation of therapy is indicated. However, most patients who have inflammatory CPPS/NBP do not experience any change in symptoms with antibacterial therapy. Other treatment regimens include anti-inflammatory agents, a-adrenergic blocking agents, regular prostatic massage and weekly ejaculation. However, all regimens are empiric and treatment is often unsatisfactory.

Prostatodynia is an imprecise diagnosis for which therapy is controversial and unproven. Although the symptoms can mimic those of CBP, the absence of inflammation or any signs of infection are presumed to mean that no microbial agent is involved. This entity is classified as noninflammatory CPPS according to the new definition of the NIDDK.[2] [3] Treatment regimens similar to those used for NBP can be tried empirically.

EPIDIDYMITIS AND ORCHITIS

Epididymitis is an acute painful swelling in the scrotum, which is usually unilateral.[44] The testes may be involved in the inflammatory process as 'epididymo-orchitis'. Inflammatory processes of the testes, especially viral orchitis, less often involve the epididymis.

EPIDEMIOLOGY

Orchitis and epididymitis are classified as acute or chronic processes according to their cause (Table 68.7). Chronic inflammation with induration develops in about 15% of patients following an episode of acute epididymitis. Viral and bacterial inflammation of the testes can lead to testicular atrophy and destruction of spermatogenesis.[45]

Epididymitis is common among individuals who have high-risk sexual behaviors (frequent change of sexual partners) and is one of the leading causes of acute admission to hospital among military personnel. It occurs in 1–2% of patients who have gonococcal and

TABLE 68-7 -- Classification of epididymitis and orchitis.

CLASSIFICATION OF EPIDIDYMITIS AND ORCHITIS		
Acute epididymitis or epididymo-orchitis	**Granulomatous epididymitis or orchitis**	**Viral orchitis**
Neisseria gonorrhoeae	*Mycobacterium tuberculosis*	Mumps
Chlamydia trachomatis	*Treponema pallidum*	Enteroviruses
Escherichia coli		
Streptococcus pneumoniae	*Brucella* spp.	
Klebsiella spp.	Sarcoid	
Salmonella spp.	Fungal	
Other urinary tract pathogens	Parasitic	
Idiopathic	Idiopathic	

chlamydial urethritis, with an equal risk from each. It is usually unilateral and is due to an extension of the urethral infection via the vas deferens to the epididymis (see Chapter 74).

In middle-aged and older men, epididymitis is usually due to the same organisms as those that cause UTI and is presumably a direct extension from the urinary tract. Epididymitis is more common in patients who have indwelling catheters. Bladder outlet obstruction and urogenital abnormalities are also risk factors for acute and chronic epididymo-orchitis.

Mumps orchitis was common before widespread vaccination. It is now rare. It occurs in 20–30% of postpubertal men who have mumps. Other viral infections can also cause orchitis, particularly enteroviruses. The testes can also be involved as a continuation of epididymitis, particularly when suppurative UTI pathogens are involved. Granulomatous orchitis is a rare condition of uncertain etiology.[46] With regard to chronic inflammatory conditions, a so-called 'low-grade autoimmune orchitis'[47] has been described.

Epididymo-orchitis can lead to abscess formation, testicular infarction, testicular atrophy, chronic epididymitis and infertility.[44] In men who have azoospermia, postinflammatory epididymal obstruction can sometimes be cured by reconstructive surgery.[48]

CLINICAL FEATURES

Inflammation, pain and scrotal swelling characterize acute epididymitis. [44] Frequently the tail of the epididymis is involved first. The spermatic cord is usually tender and enlarged. The testes may be spared or may be involved to produce a contiguous large painful mass. Acute epididymitis always requires immediate evaluation by Doppler duplex scanning to differentiate between acute epididymitis and spermatic cord torsion. The latter requires urgent surgical intervention to prevent testicular infarction.[49]

The microbiologic diagnosis of acute epididymitis must be made as specifically as possible. A urethral Gram stain, urine culture and other studies for identification of *Neisseria gonorrhoeae* and *C. trachomatis* should be obtained for all patients. Blood cultures are valuable if the patient is febrile or has systemic signs of toxicity. Ejaculate analysis according to World Health Organization criteria, including leukocyte analysis, may be of value. A transiently decreased sperm count or azoospermia is common. Infertility is a rare complication unless there is bilateral involvement.

Chronic epididymitis is characterized by thickening and induration of the epididymis. Especially in patients who are infertile, ejaculate analysis concerning semen quality is a necessary investigation to exclude azoospermia[47] and changes of sperm maturation.[50]

Orchitis, an isolated inflammation of the testis, is a rare event. Most frequently it occurs in association with epididymitis, as epididymo-orchitis (see Table 68.7). Testicular swelling, frequently accompanied by fever, is typical. Antibody and other specific serum investigations should be carried out to identify mumps, enteroviruses and other potential virus pathogens. In chronic infections, ejaculate analysis may demonstrate structural sperm defects providing reduced sperm motility and number.[47] Testicular biopsy in these cases may demonstrate focal inflammation, mixed atrophy and complete Sertoli-cell-only syndrome in the follow-up.[45]

MANAGEMENT

In acute epididymitis (epididymo-orchitis), antimicrobial agents should be chosen for initial empiric treatment based on the probability of the etiologic agent. In sexually active men who are at risk of *C. trachomatis* or *N. gonorrhoeae*, a therapeutic regimen that covers both these pathogens is mandatory. Details of the treatment of these specific pathogens is provided in Chapter 74 . Additional therapy includes scrotal support. Abscesses may require surgical drainage. If urinary tract pathogens are considered to be the probable etiologic agent, fluoroquinolones or trimethoprim-sulfamethoxazole are appropriate choices. Experimental[51] and clinical studies[52] suggest that the fluoroquinolones are very effective.

In acute mumps orchitis, interferon a has been prescribed. [47] Therapy with nonsteroidal anti-inflammatory agents has also been recommended,[53] as has treatment with long-acting gonadotrophin-releasing hormone agonists.[54]

Chapter 69 - Pyelonephritis and Abscesses of the Kidney

James R Johnson

INTRODUCTION

Acute pyelonephritis, an acute infection (usually bacterial) of the kidney and renal pelvis, is one of the most common serious infectious diseases of otherwise healthy individuals, and is an even greater problem for compromised hosts. New approaches to the diagnosis and management of this disorder and its sequelae, including intrarenal and perinephric abscess, have resulted in improved outcomes for patients.

EPIDEMIOLOGY

Annually in the USA, approximately 200,000 adults are admitted to hospital for renal infection,[1] [2] [3] many others being managed as outpatients. In Manitoba, Canada, the annual risk of hospitalization for pyelonephritis is approximately 11/10,000 for women and 3/10,000 for men.[4]

Complicated versus uncomplicated pyelonephritis

Pyelonephritis can be stratified as 'complicated' or 'uncomplicated', depending on the presence of underlying urologic or medical conditions that predispose to kidney infection or that aggravate the severity or intransigence of such infections once they occur.[2] [5] Uncomplicated and complicated pyelonephritis have distinctive host substrates, microbial flora, pathogenetic mechanisms, clinical presentations and requirements for and response to therapy.

Risk factors

Although little is known about the specific risk factors for uncomplicated pyelonephritis, recognized risk factors for uncomplicated cystitis would be predicted to predispose to pyelonephritis also. Such associations include female sex and, among adult women, sexual intercourse, a history of previous urinary tract infections (UTIs), use of spermicide-diaphragm contraception, the postmenopausal state and being a nonsecretor of blood group substances (see Chapter 67).[6] [7] Among children, the P_1 blood group phenotype is associated with an increased pyelonephritis risk.[8] Pyelonephritis in compromised hosts, which by definition is 'complicated', is promoted by almost any anatomic or functional abnormality of the urinary tract, urinary tract instrumentation, diabetes mellitus, immunosuppression, pregnancy (during which the risk of pyelonephritis is 1–2%) and conditions associated with sensory impairment (such as diabetic or alcoholic neuropathies and spinal cord injury).[2] [5] Among the commonly implicated urologic conditions are posterior urethral valves (in infant boys), congenital vesicoureteral reflux (in girls), indwelling or intermittent urinary catheterization, other instrumentation of the urinary tract, neurogenic bladder, urolithiasis, ureteral diversions, any obstruction to normal urinary flow and kidney transplantation.

Renal abscesses, which can be intrarenal, intrarenal with perirenal extension or entirely perirenal, typically develop as a consequence of acute pyelonephritis and are among the most serious local complications of this illness. They occur predominantly in compromised hosts, notably patients who have diabetes mellitus or have undergone recent surgery or instrumentation of the urinary tract.[9] [10] [11] Urinary reflux and obstruction are prominent risk factors for renal abscesses. Rarely, renal abscesses may develop during a severe episode of otherwise uncomplicated pyelonephritis in an intact host.

PATHOGENESIS

Route of infection

Irrespective of the presence of predisposing host conditions, in almost all patients acute pyelonephritis arises via an ascending route of infection. [2] [5] The causative micro-organisms enter the urethra, colonize the bladder, then ascend the ureters to the renal pelvis and subsequently invade the renal parenchyma. In most cases, the pathogens arise from the host's own intestinal (and, in women, vaginal) flora, [12] although in patients who have indwelling catheters or nephrostomy tubes organisms may be transferred on the hands of health care workers and thus bypass the intestinal, vaginal and/or bladder colonization steps.

Microbial flora

Organisms must have substantial intrinsic virulence to overcome the many defense mechanisms of a healthy urinary tract and cause pyelonephritis in an intact host. In contrast, organisms of lesser intrinsic virulence can infect the kidney in patients who have impaired urinary tract defenses. Paradoxically, the less virulent organisms associated with complicated pyelonephritis are more often resistant to antimicrobial agents than are the more virulent ones that cause uncomplicated pyelonephritis. This, together with the impaired defense mechanisms of compromised hosts, makes such infections more difficult to treat and cure than uncomplicated pyelonephritis.

In uncomplicated pyelonephritis the distribution of micro-organisms is similar to that in uncomplicated cystitis, with approximately 80% of isolates being *Escherichia coli* and the remainder other Gram-negative bacilli (predominantly *Klebsiella* and *Proteus* spp.), *Staphylococcus saprophyticus* (especially in young women), *Enterococcus* spp. (especially in older men) and occasionally group B or other streptococci.[2] [5] [13] The *E. coli* strains that cause uncomplicated pyelonephritis exhibit multiple virulence properties that contribute to their ability to invade the urinary tract and stimulate inflammation and tissue damage (Fig. 69.1).[14] [15] [16] [17]

Among the various adhesins expressed by these strains, the most prevalent and pathogenetically important are type 1 fimbriae and P fimbriae. P fimbriae are strongly epidemiologically associated with pyelonephritis[14] [15] and contribute to kidney infection in a monkey model.[18] They recognize Gala(1–4)Gal-containing receptors on host epithelial surfaces, including the mucosal lining of the colon, vagina and urinary tract. The P fimbrial adhesin molecule PapG is situated at the tip of the fimbrial stalk and mediates attachment to receptors on the host cell. PapG occurs in three known variants, of which the class II variant is the most common among strains that cause uncomplicated pyelonephritis and bacteremic UTIs,[19] [20] [21] whereas the class III variant is associated with cystitis and with complicated UTIs.[20] [21] [22]

Figure 69-1 Uropathogenic strain of *Escherichia coli.* Note the typical virulence properties, including adhesive fimbriae, cytotoxins, lipopolysaccharide (LPS), capsular polysaccharide, the aerobactin system and outer membrane proteins important in serum resistance. Bacterial interactions with host cells trigger cytokine production, inflammatory cell infiltration and bacterial internalization within epithelial cells. Internalized bacteria can multiply intracellularly and stimulate sloughing, rupture, necrosis or apoptosis of host cells.

Type 1 fimbriae are structurally similar to P fimbriae but have a binding specificity for mannose-containing receptors on host cells. Since type 1 fimbriae are produced by almost all *E. coli*, epidemiologic associations of type 1 fimbriae with UTI or pyelonephritis are difficult to demonstrate. However, in the mouse model of UTI deletion of the type 1 fimbrial adhesin gene [16] or immunization against the corresponding FimH adhesin molecule[17] reduces both bladder and kidney infection. Other important virulence factors of pyelonephritogenic *E. coli* include cytotoxins such as a-hemolysin (which destroys or impairs the function of host epithelial cells, phagocytes and lymphocytes), iron sequestration systems such as the aerobactin system, polysaccharide capsules, lipopolysaccharide and serum resistance proteins (which protect

the organism against phagocytosis and/or complement-mediated lysis).[14] [15] [23]

In complicated pyelonephritis, although *E. coli* still is the single most common pathogen, it is less prevalent than in uncomplicated pyelonephritis and is represented by less virulent strains. Other Gram-negative bacilli are more commonly encountered, including *Pseudomonas aeruginosa*, *Enterobacter* spp. and other Enterobacteriaciae.[2] [5]

Factors promoting ascending infection

Vaginal colonization with urovirulent organisms is promoted by sexual intercourse, particularly with the use of a spermicide, which kills normal lactobacillus-based vaginal flora and permits overgrowth with *E. coli* and other coliform bacteria.[12] Similar changes in the vaginal flora occur after the menopause as a result of estrogen depletion, and are induced by the use of certain antimicrobial agents, notably ß-lactams.

In women, sexual intercourse promotes the entry of periurethral bacteria into the bladder on a mechanical basis. In catheterized patients, bacteria can be introduced into the bladder at the time of catheter insertion, or can migrate into the bladder along the external or luminal surfaces of catheters.[24] With improper catheter care, infected urine from the collecting bag and drainage tubing can reflux into the bladder. Catheter-associated organisms persist within the urinary tract in part by cementing themselves to the catheter within glycocalyx matrices that protect them against natural host defense mechanisms and antimicrobial agents.

Ascent of pathogens from the bladder up the ureters is facilitated by vesicoureteral reflux, which may be pre-existing or which in the intact host can result from a reversible ureteral aperistalsis induced by exposure of the ureteral wall to lipopolysaccharide from adherent bacteria.[25] Among several UTI-promoting physiologic alterations of pregnancy, ureteral hypotonia and some degree of ureteral obstruction may contribute to bacterial entry into the upper urinary tract in pregnant women and its persistence once there.[18] Once within the renal pelvis, micro-organisms migrate up the collecting ducts into the tubules, a process promoted by intrarenal reflux (if present in the particular host) and by bacterial adhesins that recognize receptors along this epithelial surface or in subjacent tissues.[14] [15] [25]

PATHOLOGY

Within the urinary tract, pathogenic bacteria adhere to the mucosa and trigger a local cytokine/chemokine network, with production of interleukin (IL)-1, IL-6, IL-8 and tumor necrosis factor-a, and recruitment of polymorphonuclear leukocytes (PMNLs) and lymphocytes.[26] [27] Triggers include the interaction of bacterial lipopolysaccharide with host cell Toll-like receptor 4 (TLR4),[28] P fimbrial binding to host membrane glycolipids, which activates an intracellular ceramide signaling pathway,[29] and type-1-fimbria-mediated bacterial internalization.[30] The influx of inflammatory cells leads to the generation of reactive oxygen species, leukotrienes, prostaglandins and other mediators of inflammation, which together with bacterial cytotoxins produce tissue damage, edema and, in the kidney, intense local vasoconstriction (Fig. 69.1).[2] [5] [25] These phenomena are responsible for the characteristic signs and symptoms of pyelonephritis, including dysuria and suprapubic pain from bladder involvement, flank pain and costovertebral angle tenderness from kidney involvement, and

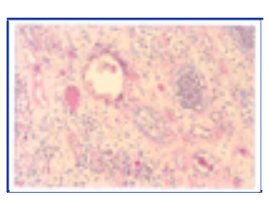

Figure 69-2 Acute pyelonephritis. Note interstitial edema, tubules packed with PMNLs and a diffuse interstitial acute inflammatory infiltrate in this autopsy specimen from a diabetic patient who had refractory *Escherichia coli* urosepsis.

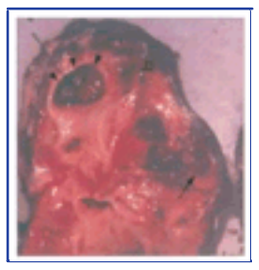

Figure 69-3 Emphysematous pyelonephritis. Cortical necrosis (solid arrow), diffuse cortical hemorrhage (open arrow) and dilatation of the collecting system (arrowheads) in a nephrectomy specimen from a diabetic patient who received combined medical/surgical therapy and survived emphysematous pyelonephritis due to an unusual pathogen, namely *Candida albicans*.

fever and malaise from inflammatory cytokines that enter the systemic circulation.

Histologically, in acute pyelonephritis the mucosa and submucosa of the collecting system, the tubules and the interstitium are edematous and infiltrated with PMNLs (Fig. 69.2). Tubules may necrose. Microabscesses form within the mucosa and interstitium, and can coalesce to form macroscopic abscesses.[2] [5] [25]

Grossly, the kidneys are diffusely or focally swollen and edematous. On sectioning, streaks of yellowish inflammatory infiltrate extend from the papillae and medulla toward the cortex, sometimes reaching the capsule and rupturing it.[2] [5] When macroscopic abscesses do form, typically they localize at the corticomedullary junction but they can be subcapsular or extend into the perirenal space.[9] In hyperglycemic diabetic patients, rapid fermentation of glucose by Gram-negative bacilli (or, rarely, yeasts) can produce gas within the renal parenchyma (emphysematous pyelonephritis; Fig. 69.3), within an abscess (gas abscess) or within the renal pelvis and collecting system (emphysematous pyelitis).[31] Papillary necrosis, which occasionally complicates acute pyelonephritis among diabetic patients, may make the infection worse because of the obstruction caused by sloughed tissue (Fig. 69.4).[2] [5]

Functionally, the intense interstitial inflammatory process leads to a reduction in urinary concentrating capacity. Decreased renal blood flow, functional tubular obstruction from inflammatory cells and

Figure 69-4 Acute papillary necrosis (arrows) in an autopsy specimen from a diabetic patient who died from refractory *Escherichia coli* urosepsis. Necrotic papillae (arrows) failed to take up formalin, so appear pink, in contrast to the grayish-tan formalinized tissue.

necrotic debris, and inflammation-induced tubular dysfunction result in delayed excretion of radiographic contrast dye[2] [5] but only rarely manifest as clinically apparent renal dysfunction.[32]

Bacteremia develops in between 10% and 65% of patients who have acute pyelonephritis, depending on the severity of infection and increasing in proportion to the age of the host. Bacterial entry into the bloodstream may be promoted by P fimbriae[19] and by tissue destruction mediated by microbial cytotoxins.[33] Systemic complications of pyelonephritis, which are more common among patients who have Gram-negative bacteremia, include septic shock, disseminated intravascular coagulation and the acute respiratory distress syndrome (ARDS). Pregnant women who have pyelonephritis are particularly prone to these complications, and also may develop premature labor as a result of the irritative effect of lipopolysaccharide on the uterus.[34]

Hematogenous renal abscesses

Intrarenal abscesses can also be caused by certain hematogenously borne pathogens, most commonly *Staphylococcus aureus*, *Candida* spp. and *Mycobacterium tuberculosis*.[9] In contrast to abscesses that form during acute ascending pyelonephritis, hematogenously derived abscesses are usually cortical in location, are not prone to rupture into the perinephric space and are not associated with the characteristic clinical syndrome of pyelonephritis. Conversely, the typical pathogens of acute

ascending pyelonephritis almost never cause renal abscesses in patients who have bacteremia arising from an extra-urinary-tract focus.[2] [5]

PREVENTION
